In addition to recognizing and understanding the patient's current sexual concern, the nurse also should assess the patient's developmental level and then, with that knowledge, gather a sexual health history. The patient's past and current health and sexual practices, as well as medications with a potential impact on sexual function, should be identified. The patient's reproductive history, STD history, sexual dysfunction history, sexual health self-care practices, frequency of mammography or testicular self-examination (TSE), and sexual identity, self-concept, and self-esteem should be assessed.

When completing a sexual health history, the nurse should incorporate the following steps and attitudes:

- Overcome any prejudices concerning sexuality.
- Be nonjudgmental—nurse approval is not necessary.
- Allow time to discuss and explore patient needs, fears, and feelings.
- Actively listen to the patient.
- Clarify vocabulary as needed.
- Be tolerant but not permissive.
- Be respectful.
- Watch for nonverbal responses.
- Respect patient privacy.
- Maintain confidentiality.

- Ask questions in a routine, matter-of-fact manner.
- Continue to be an advocate for the patient.

Sexual Harassment

Nurses have the right and responsibility to confront patients who display inappropriate sexual behavior. This behavior may be verbal, nonverbal, or physical, from either male or female patients, and may be heterosexual or homosexual in nature. To help end this inappropriate patient behavior, the nurse should implement the guidelines listed in [Box 24.7](#).

Box 24.7

Ethical, Legal, and Professional Practice

Managing Sexual Harassment in the Workplace

- Be aware that approximately 25% of nurses are sexually harassed.
- Be cautious with touching during patient care while maintaining privacy and professionalism.
- Have a chaperone present while providing care to a patient of the opposite sex or when sexual overtones exist in a patient's conversation.
- Establish a professional relationship with the patient, including minimal sharing of personal information and no sexually oriented conversations or humor.
- Be alert for personal questions of a sexual or suggestive nature from the patient, and do not respond to them. If the inquiries continue, bring in another staff member for any patient contact or conversation.
- Say “no” and make it clear to the patient, family member, or visitor that sexual harassment behaviors are inappropriate and unacceptable.
- Be aware that the patient may deny or defend the behavior if confronted about an inappropriate comment or action.
- If any deliberate physical contact takes place, be assertive so that the action can be curtailed. First, stop the action; second, tell the

patient how you feel about the inappropriate behavior.

- Document and report all sexually suggestive verbiage and sexual harassment immediately.
- Set limits and enforce consequences. Tell the patient that you will not continue to be involved in the patient's care if the behavior continues.
- Acknowledge your own feelings. It is all right to be insulted, angry, or embarrassed by inappropriate patient behavior.
- Educate yourself on the issue of sexual harassment in the workplace.
- Report any instances of harassment the you observe or experience personally. Involve supervisors and/or colleagues in the reporting process.

From Spector, P., Zhou, Z., & Che, X. (2014). Nurse exposure to physical and nonphysical violence, bullying, and sexual harassment: A quantitative review. *International Journal of Nursing Studies*, 51, 72–84; Lockhart, L. (2016). Sexual harassment in the workplace. *Nursing Made Incredibly Easy!*, 14(6), 55; Zook, R. (1997). Handling inappropriate sexual behavior with confidence. *Nursing 1997*, 27(4), 65; Zook, R. (2000). Teaching staff to handle a patient's sexually inappropriate behavior. *J Nurses Staff Dev*, 16(4), 248.

Sexual harassment also may occur in the workplace in the form of requests from a supervisor for sexual favors in exchange for employment benefits (*quid pro quo*) or unwelcomed physical or verbal conduct of a sexual nature by co-workers or nonemployees, resulting in a hostile environment. Nurses are encouraged to work with their employers to develop and enforce policies that support preventive action and workplace environments that protect against sexual harassment of all individuals.

2. Make a list of five assessment questions related to G. W.'s concern about erectile dysfunction that the nurse might ask

before discussing possible causes during the health history.

LO 24.11 ♦ Nursing Diagnosis

Multiple nursing diagnoses are available to help address patient concerns related to sexuality. Following a thorough assessment, the nurse identifies relevant nursing diagnoses to address each patient's unique needs. Some International Classification for Nursing Practice (ICNP) nursing diagnoses that focus on issues of sexuality are:

Impaired Sexual Functioning

- Supporting Data: Prostatectomy 4 weeks ago, prostate cancer, inability to maintain an erection

Problematic Sexual Behavior

- Supporting Data: Absent role model, reports texting sexually explicit material to friends, describes unprotected sexual intercourse encounters

Rape Trauma Response

- Supporting Data: Six weeks post-rape experience, attending private counseling twice per week, inquiring about a support group for rape victims

3. Identify a primary nursing diagnosis for G. W. related to his stated sexual concern. Include a cluster of supporting data from the case study and the nurse's data collection located on the online conceptual care map.

LO 24.12 ♦ Planning

In the planning phase of the nursing process, the nurse should use critical-thinking skills and assimilate information from multiple resources. The patient's individualized plan should evolve using the knowledge the nurse gained when gathering the sexual health history, along with the experience of the nurse in dealing with sexual concerns. Ethical and legal standards associated with sexual issues must be maintained by the nurse during this phase. These include protecting the patient's privacy, giving assurance of confidentiality, and providing unbiased, appropriate assistance. For each nursing diagnosis, an individualized plan of care is developed with realistic goals and measurable outcome criteria (Table 24.6). Setting priorities to address the individual needs of the patient and considering collaboration of care also are components of the planning phase (Box 24.8).

TABLE 24.6
Care Planning

ICNP NURSING DIAGNOSIS WITH SUPPORTING DATA	NURSING OUTCOME CLASSIFICATION (NOC)	NURSING INTERVENTION CLASSIFICATION (NIC)
<i>Impaired Sexual Functioning</i> Prostatectomy 4 weeks ago Prostate cancer Inability to maintain an erection	<i>Sexual functioning</i> Sustains penile erection through orgasm	<i>Sexual counseling</i> Discuss necessary modifications in sexual activity, as appropriate.

From Bulechek, G., Butcher, H., Dochterman, J., et al. (Eds.). (2018). *Nursing interventions classification (NIC)* (7th ed.). St. Louis: Mosby; Moorhead, S., Johnson, M., Maas, M., et al. (Eds.). (2018). *Nursing outcomes classification (NOC)* (6th ed.). Box 24.8

Interprofessional Collaboration and Delegation

Addressing Patient Sexual Health Needs

- The patient with a sexual health issue will benefit from a multidisciplinary team approach to managing the problem.
- The nurse, primary health care provider, and social worker should collaborate in the care and treatment plan for the patient.
- The sex therapist, psychologist, pharmacist, physical therapist, and dietitian may provide additional information and support, depending on the cause of the sexual issue.

The process of developing a care plan is summarized in the following example: A postoperative hospitalized patient has a nursing diagnosis of *Impaired Sexual Functioning* secondary to surgical intervention. The nurse works with the patient to develop the goal of improved sexual function within 1 month. Expected outcomes or goals are identified:

- Patient will discuss sexual dysfunction with the PCP before discharge from the hospital.
- Patient will report improved sexual function at the 1-month follow-up appointment with the health care provider.

4. Write a short-term goal or outcome statement that would be realistic for G. W. while addressing the identified priority nursing diagnosis.

LO 24.13 ♦ Implementation and Evaluation

The implementation and evaluation of sexual health issues focus on health education, risk prevention, patient counseling, and the outcomes of these endeavors. Interventions to address patient needs are discussed directly with the patient to maximize comfort levels and to ensure adherence.

QSEN Focus!

Being sensitive and showing respect for the diversity of patient sexual experiences is essential to providing patient-centered care.

Health Education

Therapeutic communication skills are critical for the nurse when discussing sexual values, desires, satisfaction, or issues of concern. Teach to the patient's developmental level and in an environment conducive to open communication while maintaining the patient's privacy and ensuring confidentiality. Teach the patient about measures to assess sexual health, including Papanicolaou (Pap) smears to check for cervical abnormalities, mammograms to assess breast health, monthly testicular self-examination (TSE) starting after the age of 14 years, and prostate examinations (in accordance with American Urological Association guidelines). See [Chapter 20](#) on assessment and [Chapter 41](#) on urinary elimination for more information on these topics.

Risk Prevention

Safe sex practices that prevent risk should be included in any sexual health education discussion. STD recognition and prevention measures include:

- Information regarding the symptoms of STDs
- Need for routine physical examinations with laboratory work for detection of some asymptomatic STDs
- Proper use of condoms

- HPV vaccination
- Avoidance of multiple sex partners, as well as sexual practices that increase risk (e.g., oral or anal sex)

These measures, along with avoiding IV drug use, also help prevent HIV infection.

Patient Counseling

Counseling by the nurse may be necessary to address the patient's sexual concerns. Therapeutic communication skills, privacy, and confidentiality are essential components. Sexual function associated with chronic illness, sexual desire and performance issues, and sexual abuse are areas for which counseling may occur. The issues of sexual abuse and rape cross all age, ethnic, cultural, and socioeconomic groups, and nurses are likely to care for victims at some time in their practice. Evidence of abuse may be noted on gathering a health history or completing a physical assessment. The nurse should understand the clinical and legal responsibilities involved in dealing with abuse and should have access to a safe environment for the abuse victim (Boxes 24.9 and 24.10). Family support and counseling also should be considerations for patients who have been abused.

Box 24.9

Nursing Care Guideline

Care for the Victim of Sexual Assault

Background

- An examination of the patient to collect evidence should occur within 72 hours of the assault.
- If possible, a sexual assault nurse examiner (SANE) who is trained and certified as a forensic nurse and who has been designated an expert in evidence collection and legal proceedings should perform the examination.
- A victim advocate for the patient also is needed, because the SANE is an impartial witness. A SANE usually works as a

member of a sexual abuse response team (SART) in a facility setting, and the SART usually includes an advocate for the victim.

- The goal for developing SARTs was to provide and improve the response of multidisciplinary teams of professionals to care for sexual assault victims.

Procedural Concerns

- The SANE and SART members maintain a professional, nonjudgmental attitude throughout the procedure. They document all procedures and findings, as well as maintain the chain of evidence. Evidence to be collected includes:
 - DNA evidence
 - Seminal fluid evidence
 - Physical injury evidence
 - Blood and urine evidence
 - Genital trauma evidence through colposcopic examination

The SANE and SART members comfort the patient throughout the examination and provide:

- Education and information regarding sexually transmitted infections (STIs)
- Information on or prophylactic treatment against pregnancy
- Crisis intervention and information on counseling
- After the examination, the SART provides a place to bathe, supplies clean clothes, and offers to call family or friends for a place to stay or offers information on shelters.

Documentation Concerns

- Accuracy and legibility are essential.
- Never use the term *alleged sexual assault*.
- Use the phrase “patient states” or “patient reports.”
- Document both subjective and objective findings.

Document the following concerns about the patient:

- Is the patient pregnant?

- Does the patient have allergies?
- What is the patient's general appearance?
- What is the patient's emotional status?
- What is the patient's response to examination?
- Does the patient have physical injuries?
- What are the site and time of the assault?
- Has the patient performed any self-care activities (bathing, douching, laundering clothes, brushing teeth) since the assault?
- Was there physical contact by the assailant(s), and if so, how would it be characterized? (Was there actual or attempted penetration? Was a penis or another object involved? Did ejaculation occur? Was a condom used?)
- What does the patient report about the number of assailants, descriptions, and relationship, if any, to the patient?
- Were weapons and/or restraints used during the assault?
- Was there sexual activity 72 hours before and/or since the assault?
- Has the patient been using tampons or contraception?

Evidence-Based Practice

- SARTs have been shown an increase in the frequency of victims being referred to support services, improved legal outcomes, and decreased secondary trauma to victims ([Greeson & Campbell, 2013](#)).
- Use of SANEs has improved the assessment and documentation of anogenital injury as well as STI testing ([Orr, 2016](#)).

Box 24.10

Nursing Care Guideline

Care for the Victim of Domestic Violence

Background

Domestic violence does not have to be physical violence:

- It includes a threat or promotion of fear to exert power or control over another person.

- It can occur through intimidation or isolation or via someone else.
- It can be emotional, financial, sexual, or physical.
- It can occur to anyone, by anyone.
- Leaving a domestic violence situation can be just as dangerous as staying.
- Nurses are required to screen for domestic violence by asking questions on admission of the patient to a facility.
- A cycle of violence is common.

Procedural Concerns

It is imperative to take screening seriously:

- Provide *total and complete* privacy—no exceptions!
- Listen without judging.
- Provide emotional support.
- Advocate contact with support services.
- Patient and family safety is the top priority.
- Discuss safety plans.

Victims may refuse to accept printed or written information out of fear. Repeat important information such as:

- Phone numbers of crisis centers
- Addresses of shelters
- Reassure the patient that records are confidential and that Health Insurance Portability and Accountability Act (HIPAA) compliance is ensured.

Documentation Concerns

- Accuracy and legibility are essential.
- Use the phrase “patient states” or “patient reports.”
- Detail new and old physical injuries. Photograph injuries (with patient consent).
- Document information that is provided both orally and in writing, including patient education and the resources that were suggested or provided.
- Document consultations and referrals.

Evidence-Based Practice

- Victims of domestic violence may not feel comfortable talking with a health care provider, even though they need assistance. Barriers include a health care provider's appearance of dominance, making inappropriate referrals, the absence of a safe and confidential area, and a lack of affirmation that the domestic violence is unacceptable (Keeling & Fisher, 2015).

5. Identify at least two nursing interventions to incorporate into G. W.'s plan of care.

Nurses who are counseling patients should consider outside resources as sources of additional patient support and education. Community agencies and organizations that work with patients with sexual health issues include:

- Local, state, and federal health departments
- Planned Parenthood, at www.plannedparenthood.org
- National Infertility Association, at www.resolve.org

Information and support groups for people with particular conditions:

- American Diabetes Association, at www.diabetes.org
- American Heart Association, at www.heart.org
- American Cancer Society, at www.cancer.org
- American Lung Association, at www.lung.org

- National Multiple Sclerosis Society, at www.nationalmssociety.org
- Local support groups and hotlines for sexual abuse
- National Center for Victims of Crime, at www.ncvc.org
- Women's Shelters for Physical Abuse, at www.sheltersforwomen.org
- Rape, Abuse, and Incest National Network, www.rainn.org
- North America Menopause Society, at www.menopause.org

Evaluation

Although patient affect, body language, and nonverbal communication provide some data, the nurse needs direct patient information to evaluate the outcomes of the plan of care dealing with sexual health. The evaluation should include questions on resolution of the issue, as well as satisfaction with the outcome. This information will help the nurse determine whether additional actions are necessary to meet the needs of the patient (Alfaro-LeFevre, 2017).

Summary of Learning Outcomes

LO 24.1 *Explain sexual development throughout the life cycle:* Sexual development follows the stages of physical and psychological growth and development.

LO 24.2 *Describe the structure and function of the male and female reproductive systems:* The male external reproductive organs are the scrotum and the penis; the internal reproductive organs are the seminal vesicles in the testes and the prostate. Semen is produced in the internal organs and ejaculated from the penis during orgasm. The female external genitalia, known collectively as the *vulva*, include the mons pubis, labia majora, labia minora, clitoris, Skene glands, and Bartholin glands; the internal genitalia include the vagina, uterus, fallopian tubes, and ovaries. The breasts also are considered female reproductive organs because estrogen and progesterone influence them and because they are the organs of lactation.

LO 24.3 *Differentiate among sex, sexuality, and gender identity:* A person's sex is defined by the internal and external genitalia. Sexuality is defined as the collective characteristics that mark the differences between male and female. Sexuality is associated with every aspect of an individual's life as it relates to sex and intimacy, whether associated with sex organs or not. Gender identity is one's self-concept with respect to being a male or female.

LO 24.4 *Describe the sexual response cycles of men and women:* The four phases in the female sexual response cycle are excitement, plateau, orgasm, and resolution. The phases consistently occur in this sequence, but the duration of each phase varies. The phases of the male sexual response are stimulation, erection, emission, ejaculation, and detumescence. After orgasm, males experience a refractory period during which they are physiologically incapable of having another orgasm. Because females do not have a refractory phase, they can have multiple orgasms.

LO 24.5 *Identify contraception options:* Contraceptive methods with varying degrees of effectiveness are available for males and females. They include abstinence, withdrawal of the penis before ejaculation, rhythm method, male and female condoms, spermicides, oral contraceptives, intrauterine devices, vaginal rings, hormonal injections or transdermal patches, diaphragms, cervical caps, emergency contraception, hysteroscopic sterilization, and surgical sterilization. Some methods require a prescription, whereas others do not.

LO 24.6 *Discuss sexually transmitted diseases and their causes and treatments:* Gonorrhea, syphilis, and chlamydia are caused by bacteria and can usually be treated and cured with antibiotics. Genital warts (caused by HPV) and genital herpes (due to herpes simplex) are caused by viruses; they can be treated but not cured. Human immunodeficiency virus (HIV) is a blood-borne virus that may be acquired through sexual contact and exchange of bodily

fluids; if untreated or unsuccessfully treated, HIV infection progresses to AIDS. The survival time for patients with AIDS has improved with the use of ART.

LO 24.7 *Summarize factors that affect sexuality:*

Family values and beliefs, culture, religion, self-concept, body image, previous experiences, cognition, environment, personal expectations, and ethics all affect a person's acceptance and expression of sexuality.

LO 24.8 *List factors that affect sexual function:*

Underlying disease processes and injury can have a negative impact on sexual function, as can medications and relationship issues such as differences in value systems, communication issues, and control issues. Lifestyle factors (such as work issues, family responsibilities, lack of time or sleep, and developmental and self-concept concerns) are additional stressors that may lead to sexual dysfunction.

LO 24.9 *Recognize the impact of family dynamics on sexuality:*

Age, ethnicity, culture, religion, and values affect a family's ability to communicate about sexual issues and the family members' choices regarding abortion, sterilization, contraception, and sexual preferences. The family's decision-making style, whether decisions are made by one partner or by the couple, may affect the partners' sexual practices. Sexual expression and satisfaction are enhanced in relationships in which decision-making power is shared.

LO 24.10 *Implement a sexual assessment:* Sexual health assessment is an integral component of a

total health history and physical exam.

LO 24.11 *Identify nursing diagnoses appropriate for the care of patients with potential or identified sexuality concerns: Impaired Sexual Functioning and Problematic Sexual Behavior* are the commonly identified nursing diagnoses for concerns arising from sexuality.

LO 24.12 *Develop a patient-centered care plan designed to address sexuality needs:* A patient's individualized plan evolves as the nurse uses the knowledge gained while gathering the patient's sexual health history, along with the experience of the nurse in dealing with sexual concerns. Ethical and legal standards associated with sexual issues must be maintained by the nurse during this phase.

LO 24.13 *Implement interventions to support enhanced patient sexuality before evaluating their effectiveness:* Nurses may provide sexual health teaching on topics such as sex education, safe sex practices, contraceptive use, and self-examination techniques to assist patients in attaining their identified goals and outcomes. Documentation of patient outcomes should be noted in the electronic health record.

Review Questions

1. For which reasons are patients unlikely to introduce the topic of sex with health care providers? *Select all that apply.*
 - a. Most patients have few, if any, questions or problems relating to this topic.
 - b. They are too embarrassed to discuss the topic of sex with a health care provider.
 - c. Female patients prefer to discuss problems with female health care providers.
 - d. They assume that health care professionals know little about sexual functioning.
 - e. They are concerned that the health care professionals will be judgmental.
2. A patient who had a hysterectomy 3 days ago says to the nurse, "I no longer feel like a real woman." Which response by the nurse would be most appropriate?
 - a. "Don't worry about that. The feeling will probably go away."
 - b. "You should talk to your doctor about how you feel."
 - c. "I don't blame you. I would feel like half a woman also."
 - d. "I hear your concern. Tell me more about your feelings."
3. When a patient reports having dyspareunia, which questions are appropriate for the nurse to ask? *Select all that apply.*

- a. "Have you talked with your partner about this discomfort?"
 - b. "Have you had these spasms since you became sexually active?"
 - c. "Has your health care provider offered any treatment measures?"
 - d. "Does the bleeding continue longer than 5 days?"
 - e. "Do your breasts swell up large enough for you to need a larger bra?"
4. A 75-year-old male patient reports decreased frequency of sexual intercourse, although he does not express dissatisfaction or difficulty. He seems a little embarrassed by the discussion but is engaged and asks some questions. Which nursing diagnosis does the nurse determine is most appropriate for this patient?
- a. *Impaired Sexual Functioning*
 - b. *Disturbed Body Image*
 - c. *Difficulty Coping*
 - d. *Lack of Knowledge*
5. In using the PLISSIT model, what is the first action initiated by the nurse?
- a. Present basic information about sexual functioning.
 - b. Ask permission to begin the sexual assessment.
 - c. Inquire about any medications the patient is taking.
 - d. Ask the patient about sexual activity and practices.

6. Which statement is the best resource for the nurse to use when determining appropriate nursing care for a transsexual patient?
 - a. Gender identity is altered by acute psychosis.
 - b. Sexual attraction is to individuals of both genders.
 - c. Gonadal gender, internal organs, and external genitals are contradictory.
 - d. Anatomy associated with sexual identity is not consistent with gender identity.

7. When a patient is beginning a regimen of an antidepressant medication, which information should the nurse include in the medication teaching as it pertains to sexuality?
 - a. "Your partner will be pleased because your sexual functioning is going to improve."
 - b. "You may find that your desire for sex will decrease while on this medication."
 - c. "Your skin will probably become supersensitive to touch, so you may need to change your activity during sex."
 - d. "You will be unable to have an erection while taking your antidepressants."

8. When teaching female reproduction to a group of high school students, the nurse uses what term to indicate the cessation of a woman's menstrual activity?
 - a. Menarche
 - b. Menopause
 - c. Premenstrual syndrome

- d. Menstrual dysfunction
9. When teaching a patient about surgical procedures for birth control, the nurse would include which methods? *Select all that apply.*
- a. Diaphragm
 - b. Vasectomy
 - c. Hormone injection
 - d. Tubal ligation
 - e. Oral contraceptives
10. While performing a physical assessment on a female patient, the nurse finds several bruises on the patient's inner thighs that are in various stages of healing and suspects that the patient may be a victim of sexual abuse. What should be the nurse's first action?
- a. Refer the patient to a sexual counselor.
 - b. Tell the patient about the safe house for women.
 - c. Ask the patient to describe how she got the bruises.
 - d. Report the abuse immediately to the proper authorities.

UNIT V

Nursing Principles

OUTLINE

- Chapter 25 Safety
- Chapter 26 Asepsis and Infection Control
- Chapter 27 Hygiene and Personal Care
- Chapter 28 Activity, Immobility, and Safe Movement
- Chapter 29 Skin Integrity and Wound Care
- Chapter 30 Nutrition
- Chapter 31 Cognitive and Sensory Alterations
- Chapter 32 Stress and Coping
- Chapter 33 Sleep

CHAPTER 25

Safety

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 25.1 Discuss safety concerns in the home, community, and health care environments.
- LO 25.2 List factors that affect safety.
- LO 25.3 Explain situations that alter safety in the home, community, and health care settings.
- LO 25.4 Identify safety factors that affect individuals at home, in the community, and in health care settings.
- LO 25.5 Choose nursing diagnoses relevant to patient safety–related concerns and issues.
- LO 25.6 Prepare nursing care plans that identify interventions to promote patient safety.
- LO 25.7 Implement and evaluate safety measures in the home, community, and health care settings.

Case Study

Doris Stein (D. S.) is an 88-year-old female who was admitted last night to the hospital from a local nursing home. Her symptoms include fever (T 38.2° C [100.8° F]), increasing confusion, and weakness. Her initial admitting diagnosis was pneumonia with bilateral pulmonary infiltrates. Her medical history includes hypertension and osteoarthritis, and she has fallen twice in the past month at the nursing home. The patient is allergic to heparin and is full-code status.

D. S.'s last vital signs were T 37.4° C (99.3° F), P 85 and regular, R 28 and slightly labored, BP 156/95, oxygen saturation of 95% on 2 L/min of oxygen by nasal cannula. She does not answer when asked if she is in pain. She is oriented to person only and is pleasantly confused and mumbling about her young children. The top side rails are raised to assist in turning and positioning, and her bilateral, untied mitts are in place. No redness or irritation at the mitt site was observed on intermittent release. Her Johns Hopkins Hospital (JHH) fall risk assessment score is 21, and her Braden Scale score is 17. The evening nurse begins rounds and, on entering the room, D. S. is incontinent of loose stool and trying to climb out of bed.

Medication orders are as follows:

- Ceftriaxone 1 g intravenous piggyback (IVPB) daily
- Albuterol and ipratropium nebulizer treatments q 6 hr
- Guaifenesin 600 mg PO four times a day
- Lisinopril 5 mg PO daily
- IV normal saline 0.9% at 100 mL/hr
- Acetaminophen 625 mg PO q 6 h PRN for arthritic or pleuritic chest pain rating of 3 to 6
- Hydromorphone 0.5 to 1 mg IVP q 2 h PRN for pleuritic chest pain rating of 7 to 10
- Lorazepam 0.5 to 1 mg IVP q 8 h PRN for agitation

Treatment orders are as follows:

- Vital signs q 4 h, including O₂ sat
- Activity out of bed (OOB) to chair or bedside commode *only*
- Diet: No added salt
- CBC every morning
- O₂ up to 3 L/min by nasal cannula to keep O₂ sat 92% or greater
- Incentive spirometry q 1 h while awake
- Bilateral mitt restraints

Refer back to this case study to answer the critical-thinking exercises throughout the chapter.

Safety, which is the condition of being free from physical or psychological harm and injury, is a global concern. Individuals in every setting and location care about safety. This chapter addresses the environmental safety concerns of individuals in communities and home environments and explores the key principles of maintaining patient safety in health care settings.

Nurses play a critical role in teaching patients and their families how to maintain safety in their homes and communities. In addition to promoting safe delivery of patient care, nurses need to be concerned with their own safety in the working environment. This chapter highlights practical safety concerns in the environment that may exist for nurses who are practicing in a variety of settings. The nursing process provides a framework for the assessment, diagnosis, planning, interventions, and evaluation of patient safety goals across settings.

LO 25.1 Safety in the Home, Community, and Health Care Settings

The Centers for Disease Control and Prevention (CDC) foster safe and healthful environments by working with partners nationally and worldwide. A branch of the CDC, the National Center for Health Statistics (NCHS), is instrumental in detecting and investigating health problems of the U.S. population. In 2015 the NCHS found that unintentional injuries were the fourth leading cause of death in the U.S. population (Xu, Murphy, Kochanek, et al., 2015), after heart disease, cancer, and chronic lower respiratory diseases. **Unintentional injuries** result from incidents such as falls, motor vehicle crashes, poisonings, drownings, fire-associated injuries, suffocation by ingested objects, and firearms. Injuries and poisonings can have nonfatal consequences requiring medical care. For example, according to the National Hospital Ambulatory Medical Care Survey from 2008 to 2011, an annual average of 1.1 million emergency department (ED) visits were made for drug poisoning, corresponding to an overall visit rate of 35.4 per 10,000 persons. The highest visit rate was observed for persons aged 20 to 34, and this age group showed a statistically significant increase between the reporting periods of 2004 to 2007 and 2008 to 2011 (Albert, McCaig, & Uddin, 2015).

In response to the fatal and nonfatal consequences of injuries, the CDC established in 1992 a federal agency called the National Center for Injury Prevention and Control (NCIPC), which works to reduce injury, disability, death, and the costs associated with injuries. The NCIPC studies intentional and unintentional injuries. **Intentional injuries** typically result from deliberate acts of violence or abuse and often have fatal consequences such as suicide and homicide. The risk factors and prevention mechanisms for intentional injuries are better understood than those of unintentional injuries. Unintentional injuries are often referred to as **accidents**, which are incidents that occur at random and may be unavoidable. However, after the study of unintentional injuries for almost two decades, the term *accident* has fallen from favor because the patterns of unintentional injuries are often predictable and, in some cases, preventable. Since 1999 the number of overdose deaths involving opioids has quadrupled. Ninety-one Americans die every day from an opioid overdose (including prescription opioids and heroin) (Centers for Disease Control and Prevention [CDC], 2017c). Heroin has become a major concern accounting for 12,989 deaths in 2015 (CDC, 2017c). Beyond the community focus on injury prevention is the large concern

about safety in the rapidly changing health care environment. More than a decade ago, *To Err Is Human* introduced the modern patient safety movement and pointed out the problem of medical errors in hospitals. During the past decade, many organizations such as **The Joint Commission (TJC)**, an independent, not-for-profit group in the United States that accredits hospitals and other health care–related agencies, have focused on the goal of patient safety. In 2003 TJC developed the first set of performance standards addressing crucial elements of operations related to patient safety. Known as the National Patient Safety Goals (NPSGs), these standards are reevaluated every year. Each goal has specific elements of performance that the health care worker is required to meet. The NPSGs for 2019 (TJC, 2019) include:

- Improve accuracy of patient identification.
- Improve effectiveness of communication among caregivers.
- Improve the safety of using medications.
- Reduce harm associated with clinical alarm systems.
- Reduce risk for health care–associated infections.
- The hospital identifies safety risks inherent in its patient population.

QSEN Focus!

The nurse demonstrates safety by using strategies to reduce the risk for harm to self and others and by valuing the nurse's role in preventing errors.

The largest proportion of health care workers consists of nurses, and schools of nursing have increasingly emphasized a focus on patient safety in classroom and clinical courses. In 2005 the Robert Wood Johnson Foundation funded the Quality and Safety Education for Nurses (QSEN) project with an overarching goal of preparing nurses of the future with the knowledge, skills, and attitudes needed to advance quality and safety on the job in their health care settings. A definition provided by the QSEN project states that safety “minimizes risk of harm to patients and providers through system effectiveness and individual performance” (Cronenwett, Sherwood, Barnsteiner, et al., 2007).

QSEN Focus!

Knowledge, skills, and attitudes concerning safety are demonstrated when the nurse (1) discusses the impact of national patient safety resources, initiatives, and regulations; (2) uses national patient safety resources for professional development and as a means of focusing attention on safety in care settings; and (3) values the relationship between national safety campaigns and implementation in local practice settings.

In addition, the nurse also minimizes the risk to the patients when the nurse (1) describes a culture of safety; (2) communicates observations and concerns related to hazards and errors to patient, families, and the health care team; and (3) values her or his own role in preventing errors.

LO 25.2 Factors Affecting Safety

Many factors affect the safety of people, including personal characteristics and those in home, community, and workplace environments, particularly in health care settings. In all settings, reduction of risk and prevention of accidents is the overall goal.

Individual Factors

Individual factors that affect personal safety include those related to the functioning of body systems and those associated with an individual's lifestyle. Each person's risk for injury is different based on many internal and external factors.

Body System Integrity

Normal functioning of the musculoskeletal, neurologic, cardiopulmonary, renal, hepatic, and integumentary systems is essential for individual safety. Impairment of any component of the musculoskeletal system can restrict range of motion and diminish strength, producing a loss of balance and an unsteady gait. These changes can affect overall mobility, including the ability to transfer, stand, and walk. Limitations in mobility increase the propensity for falling.

The neurologic system includes cognitive (mental) ability and sensory perception, both of which are critical for safe functioning of individuals and their interactions with the environment. When changes in mental status occur, judgment may become altered and safety awareness may become compromised. For example, an older adult with loss of short-term memory may forget to turn off the stove, increasing the risk for fire, or may neglect to use an assistive device when dressing or ambulating, escalating the risk for falling. Alterations of the five senses (i.e., vision, hearing, touch, smell, and taste) can produce safety risks. For example, an adult with chronic allergic rhinitis and numerous recurrent sinus infections may have a diminished sense of smell and be unable to recognize that something is burning. Nurses should exercise caution when using heat and cold therapy in patients with altered sensation to prevent burns and tissue damage.

A compromised cardiopulmonary system can impair perfusion, resulting in symptoms such as shortness of breath and chest pain, which can lead to activity intolerance. Inactivity can lead to an unsafe drop in blood pressure with position changes, a condition called *orthostatic*

hypotension (see [Chapter 19](#)). Safety concerns arise when the patient has difficulty tolerating or performing routine activities of daily living. For example, depending on the level of cardiopulmonary compromise, an individual may be unable to safely use the toilet, bathe, sit, stand, and walk. A person in this condition may not be able to evacuate a burning building rapidly enough to avoid sustaining burn-related injuries.

Detoxification and excretion of medications occurs in the hepatic and renal systems. Impairment of these systems can lead to symptoms of toxicity, which depend on the medications but can include cognitive and physical changes. Injury to the integumentary system can make a person more susceptible to infections, because the body's protective barrier has been altered.

Life Span Factors

Age and developmental issues can influence the safety of individuals across the life span. Infants should be placed in the supine position for safe sleeping to decrease the likelihood of sudden infant death syndrome. An infant should never be left unattended. Appropriate rear-facing car seats and carriers should be used correctly. Infants and toddlers should be rear facing until they are at least 2 years old or reach the highest weight or height allowed by the car seat manufacturer ([American Academy of Pediatrics \[AAP\], 2018](#)). In addition, all children under 13 should ride in the back seat with belt positioning booster seats until they are 4 ft, 9 inches and are 8 to 12 years of age. Other safety concerns are discussed in [Box 25.1](#).

Box 25.1

Diversity Considerations

Life Span

Infants, Toddlers, and Preschoolers

- Parents should be taught to check with the U.S. Consumer Product Safety Commission for information on approved cribs, devices, and toys.
- Slats on cribs, especially older models, can pose strangulation or entrapment hazards.
- Paint on toys may cause lead or other chemical poisoning.
- Parents need to childproof the home environment by using child locks for cabinets, childproof caps on medication bottles to prevent

poisoning, stairway gates, and safety plugs for electrical outlets; putting padding on or removing furniture with sharp edges and corners; and keeping sharp and dangerous items out of reach.

- Choking or asphyxiation can occur from toys, objects, or foods (e.g., hot dogs, grapes) that block airways. Small objects should be kept out of reach, and food should be cut in small pieces.
- Strangulation is a risk from cords on curtains and blinds. Cord-free window treatments are available and should be used.
- Liquids that are pretty colors and taste sweet, such as fluid medications and antifreeze, should be kept out of reach and secured.
- Swimming pools must be fenced and locked. All children should wear life jackets when near or in lakes and pools.
- Very young children are more sensitive to heat than are adults due to their smaller body surface area, and they can become dehydrated more easily. Adequate fluids should be provided on hot days, and children should *never* be left unattended in vehicles.

School-Age Children

- Drowning is a risk. Children should not be allowed to swim without adult supervision, and they should wear life jackets.
- Trampoline use can cause injury and death. Secure netting is necessary, as is adult supervision. Flips and tricks should not be allowed. Only children 6 years old or older should be permitted on a trampoline.
- Skating and bicycling accidents can cause injuries and deaths. Children should wear appropriately fitted helmets and knee and elbow protectors while skating, skateboarding, sledding, and riding a bike.
- Limit the amount of sedentary screen time (television, computer, gaming) to no more than 2 hours per day ([AAP, 2016](#)).

Adolescents and Teenagers

- Some teens experiment with the use of nicotine, drugs, and alcohol. Intentional and unintentional poisonings can occur in this group. Parents need to be alert to signs and symptoms of depression, poisoning, and drug use.
- Sexual curiosity and experimentation occur in this population. Conversations about safe sexual practices, including the

consequences of unprotected sex, such as pregnancy and sexually transmitted infections, are important.

- Motor vehicle crashes are common. Safety courses, driver's education, use of seatbelts, and avoidance of cell phone use, texting, and other distractions (e.g., wearing headphones, eating) while driving are important.
- Parents should be advised to limit violence exposure from television, the Internet, video games, and movies.
- Using earphones while listening to loud music can cause permanent hearing damage. Teenagers should be able to hear conversations even with earbuds inserted, otherwise the music is too loud. Parents should set limits on listening times and have teens take breaks from listening ([AAP, 2017](#)).

Adults

- Work-related hazards can result in injuries and death (see section on [Workplace Hazards](#)).
- Use of illicit substances and overdoses or poisoning from illegal and prescription drugs are a concern. Tobacco use should be avoided.
- Use of drugs or alcohol while driving can result in motor vehicle crashes.
- Unprotected sex and multiple sexual partners may lead to sexually transmitted diseases, including human immunodeficiency virus (HIV) infection.

Older Adults

- The physiologic changes that occur in the body systems with aging put older adults at risk for events such as motor vehicle crashes, falls, and burns.
- Falls are common in the older adult population.
- Basic strategies, such as removal of obstacles from walking paths indoors and outdoors, including ice from walkways, can help prevent falls.
- To prevent falls and their subsequent injuries, nurses share many strategies with older adults (see section on [Fall Prevention](#)).
- Vision and hearing screenings are recommended for older adults.
- Medication safety precautions (e.g., using pill dispensers and taking medications in a well-lit area) should be employed to

prevent incorrect or inadequate dosing and inadvertent overdosing.

- Because older adults may be sensitive to heat and cold, caution should be taken to avoid hypothermia and hyperthermia. Thermometers can be used to check water temperatures in baths and showers to avoid scald burns.
- Driving refresher and safety courses should be explored through the state department of motor vehicles.

In adulthood, life stressors such as financial concerns, work-related demands, and efforts to balance work with family life are common challenges that can take a physical toll on the body. Individuals should plan relaxation periods or vacations and schedule annual visits to a health care provider to screen for elevations in blood pressure and cholesterol levels, headaches, depression, and lung disease in smokers.

Environmental Factors

A person's environment includes the home, outdoors, workplace, community, and settings in which care is provided. For individuals to remain safe and healthful in their environment, a variety of factors must be considered and good practices maintained.

Pollution

Pollution is the contamination of air, land, water, and the environment (e.g., noise) by unnatural or harmful substances. Safety concerns are the ill-health effects that result from exposure to pollution. For example, air pollution caused by the release of chemicals or by-products of manufacturing into the atmosphere can increase the risk for chronic lung disease and some cancers. Other forms of air pollution include cigarette smoke and exhaust fumes from vehicles, which can produce allergic symptoms.

Land pollution by the improper disposal of trash or waste can be reduced by reusing and recycling materials and packaging. Land pollution is not limited to littering. Industrial and agricultural waste is associated with birth defects and cancer. Water can become polluted through improper refuse disposal, animal waste, and industrial by-products, resulting in infection and other disease.

Noise pollution from sources such as factories, construction sites, trains, planes, loud music, and cheering in sports stadiums is a real concern. Some of the health effects resulting from noise pollution include hearing loss, stress, and elevated blood pressure.

The best resource for pollution-related concerns and solutions is the Environmental Protection Agency (EPA). The EPA has been in existence since 1970, striving to protect the environment and human health.

Lighting

Inadequate lighting presents safety concerns in home, work, community, and health care environments. For an individual to safely and successfully navigate pathways and perform various activities while avoiding potential obstacles and hazards, the environment must be well illuminated. Well-lit, glare-free halls, stairways, rooms, and work spaces help reduce the risk for tripping, slipping, and falling. Night-lights reduce the risk for injuries to children, guests, and older adults.

Communicable Diseases

Communicable diseases are transmittable from one individual directly to another, usually through blood or body fluid exposure or through vectors such as insects and spores. [Chapter 26](#) discusses the transmission of communicable diseases. In addition to guidelines that are set on a national level by the CDC, most states have programs for communicable disease surveillance and prevention in their departments of health. For example, the State of Maryland has the Office of Epidemiology and Disease Control Program (EDCP). Usually, a major component of these programs is immunization to prevent disease, such as annual influenza vaccinations.

Workplace Hazards

Some adults spend as much as 40% to 50% of their waking hours at work. Over 12,000 American workers are injured on the job each day, with injuries that are preventable, amounting to an injury every 7 seconds ([National Safety Council, 2018b](#)). As the Baby Boomer generation ages, the population of older adults in the workforce is increasing. Adults and older adults encounter hazards in the workplace and are at risk for injuries that need care in a variety of settings, such as primary care offices, urgent care clinics, and EDs. Workplace safety and injury prevention are concerns for nursing and other health care professionals.

A unique and sometimes complex set of safety issues exists in each work environment. Depending on the occupation, safety concerns range from work at dangerous heights to exposure to chemicals and hazardous fumes or dust (e.g., asphalt, asbestos) to the ergonomic

issues of repetitive motion and heavy lifting. To address safety concerns, the Occupational Safety and Health Administration (OSHA) was established in 1970 to provide employers with guidelines for preventing exposure to hazardous chemicals and hazardous situations and reducing the risk for injury in the workplace. Some workplace settings are particularly hazardous. According to the Bureau of Labor Statistics in 2016, 5,190 people (14 people per day) died while doing their jobs ([National Safety Council, 2018a](#)). In the field of safety science, occupational safety officers work in conjunction with occupational health nurses to promote a healthy, hazard-free workplace. The National Institute for Occupational Safety and Health (NIOSH), a federal agency within the CDC, was established to conduct research and recommend interventions for the prevention of work-related injury and illness.

In the workplace, 104,000,000 production days were lost due to work-related injuries in 2016 ([National Safety Council, 2018b](#)). In nursing, some well-documented areas of occupational health and safety concerns include needlestick injuries, back and neck injuries resulting from lifting, and patient-on-nurse violence. Factors that contribute to these injuries include lack of appropriate equipment to ensure nurse and patient safety, rising numbers of more acutely ill patients without adequate increases in nurse staffing, an increasingly obese patient population, and lack of staff familiarity with facility safety protocols or a lack of protocols. In addition, NIOSH has developed a training program to educate nurses and managers about the health and safety risks associated with shift work, long work hours, and related workplace fatigue issues along with risk reduction strategies ([NIOSH, 2018](#)).

Patient Safety Concerns

Concerns related to patient safety in a health care agency are detailed throughout this chapter. Two different examples are fires and the use of restraints. Fires occurring in health care settings usually result from the use of flammable gases, such as anesthetics and oxygen, or electrical equipment, such as heating or cooling devices, respiratory devices, beds, and monitors. The use of physical and chemical restraints in health care settings generates concerns about patient safety and ethical treatment.

LO 25.3 Altered Safety

Nurses are in a position to educate patients about safety issues in inpatient, outpatient, home, and community settings. Prevention of injuries is the overarching goal, and providing patients with safety information gives them the tools needed to ensure their own safety.

Altered Safety in the Home and Community

Keeping individuals safe in their homes or communities depends on the prevention of illness and injury. A particular concern at home and in the community is food safety, which requires cooking food to appropriate temperatures, carefully monitoring expiration dates, using proper storage methods, and paying attention to food safety recalls announced in the media.

Another concern is the prevention of injuries resulting from motorized and nonmotorized means of transportation and recreation. Available education programs and safety gear are recommended for biking, motorcycling, skating, and driving. Each of these activities has unique environmental factors (e.g., traffic, obstacles, weather) that must be considered for the activity to be undertaken safely.

Equipment in or around the house can present another safety concern. For example, guns should be used only after training and with proper permits; when not in use, they should be locked away, with ammunition removed. Lawn mowers should be operated only while wearing sturdy, laced or Velcro, nonslip shoes and after review of the manufacturer's safety instructions. Specific home and community safety concerns are discussed in the following sections.

Poisoning

Poisoning involves the intentional or unintentional ingestion, inhalation, injection, or absorption through the skin of any substance harmful to the body. This section focuses on **unintentional poisoning**, an act in which the person did not mean to inflict harm by taking or giving the substance; this includes an inadvertent overdose.

Unintentional poisoning is a pervasive problem in the United States resulting in ED visits and unintentional death. Nurses need to be able to distinguish poisoning from other conditions that it may mimic, such as alcohol intoxication, seizure, stroke, and insulin reaction ([Mayo Clinic, 2018](#)).

Toxins

Toxins are substances that can poison or harm individuals or other living organisms through mechanisms such as ingestion, inhalation, and dermatologic exposure. Poisoning is a particular concern, because items containing toxins are commonly found in home settings and community environments. Potentially toxic items include medications (i.e., prescription and over-the-counter drugs), illegal drugs, indoor and outdoor plants, pesticides, detergents and other household cleaners, antifreeze, lead, and carbon monoxide.

Lead

Lead poisoning is a public health issue. It occurs when lead levels build up in blood over months or years, and it can affect all body systems. When lead levels are greater than 5 µg of lead/dL of blood, the CDC recommends initiation of public health actions (CDC, 2016). These blood lead levels are a common occurrence in children 1 to 5 years of age because of exposure to lead-based paint in older buildings and toys. There is not a safe lead level for children (CDC, 2018). Even small amounts of lead exposure can irreversibly damage the nervous system and impair development in children.

Lead-based paint is the most common and dangerous exposure for young children (CDC, 2015). In addition to lead-based paints in toys, buildings, and ceramic dishes, sources of lead include water from lead pipes or pipes soldered with lead, gasoline or soil contaminated by gasoline, and household dust that may contain paint chips or soil (CDC, 2015).

Carbon Monoxide

Carbon monoxide is a colorless, odorless gas that can cause sudden illness and death. It is a leading cause of unintentional poisoning deaths in the United States. Sources of carbon monoxide are combustible fumes produced by automobiles, stoves, gas ranges, portable generators, lanterns, burning charcoal and wood, and heating systems. Carbon monoxide can build up in enclosed spaces, such as in trucks and cars, and in semienclosed spaces, such as rooms of houses. Symptoms of carbon monoxide poisoning include dizziness, light-headedness, and nausea. Death can occur if exposure in an enclosed area is prolonged.

Plants

Although plants used in and around the home and community for decorative purposes can be quite beautiful, some that grow in populated areas are hazards (e.g., philodendron, poison ivy). Because many trees and plants can be poisonous, it is important to keep small children away from them and ensure that children are adequately

supervised when encountering them. Resources are available outlining dangerous plants, shrubs, and trees, including lists for specific geographic regions. The safest strategy is to avoid touching or ingesting them unless they are known to be nonpoisonous.

Medications

In the home and community setting, medications present another potential safety hazard that can result in intentional or unintentional poisoning. Medication dosage must be adjusted for children and older adults. Safe medication dosages for children are usually based on the number of milligrams of drug per kilogram of body weight. Children have lower body weights and differences in metabolism and excretion compared with adults. Older adults may have a decline in organ function, resulting in slower metabolism and excretion of drugs.

Other important safety considerations include keeping medications secured in child-resistant containers or out of reach. For older adults, pharmacists often recommend “starting low and going slow.” Older adults should understand how and when to take medications to avoid underdosing or overdosing. A medication schedule, including reminders, can help. All medications that are old, have been discontinued, or are expired should be properly disposed of and not shared with others.

In the home, the U.S. Food and Drug Administration (FDA) recommends following directions on the medication bottle for disposal or taking unused medications to community take-back programs. If no instructions are on the label and no take-back program is available, most medications can be thrown in the household trash. The drugs should be mixed with an undesirable substance such as coffee grounds or kitty litter to make them less appealing to children and unrecognizable to someone who may go through the trash. The mixture should be placed in a jar, sealable plastic bag, or can, and the container should be put in the trash after removing any personal information (FDA, 2018a). Several medications such as morphine sulfate and oxycodone hydrochloride should be flushed down the toilet to prevent ingestion by anyone else or a pet (FDA, 2018a).

In health care facilities, needleless systems are available to reduce accidental needlesticks. Red sharps containers are available in every room for safe disposal of used needles, which prevents needlestick injuries. Some facilities have similar containers in other colors for disposal of other nonhazardous and hazardous medication waste. These color-coded containers facilitate safe disposal of pills, solutions, vials, and patches.

Household Chemicals

Common toxins found in the home include household chemicals such as cleansers (e.g., detergents, ammonia, bleach), adhesives (e.g., glues), hair sprays and dyes, furniture polish, insect repellants, and gasoline. All chemicals should be kept secured and out of reach of children and older adults with cognitive impairment. Household chemicals should be used with care and according to manufacturers' instructions.

Fires and Electrical Hazards

Fire safety is an important concern in residential environments. In the United States in 2016, there were approximately 364,300 residential fires, resulting in 2,775 deaths and 11,025 injuries ([U.S. Fire Administration, 2018a](#)). Cooking has been the leading cause of residential fires for the last decade, followed by heating, electrical malfunction, and other unintentional causes or carelessness. To prevent incidences of fire when cooking, never leave a cooking surface unattended, wear short sleeves, and keep objects such as towels, potholders, and paper away from the stove. All cigarettes or cigars should be put out before leaving a room. Candles should not be left unattended and should be blown out after using and before bed. All families should have and practice a fire escape plan.

An **electrical shock** occurs when a person comes in contact with an energy source and the energy flows through the body or portion of the body to the ground. Exposure to the electrical energy source can result in no injury, burn injuries, contractures, or death from cardiac and respiratory arrest. In the home setting, electrical hazards exist from overloaded electrical circuits, use of appliances near sinks and tubs (i.e., sources of water), and use of lighting or appliances with frayed wires or electrical cords. Open or uncovered electrical outlets are potential hazards for small, curious children.

Abuse

Abuse is anything offensive, harmful, or injurious to an individual that can pose a direct safety threat. The four major types of abuse are physical, psychological or emotional, sexual, and financial. Abuse can occur in all socioeconomic, gender, age, and cultural groups, but some portions of the population are more vulnerable. Abuse is discussed further in [Chapters 17](#) and [18](#).

Bioterrorism

Before the outbreak of anthrax among U.S. postal workers after the terrorist attacks of September 11, 2001, emergency preparedness in health care and nursing was not the focus that it is today. Anthrax is a likely bioterrorism agent because the spores are easy to find, can be produced in a laboratory and then put in powder, food, or water, and are easily breathed in or ingested without the person knowing he or she has come in contact with the spores (CDC, 2014). **Bioterrorism** is the release of biologic agents such as bacteria, viruses, fungi, and other microbes with the intent to cause illness or kill people, animals, or plants. In a bioterrorist attack the agents may be spread through the air or through infection of animals, contamination of food or water supplies, or contact with an infected person or contaminated object (Department of Homeland Security, n.d.). Besides anthrax, another possible form of bioterrorism is smallpox.

Suffocation and Drowning

Suffocation results when air no longer reaches the lungs and respiration ceases. Common causes of suffocation are smothering, drowning, and choking. Other than congenital problems, drowning is the leading cause of death in children 1 to 4 years of age, with most drownings occurring in home swimming pools (CDC, 2016). This age group is at particular risk for drowning due to lack of supervision of children in bathtubs and swimming pools. The risk for drowning is increased among adults who do not use approved life jackets, who swim alone, who swim in hazardous conditions, or who swim under the influence of alcohol.

The risk for infants of smothering increases by co-sleeping and with the use of pillows and blankets. Curious toddlers are an at-risk group for suffocation due to choking on food (e.g., hot dogs, popcorn), foreign objects lodged in the trachea, and plastic bags placed over the face.

Unintentional deaths also occur as a result of playing the choking game, which has been on the rise among school-age children and teens. This game is a dangerous activity in which individuals choke each other or use a noose to choke themselves to achieve a brief high. Among older adults, death can occur from choking on food lodged in the trachea as a result of difficulties with chewing and swallowing. Risk factors include ill-fitting dentures and many comorbid conditions such as stroke and dementia.

Dukes et al. (2018) categorize falls into accidental falls, anticipated physiologic falls, and unanticipated physiologic falls. Accidental falls can be prevented through use of fall precautions on all patients such as keeping needed items close by and keeping floors clear of debris. Having patient specific interventions in place after thorough assessment prevents anticipated physiologic falls. Falls due to unknown

physiologic problems may not be preventable on the first occurrence but once a problem is identified they fall under the category of anticipated physiologic falls with patient-specific interventions for prevention.

Altered Safety in Health Care Agencies

Falls

Although patient falls have been a safety concern for the past three decades, the lack of financial reimbursement for them has made fall prevention a priority issue for hospitals. The [Centers for Medicare and Medicaid Services \(CMS\)](#) no longer makes payments to hospitals for the cost of additional care resulting from patient falls because they are considered reasonably preventable. The CMS is the federal organization that certifies all Medicare- and Medicaid-participating hospitals, which are facilities for acute care, psychiatric and rehabilitation services, and long-term care, as well as children's hospitals and treatment centers for alcohol and chemical dependence.

Restraints

Federal government and accrediting agencies have spent more than two decades working to reduce or eliminate the use of restraints in patient care environments. The Omnibus Budget Reconciliation Act of 1987, enacted in 1990 and since revised, provides guidelines on restraint use for long-term care facilities. When facilities fail to comply with the guidelines for appropriate restraint use, citations and fines may be issued by state quality assurance boards or the CMS. Restraints should be used only after careful assessment that the person is a danger to self or others and verbal deescalation is not successful ([American College of Emergency Physicians \[ACEP\], 2014](#)).

Restraints may be physical or chemical. A [physical restraint](#) is a mechanical or physical device, such as material or equipment attached or adjacent to the patient's body, preventing free movement by the patient ([Springer, 2015](#)). Examples of physical restraints are wrist or ankle restraints, a jacket or vest, and side rails. A medication that is administered to a patient to control behavior is a [chemical restraint](#).

Although restraints may be used by the nurse with the intent of preventing injury or harm to the patient, the staff, or others, there are inherent risks associated with restraint use. One of the biggest misconceptions is that physical restraints prevent injurious falls. Studies have disproved this belief, finding instead that fall-related injuries have increased with restraint use ([Hofmann & Hahn, 2013](#); [Miake-Lye,](#)

Hempel, Ganz, et al, 2013). Skin impairment, incontinence, falls, serious injuries, and even death have been associated with restraint use. A physical restraints critical element pathway is available to evaluate appropriate restraint compliance (CMS, 2013).

Medication Administration Errors

Medication errors occur in many situations. A medication error is any preventable event that may cause or lead to inappropriate medication use or patient harm (FDA, 2018c). Electronic medical records (EMRs) help reduce the incidence of medication errors. In addition, facilities are working to decrease interruptions during medication administration to prevent medication errors (Flynn, Evanish, Fernald, et al., 2016).

The lack of interprofessional collaboration and communication is a barrier to safe medication administration. Sound-alike or similarly spelled drug names are another area of concern for the safe administration of medication because the drugs often have widely different uses. Examples include heparin (anticoagulant) and Hespan (plasma volume expander) and vincristine (chemotherapeutic agent) and vinblastine (different chemotherapeutic agent). Interruptions and distractions during medication administration contribute to medication errors.

Medications should be checked and double-checked in accordance with the six rights of medication administration: the right drug, in the right dose, at the right time, to the right patient, by the right route, and with the right documentation. Chapter 35 discusses errors in medication administration and how to avoid them.

Radiation

Overexposure to radiation or radioactive materials used to diagnose and treat patients is a health hazard of concern for patients and health care professionals. Nurses at risk for radiation exposure are typically those who work with patients receiving radioactive iodine treatments, work in areas where special procedures are performed involving radiation, or are called to diagnostic areas to care for agitated patients during radiographic procedures. Excessive radiation exposure can cause injury to many body systems, including the gastrointestinal tract, skin, and reproductive organs. To prevent overexposure, hospitals and diagnostic imaging centers have detailed policies and procedures in place.

Nurses must be aware of diagnostic procedures that can increase the amount of radiation exposure to themselves and their patients. In addition to x-rays, a potential source of diagnostic radioactive exposure

is positron emission tomography (PET), which uses energy released in the breakdown of radiopharmaceutical agents to monitor metabolic activity ([International Atomic Energy Agency, 2018](#)). Another source is computed tomography (CT), which provides incredibly accurate maps, or models, of bone and soft tissue through computer interpretation of multiple-sequenced images gathered by x-ray sensors that rotate around the body ([American Society of Clinical Oncology, 2018](#)). PET and CT are used together to diagnose pathologic conditions because the CT looks at tissue and organs inside the body and the PET scan identifies abnormal activity. Combined use of PET and CT creates some special radiation safety issues because each modality is a source of x-ray exposure ([Radiologic Society of North America, 2017](#)). Diagnostic centers and hospitals performing PET/CT scanning should have updated policies and procedures to protect health care professionals and patients from overexposure.

Drug-Resistant Microorganisms

Several microorganisms have evolved strains that are resistant to common antibiotics. Methicillin-resistant *Staphylococcus aureus* (MRSA) causes skin and other organ infections and is extremely resistant to many antibiotics. It is often spread by contact with the skin of an infected person, or it can be spread by contact with infected objects. A community-associated form of MRSA can infect those who share close living quarters. Skin-to-skin contact is of concern for health care personnel, prison inmates, college dormitory residents, team athletes, and military personnel. Resistant microorganisms are discussed in [Chapter 26](#).

Procedural Errors

An example of a procedural error is the failure to properly identify a patient when entering a room to administer medication. Another example is leaving the bed in an elevated position after providing care or performing a procedure on a patient. Other procedural errors that have implications for patient safety are discussed in the section on [Reduction of Procedure-Related and Equipment-Related Events](#).

LO 25.4 ♦ Assessment

Assessment for safety hazards and potential sources of injuries is an important first step in the nursing process. The assessment includes the collection of subjective information related to the patient's symptoms and chief complaint, history of environmental hazards and exposures, and objective assessment with a focus on affected body systems. The nurse may discover information that provides clues to safety issues. While obtaining the patient's history, the nurse should inquire about causes of prior injuries and probe further into the topic when safety issues are raised. Questions that should be asked in regard to safety in the home and immediate environment are presented in [Box 25.2](#). The health history may reveal factors that place the patient at risk for safety concerns, and the physical assessment may reveal issues that should be further investigated.

Box 25.2

Health Assessment Questions

Safety in the Home

Health history and physical assessment should dictate specific safety questions:

- *Activities of daily living*: Do you require human or mechanical assistance with any of the following: walking, toileting, bathing, dressing, grooming, and eating? If yes, please describe the type of assistance you need.
- *Instrumental activities of daily living*: Do you require human or mechanical assistance with any of the following: cooking, cleaning, doing laundry, shopping, driving, and obtaining medications? If yes, please describe the type of assistance you need.
- *Medications*: Do you know how and when to take your medications? Do you know why you take them? Do you take your medications consistently? Have you been experiencing any side effects? If yes, describe them.
- *Health issues*: Do you have any injuries or health issues that place you at risk for falling or for drowsiness? Have you ever had a seizure?

- *Safety issues:* Do you have any safety concerns? Do you have a history of falling? Do you have worries about what you would do in case of a fire? Are you stressed out or tired?
- *Home situation:* Please describe your current living situation. Whom do you live with? Do any elderly people or young children live in the home?

Poisoning

- *Chemicals:* How do you store your household chemicals? Are they out of reach of children and pets?
- *Medications:* Where are your medications stored? Are they out of reach of children, or do they have childproof caps? Are any medications expired?
- *Food:* Are “leftover” foods dated and placed in airtight containers? Is the refrigerator cleared of potentially spoiled items on a weekly basis? Are separate cutting surfaces used for cutting raw fish and meats? Are meats refrigerated during marinating, and is excess marinade discarded before cooking?
- *Carbon monoxide:* Do you experience unexplained headaches, dizziness, drowsiness, nausea, or any other flulike symptoms? Do you have a carbon monoxide detector in your home?

Fire and Electrical Hazards

- Do you have adequate outlets for all of your appliances and electronic devices? If there are children in the home, are all outlets in your home covered?
- Do you check for frays or loose wires on electrical cords, including those of electronic devices such as laptops and cell phones?
- Are your circuit breaker boxes in working order?
- Are your appliances properly grounded?
- Are household appliances, such as irons, hair dryers, and electric razors, used away from sources of water? Are the electrical outlets grounded?
- Do you have smoke detectors? A fire extinguisher? An evacuation plan in case of a fire?
- Do you use an oven and stove?
- Do you smoke, or does anyone in your home smoke?

Biohazards

- *Needles*: Do you use hypodermic needles? How do you dispose of them?
- *Methicillin-resistant Staphylococcus aureus (MRSA)*: Do you have any open or inflamed areas on your skin?

Home Temperature Safety

- How do you heat your home? Is it adequate? Do you use space heaters?
- Do you have screens in your windows in the summer?
- Do you have air-conditioning? Fans?

Tripping and Falling Hazards

- Have tripping and falling hazards, such as clutter, toys, and electric cords in walking areas, been removed? Do area rugs have rug pads beneath them?
- Is there adequate lighting in hallways and on the stairs?
- Do you have night-lights?
- If there are children in the house, are gates installed in doorways and at the top and bottom of stairs?
- Are there handrails on the stairs?
- Are there grab bars in the bathroom? Is there a rubber mat in the tub and on the shower floor?

Outside Environment

- Do you have rails on steps?
- Is there adequate outside lighting?
- Do you operate any outside equipment, such as lawn mowers?
- Do you drive? Do you use car seats or safety belts?
- Do you feel safe in your neighborhood?
- What recreational activities do you engage in? Do you use safety equipment?

Work

- What do you do for a living?
- How is your work situation? Do you have any concerns?

The assessment of fall risk should be completed on admission to establish a baseline and repeated on a daily basis or with any change in the patient's condition. In any health care setting, assessment of fall risk includes personal factors (e.g., incontinence, unsteady gait) and environmental factors (e.g., tubes or drains, floor surfaces) (Phelan, Mahoney, Przybelski, et al., 2015). Many tools exist for the assessment of fall risk. Examples of tools frequently used in hospital settings are the Johns Hopkins Hospital Fall Assessment Tool, the Morse Fall Scale, and the Hendrich II Fall Risk Model. The Johns Hopkins Hospital Fall Assessment Tool (Fig. 25.1) provides a snapshot of overall fall risk. This seven-item tool, which is used nationally and internationally in hospitals, can be completed quickly and easily by the nurse at the bedside. The tool accommodates the influence of advanced age, fall history, specific medication classes, patient care equipment that tethers, and mobility, cognitive, and elimination functions. After this assessment is completed, an overall summary score is calculated; the higher the score, the greater is the patient's risk for falling. From this score a level of risk is determined, and interventions can be selected from a list of recommended fall prevention strategies (Fig. 25.2) to target patient-specific risk factors. The nurse should realize that multiple factors place patients at risk for falling. Because fall risk is multifaceted and often complex, interdisciplinary, comprehensive fall prevention strategies are most effective (Phelan, Mahoney, Przybelski, et al., 2015).

Fall Risk Factor Category 1	
Scoring not completed for the following reason(s). <i>(Check any that apply.)</i> Enter risk category (i.e., Low/High) based on box selected.	
<input type="checkbox"/> Complete paralysis, or completely immobilized. Implement basic safety (low fall risk) interventions. <input type="checkbox"/> Patient has a history of more than one fall within 6 months before admission. Implement high fall risk interventions throughout hospitalization. <input type="checkbox"/> Patient has experienced a fall during this hospitalization. Implement high fall risk interventions throughout hospitalization. <input type="checkbox"/> Patient is deemed high fall risk per protocol (e.g., seizure precautions). Implement high fall risk interventions per protocol.	
Fall Risk Factor Category 2	
For those patients who are not in the above category, complete the following risk assessment tool and calculate fall risk score. If no box is checked, the score for the category is 0.	
	SCORE
Age <i>(Select only one)</i>	
<input type="checkbox"/> 60-69 years (1 point)	
<input type="checkbox"/> 70-79 years (2 points)	
<input type="checkbox"/> 80+ years (3 points)	
Fall history <i>(Select one)</i>	
<input type="checkbox"/> One fall within 6 months before admission (5 points)	
<input type="checkbox"/> No falls (0 points)	
Elimination, bowel and bladder <i>(Select one only)</i>	
<input type="checkbox"/> No incontinence, urgency, or frequency (0 points)	
<input type="checkbox"/> Incontinence (2 points)	
<input type="checkbox"/> Urgency or frequency (2 points)	
<input type="checkbox"/> Urgency/frequency and incontinence (4 points)	
Medications: Includes PCA/opiates, anticonvulsants, antihypertensives, diuretics, hypnotics, laxatives, sedatives, and psychotropics <i>(Select one)</i>	
<input type="checkbox"/> On one high fall risk drug (3 points)	
<input type="checkbox"/> On two or more high fall risk drugs (5 points)	
<input type="checkbox"/> Sedation procedure within past 24 hours (7 points)	
Patient care equipment: Any equipment that tethers the patient (e.g., IV infusion, chest tube, indwelling catheters, SCDs, etc.) <i>(Select one)</i>	
<input type="checkbox"/> One present (1 point)	
<input type="checkbox"/> Two present (2 points)	
<input type="checkbox"/> Three or more present (3 points)	
Mobility <i>(Multiple select, choose all that may apply and add points together)</i>	
<input type="checkbox"/> Requires assistance or supervision for mobility, transfer, or ambulation (2 points)	
<input type="checkbox"/> Unsteady gait (2 points)	
<input type="checkbox"/> A visual or auditory impairment affecting mobility (2 points)	
Cognition <i>(Multiple select, choose all that may apply and add points together)</i>	
<input type="checkbox"/> Altered awareness of immediate physical environment (1 point)	
<input type="checkbox"/> Impulsivity/poor safety judgment (2 points)	
<input type="checkbox"/> Lack of understanding of one's physical and cognitive limitations (4 points)	
Total points scored	
Moderate risk = 6-13 points. High risk = 13+ points.	

Please complete the fall risk assessment tool once every 8 hours or with change in patient's condition.

FIGURE 25.1 Johns Hopkins Hospital Fall Assessment Tool.

LOW FALL RISK	MODERATE FALL RISK	HIGH FALL RISK
<i>Fall risk score: 0-5 points</i>	<i>Fall risk score: 6-13 points Color code: YELLOW</i>	<i>Fall risk score: >13 points Color code: RED</i>
<p>Maintain safe unit environment, including:</p> <ul style="list-style-type: none"> • Remove excess equipment/supplies/furniture from rooms and hallways. • Coil and secure excess electrical and telephone wires. • Immediately clean all spills in patient's room or in hallway. Place signage to indicate wet floor danger. • Restrict window openings. <p>The following are examples of basic safety interventions:</p> <ul style="list-style-type: none"> • Orient patient to surroundings, including bathroom location, use of bed, and location of call light. • Keep bed in lowest position during use unless impractical (as in ICU nursing or specialty beds). • Keep top two side rails up (excludes box beds). In ICU, keep all side rails up. • Secure locks on beds, stretchers, and wheelchairs. • Keep floors free of clutter and obstacles, with attention to path between bed and bathroom or commode. • Place call light and other frequently needed objects within patient's reach. Answer call light promptly. • Encourage patient/family to call for assistance when needed. • Display special instructions for vision and hearing. • Ensure adequate lighting, especially at night. • Use properly fitting nonskid footwear. 	<p>Institute flagging system: Yellow card outside room and yellow sticker on medical record, assignment board/electronic board; Hill ROM flag (if available).</p> <p>Implement measures listed under Low Fall Risk and:</p> <ul style="list-style-type: none"> • Monitor and assist patient in following daily schedules. • Supervise and/or assist bedside sitting, personal hygiene, and toileting as appropriate. • Reorient confused patients as necessary. • Establish elimination schedule, including use of bedside commode, if appropriate. • Activate bed/chair alarm. <p>Evaluate need for the following:</p> <ul style="list-style-type: none"> • Physical therapy consultation if patient has a history of fall and/or mobility impairment. • Occupational therapy consultation. • Slip-resistant chair mat (do <i>not</i> use on shower chair). • Use of seat belt when in wheelchair. See institution's Med/Surg Restraint policy. 	<p>Institute flagging system: Red card outside room and red sticker on medical record, assignment board/electronic board; Hill ROM flag (if available).</p> <p>Implement measures listed under Low and Moderate Fall Risk and:</p> <ul style="list-style-type: none"> • Remain with patient during toileting. • Observe q 60 min unless patient is on activated bed/chair alarm. • If patient requires an air overlay, use side rail protectors/extendors. • When necessary, transport throughout hospital with assistance of staff or trained caregivers. Consider alternatives (e.g., bedside procedure). Notify receiving area of high fall risk. <p>Evaluate need for the following:</p> <ul style="list-style-type: none"> • Moving patient to room with best visual access to nursing station. • Activated bed/chair alarm. • Low bed. • Protective devices (e.g., hipsters, helmets). • 24-hr supervision or sitter. • Physical restraint/enclosed bed (only with authorized prescriber order).

FIGURE 25.2 Johns Hopkins Hospital fall prevention intervention guidelines by risk category. *ICU*, Intensive care unit; *OT*, occupational therapy; *ROM*, range of motion. (Copyright The Johns Hopkins Health System Corporation.)

The Morse Fall Scale (Fig. 25.3) is a fall risk assessment tool that has been widely used nationally and internationally since the late 1980s in acute-care and long-term care settings. The tool is used by nurses in conjunction with physical assessment and medication review (Agency for Healthcare Research and Quality [AHRQ], 2013). The six items on the scale are weighted and focus on (1) history of falling, (2) existence of a secondary diagnosis, (3) use of an ambulatory aid, (4) use of an intravenous line or a saline lock, (5) gait, and (6) mental status. The score is totaled for the checked items. If the score is 25 or higher, the patient is considered to be at high risk for falls (AHRQ, 2013), and fall prevention interventions should be implemented as appropriate.

RISK FACTOR	SCALE	SCORE
History of falls	Yes	25
	No	0
Secondary diagnosis	Yes	15
	No	0
Ambulatory aid	Furniture	30
	Crutches/cane/walker	15
	None/bed rest/wheelchair/nurse	0
IV/Heparin lock	Yes	20
	No	0
Gait/transferring	Impaired	20
	Weak	10
	Normal/Bed rest/Immobile	0
Mental status	Forgets limitations	15
	Oriented to own ability	0

To obtain the Morse Fall Score, add the score from each category.

MORSE FALL SCORE	
High risk	45+
Moderate risk	25-44
Low risk	0-24

FIGURE 25.3 Morse Fall Scale. (From Morse, J. M., Black, C., Oberle, K., et al. [1989]. A prospective study to identify the fall-prone patient. *Social Science & Medicine*, 28[1]:81–86.)

The Hendrich II Fall Risk Model (Fig. 25.4) has been well established and used widely in acute-care settings to assess the fall risk of patients. This tool is available in English and Spanish. The tool focuses on eight independent risk factors: (1) confusion/disorientation/impulsivity, (2) symptomatic depression, (3) altered elimination, (4) dizziness/vertigo, (5) gender, (6) use of antiepileptics, (7) use of benzodiazepines, and (8) performance on the Get Up and Go Test (Hendrich, 2013). On this weighted tool, an item is assigned a zero if it does not apply to the patient. If the total score is 5 or higher on the Hendrich II Fall Risk Model, the patient is at high risk for a fall. As with the other fall assessment tools, when the nurse determines that the patient is at high risk, a care plan with a set of patient-specific fall prevention interventions needs to be implemented.

HENDRICH II FALL RISK MODEL™		
RISK FACTOR		RISK POINTS SCORE
Confusion/Disorientation/Impulsivity		4
Symptomatic Depression		2
Altered Elimination		1
Dizziness/Vertigo		1
Gender		1
Any Administered Antiepileptics (Anticonvulsants) ¹	Carbamazepine, Divalproex Sodium, Ethotoin, Ethosuximide, Felbamate, Fosphenytoin, Gabapentin, Lamotrigine, Mephenytoin, Methsuximide, Phenobarbital, Phenytoin, Primidone, Topiramate, Trimethadione, Valproic Acid	2
Any Administered Benzodiazepines ²	Alprazolam, Chlordiazepoxide, Clonazepam, Clorazepate Dipotassium, Diazepam, Flurazepam, Halazepam ³ , Lorazepam, Midazolam, Oxazepam, Temazepam, Triazolam	1
Get-Up-and-Go Test: "Rising From a Chair"		
<i>NOTE: If unable to assess, monitor for change in activity level, assess other risk factors, document both on patient chart with date and time.</i>		
Ability to rise in a single movement-no loss of balance with steps		0
Pushes up, successful in one attempt		1
Multiple attempts, but successful		3
Unable to rise without assistance during test		4
A TOTAL SCORE OF 5 OR GREATER = HIGH RISK		TOTAL SCORE:

Hendrich II Fall Risk Model© 2012 AHI of Indiana, Inc. ALL RIGHTS RESERVED. United States Patent No. 7,282,031 and U.S. Patent No. 7,682,308. Reproduction, distribution or transmission prohibited except by prior written permission of AHI of Indiana, Inc.

Ongoing Medication Review Updates:

¹ Levetiracetam (Keppra) was not assessed during the original research conducted to create the Hendrich Fall Risk Model. As an antiepileptic, levetiracetam does have a side effect of somnolence and dizziness which contributes to its fall risk and should be scored (June 2010). Banzel (Rufinamide), Sabril (Vigabatrin), Gabitril (Tiagabine) were not included in the study and are very uncommonly seen in practice, however, they are currently available and could be seen on patient medication lists (September 2018).

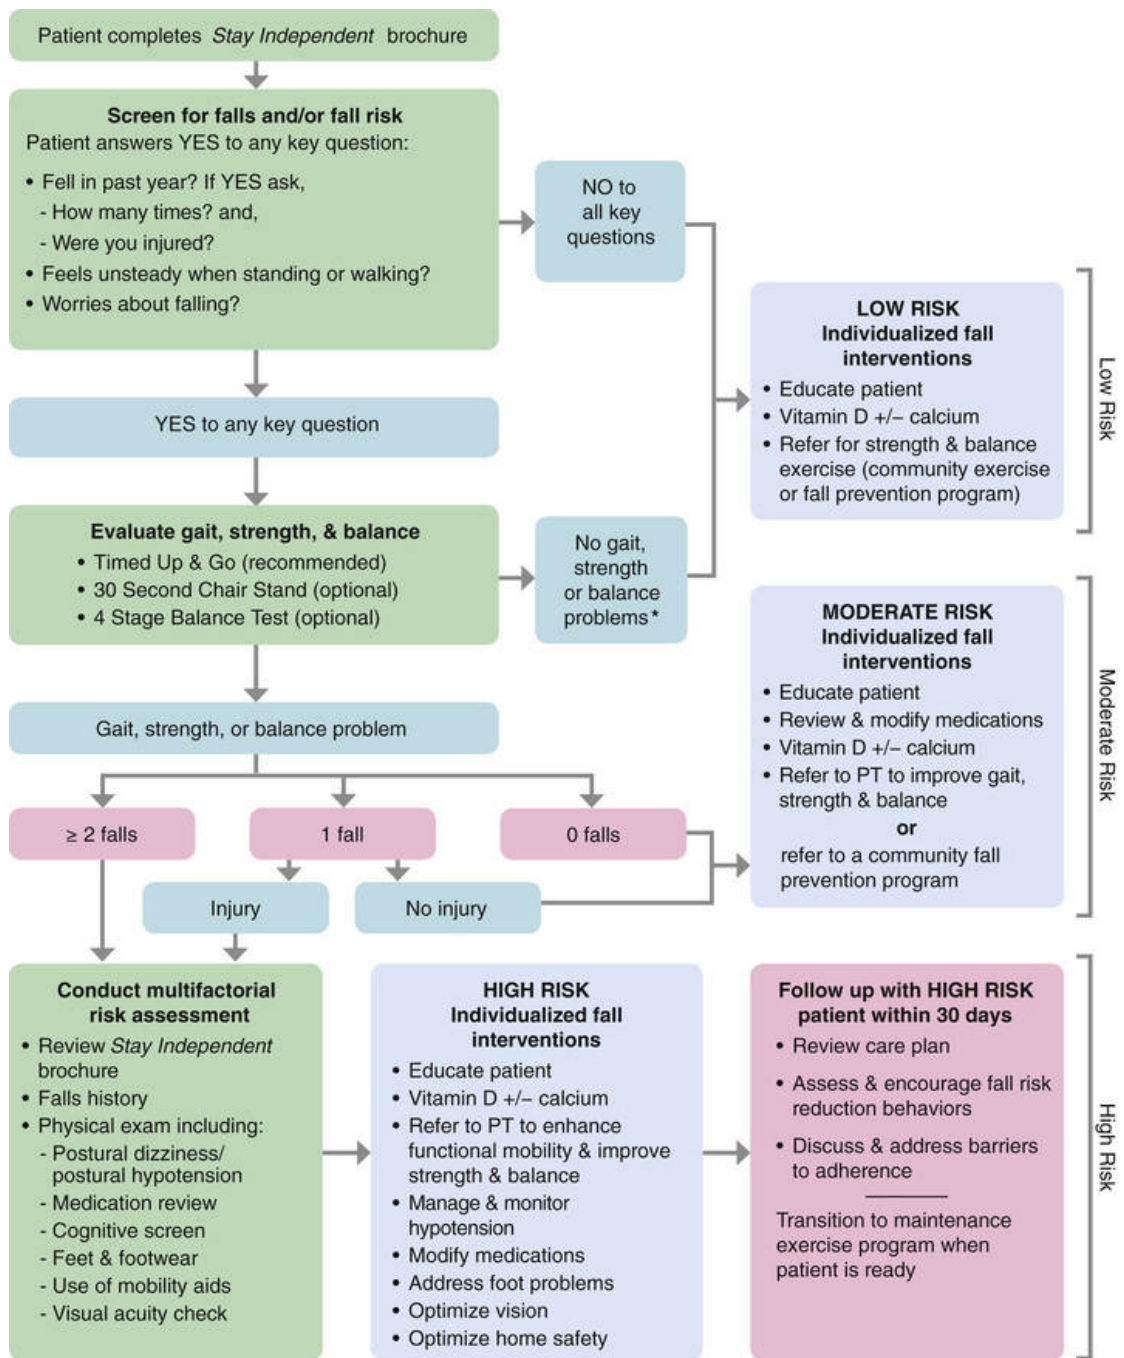

² The study did not include the effect of benzodiazepine-like drugs since they were not on the market at the time. However, due to their similarity in drug structure, mechanism of action and drug effects, they should also be scored (June 2010). Prosom (Estazolam), Doral (Quazepam), Onfi (Clobazam) were not included in the study and are very uncommonly seen in practice, however, they are currently available and could be seen on patient medication lists (September 2018).

³ Halazepam was included in the study but is no longer available in the United States. (June 2010)

V2018.1

FIGURE 25.4 Hendrich II Fall Risk Model. (Copyright 2012, AHI of Indiana Inc. All rights reserved.)

A fall prevention toolkit is available to integrate fall prevention in clinical practice. The Stopping Elderly Accidents, Deaths, and Injuries (STEADI) initiative includes a fall prevention algorithm (Fig. 25.5) to identify at-risk patients, modifiable risk factors, and interventions (CDC, 2017b)

*For these patients, consider additional risk assessment (e.g., medication review, cognitive screen, syncope)

FIGURE 25.5 STEADI algorithm for fall risk assessment and intervention. (From Centers for Disease Control and Prevention [CDC]. [2017]. STEADI older adult fall prevention. Retrieved from <http://www.cdc.gov/STEADI>.)

LO 25.5 ♦ Nursing Diagnosis

There are the several common nursing diagnoses related to safety issues. Others may apply after a safety-related event such as a fall-related hip fracture. An illness may result in *Acute Confusion*, especially in an older adult, creating safety problems. Many other nursing diagnoses are related to safety issues directly, or indirectly caused by illnesses that create safety concerns (e.g., MRSA infection, hypothermia, needlestick-related disease). Some International Classification for Nursing Practice (ICNP) nursing diagnoses related to safety are:

Risk for Injury

- Supporting Data: Confusion, oriented to person only, weakness, JHH score: 21, hypertension and taking lisinopril.

Risk for Fall

- Supporting Data: Older than 75 years of age, use of a walker, confusion

Risk for Poisoning

- Supporting Data: Household chemicals present

1. D. S. has *Acute Confusion*. Develop a goal for this nursing diagnosis. List four interventions (not mentioned in Exercise 2) with corresponding rationales that would be appropriate for managing her acute confusion.

LO 25.6 ♦ Planning

Before implementing interventions for the promotion of safety of individuals across settings, the nurse considers critical assessment findings such as the patient's developmental level, cultural background, and baseline understanding of the issue. After taking these considerations into account along with the desires and goals articulated by the patient and family, the nurse can develop individualized, patient-centered goals and interventions (Table 25.1). The following are examples of goals for the three nursing diagnoses previously listed:

TABLE 25.1
Care Planning

ICNP NURSING DIAGNOSIS WITH SUPPORTING DATA	NURSING OUTCOME CLASSIFICATION (NOC)	NURSING INTERVENTION CLASSIFICATION (NIC)
<i>Risk for Injury</i> Confusion, oriented to person only Weakness JHH score: 21 Hypertension, taking lisinopril	<i>Knowledge: Fall prevention</i> When to ask for personal assistance	<i>Fall prevention</i> Instruct patient to call for assistance with movement, as appropriate.

LO 25.7 ♦ Implementation and Evaluation

The planning, implementation, and evaluation of interventions to maintain the safety of patients across settings is often best promoted through the use of a multidisciplinary care team. [Box 25.3](#) gives examples of how nurses can work with the interprofessional team to promote patient safety.

Box 25.3

Interprofessional Collaboration and Delegation

Multidisciplinary Health Care Team

- The nurse collaborates with the pharmacist and physician to identify and implement safe medication alternatives for older adults to minimize side effects such as drowsiness, dizziness, and orthostatic hypotension, which can increase fall risk.
- Occupational therapists evaluate the patient for safe performance of activities of daily living (ADLs) such as bathing, dressing, and grooming, and make recommendations to enhance safe performance of these activities, such as the use of specialty equipment (e.g., grippers for pants, oversized shoehorns).
- Physical therapists evaluate the patient's ability to perform and maintain balance during routine activities such as sitting, standing, and walking. They make recommendations for assistive devices such as canes and walkers to promote safe performance of these activities.
- Speech therapists evaluate and treat speech, feeding, and swallowing disorders. They make recommendations for special diets and feeding to prevent aspiration.
- The social worker facilitates contact with insurance companies or other agencies to assist with referrals and the financing of recommended therapeutic assistive and specialty devices.
- Under the delegation of the registered nurse, unlicensed assistive personnel (UAP) provide hands-on care for patients who require assistance with ADLs, transfers, and ambulation. Registered nurses

are responsible for supervising and guiding UAP so that direct care is provided in a safe manner.

QSEN Focus!

Teamwork and collaboration knowledge are demonstrated when the nurse describes examples of the impact of team functioning on safety and quality of care.

For a patient with safety concerns, members of the multidisciplinary team together address the issues associated with safety-related nursing diagnoses. Team members work to accomplish the goals set forth in what is commonly referred to in hospital settings as an interdisciplinary plan of care (IPOC). The nurse may implement several safety interventions:

- Educate the patient and family about the role of protective-equipment use in injury prevention when individuals are engaged in contact sports.
- Collaborate with the social worker to identify community resources for obtaining inexpensive or free protective equipment.
- Educate the patient and family about the importance of removing clutter, throw rugs, cords, and obstacles from the floor and the path of the patient.
- Collaborate with the social worker to identify community resources to install appropriate supportive equipment in the home.
- Educate the patient and family on the importance of and strategies for preventing children from gaining access to household poisons.
- Collaborate with social services for the scheduling of periodic home safety inspections.

Safety Interventions in the Home and Community

The role of the nurse in mitigating safety risks is largely one of patient education and safety promotion. Nurses helping patients identify safety hazards at home and in the community lay the groundwork for appropriate action (Box 25.4). Nurses collaborating with other members of the health care team and with resources in the community can assist patients with arranging to have grab bars installed in the bathroom, improvements made to indoor and outdoor lighting, and increased surveillance inside and outside buildings and in parking lots. In home and community settings, nurses must be aware of specific areas of fall prevention, fire prevention, and poisoning prevention (Box 25.5).

Box 25.4

Home Care Considerations

Safety Assessment in the Home

Fire Prevention

Nurses delivering care in home settings need to assess for fire safety risk factors and should offer strategies for alleviating them:

- Do not use stoves for heating the house.
- Do not use ovens for storing food, such as crackers, cookies, or cereal.
- Do not leave irons face down on the ironing board.
- Do not smoke or have an open flame in a fireplace if oxygen is in use in the home.
- Properly dispose of or recycle trash, and do not allow it to accumulate.
- Install smoke alarms on every floor of the house.
- Change batteries in smoke alarms at least twice per year.
- Establish fire escape plans and practice them several times each year.
- Ensure that all family members know how and when to call emergency telephone numbers.
- Obtain fire extinguishers and be sure family members learn how to use them.
- Consider installing fire sprinklers in the home ([U.S. Fire Administration 2018b](#); [U.S. Fire Administration, 2017](#)).

Poisoning Prevention

Nurses offer recommendations for the prevention of poisoning:

- Ensure proper labeling and storage of chemicals and medications in original containers.
- Use alternatives to toxic chemicals, such as baking soda as a deodorizer.
- Store chemicals and medications out of the reach of small children.
- Employ cabinet safeguards and childproof caps to prevent access.
- Take medication only in a well-lit area to ensure correct dosage.
- Verify that medication dosages are appropriate for pediatric and/or geriatric patients.
- Understand potential food and drug interactions associated with the medication.
- Dispose of unused or expired medications; never share medications with others.

If poisoning is suspected, before administering an antidote, call the National Poison Control Center at 1-800-222-1222. Offer first aid for poisoning:

- If a poison has been inhaled, get the individual into fresh air as soon as possible.
- If poison gets in the eyes, flush the eyes immediately with water.
- If poison gets on the skin, remove clothing that was in contact with the poison, and rinse the skin with water for at least 15 minutes.

Be prepared to answer questions from the Poison Control Center:

- How is the person acting, or how does he or she look?
- What and approximately how much was taken?
- When was it taken?

Parents must provide a babysitter with the necessary information in case of poisoning or suspected poisoning of a child in his or her care. They should leave this information in a conspicuous location, such as on the refrigerator or near the telephone, and tell the babysitter that the information is there:

- Phone number of the Poison Control Center (1-800-222-1222)

- Age and weight of the child
- Allergies and medical conditions
- Physician's name and phone number
- Number at which parents can be reached

A medical emergency exists if a person is having seizures, is extremely drowsy, or is unconscious, having difficulty breathing or not breathing, or having any life-threatening symptoms. In such cases, call 911 immediately. While waiting for help, if the person is not breathing, initiate rescue breathing and cardiopulmonary resuscitation (CPR). Take the medication bottle or the container of the ingested substance along to the hospital emergency department. Do not attempt to induce vomiting; do not give syrup of ipecac ([Mayo Clinic, 2018](#)).

Lead

Nurses can provide strategies that may minimize lead exposure:

- Scheduling a professional lead inspection and renovation, which may be necessary in older homes; before 1978, lead-based paint was often used
- Doing careful handwashing, especially after gardening and outdoor play
- Washing and peeling vegetables
- Installing a water filter
- Letting water run from the tap for at least 1 minute before use

Carbon Monoxide

The [CDC \(2017a\)](#) recommends the use of several measures in the home or community setting to avoid carbon monoxide poisoning:

- Scheduling annual checks and service of the heating system, water heater, and any other gas, oil, or coal-burning devices by a qualified technician
- Installing a battery-operated carbon monoxide detector and checking or replacing the batteries each spring and fall, along with smoke-detector battery checks
- Immediately evacuating and then calling 911 if the carbon monoxide detector alarm goes off
- Seeking medical attention promptly if carbon monoxide poisoning is suspected (i.e., symptoms of nausea, dizziness, light-headedness)

- Using items such as charcoal grills, camp stoves, and generators outside and not inside the garage or basement
- Avoiding running cars or trucks inside a garage attached to the house
- Burning objects or materials only in vented fireplaces or stoves
- Never heating the house with a gas oven

Child Safety

Several measures can promote safety across childhood developmental age groups:

- Using outlet covers in homes with small children to prevent electrical shock
- Keeping household chemicals and medications locked in secure locations
- Ensuring parental supervision of activities such as using trampolines and swimming
- Keeping firearms locked in secure locations with bullets stored in a separate location
- Consistently using seatbelts
- Consistently and appropriately using car seats
- Encouraging teen participation in driver's education courses

Box 25.5

Patient Education and Health Literacy

Fall Prevention at Home

Health teaching for patients discharged to or residing in the home should include environmental interventions for fall prevention:

- Remove obstacles from walking paths (e.g., clutter, throw rugs, cords).
- Ensure adequate lighting in areas such as bathrooms, halls, and stairways.
- Keep assistive devices (e.g., canes, walkers) within reach.
- Use assistive devices consistently and properly when moving.
- Repair loose or uneven floor and stairway surfaces.

- Install and maintain handrails and grab bars.
- Use devices such as long-handled grabbers rather than reaching or stooping.
- Keep frequently used items close by or within reach.
- Maintain floor surfaces that are dry and free of debris.

Following these suggestions can make the patient's environment safer. Patients should be aware of environmental challenges, such as changes in ground slope and unevenness in walking surfaces and curbs. When going out into community settings, patients should be encouraged to take their assistive devices along on all occasions and properly use them. Reminders may be important for those who tend to leave canes or walkers in the car when they are “only going a short distance.”

Safety Interventions in the Health Care Environment

Consistent with the focus of the QSEN project, nurses must possess the knowledge, skills, and attitudes to maintain safety and prevent patient injury across health care settings. For example, a nurse must have adequate knowledge of the variety of risk factors for falls, the skill to select patient-specific interventions to prevent falls, and the attitude that falls are preventable. When nurses lack the necessary knowledge, skills, and attitudes to care for the population of interest, the delivery of competent care is at risk, and legal issues related to patient safety may result.

Legal Issues Related to Safety

Issues of patient safety can be disputed legally, and nurses must ensure that current and proper standards of care are upheld to ensure the safety of patients and to avoid lawsuits. Patient safety concerns that have been sources of litigation are listed in [Box 25.6](#). In addition to being guided by the legal issues related to safety, the professional practice of nursing is guided by the American Nurses Association Code of Ethics (see [Chapter 11](#)), the individual's internal ethical code of conduct, and the state's nurse practice act.

Box 25.6

Ethical, Legal, and Professional Practice

Litigation Resulting From Breaches in Patient Safety Standards of Care

- Wrong-side surgeries and amputations
- Wrong-patient errors (i.e., medications given to the wrong patients, diagnostic procedures or treatments performed on the wrong patients)
- Medication dosage errors resulting in organ damage or failure or in death (e.g., not lowering doses for children or geriatric patients)
- Fall-related injuries and death (particularly in older adults)
- Restraint-related injuries and death

Fire

Health care facilities implement several actions to prevent fires and to ensure adequate preparation if one occurs. One example is a no-smoking policy that does not permit smoking on the facility's property or allows it only outside the facility in designated areas. Oxygen is flammable and should not be used near an open fire. Fire evacuation drills and practice in the use of fire extinguishers should be conducted with enough frequency to ensure that health care professionals are prepared to properly respond in the event of a fire. Many health care facilities use the fire emergency response defined by the acronym

RACE:

- R:** *Rescue* all patients in immediate danger, and move them to safe areas.
- A:** Activate the manual-pull station or fire *alarm*, and have someone call 911.
- C:** *Contain* the fire by closing doors, *confining* the fire, and preventing the spread of smoke.
- E:** *Extinguish* the fire if possible after all patients are removed from the area.

Staff members must quickly mobilize to remove or rescue (**R**) patients close to the fire. The fire alarm (**A**) must be sounded and the exact location of the fire reported; 911 is usually called by a facility-wide operator.

Measures are taken to contain (**C**) or prevent the spread of smoke and fire, which include closing doors and turning off oxygen. Patients receiving mechanical ventilation should be disconnected and provided

with manual respiration with an Ambu bag. An **Ambu bag** is a resuscitator bag that is used to assist ventilation (see Fig. 38.10).

After all patients are removed from the area, an attempt may be made to extinguish (E) the fire if it is small enough. However, an attempt to extinguish a fire should not be made if personal or patient safety would be compromised in the process. Fig. 25.7 shows the proper technique for use of a fire extinguisher. When using a fire extinguisher, it is helpful to remember the PASS acronym: pull, aim, squeeze, and sweep.

FIGURE 25.7 When using a fire extinguisher, remembering the PASS acronym (i.e., pull, aim, squeeze, and sweep) ensures proper technique.

To enable successful evacuation, patients should be triaged on the basis of their mobility levels. Those who are ambulatory should be directed to a safe area, and those who are immobile must be transported by bed, stretcher, or wheelchair to another area.

Electrical Energy

To ensure fire safety, nurses should regularly check for faulty or loose wiring or anything unusual, and clinical engineers should conduct scheduled checks and routine maintenance of electrical equipment. Patients may be at increased risk for an electric shock because of the multiple electrical devices to which they may be connected for therapeutic purposes, such as bed, intravenous pump, oxygen, cardiac monitor, and gastrointestinal suction (Fig. 25.8). Do not use machines that are malfunctioning; rather discontinue use and tag for maintenance.

FIGURE 25.8 The risk for an electric shock may be increased for patients who need electrical equipment for therapeutic purposes. The routine use of three-pronged (grounded) outlets and plugs on equipment in health care settings helps minimize the risk for electrical exposure. (© Thinkstock.com.)

Fall Prevention

Falls are events in which an individual unintentionally and through the force of gravity drops to the ground, floor, or some other lower level. Despite the need for comprehensive fall prevention programs, many interventions are simple and involve manipulation of the environment by the nurse to meet patient needs. For example, the call light should be kept within reach and the patient reminded how to use it with each interaction so the patient can call for help. Frequently used items should be kept close to the patient to prevent reaching. Making hourly rounds ensures that patient needs are met and reduces patient falls in hospital settings (Mitchell, Lavenburg, Trotta, et al., 2014). Patients who are at a high risk for falling should be placed in rooms close to the nurses' station, and pressure-sensitive alarms can be used to alert staff about attempts to get out of bed. Some patients may require a 24-hour sitter for observation. Some facilities also have virtual video monitoring to reduce the likelihood of falls.

Nurses can intervene in the care environment to promote patient safety by ensuring that brakes are always applied on beds and that safety locks are employed on wheelchairs (Fig. 25.9). Using the brakes on beds and wheelchairs prevents the device from moving if a patient tries to get to a standing position without assistance. Other environmental adaptations that have been made in many health care facilities include the installation of grab bars near toilets and in showers

so that patients who are unsteady have something sturdy to hold on to (Fig. 25.10).

FIGURE 25.9 Nurses contribute to patient safety by ensuring that (A) the brakes are applied on beds and (B) safety locks are employed on wheelchairs.

FIGURE 25.10 Grab bars provide a measure of safety for the patient using the toilet (A) and shower (B).

Seizure Precautions

Special precautions are taken for any patient with a history of seizures. Padding is available for the bed rails to prevent injury in case a seizure occurs. Oxygen, to provide supplemental oxygen, and suction equipment, to suction the patient if he or she has increased secretions during or after a seizure, is kept at the bedside. During a seizure, a patient should be protected from injury by placing the head on a soft surface and turning it to the side to prevent aspiration and by moving sharp or hard objects out of the way.

Proper Use of Restraints

In light of all of the negative consequences that can result from the use of physical restraints, it is easy to conclude that they may do more harm than good for the patient. Nurses should employ as many restraint-free alternatives (Box 25.7) as possible before requesting orders for and applying a physical restraint (Box 25.8).

Box 25.7

Alternatives to Physical Restraints

- Orient the patient to the surroundings, and explain all care-related interventions.
- Relocate the patient to a room near the nurses' station.
- Use pressure-sensitive and motion-sensitive bed and chair alarms consistently. Tabs and bed-check alarm systems can be used in the bed or chair

Copyright © Mosby's Clinical Skills: Essentials Collection.

- Ensure that alarms and sensors are properly placed and functioning and perform battery checks according to facility protocol.
- Encourage the family and significant others to spend time with the patient.
- Minimize environmental stimuli (e.g., noise, bright lights).
- Provide distractions based on patient preferences (e.g., music, television, a doll to hold).
- Provide complimentary and alternative therapies:
 - Promote relaxation through gentle massage.
 - Use aromatherapy to relax the patient.
- Assess for sources of agitation, and ensure that the patient's basic needs are met (e.g., food, fluids, toileting, pain or discomfort relief,

sleep, ambulation).

- Obtain an order for a 24-hour sitter (i.e., unlicensed assistive personnel [UAP]).
- Cover or disguise tubes or drains with clothing, or wrap intravenous sites with gauze so that they are kept out of the patient's sight.
- Use untied, cloth-padded protective mitts on the patient's hands to prevent the patient from removing tubes or drains

Box 25.8

Evidence-Based Practice and Informatics

Restraint Use in Care Settings

- For more than two decades, physical restraints, such as safety vests, body holders, and lap and wheelchair belts, have been associated with reports of injuries and deaths due to fractures, burns, entrapment, and strangulation.
- The [American Nurses Association \(2012\)](#) position statement on the use of restraints brings into question if use of restraints is an infringement of patient rights. Other measures should be considered wherever possible.
- [The Joint Commission \(2019\)](#) patient safety standards focus on using physical restraints very infrequently and only after the many alternatives to their use have been exhausted. The goal is to increase nonrestraint safety alternatives whenever possible.

2. After D. S. was incontinent of loose stool and trying to climb out of bed, list in order four things that the nurse should do and explain why.

3. Identify at least three restraint-free alternatives that would be appropriate for D. S. that were not mentioned in an earlier answer.

After all restraint-free alternatives have been exhausted and consultation with other members of the interprofessional care team (e.g., geriatrician, geriatric clinical nurse specialist, nurse practitioner, and psychiatrist) has been unsuccessful in identifying other means of keeping the patient safe, several steps should be carefully followed before restraints are applied.

In the event of an immediate threat of harm to self or others, the nurse can apply a physical restraint without an order from the primary health care provider, but the physician order must be sought and the patient must be seen within an hour of application of the restraint. The physician must renew the physical restraint orders according to facility policy. Critical elements for the application and care of a patient requiring physical restraints for a temporary period are described in [Skill 25.1](#). The interventions and their corresponding rationales provide guidance for safe restraint application and measures that can be taken to prevent untoward consequences.

Safe Practice Alert

Frequent checks of the patient under restraint are essential because injuries due to entrapment and death from strangulation or asphyxiation are most likely to result when the patient attempts to escape physical restraint.

Safe Practice Alert

Never tie a restraint in a knot because the knot may prohibit a quick exit in the event of an emergency requiring evacuation. Instead, use quick-release ties or mechanisms such as buckles. Restraints should never be tied to side rails because injuries may result when the side rails are raised or lowered.

Proper Use of Side Rails

The top two side rails are often used by the patient for turning and positioning. In some circumstances the nurse will raise one of the bottom side rails (Fig. 25.11). When all four side rails are raised, it is considered a form of physical restraint, which requires an order from a primary care provider (PCP). As with any physical restraint, it is critical to weigh the benefits and risks of the use of side rails. In the United States, there are approximately 2.5 million nursing home and hospital beds. The FDA requires reporting of incidents involving beds with rails. From 1985 through 2013, the FDA (2018b) received reports of 901 incidents of patients being trapped, caught, entangled, or strangled in rails, with patient outcomes ranging from death (531 patients) to nonfatal injury (151 patients).

FIGURE 25.11 The top two side rails are used for patient positioning. Use of one of the bottom side rails is necessary in certain patient circumstances. Use of four side rails is considered restraint.

Side rails as a restraint should be avoided when possible. Attempting to escape the bed while navigating the side rails can cause injurious falls. The patient may be attempting to get up to do something purposeful, such as go to the bathroom, which is another high-risk situation for falls. A simple measure to promote patient safety and prevent falls is to make patient rounds hourly to attend to basic needs (Mitchell, Lavenburg, Trotta, et al., 2014). Box 25.9 outlines safety concerns related to side rail use.

Box 25.9

Nursing Care Guideline

Side Rail Safety

Background

- Use of four side rails is considered a restraint and requires a PCP order. Assess the situation carefully before using them.
- Is a specialty mattress in place? If so, use side rails cautiously, because functioning of the mattress may be affected by side rails.

Procedural Concerns

- Assessment: Is there a fall risk?
 - Are alternative solutions available?
 - Is the patient confused or at an increased safety risk?
 - Is there a disability or body-positioning requirement? Is an alternative available?
 - Is the patient violent? If so, consider other options, because the patient may hurt himself or herself with rails in place.
 - Will the patient get out of bed without supervision? If so, consider an alternative.
- Reassess the need for all four side rails:
 - When there is a change in the patient's condition
 - At frequent intervals according to facility policy
- Compare the symmetry of the patient's body (i.e., one side of the body compared with the other) for conditions such as hemiparesis or amputations. Asymmetries may compromise patient safety and necessitate the use of safety rails.
- The two top side rails are often used for patient positioning and turning, and their use is not considered a restraint. Many newer beds have controls on the top side rails that the patient can reach only if the top rails are up.

Documentation Concerns

- Follow facility policy and procedures for documentation.
- Important documentation should include both of the following:
 - The reason for using all four side rails
 - Alternatives that have been attempted or considered
 - Has a patient been injured with side rail use? If so, follow facility policy and procedure for care and documentation.

- If the patient or patient's family refuses side rail use, document the situation according to facility policy and procedure.

Evidence-Based Practice

- In a systematic review of nursing home residents who were physically restrained, Hofmann and Hahn (2014) identified decreases in cognitive performance, requiring increased assistance with activities of daily living, increase in actual falls, pressure ulcers and incontinence. Use of restraints can negatively influence physical and psychological well-being and should be used as a last resort.

Safe Medication Administration

One of the 2018 National Patient Safety Goals is to improve the safe use of medications (TJC, 2019). The QSEN project focuses on developing nurses' knowledge, skills, and attitudes, each of which is crucial for the safe administration of medication to patients. Application of the necessary knowledge, skills, and attitudes assists the entry-level nurse in performing safe medication administration. Practices essential to safely administering medications are discussed in [Chapter 35](#).

Reduction of Pathogen Transmission

Health care–associated infections (HAIs), formerly called *nosocomial infections*, are acquired by patients during the course of treatment for other conditions; pneumonia, gastroenteritis, and urinary tract infections are common examples. To reduce the incidence of HAIs, nurses play a key role in preventing the transmission of pathogens in health care facilities. When determining the best practices for preventing the spread of infection, the nurse should consider the possible routes of transmission.

Key to the prevention of pathogen transmission among patients and health care workers is the use of standard precautions, which are practiced with all patients to avoid exposure to blood and other body fluids (e.g., urine, stool, sputum, gastric fluid), which are all assumed to be infectious. The primary precaution is using proper handwashing or hand-sanitizing techniques before and after each patient contact and procedure. Another important precaution is donning personal protective equipment (PPE). [Chapter 26](#) discusses pathogen transmission and methods of prevention.

Reduction of Procedure-Related and Equipment-Related Events

Infections and injuries may occur in health care facilities as the result of errors in procedures and malfunction of medical equipment. Infections may be caused by improper insertion of therapeutic tubes or drains. A break in sterile technique or contamination of a Foley catheter during insertion may result in a catheter-associated urinary tract infection (CAUTI). Because of the reimbursement policy changes at the CMS, catheter-associated UTIs are considered to be reasonably preventable errors for which the cost of treatment is no longer covered. Infections can result from placement of a nasogastric tube for temporary tube feedings. If correct placement of the tube is not verified radiologically before administering feedings or the tube becomes dislodged during the course of routine care, aspiration pneumonia may result. To avoid these types of events during procedures, the nurse should carefully follow the steps of facility policy and procedure manuals and adhere closely to sterile technique when required.

Because injuries can result from improper equipment maintenance or equipment malfunction, several safeguards are in place to prevent them. For example, infusion pumps for intravenous therapy or patient-controlled analgesia (PCA) often have free-flow protection devices to prevent excessively rapid administration. Routine checks of battery-operated equipment, along with testing and replacement, may be performed by nursing or clinical engineering staff, depending on equipment type. If routine quality-control checks on equipment such as blood glucose meters are not performed, inaccurate readings and inappropriate insulin coverage, with associated hyperglycemia or hypoglycemia, may occur. These examples demonstrate the necessity for thoughtful facility protocols regarding equipment safety checks and maintenance, which must be carefully followed by staff from a variety of disciplines, including nursing, pharmacy, and clinical engineering.

When working with radiation diagnostics or treatments, preventive measures should be followed to avoid exposure. Lead shielding should be used for patients and staff. Staff should be kept as far as possible from the radiation source and the length of exposure limited. Health care professionals working with radiation or radioactive materials should wear a radiation-monitoring device or badge that is periodically checked for cumulative radiation exposure levels to ensure safety.

Bioterrorism

Successful management of a bioterrorist attack depends on the emergency response plans of health care facilities. In addition to nurses

taking part in public health awareness programs, they should be familiar with the disaster management and preparedness programs of the facilities in which they work.

◆Evaluation

Evaluation is an ongoing process that involves collaboration with the patient, family, and multiple health care professionals to keep patients safe in health care agencies, community environments, and at home. Nurses develop patient-specific interventions that are continually evaluated to measure the patient's progress toward goal attainment. After evaluation, each patient's safety care plan is updated to reflect changes in his or her condition.

SKILL 25.1 Applying Physical Restraints

Purpose

- Physical restraints can be applied only with a primary care provider (PCP) order and only after all reasonable alternatives to restraint use have failed.
- Physical restraints can be applied for either or both of two reasons:
 - Medical necessity
 - Behavioral or mental health issues
- Examples of common reasons for the use of physical restraints are as follows:
 - To immobilize an extremity
 - To prevent harmful patient behavior
 - To allow treatments or procedures to proceed without patient interference

Resources

- Cloth restraint of correct size for the patient, situation, or site
- Soft cloth or foam (for padding)

Interprofessional Collaboration and Delegation

- Most facilities require restraints to be applied by a registered nurse or licensed practical nurse.
- Assistance with applying and monitoring a physical restraint may be delegated to unlicensed assistive personnel (UAP) after the initial assessment of the patient.
- UAP should report any of the following to the nurse:

- Skin changes (e.g., sores, wounds, irritations, lesions) in the area where the restraint is to be applied
- Patient complaints related to restraint application, especially tightness, numbness, tingling, or pain
- Changes in patient monitoring that can be delegated to UAP, such as changes in vital signs
- Patient communications of an unusual nature and any new patient concerns
- UAP should be instructed in the following:
 - Appropriate placement of restraints and reason for applying restraints
 - Appropriate use and type of restraint equipment
 - Appropriate observations and documentation in accordance with institution policy
 - Ethical standards and basic therapeutic communication

Evidence-Based Practice

- Restraint use has caused negative health outcomes, such as deterioration in the ability to walk, in cognitive abilities, and in performing activities of daily living (Hofmann & Hahn, 2014).
- Waist restraints or lap restraints are as harmful and restrictive as vest restraints, and they have just as many adverse events attributed them. All other alternatives must be implemented before initiating any type of restraint (Berry & Kiel, 2018).

- Proper training and education of staff can reduce the use of restraints. Education includes understanding alternative options, deescalation techniques, regulatory standards, barriers to change and overcoming resistance, and issues of violence, aggression, and power (Berry & Kiel, 2018; Evans, Rhemtulla, Fruetle, et al., 2014; Hofmann & Hahn, 2014; Miake-Lye, Hempel, Ganz, et al., 2013)
- Ethical considerations do not preclude the use of restraints, but alternatives should be implemented before restraint initiation to avoid further physical, mental, ethical, and social harm (American Nurses Association [ANA], 2012).
- During application of a restraint, the primary nurse should be calm and reassure the patient that it is not a punishment. Focus must remain on the emotional and social health of the patient, or the situation may escalate for the patient and staff (Springer, 2015).

Special Circumstances

1. **Assess:** What are the possible causes of harmful patient behavior?
Intervention: Document alternatives to restraints that have been tried and failed (to justify the use of restraints). Exhaust other treatment options (e.g., patient sitters, frequent toileting, monitoring, medications, proper positioning, treatment of pain, assessment and treatment of infections) that may underlie the patient's behavior before applying restraints.
2. **Assess:** What is the condition of the skin at the site of restraint application?
Intervention: If wounds, irritations, or sores occur, use an alternative to the restraint. If bony prominences are involved, pad them with a soft cloth or foam. Perform frequent circulation, movement, and sensation checks, and document the results.

3. **Assess:** What is the least restrictive restraint choice?
Intervention: Exhaust other treatment choices first. Do not restrain the entire body if only one limb needs to be restrained. May need to consider a waist or vest restraint instead of bilateral wrist restraints. In some circumstances, bilateral wrist restraints may cause increased agitation because the patient cannot use the upper extremities.
4. **Assess:** Has the primary care provider (PCP) been notified?
Intervention: Obtain the PCP order (including time frame for restraints) and patient or guardian informed consent before applying restraints. If a significant risk exists, apply restraints before contacting the PCP and obtaining an order for the restraints, and notify the PCP immediately after application.
5. **Assess:** Does the patient have abdominal or chest incisions or devices?
Intervention: Do not use vest or body restraints; use an alternative restraint.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct PPE is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient, using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record.

The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Use of Restraints

Follow preprocedure steps I through VIII.

1. Obtain the correct restraint for the situation:

a. Lap belt

Keeps the patient from standing up or sliding or falling out of the wheelchair.

STEP 1A (Courtesy Posey Company, Arcadia, CA.)

b. Limb (wrist or ankle) restraint

Keeps the patient from pulling at tubes or thrashing limbs.

STEP 1B (Courtesy Posey Company, Arcadia, Calif.)

c. Mitt restraint

May be used just to restrain a hand or restrict finger movement; keeps the patient from interfering with medical devices, removing dressings, and pulling at tubes or scratching skin.

STEP 1C (Courtesy Posey Company, Arcadia, Calif.)

d. Vest restraint

Keeps the patient in the bed or wheelchair; prevents the patient from fully sitting up in bed or bending over far in the wheelchair.

STEP 1D (Courtesy Posey Company, Arcadia, Calif.)

e. Roll belt

Keeps the patient from falling out of bed; permits side-to-side movement in bed.

STEP 1E (Courtesy Posey Company, Arcadia, Calif.)

2. Place the padded side of the restraint toward the skin.
Prevents skin breakdown.
3. Wrap the strap to ensure that two fingers, side by side, fit between the restraint and the skin.
Allows proper circulation.
4. Secure the strap in a loop or buckle.
Prevents removal by patient.

STEP 4

5. Tie the end of the strap to the appropriate location, using a quick-release knot.

Allows emergency release; some manufacturers provide quick releases in buckle devices.

How to tie the quick-release tie

STEP 5

- 1 Wrap the strap once around a movable part of the bed frame leaving at least an 8" (20 cm) tail. Fold the loose end in half to create a loop and cross it over the other end.
- 2 Insert the folded strap where the straps cross over each other, as if tying a shoelace.
- 3 Pull on the loop to tighten. Test to make sure strap is secure and will not slide in any direction.
- 4 Repeat on other side. Practice quick-release ties to ensure the knot releases with one pull on the loose end of the strap

(Courtesy Posey Company, Arcadia, CA.)

- a. *Bed*: Tie to a part of the bed frame that moves with the patient, not to the side rails.
Permits position changes (a safety concern).

STEP 5A (Copyright © Mosby's Clinical Skills: Essentials Collection)

- b. *Wheelchair*: Cross-tie to the frame.
Permits wheels to roll (a safety concern).

STEP 5B

6. Assess the patient every hour or more often. Consult agency policy, because some require assessment of the patient every 15 minutes for behavioral health reasons or every 30 minutes for medical reasons. Place the call bell within reach.
Ensures safety, enables determination of when to discontinue restraint use, provides patient stimulation, reassures the patient, and allows care plan update and other interventions to be made.
7. Remove the restraint. Assess skin and range of motion every 2 hours or more often, according to facility policy.
Ensures safety, health, and comfort; ensures compliance with regulations and standards.

Follow postprocedure steps I through VI.

Postprocedure

- I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.
Precautions are taken to maintain patient safety. Top side

rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Summary of Learning Outcomes

LO 25.1 *Discuss safety concerns in the home, community, and health care environments:* Major safety concerns in the home and community are unintentional injuries. The Joint Commission has developed National Patient Safety Goals to highlight areas of critical concern in hospital, long-term care, home care, and outpatient settings.

LO 25.2 *List factors that affect safety:* An individual's safety is affected by physical, mental, and cognitive health; age; environmental factors; and workplace hazards.

LO 25.3 *Explain situations that alter safety in the home, community, and health care settings:* Injuries, poisoning, fires, and biohazards exist in the home and community. Falls, injuries from restraints, and radiation exposure are risks in the health care setting.

LO 25.4 *Identify safety factors that affect individuals at home, in the community, and in health care settings:* Nursing assessment includes the collection of subjective information about the patient's symptoms, chief complaint, and environmental hazards and exposures and a corresponding objective assessment. Information in the patient's history may provide clues about safety issues. The physical assessment may reveal issues that should be further investigated.

LO 25.5 *Choose nursing diagnoses relevant to patient safety-related concerns and issues:* Some nursing diagnoses pertinent to patient safety include *Risk for Injury*, *Risk for Fall*, and *Risk for Poisoning*.

LO 26.6 *Prepare nursing care plans that identify interventions to promote patient safety:* Numerous nursing interventions specific to safety promotion are individualized to prevent the negative influence that untoward events can have on patient outcomes.

LO 25.7 *Implement and evaluate safety measures in the home, community, and health care settings:* The nurse provides patient education and safety promotion for patients to minimize safety risks in the home and community. Through the use of fall assessment tools, the nurse decreases the risk for injury from falls by implementing safety measures according to each patient's risk. Keeping patients and staff safe from the risks for electrical hazards, fire, radiation exposure, and infections is part of the nurse's role.

Review Questions

1. When teaching a patient about fire safety, which activity does the nurse know is the leading cause of fire-related death?
 - a. Cooking
 - b. Playing with matches
 - c. Smoking
 - d. Heating with kerosene heaters
2. Which measures can the nurse teach to prevent poisoning of children? (*Select all that apply.*)
 - a. Install safety latches on reachable cabinets.
 - b. Keep syrup of ipecac on hand.
 - c. Use childproof caps on medications.
 - d. Use a plunger rather than a chemical drain cleaner.
 - e. Keep cleaning supplies under the kitchen sink.
3. Which restraint-free alternative is best for the nurse to use for an 84-year-old patient after hip replacement who has confusion and incontinence?
 - a. A room near the nurses' station and decreased sensory stimuli
 - b. A pressure sensor alarm and a room near the nurses' station
 - c. Side rails up and decreased sensory stimuli
 - d. A 24-hour sitter and the patient's favorite TV program
4. The nurse is performing a fall risk assessment on a newly admitted patient. Which finding is a greater known risk factor for falls?

- a. Taking aspirin
 - b. Urinary incontinence
 - c. Multiple comorbidities
 - d. Malnutrition
5. The nurse is aware that parents are being safety advocates when they do which of the following?
- a. Keep a rear-facing car seat until the child is at least 12 months old.
 - b. Limits the amount of TV and video viewing of school age children to 3 to 4 hours per day.
 - c. Asks the teenager to turn the headphone volume down when the music is audible to others.
 - d. Avoid painting in a house unless the temperature is above 60 degrees Fahrenheit.
6. An elderly client residing in the community with cardiopulmonary compromise and impaired ability to perform activities of daily living (ADLs) presents safety concerns to the nurse. Which is the greatest concern?
- a. Ability to obtain and take medications correctly
 - b. Ability to safely get on and off a toilet
 - c. Ability to safely procure food and prepare meals
 - d. Ability to safely eat without choking
7. What other health care professional should the nurse consult first when a patient has difficulty with activities of daily living (ADLs) such as bathing and dressing and why?
- a. Occupational therapist to evaluate the ability to perform ADLs

- b. Physical therapist to evaluate the patient's need for assistive devices
 - c. Social worker to arrange for needed assistive devices
 - d. Area agency on aging to arrange for Meals on Wheels
8. A 56-year-old man who has been staying at a cabin while hunting arrives at the emergency department with complaints of dizziness, light-headedness, and nausea. What does the nurse initially suspect?
- a. Lead poisoning
 - b. Radon exposure
 - c. Food poisoning
 - d. Carbon monoxide poisoning
9. Which activity would be most appropriate for the registered nurse (RN) to delegate to unlicensed assistive personnel (UAP)?
- a. Assessing the patient for fall risk and complications of restraint use
 - b. Evaluating the patient's ability to perform activities of daily living (ADLs)
 - c. Assisting with or performing the patient's ADLs
 - d. Teaching the patient use of assistive devices
10. When working with radiation diagnostics or treatments, which preventive measures should be followed to avoid exposure? (*Select all that apply.*)
- a. Using lead shielding of patients and staff
 - b. Keeping staff at the farthest distance possible from the radiation source

- c. Limiting the length of exposure
- d. Wearing a badge to monitor the length of exposure
- e. Following procedures and safety checks

CHAPTER 26

Asepsis and Infection Control

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 26.1 Summarize the body's defense system.
- LO 26.2 Explain the links of the chain of infection.
- LO 26.3 Outline techniques of assessing for infection or risk for infection.
- LO 26.4 Identify nursing diagnoses for patients with infection or at risk for infection.
- LO 26.5 Use measurable goals for patients with complications from infection.
- LO 26.6 Carry out and evaluate interventions to decrease the risk for infection and reverse the negative effects of infection.

KEY TERMS

- airborne transmission, [p. 475](#)
- antibodies, [p. 473](#)

Case Study

Dorothy Payne (D. P.) is a 76-year-old female who was admitted to the hospital 2 days earlier with complaints of right lower quadrant abdominal pain. Her medical history includes type 2 diabetes mellitus. She was evaluated in the emergency department and sent to the operating room for an appendectomy 8 hours after coming to the hospital.

D. P.'s vital signs are: temperature 38.4° C (101.2° F), P 96 and regular, R 22 and unlabored, BP 130/72, and pulse oximetry of 96% on room air. She rates pain in her right lower abdomen as 3 of 10, but with movement the pain level increases to 8 of 10. She reports sharp, stabbing pain in the abdominal area around her incision site. Pain medication and position change relieve the pain. The skin around the incision is warm and red, and the area is tender to the touch.

Laboratory results are WBC 20,000 (cells/mm³), Hgb 16 g/dL, Hct 47%, BUN 25 mg/dL, creatinine 0.8 mg/dL, K 4.0 mEq/L, blood glucose 150 mg/dL, and Na 142 mEq/L.

Treatment orders are as follows:

- Vital signs q 4 h and as needed (PRN)
- Regular diet with supplements twice daily
- Intake and output (I&O)
- Activity: Up with assist of one
- Right abdominal dressing: Dry sterile dressing, cleanse incision with sterile saline solution, change q 8 h
- Turn, cough, and deep breathe q 4 h while awake
- Incentive spirometry q 2 h while awake
- Antiembolism stockings while out of bed
- Sequential compression devices (SCDs) while in bed
- Complete blood count (CBC) every morning
- Fall precautions

- Physical therapy (PT) for ambulation daily

Medication orders are as follows:

- Continuous intravenous 5% dextrose in 0.45% normal saline (D₅/0.45 NS) at 50 mL/h
- Enoxaparin 40 mg subcutaneously daily
- Metformin 500 mg PO twice daily
- Hydrocodone 5 mg and acetaminophen 500 mg PO q 4 h PRN for pain
- Cefuroxime 750 mg IV q 8 h

Refer back to this case study to answer the critical-thinking questions throughout the chapter.

Nurses are responsible for understanding their role in preventing the transmission of infectious agents. Infection control practices are essential for providing a safe health care environment for patients and the health care team who care for them. During the past several years, the number of health care–associated infections (HAIs) has increased significantly, endangering everyone in the health care environment. This chapter explores the basic aseptic technique and infection control measures necessary to protect patients and the community from the spread of potentially harmful microorganisms.

LO 26.1 Normal Structure and Function of the Body's Defense System

An **infection** is the establishment of a pathogen in a susceptible host; a disease state is caused by the infectious agent. Many microorganisms are contagious and can cause serious illness. Nurses cannot be familiar with every microorganism, but they can prevent the spread of infection through aseptic interventions. **Asepsis** refers to freedom from and prevention of disease-causing contamination.

The body has many defenses against microorganisms that can cause illness. The three main defenses are normal flora, the inflammatory response, and the immune response.

Normal Flora

Normal flora is a group of non-disease-causing microorganisms (e.g., bacteria, fungi, protozoa) that live in or on the body. These benign microorganisms are found in and on the skin, eyes, nose, mouth, upper throat, lower urethra, small intestine, and large intestine. The normal flora constitutes the body's first line of defense against infection because it inhibits pathogenic microorganisms from colonizing healthy individuals (Huether & McCance, 2017).

Inflammatory Response

The second line of defense is the **inflammatory response**. Inflammation is a local response to cellular injury or infection that includes capillary dilation and leukocyte infiltration. This response produces redness, heat, pain, and swelling. The leukocytes release a chemical that increases the temperature in the area. The dilation, infiltration, and increase in temperature are protective mechanisms that help the body neutralize, control, and eliminate invading pathogens, preventing them from surviving and multiplying. The [“Inflammatory Response”](#) animation illustrates this process. If inflammation becomes systemic, signs include fever (caused by prostaglandins acting on the hypothalamus), chills, malaise, and altered mental status. Inflammation causes the body to mount the third defense, which is the immune response.

Immune Response

Inflammation activates the **immune response**, which is the body's attempt to protect itself from foreign and harmful substances. The immune response is initiated by recognition of antigens. An **antigen** is any substance that provokes an adaptive immune response. Antigens include protein molecules on the surface of pathogens and nonliving substances such as toxins, chemicals, drugs, or particles. The immune system recognizes and destroys substances that contain foreign antigens.© The animation “**Antibodies and Antigens**” further explains the immune response.

Most people are born with innate (nonspecific) immunity (**Huether & McCance, 2017**). The adaptive mechanisms of direct (active) and indirect (passive) immunologic memory determine how a person's immune system recognizes antigens.

Innate Immunity

The innate (nonspecific) immune system provides immediate defense against foreign antigens. The skin, cough reflex, mucus, enzymes on the skin and in tears, and acid in the gastrointestinal tract prohibit harmful substances from entering the body. In addition to acting as a barrier to infectious agents, the innate immune system produces chemical mediators that fight infection, remove foreign substances, and activate the adaptive immune system.

Adaptive Immunity

The adaptive (acquired or specific) component of the immune system provides long-term immunity when the body is exposed to an antigen. Humoral (antibody-mediated) and cellular (cell-mediated) immunity are two types of adaptive immunity.

Humoral Immunity

Humoral immunity is a defense system that involves white blood cells (WBCs; B lymphocytes) that produce antibodies in response to antigens or pathogens circulating in the lymph and blood. **Antibodies** are immunoglobulin molecules that recognize foreign invaders. The antigen-antibody reaction initiates a complex chain of events to protect the body from the invading microorganism.

Humoral immunity enables production of inflammatory molecules such as interferon and interleukin-1, which cause fever. If a pathogen gets past the innate response, it is attacked by the adaptive immune system, which generates antigen-specific antibodies and lymphocytes (**Huether & McCance, 2017**).

Cellular Immunity

Cellular immunity involves defense by WBCs against any microorganisms that the body does not recognize as its own. T lymphocytes, such as cytotoxic T cells, directly attack cells displaying nonself antigens (e.g., infected cells). Helper T cells release interleukins and other substances that stimulate antibody production by B cells and antigen destruction by other cells (e.g., macrophages).

Immunologic Memory

Adaptive immunity is antigen specific and involves active, long-term immunologic memory. As B cells and T cells develop, they learn to differentiate between the body's tissues and substances that are not normally found in the body. Some cells are sensitized by interaction with a specific antigen and become memory cells. Subsequent exposure to the antigen produces a stronger and faster immune response by these memory cells, which can ease or prevent later illness in many cases. Long-term active immunity can be artificially acquired by immunization with vaccines.

Passive immunity occurs when a person receives an antibody produced in another body. Passive immunization provides immediate but short-term protection against antigens. Infants acquire passive immunity naturally in utero or through breast milk, and these antibodies disappear between the ages of 6 and 12 months. Passive immunity can be acquired artificially when antibodies are transferred from one person to another by injection of an antibody-rich serum (e.g., immune globulin).

Other Body Systems

The integumentary, respiratory, and gastrointestinal systems have roles in fighting infection. Skin is a barrier that is impermeable to most infectious microorganisms. Any break in the skin can create a portal of entry or exit for pathogens. The skin contains squamous epithelial cells, which help remove microorganisms and other infectious agents. Sweat decreases the likelihood of infection because its low pH inhibits bacterial growth (Huether & McCance, 2017).

The respiratory system plays a role in helping the body fight infection. The respiratory system contains cilia and mucus, which move or trap foreign bodies and therefore decrease the risk for infection. The respiratory system is equipped with proteins that have antimicrobial properties and promote phagocytosis (Huether & McCance, 2017).

The gastrointestinal system plays an active role in helping the body fight infection. The flora and low pH of the gastrointestinal tract prevent

the colonization of pathogenic microorganisms by secreting toxic substances or competing with the microorganism for the nutrients needed to make it thrive ([Huether & McCance, 2017](#)).

LO 26.2 Altered Structure and Function of the Body's Defense System

To understand how to prevent the spread of potentially harmful microorganisms, nurses must understand the chain of infection. Breaking the chain of infection helps prevent most infections.

Chain of Infection

The chain of infection has six main components: the infectious agent, the source of infection, the portal of exit, the mode of transmission, the portal of entry, and the susceptible host (Fig. 26.1). Infectious agents are the first link of the chain of infection that is necessary to spread disease-causing organisms.

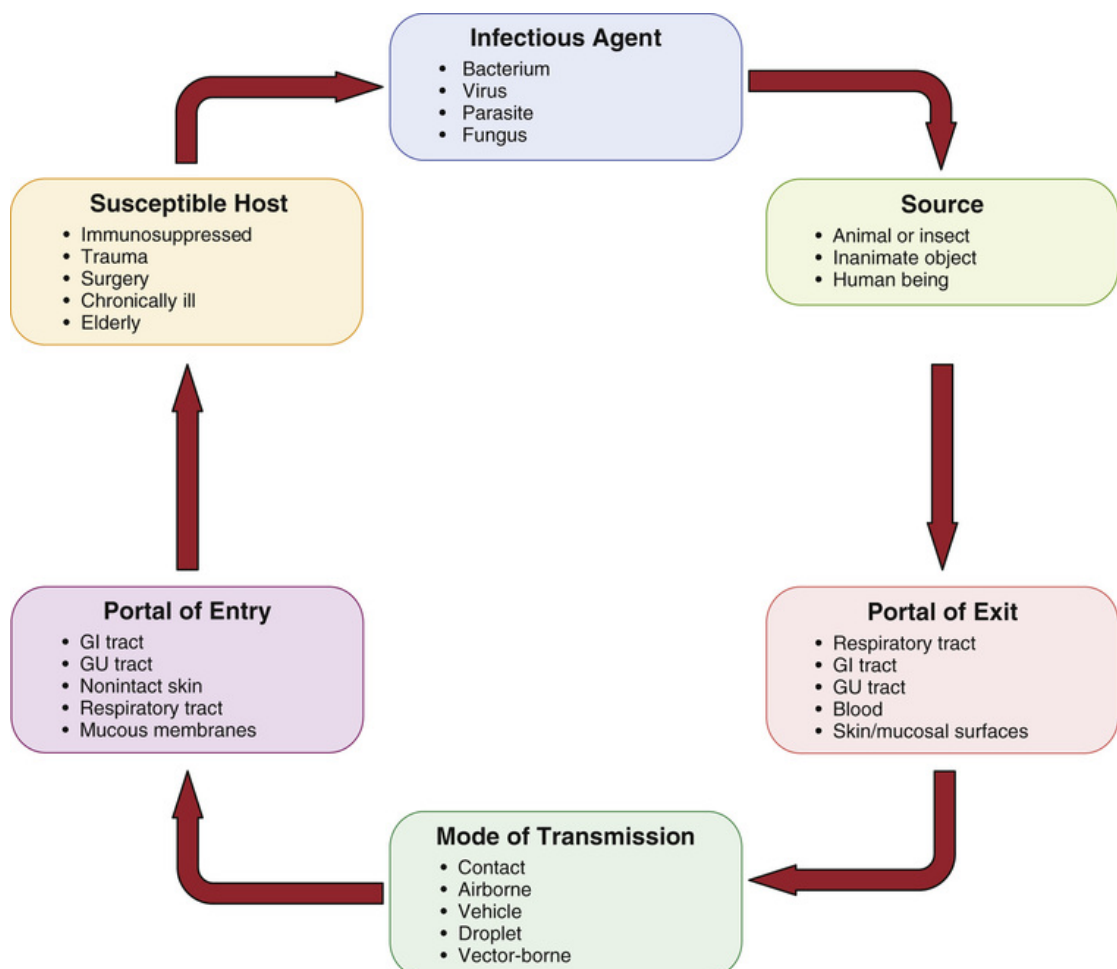

FIGURE 26.1 The chain of infection. *GI*, Gastrointestinal; *GU*, genitourinary.

Infectious Agents

Any infectious agent that causes disease is referred to as a **pathogen**. Pathogens include bacteria, viruses, fungi, and parasites.

Bacteria are single-cell organisms. Bacteria live as normal flora on and in the skin, eyes, nose, mouth, upper throat, lower urethra, lower intestine, and large intestine. They are capable of causing disease in the human population when they overgrow as a result of immune system compromise or when they enter different areas of the body. Bacteria have different sizes, shapes, growth patterns, and means of **replication**, which is a term used to describe bacterial reproduction or duplication. They are named according to their shape and are classified by their ability to live with or without oxygen (i.e., aerobic or anaerobic) and their staining qualities (i.e., gram positive or gram negative). Bacteria reproduce by dividing; one cell becomes two identical cells. Bacteria are identified when a sample taken from the body is cultured, and exact antibiotic sensitivity is tested so that appropriate antibiotics are prescribed.

Viruses are the smallest microorganisms. Viruses reproduce inside living cells of the host and are responsible for causing many different types of disease. Illnesses range from the common cold to acquired immune deficiency syndrome (AIDS). Viruses cannot be killed by antibiotics. Certain antiviral medications are used to manage the symptoms of a viral infection. These medications, if given during the early phases of illness, can decrease the amount of time that the patient has viral symptoms.

Fungi, like bacteria, are single-cell organisms that can cause infection. Molds and yeasts are examples of common fungi. Fungi are present in the air, the soil, and water and are responsible for conditions such as athlete foot, ringworm, and yeast infections. Infections that are caused by fungi are treated with antifungal medications.

Parasites are organisms that live on or in other organisms. Examples of these organisms include protozoans, helminths, and arthropods. Parasites are typically transmitted by sexual contact, insects, and domestic animals. They cause many diseases in humans. Protozoans cause malaria, helminths are responsible for intestinal worm infestations, and arthropods are responsible for transmitting many skin and systemic diseases such as malaria.

Source of Infection

The second link of the chain is the source of infection, also called a **reservoir** or **host**. Reservoirs can be inanimate objects such as surfaces, equipment, medication, air, food, and water on which microorganisms

can find nourishment and survive. Human sources of infection are health care personnel, family, friends, and patients. Animals such as insects, rats, birds, pigs, and cows spread disease and have been the reservoirs for many epidemics in the past and for current diseases such as avian flu and mad cow disease ([Centers for Disease Control and Prevention \[CDC\], 2018a](#)).

Portal of Exit

Infection spread requires a **portal of exit**, which is the means by which the pathogen escapes from the reservoir of infection. Microorganisms escape through emesis, sputum, urine, stool, blood, genital secretions, and wound drainage.

Mode of Transmission

The microorganism must have a way to travel from the source to the susceptible host. The form of transportation is referred to as the **mode of transmission**. Modes of transmission include contact, airborne, vehicle (e.g., food, water, contaminated objects), droplet, and vector-borne (e.g., insects, animals).

Most microorganisms are transmitted by **contact**, which is when body surfaces touch surfaces of other bodies or objects. Direct contact involves a physical transfer of the microorganism from the infected individual to a susceptible host. Indirect contact occurs when the microorganism is transferred by way of a contaminated object, such as a dressing, needle, or surgical instrument such as a retractor or scalpel. In the health care setting, the most common means of transmission is contaminated hands ([CDC, 2017b](#)).

Some microorganisms can be transmitted through the air. **Airborne transmission** occurs when microorganisms are dispersed by air currents and inhaled or deposited on the skin of a susceptible host. Examples of illnesses transmitted through the air include tuberculosis, measles, and chickenpox.

Some microorganisms are transmitted by droplets. **Droplet transmission** occurs when the mucous membranes of the respiratory tract (i.e., nose, mouth, or conjunctiva) are exposed to the secretions of an infected individual. Droplets cannot remain suspended in the air for long periods and seldom travel more than 3 feet. Examples of illnesses transmitted by droplets are influenza and respiratory syncytial virus infection ([Siegel, Rhinehart, Jackson, et al., 2017](#)).

Airborne transmission and droplet transmission are often hard to differentiate. Microorganisms travel through the air in both cases, but the difference between the two modes is the size of the microorganism.

Because smaller microorganisms can travel longer distances and remain suspended for longer periods, they are considered to be transmissible by air. Larger microorganisms cannot travel long distances and usually require closer contact for transmission; they are considered to be transmissible by droplet.

Special precautions have been written by the CDC for certain diseases such as Ebola. See the CDC website (<http://www.cdc.gov/infectioncontrol>) for specifics on these special types of isolation.

Vectors carry the pathogens from one host to another. Vectors often are invertebrate animals such as ticks, but they also can be vertebrate animals such as raccoons, which can transmit rabies by biting. Vector-borne diseases include Lyme disease, Rocky Mountain spotted fever, West Nile virus, and viral encephalitis.

Portal of Entry

For the chain of infection to continue and the microorganism to be successfully transmitted from a primary host to a susceptible host, there must be a **portal of entry**, or the means by which the microorganism enters the susceptible host. There are many portals of entry: the gastrointestinal tract by ingestion, the genitourinary tract by contact with mucous membranes, the respiratory tract by inhalation, the integumentary system by breaks in the skin, and the urinary tract by introduction through the urethra. Individuals who are hospitalized are at increased risk for infection because of greater exposure to infectious agents and because many of the invasive procedures that are performed access the portals of entry.

The nurse can take steps at any link in the chain to halt the spread of infection. Standard precautions are used with all patients to limit direct exposure to blood and bodily fluids. Bodily discharges are disposed of immediately and properly to prevent spreading potentially harmful microorganisms. Handwashing destroys microorganisms so that others are not infected. Patients with contagious illnesses are isolated and personal protective equipment (PPE) is used when entering the room so a removable barrier is formed between the health care worker and the patient. These and other interventions practiced to break the chain of infection are discussed later in the chapter.

Susceptible Host

After the pathogen exits the reservoir, it must be transported to a susceptible host for the chain to be completed. A **susceptible host** is someone exposed to an infectious disease who is likely to contract the

disease. Increased susceptibility is associated with people at the extremes of age, those who are nutritionally compromised, and those who have had recent trauma or surgery. Those who are immunocompromised because of chemotherapy, radiation treatments, long-term use of steroids, or transplantation have lower resistance to infection. Patients with chronic illnesses, such as heart or lung disease, diabetes, liver or kidney disease, and human immunodeficiency virus (HIV) infection or AIDS, also have lower resistance to infection.

Health Care–Associated Infections

Health care–associated infections (HAIs), formerly referred to as *nosocomial infections*, are infections acquired while the patient is receiving treatment in a health care facility such as a hospital, long-term care facility, clinic, or primary care office. HAIs cost \$28.4 billion to \$38.8 billion annually (CDC, 2018b). Their impact includes prolonged recovery times, extended stays in health care institutions, increased disability, increased costs associated with prescriptions, loss of earnings, disruption of family routine, anxiety, pain, and death. Costs of HAIs are often not reimbursed; as a result, prevention has a beneficial financial impact and is an important factor of managed care. Data about HAIs are collected by the CDC in an effort to improve the infection control methods used by health care providers.

HAIs are associated with the use of medical devices such as catheters and ventilators, complications after a surgical procedure, contagious transmission between patients and health care workers, and the overuse of antibiotics (CDC, 2018b). HAIs may be caused by drug-resistant microorganisms such as methicillin-resistant *Staphylococcus aureus* (MRSA); vancomycin-resistant *S. aureus* (VRSA); vancomycin-resistant enterococci (VRE); blood-borne pathogens such as hepatitis B and C and HIV; *Clostridium difficile* (*C. diff*); and other microorganisms that affect the gastrointestinal tract (CDC, 2018b).

Safe Practice Alert

Handwashing is the most effective method for preventing hospital-acquired infections.

Resistant Organisms

Microorganisms adapt to their environment to compete for survival. As early as the 1940s, there were documented cases of microorganisms developing resistance to medications that had been previously

successful at treating the infection. This phenomenon is known as *drug resistance* (CDC, 2018b). A microorganism is considered resistant if replication cannot be stopped by two or more antibiotics sequentially or simultaneously (Huether & McCance, 2017).

Resistance is observed for community- and hospital-acquired infections. Community-acquired microorganisms that have developed drug resistance include Enterobacteriaceae (*Salmonella* and *Shigella*), *Mycobacterium tuberculosis*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria gonorrhoeae*. Microorganisms that have developed resistance in the hospital setting include MRSA, VRSA, VRE, and *C. difficile* (CDC, 2018b).

Many factors contribute to resistance, including overprescribing of antibiotics for nonbacterial infections, use of inappropriate antibiotics for the infecting microorganism, and incomplete courses of antibiotics. Infections are becoming increasingly hard to treat, and some microorganisms cannot be effectively destroyed by any known antibiotic.

Until recently, new drugs have been provided in time to treat bacteria that had become resistant to older antibiotics. This is no longer the case because the cost of developing new antibiotics is astronomical, and the development of new antibiotics has slowed (CDC, 2018b).

Safe Practice Alert

Drug-resistant microorganisms pose a considerable health risk for the general population and health care workers. Appropriate use of PPE and handwashing can decrease the risk for transmission.

Blood-Borne Pathogens

Several blood-borne pathogens can put patients and health care providers at risk for infection. They include hepatitis B and C viruses and HIV. Exposure occurs through contact with contaminated blood or bodily fluids. Exposure does not necessarily mean disease development. Exposure and disease development can be decreased with the appropriate precautions and barriers (CDC, 2017a).

If exposure occurs, several steps can be taken to decrease the risk for developing disease. These steps vary by individual institution, but anyone who is exposed to a blood-borne pathogen should have baseline laboratory work completed to check for HIV and hepatitis. If the patient source is known, the patient is tested. Subsequent testing and medical prophylaxis also may be warranted (CDC, 2017a).

Signs and Symptoms of Infection

The type and location of the infection determine the specific signs and symptoms observed during assessment. Infections are classified as localized or systemic. Localized infections can cause redness, swelling, warmth, pain, tenderness, drainage, numbness or tingling, and loss of function to the affected area. Systemic infections (i.e., infections that infiltrate the bloodstream) can cause fever, increases in heart and respiratory rates, lethargy, anorexia, and tenderness or enlargement of lymph nodes.

Many factors can cause an individual to be more susceptible to infections ([Box 26.1](#)).

Box 26.1

Diversity Considerations

Life Span

- Extremes in age cause an individual to be more susceptible to infection. Infants and the elderly are at the greatest risk for infection.
- Infants are more susceptible to infection because they have immature immune systems and have not been immunized against communicable diseases.
- As people age, the immune system becomes less effective due to decreased numbers of macrophages and other white blood cells.
- The elderly are at an increased risk for respiratory, urinary, and skin infections. Respiratory infections are increased due to decreased cough reflex, decreased elastic recoil of the lungs, decreased activity of the cilia, and abnormal swallowing reflex. Urinary tract infections (UTIs) in the elderly are caused by incomplete emptying of the bladder, decreased sphincter control, bladder outlet obstruction due to an enlarged prostate gland, pelvic floor relaxation because of estrogen depletion, and reduced renal blood flow. The Joint Commission (TJC) lists several national patient safety goals focusing on the care of older adults including clinical alarm safety and preventing infection ([TJC, 2019](#))
- The elderly are at an increased risk for skin infections due to loss of elasticity, increased dryness, thinning of the epidermis, slowing of cell replacement, and decreased vascular supply.

Gender

- Females are at greater risk for UTIs because of the anatomy of the genitourinary system.
- Males with an enlarged prostate may have incomplete emptying of the bladder, leaving them vulnerable to UTIs.

Culture, Ethnicity, and Religion

- Various cultural, ethnic, and religious factors may influence a patient's ability or desire to seek medical assistance, which can increase the risk for developing or maintaining an infection.

Disability

- Disabilities causing immobility can increase the risk for respiratory, skin, and urinary tract infections.

Morphology

- Obesity has been linked to an increased risk for certain skin infections in the skin folds.

1. Identify at least four diversity considerations related to D. P. and infection control.

LO 26.3 ♦ Assessment

Health History

During assessment, a history is obtained before observation. A vigilant nursing assessment considers the patient's susceptibility and clinical appearance and the effectiveness of the patient's defenses against disease (Box 26.2).

Box 26.2

Health Assessment Questions

Infection Assessment

The nurse observes the patient's general appearance to detect infection. Specific questions can help determine whether the patient already has or is at risk for an infection:

- Do you feel tired or fatigued?
- Do you feel short of breath?
- Do you often feel chilled and require a blanket when others in the room are comfortable?
- How is your appetite?
- Do you have any areas of pain, redness, swelling, and warmth?
- Do you have any rashes, breaks in the skin, or reddened areas?
- Do you have swollen lymph nodes?
- Do you feel that you empty your bladder when you go to the bathroom?
- Do you have a cough or difficulty swallowing?
- Have you had a fever?
- What medications are you on? Have you taken an antibiotic recently?
- Are your immunizations up to date?
 - Have you been exposed to anyone with an infection?
 - Have you traveled anywhere recently?

Effects of Infection on the Body's Defense System

Infections are classified as acute or chronic. Acute infections develop and run their course rapidly. Examples of acute infections include coughs, colds, and ear infections, which last 10 to 14 days. Chronic infections, such as infectious mononucleosis, may persist for months, as may wound and bone infections. Infectious diseases such as hepatitis and AIDS may last for years.

Some patients with an infectious disease may have no visible symptoms at presentation, whereas others can have a varied clinical picture, depending on the specific infection. Signs and symptoms of infection that may be observed are fever, chills, malaise, altered mental status, headache, and fatigue. Confusion is a common presentation in the elderly and is often the first indication of an infection such as pneumonia or a urinary tract infection.

Assessment of Vital Signs

Altered vital signs can indicate an infection. Temperature elevates slightly as the infection process begins. This is one of the body's defense mechanisms. As time passes and no interventions are initiated, the temperature continues to increase and other symptoms occur. As the infection progresses, the blood pressure rises and pulse and respiratory rates increase. Some patients with a severe infection such as sepsis may have damage to the body's organs and may be hypothermic. Decreased blood pressure is a late sign of infection, indicating septicemia and shock.

Nutritional Assessment

Adequate nutrition is important in the body's defense against infection. Infection depletes proteins, vitamins, minerals, and water in the body. These nutrients must be replaced to ensure adequate functioning of the body's defense mechanisms. During the physical assessment, the nurse assesses the patient's skin, mucous membranes, and overall appearance in addition to asking the patient about dietary intake.

Risk Assessment

Nurses must be aware of the many conditions that place patients at increased risk for infection. Chronic diseases, alterations in the immune system, medications such as chemotherapeutic drugs, alterations in skin integrity, malnutrition, indwelling medical devices such as urinary catheters, lack of proper immunizations, and other conditions can cause a patient to develop an infectious disease when exposed to certain microorganisms. During the physical assessment, the nurse assesses the

patient's skin and dietary intake and the integrity of invasive catheters to detect any subtle signs of infection.

2. List the techniques necessary to assess D. P.'s possible infection.

Laboratory and Diagnostic Tests

The nurse monitors several laboratory tests when assessing for infection. Tests include a CBC and a differential WBC count. The normal WBC count for adults is 5000 to 10,000 cells/mm³. The differential WBC count is the proportion of each type of WBC in a sample of 100 WBCs. It helps determine whether the body is mounting an immune response to an infection. A shift to the left (i.e., relative increase in immature forms of blood cells) with a higher percentage of neutrophils than normal indicates an infection.

Culture and sensitivity testing of the blood, urine, stool, or wound drainage may be indicated. Culture of a specimen determines which microorganism is causing an infection, and sensitivity testing determines which antibiotics, if any, can be used to treat the infection. The presence of pathogens in a specimen is a positive result.

Another laboratory test that is useful in assessing infection is the erythrocyte sedimentation rate (ESR). The ESR measures the degree of inflammation in the body, and the result can be an indicator of infection. An ESR that remains elevated indicates a poor response to current therapy, whereas an ESR that decreases indicates a good response. An ESR test is performed by timing how fast red blood cells settle to the bottom of a tube of whole blood; they settle faster when inflammation is present. [Chapter 34](#) provides CBC and differential WBC count values.

LO 26.4 ♦ Nursing Diagnosis

Nursing diagnoses are developed on the basis of patient data collected by the nurse. Nursing diagnoses clearly identify patient problems for which a nursing intervention is required and nursing care plans are developed. Many appropriate nursing diagnoses can be used for a patient with an infection. The following examples of International Classification for Nursing Practice (ICNP) nursing diagnoses are applicable to infectious disease patients:

Risk for Infection

- Supporting Data: Surgical break in skin integrity, chronic disease: diabetes mellitus, RLQ incision: skin around incision warm, red, and tender to touch

Lack of Knowledge

- Supporting Data: Lack of knowledge about what causes infection, patient not washing hands after toileting or before meals

Impaired Skin Integrity

- Supporting Data: Prolonged bed rest, inadequate diet, open area on the coccyx

Nursing diagnoses based on the effects of infection on various body systems also may be appropriate.

LO 26.5 ♦ Planning

The planning stage of the nursing process involves prioritizing identified nursing diagnoses, evaluating patient abilities and resources, and setting goals. The nurse carefully considers the importance of each nursing diagnosis and addresses the most critical ones first in the nursing care plan (Table 26.1). Maslow's hierarchy of needs is a helpful resource for ranking nursing diagnoses.

TABLE 26.1
Care Planning

ICNP NURSING DIAGNOSIS WITH SUPPORTING DATA	NURSING OUTCOME CLASSIFICATION (NOC)	NURSING INTERVENTION CLASSIFICATION (NIC)
<i>Risk for Infection</i> Break in skin integrity Chronic disease: diabetes mellitus	<i>Tissue integrity: Skin and mucous membranes</i> Erythema	<i>Incision site care</i> Monitor incision for signs and symptoms of infection.

From Butcher, H. K., Bulechek, G. M., Dochterman, J. M., et al. (Eds.). (2018). *Nursing interventions classification (NIC)* (7th ed.). St. Louis, MO: Mosby; Moorhead, S., Swanson, E., Johnson, M., et al. (Eds.). (2018). *Nursing outcomes classification (NOC)*, (6th ed.). St. Louis, MO: Mosby; ICNP is owned and copyrighted by the International Council of Nurses (ICN). Reproduced with permission of the copyright holder.

Reviewing data collected during the assessment process helps the nurse set realistic outcome criteria based on identified patient capabilities. Goals take into consideration the economic, psychosocial, physical, and other resources available in individual situations.

Collaboration with patients and families and with members of the interprofessional health care team is imperative to identify desired patient outcomes and set mutually acceptable goals. Goals are directed at alleviating the specific problems identified in each nursing diagnosis, are patient centered, and are measurable.

From each nursing diagnosis the nurse develops specific goals for the patient who has or is at risk for an infection. Examples of goal and outcome statements follow:

- Patient's incision will remain infection free during hospitalization.
- Patient will maintain good personal hygiene by the end of day 3 after admission.

- Patient's open area on the coccyx will decrease in size by the end of day 4 after admission.

3. Write a goal for the nursing diagnosis of *Risk for Infection*;
Supporting Data: break in skin integrity, chronic disease:
diabetes mellitus.

The conceptual care map for D. P. provided in **Fig. 26.2** is partially completed to indicate how to use the map as a learning tool. Using it as an example, go to the website at <http://evolve.elsevier.com/YoostCrawford/fundamentals/> to complete Nursing Diagnoses 2 and 3.

LO 26.6 ♦ Implementation and Evaluation

The nurse plays an important role in infection control. The nurse must be proficient in aseptic technique to reduce the patient's risk for an HAI.

Infection Control and Aseptic Interventions

Nurses can implement many interventions to decrease the risk of infectious illness ([Table 26.2](#)). Diligence in performing these interventions decreases the likelihood of spreading infections from one patient to another in a health care facility.

TABLE 26.2**Prevention of Infection**

INTERVENTION	RATIONALE
Wash hands before and after giving care to each patient.	Washing hands is the single best way to avoid spreading infection. This process interrupts the chain of infection.
Educate patients regarding handwashing techniques, factors that increase the risk for infection, and the signs and symptoms of infection.	Patients can participate in their care, and this helps establish and maintain a healthy lifestyle.
Wear gloves to maintain asepsis during any direct patient care when there is a risk for exposure to blood or other bodily fluids.	Gloves offer a barrier of protection.
Monitor the patient's temperature q 4 h.	A temperature that is elevated after surgery or a diagnostic procedure may indicate the start of an infection.
Monitor the white blood cell (WBC) count as ordered.	An elevated total WBC count indicates infection.
Assist the patient with oral hygiene q 4 h.	Oral hygiene helps prevent colonization of bacteria.
Use strict aseptic technique when inserting an intravenous (IV) or urinary catheter and when performing suctioning of the lower airway.	Sterile technique helps prevent the spread of pathogens.
Change IV tubing, and give site care q 24-48 h or in accordance with hospital or facility policy.	Changing the tubing helps keep pathogens from entering the body.
Rotate the IV catheter site q 48-72 h or in accordance with hospital or facility policy.	Rotating the IV catheter site reduces the chance of infection at the site by decreasing the time that the vein is compromised.
Have the patient perform cough and deep-breathing exercises q 4 h.	Cough and deep-breathing exercises help remove secretions and prevent respiratory complications.
Turn the patient q 2 h, and perform skin care, especially over bony prominences.	Turning helps prevent skin breakdown that can lead to pathogens entering the open tissue.
Ensure optimal nutrition by offering high-protein supplements unless contraindicated.	Optimal nutrition assists in stabilizing the patient's weight, aids in wound healing, and improves muscle tone and mass.

Hand Hygiene

Hand hygiene includes handwashing with soap and water, use of an alcohol-based sanitizer, or use of a surgical hand scrub. It is one of the most important acts that a nurse can perform to protect the patient, self, and other patients from the spread of infection (**Box 26.3**). Hand hygiene (**Skill 26.1**) breaks the chain of infection by interrupting the mode of transmission.

Box 26.3

Evidence-Based Practice and Informatics

Infection Control

All nursing practice should be guided by research. Infection control measures are constantly updated so that the best and most evidence-based practices can be accessed and used. Keeping abreast of these changes can be challenging to the nurse who is busy with day-to-day clinical practice. Evidence-based practices can be found at the following websites:

- Centers for Disease Control and Prevention (CDC) at <http://www.cdc.gov> provide information to promote healthy decisions and focus on disease prevention and control, especially infectious diseases.
- National Institute for Health and Clinical Excellence (NICE) at <http://www.nice.org.uk> provides access to authoritative health and social care evidence and best practice.
- International Resource for Infection Control at <http://www.nric.org.uk> provides access to resources regarding infection control.
- The Cochrane Collaboration at <http://www.cochrane.org> provides access to evidence for best practice.
- World Health Organization at <http://www.who.int> provides access to evidence for best practice.

A surgical hand scrub must be performed before all surgical procedures and before other procedures as necessary. This type of hand hygiene is performed with an antiseptic agent. A disposable sponge is used to scrub the hands, fingers, and wrists to reduce the number of microorganisms on intact skin. [Chapter 37](#) provides more detailed information on the surgical scrub.

Precautions and Isolation

Use of standard, airborne, droplet, and contact precautions reduces the transmission of pathogens. Standard precautions are used with every patient. They are the practices that prevent the spread of infectious diseases by minimizing the risk for transmission or exposure ([Box 26.4](#)). Because it is not possible to identify patients who may or may not be

infectious at any given time, the nurse practices standard precautions in dealing with every patient to protect other patients, visitors, and staff from exposures (Siegel, Rhinehart, Jackson, et al., 2017).

Box 26.4

Nursing Care Guideline

Standard Precautions

Background

The use of standard precautions (i.e., basic aseptic techniques) prevents and controls the spread of microorganisms among patients and providers.

Procedural Concerns

- Use standard precautions for all patients when contact with potentially infectious bodily materials is possible.
- Use standard precautions during contact or potential contact with the following:
 - Blood and bodily fluids (except perspiration), secretions, and excretions; precautions *must* be used whether blood is visible or not
 - Nonintact skin
 - Mucous membranes
 - Other potentially infectious material
- Use gloves routinely with any patient care where blood or bodily fluid might be present. If splashing is possible, use conservative judgment about whether other PPE is necessary:
 - Eyewear
 - Mask
 - Gown
- Practice good hand hygiene:
 - Good hand hygiene (see [Skill 26.1](#)) is essential at all points of a procedure:
 - Before and after a procedure
 - Before applying and after removing gloves
 - When hands are visibly soiled, they must be washed. If hands are not visibly soiled, alcohol-based hand sanitizer may be used.

- Is there possible contact with *Clostridium difficile*? If so, use soap and water to disinfect hands, because alcohol-based hand sanitizers are ineffective against *C. difficile*.
- Clean or discard equipment after use.
- Follow special precautions when using needles (sharps) (Box 26.7):
 - Discard needles in sharps containers.
 - Use safety needles.
 - Needleless systems are preferred when their use is feasible.
- Educate patients and staff regarding the procedure to be performed on the patient (Box 26.8).

Box 26.8

Patient Education and Health Literacy

Preventing the Spread of Infection

Standard Precautions

Teach patients and their families the importance of the following on admission to the health care facility:

- Appropriate hand hygiene
- Respiratory hygiene and cough etiquette
- Importance of vaccinations (especially against influenza)

Transmission-Based Precautions

If a patient is diagnosed with a transmission-based illness and requires precautions, educate the patient and the family:

- Provide fact sheets or pamphlets on the illness.
- Provide rationales for the new precautions.
- Explain any risk to family members.
- Explain the personal protective equipment being used and provide directions for its use by the family.
- Be available to explain and ask questions as necessary.

From Siegel, J., Rhinehart, E., Jackson, M., et al. 2017 *Guidelines for isolation precautions: Preventing transmission of infectious agents in healthcare settings*. Updated. Retrieved from <https://www.cdc.gov/infectioncontrol/guidelines/isolation/updates.html>.

Documentation Concerns

- Standard precautions themselves do not require documentation.
- Patient and family education regarding standard precautions should be documented.

Evidence-Based Practice

Siegel et al. and the Healthcare Control Practices Advisory Committee (2017) added respiratory etiquette as a part of standard precautions. This includes covering the mouth and nose with a tissue when sneezing or coughing and disposing of the tissue immediately, washing hands promptly thereafter, wearing a mask if infected, posting signs and educating patients and staff regarding etiquette, and remaining more than 3 feet away from another person. These simple steps have reduced transmission of many organisms and prevented infections in health care facilities.

Patients who are immunocompromised (i.e., neutrophil count $<500/\text{mm}^3$) may be placed in protective isolation. This type of isolation protects susceptible patients, who may not be able to fight infection, from microorganisms in the environment. Patients who are undergoing chemotherapy, irradiation, or bone marrow transplantation and patients with severe burns may be placed in protective isolation.

Transmission precautions (i.e., airborne, droplet, and contact) are used in addition to standard precautions to decrease the transfer of highly transmissible pathogens (Box 26.5). Each transmission-based precaution requires the use of specific PPE to prevent the spread of a communicable illness (Box 26.6).

Box 26.5

Nursing Care Guideline

Contact, Airborne, and Droplet Precautions and Protective Isolation

Background

- Basic standard precaution principles apply to all patients (see Box 26.4).
- Personal protective equipment (PPE) and supplies are usually found on an isolation cart outside the room (in an anteroom).

Contact Precautions

Contact precautions are used when a known or suspected contagious disease may be present.

- Transmission of a contagious disease may occur through several routes:
 - Direct transmission (contact with the patient).
 - Indirect transmission (contact with equipment or items in the patient's environment).
- The following are typical diseases and conditions requiring use of contact precautions:
 - Multidrug-resistant organisms, including vancomycin-resistant enterococci (VRE), methicillin-resistant *Staphylococcus aureus* (MRSA), *Clostridium difficile*, respiratory syncytial virus, and hepatitis A
 - Scabies and herpes simplex virus
 - Draining wounds in which certain organisms have been cultured

Airborne Precautions

Airborne precautions are used when known or suspected contagious diseases can be transmitted by means of small droplets or particles that can remain suspended in the air for prolonged periods. Small droplets or particles can cause disease transmission over a greater distance and longer time than larger droplets (see section on [Droplet Precautions](#)).

Precautions include the following:

- A negative-pressure room with a high-efficiency particulate air (HEPA) filtration system is necessary.
- A special N95 respirator mask is required. Medical evaluation and measurement for the wearer are required before obtaining the respirator. It must be fit-tested by the facility.

Typical diseases and pathogens include the following:

- Varicella or disseminated varicella zoster (chickenpox)
- Rubeola (measles)
- *Mycobacterium tuberculosis* (pulmonary or laryngeal tuberculosis)

Droplet Precautions

Droplet precautions are used when known or suspected contagious diseases can be transmitted through large droplets suspended in the air.

- Droplets may be generated when an infected patient coughs, sneezes, or talks.
- Droplets may be produced during medical procedures such as suctioning, endotracheal intubation, cardiopulmonary resuscitation, or chest physiotherapy.

Typical diseases include the following:

- Pharyngeal diphtheria
- Mumps, rubella, and pertussis
- Streptococcal pharyngitis and scarlet fever
- Pneumonias (streptococcal, mycoplasmal, meningococcal)
- Pneumonic plague
- Meningococcal sepsis
- Influenza

Protective Isolation

Protective isolation is used for patients who have compromised immune systems. This type of isolation protects the patient from microorganisms in the environment. Protective isolation varies according to the reason that the patient's immune system is compromised, and a variety of protective precautions may be used:

- A positive-pressure room with a HEPA filtration system may be required.
- A mask is required for anyone entering the room or for the patient if leaving the room.
- Meticulous handwashing is essential.
- The patient must be assessed carefully for signs and symptoms of infection.
- No live plants, fresh flowers, fresh raw fruit or vegetables, sushi, or bleu cheese may be brought into the room because they may harbor bacteria and fungi.
- Several conditions require protective precautions:
 - Allogeneic hematopoietic stem cell transplantation
 - Chemotherapy
 - Certain diseases or disorders in which medications have caused immunosuppression, including leukemia, myelodysplastic syndrome, aplastic anemia, systemic

lupus erythematosus, rheumatoid arthritis, HIV infection, and severe sepsis

Procedural Concerns

- Address room concerns.
 - A private room is preferred for a patient who has a contagious disease or who needs protective isolation.
 - Cluster care to avoid multiple trips in and out of the patient's room.
- Address equipment concerns:
 - Keep some equipment in the patient's room, including a thermometer, a stethoscope, and a blood pressure cuff.
 - Thoroughly clean all equipment with an alcohol-based cleaning agent after each use.
- Avoid contamination by donning and removing PPE in a prescribed sequence (see [Skill 26.3](#)).
 - Place used linens from the patient's room into special isolation linen bags to prevent spread of microorganisms. A second “clean” person outside the room may be needed to double-bag items to prevent contamination outside the patient's room.
 - Assemble all equipment and supplies for use in the patient's room before entering the room. If additional items are needed while in the room, do the following:
 - Have another staff member retrieve the needed items.
 - Perform a hand-off (by having a clean person outside the room assemble the needed equipment and pass it into the isolation room) to avoid leaving the room if possible.
- To transport a patient on isolation precautions, apply these guidelines:
 - The patient should wear PPE.
 - The receiving department should be notified before transport of the patient so that all necessary arrangements can be made at the patient's destination.
 - Transport should occur only when absolutely necessary.

Documentation Concerns

- Document isolation when it is begun and discontinued.

- Document patient and family education concerning the proper procedures.
- Mark “Isolation Precautions Required” on the chart.
- Place signs in clear view on the door: “Visitors should report to the nurses’ station before entering the room.”
- If isolation is broken, refer to institutional policy and procedures.

Box 26.6

Interprofessional Collaboration and Delegation

Isolation Precautions

The skill of caring for a patient in isolation precautions can be delegated to unlicensed assistive personnel. However, it is the nurse who assesses the patient's status and isolation indications. Review with unlicensed assistive personnel:

- Reason patient is on isolation precautions
- Precautions regarding taking equipment into patient's room
- Special precautions regarding individual patient needs such transportation to diagnostic testing.

Personal Protective Equipment

Personal protective equipment (PPE) is the equipment that health care personnel use to protect against the spread of infection. Gloves, masks, goggles, face shields, gowns, caps, and shoe coverings are examples. Clean, nonsterile gloves are used when direct contact with body secretions is possible. Sterile gloves ([Skill 26.2](#)) are needed during sterile procedures, such as urinary catheter insertion. Gloves decrease the risk for transferring organisms from one individual to another. Gloves are changed if they become soiled and are always changed between patients. Proper use of PPE is essential to stop the spread of microorganisms ([Skill 26.3](#)).

Qsen Focus!

The nurse creates a culture of safety when standard and transmission-based precautions are followed and when education is provided to

patients, families, and the health care team about the hazards of not following specific precautions.

Patients and their families can become partners in preventing the spread of infectious illnesses. It is important to educate them on how they can play a role in reducing the spread of infectious illnesses.

Box 26.7

Ethical, Legal, and Professional Practice

Occupational Safety and Health Administration (OSHA) and Needlesticks

- All sharps must now be either needle safe or needleless since the Needlestick Safety and Prevention Act in 2000 ([OSHA, 2012](#)).
- Sharp boxes must be at the site of use; this is an OSHA requirement.
- Report needlestick immediately. Access to testing the source patient is stated in the testing law for each state. Some states have deemed consent, which means that the state has granted the patient's consent to be tested. Other states require the patient to grant consent in order to be tested for bloodborne pathogens.
- Health care facilities and agencies and workers' compensation require exposed employees to complete an injury report and seek appropriate treatment if needed. The treatment is linked to the results of a risk assessment and the testing of the patient.
- It is required that the exposed employee be given the patient's testing results. This is not a violation of the Health Insurance Portability and Accountability Act (HIPAA) of 1996.

Safe Practice Alert

Never recap a dirty or used needle because doing so increases the risk for exposure to blood-borne pathogens.

Qsen Focus!

The nurse demonstrates effective use of strategies to reduce the risk of harm to self or others by properly using PPE.

Safe Practice Alert

When abrasions or skin breakdown is noticed, be sure to wear gloves during patient care.

Masks protect against the transmission of infectious agents through the air. The individual is protected against large particles that travel only a short distance (usually <3 feet) and small particles that can remain suspended in the air and can travel much farther. The effectiveness of masks is decreased when they get wet or are worn for long periods. Special particulate respirators (e.g., N95 masks) are used when a patient is suspected of having or has a contagious airborne disease such as tuberculosis. These special masks look like regular masks but fit securely against the face. The nurse is fitted to determine which mask size to use. The nurse who works in high-risk communities should have a particulate respirator on hand at all times.

Waterproof gowns are used when there is a possibility that the health care provider's clothes will become soiled. Gowns are used only once and are discarded or cleaned after each use. Some health care facilities use disposable gowns.

Caps are used to cover the individual's hair, and shoe covers are used to protect the shoes. They are used in areas where there is a high risk for contamination, such as in the labor and delivery room and the operating room.

Immunization

Immunization is the process by which an individual develops immunity against a specific agent; it is important in preventing the spread of communicable diseases. Immunizations can be acquired through various techniques, the most common of which is vaccination. The “Vaccination” animation explains how immunity is acquired through immunizations.

Immunizations provided by vaccination protect an individual against a particular communicable disease. Although vaccine-preventable diseases are at an all-time low, there is still an issue with underimmunized children, adolescents, and adults. The CDC has recommended schedules for immunizations for children and adults. Schedules can be accessed at <http://www.cdc.gov/vaccines/schedules/index.html>. This information is regularly updated, and the nurse must remain vigilant about educating patients to decrease the spread of preventable contagious diseases.

Safe Practice Alert

All women of childbearing age should be up to date on immunizations according to CDC recommendations. Urge women trying to conceive to avoid exposure to infectious diseases.

Medical Asepsis and Surgical Asepsis

Medical asepsis and surgical asepsis are techniques used to prevent infection or to break the chain of infection (Box 26.9). **Medical asepsis** is often referred to as *clean technique*. Medical aseptic procedures include handwashing, wearing gloves, gowning, and disinfecting. **Surgical asepsis**, or sterile technique, is used to prevent the introduction of microorganisms from the environment to the patient. Surgical asepsis is used for surgical procedures, invasive procedures such as catheterization, procedures that invade the bloodstream or break the skin, dressing changes, and wound care (Skill 26.4).

Box 26.9

Medical Asepsis Versus Surgical Asepsis

MEDICAL ASEPSIS	SURGICAL ASEPSIS
<ul style="list-style-type: none"> • Perform diligent hand hygiene to assist in interrupting the chain of infection. • Avoid allowing soiled items such as linen to touch clothing to decrease the chance of spreading infectious material to other patients. • Keep soiled items off the floor to decrease the chance of contamination. • Teach patients the proper use of tissues to cover sneezes and coughs. Prevent patients from coughing, sneezing, or breathing directly on others. • Avoid shaking linens to decrease the chance of infectious particles becoming airborne. • Clean from less soiled to more soiled areas to avoid increasing contamination. • Place items that are moist from body fluids in the appropriate receptacle immediately. Wrap heavily soiled items in plastic to prevent direct contact with the substance by others. • Pour liquids (e.g., bath water, mouthwash) directly into the drain to avoid splashing. • Sterilize or dispose of items suspected of being contaminated. • Maintain personal hygiene. Keep fingernails short, keep hair short or pulled back, and avoid wearing rings with grooves or stones, which can harbor microorganisms. • Follow agency guidelines for standard and transmission-based precautions carefully. 	<ul style="list-style-type: none"> • Perform hand hygiene before sterile procedures. • Ensure that sterile objects touch only other sterile objects to maintain a sterile environment. • Open a sterile package away from the body to avoid contamination. • Keep sterile surfaces dry. Avoid spilling liquids on a cloth or paper that is used as a sterile field. Fluids give organisms a means of transportation. • Keep all sterile items above the waistline to ensure the sterile object is kept in sight. • Avoid coughing, talking, sneezing, or reaching across the sterile field. • Face the sterile field. Never turn your back on or walk away from a sterile field. • Keep items sterile that are used to enter a normally sterile environment (e.g., those that penetrate the skin or body). This includes dressings, needles, and catheter tubes. • Use dry, sterile forceps when necessary. • Remember that the outer 1-inch edge of a sterile field is contaminated. • Consider an object contaminated rather than sterile if there is any doubt.

4. Identify at least three nursing interventions with rationales for the goal for D. P.: *Patient's incision will remain infection-free during hospitalization.*

Disinfection and Sterilization

Disinfection and sterilization are used to remove potentially harmful microorganisms and eliminate microorganisms as potential sources of infection. **Disinfection** is the removal of pathogenic microorganisms; it typically destroys all pathogenic microorganisms except spores from

inanimate objects. Germicidal agents are used to disinfect objects, and antiseptic agents are used to disinfect skin. Examples of chemical disinfectants include alcohol and chlorhexidine (Rutala & Weber, 2014).

Sterilization is a process used to destroy all microorganisms, including their spores. Sterilization is used on equipment that is entering a sterile body cavity. Many items are purchased as sterile or can be sterilized through physical or chemical means. The nurse should always check the expiration on the package before use. If the date on the package has expired, the contents are no longer considered sterile. Physical sterilization occurs through steam, boiling water, dry heat, or radiation. Chemical sterilization occurs through the use of gases such as ethylene oxide gas or solutions (Rutala & Weber, 2014).

Infection Control and Aseptic Interventions in the Home

Asepsis in the home environment requires educating patients and their families or caregivers about the mode of transmission of pathogens and the means of prevention. Many aseptic procedures that are performed in the health care environment can be performed in the home with some modifications. The nurse must know what these modifications are and how to teach patients and their families the necessary skills before discharge (Box 26.10).

Box 26.10

Home Care Considerations

Infection Control

- Teach proper hand hygiene (before handling foods, before eating, after toileting, before and after required home care treatment, and after touching body substances such as wound drainage) and related hygienic measures for all family members.
- Instruct the patient and family not to share personal care items, such as toothbrushes, washcloths, and towels. Infections can be transmitted from shared personal items.
- Discuss antimicrobial soaps and effective disinfectants.
- Instruct about cleaning reusable equipment and supplies: Use soap and water, and disinfect with a chlorine bleach solution.

- Teach the patient and family members the signs and symptoms of infection, how to avoid infections, and when to contact a health care provider.
- Remind them to avoid coughing, sneezing, or breathing directly on others and to cover the mouth and the nose to prevent the transmission of airborne microorganisms.
- Emphasize the need for proper immunizations of all family members.
- For patients with wound care:
 - Teach the patient and family the signs of wound healing and wound infections.
 - Explain the proper technique for changing dressings and disposing of the soiled ones. Reinforce the need to place contaminated dressings and other disposable items containing body fluids in moisture-proof plastic bags.
 - Have the patient and family repeat instructions and demonstrate skills.
- If self-injections are required, advise the patient to put used needles in a puncture-resistant container with a screw-top lid and to label the container so that it will not be discarded in the garbage.
- Teach all female patients the importance of wiping front to back, because this will decrease their risk for developing a urinary tract infection (UTI); as the most common cause of a UTI is *Escherichia coli*, which is found in the gastrointestinal tract.

Evaluation

Evaluation is an ongoing portion of the nursing process. Measure the success of infection prevention and control techniques by determining whether the patient and health care team achieved the goals for reducing or preventing infection. A clear description of any signs and symptoms of systemic or local infection is necessary to give all nurses a baseline for comparative evaluation. Document the patient's response before and after an infection control measure, such as the absence of a fever or wound infection. These would be expected outcomes for measuring the success of nursing interventions. Determine the degree of wound healing and signs of infection by observing wounds during dressing change. Closely monitor patients determined to be at risk for any signs and symptoms of an infection. For example, the patient with an indwelling catheter is at risk for a urinary tract infection. In addition, the patient who has undergone a surgical procedure is at risk for a surgical site infection, and the patient with decreased mobility is at risk for a respiratory tract infection. Closely assess all surgical sites for

swelling, erythema, or purulent drainage. Monitor breath sounds for changes and observe sputum character for change in color or consistency. Laboratory test results should be reviewed for leukocytes or an abnormality in the neutrophil count. In addition, assess the patient's knowledge related to infection. A patient at risk for infection needs to understand the measures needed to reduce the risk for obtaining or spreading an infection. Give the patients and/or family caregivers the opportunity to discuss prevention and control measures while demonstrating procedures such as hand hygiene to assess their ability to comply with care techniques. Sometimes patients and/or family caregivers require new information or previously instructed information needs reinforcement.

SKILL 26.1 Hand Hygiene

Purpose

- Hand hygiene is essential to prevent the spread of microorganisms.
- It is standard practice for patient care.

Resources

- Soap
- Warm running water
- Paper towels
- Alcohol-based hand sanitizer

Interprofessional Collaboration and Delegation

- Hand hygiene is mandatory for all health care workers who come in contact with patients or their belongings; it is not delegated. Hand hygiene is mandated for all patients.
- It is important for the nurse to speak up when observing anyone not following required hand hygiene.

Evidence-Based Practice

- Alcohol-based products and sanitizers should not be used when one or both hands are visibly soiled ([CDC, 2017b](#); [Gould, Moralejo, Drey, et al, 2011](#); [WHO 2009](#)).
- Natural fingernails should be kept short and be trimmed often ([CDC, 2017b](#)).
- Health care providers do not wash their hands in accordance with the CDC's guidelines, which leads

to an increased rate of hospital-acquired infections. The rate of handwashing can be increased and the rate of infections decreased by implementing an educational model aimed at increasing the behavior of handwashing; this may be as simple as getting health care providers to speak up when they see another provider not washing his or her hands (CDC, 2017b; Kwok, Harris, & McLaws, 2017).

Special Circumstances

1. **Assess:** Are there any cuts, open sores, or breaks in the skin around cuticles, including hangnails?
Intervention: Cover the injuries with appropriate dressing after washing; wear gloves; or delegate the assignment or request a different one.
2. **Assess:** Are fingernails long or do they have artificial nails or nail polish?
Intervention: File nails, remove artificial nails, and remove nail polish.
3. **Assess:** Is the handwasher wearing jewelry?
Intervention: Remove jewelry; a plain wedding band, thoroughly washed and dried, is permitted.
4. **Assess:** Is the handwasher wearing a watch or long sleeves?
Intervention: Push the watch and sleeves above the wrist.
5. **Assess:** Is there visible soiling or dirt on the hands?
Intervention: Soap and water must be used to thoroughly clean hands if there is any visible soiling or dirt; otherwise, an alcohol-based hand sanitizer may be substituted.

Special Circumstances During the Procedure

1. **Assess:** Did hands (skin) directly touch any individual or surface (e.g., sink, clothing) when washing them?
Intervention: Body, clothing, sink, and other surfaces are considered contaminated. Start handwashing again.
2. **Assess:** Did hands (skin) touch any other surface when retrieving paper towels?
Intervention: Body, clothing, sink, and other surfaces are considered contaminated. Start handwashing again.

Procedure

Handwashing: Soap and Water Method

1. Introduce self, and educate the patient regarding handwashing if a procedure is taking place within a patient room.
Builds a trusting, professional relationship; eases patient anxiety; facilitates cooperation.
2. Turn on warm water at a medium flow.
Warm water removes dirt and microorganisms but, unlike hot water, does not remove protective skin oils; medium flow prevents splashing.
3. Wet the wrists and hands, with fingers pointing downward.

STEP 3

Washing should be done from the least contaminated to the most contaminated area (i.e., from the area of fewer microorganisms to the area of more microorganisms).

4. Apply soap.
Soap removes microorganisms.
5. Lather; rub using a circular movement; wash for 15 to 20 seconds in this order:
 - a. Palms of hands with fingertips

STEP 5A

- b. Backs (dorsum) of hands
- c. Wrists
- d. Between fingers (interlaced, including thumbs)

STEP 5D

- e. Fingers
- f. Fingertips; clean under nails

Friction helps remove microorganisms; lather indicates friction has occurred.

6. Rinse from wrist to fingertips, keeping hands with fingers pointing downward, hands slightly apart.

STEP 6

Prevents spread of microorganisms.

7. Using clean paper towels, dry thoroughly in the same order (from wrists to fingers) using a patting motion.
Prevents spread of microorganisms, which like dampness; patting (rather than rubbing) dry prevents injury to the skin.
8. Throw the paper towels in an appropriate receptacle.
Prevents spread of microorganisms.
9. Turn off the water by holding the faucet with a clean, dry paper towel.

STEP 9

- Prevents spread of microorganisms back to the hands.*
10. Throw the paper towel in an appropriate receptacle.
Prevents spread of microorganisms.

Hand Hygiene: Sanitizer Method

1. Apply an appropriate amount of hand sanitizer into the palm of one hand.

STEP 1

- Soap and water must be used to thoroughly clean hands if there is any visible soiling or dirt and with certain infections such as Clostridium difficile and vancomycin-resistant enterococci when preparing for a sterile or surgical procedure, before and after eating, and after using the restroom. In all other situations, a hand sanitizer is as effective as soap and water.*
2. Rub hands together using a circular motion, spreading sanitizer over palms and backs of both hands, then the wrist; continue until dry. Do not wave hands to dry because microorganisms may be in the air.
Friction from rubbing helps remove microorganisms; the sanitizer is not effective until dry.
 3. Gloves should not be applied until hands are dry.
Moisture inside gloves may contribute to skin breakdown, and gloves will be easier to apply on dry hands.

SKILL 26.2 Sterile Gloving

Purpose

- Sterile gloving technique protects highly susceptible patients, open wounds, and sterile objects from the transfer of microorganisms.
- Sterile gloving technique is required in most procedures requiring sterile technique.

Resources

- Sterile gloves of correct size
- A flat, clean, dry work surface above waist height near the location of the procedure

Interprofessional Collaboration and Delegation

- Sterile gloving is mandated for any health care provider who is participating in a procedure that requires sterile technique; it is not delegated.
- Sterile gloving may be performed by unlicensed assistive personnel (UAP) who are assisting in a procedure and have been trained in the proper application. The nurse must make sure that sterile technique is maintained. The nurse should verify facility policy before involving UAP in sterile procedures.

Special Circumstances

1. **Assess:** Are there breaks in the skin or around cuticles, cuts, open sores, or hangnails?
Intervention: Cover the injuries with appropriate dressing after washing, or request a different assignment.

2. **Assess:** Are fingernails long or do they have artificial nails or nail polish?
Intervention: File nails; remove artificial nails; remove nail polish.
3. **Assess:** Is jewelry being worn?
Intervention: Remove all jewelry for sterile gloving to avoid the possibility of tearing and contaminating the gloves.
4. **Assess:** Is the glove package damaged or past its expiration date?
Intervention: Acquire a new pair of sterile gloves.
5. **Assess:** Is the work surface below waist level?
Intervention: Work surfaces below waist level are considered contaminated; gloved hands are considered contaminated if they fall below waist level. Raise the work surface or find a new surface to use when applying sterile gloves.
6. **Assess:** Did skin touch a sterile part of the glove or the sterile field? Did the glove touch skin or anything outside the sterile field? Did the patient touch the gloves?
Intervention: Any contact between a sterile glove or item from a sterile field and skin or a nonsterile item outside the sterile field is considered contamination. Acquire a new pair of gloves; start the gloving process again.
7. **Assess:** Was the glover's back turned on the gloves or sterile area?
Intervention: Acquire a new pair of gloves; start over.
8. **Assess:** Did the gloves tear or were they punctured during the procedure?
Intervention: Acquire a new pair of gloves; start over.

Procedure

Applying Sterile Gloves

1. If gloving is taking place in a patient room, introduce self; explain the procedure.
Builds a trusting, professional relationship; eases patient anxiety; facilitates cooperation.
2. Perform hand hygiene (see [Skill 26.1](#)).
Prevents spread of microorganisms.
3. Peel open the glove package using a slow, smooth motion.

STEP 3

Prevents inner package from being inadvertently opened and the gloves becoming contaminated.

4. Put the inner glove package on the working surface. The working surface must be above waist level; the side of the package marked “cuff” must be closest to the person who is to glove.

Below the waist is considered contaminated. The cuff marking on the packaging ensures correct placement of the gloves so it will not be necessary to reach over the gloves to pick them up after the inner package is opened (gloves must be picked up using the cuff side).

5. Open the inner package, using thumbs and index fingers to gently pull the package edges apart.

STEP 5

The outer 1-inch margin of the inside package is not sterile.

6. With the thumb and two fingers of the nondominant hand, grasp the inside edge of the cuff of the glove for the dominant hand.

STEP 6

The cuff is folded over; the inner edge of the cuff will lie against skin and therefore is not sterile, so it can be touched without contaminating it.

7. Pull the glove onto the dominant hand, with both hands held above the waist and over the sterile field.

STEP 7

Moving hands away from the sterile field increases the risk for contamination.

8. Slide all gloved fingers underneath the cuff of the remaining glove (sterile gloved hand to sterile outer glove); hold the gloved thumb apart.

STEP 8

The sterile glove on the dominant hand touches only the sterile part of the other glove; holding the thumb away from the nongloved hand avoids risk for contamination.

9. Pull the glove onto the nondominant hand, with hands held above the waist and over the sterile field; keep the gloved thumb apart. Do not use the sterile-gloved thumb to help pull on the second glove.

STEP 9

Avoids risk for contamination.

10. Adjust the gloves to fit correctly by carefully pinching and shifting each glove with the other hand. Do not “snap” the gloves to adjust them.

Sometimes gloves do not go on correctly and must be adjusted; the fit can be corrected without contamination. Snapping may cause contamination.

11. Hold both hands together and interlock the fingers; hold hands above the waist and away from the body.

STEP 11

Avoids risk for contamination before the procedure.

Removing Sterile Gloves

1. With the dominant hand, grasp the surface of the glove from the nondominant hand right below the base of the thumb; pull off without touching exposed skin.

STEP 1

Prevents spread of microorganisms.

2. Keep the removed glove crumpled in the hand that is still gloved.

STEP 2

Prevents spread of microorganisms.

3. Slide a finger or thumb of the gloveless hand under the cuff of the glove on the other hand (skin to skin); the remaining fingers of the ungloved hand should avoid touching the glove.

STEP 3

Prevents spread of microorganisms; the fingers of the ungloved hand do not touch the contaminated surface of the glove.

4. Peel off the second glove, turning it inside out and encasing the first glove inside the second glove.

STEP 4

Prevents spread of microorganisms.

5. Discard the gloves in an appropriate receptacle.

Prevents spread of microorganisms.

6. Perform hand hygiene.

Prevents spread of microorganisms.

SKILL 26.3 Personal Protective Equipment

Purpose

- Use of personal protective equipment (PPE) prevents the spread of microorganisms.
- PPE may be required for specialized procedures.
- Use of PPE protects self and others when:
 - Caring for patients on isolation precautions.
 - Caring for patients when any contact with blood or body fluids may be expected.

Resources

- Surgical mask with ties or ear loops; face shield; N95 respirator
- Long-sleeved, nonsterile isolation gown
- Goggles or protective eyewear (if a face shield is not facility protocol)
- Nonsterile gloves
- Laundry receptacle (provided inside the room)
- Container or receptacle for eyewear (if not disposable; provided inside the room)

Interprofessional Collaboration and Delegation

- PPE is mandated for all health care workers who come in contact with patients in isolation or in situations in which contact with blood or body fluids may be expected; it is not delegated.
- It is important to speak up when you see anyone not following appropriate and prescribed PPE requirements. Not following PPE requirements may

cause harm to the health care worker and the patient.

- UAP care for patients under these conditions. UAP should report any of the following to the nurse:

- Any need for further patient education regarding use of PPE
- Personnel or visitors not following required PPE guidelines
- Concerns regarding care of patients when PPE is required
- UAP should be instructed in the following:
 - Appropriate technique and PPE equipment required for patient care
 - Appropriate donning and removal of PPE
 - Appropriate communication techniques for discussing the need for PPE with the patient

Evidence-Based Practice

- The order of donning and removing PPE is important in preventing contamination. Equipment is put on in order, starting with whatever part of the body is considered most contaminated and moving to the cleanest. Removing PPE should occur in an isolation anteroom, if available, or just inside the patient's door before leaving the room ([CDC, 2018b](#); [Siegel, Rhinehart, Jackson, et al., 2017](#)).
- The mask is removed last because it prevents airborne particles from other garments from entering the respiratory system ([CDC, 2018b](#)).

Special Circumstances

1. **Assess:** What type of PPE is needed?
Intervention: Check chart, orders, care plan, symptoms, facility policy, laboratory work, and diagnoses to ensure that the most appropriate PPE is used.
2. **Assess:** What is the state of the PPE? Is it torn, soiled, mispackaged, past expiration date, or damaged?
Intervention: Acquire new PPE.
3. **Assess:** What care and procedures are to be performed while in the patient room?
Intervention: Gather all equipment needed before entering the room; decide whether all PPE is necessary.
4. **Assess:** Has the PPE become wet, soiled, damaged, or torn during the procedure?
Intervention: Stop patient care as soon as possible; remove equipment; wash hands; inspect self; start over; report the incident and document as needed in accordance with facility policy.
5. **Assess:** What should be done if a needed item has been left outside the room?
Intervention: Ring the call bell for assistance. Ask another staff member to acquire any needed supplies.

Procedure

Applying PPE

1. Wash hands (see [Skill 26.1](#)).
2. Put on a gown.

STEP 2

Tie at the neck, tie at the waist, and pull sleeves to wrists. Ensures protection and correct fit.

3. Put on a mask.

- a. For a surgical mask with ties, tie the top strings above ears; tie bottom strings around neck; adjust the metal nose bridge (if applicable).

STEP 3A

Ensures protection and correct fit.

- b. For a surgical mask with ear loops, loop around ears; adjust the metal nose bridge (if applicable).

STEP 3B

Ensures protection and correct fit.

4. Put on eyewear, which fits over the mask if not connected to the mask.

STEP 4

Ensures protection from microorganisms and prevents fogging. Some manufacturers provide a splash guard for the eyes that is attached to the mask.

5. Put on gloves, and pull cuffs over the gown.

STEP 5

Ensures protection from microorganisms.

6. Introduce self, and explain the procedure and the need for PPE.
Creates a professional relationship and trust; promotes comfort of the patient; eases fear of PPE.

Removing PPE

1. Remove gloves (see [Skill 26.2](#)).
Gloves are contaminated; removing gloves first prevents contamination of the face and eyes during removal of the mask and prevents spread of microorganisms.
2. Remove eyewear (if separate from mask): Handle by the earpieces, and lift away from the face.

STEP 2

The outside of eyewear is contaminated; holding eyewear by the earpieces lessens the chance of contaminating hands.

3. Put eyewear into an appropriate receptacle for disposal or cleaning.
Prevents spread of microorganisms.
4. Remove gown: Untie at the waist, untie at the neck, and grasp the gown on the inside of the neck in back and pull it down from the shoulders, pulling it off inside out and rolling it into a ball.

STEP 4

The front of the gown and the sleeves are contaminated; touching only the inside with bare hands prevents spread of microorganisms.

5. Put the gown into an appropriate receptacle for disposal or cleaning.
Prevents spread of microorganisms.
6. Remove mask: Untie at the bottom, and then untie at the top or slide ear loops over ears while holding onto the ties or loops; pull away from the face without touching the outside of the mask.
Holding onto the ties or loops keeps the mask from falling and causing contamination; removing the mask last prevents spread of respiratory microorganisms.
7. Throw the mask into an appropriate receptacle.
Prevents spread of microorganisms.

8. Perform hand hygiene (see [Skill 26.1](#)).

SKILL 26.4 Sterile Fields

Purpose

- Use of a sterile field prevents the spread of microorganisms.
- A sterile field is used in procedures requiring sterile technique.

Resources

- Sterile procedural kit
- Sterile disposable drape
- Flat, clean, dry work surface above waist height near the location of the procedure

Interprofessional Collaboration and Delegation

- Preparing a sterile field may not be delegated to UAP without special training to work in areas such as surgical units or possibly the emergency room.
- Check facility policy before considering delegation.

Special Circumstances

1. **Assess:** Does the sterile kit contain all needed items?
Intervention: Acquire all items needed according to facility policy.
2. **Assess:** Are extra gloves and sterile drapes included?
Intervention: To avoid having to restart the entire process if contamination occurs during the procedure, bring extra gloves and sterile drapes into the room.
3. **Assess:** Is the sterile kit damaged, wet, or past its expiration date?
Intervention: Acquire a new sterile kit.

4. **Assess:** Is the work surface below waist level?
Intervention: Work surfaces below the waist level are considered contaminated. Raise the work surface or find a new surface to prepare the sterile field.
5. **Assess:** Did skin touch the sterile field? Did the patient touch the sterile field?
Intervention: Any contact between the sterile field and skin or a nonsterile item outside the sterile field is considered contamination. Acquire a new sterile drape or kit, and start over.
6. **Assess:** Did the preparer turn his or her back toward the sterile field?
Intervention: Acquire a new sterile drape or kit, and start over.
7. **Assess:** Did the sterile drape tear during the procedure?
Intervention: Acquire a new sterile drape or kit, and start over.

Procedure

Preparing an Individually Wrapped Sterile Drape

1. If procedure is taking place in a patient room, introduce self; explain the procedure and the need for special handling.
Builds a trusting, professional relationship; eases patient anxiety; facilitates cooperation.
2. Wash hands (see [Skill 26.1](#)).
Prevents spread of microorganisms.
3. Open the packaging.
4. With the thumb and index finger, lift the drape out of its cover by the corner.

STEP 4

Do not reach across the kit; reach around it to grasp the drape. Reaching across the field contaminates it.

5. Hold the drape above the waist and away from the body. With the thumb and index finger of the other hand, grasp the other corner and let the drape unfold.
Below the waist is considered contaminated. The outer 1-inch margin is not sterile. Holding the drape this way allows for positioning on the work surface and maintains sterility of the field.
6. Place the lower section of the drape on the work surface farthest from you; then place the upper section onto the surface closest to you.

STEP 6

- Reaching across the field contaminates it.*
7. To place items that were not included in the kit onto the sterile field (see the section on [Adding Sterile Supplies to a Sterile Field](#)).
- The procedure may require additional items, which must be accessible in a sterile manner.*

Preparing a Sterile Field Using a Commercial Procedural Kit

Some commercial kits contain a sterile drape for establishing a sterile work field near the patient or over the body.

1. If procedure is taking place in a patient room, introduce self; explain the procedure and the need for special handling.
Builds a trusting, professional relationship; eases patient anxiety; facilitates cooperation.
2. Wash hands (see [Skill 26.1](#)).
Prevents spread of microorganisms.
3. Open the outer packaging, and remove the procedural kit; place it on the work surface.

STEP 3

The outer packaging protects the inner package from opening and becoming contaminated; the inside covering opens to become the sterile field.

4. With the thumb and index finger:
 - a. Grasp the outer 1 inch of the drape.
 - b. Unfold the first flap away from you to open.
 - c. Do not reach across the kit; reach around it to open.

STEP 4A

STEP 4B

The 1-inch outer margin of the covering is not sterile. Grasping the outside eliminates the possibility of touching beyond this 1-inch field; reaching across the field contaminates it.

5. Continue opening the cover by opening the first side flap keeping the hand and arm to the side of the field; then the second side flap.

STEP 5

The outer margin of the covering is not sterile; grasping the outside eliminates the possibility of touching the sterile field.

6. Finish opening the sterile packaging by unfolding the last flap toward you; stand back, and let it fall flat on the work surface. Do not let it touch you or your clothing.

STEP 6

The order used in opening the cover maintains sterility of the field.

7. To place items that were not included in the kit onto the sterile field (see the section on [Adding Sterile Supplies to a Sterile Field](#)).

The procedure may require additional items, which must be accessible in a sterile manner.

8. Apply sterile gloves (see [Skill 26.2](#)).

All items in the kit are sterile; they cannot be touched until sterile gloves have been donned.

9. Place items included in the kit onto the field; do not place them on the outer edge.

The outer 1-inch border on the inside covering of the sterile field is not sterile.

Adding Sterile Supplies to a Sterile Field

1. The hands are not yet gloved.
Items are sterile inside the package; the outside wrapper is not sterile.
2. Following the package instructions, open each individually wrapped sterile item while holding it away from the body. Drop the item from a height of 10 inches onto the center of the sterile field. Do not hold the arm across the sterile field; approach from the side of the field.

STEP 2

- Prevents contamination; prevents reaching across field, which contaminates it.*
3. To open a large, sterile item, hold it in the nondominant hand and peel away the packaging with the dominant hand. Let the outer (nonsterile) side of the wrapping cover the nondominant hand while dropping or placing the item in the center of the field. Do not hold the arm across the sterile field; approach from the side of the field.
Prevents contamination of the sterile item.
 4. To pour liquid into a sterile container within the sterile field, hold the lid of the bottle in the nondominant hand with the inside facing up. Hold the bottle in the dominant hand and pour the liquid slowly into the sterile container. Place the bottle on a nonsterile surface, and replace the lid.

STEP 4

The inside of the sterile liquid bottle is not contaminated, and putting the lid down risks contamination. Pouring slowly prevents splashing and possible contamination.

Summary of Learning Outcomes

LO 26.1 *Summarize the body's defense system:* The risk for infection decreases when the three main defenses of the body are kept intact. These defenses are normal flora, the inflammatory response, and the immune response.

LO 26.2 *Explain the links of the chain of infection:* The chain of infection includes an infectious agent, source of infection, portal of exit, mode of transmission, portal of entry, and susceptible host.

LO 26.3 *Outline techniques of assessing for infection or risk for infection:* The nurse assesses the patient's risk factors, general appearance, vital signs, skin, laboratory results, and nutritional status to determine the patient's risk for infection or presence of an infection.

LO 26.4 *Identify nursing diagnoses for patients with infection or at risk for infection:* Examples of nursing diagnoses related to asepsis and infection control are *Risk for Infection, Lack of Knowledge, and Impaired Skin Integrity*.

LO 26.5 *Use measurable goals for patients with complications from infection:* The planning of care is designed around and involves prioritizing identified nursing diagnoses related to asepsis and infection control, evaluating the patient and the resources available, and setting patient-centered, measurable goals.

LO 26.6 *Carry out and evaluate interventions to decrease the risk for infection and reverse the negative effects of infection:* Specific nursing interventions and patient activities can enhance the body's natural defense

mechanisms. Some of them are handwashing and hand hygiene, precautions (i.e., standard, airborne, droplet, and contact), personal protective equipment, immunizations, asepsis, and disinfection and sterilization. Evaluation of goals measures the success of infection prevention and control techniques by determining whether the patient and health care team achieved the goals for reducing or preventing infection.

Review Questions

1. The nurse is caring for a patient who has been diagnosed with methicillin-resistant *Staphylococcus aureus* located in her incision. What transmission-based precautions will the nurse implement for the patient?
 - a. Private room
 - b. Private, negative-airflow room
 - c. Mask worn by the staff when entering the room
 - d. Mask worn by the staff and the patient when leaving the patient's room
2. A new patient is admitted to a medical unit with *Clostridium difficile*. Which type of precautions or isolation does the nurse know is appropriate for this patient?
 - a. Airborne precautions
 - b. Droplet precautions
 - c. Contact precautions
 - d. Protective isolation
3. In which situations does the nurse wear clean gloves as part of standard precautions? (*Select all that apply.*)
 - a. In the care of a patient diagnosed with an infectious process
 - b. When the patient is diaphoretic
 - c. During perineal care of each individual under treatment in the facility
 - d. In the presence of urine or stool
 - e. When taking the patient's blood pressure

4. The nurse is providing patient education on infection prevention. Which definition of an infection does the nurse use as a teaching point?
 - a. An illness resulting from living in an unclean environment
 - b. A result of lack of knowledge about food preparation
 - c. A disease resulting from pathogens in or on the body
 - d. An acute or chronic illness resulting from traumatic injury
5. The nurse is caring for a patient who had abdominal surgery and has developed an infection in the wound while hospitalized. Which agent is most likely the cause of the infection?
 - a. Virus
 - b. Bacterium
 - c. Fungus
 - d. Spore
6. A nurse is preparing to change a sterile dressing and has donned a pair of sterile gloves. To maintain surgical asepsis, what else must the nurse do?
 - a. Keep the amount of splashes on the sterile field to a minimum.
 - b. If a sneeze is imminent, cover the nose and mouth with a gloved hand.
 - c. With a moist saline sponge, use the dominant hand to clean the wound and then apply a dry dressing.
 - d. Regard the outer 1 inch of the sterile field as contaminated.

7. What is the proper order of removal of soiled personal protective equipment when the nurse leaves the patient's room?
 - a. Gown, goggles, mask, gloves, and exit the room
 - b. Gloves, wash hands, remove gown, mask, and wash hands
 - c. Gloves, goggles, gown, mask, and wash hands
 - d. Goggles, mask, gloves, gown, and wash hands
8. Of the following hospitalized patients, who is most at risk for acquiring a health care–associated infection?
 - a. A 60-year-old who smokes two packs of cigarettes per day
 - b. A 40-year-old who has an indwelling urinary catheter in place
 - c. A 65-year-old who is a vegetarian and slightly underweight
 - d. A 60-year-old who has a white blood cell count of 6000
9. A patient develops food poisoning from contaminated food. What is the means of transmission for the infectious organism?
 - a. Direct contact
 - b. Vector
 - c. Vehicle
 - d. Airborne
10. Of the following assessment findings, which signs indicate to a nurse that a patient has a surgical site infection? (*Select all that apply.*)
 - a. Redness or warmth at the affected site

- b. Purulent drainage at the incision site
- c. Tenderness and localized pain
- d. Wound with well-approximated edges
- e. White blood cell count 6500 cells/mm³

CHAPTER 27

Hygiene and Personal Care

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 27.1 Describe the importance of hygiene related to skin, hair, nails, and mucous membranes.
- LO 27.2 Identify how alterations in skin, hair, nails, and mucous membranes affect hygiene care.
- LO 27.3 Assess patients' hygiene status and need for assistance with care.
- LO 27.4 Select nursing diagnoses for patients who need assistance with hygiene or are experiencing alterations in self-care abilities.
- LO 27.5 Establish measurable, patient-centered goals for patients with hygiene concerns and self-care alterations.
- LO 27.6 Implement and evaluate nursing care plans that include interventions to address the hygiene needs of patients.

Case Study

Larry Randall (L. R.) is a 78-year-old widowed father of four and grandfather of seven who has a history of hypertension and chronic obstructive pulmonary disease (COPD). L. R. was admitted the previous night for worsening of COPD symptoms. He is allergic to sulfa drugs. He has a history of a two-pack-per-day (ppd) smoking habit, which he quit 10 years ago. His surgical history includes removal of his appendix 30 years ago and a total right knee replacement 8 years ago. He states that his “left knee is bad, but I can't get it replaced because of my lungs.” A chest x-ray, complete blood count (CBC), and basic metabolic panel were performed on admission, and results are pending.

L. R.'s vital signs are T 38.8° C (101.8° F), P 82 and regular, R 26 and labored, and BP 136/84, with a pulse oximetry reading of 88% on room air (RA). The intravenous (IV) access in the left antecubital space has no redness or swelling. He exhibits shortness of breath (SOB) with activity. His pain level is 2 of 10, with pain in the chest when coughing. His Braden score is 20 and Morse Fall score is 45. L. R. admits that he is not able to take care of himself “like he used to.” He states that it is difficult for him to get in and out of the tub shower at home, and he often just “washes up by the sink.” His hair is unkempt and shaggy. His face shows a few days' growth of a beard. He has strong body odor.

Treatment orders are as follows:

- Vital signs q 4 h
- Oxygen by nasal cannula at 2 L/min
- No-added-salt diet
- IV access saline lock
- Bathroom privileges with assistance
- Intake and output
- Daily weights

Medication orders are as follows:

- Lisinopril 20 mg daily
- Ipratropium multidose inhaler (MDI), 2 puffs four times daily
- Albuterol MDI, 2 puffs q 4 h PRN for wheezing
- Acetaminophen 650 mg q 4 h PRN for pain or temperature higher than 38° C (101.4° F)

Refer back to this case study to answer the critical-thinking questions throughout the chapter.

Assisting patients with **hygiene** (practices such as cleanliness that promote and preserve health) is an essential part of patient care. The hospitalized patient may depend on the nurse for basic care that is usually completed independently at home. Hygiene practices include bathing, oral care, **perineal care** (cleansing the genital area, urinary meatus, and anus), foot care, and shaving. These practices vary according to personal habits, cultural beliefs, ethnic customs, and age. The nurse assesses patients' backgrounds and provides hygiene care in a manner that is sensitive to their differences in habits and customs. During patient care, the nurse communicates with the patient, assesses the skin, and observes for any abnormalities. Bathing cleans the skin, removes organisms that can cause infection and odor, provides comfort, and contributes to the patient's health and well-being.

LO 27.1 Structure and Function of Skin, Hair, and Nails

While performing hygiene care, the nurse observes the entire integumentary system and aspects of the respiratory, gastrointestinal, and genitourinary systems. Healthy skin, hair, nails, and mucous membranes contribute to the overall health and well-being of patients. The nurse has the opportunity to assess all of these areas during bathing.

Skin, Hair, and Nails

Skin, nails, hair, sweat glands, and sebaceous (oil) glands form the **integumentary system**. Skin covers the body and is the vulnerable barrier to the outside world. It makes up around 20% of the body's weight (Huether & McCance, 2017). Mucous membranes of the lips, nostrils, anus, urethra, and vagina join seamlessly with the skin. Chapter 29 provides a detailed description of the skin and its structure and functions.

Sweat glands are an accessory organ of the skin and produce a water-like substance. These glands are activated by heat, nervousness, or stress. Sweat can produce a foul-smelling body odor. During hygiene care, the nurse cleanses all areas of the integumentary system to maintain healthy tissue, reduce body odor, and enhance comfort. Cleansing rids the skin of microorganisms that can cause infection and odor.

Hair follicles, sebaceous glands, nails, and sweat glands are accessory organs of the skin. Hair follicles arise from the dermis, are made up of **epithelial tissue** (tissue that lines tubes and cavities and the surface of the skin), and generate hair. When hair follicles go into a resting cycle, hair may fall out. The hair follicle begins a growing cycle again and produces a new hair. When hair follicles completely die, **alopecia** (absence or loss of hair) develops. Located in the dermis, **sebaceous glands** secrete an oily substance called sebum that keeps the hair and skin soft (Huether & McCance, 2017). If left unwashed, hair becomes oily as a result of these secretions.

Nails arise from the epidermis and are composed of keratinized epithelial cells. They grow from the nail matrix, which is the actively growing portion of the nail. Nails protect the ends of fingers and toes (Huether & McCance, 2017). Unlike skin, nails do not slough off and must be cut. Normal nails are smooth and pink (see Chapter 20, Fig. 20.7).

Nose, Mouth, and Oral Cavity

Mucous membranes are surfaces that line the passages and cavities of the body, such as nasal, oral, vaginal, urethral, and anal areas. The outer layer of mucous membranes is composed of epithelial cells. **Mucus** (fluid secreted by mucous membranes) traps particles in the nose, and **cilia** (tiny hairs lining the nasal passages) help move the trapped particles to the throat, where they are swallowed. The **salivary glands** in the mouth secrete mucus, enzymes, and a watery fluid, which mix to form saliva. This fluid begins chemical digestion of food and keeps the oral cavity moist. Teeth begin mechanical digestion through **mastication**, or chewing (Patton & Thibodeau, 2016). The roots of the teeth are surrounded by **gingivae** (gums), which are composed of connective tissue and epithelial cells. The ability to ingest and chew food depends on the health of all parts of the oral cavity (see Chapter 20, Fig. 20.20).

LO 27.2 Alterations in Structure and Function Affecting Hygiene Care

Many alterations of the skin and mucous membranes affect the nurse's decisions about hygiene care. Knowledge of how these alterations change the normal structure and function enables the nurse to plan interventions specific to each patient.

Ulcers, Incisions, and Wounds

Many hospitalized patients have openings in the layers of skin caused by wounds, incisions, or pressure injuries. Any interruption in the skin, which is the body's first line of defense, may lead to infection.

Excessively dry skin can lead to cracks and openings in the integumentary system. **Excoriation** (red, scaly areas with surface loss of skin tissue) occurs in patients whose skin is exposed to bodily fluids such as stool, urine, or gastric juices. Excoriation also occurs in areas where skin rests on skin, such as in the **axilla** (armpit); under large, pendulous breasts; or in abdominal folds.

Decreased Sensation

Damage to peripheral nerves occurs for a variety of reasons. Patients with neurologic deficits, such as peripheral neuropathy due to diabetes, may not be able to identify extremes of hot and cold. The nurse should monitor the temperature of bath water for patients with decreased sensation. Burns may result if skin is exposed to extremely hot water during bathing.

Alopecia

Patients may have alopecia due to hereditary factors, certain illnesses, or the effects of drugs such as those used in chemotherapy. This condition may affect the patient's self-esteem. Collaboration with a beautician or barber may be needed if a patient is actively losing hair as a result of treatment. Special care should be given to the scalp. [Box 27.1](#) outlines some education suggestions for patients with alopecia.

Box 27.1

Patient Education and Health Literacy

Alopecia

- Educate patients undergoing treatments (e.g., chemotherapy) that cause alopecia about when hair loss will occur, special care of the scalp, and protection of the skin.
- Arrange referrals to beauticians or barbers affiliated with the health care facility for patients who want to have their hair cut shorter before hair loss begins.
- Provide resources such as where the patient can obtain a wig or find a support group.
- Make available to patients any information on community agencies that may be helpful in providing care during chemotherapy.

Pediculosis

A contagious scalp infection, **pediculosis**, is caused by *Pediculus humanus capitis*. This disorder is more commonly known as head lice (Fig. 27.1). Transmission occurs through contact with infested personal items such as combs, hats, or linens. Symptoms of pediculosis are itching and redness of the scalp. If the condition is untreated, secondary bacterial infections can occur.

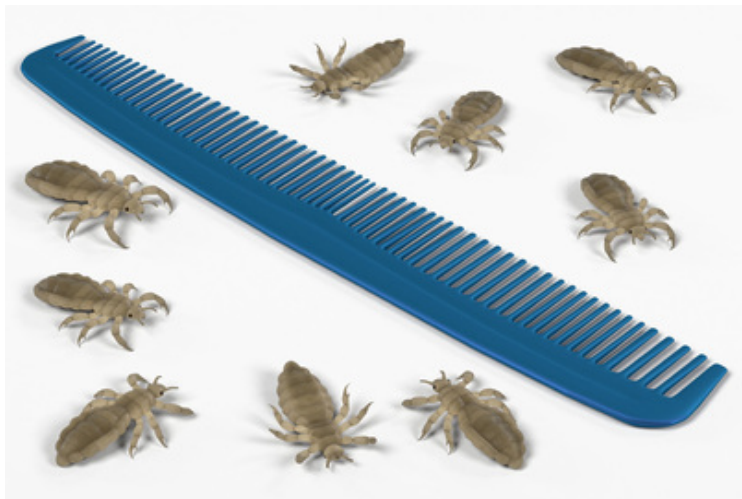

FIGURE 27.1 Head lice. (Copyright Thinkstock.com.)

Nails

Fungal, bacterial, and viral infections of the fingernails and toenails occur that cause discoloration and thickening of the nails. Some patients have a decreased ability to heal due to poor circulation. Any cut in the

skin can lead to an ulcer in these patients. An order from the primary care provider (PCP) may be necessary for nail trimming, or a podiatrist may be consulted.

Oral Cavity

Alterations in the health of the oral cavity can affect the patient's ability to chew or overall health. Sores anywhere in the oral cavity, **gingivitis** (inflammation of the gums), and broken or missing teeth create problems with chewing. Certain medications cause the mouth to be dry, creating discomfort for the patient. **Halitosis** (unpleasant breath odor) may result from poor dental hygiene, fungal or bacterial infections, and complications of medical conditions such as diabetic ketoacidosis or renal failure. Oral health depends on diligent oral hygiene.

Self-Care Alterations

Many hospitalized patients have alterations in self-care abilities due to illness, recent surgery, immobility, and cognitive dysfunction. Assessing the patient's level of ability to perform skills such as self-bathing helps the nurse devise an appropriate plan of care and assist the patient when needed. Some diversity issues related to hygiene are outlined in [Box 27.2](#).

Box 27.2

Diversity Considerations

Life Span

- Infants and young children depend on others to care for their hygiene needs.
- Skin becomes thinner, drier, and less elastic with age, making older adults more susceptible to skin breakdown.

Gender

- Proper perineal care is an important step in preventing urinary tract infections, especially in women. The female urethra is shorter than the male urethra and is closer to the anus.
- Providing perineal care for a patient of the opposite sex should be done with sensitivity to the patient's feelings. If the nurse

approaches personal care with a professional attitude and communicates the importance of the procedure, the patient's comfort level is likely to increase.

Culture, Ethnicity, and Religion

- In some cultures, male nurses may be prohibited from performing perineal care or examining private areas of a female patient's body. Similar cultural restrictions may be true for a female nurse caring for male patients (Giger, 2017).
- Cultural traditions and religious beliefs affect hygiene practices. North American and many other cultures consider it common to shower or bathe daily. In other cultures, bathing weekly is the norm.
- A beard in certain religions or cultures indicates that a man is married.
- Women of some cultures shave their axillae (armpits) and legs. In other regions of the world, women do not shave these areas. The nurse should always consult with the patient or family before shaving or cutting a patient's hair.
- People of African descent tend to have hair that is drier and requires less frequent washing.

Disability

- Patients with disabilities that affect mobility and range of motion may depend on the nurse for bathing, hygiene, and personal care.

Morphology

- Obesity creates unique concerns for the nurse providing hygiene care. Areas on the body where skin touches skin, such as in abdominal folds, under breasts, in the axilla, and in the groin area, are prone to accumulation of moisture and **chafing** (inflammation due to friction). This can lead to skin breakdown and bacterial or fungal infections.
- It may be difficult for the nurse to move and position obese patients for bathing and care. Use of mechanical lift equipment is necessary to ensure patient safety and avoid health care team injuries.

QSEN Focus!

Patient-centered care requires the nurse to understand how diverse cultural, ethnic, and social backgrounds function as sources of patient, family, and community values. The nurse provides hygiene care with sensitivity and respect for the diversity of human experience and supports care for individuals and groups whose values differ from those of the nurse.

◆ LO 27.3 Assessment

During patient care the nurse has an opportunity to establish a therapeutic relationship with the patient and assess cognitive functioning, range of motion, condition of the skin, and hygiene practices. Good hygiene has a direct impact on the health of the integumentary system. Gathering subjective and objective data about the effects of hygiene practices helps the nurse decide on a specific care plan for the patient (Box 27.3).

Box 27.3

Health Assessment Questions

Self-Care Focus

- Are you able to bathe yourself?
- How often do you bathe or shower?
- Has there been a change in your ability to care for yourself?
- Can you reach your feet and legs when you bathe or shower?
- Are you ever incontinent of urine or stool?
- Do you become short of breath during your bath?
- Can you raise your arms up to brush your teeth?
- Are you able to shampoo and comb your hair?

1. Write at least five assessment questions that the nurse should ask L. R. about his personal hygiene habits at home.

Assess Skin, Hair, Nails, and Oral Cavity

Assessment of the skin occurs before and during hygiene care. Before care, the nurse asks if the patient has noticed dry skin, rashes, skin changes, or sores. The nurse observes the condition of the exposed skin

and notes body odors. During a complete bed bath, the nurse has the opportunity to objectively assess the skin for changes, performing inspection and palpation to note the color, texture, warmth, and intactness of the skin and related structures. After inspection, the nurse documents the skin assessment and calculates the Braden score to document the patient's risk for impaired skin integrity. [Chapter 29](#) provides more information.

While gathering the health history, the nurse observes the patient's hair for cleanliness and grooming. Poor hygiene practices or self-care deficits are indicated by oily, matted, or tangled hair. Inspection of a patient's hair may reveal **dandruff** (scaling and flaking of scalp skin) or head lice.

While assessing the patient's peripheral vascular status, the nurse observes the condition of the fingernails and toenails. The nails are assessed for color, thickness, cracking, odor, and capillary refill.

Inspection of the oral mucosa and teeth is part of a complete head-to-toe assessment. By inspecting the condition of the patient's mouth, the nurse assesses oral hygiene. Broken or missing teeth, red gums, halitosis, and open sores are all indications of altered oral health and poor oral hygiene. The nurse assesses for excessive dryness, color of the oral mucosa, and presence of any sores.

Assess Self-Care Abilities

The patient's self-care ability related to hygiene needs affects the nursing care plan. If a patient is unable to care for basic needs, the nurse assists the patient during hospitalization and refers the patient to appropriate community resources for assistance after discharge. The patient's self-care abilities are assessed during the health history by asking questions about home care and by observing for any odors or signs of poor hygiene. The nurse must observe the patient's abilities to complete **activities of daily living (ADLs)**, which include bathing, mouth care, grooming, toileting, dressing, and eating.

Hygiene and Infection

The presence of skin, scalp, or oral infections may indicate poor hygiene. The nurse observes for signs of infection on the skin by looking for redness, swelling, or drainage. Infections, redness, itching, or sores on the scalp may indicate poor hygiene or exposure to an infestation, as in pediculosis. Red, swollen gums or sores in the oral cavity may be signs of poor oral hygiene. The nurse assesses patients for signs of infection due to poor hygiene practices during the initial interview and

while giving care. Patient education may be needed to change the patient's view of hygiene and its relation to health.

2. List three focused assessments related to hygiene that the nurse should perform on L. R. Give rationales for each.

◆ LO 27.4 Nursing Diagnosis

Nursing diagnoses related to hygiene and patient care are formulated after assessing patient hygiene practices and self-care abilities using subjective and objective data. Patients may have nursing diagnoses based on self-care abilities and hygiene. Examples of International Classification for Nursing Practice (ICNP) nursing diagnoses related to hygiene are listed:

Self-Care Deficit (i.e., bathing)

- Supporting Data: SOB with activity, strong body odor, unkempt hair, patient admits that he is not able to care for himself “like he used to”

Able to Perform Self-Care

- Supporting Data: Patient able to get out of bed and stand at sink, patient expressing a desire to be independent in ADLs

Impaired Health Maintenance

- Supporting Data: Impaired ability to understand, cognitive changes, poor hygiene, unkempt appearance, halitosis

◆ LO 27.5 Planning

During the planning stage of the nursing process, the nurse prioritizes identified hygiene-related nursing diagnoses based on patient needs and recognized risks. Nursing care plans are developed for each nursing diagnosis after considering the patient's self-care abilities, available resources, and family involvement. Setting realistic goals helps the nurse develop a plan of care that will enable the patient to meet goals (Table 27.1). These goals must take into consideration the patient's self-care abilities, family involvement, living situation, extent of hospital stay, and available resources.

TABLE 27.1
Care Planning

ICNP NURSING DIAGNOSIS WITH SUPPORTING DATA	NURSING OUTCOME CLASSIFICATION (NOC)	NURSING INTERVENTION CLASSIFICATION (NIC)
<i>Self-Care Deficit (i.e. bathing)</i> SOB with activity Strong body odor Unkempt hair Patient admits that he is not able to care for himself “like he used to”	<i>Self-care: Hygiene</i> Shampoos hair	<i>Bathing</i> Wash hair as needed and desired

From Butcher, H. K., Bulechek, G. M., Dochterman, J. M., et al. (Eds.). (2018). *Nursing interventions classification (NIC)* (7th ed.). St. Louis: Mosby; Moorhead, S., Swanson, E., Johnson, M., et al. (Eds.). (2018). *Nursing outcomes classification (NOC)* (6th ed.). St. Louis: Mosby. ICNP is owned and copyrighted by the [International Council of Nurses \(ICN\)](#). Reproduced with permission of the copyright holder.

Collaboration with other health care professionals, patients, and families is necessary when setting long- and short-term goals (Box 27.4). Each identified nursing diagnosis must have goal statements that are intended to address the specific problem. Examples of goals or outcome statements are as follows:

Box 27.4

Interprofessional Collaboration and Delegation

Hygiene Care

- Collaboration with colleagues is necessary when a patient requires a caregiver of the same sex for personal care because of cultural or religious reasons or personal preference.
- Family members or friends need to be involved in goal setting if the patient needs assistance with self-care activities after discharge from the hospital.
- Some aspects of personal care and hygiene may be delegated to unlicensed assistive personnel after assessment of the patient and specific instruction. The Skill features in this chapter provide delegation guidelines.
- Interprofessional collaboration with physical therapists for assessment of the patient's motor abilities and with occupational therapists for evaluation of the patient's activities of daily living may be necessary.

- Patient will accept assistance with hygiene within 24 hours.
- Patient will perform 100% of ADLs while hospitalized.
- Patient will remain free of body odors during hospitalization.

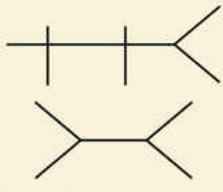

<p>Medications</p> <p>Lisinopril 20 mg daily Ipratropium multidose inhaler (MDI), 2 puffs four times daily Albuterol MDI, 2 puffs q 4-6 h PRN for wheezing Acetaminophen 650 mg q 4 h PRN for pain or temperature >38° C (101.4° F)</p> <p>IV Sites/Fluids/Rate</p> <p>IV access left antecubital: saline lock</p>	<p>Conceptual Care Map</p> <p>Student name _____ Patient initials <u>L.R.</u> Date _____ Age <u>78</u> Gender <u>M</u> Room # _____ Admission date <u>last night</u> CODE Status _____ Allergies <u>Sulfa drugs</u> Braden score <u>20</u> Diet <u>no added salt</u> Activity <u>bathroom privileges with assistance</u> Weight _____ Height _____ Religion _____</p>	<p>Lab Values/Diagnostic Test Results</p>  <p>CBC, chem 7 pending Chest x-ray pending</p>

FIGURE 27.2 Partially completed conceptual care map based on L. R., the case study patient in this chapter.

The conceptual care map for L. R. provided in Fig. 27.2 is partially completed to indicate how to use the map as a learning tool. Using it as an example, go to the website at <http://evolve.elsevier.com/YoostCrawford/fundamentals/> to complete Nursing Diagnoses 2 and 3.

3. Write a goal for this nursing diagnosis: *Self-Care Deficit* (i.e., bathing) with supporting data of weakness, decreased tissue perfusion, strong body odor, unkempt hair.

◆ LO 27.6 Implementation and Evaluation

Hygiene is a fundamental nursing activity (Box 27.5). Implementing evidence-based hygiene care improves patient health (Mahanes, Quatrara, & Shaw, 2013). Interaction with the patient during bathing and personal care helps in the development of a therapeutic relationship and provides comfort for the patient. Evaluation of hygiene and personal care is ongoing.

Box 27.5

Ethical, Legal, and Professional Practice

Respect, Competence, and Compassion

- A provision in the American Nurses Association (ANA) Code of Ethics for Nurses states that the principle underlying nursing practice is respect for the dignity, worth, and human rights of each person (see Chapter 11).
- Showing respect for a patient's dignity is apparent when the nurse cares for the patient's basic needs for cleanliness and hygiene.
- A nurse's ethical response to patients who are unable to care for themselves is to provide care with competence and compassion.

Interventions

Nursing care plans for hygiene-oriented nursing diagnoses are tailored to the patients' specific needs. Plans contain interventions focused on cleanliness, comfort, and prevention of injury or infection. Side benefits of assisting patients with their personal care include the opportunity to thoroughly assess each patient's skin and communicate with the patient in a therapeutic manner. Patient and family education regarding proper hygiene practices and assessment of the patient's home situation (Box 27.6) occur during this time.

Box 27.6

Home Care Considerations

Self-Care Deficits in Patients Discharged to Home

Patients with self-care deficits who are being discharged to home require special considerations to ensure that hygiene care continues:

- What are the patient's self-care deficits?
- Will there be caregivers in the home to help the patient with hygiene needs?
- Is there a bathroom that will be accessible to the patient?
- Does the patient need equipment to facilitate care in the home such as a shower stool or stabilizing bars in the bathroom?
- Are referrals to community agencies necessary to meet the patient's needs in the home?
- Patients may be able to return home if the proper aids are used or installed. They include handrails near stairs and in the bathroom, raised toilet seats, extension grabbers, and other adaptive tools.

Bathing and Skin Care

Bathing and skin care are essential components of patient care. The amount of assistance patients need depends on their self-care abilities. Hygiene teaching can be incorporated throughout care. There are many methods of bathing a patient, depending on the setting and the equipment available. Individual bathing preferences should be taken into account when planning bathing care.

QSEN Focus!

Patient-centered hygiene care integrates an understanding of patient and family preferences and values, coordination of care, provision of physical comfort, and emotional support. The nurse elicits the patient's values and preferences when planning care.

Bathing removes dead skin, bacteria, and body fluids that build up on the skin. Keeping the skin clean and dry can help prevent problems caused by breakdown of the skin. Bathing provides comfort and is a therapeutic intervention; it offers relaxation and skin benefits such as prevention of **maceration** (breakdown of the skin caused by fluid) and infection caused by breeding microorganisms. After the bath, the nurse documents the type of care performed, date and time, skin assessment,

and the patient's current position, ability to assist, and response to bathing.

Safe Practice Alert

Avoid massaging reddened areas on the skin during the bath. Further tissue breakdown can occur if reddened areas are massaged.

Complete Bed Bath

A complete bed bath is performed for patients who are bedridden or depend totally on others for care. [Skill 27.1](#) outlines the steps for the bath, which the nurse can adapt for patient's individual needs. Nurses or unlicensed assistive personnel (UAP) wash the patient and perform passive range-of-motion exercises as appropriate. Assessment of the patient's tolerance of this activity is essential before the bath.

Equipment used during the bath is facility-specific and tailored to patient needs. Some facilities use bath basins, washcloths, towels, and soap or skin cleanser, whereas others use prepackaged bath cloths ([Fig. 27.3](#)). The packages contain several premoistened, disposable, no-rinse cloths that can be used instead of soap and water.

FIGURE 27.3 Pack of disposable bath cloths. (Copyright Mosby's Clinical Skills: Essentials Collection.)

Partial Bed Bath

A partial bed bath is performed when only part of the body is washed. Some patients want to wash their hands and face before breakfast. Others need perineal care after using the bedpan. Many patients can independently perform parts of the bath but need help with washing their back and feet.

After assessment, the nurse may decide to do a partial bath if a patient has extremely dry skin. Many older adults find that a complete bath daily causes excessive drying of their skin. If a patient cannot tolerate a complete bed bath because of weakness or activity intolerance, the nurse washes only the areas where skin problems could develop or are causing discomfort.

Sink Bath

Patients who are ambulatory may prefer to wash while standing or sitting in front of a bath basin or sink. Patients may still need assistance with their legs, feet, and back. Assessment of the patient's ability to ambulate and wash independently is necessary.

Shower

Some hospital rooms or units are equipped with stand-up showers for patients who are strong enough to shower independently. The nurse assesses the patient and checks PCP orders to determine whether it is safe for a patient to shower.

Safe Practice Alert

Patients with peripheral neuropathy may not be able to feel the water temperature on their extremities. It is the nurse's responsibility to adjust the bath or shower water to a comfortably warm temperature: 40.5° to 43.3° C (105° to 110° F).

Chair Shower

Some long-term care patients are washed in the shower while sitting in a shower chair. A shower chair is durable, waterproof, and easily disinfected. It allows nurses or UAP to wash patients in the shower who are physically dependent or cognitively impaired. Shower chairs have an open seat so that perineal care can be completed. Some shower chairs have hydraulic lifts, making it easier for the caregiver to clean all areas of the body. Showering is a more efficient method of cleansing and is usually completed on a scheduled basis for dependent patients in long-term care.

For patients with dementia or other cognitive impairments, an individualized bathing routine must take into account their former bathing preferences, current abilities and limitations, and responses to environmental stimuli. Adapting the routine to the patient helps maintain a calm environment. A soft voice, soothing music, and a warm room help the patient relax.

Safe Practice Alert

An individualized bathing routine should be established for patients with dementia or other cognitive impairments.

Perineal Care

Perineal care, or personal care, involves cleaning the genital area, urinary meatus, and anus ([Skill 27.2](#)). This care is particularly important for patients who are dependent or incontinent or those who have a urinary catheter. The caregiver always wears gloves to provide perineal care due to the risk for exposure to body fluids. Patients recovering from perineal or genital surgery and women who are menstruating require diligent care to prevent infections and odors. **Sitz baths** (baths for soaking a patient's perineal area) are sometimes used therapeutically after perineal surgery or childbirth to cleanse the area. Patients who can perform personal care independently should be allowed to do so after the nurse assesses their abilities and risks for complications.

Perineal care is provided during a bath or shower but may be necessary more frequently, especially for incontinent patients. Patients are sometimes embarrassed to depend on others for personal care. A professional approach and caring attitude can allay patients' anxiety.

Documentation after personal care includes the type of procedure performed, the date and time, skin-related issues, incontinence, drainage or odors, catheters or dressings, and the patient's self-care abilities and response to the procedure. This documentation is included even if personal care was done as part of a complete bath.

Safe Practice Alert

Always keep the top side rails up and the bed in its lowest position with the wheels locked when not at the bedside.

Male Perineal Care

Male personal care is an important part of hygiene. It can be provided during a bath or after an incontinence episode. A caregiver of either gender can provide male perineal care, but in some cultures it is taboo for an unrelated female to touch male genitals. If the patient or family requests a caregiver of the same gender, this request should be honored.

A male patient may have an erection during care, which is a normal response to tactile stimulation. The care provider can ignore the erection and continue with the procedure or return later to complete the care, depending on the comfort level and the situation. Documentation is part of hygiene care. Document any redness, drainage, odor, edema, or skin changes.

Female Perineal Care

Personal care for females is always performed by cleansing from the front to the back of the perineal area. This essential component of good hygiene practice is completed as often as necessary to keep the patient clean, dry, and odor free. Providing privacy is an important aspect of personal care.

Some female patients request that a female caregiver perform their personal care. This may be a cultural tradition or may be personal preference. Staffing in most hospitals allows the nurse to honor this request. Documentation after care should include noting any odor or areas of redness, drainage, or swelling.

Safe Practice Alert

Always wash the female patient from the urinary meatus back to the anus to prevent introducing organisms into the urinary tract.

Foot and Hand Care

Care of the hands and feet is part of the bathing routine or can be completed separately ([Skill 27.3](#)). Feet and hands are soaked briefly during the bath if this is not contraindicated by the patient's condition. Diligent foot care provides comfort while preventing odors and skin breakdown. Assessment of the patient's self-care abilities and patient education on care of the feet and hands are accomplished during the procedure.

Some patients require specialized care of the hands, feet, and nails. If the patient has decreased sensation in the lower extremities, the feet are inspected for redness, sores, and dry areas. Patients with peripheral neuropathy should not soak their feet due to drying of the tissue and the risk for infection. Care is taken to avoid nicks or cuts in the skin

when cutting toenails of a patient with circulatory impairment in the lower extremities due to the decreased ability to heal. In some care settings, a PCP order is necessary before trimming toenails, or patients are referred to a podiatrist for this procedure.

Safe Practice Alert

Soaking the feet of a diabetic patient is contraindicated. Diabetic patients have a decreased ability to heal, and soaking their feet may lead to skin breakdown.

Documentation of hand and foot care includes the procedure performed, date and time, problems observed during the procedure such as sores and skin breakdown, odors, and the patient's response to the procedure. This important documentation is included even if the care was done as part of a complete bath.

Massage

Massage is a complimentary and alternative therapy that provides relaxation and comfort, increases circulation, and promotes sleep. Areas of the body that can be massaged are arms, hands, legs, feet, neck, and back. Always check the electronic health record before massage to be sure the patient has no existing conditions that contraindicate the procedure. A patient with deep vein thrombosis in the lower legs should not have a leg massage. Patients with open wounds should not have the affected areas massaged.

A back massage may be given as part of a complete bed bath or at any time of the day (Skill 27.4). A variety of techniques are used during the back massage. **Effleurage** is a massage technique that employs long hand movements along the length of the back muscles. The nurse's hands move in a continuous, firm motion, forming a circle near the shoulders, running down the length of the spine, and forming another circle on the lower back. This cycle is repeated several times. **Pétrissage** is performed by using a kneading motion with the fingers and thumb along the patient's back and shoulders. This technique provides stimulation to the deep muscle tissue. A third technique, called **tapotement**, involves a tapping or percussion motion with the palm or ulnar side of the hand. This technique stimulates the skin but should not be used over the kidney area. The nurse may use one or all of these techniques during a back massage, making sure to continually assess the patient's tolerance of the procedure.

Documentation includes the date, time, and duration of the massage. The patient's response and any areas of tenderness also should be noted.

Hair Care

Shampooing a patient's hair and cleansing the scalp increases comfort and provides a sense of well-being. Patients who are weak or debilitated may be unable to follow their usual grooming routine, and their hair may become oily and matted. Routinely combing or brushing a patient's hair during morning and evening care helps prevent tangling.

Shampooing can be accomplished during a shower for patients who use a stand-up shower or shower chair. For bedridden patients, a variety of shampooing methods exist, depending on the equipment available in each facility. The nurse can pad the bed with waterproof pads or use a shampoo basin. Some facilities have no-rinse shampoos, which are lathered in and toweled dry. Others have shampoo caps (Fig. 27.4) that have a shampoo solution in them. The cap is applied and the hair is lathered under the cap and then dried with a towel. Skill 27.5 lists the steps for shampooing a patient's hair in bed.

FIGURE 27.4 Shampoo cap. (Copyright Mosby's Clinical Skills: Essentials Collection.)

Special shampoos called *pediculicidal shampoos* are sometimes used when a patient has head lice. These shampoos can be toxic and may cause central nervous system side effects such as headache, dizziness, and seizures. They are contraindicated for patients with a history of

seizures, pregnant women, and young children. The nurse uses personal protective equipment when bathing and providing care for patients with pediculosis to avoid spreading the infestation. Combing the patient's hair with a fine-tooth comb before and after application of the shampoo helps remove the lice and their eggs (**nits**).

Documentation of hair care includes the assessment of the patient's scalp and tolerance of the procedure. If the patient is being treated for pediculosis, the medicated shampoo may be documented on the medication administration record.

Oral Care

Oral care is an essential nursing intervention that provides patient comfort, removes plaque and bacteria, reduces the risk for tooth decay, and decreases halitosis. Oral care includes brushing the teeth and tongue, flossing, rinsing the mouth, and cleaning dentures. When helping a dependent patient with oral care, the UAP or nurse always wears gloves.

Teeth should be brushed several times daily using fluoride toothpaste. Encourage patients to floss their teeth daily at home. Patients should perform oral hygiene independently if possible. If patients have a difficult time grasping or maneuvering the toothbrush, adaptive equipment such as a large-handle toothbrush may be necessary. The patient may find that using an electric toothbrush at home makes brushing easier. Performing oral care for patients who are dependent cleans the teeth and moistens the oral mucosa (**Skill 27.6**). Documentation of oral care includes the procedure, date and time, patient's tolerance, and findings of unusual sores, bleeding, or tenderness.

Dentures

Care of **dentures** (artificial teeth) should be performed at least every morning and evening (see **Skill 27.6**). The nurse or UAP performs this procedure for patients who cannot clean their own dentures. Denture care is performed wearing gloves.

Patients With Special Needs

Patients who are to receive nothing by mouth (NPO) or are receiving oxygen are susceptible to drying of the oral mucosa. Unconscious or intubated patients may not be able to swallow their own saliva. Oral care should be provided every 2 hours for these patients by using a toothbrush and a small amount of water or a moistened **toothette**, which is a disposable foam swab that is used for oral care (**Fig. 27.5**). Unconscious patients are at risk for aspiration, and the oral care

procedure is modified for them (see [Skill 27.6](#)). Patients who have undergone chemotherapy for cancer have special oral care needs ([Box 27.7](#)).

FIGURE 27.5 Use of a toothette for oral care.

Box 27.7

Evidence-Based Practice and Informatics

Oral Care During Cancer Therapy

Routine oral hygiene reduces the severity and incidence of oral problems during cancer therapy. Patients should tell the primary care provider (PCP) or oncologist if they have the following:

- Changes in taste or smell
- Dry mouth
- Pain when eating hot or cold foods
- Trouble eating or swallowing
- White spots in the mouth
- Sores on the lips or in the mouth

Basic guidelines include the following:

- Brushing with a soft-bristle brush and baking soda or fluoride toothpaste after meals and before bedtime

- Rinsing the oral cavity frequently with a baking soda, salt, and water mixture
- Applying a lip balm to keep the lips from drying
- Taking frequent sips of water or sucking on ice cubes to keep oral mucosa moist
- Avoid alcohol including mouthwash that contains alcohol
- Avoid drinking citrus juices and tomato juice

These strategies reduce the risk for oral soft tissue infection in patients undergoing cancer therapy. Preventing dryness of the lips reduces the risk for tissue injury.

From National Cancer Institute. (2012). Managing chemotherapy side effects: Mouth and throat changes. Retrieved from <http://www.cancer.gov/cancertopics/coping/chemo-side-effects/mouth-and-throat.pdf>.

Safe Practice Alert

Patients on anticoagulants should use a soft-bristle toothbrush.

Safe Practice Alert

Always have suction equipment at the bedside of comatose patients or patients with decreased gag reflex during oral care.

Eye Care

Eye care is part of the bathing routine. Eyes are washed with plain water from the inner to the outer canthus, using a different part of the washcloth for each eye. If the patient has dry, crusty drainage around the eyes or on the eyelids, a washcloth moistened with warm water or gauze moistened with saline can be applied. For patients whose eyes do not totally close at night, an eye patch and prescribed eyedrops may be necessary to prevent corneal drying.

Visual Aids

Patients who need glasses or contact lenses should be encouraged to use them in the health care setting. Nurses help patients keep their glasses clean during hospitalization using the technique that the patient uses at home (Box 27.8). Glass lenses can be cleaned with water and dried with

a soft cloth. Plastic lenses scratch easier and should be cleaned with an appropriate solution and dried with a lens cloth. Glasses are stored in a glasses case when not worn and are labeled with the patient's name.

Box 27.8

Nursing Care Guideline

Care of Contact Lenses and Glasses

(Copyright [Thinkstock.com.](https://www.thinkstock.com/))

Background

- Contact lenses fit on the cornea directly over the pupil. They improve vision by correcting:
 - Shape abnormalities
 - Refractive errors
- There are three types of corrections:
 - Single vision
 - Bifocal
 - Alternative bifocal (i.e., one contact corrects for near vision and the other for far vision)
- Contacts are made to be worn under one of three wear conditions:
 - Daily-wear contact lenses
 - Inserted and removed daily

- Not discarded until a new prescription is issued
- Extended-wear contact lenses
 - Worn for up to 1 week (including overnight use)
 - Not discarded until a new prescription is issued
- Disposable-wear contact lenses
 - Used for daily or extended wear
 - Discarded daily, weekly, or monthly, based on the prescription
- Glasses are worn by many patients and are necessary for vision correction.
 - Clean glasses with a soft cloth.
 - If extremely soiled, glasses can be cleaned with liquid soap and water and dried with a soft cloth.

Procedural Concerns for Contact Lenses

- Start with the same eye for insertion and removal.
 - This prevents inserting a lens into the wrong eye.
 - Some lenses are manufactured with a small mark on the right lens to avoid confusing which lens is for which eye.
- Clean lenses immediately after removing them.
- Store the lenses in a manufacturer-recommended lens solution until they are reinserted.
- Store each lens in its own compartment that is clearly labeled to indicate the eye (right or left) in which the lens should be inserted.
- Never reuse the lens solution.
- After reinserting the lenses, thoroughly clean the storage container.
- Air-dry the container to prevent contamination by microorganisms.
- If a lens is dropped, do the following:
 - Moisten a finger with the lens solution, and then gently touch the lens with the moistened finger to pick it up.
 - Clean, rinse, and disinfect the lens to avoid a potential eye infection from microorganisms that might have adhered to the lens.
- If the patient is able to insert and remove contact lenses independently, allow the patient to continue to use the contact lenses. If not, have the patient return to wearing glasses.
- If eyedrops must be instilled, remove the patient's contact lenses.
- If emergency removal of contact lenses is necessary:
 - For soft lenses, wear clean nonsterile gloves, pull down the lower lid, and have the patient look up. Use the thumb

and forefinger to pinch the edges of the contact lens together. Squeeze the lens, and remove it from the eye.

- For hard lenses, place a gloved thumb below the patient's lower eyelid and an index finger on the upper lid. Separate the lids, and have the patient blink. The lens should pop out.
- Place the lenses in sterile normal saline solution in a sterile closed container, and label the container with the patient's name and room number.

Documentation Concerns

- Record the type of lens worn by the patient, including when and how often the lenses are worn.
- Record the typical cleaning and storage of the lenses.
- Document patient complaints, signs, and symptoms associated with contact lens wear.
- Complaints may include dryness, tearing, redness, irritation, swelling, and burning, which may be caused by overwear.
- Signs and symptoms may include redness, sensitivity, vision problems, and pain (RSVP); these are reasons to contact the ophthalmologist or optometrist for an examination of the patient.

Evidence-Based Practice

- Failure to properly care for contact lenses is one of the largest contributors to microbial keratitis, a potentially dangerous infection of the eye that can cause loss of vision and most often results from contact lens wear. Health care providers and patients must adhere to all instructions regarding care to prevent these infections, and health care providers need to educate their patients and stress the importance of this matter.
- [Cohen \(2009\)](#) found patients failed to effectively follow manufacturer instructions regarding cleaning solutions, causing microorganisms to remain on the lenses and transfer to the eye on the next insertion, despite soaking overnight. [Wu, et al. \(2010\)](#) found that typical issues were poor hand hygiene, improper cleaning of the lenses or storage case, and not knowing when to return to the care provider.

If a patient wears contact lenses, it is important for the nurse to know the type of lens. Some contact lenses are disposable; others are made of a more rigid plastic and are cleaned after wearing. Each type of contact lens should be cleaned with the appropriate cleaning solution. If the lenses are to be worn again, store them in an appropriately marked container with the correct lenses in the right and left sides of the storage cup.

Prosthetic Eye

A **prosthetic**, or artificial, eye may be a permanent implant or one that is removed for cleaning. Most patients care for their own prosthesis. If the patient requires assistance, the eye can be removed by pulling down on the lower lid with a gloved hand and exerting pressure on the lower edge of the artificial eye. This breaks the suction that holds the eye in the socket. The prosthesis and the socket can be cleaned with saline.

Nose Care

Some patients need specialized care of the nose to provide comfort and remove secretions. The nurse may have to remove mucus or secretions from the nares of patients who are unable to blow into a tissue.

Removing moist secretions is accomplished by using suction. Removing dried mucus is performed using a moistened, cotton-tipped applicator. The applicator should never be inserted into the nostril further than the depth of the cotton tip. If a patient is on oxygen by a nasal cannula, the nasal passages may become dry. Humidifying the oxygen can help alleviate this problem.

Patients with nasogastric feeding or suction tubes may have crusting around the tube. The crusting may be gently removed using saline on gauze or a cotton-tipped applicator. If tape is being used to hold the tube in place, the tape should be removed daily during cleaning of the area.

Ear Care

Routine ear care is accomplished during bathing. Washing the ear with a washcloth and soap is sufficient for most patients. If the patient has a buildup of wax, or **cerumen**, the PCP may order special oil drops to soften the wax before irrigating the ear canal. Do not try to remove the wax using a cotton-tipped applicator because it can push the wax farther into the ear canal.

Safe Practice Alert

Caution patients to never insert anything sharp, such as bobby pins, into the ear. Sharp objects can rupture the tympanic membrane.

Many patients wear hearing aids to amplify sound. These small electronic devices are expensive and must be kept dry. Handle hearing aids carefully, and clean them with a dry cloth (Box 27.9). When not in use, they are stored in a container labeled with the patient's name.

Box 27.9

Nursing Care Guideline

Care of Hearing Aids

Background

Hearing aids are used for mild, moderate, severe, or profound hearing loss. They range from simple amplifiers, in which sound comes into the device and enters the ear with a higher volume, to complex, computerized aids that reduce background noise and adjust tone, pitch, and amplitude.

- Hearing aids are available in three basic types:
 - In-the-canal (ITC) hearing aids are the smallest of the three types. ITC hearing aids fit entirely inside the ear canal, which may improve comfort and be cosmetically desirable. They require special fitting.
 - In-the-ear (ITE), or inraural, hearing aids are an intermediate size. No part of the device is outside the ear; it fits snugly into the external ear canal. This type is more noticeable than the ITC hearing aid but can accommodate more hearing adjustments.
 - Behind-the-ear (BTE) hearing aids are the largest type. Plastic tubing goes in the ear canal, and a receiver fits behind the ear. It is very noticeable because of its size and is used for the most profound cases of hearing loss.
- Battery life depends on the model. Placement and removal may be delegated to unlicensed assistive personnel (UAP), but they must be instructed and trained in proper procedural care and concerns related to the specific hearing aid device for an individual patient.
- A cochlear implant is a specialty hearing device:

- Use of a cochlear implant is indicated for patients with severe to profound hearing loss after a multidisciplinary assessment and after a 3-month trial of hearing aids has failed to demonstrate appropriate improvement.
- The plastic earpiece contains a tiny microphone, and a sound transmitter fits behind the ear. This electronic device can be removed for bathing. It should be kept away from water.
- The receiver, which is surgically implanted behind the mastoid bone, stimulates nerve fibers to simulate hearing.

Procedural Concerns

- Assess the hearing aid before insertion:
 - Is the hearing aid clean?
 - Are the batteries charged and inserted?
 - Is the battery compartment shut?
 - Is the cord or tubing intact?
 - Are the dials clean and rotating easily?
 - Is static absent?
- Hearing aid insertion:
 - Place the hearing aid in the patient's ear.
 - Turn the hearing aid on to one-third volume, slowly increasing it to half volume.
 - Ensure that the volume is properly adjusted: The patient should be able to hear a normal speaking voice at a distance of 3 feet.
 - If the patient complains of whistling, check for possible causes:
 - An improper fit
 - Cerumen in the auditory canal or device
 - Fluid in the ear
 - Improper insertion into the canal
 - Volume turned too high
- Observe precautions:
 - Avoid getting the device wet.
 - Avoid exposing it to extreme temperatures.
 - Avoid spraying products such as hair spray or perfume around the hearing aid.
- Clean with a dry soft cloth.
- Follow the manufacturer's instructions.

Documentation Concerns

- Document which ear (left, right, or both) requires the device.
- Include the following specifics about the hearing aid:
 - The type of hearing aid and the batteries required
 - The procedure to turn on the hearing aid, adjust its volume, and change batteries
 - Typical storage and cleaning instructions
- Note patient complaints about an inability to hear or discomfort.

Shaving a Patient

Shaving a patient may be part of hygiene care. Many men shave their faces daily. Some women shave their legs and axillae during bathing or showering. Many older women have facial hair that they prefer to shave. The nurse or UAP can provide assistance with this grooming task when the patient is weak or debilitated. Some patients have their own electric razor, or an inexpensive hospital-supplied electric razor can be used. Razors should not be shared. If the patient's condition permits, shaving can be accomplished with a disposable razor ([Skill 27.7](#)). Having a clean-shaven face or legs boosts the patient's self-esteem. Document the date and time, body part shaved, type of razor, and skin issues observed during or after shaving.

Safe Practice Alert

Patients on anticoagulants should use an electric razor for shaving.

Beards or mustaches should not be shaved off without the consent of the patient or the family. Grooming of beards and mustaches is a part of daily hygiene care. These areas can be washed with soap and water and rinsed well during the bath. If the hair is long, it can be combed out to remove tangles.

4. Identify at least five nursing interventions for L. R. designed to meet the goals written in question 3.

Bed Making

Providing the patient with a clean, dry bed that is free of wrinkles is a basic comfort nursing measure. Bed linens may be changed after a bed bath. If the bed is not soiled, the nurse may wait until the patient is sitting in a chair or off of the nursing unit for testing. A lift may be used to temporarily lift the patient off the bed surface if the patient is on bed rest. Making an unoccupied bed is easier on the nurse or UAP and the patient.

If it is not possible to move the patient out of bed, the nurse can change the linens with the patient lying in bed. When making an occupied bed ([Skill 27.8](#)), the nurse should have all linens in the room before beginning the procedure. Making the bed can be done during or after the bath or after perineal care for incontinence.

Evaluation

Evaluation of hygiene and personal care patient goals is ongoing. The nurse observes the patient during care to assess the attainment of self-care goals. When goals are reached, new ones are established that may be longer-term goals. Noticeable improvement in the patient's hygiene practices shows the nurse that the patient understood teaching regarding hygiene. Patients who are able to do more of their own care on a daily basis are showing increased self-care abilities.

Goal statements and outcome criteria related to hygiene guide care. Most strive for the patient to become more independent. The focus of the care plan is on helping the patient gain self-care abilities and move toward independence. Diligent hygiene nursing care is needed for the dependent patient whose care plan includes as much assistance as is necessary for good hygiene practices.

Skill 27.1 Bathing a Patient in Bed

Purpose

- Bathing a patient serves many functions:
 - Provides routine hygiene care
 - Reduces body odor
 - Promotes circulation and blood flow
 - Prevents skin breakdown
 - Provides range of motion
 - Provides comfort and relaxation
 - Strengthens a general feeling of health and wellness

Resources

- Bath basin
- Bath blanket
- Drawsheet
- Laundry bag
- Personal protective equipment (PPE) when appropriate
- Skin cleanser, soap, or disposable bath cloths
- Towels
- Warm running water
- Washcloths
- Clean hospital gown
- Deodorant
- Shampoo
- Body lotion
- Prescribed skin care products

Interprofessional Collaboration and Delegation

- Bathing a patient may be delegated to unlicensed assistive personnel (UAP) after the initial assessment of the patient.
- UAP should report the following to the nurse:
 - Sores, wounds, irritations, lesions, redness, or rashes on the patient
 - Concerns regarding the procedure or patient
 - Any portion of the bath not completed
- UAP should be instructed in the following:
 - The type and time of bath for the patient
 - Special hygiene care that should be performed with the bath, such as foot and hand care or shampoo
 - Never soak the feet or trim toenails of a patient when contraindicated
 - Appropriate encouragement of the patient's abilities to assist with the procedure
 - Positioning concerns specific to the patient
 - Do not massage reddened areas on the patient's skin
 - Appropriate care and positioning of specialized medical interventions for the patient during the procedure (e.g., a Foley catheter, intravenous [IV] catheter, casts, traction)
 - Appropriate documentation according to facility policy
- Occupational therapists, physical therapists, or hospice aids and nurses may want to assist with or perform bathing for a patient to whom they are assigned. Consider timing and the needs of these collaborative caregivers when planning this procedure.

- Family members may want to assist with bathing.

Evidence-Based Practice

- Nurses are accountable for all components of hygiene care, even when they are delegated. [Bittner and Gravlin \(2011\)](#) found that care is often not completed in its entirety, resulting in poor patient outcomes. Because basic hygiene procedures prevent the spread of microorganisms and increase the sense of health and well-being, omission may result in life-threatening conditions in certain patient populations. These factors must be considered when performing and delegating hygiene procedures.
- Some cultural beliefs, such as in the Afghan and Hispanic cultures, restrict touching between nonrelatives of the opposite sex ([Giger, 2017](#)). In such situations, it is prudent to provide a same-sex caregiver if at all possible, thoroughly explain the purpose of the care you are about to provide, and ask for permission before touching the patient.

Special Circumstances

1. **Assess:** Is the patient able to assist?
Intervention: Allow the patient to perform as many steps as possible to promote independence.
2. **Assess:** Considering the patient diagnosis, are there pain concerns?
Intervention: Consider pain medication in accordance with orders before performing the procedure to prevent discomfort.
3. **Assess:** Are disposable bath cloths available?
Intervention: Warm the bath cloths if possible, using a new cloth for each step.
4. **Assess:** What is the room temperature?
Intervention: Adjust the room temperature if possible so the

- patient is comfortable; otherwise, add blankets, using warmed blankets if available.
5. **Assess:** Has the patient had recent blood clots?
Intervention: Lightly wash the patient's legs and pat them dry instead of using firm strokes.
 6. **Assess:** What is the assessment of the patient's skin determined by the thorough evaluation performed during bathing?
Intervention: Gently wash any reddened or swollen areas, and pat them dry. Use clean, nonsterile gloves as needed to comply with standard precautions. Do not apply lotion or powder to any open areas. Document the findings from the assessment.
 7. **Assess:** Is the patient able to move his or her limbs?
Intervention: Provide passive or active range-of-motion exercises (see [Chapter 28](#)).
 8. **Assess:** Is the bathwater dirty or cold?
Intervention: Change the bathwater.
 9. **Assess:** Does the patient wear hearing aids?
Intervention: Remove the hearing aids while washing the patient's ears and neck, and then replace the hearing aids.
 10. **Assess:** Does the patient wear contact lenses?
Intervention: Carefully wash around the eyes, or remove the contact lenses.
 11. **Assess:** Is there crusting around the eyes?
Intervention: Place a warm washcloth over the patient's eyes to soak the crust before washing for easier removal.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct PPE is required whenever contact with

bodily fluids is possible, to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient by using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record.

The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Bathing a Patient

Follow preprocedure steps I through VIII.

1. Prepare supplies on the bedside table. Offer the bedpan or urinal.

STEP 1 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Preparing supplies and providing for elimination before the procedure avoid interruptions during the procedure.

2. Follow the steps in [Skill 27.6](#) as needed if the patient needs oral care.

Routine hygiene care is ideally performed with bathing.

3. Raise the bed to working height; lower the top side rail and the head of the bed if tolerated by the patient.

The bed should be at a height that does not require the provider to stretch or bend unnecessarily to prevent discomfort and possible injury. A flat bed, if tolerated, provides for patient comfort during turning.

4. Cover the patient with a bath blanket or linens for comfort. Pull the bed blanket and top sheet toward the bottom of the bed and remove. Place the soiled sheet and blanket in the linen bag. Remove the patient's gown sufficiently to expose only the body part currently being bathed, and do so throughout the procedure. If the patient has an intravenous line, an injury, or reduced mobility on one side, begin from the unaffected side.

STEP 4 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Proper positioning of the bath blanket, bed linens, and patient gown provides warmth, comfort, and privacy while protecting the linens and gown from becoming dirty or wet.

5. If the patient is unable to assist or roll (see [Skill 28.1](#)), place a drawsheet. Seek assistance from another health care team member if needed.

STEP 5

Minimize provider discomfort and possible injury by following the

proper procedure. Use of a drawsheet reduces the force necessary to roll the patient and prevents possible injury to the patient. Having enough help provides for patient safety.

6. Place a towel over the pillow and under the patient's head. Place another towel across the patient's chest. Put on nonsterile gloves for any portion of the bath in which there may be exposure to mucous membranes or open sores. Using a washcloth and warm water without soap, wash the patient's eyes, wiping from the inner to outer canthus. Use a different part of the cloth for each eye.

STEP 6 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Properly placed towels protect the linens from becoming dirty or wet. Gloves prevent the spread of microorganisms. Avoid the spread of microorganisms by wiping from the inner to outer canthus (i.e., less contaminated to more contaminated region) and using a fresh surface of the cloth for each eye. Warm water is typically the most comfortable for the patient. Avoid using soap to prevent stinging, burning, and irritating the eyes.

7. Assess the skin thoroughly throughout the bath.
Bathing is an opportune time for skin assessment because all areas are visible.
8. Wash the face with warm water and soap if the patient prefers. Wash the ears and neck with soap and water. Rinse and dry the face, ears, and neck. Remove the towel. Use soap sparingly, and change the water frequently during the bath. Ask a male patient if he wishes to be shaved (see [Skill 27.7](#)).
Soap can dry the skin on the face. Giving patients a choice enables them to have some control over their care. Soap can be difficult to rinse off the skin. Keeping water clean and warm provides for patient safety and comfort.
9. Wrap the washcloth around the dominant hand, or continue to use new cloths from the packet of disposable bath cloths throughout the bath if available.

STEP 9 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Wrapping a washcloth around the hand maintains heat and water in the cloth and prevents the washcloth from touching surfaces. Using clean cloths from the packet helps prevent the spread of microorganisms.

10. Lower the top side rail. Uncover the closest arm, and place a towel under the arm. Wash, rinse, and dry the arm, moving from fingers to shoulder. Provide passive range of motion of the fingers, hand, wrist, elbow, and shoulder during care if the patient is unable to perform active range of motion movements. See [Skill 27.3](#) for hand care specifics.

STEP 10 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Lowering the rail prevents provider discomfort and possible injury, and the towel prevents the sheets from becoming dirty or wet. Washing from distal to proximal promotes circulation and blood return. Range-of-motion exercise maintains joint flexibility.

11. Apply deodorant and lotion if preferred by the patient. Remove the towel.
Routine hygiene care prevents body odor and dry skin. Asking the patient about his or her preferences allows the patient to have some control and facilitates cooperation.
12. Raise the side rail of the bed.
Precautions must be taken to maintain patient safety.

13. Repeat steps 10 through 12 on the opposite side of the patient.
Moving to the other side of the bed facilitates provider safety.
14. Lower the side rail on the side from which the work will be done. Fold down the bath blanket, and place a towel over the patient's chest.
This provides the patient with warmth, comfort, and privacy.
15. Lift the towel with one hand; wash, rinse, and dry the chest and abdomen with the other hand, taking care to include the areas under skin folds. Check the water temperature after washing the chest and abdomen, and change the water if necessary.

STEP 15 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- This continues to provide warmth and privacy. Cleansing and drying under the skin folds prevent skin breakdown from excessive moisture.*
16. Remove the towel, put a new gown on the patient, and cover the patient with a bath blanket. Raise the side rail.
This provides the patient with warmth, comfort, and privacy while ensuring that safety needs are met.
 17. Uncover the closest leg, and place a towel under the leg. Wash, rinse, and dry the leg, working from the ankle to the knee and then from the knee to the thigh. Next wash the patient's foot, making sure to dry thoroughly between the toes. See [Skill 27.3](#) for foot care specifics.

STEP 17 (Copyright Mosby's Clinical Skills: Essentials Collection.)

The towel prevents the sheets from becoming dirty or wet. Washing from distal to proximal promotes circulation and blood return. Ensuring that skin between the toes and under skin folds is dry helps prevent breakdown.

18. Apply lotion if preferred by the patient. Remove the towel.
Using lotion prevents dry skin. Asking the patient about his or her preferences allows the patient some control and facilitates cooperation.
19. Repeat steps 17 and 18 on the patient's opposite side.
20. Follow the steps for perineal care in [Skill 27.2](#).
21. Change gloves and obtain clean water and a fresh washcloth when they are soiled.
This helps prevent the spread of microorganisms.
22. Lower the side rail, and assist the patient onto his or her side, facing away from you. Use a drawsheet if necessary (see [Skill 28.1](#)). Expose the patient's entire back if possible.
Lowering the rail prevents provider discomfort and possible injury while preparing the patient for having his or her back washed. One goal is to minimize the exertion and activity required from the patient.
23. Place a towel lengthwise next to the patient's back. Wash, rinse, and dry the back, progressing from the neck to the buttocks. Tie the patient's clean gown.

STEP 23 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Proper positioning of the towel prevents the sheets from becoming dirty or wet. Washing from the neck to the buttocks promotes circulation and relaxation.

24. Wearing gloves, wash, rinse, and dry the buttocks and anus. Cover the patient. Remove and discard the gloves, and raise the side rail.

Covering the patient provides warmth, comfort, and privacy. Using and properly disposing of gloves prevents the spread of microorganisms. Raised side rails ensure safety.

25. Provide a back massage if desired by the patient (see [Skill 27.4](#)). *Massage promotes relaxation; asking the patient about his or her preferences allows the patient some control and facilitates cooperation.*
26. Discard the water, clean the bedside table, place dirty linens in a laundry bag, and remove the bag from the room. Raise the head of the bed.

Removal of potentially contaminated items reduces the spread of microorganisms. The bed position ideally should promote patient comfort.

27. Comb the patient's hair, unless shampooing is to be done (see [Skill 27.5](#)). Ask for the patient's input on the desired hair styling. *Routine hygiene care is ideally performed with bathing. Combing the hair removes tangles, and asking about styling preferences allows the patient to have some control and facilitates cooperation.*
28. Follow the steps in [Skill 27.8](#) if the linens need to be changed. *Linen changes are performed after the bed bath to provide a clean, dry surface for the patient.*

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Skill 27.2 Perineal Care

Purpose

- Prevents infection
- Prevents skin breakdown
- Provides routine hygiene care
- Removes buildup of secretions
- Prevents odor
- Provides comfort
- Strengthens a general feeling of health and wellness

Resources

- Bath basin
- Peri-bottle (optional for females)
- Bath blanket
- Clean, nonsterile gloves
- Bed protector
- Laundry bag
- Personal protective equipment (PPE), if appropriate
- Skin cleanser, soap, or disposable bath cloths
- Towels
- Warm water
- Washcloths
- Bedpan
- Clean linens, if needed
- Barrier creams or other prescribed special perineal care products

Interprofessional Collaboration and Delegation

- Perineal care may be delegated to unlicensed assistive personnel (UAP) after assessment of the patient.
- UAP should report the following to the nurse:
 - Sores, wounds, irritations, lesions, redness, or rashes on the patient
 - Episodes of incontinence (urinary or fecal), including quantity and unusual characteristics
 - Patient discomfort reported during the procedure
- UAP should be instructed in the following:
 - Positioning concerns specific to the patient
 - Appropriate techniques for the procedure
 - Cultural, privacy, and ethical concerns
 - Appropriate documentation

Special Circumstances

1. **Assess:** Has the patient had recent surgery, or are there wounds, sores, or drains in the perineal area?
Intervention: Do not delegate the procedure; refer to [Chapter 29](#) for specific care.
2. **Assess:** Does the patient have a urinary catheter?
Intervention: [Chapter 41](#) describes catheter care.
3. **Assess:** Is the foreskin difficult to retract on a male patient?
Intervention: Wash the penis with soap and water, which may lubricate the foreskin; if the foreskin still is not easily retracted after washing, repeat the washing procedure. Do *not* force the skin. Check the patient's chart for notations about previous concerns, notify the PCP, and document the findings.
4. **Assess:** What should be done if the patient has fecal incontinence?
Intervention: Clean the feces from the area, restart the perineal cleansing procedure from the beginning, and document the intervention.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct PPE is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.
- VI. Provide for patient privacy.
It is important to maintain patient dignity.
- VII. Identify the patient by using two identifiers.
Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.
- VIII. Explain the procedure to the patient.
The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Male Perineal Care

Follow preprocedure steps I through VIII.

1. If performing a bed bath (see [Skill 27.1](#)), proceed to step 2; if not, prepare supplies on the bedside table. Raise the bed to working

height, and lower the top side rail. Lower the head of the bed if tolerated by the patient.

Preparing supplies avoids unnecessary interruption of the procedure. Setting the bed at the correct working height for the provider prevents provider discomfort and possible injury. A flat bed provides for patient positioning, if tolerated.

2. Put on nonsterile gloves. The patient should be in the supine position. Fold down the bath blanket or bed sheets, raise the patient's gown, and cover the remainder of the body with a bath blanket or towel. Place a towel on the bed close to the buttocks.
Using gloves reduces the spread of microorganisms. Keeping the patient covered provides the patient with comfort and privacy. The towel protects the linens from becoming dirty or wet.
3. Wash, rinse, and dry the patient's thighs. Gently hold the shaft of the penis; if the patient is uncircumcised, retract the foreskin by gently pushing it toward the body. Starting at the urinary meatus, wash the tip of the penis with soap, using a circular motion; wash the shaft of the penis using downward strokes.

STEP 3 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Proper cleansing prevents infection and the buildup of secretions.

4. Rinse and dry the penis. Reposition the foreskin in uncircumcised patients by gently pushing the skin toward the tip of the penis.
The foreskin must be in its normal position to prevent contraction and swelling.
5. Using a clean area of the washcloth, wash, rinse, and dry from the scrotal area to the buttocks, including all skin folds.
Proper cleaning should be used to prevent the spread of microorganisms. Thorough drying prevents skin irritation.
6. If performing a bed bath, return to [Skill 27.1](#); if not, cover the patient with his gown and blanket, discard the water, and clean the bedside table.
This avoids unnecessary interruption of the procedure. Removal of potentially contaminated items reduces the spread of microorganisms.

Follow postprocedure steps I through VI.

Female Perineal Care

Follow preprocedure steps I through VIII.

1. If performing a bed bath (see [Skill 27.1](#)), proceed to step 3; if not, prepare supplies on the bedside table. Raise the bed to working height, and lower the top side rail. Lower the head of the bed if tolerated by the patient.

Preparing supplies in advance avoids interruption during the procedure. Setting the bed at the correct working height for the provider prevents provider discomfort and possible injury. A flat bed provides for patient positioning if tolerated.

2. Put on nonsterile gloves. Place the patient in the supine or dorsal recumbent position. Fold down the bath blanket or bed sheets; raise the patient's gown, and cover the remainder of the body with a bath blanket or towel. Place a towel on the bed close to the buttocks.

STEP 2

Using gloves reduces the spread of microorganisms. Keeping the patient covered provides the patient with comfort and privacy. The towel protects the linens from becoming dirty or wet.

3. Wash, rinse, and dry the upper thighs. Using your nondominant hand, gently separate the labia. Clean the pubic area by using downward strokes toward the anus. Use a different part of the washcloth for each stroke. Repeat until the area is clean. Rinse and dry the area. Continue to clean thoroughly around the labia minora, clitoris, urinary meatus, and vaginal orifice, then rinse and dry the area. If the patient uses a bedpan, you can rinse by pouring warm water from a peri-bottle over the perineal area. Then dry the area thoroughly, again working from front to back.

STEP 3 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Proper cleansing prevents infection and the buildup of secretions. Wiping from front to back and using a clean washcloth surface each time prevents microorganisms from entering the urinary tract. Thorough drying prevents skin irritation.

4. If performing a bed bath, see [Skill 27.1](#); if not, cover the patient with her gown and blanket, discard the water, and clean the bedside table.

Avoids unnecessary interruption of the procedure. Removal of potentially contaminated items reduces the spread of microorganisms.

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Skill 27.3 Foot and Hand Care

Purpose

- Provides routine hygiene care
- Removes buildup of secretions and oils on the feet and hands
- Prevents foot odor
- Promotes circulation and blood flow
- Prevents infection
- Softens rough skin and calluses
- Removes buildup of dirt and dead skin cells under the nails
- Provides comfort and relaxation

Resources

- Bath basin or emesis basin (can be used for soaking hands)
- Bath blanket
- Laundry bag
- Personal protective equipment (PPE), when appropriate
- Skin cleanser, soap, or disposable bath cloths
- Towels
- Warm water
- Washcloths
- Lotion
- Nail clippers (if facility policy allows)
- Nail file or emery board (if facility policy allows)
- Cuticle stick (if facility policy allows)

Interprofessional Collaboration and Delegation

- A patient diagnosed with diabetes is usually seen by a podiatrist or diabetic specialist for foot care. Appropriate collaboration should be planned for these patients.
- Foot care may be delegated to unlicensed assistive personnel (UAP) after assessment of the patient, provided the patient does not have diabetes.
- Hand care may be delegated to UAP after assessment of the patient.
- UAP should report the following to the nurse:
 - Sores, wounds, irritations, lesions, redness, or rashes on the patient
 - Nails that are thick, yellowed, or otherwise unusual
 - Concerns regarding the procedure or patient
- UAP should be instructed in the following:
 - Appropriate care, including trimming and filing of nails, if allowed by facility policy
 - Positioning concerns specific to the patient
 - Appropriate documentation
- Hospice aids and nurses may want to assist with or perform foot and hand care for a patient to whom they are assigned. Consider timing and the needs of these collaborative caregivers when planning this procedure.

Evidence-Based Practice

- Neglecting to file and trim fingernails and toenails can result in trauma to the skin through inadvertent scratches. Long nails can get caught on medical paraphernalia in the hospital setting, causing the nail to tear from the nail bed.

- Nurses often omit nail care, especially for patients with diabetes. This can result in increased rates of infection and poor hygiene. The registered nurse is trained to perform proper nail care, seeking interprofessional collaboration with podiatry or a certified foot and nail care nurse (CFCN) as necessary. A CFCN has the skill and knowledge to provide foot care to older patients and those with diabetes, and peripheral arterial disease. CFCNs promote foot health and help prevent infections and amputations through patient education and proper foot and nail care (Etnyre, Zarate-Abbott, Roehrick, et al., 2011).

Special Circumstances

1. **Assess:** Does the patient have peripheral vascular disease or cardiovascular disease?
Intervention: Do not soak the feet; this may cause skin breakdown or infection.
2. **Assess:** Does the patient have diabetes or peripheral neuropathy?
Intervention: Do not soak hands or feet; this may cause skin breakdown or infection. Seek referral to a podiatrist or diabetic foot care specialist.
3. **Assess:** Does the patient have thick, brittle nails?
Intervention: Soak longer for easier filing and trimming.
4. **Assess:** Is clipping nails contraindicated by the patient's diagnosis, condition, or medications or by facility policy?
Intervention: Do not proceed. Document the need for intervention, but allow the PCP to attend to trimming of nails, or ordering podiatry care.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe

patient care.

II. Gather supplies and equipment.

Preparing for the patient encounter saves time and promotes patient trust.

III. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

IV. Maintain standard precautions.

Use of the correct PPE is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient by using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record.

The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Follow preprocedure steps I through VIII.

1. If performing a bed bath (see [Skill 27.1](#)), proceed to step 2; if not, prepare supplies on the bedside table. Raise the bed to working height, and lower the top side rail.

Preparing supplies in advance avoids interruption during the procedure. Setting the bed at the correct working height for the provider prevents provider discomfort and possible injury.

2. Place a towel or waterproof pad on the bed; place a basin of warm water on the towel or pad, and pad the edge of the basin with a towel. Soak the hand or foot for about 10 minutes. If the patient is unable to sit in a chair and foot care is being performed in bed, support the patient's knees with pillows as needed.

STEP 2 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Raising the knees with a pillow reduces pressure on the skin on the back of the leg and increases patient comfort. Soaking loosens dirt, softens skin and nails, and promotes relaxation.

3. Remove the hand or foot from the water. Wash with soap, rinse, and dry, working especially between the fingers or toes. *Thorough washing prevents infection and reduces odor. Thorough drying prevents skin irritation.*
4. Inspect the fingernails or toenails. File or trim the nails at the level of the finger or toe (straight across) if within facility policy. When finished, use a new disposable emery board to round off any sharp corners.

STEP 4 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Inspection is part of a thorough assessment procedure. Filing straight across helps avoid injury to the cuticles and skin surrounding the nails. Following facility policy ensures that the caregiver is practicing within the scope and standards of the facility.

5. Gently clean debris from beneath the patient's nails with the cuticle stick if doing so is not contraindicated.

- Keeping nails clean helps prevent the spread of microorganisms.*
6. Apply lotion if desired by the patient.
Lotion prevents dry skin.
 7. Repeat steps 2 through 6 as needed for each hand or foot.
 8. If foot or hand care is part of the procedure for bathing a patient, see [Skill 27.1](#), procedure step 11 after the hand care is completed, or procedure step 20 after the foot care is completed. Otherwise, discard the water, and clean the bedside table.
Avoids unnecessary interruption of the procedure. Removal of potentially contaminated items reduces the spread of microorganisms.

Follow postprocedure steps I through VI.

Postprocedure

- I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.
Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.
- II. Assess for additional patient needs and state the time of your expected return.
Meeting patient needs and offering self promote patient satisfaction and build trust.
- III. Properly dispose of PPE.
Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.
- IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.
Disinfection eliminates most microorganisms from inanimate objects.
- V. Perform hand hygiene.
Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure. *Accurate documentation is essential to communicate patient care and to provide legal evidence of care.*

Skill 27.4 Therapeutic Massage

Purpose

- Decreases tension in muscles
- Decreases pain
- Stimulates blood flow to the skin, helping prevent skin breakdown
- Induces feelings of sleep and relaxation
- Strengthens general feeling of health and wellness

Resources

- Lotion
- Towels
- Bath blanket
- Nonsterile gloves if needed for standard precautions

Interprofessional Collaboration and Delegation

- Back massage may be delegated to unlicensed assistive personnel (UAP) after assessment and consent of the patient. Nurses should encourage UAP to incorporate back massage into patient care routines.
- UAP should report the following to the nurse:
 - Sores, wounds, irritations, lesions, redness, or rashes on the patient
 - Patient discomfort reported during the procedure
- UAP should be instructed in the following:
 - Positioning concerns specific to the patient

- Appropriate techniques for the procedure (e.g., effleurage, pétrissage, tapotement)
- Avoidance of pressure over bony prominences
- Appropriate documentation
- Hospice aides and nurses may want to perform a back massage for a patient to whom they are assigned. Consider timing and the needs of these collaborative caregivers when planning this procedure.
- Licensed massage therapists may provide therapeutic massage as part of care for some patients.

Evidence-Based Practice

- Massage provides an alternative to pain relievers in the elderly adult who may have pharmacokinetic concerns about traditional pain medications, especially narcotics (Baumann, 2009).
- Massage provides relaxation, relieves pain, and offers stress management (Fritz, 2017; Huether & McCance, 2017;).

Special Circumstances

1. **Assess:** Are there musculoskeletal concerns related to the neck, back, or spinal cord?
Intervention: Do not perform the procedure.
2. **Assess:** Is the patient unable to position himself or herself on one side or prone?
Intervention: Assist the patient with pillows, adjust a bath blanket to keep the patient covered, and expose only the back and buttocks.
3. **Assess:** Does the patient have any open lesions or rashes?
Intervention: Wear nonsterile gloves for the procedure, and

- avoid massaging any skin areas that are open.
4. **Assess:** Using a pain scale, what is the patient's level of pain?
Intervention: Using a pain scale before and after procedure will determine effectiveness of massage as a means to reduce pain.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct PPE is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.
- VI. Provide for patient privacy.
It is important to maintain patient dignity.
- VII. Identify the patient by using two identifiers.
Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.
- VIII. Explain the procedure to the patient.
The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Follow preprocedure steps I through VIII.

1. If performing a bed bath (see [Skill 27.1](#)), proceed to step 4; if not, prepare supplies on the bedside table.
Preparing supplies in advance avoids interruption during the procedure.
2. Raise the bed to a comfortable working height, with the side rail lowered.
The bed should be at a height that does not require the provider to stretch or bend unnecessarily; this prevents provider discomfort and possible injury.
3. The patient should be on his or her side, facing away from you, or be put in the prone position, using the drawsheet if necessary.
The patient must be in the proper position for the procedure; either of these positions minimizes exertion and activity for the patient.
4. Untie the patient's gown; expose the entire back and buttocks if possible. Cover the rest of the patient with the bath blanket.
This provides the patient with warmth, comfort, and privacy.
5. Pour lotion in your hands, and rub them together.
Lotion provides lubricant for the massage and prevents injury to the patient's skin. The friction from rubbing the hands together warms the lotion.
6. Massage from the buttocks to the shoulders and then back to the buttocks, using long, firm strokes (i.e., effleurage technique) for several minutes.

STEP 6 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Effleurage prevents tickling, promotes relaxation, promotes trust, and imparts a sense of caring.

7. If specific muscles are tense, apply pressure with your palm. Knead the muscle or rub it if indicated (i.e., pétrissage technique).

STEP 7 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Pétrissage promotes specific muscle relaxation. It may be contraindicated for or disliked by some patients.

8. If tolerated and preferred by the patient, tap with the sides of the palm or ulnar surface of the hand up and down the patient's back, avoiding the lower back and kidneys (i.e., tapotement technique).

STEP 8 (From Fritz, 2017.)

Tapotement promotes circulation, respiratory function, and relaxation. It may not be tolerated by some patients; tapping over the kidneys may cause injury.

9. Friction is accomplished by performing strong circular strokes. Apply strong circular strokes going from the buttocks to the neck. End the massage with long stroking effleurage movements.
Friction also promotes circulation and relaxation.
10. Wipe excess lotion off the back with a towel.
Removal of excess lotion promotes patient comfort.
11. If performing a bed bath, see [Skill 27.1](#); if not, proceed to postprocedure steps.
Avoids interruption during the procedure.

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Step 8 photo from Fritz, S. (2017). *Mosby's fundamentals of therapeutic massage* (6th ed.). St. Louis: Elsevier.

Skill 27.5 Hair Care

Purpose

- Provides routine hygiene care
- Promotes circulation and blood flow
- Provides comfort and relaxation
- Strengthens a general feeling of health, wellness, and self-esteem

Resources

- Shampoo basin
- Bath basin for drainage, if required
- Shampoo
- Conditioner, if desired
- Comb or hair brush
- Graduated cylinder or other container for water
- Laundry bag
- Gloves
- Blow dryer
- Towels
- Washcloth
- Waterproof pads
- Warm water
- Shampoo cap or dry shampoo

Interprofessional Collaboration and Delegation

- Shampooing a patient's hair in bed may be delegated to unlicensed assistive personnel (UAP) after assessment of the patient.
- UAP should report the following to the nurse:

- Sores, wounds, irritations, lesions, redness, or rashes on the patient
- Patient complaints regarding neck or back discomfort
- Provider concerns regarding the procedure or patient
- Completion of the procedure
- UAP should be instructed in the following:
 - The type of shampoo for the patient and the appropriate time for hair care
 - The patient's abilities to assist with the procedure, such as combing and styling
 - Positioning concerns specific to the patient
 - Appropriate care and positioning of specialized medical devices needed by the patient during the procedure (e.g., hearing aid)
 - Ethnic hair variations and specific interventions (e.g., use of a wide-tooth comb)
 - Appropriate documentation
- Hospice aids and nurses may want to assist with or provide shampooing for a patient to whom they are assigned. Consider timing and the needs of these collaborative caregivers when planning this procedure.
- Long-term care facilities often have a barber or hairdresser for patients. Before performing a shampoo, determine whether the patient has other appointments and coordinate the care accordingly.

Special Circumstances

1. **Assess:** Does the patient wear hearing aids?
Intervention: Remove hearing aids from the ears before shampooing with water.
2. **Assess:** Are there musculoskeletal concerns related to the patient's neck, back, or spinal cord?
Intervention: Use an alternative dry or no-rinse method (e.g., shampoo cap), or defer the procedure. Document the intervention.
3. **Assess:** Does the patient's hair have tangles?
Intervention: Apply warm water and a conditioner or a detangler if available to release tangles and avoid injury to the scalp. Use a comb or fingers to work through the tangles individually before shampooing.
4. **Assess:** Does the patient have matted hair in the hair?
Intervention: Mix a solution of 25% hydrogen peroxide and 75% saline, and apply the solution to the matted area with cotton balls to dissolve the mats. Use a comb or gloved fingers to work through the matted tangles individually before shampooing.
5. **Assess:** What should be done if the patient is unable to lie flat in the supine position?
Intervention: Use an alternative dry or no-rinse method (e.g., shampoo cap), or defer the procedure. Document the intervention.
6. **Assess:** Does the patient have sores on the scalp?
Intervention: Use nonsterile gloves when washing the patient's hair.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct PPE is required whenever contact with

bodily fluids is possible, to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient by using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record.

The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Follow preprocedure steps I through VIII.

1. If performing a bed bath (see [Skill 27.1](#)), proceed to step 2; if not, prepare the supplies on the bedside table. Raise the bed to working height, lower the top side rail, and lower the head of the bed.
Preparing supplies avoids unnecessary interruption of the procedure. Setting the bed at the correct working height for the provider prevents provider discomfort and possible injury. The procedure requires supine positioning.
2. Remove the pillow, place towels or waterproof pads under the patient's head, and place a towel across the chest.
This protects the linens from becoming dirty or wet and keeps the patient dry.
3. Place the shampoo basin under the patient's head, with the spout directed over the edge of the bed draining into a receptacle. Pad the edge of the basin and the shoulder area with towels. *Comb the patient's hair.* Offer a washcloth to the patient to hold over the eyes. Wet the hair with warm water. (If a shampoo cap is used, pad the bed with towels, and omit the shampoo basin.)

STEP 3 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Water must be drained appropriately. Padding the basin provides comfort and prevents unnecessary pressure on the skin and neck. Combing removes tangles before beginning the procedure. Using a washcloth protects the patient's eyes from water and shampoo, and it will stay on the face without the patient straining to hold it. Asking the patient for preferences allows the patient some control and facilitates cooperation.

4. Apply shampoo, lather, massage, and rinse. (If a shampoo cap is used, apply the cap, and massage to lather.)
The process removes the buildup of oily secretions and promotes relaxation.
5. Remove the shampoo basin and the top layer of wet linen.
Provides the patient with warmth and comfort.
6. Dry the hair, and massage the scalp with a towel.
Both processes provide warmth. Massage promotes relaxation, circulation, and blood flow.
7. Comb and style the patient's hair; ask for patient input on style.
Combing removes tangles. Asking about style preferences allows the patient some control and facilitates cooperation.
8. If performing a bed bath, see [Skill 27.1](#); if not, proceed to the postprocedure steps.
Avoids unnecessary interruption of the procedure.

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.

Precautions are taken to maintain patient safety. Top side

rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Skill 27.6 Oral Hygiene

Purpose

- Provides routine hygiene care
- Removes tartar, plaque, and food particles from, around, and between teeth
- Prevents infection and irritation of teeth and the oral cavity
- Prevents halitosis
- Strengthens general feelings of health and wellness

Resources

- Toothbrush, toothpaste, dental floss
- Disposable oral swabs or toothettes
- Paper cups and water
- Straw, if not contraindicated
- Mouthwash, as desired
- Emesis basin
- Towels
- Paper towels
- Nonsterile gloves
- 4 × 4 gauze pad, if required
- Water-soluble lubricant for lips, if required

Interprofessional Collaboration and Delegation

- Oral care may be delegated to unlicensed assistive personnel (UAP) after the initial assessment of the patient.
- UAP should report the following to the nurse:

- Coughing or choking symptoms (report immediately)
- Sores, wounds, irritations, lesions, or bleeding in and around the mouth
- Complaints of discomfort related to teeth, such as sensitivities that may indicate cavities or other dental concerns
- Discomfort or refusal related to denture wear or any damage noted to dentures
- Lost or missing dentures
- Obvious tooth decay or dental problems
- Difficulties during the procedure
- UAP should be instructed in the following:
 - Appropriate adaptations and emergency care for patients at risk for choking
 - Appropriate encouragement of the patient's abilities to assist with the procedure
 - Positioning concerns specific to the patient
 - Appropriate care and positioning of specialized dental devices for the patient during the procedure, such as braces, full or partial dentures, or retainers
 - Appropriate documentation, as required
- Hospice aids and nurses may want to assist with or provide oral care for a patient to whom they are assigned. Consider timing and the needs of collaborative caregivers when planning this procedure.

Evidence-Based Practice

- Evidence shows that diligent oral care provides patient comfort, reduces plaque build-up on teeth,

and decreases inflammation of the oral mucosa. To reduce the risk for infection and associated dental and oral complications, oral care routines should be performed twice daily using a soft toothbrush. Moisturizer should be applied to the lips every 2 hours, and oral care performed more often in patients who are intubated or are using oxygen. Chlorhexidine gluconate (0.12%) rinse should be used twice daily for patients who are intubated to prevent ventilator-associated pneumonia (VAP) ([American Association of Critical-Care Nurses \[AACN\], 2017](#)).

Special Circumstances

1. **Assess:** Has the patient had anticoagulant therapy or bleeding disorders?
Intervention: Using a soft-bristle toothbrush, make gentle brushing strokes to clean the teeth and gums. Do not floss. Assess carefully for bleeding. Notify the PCP if excessive bleeding occurs. Document assessment findings.
2. **Assess:** Does the patient cough or gag during the cleaning procedure?
Intervention: Remove any equipment from the patient's mouth; assist the patient as needed; and document the occurrence.
3. **Assess:** Is the toothbrush frayed?
Intervention: Supply a new toothbrush.

Special Resources and Circumstances for Specific Patient Populations

Conscious Patient

Special Circumstances

1. **Assess:** Is the patient complaining of tooth sensitivities or showing overt signs of cavities or other tooth decay?
Intervention: Notify the PCP or dentist, and document.

2. **Assess:** Has the caregiver inadvertently been bitten during the procedure?
Intervention: Stop the procedure; clean the wound; report and document the injury according to facility policy.
3. **Assess:** Does the patient have orthodontic braces, retainers, mouth guards, or other specialized dental devices?
Intervention: Clean the devices appropriately, referring to the patient's chart for specific recommendations, and document.

Patient With Dentures

Special Resources

- Denture cup
- Denture adhesive, if required

Special Circumstances

1. **Assess:** Is the patient unable to remove the dentures?
Intervention: Use a gentle side-to-side rocking motion to release suction, and remove the dentures.
2. **Assess:** Are there cracks or breaks in the dentures?
Intervention: Notify the PCP and dentist; do not place the dentures in the patient's mouth if sharp edges are present. Document the problem.

Unconscious Patient

Special Resources

- Towels
- Yankauer suction catheter and suction equipment
- Irrigation kit (i.e., cylinder with piston or bulb syringe) or oral syringe
- Bite block or oral airway, if required

Special Circumstances

1. **Assess:** Has the patient demonstrated a gag reflex?
Intervention: If no, carefully consider whether to delegate oral

care to UAP; check facility policy for delegation in this situation. If the procedure is delegated, UAP must be carefully trained and instructed on positioning and suctioning techniques.

2. **Assess:** Are there positioning concerns, such as the patient being unable to lie flat?

Intervention: Lower the head of the bed as appropriate. Turn the patient's head toward the side facing you, and place a towel on the pillow with an emesis basin on top of the towel, as appropriate. Have suction equipment turned on and easily available.

Preprocedure

- I. Check PCP orders and the patient care plan.

Knowledge of patient-specific orders is critical for safe patient care.

- II. Gather supplies and equipment.

Preparing for the patient encounter saves time and promotes patient trust.

- III. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

- IV. Maintain standard precautions.

Use of the correct PPE is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.

- V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

- VI. Provide for patient privacy.

It is important to maintain patient dignity.

- VII. Identify the patient by using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Conscious Patient

Follow preprocedure steps I through VIII.

1. Prepare supplies on the bedside table. Place paper towels under the emesis basin.

Preparing materials before beginning the procedure avoids interruption during the procedure. Placing paper towels under the emesis basin keeps the work area clean.

2. Raise the bed to a comfortable working height, and lower the top side rail. Raise the head of the bed. Place a towel across the patient's chest, and put on nonsterile gloves.

Proper bed position prevents provider discomfort and possible injury. Raising the head of the bed reduces the risk for choking. A properly placed towel can prevent the bed linens and patient's gown from becoming dirty or wet. The use of nonsterile gloves complies with standard precautions.

3. Apply water and toothpaste to the toothbrush.

Toothpaste helps clean teeth and freshen breath.

4. Brush the teeth, gums, and tongue using short, gentle strokes.

STEP 4 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Brushing removes tartar, plaque, microorganisms, and food or loose particles.

- a. *Front teeth:* Brush the upper and then the lower teeth, working on the outside surfaces of the teeth and then the inside surfaces. Use the entire brush surface of the toothbrush, and brush starting at the gum line.
 - b. *Outside of side teeth:* Hold the toothbrush at a 45-degree angle, and brush the upper and then the lower teeth, rolling the brush away from the gum line.
 - c. *Inside of side teeth:* Brush the upper and then the lower teeth, rolling the brush away from the gums.
 - d. *Chewing surface of teeth:* Brush the upper and then lower teeth using a back-and-forth motion.
 - e. *Tongue:* Brush gently from front to back; use a 4 × 4 gauze pad to hold the tongue if needed. Care must be taken to prevent triggering the gag reflex and to reduce the risk for aspiration.
5. Give the patient water. Have the patient rinse the mouth and spit into the emesis basin; repeat the rinse and spit.
Using a water rinse removes loosened particles.

6. Provide time for the patient to floss.
Flossing removes plaque from between the teeth.
7. Give the patient water. Have the patient rinse the mouth and spit into the emesis basin; repeat the rinse and spit.
Using a water rinse removes loosened particles.
8. Offer mouthwash. Instruct the patient to swish the mouthwash inside the mouth and spit into the emesis basin.
Mouthwash freshens breath; asking about preferences allows for patient control and facilitates cooperation.
9. Dry the patient's mouth; offer lubricant for the lips.
Drying the mouth promotes comfort. Lubricant prevents drying and cracking of tissues, and asking about preferences allows for patient control and facilitates cooperation.
10. If performing a bed bath, see [Skill 27.1](#); if not, proceed to the postprocedure steps.
Avoids unnecessary interruption of the procedure.

Follow postprocedure steps I through VI.

Patient With Dentures

Follow preprocedure steps I through VIII.

1. Follow procedure steps 1 and 2 in the Conscious Patient section.
Preparing materials before beginning the procedure avoids interruption during the procedure. The positioning and setup for the procedure are unchanged for a patient with dentures. Proper use of personal protective equipment (PPE) prevents the spread of microorganisms.
2. Partially fill a denture cup with water, remove the lower and then upper dentures with 4 × 4 gauze pad, and place the dentures in the denture cup.

STEP 2 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Soaking dentures in water allows easier removal of debris. A 4 × 4

gauze pad provides a more secure grip on the dentures than gloved fingers. Lower dentures are easier to remove, because upper dentures have stronger suction. Using the water-filled denture cup prevents damage to dentures during the cleaning procedure or while carrying them to the sink.

3. Follow procedure steps 3 through 5 in the Conscious Patient section to brush the gums and oral mucosa.
4. Raise the side rail.
Proper side rail positioning ensures patient safety.
5. Place a towel in the sink, and fill the sink with about an inch of water. Brush the dentures over the towel. Follow procedure steps 4a through 4d in the Conscious Patient section to clean the dentures. Rinse the dentures using warm water.
The towel prevents damage to the dentures during the cleaning procedure if the dentures are dropped. The brushing technique used with dentures is the same as that used with teeth; it removes tartar, plaque, microorganisms, and food or loose particles.
6. Brush the remaining surfaces of the dentures, and rinse the dentures. Rinse the denture cup with tap water. Place the dentures into the denture cup.

STEP 6 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Loosened particles must be removed; using fresh water prevents the spread of microorganisms.

7. Lower the side rail. Offer the patient mouthwash. Instruct the patient to swish the mouthwash, and spit into the emesis basin. Apply denture adhesive (if used), and using 4 × 4 gauze, insert the upper plate first and then the lower plate. Offer water for the patient to drink or rinse. (The patient may prefer to store the dentures. If so, store them in warm water in a denture cup labeled with the patient's name.)
Mouthwash freshens breath; asking about preferences allows for patient control and facilitates cooperation. The 4 × 4 gauze pad provides a

better grip than gloved fingers and prevents damage to the dentures during the procedure. Although lower dentures are easier to insert, the upper dentures are easier to insert without lower dentures in place.

8. Dry the patient's mouth; offer lubricant for lips.
Drying the mouth promotes comfort. Lubricant prevents drying and cracking of tissues, and asking about preferences allows for patient control and facilitates cooperation.
9. If performing a bed bath, see [Skill 27.1](#); if not, proceed to the postprocedure steps.
Avoid unnecessary interruption of the procedure.

Follow postprocedure steps I through VI.

Unconscious Patient

Follow preprocedure steps I through VIII.

1. If performing a bed bath (see [Skill 27.1](#)), proceed to step 2; if not, prepare supplies on the bedside table. Raise the bed to working height and lower the top side rail. Apply clean gloves and assess for a gag reflex. Use a tongue blade and a pen light to inspect the condition of the oral cavity. Remove and dispose of your gloves. If suctioning is needed, connect the tubing to the suction, turn on the machine, and test the suction catheter.
Preparing materials before beginning the procedure avoids interruption during the procedure. Proper bed position prevents provider discomfort and possible injury. Assessment before the procedure helps the nurse decide how to proceed.
2. Lower the head of the bed to 30 degrees or less, if tolerated by the patient. Using a drawsheet, place the patient on his or her side, facing you (see [Skill 28.1](#)), if not contraindicated by a head or neck injury or other condition. Place a towel on the bed along the side of the patient's face, and place an emesis basin along the side of the patient's mouth. Put on nonsterile gloves. Hold the suction catheter in the non-dominant hand and the tooth brush or toothette in the dominant hand.

STEP 2

If tolerated, a flat bed provides for patient comfort. Turning the patient's head to the side facing you allows fluid to drain from the side of the mouth and reduces the risk for choking. A properly placed towel prevents linens from becoming dirty or wet. Proper use of PPE prevents the spread of microorganisms. The suction catheter is ready, if needed.

3. Follow procedure steps 3 and 4a through 4d in the Conscious Patient section. Use a bite block or an oral airway to keep the patient's mouth open. Suction any accumulated secretions.
A bite block or an oral airway prevents inadvertent injury to the care provider because the normal reflex of oral stimulation is to bite down.
4. Use a toothbrush moistened with water. Apply toothpaste or an antibacterial solution to the toothbrush and use it to loosen any crusts. Disposable oral swabs dipped in water to clean oral tissues (i.e., cheeks, roof of mouth, bottom of mouth, tongue) may be used if a toothbrush is contraindicated. Use a new swab for each area.
Using disposable swabs that are frequently replaced prevents the spread of microorganisms. Swabs remove excess debris and dead tissue; the water keeps oral tissues moist.
5. Use a bulb syringe or Yankauer suction catheter to remove excess water from the oral cavity.
A Yankauer catheter is designed for oral suctioning; water that is not suctioned may be aspirated after the patient is repositioned.
6. Dry the patient's mouth with a towel, and lubricate the lips if needed.
Drying the mouth promotes comfort. Lubricant prevents drying and cracking of tissues.
7. If performing a bed bath, see [Skill 27.1](#); if not, proceed to the postprocedure steps.
Avoids unnecessary interruption of the procedure.

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Skill 27.7 Shaving a Male Patient

Purpose

- Provides routine hygiene care
- Removes unwanted hair
- Strengthens a general feeling of health and wellness

Resources

- Disposable safety razor or electric razor, as appropriate
- Bath basin
- Shaving cream or soap
- Towels
- Warm water
- Washcloths
- Nonsterile gloves
- Aftershave lotion or powder, if desired
- Mirror

Interprofessional Collaboration and Delegation

- Shaving a patient may be delegated to unlicensed assistive personnel (UAP) after assessment the patient.
- UAP should report the following to a nurse:
 - Any nicks or cuts that occur during the procedure
 - Sores, wounds, irritations, lesions, redness, or rashes on the patient
 - Difficulties in performing the procedure
- UAP should be instructed in the following:

- Appropriate equipment and training for the procedure
 - Conditions specific to the patient (e.g., bleeding tendencies) and training for interventions and reporting concerns
 - Appropriate positioning specific to the patient and diagnosis
 - Ethnic and cultural variations and concerns, such as differences in hair texture
 - Consent for and desires regarding care of the mustache and beard
 - Appropriate documentation
- Hospice aids and nurses may want to assist with shaving or shave patients to whom they are assigned. Consider timing and the needs of these collaborative caregivers when planning this procedure.

Special Circumstances: All Methods

1. **Assess:** Does the patient have a mustache or beard?
Intervention: Do not shave the patient unless consent is obtained; wash and comb the facial hair instead.
2. **Assess:** Does the patient have any bleeding disorder, or is the patient being treated with anticoagulant therapy?
Intervention: Use an electric razor.
3. **Assess:** Does the patient have very sensitive skin, or is the patient prone to ingrown hairs in the shaved area?
Intervention: Shave the patient first in the direction of hair growth; then shave again against the direction of hair growth. Shaving against the direction of hair growth gives a closer shave but may more easily nick the patient's skin and may cause ingrown hairs because the hair is shaved off at a level closer to the skin surface.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct PPE is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.
- VI. Provide for patient privacy.
It is important to maintain patient dignity.
- VII. Identify the patient by using two identifiers.
Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.
- VIII. Explain the procedure to the patient.
The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Follow preprocedure steps I through VIII.

1. If performing a bed bath, proceed to step 2; if not, prepare supplies for shaving with a safety razor on the bedside table. Raise the bed to working height, raise the head of the bed, and

lower the top side rail.

Preparing supplies in advance avoids interruption during the procedure. Setting the bed at the correct working height for the provider prevents provider discomfort and possible injury. Raising the head of the bed promotes patient comfort.

2. Place a towel around the patient's neck and across his chest. Put on nonsterile gloves.

Using a towel prevents the bed linens and patient's gown from becoming dirty or wet. Gloves are required to comply with standard precautions in case a cut occurs.

3. Apply warm water to the patient's face with a washcloth for several seconds.

Moist warmth softens the hair for easier removal and lowers the risk of nicks.

4. Put the shaving cream in your hands or lather soap in your hands, rub hands together, and apply the cream or soap over the hair on the patient's face and neck that is to be removed. The patient should be given the choice between shaving cream and soap.

Friction warms the cream or soap and provides comfort, and the lather lubricates the skin and protects it from injury. Allowing the patient to make choices about care gives the patient a sense of empowerment.

5. Hold the skin taut; shave one side of the face using long, firm strokes in the direction in which the hair grows. Use short strokes around the chin and lips. Rinse the razor with warm water after each stroke.

STEP 5 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Taut skin provides a smooth surface and prevents injury to the skin. Shaving in the direction of hair growth is better for sensitive skin and prevents ingrown hairs. Using warm water cleans the razor and softens the hair, easing its removal.

6. Dispose of the used razor in the sharps container. Rinse excess shaving cream or soap from the patient's face with warm water. Proper disposal protects the patient and staff from injury. Removing residual cream or soap prevents drying of the skin and irritation.

7. Offer aftershave or lotion. If the patient wants either, apply it with a patting motion of the fingertips.
Using aftershave or lotion promotes comfort and prevents skin irritation. Asking about preferences allows the patient some control and facilitates cooperation.
8. If performing a bed bath, see [Skill 27.1](#); if not, proceed to the postprocedure steps.
Avoids unnecessary interruption of the procedure.

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Skill 27.8 Making an Occupied or Unoccupied Bed

Purpose

- Provides routine hygiene care
- Prevents skin irritations
- Helps prevent the spread of infection
- Provides comfort and relaxation
- Reduces body odor
- Strengthens a general feeling of health and wellness

Resources

- Flat or fitted bottom sheet
- Top sheet
- Blanket and/or bedspread
- Pillowcases
- Drawsheet
- Bed protector or waterproof pad, if required
- Laundry bag
- Bath blanket (if the bed is occupied)
- Clean, nonsterile gloves

Interprofessional Collaboration and Delegation

- Making a bed is often delegated to unlicensed assistive personnel (UAP). Nurses should encourage UAP to incorporate bed making into routine care duties.
- UAP should report the following to the nurse:
 - Injury or potential injury (e.g., dislodged medical devices or dressings) that may

- occur while making an occupied bed
- Medications found in bed linens
- Difficulties in performing the procedure
- UAP should be instructed in the following:
 - Appropriate activity level of the patient and type of bed-making procedure (occupied or unoccupied) required
 - Procedure for handling clean and soiled linens
 - Importance of checking for personal items left in the bed linens (e.g., eyeglasses, jewelry, dentures)
 - Appropriate assistance required for moving the patient into and out of bed
 - Necessity of keeping the call bell within reach of the patient when the patient is out of bed
 - Restraint and safety policies regarding side rails and over-bed tables
 - Appropriate documentation of the patient's tolerance and experience of the procedure

Special Circumstances: Unoccupied or Occupied Bed

1. **Assess:** Will the linens, such as bedspread or top sheet, be reused for the patient?
Intervention: Remove and fold the linens before starting the procedure. Fold the bedspread or top sheet down in half, and then fold it from side to side. Place the linens on the bedside table or chair. Cover the patient with a bath blanket if removing the top linens.
2. **Assess:** Does the patient require additional space in the foot area to accommodate his or her diagnosis or concerns (e.g., space for a cast)?

Intervention: Apply a horizontal toe pleat to the top sheet of the bed while making it:

- Pinch 2 to 4 inches of the sheet together near the foot of the bed.
- Fold this pinched pleat neatly over itself.
- Do not complete procedure step 8 of the mitered corner in the Unoccupied Bed section.
- Tuck the top sheet in at the foot of the bed.
- Continue to make the bed according to the skill procedure steps 9 through 13.

Special Circumstances: Occupied Bed Only

1. **Assess:** Does the patient diagnosis include pain concerns if the patient is moved?

Intervention: Consider pain medication according to orders before performing the procedure to prevent discomfort.

2. **Assess:** Are there positioning concerns such that the patient is unable to lie flat?

Intervention: Lower the head of the bed as far as is appropriate.

3. **Assess:** Are there musculoskeletal concerns?

Intervention: Obtain appropriate assistance (personnel or mechanical) before repositioning the patient. Check the patient's chart and orders regarding proper positioning, and use pillows if needed to assist or elevate.

4. **Assess:** Are the dirty linens wet and soiled?

Intervention: Place an extra sheet or towel around them to absorb additional moisture. Clean the mattress before applying a clean bottom sheet.

Preprocedure

I. Check PCP orders and the patient care plan.

Knowledge of patient-specific orders is critical for safe patient care.

II. Gather supplies and equipment.

Preparing for the patient encounter saves time and promotes patient trust.

III. Perform hand hygiene.

Frequent hand hygiene prevents the spread of

microorganisms.

IV. Maintain standard precautions.

Use of the correct PPE is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient by using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Unoccupied Bed

Follow preprocedure steps I through VIII.

1. Check around the bed for spills. Check that the bed is locked. Prepare supplies on the bedside table or chair; do *not* use another patient's bed. Raise the bed to the appropriate working height, lower all side rails, and lower the head and foot of the bed. Wear nonsterile gloves when there is potential for coming into contact with soiled linens or body fluids.
Checking for spills prevents injury to the staff. Using a table or chair prevents the spread of microorganisms between patient beds. Setting the bed at the correct working height for the provider prevents provider discomfort and possible injury. A flat bed provides for proper fit of linens. Wearing gloves prevents the spread of microorganisms.
2. Remove the dirty linens.

- a. Slide the pillowcase off the pillow and place the pillowcase in the center of the bed. Place the pillow on the bedside table or chair.

STEP 2A (Copyright Mosby's Clinical Skills: Essentials Collection.)

Proper temporary storage of bedding is used to prevent the spread of microorganisms.

- b. Systematically loosen the linens at the foot of the bed. Remove the bedspread and blankets separately. If they are soiled, place them in the linen bag. If they are to be reused, fold them into a square and place them in a chair. Walk around the bed and loosen the linens at the head of the bed.

STEP 2B (Copyright Mosby's Clinical Skills: Essentials Collection.)

Walking around the bed prevents provider discomfort and possible injury from stretching and reaching.

- c. Roll the linens toward the center of the bed.

STEP 2C (Copyright Mosby's Clinical Skills: Essentials Collection.)

Rolling the dirty side of the sheets inside prevents the spread of microorganisms.

- d. Hold the dirty linens away from you and place them in a laundry bag.

STEP 2D (Copyright Mosby's Clinical Skills: Essentials Collection.)

Avoids spreading microorganisms by contact with the caregiver's clothing.

- e. Position and align the mattress to fit the bed frame, and wipe down the mattress with an appropriate solution if needed.

The mattress may slip toward the foot of the frame if the head of the bed is elevated. Alignment of the mattress with the bed frame provides patient safety and comfort and restores foot space that was affected by a slipping mattress.

Proper cleaning prevents the spread of microorganisms.

3. Wash hands and apply clean gloves if needed.

Washing hands and changing gloves after handling the dirty sheets

prevents the spread of microorganisms from dirty sheets to clean sheets.

4. For all linen applications, fold the sheets out on the bed, opening them from side to center and center to side. Do *not* shake the sheets.

Shaking sheets spreads microorganisms into the air. Holding linens up and out to shake them can cause provider discomfort and possible injury.

5. Apply the bottom fitted sheet, or use a flat sheet and miter the top corners; walk around the bed to do so.

Walking around the bed prevents provider discomfort and possible injury from stretching and reaching.

6. If the patient is incontinent, apply a waterproof pad. If the patient requires assistance with movement in bed, apply a drawsheet.

STEP 6 (Copyright Mosby's Clinical Skills: Essentials Collection.)

A waterproof pad protects the bed linens from becoming soiled and/or wet. A drawsheet prevents injury if the patient needs to be moved.

7. Apply the top sheet with the hems facing up, and apply the blanket and bedspread with the hems facing down. The top blanket or bedspread should be 6 to 8 inches down from the top of the top sheet.

Keeping the rough edges of bed linens away from the patient's skin prevents skin irritation. The top sheet can be folded down to have a clean and neat appearance (see procedure step 10).

8. Use mitered corners at the bottom of the bed. Tuck the top sheet and blanket (or bedspread) together.
 - a. Tuck in the linens across the foot of the bed.
 - b. Pull up the side of the linens near the bottom edge of the sheet to form a triangle, with equal amounts of sheet above and below the mattress.

STEP 8B (Copyright Mosby's Clinical Skills: Essentials Collection.)

- c. Tuck in the linens at the bottom part of the triangle in line with the bottom of the mattress.

STEP 8C (Copyright Mosby's Clinical Skills: Essentials Collection.)

- d. Fold down the top corner of the triangle over the mattress.

STEP 8D (Copyright Mosby's Clinical Skills: Essentials Collection.)

Mitered corners secure linens on the bed while providing a clean and neat appearance.

9. Make a cuff by turning down the top sheet over the top edge of the blanket or bedspread.
The cuff is easy for a patient to grab to pull up the sheets, and it provides a clean and neat appearance.
10. Make a horizontal toe pleat. At the foot of the bed fanfold the sheet 5 to 10 cm (2 to 4 inches) across the bed. Pull the sheet up from the bottom to make a fold about 15 cm (6 inches) from the

bottom of the mattress.

Allows room for the patient's feet.

11. Apply the pillowcase.

STEP 11 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Grasp the center of the outside seam of the closed end of the pillowcase with your dominant hand; use the other hand to pull the pillowcase inside out over your dominant hand.
This approach prevents shaking of the pillow or case.
 - b. Grasp the center of the edge of the pillow with the same hand.
 - c. Slide the pillowcase around the pillow using your nondominant hand.
12. Place the pillow on the bed with the open end of the pillowcase away from the door.
The overall appearance of the room should be clean and neat.
 13. If the patient is not in the room, place the call light on the bed; if the patient is in the room and wants to get back into the bed, provide assistance, and then proceed to the postprocedure steps. Remove the soiled linen from the patient's room.
This avoids unnecessary interruption of the procedure or prepares the bed for the patient's return.

Follow postprocedure steps I through VI.

Occupied Bed

Follow preprocedure steps I through VIII.

1. If performing a bed bath (see [Skill 27.1](#)), proceed to procedure step 3; if not, prepare supplies on the bedside table, raise the bed to working height, and lower the top side rail.
Preparing supplies avoids unnecessary interruption of the procedure. Setting the bed at the correct working height for the provider prevents provider discomfort and possible injury.

2. Lower the head and foot of the bed if appropriate. Put on clean gloves. Untuck the top sheet at the foot of the bed. Remove the bedspread and blanket separately. If they are soiled, place them in the linen bag. If either is to be reused, fold the items into a square and place them on the back of a chair. Place a bath blanket over the top sheet on the patient.

The bed should be flat to reduce provider discomfort and possible injury and to allow for proper fit of linens. The bath blanket provides warmth, comfort, and privacy for the patient during the linen change.

3. Remove the top sheet by reaching under the bath blanket, grasping the top of the sheet, and pulling it down to the foot of the bed. Hold the linens away from you, and place them in a laundry bag.

Proper removal prevents spread of microorganisms.

4. Assist the patient onto the side facing away from you, keeping that side rail up for safety. Loosen the four corners of the bottom sheet, and roll the sheet on the working side (i.e., along the patient's back) in toward the patient.

STEP 4 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Make one side of the bed at a time. Loosening all four corners at once minimizes the time that the patient must be on his or her side.

5. With assistance, reposition the mattress to align with the bed frame. Clean the mattress if appropriate. Remove gloves and perform hand hygiene.

The mattress may slip toward the foot of the frame if the head of the bed is elevated. Alignment of the mattress with the bed frame provides patient safety and comfort and restores foot space that was affected by a slipping mattress. Cleaning the mattress reduces the risk for infections.

6. Apply a fitted sheet (or use a flat sheet as the bottom sheet) to one side of the bed by unfolding it lengthwise from the center of the bed and tucking in the corners. Wearing clean gloves, fan-fold the remaining half of the clean sheet, and tuck it under the cleaner underside of the dirty linens.

STEP 6 (Copyright Mosby's Clinical Skills: Essentials Collection.)

The side of the dirty sheet that was exposed to patient contact is rolled into itself so that only the cleaner underside contacts the clean sheets; this reduces the spread of microorganisms.

7. Follow step 6 in the Unoccupied Bed section for applying a waterproof pad or drawsheet if required.
A waterproof pad protects the bed linens from becoming soiled and wet. A drawsheet prevents injury to the patient if he or she needs to be moved.
8. Raise the top side rail; roll the patient over the roll of bedding onto the opposite side to face toward you. Walk around the bed. *Precautions must be taken to maintain patient safety while you make the other side of the bed.*
9. Lower the top side rail. Fold the dirty linens inward into a bundle, and remove it from the bed. Hold the linens away from you, and place them in a laundry bag. Remove dirty gloves and wash hands.
The bed rail is positioned to prevent provider discomfort and possible injury. Proper handling of dirty linens and frequent handwashing prevent the spread of microorganisms.
10. Unfold and smooth the bottom sheet, waterproof pad, and drawsheet from under the patient.

STEP 10 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Removing wrinkles from the bedding avoids skin irritation and patient discomfort.

11. Tuck in the corners of the fitted sheet (or miter the top corners of a flat sheet used as a bottom sheet), and tuck the drawsheet

under the mattress.

This secures the bedding to complete the application of the bottom sheets of the bed.

12. Raise the top side rail, and roll the patient onto his or her back.

This ensures patient safety and provides a position of comfort for the patient.

13. Place the top sheet over the patient with the hems facing up, remove the bath blanket by sliding it out from under the top sheet, and place the blanket or bedspread with the hems facing down.

Keep the rough edges of bed linens away from the patient's skin to prevent skin irritation.

14. Follow procedure steps 8 through 12 in the Unoccupied Bed section.

Linens are secured on the bed, providing a clean and neat appearance.

Follow postprocedure steps I through VI.

Postprocedure

- I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

- II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

- III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

- IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Summary of Learning Outcomes

LO 27.1 *Describe the importance of hygiene related to skin, hair, nails, and mucous membranes:* Caring for patients' basic needs of cleanliness and hygiene is at the core of nursing care. Diligent hygiene care provides patient comfort and prevents infections and odors.

LO 27.2 *Identify how alterations in skin, hair, nails, and mucous membranes affect hygiene care:* Alterations in skin, hair, nails and mucous membranes affect the hygiene care plan.

LO 27.3 *Determine patients' hygiene status and need for assistance with care:* Self-care deficits lead to open skin lesions, infection, body odor, and halitosis, which are evident during assessment. Assessment determines the level of assistance needed for the patient's hygiene care while in a care facility or after discharge.

LO 27.4 *Select nursing diagnoses for patients who need assistance with hygiene or are experiencing alterations in self-care abilities:* Some nursing diagnoses related to hygiene are *Self-Care Deficit, Able to Perform Self-Care, and Impaired Health Maintenance*.

LO 27.5 *Establish measurable, patient-centered goals for patients with hygiene concerns and self-care alterations:* The planning phase of the nursing process involves prioritizing hygiene-related nursing diagnoses, evaluating patient self-care abilities and resources, and setting realistic goals and outcomes.

LO 27.6 *Implement and evaluate nursing care plans that include interventions to address the hygiene needs of patients:* Specific nursing interventions are designed

to provide thorough hygiene care for patients who cannot care for themselves and to encourage self-care by patients who are able to attend to some of their own hygiene needs. Evaluation involves measuring progress toward goals and adjusting the care plan accordingly.

Review Questions

1. An ambulatory diabetic patient states that she is unable to reach her feet to clip her toenails. The patient's toenails are long and thick. What is the next step the nurse should take?
 - a. Soak the patient's feet, and trim her toenails using clippers.
 - b. Delegate foot care of this patient to the unlicensed assistive personnel (UAP).
 - c. Assess the patient's self-care abilities.
 - d. Ask the primary care provider (PCP) for a referral to a podiatrist.

2. An alert and oriented elderly male patient has been admitted to the hospital with a diagnosis of chronic obstructive pulmonary disease (COPD). He is unshaven, has unkempt hair, and has a foul body odor. Asking which hygiene-related assessment question is a priority for the nurse?
 - a. "Do you have friends or family nearby?"
 - b. "Can you raise your arms up to brush your teeth?"
 - c. "Do you become short of breath during your shower?"
 - d. "Are you able to get in and out of your bed at home?"

3. Which action by a female patient lets the nurse know the patient has understood perineal care teaching?
 - a. The patient washes her perineum with a circular motion beginning at the urinary meatus.

- b. The patient washes her perineum from front to back using a clean washcloth.
 - c. The patient washes her perineum from back to front with long, firm strokes.
 - d. The patient washes her perineum lightly to prevent tissue damage.
4. What should the nurse do before leaving a patient's room after giving a complete bed bath?
- a. Place the call light within reach so the patient can call for help if needed, and leave the bed as it was during the bath.
 - b. Lower the bed to its lowest position, raise all four side rails so that the patient does not fall out of bed, and place the call light within reach.
 - c. Lower the bed to its lowest position, raise the top two side rails to assist the patient in turning and positioning, and place the call light within reach.
 - d. Leave the bed in a position that is comfortable for the caregiver because more care will be needed, raise the top two side rails, and place the call light within reach.
5. Which actions by the nurse concerning oral care for an unconscious patient are considered safe? (*Select all that apply.*)
- a. Performing oral care with the patient in a supine position
 - b. Performing oral care with the patient turned to the side
 - c. Installing suction equipment at the bedside
 - d. Providing oral care every 2 hours

- e. Using a hard-bristle toothbrush
6. Which safety precaution is a priority for the nurse when bathing a patient with peripheral neuropathy?
 - a. Keeping the top two side rails up during the bath
 - b. Checking the bath water temperature before the bath
 - c. Encouraging independence with perineal care during the bath
 - d. Facilitating range-of-motion exercises and dangling before the bath
 7. Which nursing diagnosis is a priority for a patient who needs assistance with activities of daily living?
 - a. *Self-Care Deficit*
 - b. *Lack of Knowledge*
 - c. *Activity Intolerance*
 - d. *Able to Perform Self-Care*
 8. Which statements are true regarding back massage? (*Select all that apply.*)
 - a. Only a licensed massage therapist can perform back massage.
 - b. Back massage may stimulate the deep muscles.
 - c. Massage provides relaxation and comfort.
 - d. Tapotement stimulates the skin.
 - e. A massage may promote sleep.
 9. A patient diagnosed with head lice has an order for pediculicidal shampoo. Which statement is true about this shampoo?

- a. It can be used only on patients with the ability to stand in the shower.
 - b. It can cause central nervous system side effects, including dizziness.
 - c. It is used by pregnant women and young children.
 - d. It is safe for patients with seizures or epilepsy.
10. Which statement indicates an understanding by the unlicensed assistive personnel of eye care during a patient's bath using washcloths and a bath basin?
- a. "The eyes are washed with soap and water from the inner canthus to the outer canthus."
 - b. "The eyes should always be washed using sterile normal saline and a gauze sponge."
 - c. "The eyes are washed from the outer canthus to the inner canthus using water only."
 - d. "The eyes are washed with water using a clean part of the washcloth for each eye."

CHAPTER 28

Activity, Immobility, and Safe Movement

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 28.1 Describe the function of the musculoskeletal, neurologic, and cardiopulmonary systems in normal activity and movement.
- LO 28.2 Identify changes in the musculoskeletal, neurologic, and cardiopulmonary systems that cause alterations in activity and movement throughout the life span.
- LO 28.3 Assess the effects of decreased activity and immobility on multiple body systems.
- LO 28.4 Discuss nursing diagnoses for patients experiencing immobility and impaired levels of activity.
- LO 28.5 Generate nursing care goals and outcome criteria for patients with complications from inactivity or immobility.
- LO 28.6 List interventions to enhance patient activity, promote safety, and reverse negative effects of immobility that can be evaluated after implementation.

Case Study

Tara Ryan (T. R.) is a 75-year-old female who was admitted to the hospital 72 hours earlier because of a right hip fracture sustained while walking her dog. She is currently 36 hours status post (S/P) total right hip replacement. She has a medical history of hypertension, no known drug allergies (NKDA), and a full code status.

T. R.'s vital signs are T 36.6° C (97.9° F), P 84 and regular, R 20 and unlabored, BP 164/90, with a pulse oximetry reading of 99% on room air. The right hip incision is well approximated, with slight redness at the edges, no swelling, and minimal serosanguineous drainage on the dressing. She rates her pain as 8 of 10, located primarily at the surgical site when she moves in bed or tries to get up to go to the chair or bathroom. She states, "The pain is sharp and shooting from my hip to midcalf when I move too fast." She grimaces when changing position and is reluctant to move. T. R. complains of weakness and fatigue while bathing or ambulating. Her Braden score is 20, and her Morse Falls Risk score is 80. Her hemoglobin and hematocrit are 10.5 g/dL and 36.9%, respectively.

Treatment orders are as follows:

- Vital signs every 4 hours, including neurovascular checks
- Adult regular diet
- Intravenous (IV) access saline lock
- Bathroom privileges (BRPs) and ambulation with assistance
- Dry, sterile dressing to incision site, change every 8 hours
- Intake and output (I&O)
- Encourage coughing and deep breathing
- Incentive spirometry every hour while awake
- Knee-high antiembolism stockings
- Sequential compression devices (SCDs) while in bed
- Complete blood count (CBC) every morning

Medication orders are as follows:

- Morphine sulfate: 4 mg intravenous piggyback (IVPB) every 4 hours as needed (PRN) for severe pain
- Enoxaparin: 60 mg subcutaneously every 12 hours
- Metoprolol: 50 mg PO (by mouth) bid

Refer back to this case study to answer the critical-thinking exercises throughout the chapter.

The ability to move has a tremendous impact on the physical health and psychological well-being of individuals. Activity and immobility influence many body systems. Although the methods of safely moving patients have changed significantly in the past couple of decades, the impact of lack of activity and immobility has remained constant. Patients must be encouraged and supported by nurses to achieve or maintain their highest level of independent function. Knowing the effects of activity, immobility, and safe movement is essential to nursing practice.

LO 28.1 Normal Structure and Function of Movement

Movement depends on many body systems. The musculoskeletal, neurologic, and cardiopulmonary systems work together to ensure a person's ability to move and maintain posture, alignment, and balance.

Musculoskeletal System

The musculoskeletal system provides the framework for movement. Five types of bones in conjunction with muscles, tendons, ligaments, cartilage, and joints provide the essential components of this system. Bones are classified by their shape: long (femur), short (carpal), flat (skull), irregular (vertebrae), and sesamoid or round (patella) (Patton & Thibodeau, 2016). Bones such as the rib cage protect critical organs in the body. Bones assist in the maintenance of calcium and phosphorus balance and the production of blood cells.

Skeletal muscles consist of contractile tissue. They provide stability and facilitate posture and movement. Ligaments connect bones and cartilage to bones, and tendons connect muscles to bones. Joints can be classified according to their ability to move or by tissue type: fibrous (immobile), cartilaginous (slightly movable), and synovial (movable).

Nervous System

The nervous system controls voluntary movement, posture, balance, and gait (Fig. 28.1). The cerebral cortex regulates motor activity, with coordination primarily controlled by the cerebellum. Motor activity on the right side of the body is controlled by the motor fibers on the left side of the brain, and motor activity on the left side of the body is controlled by the motor fibers on the right side of the brain.

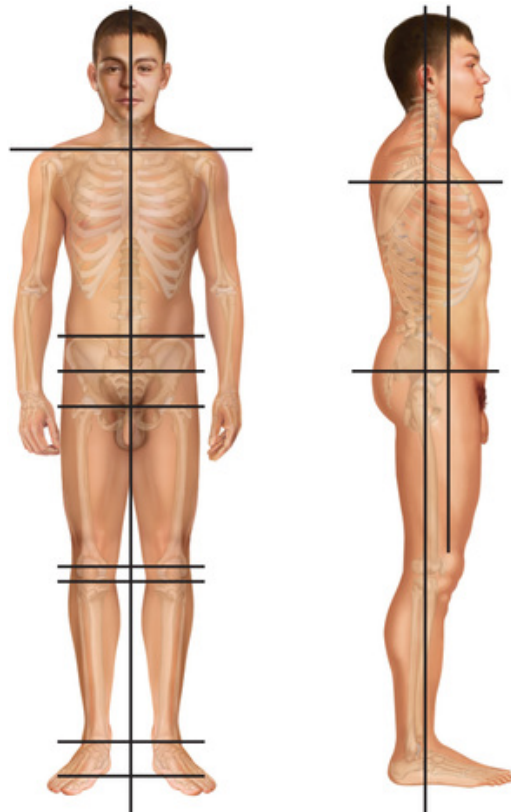

FIGURE 28.1 Correct upright body alignment.

Neurotransmitters communicate electrical impulses from nerves to muscles, facilitating movement. The nervous system controls posture and gait through **proprioception** (awareness of posture and movement) and balance. **Equilibrium** (balance) depends on the cerebellum and inner ear. Inner ear fluid remains stationary when the head moves quickly and allows a person to maintain balance.

Cardiopulmonary System

The cardiopulmonary system provides oxygen and circulates nutrients to body tissues. Blood circulates throughout the body, supplying bones, muscles, and organ tissues with oxygen, chemicals, and fluids that are essential for normal cell function. Adequate circulation and oxygenation are needed for movement and exercise.

LO 28.2 Altered Structure and Function of Movement

The musculoskeletal, nervous, and cardiopulmonary systems coordinate to facilitate normal body movement. Alterations in any of these systems may lead to impaired mobility or decreased capacity for exercise. Impaired mobility has serious implications for patient well-being and treatment outcomes.

Musculoskeletal System

Impairment or injury of any component of the musculoskeletal system affects the body's ability to move. Inadequate dietary intake of calcium and vitamin D, which is necessary for calcium absorption, or impaired calcium metabolism may result in osteoporosis, which increases bone fragility and may lead to fractures. Decreased physical exercise and lack of weight-bearing exercise also contribute to bone fragility, deterioration, and loss of strength. **Flaccidity** or **hypotonicity** (lack of muscle tone) may result from lack of physical activity, injury, or neurologic impairment.

Many factors cause alterations that affect the musculoskeletal system (Box 28.1). Rheumatoid arthritis and osteoarthritis cause inflammation of joints, resulting in pain and limited joint mobility. Genetic disorders (such as muscular dystrophy) result in muscle weakness and gradual muscle wasting, causing difficulty with maintaining posture and impairing mobility.

Box 28.1

Diversity Considerations

Life Span

Children

- Children with developmental disorders (such as cerebral palsy) or genetic disorders (such as spina bifida) may have limited mobility. Assessment may reveal **spasticity** or **hypertonicity** (increased muscle tone), which results in reduced range of motion (ROM) and abnormal movement patterns. Flaccidity may also affect movement.

Older Adults

- Osteoporosis (loss of bone mass) and osteoarthritis (deterioration of joint cartilage) are two diseases prevalent in the older adult population

that cause reduced mobility. Bones deteriorate in osteoporosis, and joint tenderness results from cartilage breakdown in osteoarthritis.

Gender, Culture, and Morphology

- Caucasian and Asian women are at a greater risk for osteoporosis than African Americans (Huether & McCance, 2016).
- In midlife, loss of bone mineral density usually increases in men and women ([National Osteoporosis Foundation, 2018](#)).

Nervous System

Damage to the cerebrum or cerebellum and spinal cord injury impair a person's ability to ambulate and control movement. **Ischemia** (reduced blood flow) or brain injury to the right side of the brain results in left-sided **hemiparesis** (weakness on one side of the body) or **hemiplegia** (paralysis of one side of the body). Left-sided brain injury results in right-sided hemiparesis or hemiplegia. These types of limitations can be caused by strokes (i.e., cerebrovascular accidents [CVAs]) and traumatic brain injuries. The level and severity of a spinal cord injury determines the limitations associated with movement. **Paraplegia** (lower body paralysis) and loss of sensation are most commonly associated with lower spinal cord trauma. Cervical spinal cord injuries may result in **quadriplegia** (inability to move all four extremities) and cause difficulty with breathing.

Cardiopulmonary System

Compromised cardiac function, decreased tissue perfusion, and diminished respiratory capacity directly affect a person's ability to perform activities of daily living (ADLs) and exercise. Heart failure (HF), peripheral vascular disease, and chronic obstructive pulmonary disease (COPD) decrease the body's ability to deliver oxygen and nutrients to body organs and tissues. Without these essential components, normal cell function is impaired, resulting in diminished capacity for exercise.

LO 28.3 ♦ Assessment

Assessment of a person's level of activity and the possible effects of immobility begins with observation and continues by asking a variety of questions (Box 28.2). Answers to these questions provide data about body systems that are affected by a person's activity and agility.

Box 28.2

Health Assessment Questions

Immobility Focus

- Are you experiencing any stiffness, joint discomfort, or pain with movement?
- How far do you walk each day? Do you ever use any assistive devices, such as a walker or cane?
- Have you noticed any dizziness or difficulty with balance?
- Do you require help with your activities of daily living (ADLs)?
- Do you become short of breath or easily fatigued when completing your ADLs?
- How is your appetite? What is your typical dietary intake in a day?
- What is the frequency of your bowel movements?
- Describe your normal sleep pattern.

Effects of Immobility

Immobility may cause weakness, instability, anorexia, elimination alterations, decreased muscle tone, circulatory stasis, and skin breakdown. Knowing the effects of immobility on various body systems allows the nurse to quickly assess a patient's risk and recognize signs of impending complications.

Musculoskeletal System

Immobility predisposes a person to weakness, decreased muscle tone, decreased bone and muscle mass, muscle **atrophy** (wasting), and **contracture** (permanent fixation of a joint) (Fig. 28.2).

FIGURE 28.2 Joint contracture. (From Sorrentino, S. A., & Remmert, L. [2019]. *Mosby's essentials for nursing assistants* [6th ed.]. St. Louis: Elsevier.)

Joint contractures can occur in bedridden patients. **Footdrop** (Fig. 28.3), one of the more common contractures, results in permanent plantar flexion. Lack of physical activity reduces muscle mass with noticeable muscle deconditioning after just a few days of inactivity. Muscle strength diminishes at a rate of 3% daily from baseline when a patient is on bed rest (Huether & McCance, 2017).

FIGURE 28.3 Footdrop. (From Rosenberg, R. N. [2009]. *Atlas of clinical neurology* [3rd ed.]. Philadelphia: Current Medicine Group, Springer Science and Business Media.)

Sustained lack of activity may lead to resorption of bone, causing bones to become less dense and calcium to be released into the bloodstream. Excess calcium is excreted through the kidneys and intestinal tract. Reduced bone density can lead to **disuse osteoporosis** (loss of bone mass due to lack of activity) and **pathologic bone fractures** (spontaneous breaks without trauma).

Joint stiffness and pain with movement, which result from immobility, discourage activity and exercise. The pain scale should be used with particular attention to the behavioral effects of patients' pain and the observed and reported activity tolerance. Lack of muscle tone and weakness increase the incidence of falls, contribute to poor posture, and result in unsteady gait. These musculoskeletal impairments require careful assessment by nurses.

Initial assessment of mobility and patient activity includes observation (i.e., inspection) of the patient's gait and coordination. Observe the patient's position and body alignment standing or lying in bed. Lack of proper body alignment may indicate musculoskeletal abnormalities and lead to increased pain or an unsteady gait. The patient's **range of motion** (ROM; degrees of movement) is assessed either actively or passively (Fig. 28.4).

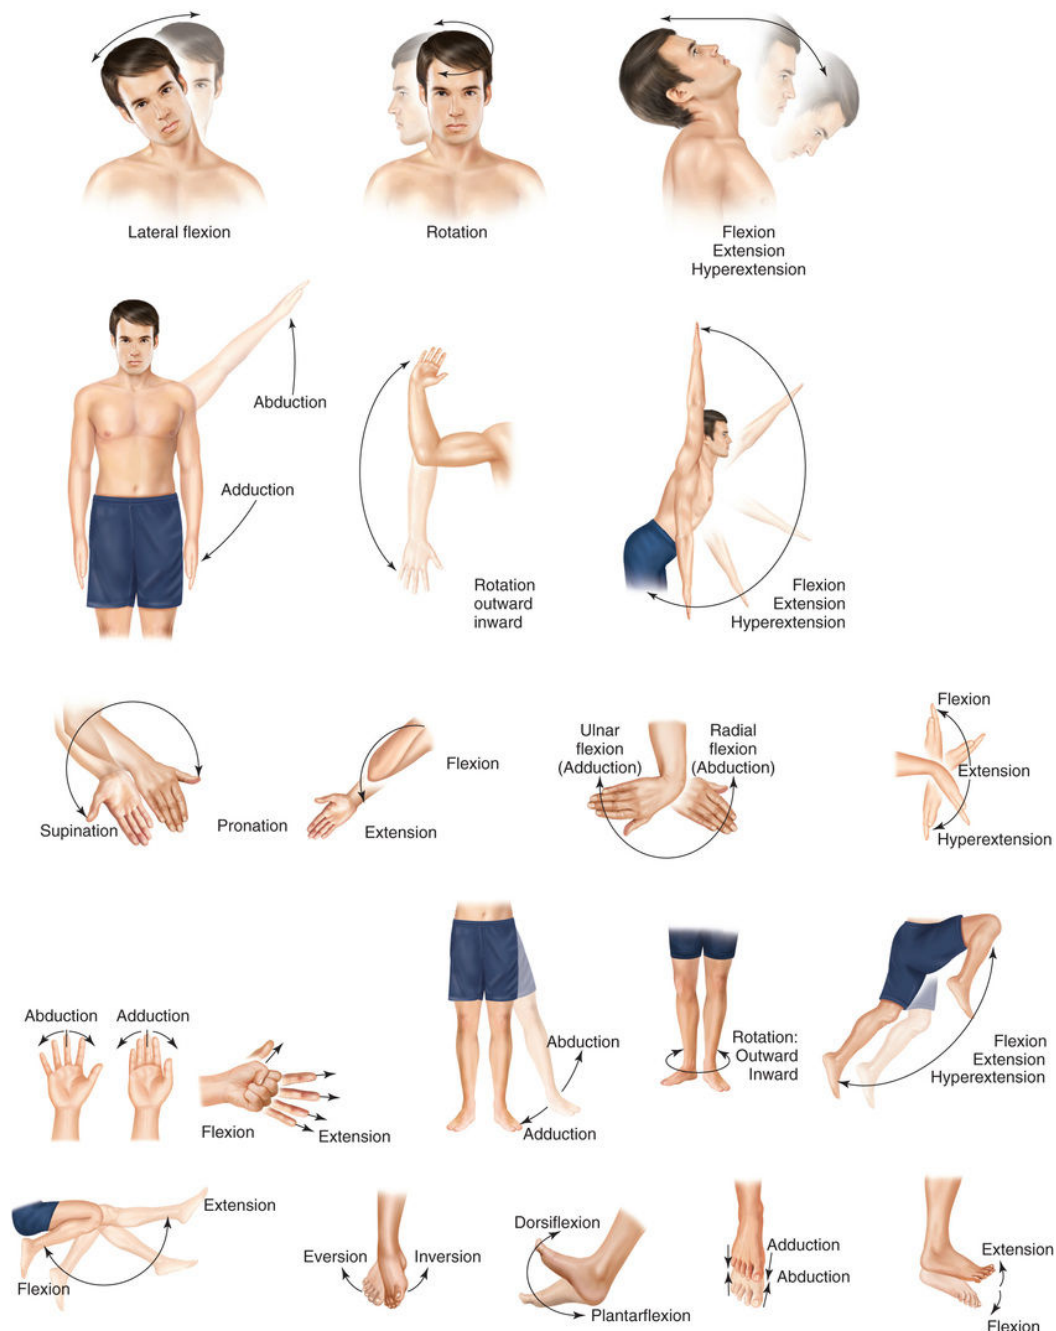

FIGURE 28.4 Joint movements and range of motion (ROM).

A fall risk assessment should be completed on all patients at least daily (Box 28.3). Many tools exist for the assessment of fall risk. The Johns Hopkins Hospital Fall Assessment Tool, the Morse Fall Scale, and the

Hendrich II Fall Risk Model are examples of resources available to nurses (see [Figs. 25.1](#), [25.2](#), [25.3](#), and [25.4](#)). Nurses should familiarize themselves with facility- or institution-specific guidelines.

Box 28.3

Nursing Care Guideline

Fall Precautions

Background

- Fall risk assessment:
 - An initial fall risk assessment must be performed on every patient admitted to any facility.
 - Assessment must be repeated at least daily and more often, as needed, in acute care settings.
- Fall reduction programs:
 - Programs for reducing the number of falls should be outlined in every facility's policies and procedures.

Procedural Concerns

- On the basis of the fall risk assessment score and institutional policy and procedure, implement specialized fall precautions:
 - Frequently observing the patient
 - Placing the patient in a room near the nurses' station
 - Using a low bed
 - Using a mattress or wheelchair seat with pressure sensitive alarms
 - Using floor mats beside the bed
 - Using side rails (use of four side rails is considered a restraint)
- Implement generalized fall prevention interventions:
 - Always return the bed to its lowest position.
 - Keep the call light within reach of the patient.
 - Remind the patient about how to use the call light.
 - Immediately answer the call light if it is activated.
 - Keep the wheels of any wheeled device (e.g., bed, wheelchair) in the locked position.
 - Leave lights on or off at night, depending on the patient's cognitive status and personal preference.
 - Keep patient belongings (e.g., tissues, water, urinals, personal items) within the patient's reach.
 - Frequently orient and reorient the patient.

- If the patient is ambulatory, require the use of nonskid footwear.
- Clear potential obstructions from the walking areas.
- Ensure that the patient's clothing fits properly; improper fit can cause tripping.

Documentation Concerns

- Document the fall risk assessment and reassessment scores (e.g., Morse Fall Risk score).
- In the general assessment, include the patient's medical history, subjective and objective data, medication review, musculoskeletal status, and history of falls.
- List the use of ambulatory assistive devices.
- Include interventions implemented (specific and general), nursing diagnosis, outcomes, and plan of care.
- Thoroughly document a fall or reported fall:
 - Document the primary concern—nursing care and intervention.
 - Document the fall in accordance with institutional guidelines.
 - Include patient and family education.

Evidence-Based Practice

- Using palpation, nurses identify muscle strength, muscle tone, and joint **range of motion** (ROM). Muscle strength is measured by asking the patient to squeeze the nurse's hands and having the patient plantar-flex the feet against resistance by the nurse's hands. Nurses must evaluate muscle symmetry by comparing one side of the patient's body with the other. Decreased muscle tone may indicate muscle wasting or atrophy.
- To assess joint ROM, the nurse asks the patient to actively demonstrate full movement of each joint (**active range of motion**), or the nurse passively moves each joint to the point of resistance while evaluating patient comfort level (**passive range of motion**) (see Fig. 28.4).

Safe Practice Alert

Stop range-of-motion exercises if the patient begins to complain of pain or if resistance to movement is experienced. Never hyperextend or flex a patient's joints beyond the position of comfort.

Nervous System

The patient's ability to actively perform ROM may be significantly affected by neurologic alterations. After a prolonged period of immobility, proprioception and equilibrium can be altered. The nurse should assist the patient who is getting out of bed for the first time. **Dangling**, in which the patient sits on the side of the bed before standing, is important to prevent injury to previously nonambulatory patients.

Safe Practice Alert

Assess patients for dizziness and their ability to stand unassisted before allowing ambulation.

Observe the patient's **gait** (manner of walking), posture, and balance after a period of bed rest. Problems with equilibrium and posture are magnified in patients with cerebellar problems.

Cardiopulmonary System

Bed rest has profound effects on the cardiopulmonary system. The cardiac workload is increased when the body is in the supine position due to increased venous return to the heart. Lung expansion is decreased, because the body's weight against the bed puts pressure on the rib cage. The diaphragm has less room to expand than in an upright position due to pressure from abdominal organs. Decreased lung expansion and dependent positioning of areas of the lungs can lead to pooling of secretions in the lungs, pneumonia, or atelectasis.

Circulatory stasis occurs as the heart works harder to pump the circulating blood. The pooled blood combined with weakened calf muscles can lead to deep vein thrombosis (DVT), also known as *venous thromboembolism (VTE)*, especially in the lower extremities. When a patient has been immobile, changes in position can result in postural or orthostatic hypotension due to pooling of blood in the lower extremities and lack of vasoconstriction. The heart suddenly has less blood to pump, leading to a drop in blood pressure.

Apical and peripheral pulses and baseline vital signs should be routinely assessed by the nurse for patients who are immobile. It is especially important to monitor blood pressure and pulse when a patient changes position from lying or sitting to standing for the first time. A drop in systolic blood pressure of 20 mm Hg, an increase in heart rate of 20 beats/min, or a drop of diastolic blood pressure of 10 mm Hg when a patient stands is classified as orthostatic hypotension.

Completing a thorough peripheral vascular assessment is essential to identify potential DVTs and weak pedal pulses due to decreased circulation in the lower extremities (**Box 28.4**). If an area of warmth, redness, swelling, or pain is observed in an extremity, an ultrasound examination may be

needed to rule out DVT. Edema may develop from decreased peripheral circulation. Determine whether the edema is nonpitting or pitting, and assess pitting depth by following the guidelines outlined in [Chapter 20](#).

Box 28.4

Evidence-Based Practice and Informatics

Venous Thromboembolism: Pulmonary Embolism and Deep Vein Thromboses

- Venous thromboembolisms (VTE) include pulmonary embolism (PE) and deep vein thrombosis (DVT).
- One of the most life-threatening side effects of immobility is a PE. A PE may develop as a result of untreated DVT.
- Traditionally, Homans sign (calf pain with flexion of the knee and dorsiflexion of the foot) was used in the assessment and diagnosis of DVT.
- Years of research found that Homans sign was an inaccurate method for DVT assessment and potentially dangerous because of possible clot dislodgment.
- Nurses should no longer use Homans sign to assess for DVT.

More information on the diagnosis and treatment of VTE, DVT, and PE is available at: <https://www.nhlbi.nih.gov/health-topics/venous-thromboembolism#Risk-Factors>

Activity intolerance may also develop as a result of bed rest. Observing patients while they complete their ADLs provides insight into the level of activity intolerance. Signs of shortness of breath, dyspnea on exertion, or patient reports of fatigue with minimal activity indicate the significant impact of bed rest.

Nutrition

Diminished activity reduces the basal metabolic rate (BMR). When the BMR decreases, the body begins breaking down muscle protein (i.e., catabolic activity) for energy. Catabolism of protein leads to a negative nitrogen balance in the body if dietary protein is insufficient. Continued immobility may lead to anorexia (decreased appetite) and nausea due to the body's lower nutritional demands. Assess patients for nutritional intake, and monitor serum albumin levels.

Elimination

Immobility has a significant impact on urinary elimination. Urinary stasis may develop due to the dependent position of the bladder when patients are supine. Stagnant urine trapped in the bladder provides a breeding ground for urinary tract infections (UTIs). A combination of urinary stasis and excess calcium excretion due to bone resorption associated with disuse osteoporosis increases the risk of renal calculi (i.e., kidney stones) formation. Carefully assess intake and output (I&O), the concentration and odor of urine, and the frequency of urination.

Inactivity, decreased appetite, and decreased fluid intake cause hypomotility of the gastrointestinal tract. This is manifested by decreased bowel sounds on auscultation and by constipation. Complete a thorough abdominal assessment by auscultating bowel sounds in all four quadrants and palpating the abdomen for distention and discomfort. Patients' dietary intake should be monitored for adequate fiber and fluid volume while on bed rest. Observe and record the frequency of bowel movements to avoid a potential fecal impaction (buildup of hardened feces in the lower intestine).

Skin

The impact of immobility on skin integrity is potentially catastrophic. Pressure on bony prominences can cause tissue ischemia. Prolonged tissue ischemia may lead to **necrosis** (death of cells, tissues, or organs) and destruction of all layers of the skin, muscle, and fat. **Pressure injuries** (pressure sores, pressure ulcers, bedsores, or decubitus ulcers) may develop on areas damaged due to tissue ischemia caused by compression and inactivity. Areas most at risk for pressure injuries include the buttocks, coccyx, heels, hips, shoulders, elbows, and ears.

Assessment of the skin includes overall observation of color, texture, warmth, and intactness. Special attention should be given to areas that appear darkened in tone or reddened. Assess for tissue blanching and normal reactive hyperemia (increased blood flow after restoration of the blood supply). A standardized skin assessment tool (such as the Braden Scale) should be used to identify patients at risk for compromised skin integrity (see [Fig. 29.14](#)).

Psychosocial Impact

Isolation may result from inactivity and bed rest, causing a variety of psychosocial challenges for patients. With limited ability to ambulate or interact with people outside their immediate space, immobile patients may become lonely, anxious, angry, depressed, or confused. Sensory deprivation (lack of external stimuli) may result from decreased interaction with others. A patient's self-concept may be altered by the inability to interact with the environment. Traditional coping strategies may not be effective, causing irregular patterns of behavior.

Sleep and rest patterns may be disturbed because of inactivity, environmental noise, constant disruptions for direct care and treatments, and frequent napping throughout the day. Anxiety related to medical diagnoses or concerns may also contribute to dyssomnia (difficulty sleeping).

Observe patients for mood, behavior, and sleep patterns. Interviewing patients regarding their typical hours and nature of sleep is important to establish a baseline. Watch for subtle changes in mood or behavior that may indicate concern related to immobility or isolation.

1. List focused assessments with rationales that should be completed on T. R. during her second postoperative day.

LO 28.4 ♦ Nursing Diagnosis

Common International Classification for Nursing Practice (ICNP) nursing diagnoses directly associated with immobility are:

Impaired Mobility

- Supporting Data: Postoperative hip replacement status, pain 8 of 10 and grimacing with movement, reluctant to move

Risk for Fall

- Supporting Data: Altered mobility, cerebrovascular accident

Activity Intolerance

- Supporting Data: Deconditioning effects of bed rest, shortness of breath, oxygen saturation below 90%, pulse rate above 100 with activity

LO 28.5 ♦ Planning

Carefully consider the importance of each identified nursing diagnosis, and address the most critical ones first in the nursing care plan (Table 28.1). Collaboration with patients, families, and members of the interprofessional health care team is imperative when addressing problems associated with mobility (Box 28.5). Short-term and long-term goals must be directed at alleviating the specific problems identified in each nursing diagnosis.

TABLE 28.1
Care Planning

ICNP NURSING DIAGNOSIS WITH SUPPORTING DATA	NURSING OUTCOME CLASSIFICATION (NOC)	NURSING INTERVENTION CLASSIFICATION (NIC)
<i>Impaired Mobility</i> Postoperative hip replacement status Pain 8 of 10 and grimacing with movement Reluctant to move	<i>Ambulation</i> Walks at slow pace	<i>Exercise Therapy: Ambulation</i> Assist patient to stand and ambulate specified distance with specified number of staff.

Box 28.5

Interprofessional Collaboration and Delegation

Multidisciplinary Strategy for Care of the Immobilized Patient

- Nurses use a interprofessional health care team approach when planning care for immobilized patients to ensure maximal recovery.
- Physical therapists, occupational therapists, and social workers provide ambulation support, assistive devices, activities, and psychosocial resources.
- Dietitians address nutritional concerns.
- Speech therapists evaluate patients' ability to chew and swallow.
- Unlicensed assistive personnel (UAP) provide hands-on care for immobilized patients under the direct supervision of registered nurses.

Turning and positioning of patients, range-of-motion exercises, transfers, and assistance with ambulation may be delegated to properly trained UAP.

Examples of goals or outcome statements follow:

- Patient will ambulate with the assist of one caregiver within 24 hours.
- Patient will experience no falls during hospitalization.
- Patient's pulse oximetry reading will remain above 92% with activity by the end of the shift.

FIGURE 28.5 Partially completed conceptual care map based on T. R., the case study patient in this chapter.

The conceptual care map for T. R. provided in Fig. 28.5 is partially completed to indicate how to use the map as a learning tool. Using it as an

example, go to the website at <http://evolve.elsevier.com/YoostCrawford/fundamentals/> to complete Nursing Diagnoses 2 and 3.

2. Write a short-term and long-term goal for this nursing diagnosis:

Impaired Mobility

- Supporting Data: Postoperative hip replacement status, pain 8 of 10 and grimacing with movement, reluctant to move

LO 28.6 ♦ Implementation and Evaluation

Interventions to address activity and mobility concerns are designed to respond to individual patient needs. Various interventions assist patients with multisystem issues. Critically evaluating interventions and patient outcomes is essential before determining whether the patient's plan of care should be modified, continued, or discontinued.

Musculoskeletal and Nervous System Interventions

Exercise is essential to prevent the negative impact of immobility on patients, and it should be encouraged. Early ambulation after injury, illness, or surgery promotes muscle strength, retains joint flexibility, minimizes joint pain and stiffness, and arrests bone reabsorption. Exercises are defined by muscle status (i.e., isotonic or isometric exercise) or by energy source (i.e., aerobic or anaerobic exercise).

- **Isotonic exercise** involves active movement with constant muscle contraction. Examples include walking, turning in bed, and self-feeding.
- **Isometric exercise** requires tension and relaxation of muscles without joint movement. An example is tension and relaxation of pelvic floor muscles (i.e., Kegel exercise).
- **Aerobic exercise** requires oxygen metabolism to produce energy. Patients may engage in rigorous walking or repeated stair climbing to achieve the positive effects of aerobic exercise.
- **Anaerobic exercise** builds power and body mass. Without oxygen to produce energy for activity, anaerobic exercise takes place. Heavy weight lifting is an example of anaerobic exercise.

If patients are restricted to bed rest, active or passive range-of-motion exercises must be employed to prevent joint contractures (see [Fig. 28.2](#)). It is important to educate patients on the steps they can take to ensure continued mobility ([Box 28.6](#)).

Box 28.6

Patient Education and Health Literacy

Activity

- Teach patients to actively move each joint to its fullest extent at least four times each day to ensure continued mobility.
- Ask patients to verbalize an understanding of the importance of continued joint movement and demonstrate ROM of each joint.

Pain is assessed by the nurse during each patient interaction. Nonsteroidal antiinflammatory drugs (NSAIDs) are used for mild to moderate pain relief and are particularly beneficial for patients with inflammatory disease of the joints. Narcotic analgesics are administered for moderate to severe pain. Medicating patients for pain before activity or positioning enhances the patient's ability to move. Complimentary and alternative therapy pain relieve measure are used to enhance pain relieve and reduce the need for narcotic analgesics. These therapies include massage, guided imagery, and relaxation techniques. See [Chapter 36](#) for a complete discussion on Pain Management.

Safe Practice Alert

Monitor the patient's vital signs and stability with position changes when narcotic analgesics are prescribed for pain relief. Potential adverse side effects of narcotics include respiratory depression, hypotension, confusion, sedation, constipation, and dizziness.

Positioning devices help maintain proper body alignment and positioning of joints. Pillows are used for positioning patients. Placing a pillow between the legs and arms of a side-lying patient helps prevent pressure on the bony prominences of the knees and elbows. This pillow position is also used when rolling a patient after hip surgery to prevent movement of the femur. A pillow positioned under the calves of a supine patient alleviates pressure on the heels but should not impede circulation in the calves. Pillows can also be used to support a body part in a functional position or to elevate an injured extremity.

Splints and braces are used on extremities to keep joints in functional positions ([Fig. 28.6](#)). An ankle-foot orthotic (AFO) is a brace or splint that holds the foot at a right angle to the leg. This device is used to prevent footdrop. A footboard at the end of the bed or high-top tennis shoes can have the same effect. Custom-made splints for the upper extremities can maintain proper alignment of the hand and wrist. Hand rolls may be used to keep the hand in a functional position and prevent contractures on a short-

term basis. Long-term use of hand rolls should not be employed to prevent the stimulation of flexion. Hand rolls can be specially made, or a washcloth can be rolled and placed in the patient's palm.

FIGURE 28.6 Splints and braces are used on extremities to keep joints in functional positions. A, Ankle-foot orthotic (AFO). B, Foot board. C, Hand roll. (A and B, From Sorrentino, S. A., & Remmert, L. [2017]. *Mosby's textbook for nursing assistants* [9th ed.]. St. Louis: Elsevier.)

Trochanter rolls are used to keep the hip from externally rotating when the patient is in the supine position. One can be made by rolling a large towel or bath blanket and placing it alongside the patient's hip joint (Fig. 28.7). This type of positioning aid is often used after hip surgery.

FIGURE 28.7 Trochanter roll positioned next to the patient.

Patients with spinal cord injuries or who have had spinal surgery may require **logrolling** (moving the whole body as a unit) during positioning (**Skill 28.1**). The assistance of at least one or two caregivers in addition to the nurse is required. The nurse must ensure that the patient's spine remains aligned during repositioning. A pillow is placed between the patient's legs during logrolling and may remain there if the patient is in the side-lying position.

Safe Practice Alert

Smooth movement that maintains straight and stabilized alignment of the patient's spine prevents possible injury.

Fall prevention is a high priority for patients with unsteady gait, poor posture, or balance concerns. Encourage patients who have been immobile to call for assistance before ambulation. The importance of allowing a previously nonambulatory patient to dangle on the side of the bed before ambulation to prevent injury cannot be overstated.

A variety of nursing interventions can provide support to ensure patient safety and prevent falls. Observe patients' rooms for physical obstacles, including electrical and call light cords, intravenous (IV) and oxygen tubing, drains and catheters, phone cords, and other potential tripping hazards. Keep linens off the floor. Clean up spills immediately. Provide nonskid slippers and barrier-free access to the bathroom.

Safe Practice Alert

Assisting patients to ambulate who have intravenous (IV) therapy, nasogastric tubes, or urinary catheters helps prevent falls.

Position needed items within reach of the patient, including the call light and over-the-bed table. Patients at risk for falls should be assigned to rooms close to the nurses' station. Sitters or family members at the bedside may be helpful in situations that require constant monitoring.

Ambulation aids, such as transfer (ambulation or gait) belts, crutches, canes, walkers, or mobile ambulation devices, should be used to promote safety for weak or unsteady patients. Each device has specific procedures associated with its use to ensure patient safety. Nurses play an integral role in making sure mobility devices are used properly in all settings.

Transfer Belts

Transfer belts should be used for patients with an unsteady gait or generalized weakness. Canvas transfer or gait belts are applied snugly around the patient's waist, leaving only enough room for the nurse to grasp the belt firmly during ambulation (Fig. 28.8). Some belts may have handles.

FIGURE 28.8 Placing a gait belt on a patient. (Copyright Mosby's Clinical Skills: Essentials Collection.)

If the patient has a weaker side, the nurse should stand on that side and hold the gait belt firmly at the back of the patient's waist while ambulating (Skill 28.2).

Canes

Patients who need additional support when walking due to balance problems or weakness may use a cane. Canes may be straight, wooden or metal, and have one point of support on the ground or four points of support (quad cane). Fig. 28.9 shows types of canes.

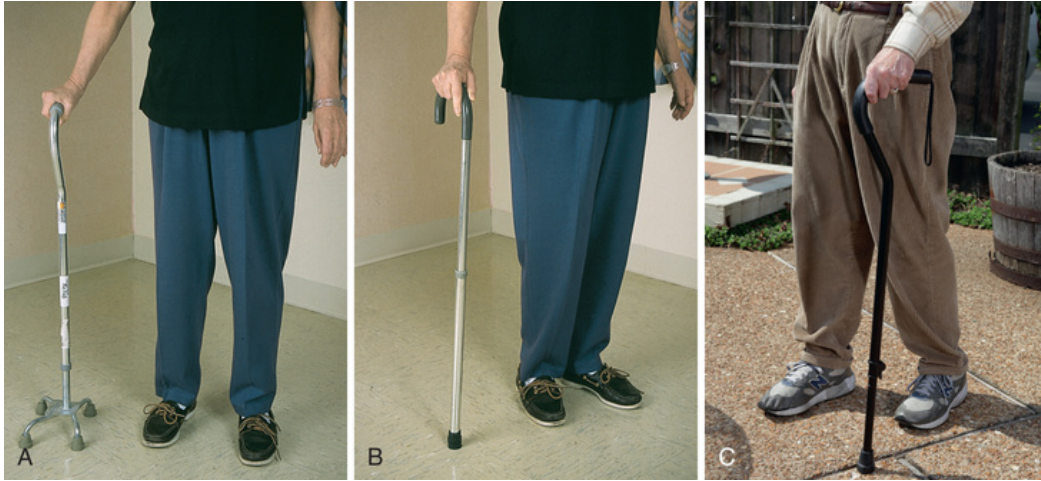

FIGURE 28.9 Types of canes. A, Quad cane. B, Curved-handle aluminum cane. C, Offset-handle cane. (A and B, From Sorrentino, S. A., & Remmert, L. [2017]. *Mosby's textbook for nursing assistants* [9th ed.]. St. Louis, MO: Elsevier; C, From Birchenall, J. M. [2013]. *Mosby's textbook for the home care aide* [3rd ed.]. St. Louis: Mosby.)

The top of the cane should be level with the hip joint, and the patient's arm should be comfortably bent when the patient is walking. The patient should hold the cane on his or her stronger side and move the cane forward first, followed by the weaker leg and then the stronger leg. This ensures that another point of support is always on the ground when the weaker leg is bearing weight and gives the patient a wide base of support (see [Skill 28.2](#)). A patient using a cane should be encouraged to stand up straight and look forward. Leaning to one side or looking down can jeopardize safety and cause poor posture.

Crutches

Crutches facilitate increased patient mobility. Different types of crutches may be used on a short-term or long-term basis for patients with lower extremity injury or paralysis ([Fig. 28.10](#)). Underarm crutches should be fitted to allow approximately 2 inches or three finger widths of space between the top of the crutch and the axilla when the crutch is placed slightly in front of and 6 inches to the side of the foot. The patient's elbow should be comfortably bent to avoid pressure on the nerve running into the axilla. Encourage the patient to immediately report tingling in the hands. Forearm or Lofstrand crutches are traditionally used for patients with long-term or permanent impairment. Forearm crutches are designed with a handgrip and a metal cuff that partially or completely surrounds the lower arm. Platform crutches are used with the arm bent at the elbow and the forearm resting on a platform where the weight is supported. There is a handgrip in front of the platform.

FIGURE 28.10 Types of crutches. A, Underarm. B, Forearm. (B, From Sorrentino, S. A., & Remmert, L. [2017]. *Mosby's textbook for nursing assistants* [9th ed.]. St. Louis: Elsevier.)

Patients need to possess adequate upper body strength and coordination when using all types of crutches. The crutch-walking pattern employed depends on the extent and nature of the patient's disability.

The two-point crutch-walking pattern is used by patients who can bear partial weight on either or both lower extremities. This method provides stability and support for ambulation. Patients move one crutch forward simultaneously with the opposite leg, providing a wide base of support.

Three-point crutch walking is employed by patients who have injury to one leg. To begin this gait pattern, both crutches are placed forward, and patients swing their legs to the center of the crutches, bearing weight on only the uninjured leg. A similar crutch walking pattern is referred to as a *swing-to* gait used by paraplegics. Crutches are placed forward, and the patient swings both legs to the center of the crutches.

The four-point crutch gait requires partial weight bearing on both lower extremities. This provides more stability than the two-point pattern, because only one of four points of support is lifted off the floor at any time. In this ambulation technique, the patient moves one crutch forward, followed by the opposing leg, and repeats the pattern by moving the opposite crutch and then the leg forward. [Skill 28.3](#) illustrates the different crutch-walking patterns.

[Fig. 28.11](#) shows a patient with crutches ascending stairs. The patient transfers weight from the crutches to the unaffected leg on the stairs. The crutches are then brought up onto the stair and aligned with the unaffected leg. In descending stairs ([Fig. 28.12](#)), body weight is transferred from the

unaffected leg to the crutches. The unaffected leg is then brought down onto the stair and aligned with the crutches.

FIGURE 28.11 Use of crutches to ascend stairs.

FIGURE 28.12 Use of crutches to descend stairs.

Walkers

Walkers are metal ambulation aids that come with and without wheels. They provide more support than a cane and can be used for patients who have weakness or balance problems or who are recovering from back or leg injuries. Walkers should be waist high and slightly wider than the patient.

A walker without wheels is used in a manner similar to crutches. While standing in the walker, the patient lifts the walker forward one step, plants it on the ground, and then steps into the walker (see [Skill 28.2](#)). This type of device can be used in the same manner as a three-point crutch walk: The patient lifts the walker forward one step and then swings both legs into it. Caution must be taken to prevent loss of balance. A home assessment should be conducted for the patient being discharged with an assistive device ([Box 28.7](#)).

Box 28.7

Home Care Considerations

Home Assessment Before Discharge

Patients being discharged with assistive devices (such as canes, walkers, and crutches) should have a home assessment to ensure safety during ambulation.

- Are the patient's living quarters on one floor?
- Are there throw rugs that pose a tripping hazard?
- Are nonskid mats in place in front of sinks, tubs, and showers?
- Is there a clear way to exit in case of emergency?

Front-wheel walkers are used for patients who need support when walking but do not have the strength to pick up a walker and move it forward. The patient must be able to bear weight on both legs to use a front-wheel walker. The patient pushes the walker ahead while ambulating. Three- and four-wheel walkers with seats, baskets, and brakes are available. They can be used for patients who have activity intolerance and need a place to sit and rest frequently during ambulation. [Fig. 28.13](#) shows a front wheel walker.

FIGURE 28.13 Ambulation with a front wheel walker. (From Sorrentino, S. A., & Remmert, L. [2017]. *Mosby's textbook for nursing assistants* [9th ed.]. St. Louis: Elsevier.)

Mechanical Lifts

Mechanical lifts and lift teams are preferred transfer methods to decrease the incidence of patient and staff injuries. Mobile mechanical lift devices and some overhead lifts can be used for ambulation when equipped with a special harness. The patient is placed in the harness and lifted to a point where the feet are just touching the ground. The patient walks holding onto the lift device. This is an extremely safe method for ambulating an unsteady patient, because the patient's weight is supported by the lift device. If the patient becomes unsteady, the mechanical lift prevents falls and injuries (Box 28.8).

Box 28.8

Nursing Care Guideline

Mechanical Lift Devices

Background

- The [National Institute for Occupational Safety and Health \(NIOSH; 2018\)](#) recommends the use of mechanical lift equipment and other safe patient handling procedures when moving patients to reduce the risk of overexertion injuries to health care workers.
- Mechanical lift devices:
 - Are hand operated or electrically operated
 - Are used to prevent injury to caregivers and patients when transferring patients

Procedural Concerns

- Facility- and equipment-specific training is required before use of mechanical lift devices.
- Devices should be checked for operational status before use.
- The proper and safe use of all mechanical lift devices requires at least two health care professionals or unlicensed assistive personnel (UAP), but it is recommended that at least three caregivers carry out the procedure.
- There are algorithms for determining the appropriate lift device and number of caregivers needed to move a patient:
 - The algorithms were created by the U.S. Department of Veterans Affairs and are recommended by the American Nurses Association (ANA) and NIOSH.
 - Nurses should refer to facility-specific policies and procedures to determine the proper lifting choices.
 - Each mechanical lift has a weight limit assigned to it by the manufacturer of the device. This can usually be found on the device or in the operator's manual. Know the patient's weight and the weight limit of the device to avoid exceeding the weight limit, which risks injury to the patient or staff.
- The following are specific types of mechanical lift devices:
 - *Hydraulic lifts* are also known as *Hoyer lifts* or *powered full-body lifts*. They have independently mounted sling devices for non-weight-bearing or immobile patients.

Hydraulic lift. (Copyright Mosby's Clinical Skills: Essentials Collection.)

- *Ceiling lifts* have a ceiling-mounted track sling and stay in the patient's room, which helps maintain infection control standards.

Ceiling lift. (Courtesy MedCare Products, Burnsville, MN.)

- *Stand-up assist lifts* use a hydraulic sling lift for partial-weight-bearing and cooperative patients, and they promote independence.

Stand-up assist lift. (From Sorrentino, S. A., & Remmert, L. [2014]. *Mosby's essentials for nursing assistants* [5th ed.]. St. Louis: Elsevier.)

- *Transfer chairs* are convertible chair-stretcher devices for non-weight-bearing or immobile patients, and they are useful for confused or uncooperative patients. Many types have lateral assist devices incorporated into the design.
- *Lateral assist lifts* are motorized or hand-cranked transfer devices built onto a stretcher for immobile patients who are unable to assist in transfers. They allow the space between the bed and the stretcher to be bridged without the caregiver reaching or pulling, avoiding potential injuries.
- Basic body mechanics ([Box 28.9](#)) should be used during a lift to prevent injury to the nurse.
- Ensure that the lift device works correctly before using it with a patient. Remove the device from service if any parts are missing or damaged.

Documentation Concerns

- Document any repositioning or transfer that occurred, the reason, and the new position.
- Include the weight-bearing status and the use of a caregiver to assist in the transfer, and identify which lift device was used.
- Itemize any difficulties that arose during the transfer.

- Note the patient response to the repositioning or transfer, including musculoskeletal strength assessment and the patient's assistance and cooperation.
- Specify the need to collaborate with or refer the patient to a physical or occupational therapist.
- Document the patient and family education that was provided.

Evidence-Based Practice

Evidence-based research has identified risks associated with patient movement. It has been shown that the use of safe patient handling interventions, such as the use of mechanical lifts, and the principles of ergonomics (designing the patient handling task to fit the ability of the health care worker) can reduce caregiver injury. These interventions also ensure the safety and comfort of the patient ([NIOSH, 2018](#)).

- Safe patient handling and mobility programs have decreased healthcare workers' injuries for the first time in 30 years but nurses still suffer musculoskeletal injuries. Body mechanics and proper lifting techniques are important but alone cannot prevent injuries caused by moving patients without using lift equipment ([Garcia, 2014](#)).
- Although manual lifting is sometimes necessary, through commitment of the facility and education of the staff, it can be almost eliminated, increasing safety for staff and patients.
- Eleven states have passed safe patient handling legislation. There is no federal law yet, but a bill was introduced in 2015 ([NIOSH, 2018](#)). It is imperative to check with your state board of nursing and facility for specific policies and procedures before attempting lift techniques.

Box 28.9

Principles of Body Mechanics

- Keep the spine in natural alignment while lifting or transferring.
- Elevate work surfaces to approximately elbow height, close to the body's center of gravity.
- Never lift more than 35 pounds independently; use additional caregivers and mechanical lifts when appropriate.
- Work with gravity whenever possible.
- Push rather than pull patients or objects.
- Bend from the knees rather than the waist when lifting.
- Avoid twisting while lifting by keeping feet apart, with one foot placed in the direction of transfer.

- Keep patients or objects close to the body to minimize reach.
- Diminish friction and shear by using friction-reducing devices during transfers and having patients lay their arms across the chest during repositioning.
- Use safe patient-handling and mobility algorithms for decision making in all patient transfers.

Safe Patient Movement

Nurses have a history of musculoskeletal injuries from moving and lifting patients. Maximizing patient assistance in movement and proper use of lift equipment when needed can drastically reduce injuries to nurses (Nelson, Matacki, & Menzel, 2009). Often lift equipment is available, but nurses and unlicensed assistive personnel (UAP) are reluctant to use it when appropriate. Training staff on the use of lift equipment and coordination of care may help remove some of the perceived obstacles, such as lack of knowledge about the equipment and how to assess patient needs (Kanaskie, Snyder, & Salisbury, 2016).

If patients on bed rest have some mobility, the nurse should teach them to shift their position every 15 minutes while awake. Top side rails should be left up to aid in positioning. Patients with upper body strength can use a **trapeze** (a triangular device suspended above the bed) to facilitate repositioning and transfers.

As with many of the complications of bed rest, early ambulation can greatly diminish problems with skin integrity. Patients who lack upper body strength or the ability to move independently may require the assistance of specialized positioning equipment (Box 28.10).

Box 28.10

Nursing Care Guideline

Specialized Transfer and Positioning Equipment

Background

Special Mattress

Special mattresses or beds are designed to minimize transfer and repositioning. Several types are available:

- A surface redesign mattress has rotating surfaces that eliminate the need to move the patient (bed surface moves instead) and has an air cushion that eliminates friction during movement.
- A Gatch bed has a frame that is made in three sections, which permits raising the head, foot, and middle of the bed; for example, raising the

middle of the bed helps prevent the patient from sliding down in bed.

- A foam mattress reduces pressure to avoid or alleviate pressure injuries.
- A foam or gel combination mattress reduces pressure.
- A low-air-loss bed uses multiple air-filled cushions and various amounts of air, can support a wide range of patient weights, and reduces pressure to avoid or alleviate pressure injuries.
- An air-fluidized bed uses airflow to move silicone particles in the bed, creating a watery, fluid-like movement and resulting in lower pressure to avoid or alleviate pressure injuries.

Trapeze Bar

- A trapeze bar fastens to an overhead bar that is attached to the bed frame.
- It is used for patients with equal bilateral upper extremity strength.
- Patients can use a trapeze bar to assist with repositioning.
- Use of the bar decreases the risk of shearing.
- Musculoskeletal strength increases because the bar accommodates upper extremity exercises.
- Having a trapeze bar available to the patient promotes independence.

Transfer or Slide Board

- A transfer or slide board is made of plastic-like material that reduces friction.
- Linens easily slide over the board, facilitating bed linen changes.
- Patients can be repositioned or transferred with a minimum of force required.

(Copyright Mosby's Clinical Skills: Essentials Collection.)

Friction-Reducing Sheet

Friction-reducing sheets are somewhat similar to transfer or slide boards:

- They are made of a specialized material that reduces shear and friction.
- When placed under a patient, the sheet minimizes the force required for repositioning or transfer.

Trochanter Roll

- A trochanter roll prevents outward rolling of the hip when a patient is lying on his or her back.

Procedural Concerns

- Devices are available from many different manufacturers.
- Follow the guidelines for the specific brands being used and attend trainings for use of new and updated equipment.
- Follow institution policy and procedures for the use and cleaning of special mattresses, transfer or slide boards, and friction-reducing sheets.
- Trapeze bar:
 - The patient grabs the bar with one or two hands and pulls the upper body off the bed.
 - The bar assists in repositioning, transferring, or performing basic hygienic care.
- Trochanter roll:
 - A blanket or sandbag may be substituted for a trochanter roll.
 - When the device is placed correctly next to the patient's thigh, the patella faces directly up.

Documentation Concerns

- Explain if repositioning or transfer occurred, the reason for it, and the new position.
- Note the patient's weight-bearing status, the need for caregiver assistance in the transfer, and use of a lift or specialized device.
- Document the patient's response to repositioning or transfer, including musculoskeletal strength and integumentary assessment and the patient's assistance and cooperation.
- Indicate the need to collaborate with or refer the patient to a physical or occupational therapist.
- Note the patient and family education that was provided.
- Specify difficulties that occurred during the transfer.

Evidence-Based Practice

- Safe patient handling programs have reduced staff injuries, and decreased falls, skin breakdown and other adverse effects of immobility in patients ([U.S. Department of Veterans Affairs, 2016](#)).
- Research indicates that proper body mechanics are not adequate to prevent injury during patient transfers.
- Staff should avoid handling over 35 pounds. All dependant adult patients should be lifted and transferred using safe patient handling and mobility principles to prevent injury to caregiver's backs during patient transfers ([U.S. Department of Veterans Affairs, 2016](#)).
- Studies reveal that implementation of safe patient movement programs and use of specialized positioning equipment does not negatively affect functional outcomes in patients ([Arnold, Radawiec, Campo, et al., 2011](#)).

The first step in safely moving patients is to assess their ability to assist. A useful assessment tool for safe patient-handling and mobility (SPHM) is shown in [Fig. 28.14](#).

I. Patient's Level of Assistance:
 Independent—Patient performs task safely, with or without staff assistance, with or without assistive devices.
 Partial Assist—Patient requires no more help than standby, cueing, or coaxing, or caregiver is required to lift no more than 35 pounds (lbs) of a patient's weight.
 Dependent—Patient requires nurse to lift more than 35 lbs of the patient's weight, or patient is unpredictable in the amount of assistance offered. In this case, assistive devices should be used.

An assessment should be made prior to each task if the patient has varying level of ability to assist due to medical reasons, fatigue, medications, etc. When in doubt, assume the patient cannot assist with the transfer/repositioning.

II. Weight-Bearing Capability: Full Partial None

III. Bilateral Upper-Extremity Strength: Yes No

IV. Patient's level of cooperation and comprehension:
 Cooperative—may need prompting; able to follow simple commands.
 Unpredictable or varies (patient whose behavior changes frequently should be considered as unpredictable), not cooperative, or unable to follow simple commands.

V. Weight: _____ **Height:** _____
Body Mass Index (BMI) [needed if patient's weight is over 300 lbs]': _____
If BMI exceeds 50, institute Bariatric Algorithms

The presence of the following conditions are likely to affect the transfer/repositioning process and should be considered when identifying equipment and technique needed to move the patient.

VI. Check applicable conditions likely to affect transfer/repositioning techniques.

<input type="checkbox"/> Hip/Knee/Shoulder Replacements	<input type="checkbox"/> Respiratory/Cardiac Compromise	<input type="checkbox"/> Fractures
<input type="checkbox"/> History of Falls	<input type="checkbox"/> Wounds Affecting Transfer/Positioning	<input type="checkbox"/> Splints/Traction
<input type="checkbox"/> Paralysis/Paresis	<input type="checkbox"/> Amputation	<input type="checkbox"/> Severe Osteoporosis
<input type="checkbox"/> Unstable Spine	<input type="checkbox"/> Urinary/Fecal Stoma	<input type="checkbox"/> Severe Pain/Discomfort
<input type="checkbox"/> Severe Edema	<input type="checkbox"/> Contractures/Spasms	<input type="checkbox"/> Postural Hypotension
<input type="checkbox"/> Very Fragile Skin	<input type="checkbox"/> Tubes (IV, Chest, etc.)

FIGURE 28.14 Assessment criteria and care plan for safe patient handling and movement. (Courtesy The Tampa VA Research and Education Foundation, Inc.)

SPHM algorithms were developed by the Veterans Integrated Services Network 8, Patient Safety Center, in Tampa, FL, to assist nurses in promoting safe patient positioning and transfers (U.S. Department of Veterans Affairs, 2016). These algorithms are designed to keep nurses and patients safe. Algorithms essential to caring for the immobilized patient are shown in Figs. 28.15 through 28.17.

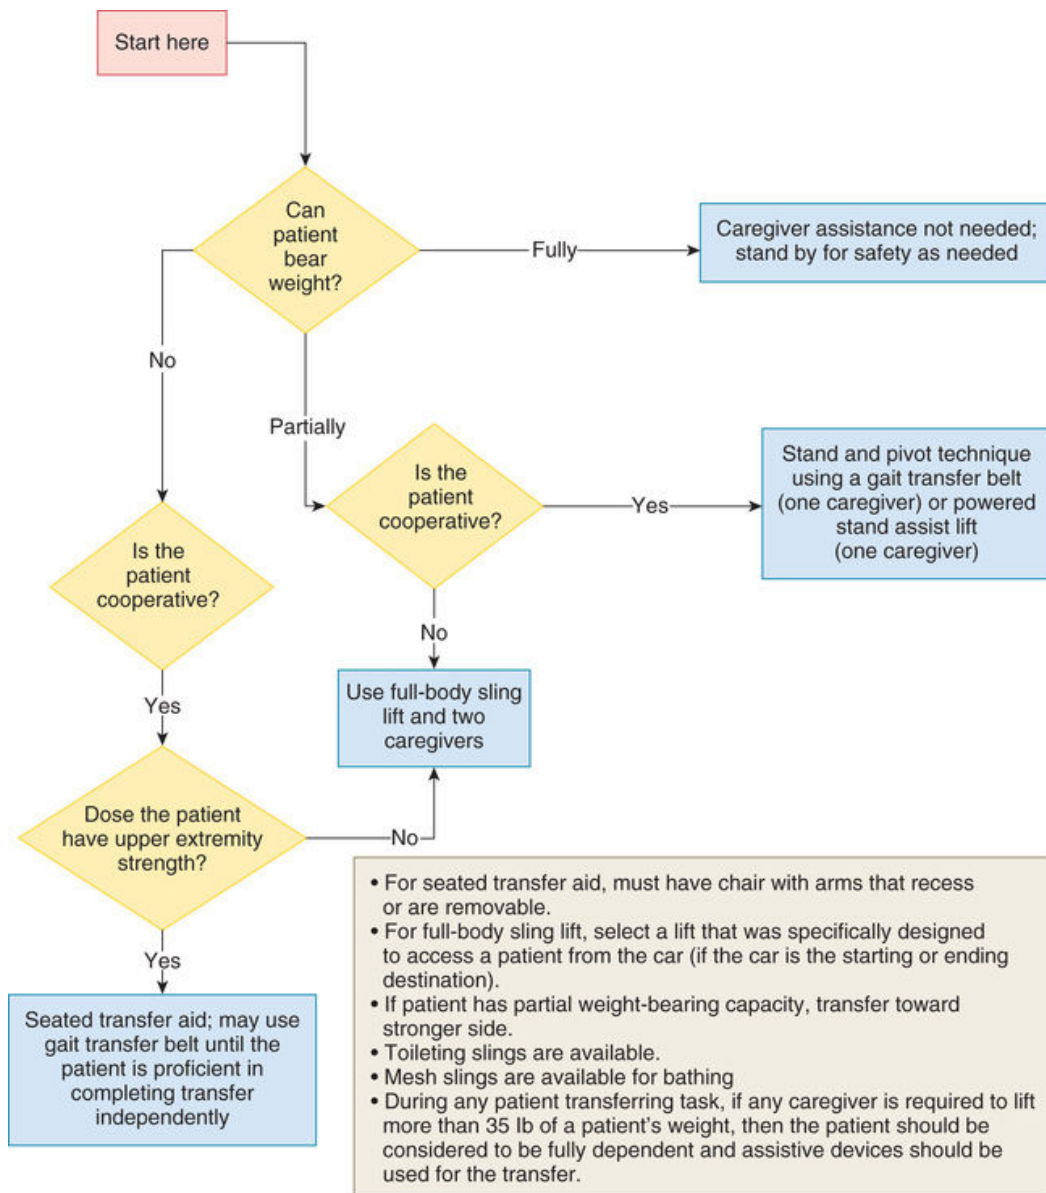

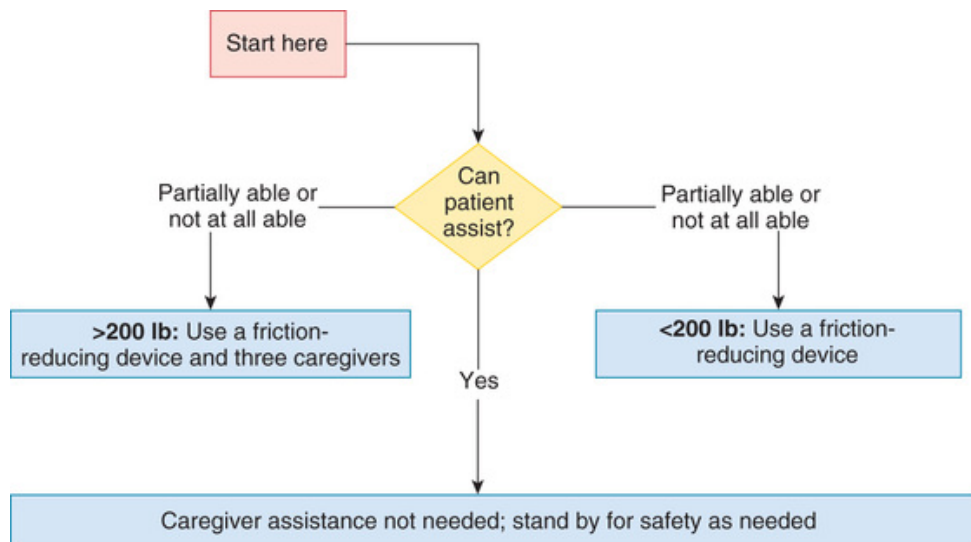

FIGURE 28.15 Algorithm 1: Transfer to and from bed to chair, chair to toilet, chair to chair, or car to chair. (Courtesy U.S. Department of Veterans Affairs.)

- Surfaces should be even for all lateral patient moves.
- For patients with stage III or IV pressure ulcers, care must be taken to avoid shearing force.

FIGURE 28.16 Algorithm 2: Lateral transfer to and from bed to stretcher or trolley. (Courtesy U.S. Department of Veterans Affairs.)

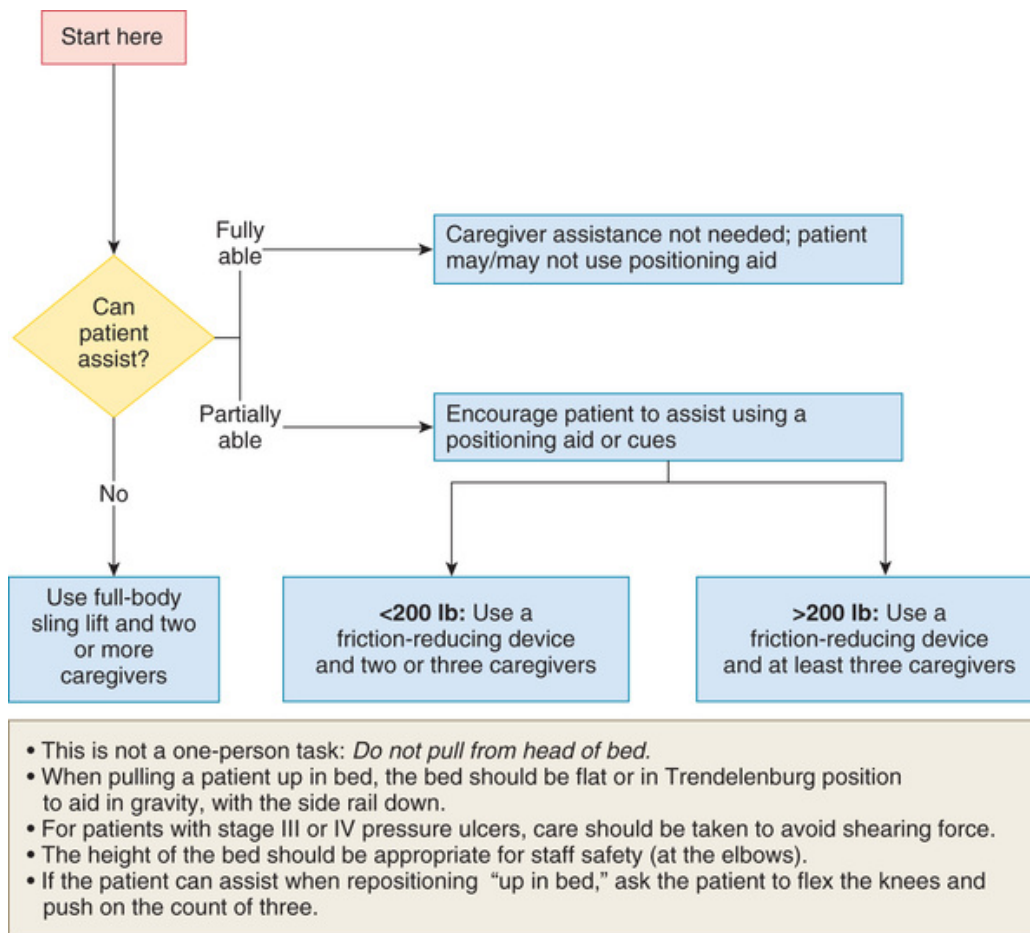

FIGURE 28.17 Algorithm 4: Reposition in bed side to side, up in bed. (Courtesy U.S. Department of Veterans Affairs.)

Additional algorithms are available for other patient care situations. Special bariatric patient care algorithms have been developed for this growing population.

QSEN Focus!

Referencing guidelines on mechanical lift devices from national patient safety resources demonstrates an appreciation for the values of research and interventions designed to prevent patient and caregiver injury.

Cardiopulmonary System Interventions

Every effort should be made to keep the lungs expanded in an immobile patient. If the patient's condition permits, raising the head of the bed can enhance lung expansion by relieving pressure on the diaphragm and chest wall. Routine coughing and deep-breathing exercises and the use of an incentive spirometer aid in lung expansion. Turning and repositioning the immobilized patient, incentive spirometry, and chest physiotherapy

decrease the likelihood of pulmonary secretions pooling in dependent areas of the lungs.

Several nursing interventions can help prevent VTEs in patients on bed rest. Teach the patient to perform leg, ankle, and foot exercises, or perform passive ROM if the patient is unable to exercise without assistance (Box 28.11). Two means of applying pressure to the calf to promote venous return are antiembolism hose (Skill 28.4), which are tightly fitting elastic stockings (e.g., thrombo-embolic deterrent [TED] hose), and sequential compression devices (SCDs), which are plastic or cloth sleeves that fit over the patient's legs and are intermittently inflated and deflated with an electric air pump (Skill 28.5).

Box 28.11

Nursing Care Guideline

Active, Active Assistive, and Passive Range of Motion

Background

- Range of motion (ROM) is the distance a joint can move in any direction that is considered normal for the patient (Fig. 28.4).
- There are three types of ROM:
 - *Active ROM*: The patient has full independent movement of all joints; this is also known as *isotonic exercise*.
 - *Active assistive ROM*: The caregiver minimally assists the patient or the patient minimally assists himself or herself in the movement of joints through a full motion.
 - *Passive ROM*: The caregiver moves the patient's joints through a full motion. This exercise does not maintain or improve strength but maintains flexibility and prevents contractures and atrophy.
- ROM activities have several goals:
 - To maintain or improve functioning of the musculoskeletal system
 - To ultimately improve the patient's abilities to perform activities of daily living (ADLs)
- Coordination of care can be done while performing ROM activities:
 - The caregiver can perform a full assessment of the integumentary system while performing ROM activities.
 - The caregiver can coordinate ROM activities with hygienic care.
- ROM activities can be delegated to unlicensed assistive personnel (UAP):

- UAP must receive proper instruction regarding the procedure and must know when to notify a nurse for assistance.
- UAP may not perform an assessment of the integumentary system but should notify the nurse if skin issues are noticed.

Procedural Concerns

- Have the patient wear comfortable, loose-fitting clothing.
- Encourage the patient to perform ROM exercises as independently as possible to achieve his or her highest level of function.
- Exercises usually should be performed consistently:
 - Two times per day
 - Three to five times per joint
 - Move the joints smoothly and slowly until resistance is met, and stop before pain begins.
- Prevent injury by supporting the joint during exercise. Support may be in one of three forms:
 - A cup is provided when one hand holds the joint while the other hand exercises the extremity.
 - A cradle is provided when one hand holds the joint while the other arm supports the rest of the extremity.
 - Support is provided when one hand holds the muscles above the joint while the other holds the muscles below the joint and moves the extremity.
- Stop an exercise if the patient's condition warrants a professional opinion and assessment.
- Perform the exercises in the same order or sequence, and move from head to toe to avoid omitting any joints.

Documentation Concerns

- Include ROM on the care plan, clearly specifying achievable, measurable goals.
- Document the following patient responses to exercises if they occur:
 - Assistance needed with exercises
 - Patient's response to the activity
 - Pain or discomfort
 - Resistance or contractures
- Note joints that did achieve full ROM, the degree of motion achieved, and the movement that was being attempted.
- Include the frequency and times that ROMs were performed.
- Add observations regarding the need to collaborate with or refer the patient to a physical or occupational therapist.

- Describe the patient and family education that has occurred.

Evidence-Based Practice

- Studies have indicated that active ROM is the best method of exercise for intensive care patients to prevent the development of deep vein thrombosis (DVT) (Palamone, Brunovsky, Groth, et al., 2011).
- Exercises performed twice daily have been shown to reduce muscle spasticity and improve functional ability in debilitated patients (Arbesman & Sheard, 2014).
- Range-of-motion exercises diminish the incidence of skin breakdown and prevent joint contractures in bedridden patients (Bowyer & Glover, 2010).

Anticoagulation therapy may be prescribed for patients with decreased mobility. Heparin, low-molecular-weight heparin (such as enoxaparin), or warfarin is given to prevent DVT and pulmonary embolism (PE). Postoperative patients or those on bed rest are most likely to be prescribed prophylactic anticoagulants. Monitor coagulation laboratory values before administering anticoagulants to ensure patient safety.

Safe Practice Alert

Assess patients who are receiving anticoagulation therapy for bruising or hemorrhage. Patients may be placed on bleeding precautions, which include the use of electric shavers and soft-bristle toothbrushes to avoid bleeding.

Position immobilized patients so that there are no areas of pressure on the lower extremities or under the knees to prevent occlusion of blood flow (Box 28.12). Caution patients against crossing their legs or ankles, because these positions can occlude blood flow. Ambulation as soon as possible is an important preventive measure.

Box 28.12

Nursing Care Guideline

Positioning in a Bed

Background

- The patient's position in a bed is important to maintain proper respiratory status and body alignment, prevent skin breakdown, and

provide comfort for a patient who is unable to reposition himself or herself.

- Coordination of care may be performed while the patient is being repositioned.
- The caregiver can perform a full assessment of the integumentary system.
- The caregiver can perform a full assessment of the musculoskeletal system.
- Repositioning a patient can be delegated to unlicensed assistive personnel (UAP):
 - Provide proper instruction regarding specific positioning techniques, individualized patient concerns, and circumstances that require notifying a nurse.
 - UAP may not perform assessments but should notify the nurse about any skin or musculoskeletal issues.
 - UAP should report difficulties with the procedure.

Procedural Concerns

- Determine whether mechanical lift devices or other specialized devices are needed (see [Boxes 28.8](#) and [28.10](#)) and how many caregiver assists are necessary.
- Assess the patient's medical history and current diagnoses to determine whether there are contraindications to the procedure.
- Assess the medical equipment in the room to determine whether the patient needs to be repositioned to optimize equipment function.
- When changing the patient's position, complete the following:
 - Lower the head of the bed to reduce resistance to gravity during repositioning, as tolerated and permitted by the patient's condition.
 - Raise the bed to waist height of the nurse or UAP assisting in positioning to avoid back injury.
 - Use bed side rails or lift equipment to assist the patient during repositioning, as appropriate.
 - Align the patient's spine in the center of the bed.
 - Place pillows or supportive devices (such as trochanter rolls) for comfort, to prevent skin breakdown on bony prominences, and to assist the patient in maintaining the new position.
 - Raise two or three side rails and lower and lock the bed to provide for patient safety following repositioning.

Documentation Concerns

- Include repositioning of the patient on the care plan.

- Include a systematic schedule of positions.
- Document the patient's response to positioning changes, including any of the following that apply:
 - Patient's assistance with positioning
 - Patient's response to and tolerance of the activity
 - Pain or discomfort experienced by the patient
- Document the times when repositioning was performed, current position, body alignment, and support devices used.
- Explain the need to collaborate with or refer the patient to a physical or occupational therapist.
- Document the patient and family education that was provided.

Evidence-Based Practice

Repositioning helps prevent the complications of immobility, including atelectasis, pneumonia, pulmonary embolism (PE), deep vein thrombosis (DVT), orthostatic hypotension, constipation, ileus, urinary stasis, hyperglycemia, insulin resistance, muscle atrophy, bone demineralization, contractures, pressure injuries, and depression ([Palamone, Brunovsky, Groth, et al., 2011](#)).

Allow the patient to participate in ADLs, and plan for frequent rest periods between activities. Gradually increase the amount of activity that the patient performs independently so that activity intolerance is minimized.

Dangling can prevent a previously nonambulatory patient from being injured. Raise the head of the bed slowly, and assist the patient to a sitting position. Ease the patient's legs over the side of the bed, and have the patient place the feet on the floor. Postural hypotension and syncope (i.e., fainting) may be prevented by allowing patients to sit with their legs in a dependent position for a few minutes before standing ([Fig. 28.18](#)). Monitor vital signs before, during, and after dangling and ambulation to assess for orthostatic hypotension.

FIGURE 28.18 Patient dangling on side of bed.

3. Identify at least four nursing actions with rationales that should be taken to provide for T. R.'s safety and prevent her from falling.

Nutrition Interventions

Patients on prolonged bed rest need adequate protein intake to prevent negative nitrogen balance. Patients should be offered meals that include lean protein. Because immobilized patients often have a decreased appetite, offer smaller, more frequent meals. Involving patients in dietary choices and increasing patient activity as tolerated may also increase appetite.

Adequate fluid intake is an essential component in preventing many complications of immobility, including DVT, UTIs, thickened pulmonary secretions, and constipation. The nurse should encourage intake of at least 2 liters of fluid in 24 hours unless contraindicated. Before discharging a patient with mobility issues, the nurse should consider the patient's dietary needs ([Box 28.13](#)). [Chapter 30](#) provides more information on nutritional support.

Box 28.13

Home Care Considerations

Nutritional Concerns for Patients Living Alone

- Consider the dietary needs of patients discharged to home who live independently.
- How will the patient prepare or receive well-balanced, nutritious meals necessary to promote wound healing?
- Is the patient able to grocery shop, or have arrangements been made with a supportive person to bring food or meals to the patient's home?
- Is the patient's water supply adequate and safe for drinking and food preparation?
- Has the patient verbalized an understanding of the necessity of adequate fluid intake to prevent significant urinary, bowel, and circulatory complications?

Elimination Interventions

Adequate fluid intake prevents some of the urinary and bowel complications associated with bed rest. When encouraging patients to drink 2 liters of fluids each day, the nurse should plan to offer at least half of the fluid intake during the day shift, which is when the patient is most alert and active. Position changes, toileting programs, a bedside commode, and provision of a bedpan for immobile patients at regular intervals help prevent urinary stasis.

Increasing the fiber in a patient's diet helps prevent constipation. A diet rich in whole grains, fruits, and vegetables helps soften and increase the mass of stools, making it easier for the patient to defecate (i.e., evacuate the bowels). Assisting patients to sit upright on a bedpan can aid in elimination (Fig. 28.19).

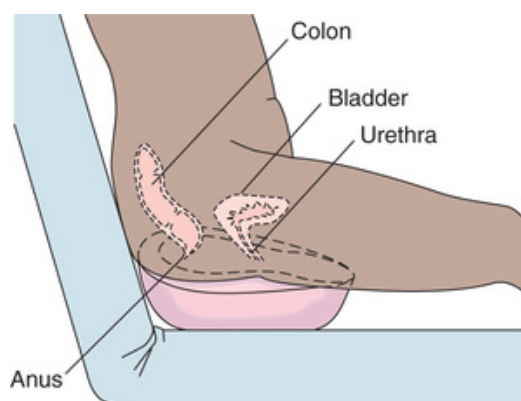

FIGURE 28.19 Proper positioning on a bedpan. (From Sorrentino, S. A., & Remmert, L. [2017]. *Mosby's textbook for nursing assistants* [9th ed.]. St. Louis: Elsevier.)

Because activity and exercise contribute to healthy bowel patterns, early ambulation is desirable. If a patient is having difficulty with constipation, a doctor's order may be required for a stool softener, laxative, or enema.

Skin Interventions

After at-risk patients are identified by using a skin assessment tool, interventions should be initiated to prevent skin breakdown. Turn immobile patients at least every 2 hours. A more frequent turning schedule should be employed for patients who have other risk factors, such as poor nutrition, fragile skin, lack of adipose tissue, or incontinence. Nurses should direct and supervise assistive personnel to whom patient turning and positioning responsibilities have been delegated ([Box 28.14](#)).

Box 28.14

Ethical, Legal, and Professional Practice

Pressure Injury Prevention

- Registered nurses are legally responsible for planning patient care related to pressure injury prevention.
- Unlicensed assistive personnel (UAP) provide direct patient care in many settings.
- Educating UAP on the importance of thorough skin care can prevent poor patient outcomes.
- The registered nurse demonstrates leadership and retains accountability for care that has been delegated to the UAP ([American Nurses Association \[ANA\], 2015](#)).

Safe Practice Alert

Position patients so that pressure is minimized on all bony prominences.

Pressure-relieving and pressure-reducing mattresses can be used to further reduce the risk of skin compromise. [Fig. 28.20](#) shows different positions with pillow placement and positioning devices.

FIGURE 28.20 Patient positioning.

Heel and elbow protectors are used to cushion bony prominences and prevent **friction** (rubbing) between the patient's skin and the bed sheets. These types of protectors can be made of cloth-covered foam, foam, or sheepskin and can be tubular or shaped like boots (Fig. 28.21). Special AFOs called *pressure-relief ankle-foot orthotic (PRAFO)* boots can be used to prevent pressure on the heels. A rigid aluminum frame lined in sheepskin is applied to the lower leg and foot using Velcro straps. PRAFO boots have the added benefit of keeping the ankle and foot in proper alignment. Before discharging patients to home who have an increased potential for skin breakdown, the nurse needs to thoroughly assess the patient's mobility, environment, and available support services (Box 28.15).

FIGURE 28.21 Heel protectors provide protection against skin breakdown. (Courtesy Posey Company, Arcadia, CA.)

Box 28.15

Home Care Considerations

Assessing Potential Immobility Concerns for Discharged Patients

When patients are discharged to home, their activity and exercise need to continue to prevent significant skin breakdown and psychosocial isolation.

- Is the patient able to move independently, or is it necessary for a caregiver to reposition the patient on a scheduled frequency?
- Are preventive skin care measures in place for patients confined to bed?
- Does a pressure-reducing mattress need to be ordered for the patient's home convalescence?
- How often are caregivers or other support people visiting or scheduled to visit and provide diversional activities for the home-bound patient?
- Are referrals to community agencies in place to support the home-bound patient?

Psychosocial Interventions

Preventing social isolation of immobilized patients can be challenging. Include patients in planning and implementing care so that they have some control over their environment. Patients should be encouraged to have contact with their family and friends through visits, phone calls, or e-mail. Provide spiritual support as needed or requested.

During hospitalization, disruption of sleep and rest patterns should be minimized. Nursing care should be planned to limit the number of times patients are awakened at night. Noise and light from the hallway should be kept at a minimum. During the day, open window blinds to provide the sunlight needed to maintain sleep–wake cycles.

The nurse should always talk with the patient and explain all procedures. Knowing what is going to happen in advance allows patients to assist in their care when possible and helps them cope with uncomfortable procedures.

Reality orientation is important. Patients should be able to see a clock and a calendar. Access to television or radio may help prevent sensory deprivation and boredom. Occupational therapists may assist in providing patient activities. If the immobilized patient is a child, specialized play therapists (i.e., child life specialists) can be valuable in providing therapeutic activities.

Mobilization of the patient's support system is especially important if a long recovery period is anticipated. Referrals to community resources (such

as transportation assistance and outpatient therapy) may be necessary for some patients. Early involvement of social services is beneficial. If the nurse notices changes in a patient's behavior, referral to a counselor may be necessary.

4. Identify a minimum of five nursing interventions with rationales necessary to prevent postoperative complications of immobility.

Evaluation

To evaluate treatment interventions for patients who have limited mobility or are confined to bed rest, pay particular attention to nursing care plan goals and outcome criteria. Nurses must continually evaluate the effectiveness of interventions on the basis of attainment of short- and long-term goals. Evaluation is a dynamic aspect of the nursing process that determines the need for revision of patients' individualized plans of care.

SKILL 28.1 Manual Logrolling

If the patient is to be rolled using a special bed adaptation or mechanical device, refer to facility policy and training for the specific manufacturer's device. The procedure described here should be used only if a mechanical device is not used.

Purpose

- To maintain the patient's spinal alignment through special repositioning
- To maintain skin integrity
- To prevent pressure injuries
- To promote patient comfort
- As needed to provide basic hygiene (e.g., changing linens, bathing)

Resources

- Appropriate staffing numbers
- Pillows
- Drawsheet

Interprofessional Collaboration and Delegation

- Logrolling a patient may be delegated to unlicensed assistive personnel (UAP) without a nurse's assistance after the initial assessment of the patient, provided a spinal cord injury or surgical site is stabilized (at the nurse's discretion).
- UAP should report the following:
 - Pain before, during, or after the procedure
 - Sores, wounds, irritations, and lesions
 - Difficulties in performing the procedure
- UAP should be instructed in the following:
 - Appropriate number of staff required to safely perform the procedure

- Appropriate procedure and timing
- Appropriate documentation
- Collaborate with the physical therapist if he or she would like assistance in assessing the patient's abilities
- Collaborate and coordinate the procedure with the primary care provider (PCP) or surgeon rounds if dressings or surgical implementation must be examined or changed

Evidence-Based Practice

- Logrolling orthopedic patients who have a halo brace or are postoperative total hip replacement is a high risk nursing task. Algorithms have been developed for these tasks, and it is important to determine whether mechanical or bed assistive repositioning devices should be used instead of nursing personnel for turning the patient ([Sedlak, Doheny, Nelson, et al., 2009](#)).
- Decreasing the risk of caregiver injuries while practicing safe patient-handling requires use of a patient care ergonomic assessment. Many manual patient handling tasks are unsafe, because the weights lifted and movements required are beyond the ability of most caregivers. The key is to identify the task to be accomplished, and then use the required equipment and personnel so that the task fits the capabilities of the staff ([U.S. Department of Veterans Affairs, 2016](#)).
- The patient's level of cooperation is taken into consideration when using the safe patient-handling and mobility (SPHM) algorithms to decide the best method of moving the patient. The patient's weight, medical conditions, and ability to assist are also considered ([U.S. Department of Veterans Affairs, 2016](#)).

Special Circumstances

1. **Assess:** Is the patient experiencing pain?

Intervention: Determine whether the pain is new or preexisting.

- Anticipate whether the procedure will produce pain and therefore require pain medication before moving the patient.
- Stop the procedure if the patient complains of new pain.
- Medicate according to orders.
- Notify the PCP if no orders exist for pain medication.

2. **Assess:** What is the most appropriate assistance for the specific patient situation?

Intervention: Identify the patient's weight and level of cooperation, medical interventions, orthopedic interventions, and facility policies.

- Use a lift team, mechanical assistive device, or multiple staff members to move the patient.
- One additional staff member may be needed for each orthopedic intervention (e.g., cast, brace), depending on the appliance and the patient's ability to assist.
- Before the other staff arrives, arrange medical interventions (e.g., intravenous [IV] lines, tubing) to avoid twisting or other complications.

Preprocedure

I. Check PCP orders and the patient care plan.

Knowledge of patient-specific orders is critical for safe patient care.

II. Gather supplies and equipment.

Preparing for the patient encounter saves time and promotes patient trust.

III. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

IV. Maintain standard precautions.

Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient, using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Logrolling

Follow preprocedure steps I through VIII.

1. Raise the bed to a working height, lower the side rails as appropriate and safe, and ensure that the bed wheels are locked.

Proper positioning of equipment prevents provider discomfort and reduces the chance of possible injury.

2. Place the drawsheet.

Using a drawsheet helps avoid friction or shearing injuries to the patient that may accompany movement and prevents provider discomfort and possible injury by facilitating the movement of the patient.

3. Place pillows:

- a. Between the patient's knees
- b. Move pillow to the side of the patient's head

Appropriately placed pillows help maintain spinal alignment during movement.

4. Position the patient's arms across his or her chest.

STEP 4 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Proper arm position prevents twisting of the extremities during movement

and reduces the risk of injury to the patient.

5. Nurses may assume various positions in preparation for turning the patient:
 - a. At the head of the bed to support the patient's head and neck alignment
 - b. At the patient's back or chest to support back alignment
 - c. At the legs to support hip and leg alignment
 - d. Where needed to watch tube placement and beside casts or braces, which require one nurse for each device

Proper position of personnel around the patient ensures patient safety by maintaining spinal alignment and prevents provider discomfort and possible injury by ensuring there is enough assistance to minimize injury to providers during patient repositioning.

6. Make sure side rails are raised on the side of the bed opposite the nurses. On the count of three, pull the patient toward the nurses' side of the bed. The nurse at the head of the bed should initiate the count. *Starting with the patient on one side of the bed allows room for the patient to be turned safely throughout the roll.*
7. On a second count of three, roll the patient, and then place pillows behind the patient to support him or her in the new position.

STEP 7(1) (Copyright Mosby's Clinical Skills: Essentials Collection.)

STEP 7(2) (Copyright Mosby's Clinical Skills: Essentials Collection.)

Counting allows the staff to coordinate their actions and move the patient as a team, which gives the best opportunity to maintain spinal alignment.

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

SKILL 28.2 Ambulation With Assistive Devices

Purpose

- Increases patient activity level
- Promotes independence
- Promotes self-esteem
- Prevents complications of immobility
- Increases muscle strength
- Promotes safety
- Decreases risk of further injury

Resources: All Methods

- Appropriate assistive device (e.g., gait belt, cane, walker), as prescribed.
- Sturdy shoes with nonskid soles.

Interprofessional Collaboration and Delegation: All Methods

- Educating patients on how to walk with assistive devices may not be delegated to unlicensed assistive personnel (UAP).
- Ambulation of a patient may be delegated to UAP only if the patient's musculoskeletal strength is stable and the patient has been educated in use of the device.
- UAP may assist the nurse so that adequate staff is available to prevent injury to the patient or staff members.
- UAP should report any of the following:
 - Noticeable incorrect usage or fit of assistive devices
 - Complaints of soreness or weakness
 - Difficulties involving balance or strength

- Difficulties in performing the procedure or other concerns verbalized by the patient
- UAP should be instructed in the following:
 - Appropriate ambulation assistive techniques
 - Appropriate equipment usage
 - Appropriate documentation
- Physical therapists work with patients for rehabilitation. Collaborate with these specialists.
- Check the primary care provider (PCP) orders to ensure that duplication of activity for the patient is not occurring.
- A physical therapist may ambulate the patients on the unit and assist as appropriate to ensure safety for all involved.
- Orthopedic specialists may change dressings or assess patient outcomes. Attempt to coordinate ambulation with visits by the orthopedic specialists, as appropriate.
- Home health workers ensure safety in the home. They should be aware of assistive devices and the home layout.

Evidence-Based Practice

- To assess mobility in patients, tests (such as the Timed Up and Go [TUG] test) can be performed. Patients who do not complete the test in the allotted time are at a high risk for falling and assistive interventions should be initiated ([Centers for Disease Control and Prevention \[CDC\], 2017](#)).
- Staff should assist with ambulation only if the patient is stable or if a mechanical device is not available. Safe patient-handling recommendations include the use of mechanical devices, specialized patient teams, and special ambulation and lift policies. Facility policies and

safe patient-handling recommendations should be followed for the safety of the patient and staff.

- Powered stand-assist lifts should be used to move patients who are not steady enough to ambulate. Ceiling lifts and full body lifts can be used with ambulation slings when ambulating patients who are weak or unsteady. The use of a lift prevents falls, as well as patient and caregiver injuries ([U.S. Department of Veterans Affairs, 2016](#)).

Special Circumstances: All Methods

1. **Assess:** Is the patient in pain?

Intervention: Determine whether the pain is new or preexisting.

- Anticipate whether ambulating will produce pain and whether there is a need for pain medication.
- Stop the procedure if the complaint is for a new pain.
- Medicate or premedicate the patient according to the PCP orders.
- Notify the PCP if no orders exist for pain medication.

2. **Assess:** Is the patient on a medication regimen?

Intervention: Determine whether any of the medications may cause issues with balance, coordination, or alertness.

- Stop the procedure if any adverse medication side effects are evident.
- Notify the PCP.

3. **Assess:** During the musculoskeletal assessment, was there any indication of difficulty with balance, weakness (unilateral versus bilateral), upper or lower extremity strength, weight bearing, injuries, or range of motion (ROM)?

Intervention: Ensure that the appropriate assistive device and the prescribed walking technique can be used.

- If the patient can raise the legs 1 inch off the bed, the patient has enough strength to begin ambulation.
- If the patient is weak, place chairs along the intended route at appropriate unobtrusive areas so that the patient may safely rest if necessary.
- If the patient is severely weak or this is the first opportunity to ambulate, ensure that a staff member is available to follow with a wheelchair.
- Cane use:
 - To fit properly, a cane should come to the hip of the patient.

- Canes should be held on the stronger side.
 - Quad canes, with four points of support, should be used by patients with a poor sense of balance.
 - Straight-handle canes are not recommended for patients with poor balance.
 - Curved-handle canes provide minimal support.
4. **Assess:** Is the patient wearing sturdy, nonskid footwear with low or no heels?
Intervention: Educate the patient, and obtain nonskid shoes or slippers to provide the necessary support and reduce the risk of falling with ambulation.
 5. **Assess:** Are appropriate numbers of staff available to assist?
Intervention: Do not proceed until adequate staff are available; otherwise, staff and patient may be injured.
 6. **Assess:** Is the intended ambulatory route clear of obstacles?
Intervention: Remove any items that may impede the staff or patient from walking appropriately.
 7. **Assess:** Is the assistive device sturdy and intact (e.g., tips intact, aluminum not bent, wood not cracked, padding intact, tips dry)?
Intervention: For safety reasons, replace any portion of the device that has wear and tear. Dry any portion of the device that is wet. Educate the patient on appropriate inspection and safety techniques.
 8. **Assess:** Do the patient's normal routines require modifications at home?
Intervention: Educate the patient.
 - Further assistive devices may be needed (e.g., “reachers”).
 - Instruct the patient to check for furniture in the household that may be creating a safety issue.
 9. **Assess:** Does the patient have a diagnosis of osteoporosis?
Intervention: Do not use a gait belt. It may cause vertebral compression fractures due to pressure.

Preprocedure

I. Check PCP orders and the patient care plan.

Knowledge of patient-specific orders is critical for safe patient care.

II. Gather supplies and equipment.

Preparing for the patient encounter saves time and promotes patient trust.

III. Perform hand hygiene.

Frequent hand hygiene prevents the spread of

microorganisms.

IV. Maintain standard precautions.

Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient, using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Gait Belt: One Nurse, Independent Ambulation

Follow preprocedure steps I through VIII.

1. Fit the gait belt around the patient's waist; ensure that it is securely fastened and fits snugly.
Precautions must be taken to maintain patient safety.
2. Stand behind the patient on the patient's weaker side, and grasp the belt at the patient's back; ambulate at the patient's pace.
Caregiver position should be such that it promotes patient safety.

Follow postprocedure steps I through VI.

Gait Belt: One Nurse, Minimal Assist

Follow preprocedure steps I through VIII.

1. Fit the gait belt around the patient's waist; ensure that it is securely fastened and fits snugly.

Precautions must be taken to maintain patient safety.

2. Stand on the patient's weaker side. Using an underhand grasp, hold the gait belt at the patient's back, and walk with the patient at the patient's pace.

Caregiver position should be such that it promotes patient safety.

Follow postprocedure steps I through VI.

Gait Belt: Two Nurses, Minimal Assist

Follow preprocedure steps I through VIII.

1. Fit the gait belt around the patient's waist, and ensure that it is securely fastened and fits snugly.
2. One nurse stands on each side and slightly behind the patient. The nurses support the patient under the axillae and ambulate with the patient at the patient's pace.

Precautions must be taken to maintain patient safety.
Caregiver position should be such that it promotes patient safety. The nurses should be able to easily reach the gait belt if needed.

Follow postprocedure steps I through VI.

Gait Belt: Two Nurses, Maximum Assist

Follow preprocedure steps I through VIII.

1. Fit the gait belt around the patient's waist; ensure that it is securely fastened and fits snugly.
2. One nurse stands on each side of the patient, with the arm closest to the patient holding the gait belt. Each nurse supports the patient's arm with the nurse's outside arm and ambulates with the patient at the patient's pace.

STEP 2 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Caregiver position should be such that it promotes patient safety.

Follow postprocedure steps I through VI.

Cane Walking: Maximum Support

Follow preprocedure steps I through VIII.

1. The patient holds the cane on his or her stronger side.
Using the patient's stronger side promotes optimal alignment of the body while ambulating and promotes optimal support.
2. The patient moves the cane forward 6 inches in front and 6 inches to the side of the strong leg, with the elbow flexed 30 degrees.

STEP 2

- This position gives the patient a wide base of support for the weaker side.*
3. The patient moves the weak foot forward to the cane.
This position gives the patient a wide base of support for the weaker side.
4. The patient moves the strong leg past the cane.
The cane and the weaker side support the patient's weight while the stronger side moves forward.
5. Repeat procedure steps 2 through 4.

Follow postprocedure steps I through VI.

Cane Walking: Minimal Support

Follow preprocedure steps I through VIII.

1. The patient holds the cane on his or her stronger side.
Using the patient's stronger side promotes optimal alignment of the body while ambulating and promotes optimal support.
2. The patient moves the cane and the weak leg forward at the same time.
This position gives the patient a wide base of support for the weaker side.
3. The patient moves the strong leg past the cane.
The cane and the weaker side support the patient's weight while the stronger side moves forward.
4. The patient repeats steps 2 and 3 (i.e., mimics walking).

Follow postprocedure steps I through VI.

Rising from a Chair to a Walker

Follow preprocedure steps I through VIII.

1. The patient moves to the edge of the chair.
Positioning the patient on the edge of the chair eases the patient's burden of lifting the body out of the chair.
2. The patient positions his or her legs close to the chair and slightly apart. The patient's hands are placed on the armrests of the chair, and the walker is in front of the chair.

STEP 2

This position provides the strongest base of support to facilitate lifting the body and standing.

3. The patient pushes off the chair and balances.
Taking the time to balance more fully ensures patient safety before moving and reduces the risk for falls.
4. The patient moves his or her hands, one at a time, to the walker.
The patient should always have one hand grasping an arm of the chair or the

- walker to ensure safety before moving. This reduces the risk for falls.*
5. Proceed to the “Walker: Maximal Support” or “Walker: One Leg Weaker” section.

Follow postprocedure steps I through VI.

Walker: Maximum Support

Follow preprocedure steps I through VIII and procedure steps 1 through 4 in the “Rising from a Chair to a Walker” section.

1. The patient moves the walker 6 to 8 inches forward.
The walker is moved forward first for support.
2. The patient moves the right foot forward.
The patient steps into the walker, which offers support; mimics walking.
3. The patient moves the left foot forward.
The patient steps into the walker, which offers support; mimics walking.
4. Repeat procedure steps 1 through 3.

Follow postprocedure steps I through VI.

Walker: One-Leg Weaker

Follow preprocedure steps I through VIII and procedure steps 1 through 4 in the “Rising from a Chair to a Walker” section.

1. The patient moves the walker and the weak leg forward at the same time.
This position gives the patient a wide base of support for the weaker side.
2. The patient moves the strong leg forward.
The walker and the weaker side support the patient’s weight while the stronger side moves forward.
3. Repeat procedure steps 1 and 2.

Follow postprocedure steps I through VI.

Postprocedure

- I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.
Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

SKILL 28.3 Walking With Crutches

Purpose

- To increase activity level
- To promote independence
- To promote safety
- To decrease risk of further injury
- To limit weight bearing on the affected extremity, as ordered

Resources

- Appropriate crutches as prescribed by the primary care provider (PCP) or physical therapist: underarm (axillary), Lofstrand, or platform
- Sturdy shoes with nonskid soles

Interprofessional Collaboration and Delegation

- Education on how to walk with crutches may not be delegated to unlicensed assistive personnel (UAP).
- Ambulation of a patient who is crutch walking may be delegated to UAP, provided the patient is experienced and stable on the crutches.
- UAP should report any of the following:
 - Noticeable incorrect usage or fit of crutches
 - Complaints of soreness or weakness
 - Difficulties with balance or strength
 - Difficulties with the procedure or other concerns verbalized by the patient
- UAP should be instructed in the following:
 - Appropriate ambulation assistive techniques
 - Appropriate equipment usage
 - Appropriate documentation

- Physical therapists work with patients for rehabilitation. Collaborate with these specialists.
- Check the orders to make sure that duplication of activity for the patient is not occurring.
- A physical therapist may ambulate the patient on the unit and assist as appropriate to ensure safety for all persons involved.
- Orthopedic specialists may change dressings or assess patient outcomes. Attempt to coordinate ambulation with orthopedic visits as appropriate.
- Home health workers ensure the patient's safety in the home. They should be aware of assistive devices and the home layout.
- If the patient is an inpatient, stair climbing should be taught by a physical therapist, because the physical therapy department has appropriate safety stairs on which the patient can practice. If the patient is in the emergency department, it is important to review the basics of stair climbing with the patient, who should indicate comprehension.

Evidence-Based Practice

- Spring-loaded crutches are a better choice for patients because they assist in the biomechanics of the patient's gait. [Zhang et al. \(2013\)](#) found that spring-loaded crutches were mechanically more efficient than standard crutches during ambulation.
- Powered stand-assist lifts should be used to move patients who are not steady enough to ambulate. Ceiling lifts, and full body lifts can be used with ambulation slings when ambulating patients who are weak or unsteady. The use of a lift prevents falls and caregiver injuries ([U.S. Department of Veterans Affairs, 2016](#)).

- Crutch walking may be a progressive ambulation technique for patients who originally started their rehabilitation with more supportive devices. To assess mobility in patients, tests (such as the Timed Up and Go [TUG] test) can be performed. Patients who do not complete the test in the allotted time are at a high risk for falling and assistive interventions should be initiated ([CDC, 2017](#)).

Special Circumstances

1. **Assess:** Is the patient experiencing pain?
Intervention: Determine whether the pain is new or preexisting.
 - Anticipate whether ambulation will produce pain and require pain medication.
 - Stop the procedure if the patient complains of new pain.
 - Medicate or premedicate the patient for pain according to orders.
 - Notify the PCP if no order exists for pain medication.
2. **Assess:** In a musculoskeletal assessment, does the patient show any difficulty with balance, weakness (unilateral or bilateral), or upper extremity strength?
Intervention: Ensure that the patient is using the appropriate crutches and the prescribed walking technique.
 - Evaluate the size of crutches for the patient. There should be three finger widths between the axilla and axillary piece when the patient is standing erect, with elbow flexion of 30 degrees for the hand bar when supporting weight.
 - Stress the importance of performing exercises that are intended to increase upper extremity strength.
 - There are four crutch-walking techniques:
 1. *Two-point:* Both feet bear partial weight.
 2. *Three-point:* One foot bears weight, and the other foot can be used for balance.
 3. *Four-point:* Both feet bear weight.
 4. *Swing-to:* Both feet are able to bear weight, but there is hip and leg paralysis and weaker upper body strength.
3. **Assess:** Is the patient wearing sturdy, nonskid shoes with low or no heels?
Intervention: Educate the patient, and obtain nonskid shoes or slippers to provide the necessary support and reduce the risk of falling with ambulation.

4. **Assess:** Are the crutches sturdy and intact (e.g., crutch tips are intact, aluminum is not bent, wood is not cracked, padding is intact, crutch tips are dry)?
Intervention: Replace any portion of the crutch that is indicating wear and tear for safety; dry any portion that is wet; and educate the patient on appropriate inspection and safety techniques.
5. **Assess:** Do the normal routines require modifications?
Intervention: Educate the patient with regard to further assistive devices that may be needed (e.g., reachers), household furniture that may create a safety issue, and stairs and elevators at home or work.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.
- VI. Provide for patient privacy.
It is important to maintain patient dignity.
- VII. Identify the patient, using two identifiers.
Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.
- VIII. Explain the procedure to the patient.
The nurse has a responsibility to inform a patient before

initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Rising From a Chair by Using Crutches

Follow preprocedure steps I through VIII.

1. The patient moves to the front edge of the chair. Check that the chair is secure. If it is a wheelchair, make sure that the wheels are locked. *By starting close to the edge of the chair, the patient eases the burden of lifting the body out of the chair.*
2. The patient's strongest leg should be close to the chair. The patient's hand on the weak side holds the hand bar of the crutches, and the hand on the patient's strong side holds onto the armrest of the chair.

STEP 2

This position provides the strongest base of support to facilitate lifting the body and standing.

3. The patient pushes up and off the chair and then balances. *Taking the time to balance properly ensures patient safety before moving and reduces the risk for falls.*
4. The patient moves the crutches to a tripod position (i.e., starting point for a gait). Crutches are held 6 inches in front of the patient and 6 inches to the side of each foot. *The stable tripod position ensures the patient's safety before moving and reduces the risk for falls.*
5. Proceed to the "Two-Point Gait," "Three-Point Gait," "Four-Point Gait," "Swing-To Gait," or "Sitting onto a Chair" section.

Two-Point Gait

Follow preprocedure steps I through VIII and procedure steps 1 through 4 in the “Rising from a Chair by Using Crutches” section.

1. The patient starts in the tripod position with the crutch tips on the floor approximately 6 inches in front of and 6 inches to the side of the patient's feet.

STEP 1

The tripod position is relatively stable, and it ensures the patient's safety before moving and reduces the risk for falls.

2. The patient moves the right crutch and left foot forward at the same time.

STEP 2

This pattern mimics walking and provides a wide base of support.

3. The patient moves the left crutch and right foot forward at the same time.

This pattern mimics walking and provides a wide base of support.

4. Repeat procedure steps 2 and 3 to mimic walking.
5. The patient ends in the tripod position.

The tripod position is relatively stable, and it ensures the patient's safety before moving and reduces the risk for falls.

Follow postprocedure steps I through VI.

Three-Point Gait

Follow preprocedure steps I through VIII and procedure steps 1 through 4 in the "Rising from a Chair by Using Crutches" section.

1. The patient starts in the tripod position with the crutch tips on the floor approximately 6 inches in front of and 6 inches to the side of the

patient's feet.

The tripod position is relatively stable, and it ensures the patient's safety before moving and reduces the risk for falls.

2. The patient moves both crutches and the weak foot forward at the same time. Alternately, if the patient is non-weight bearing on one side, the leg can be held off the ground.

STEP 2

This technique provides a wide base of support for the weaker foot.

3. The patient moves the strong foot forward.
The crutches and weaker foot support the patient's weight, while the stronger foot moves forward.
4. Repeat procedure steps 2 and 3.
5. The patient ends in the tripod position.
The tripod position is relatively stable, and it ensures the patient's safety before moving and reduces the risk for falls.

Follow postprocedure steps I through VI.

Four-Point Gait

Follow preprocedure steps I through VIII and procedure steps 1 through 4 in the "Rising from a Chair by Using Crutches" section.

1. The patient starts in the tripod position with the crutch tips on the floor approximately 6 inches in front of and 6 inches to the side of the patient's feet.

The tripod position is relatively stable, and it ensures the patient's safety before moving and reduces the risk for falls.

2. The patient moves the right crutch forward.

STEP 2

In this pattern there are three points of support on the ground at all times.

3. The patient moves the left foot forward.

STEP 3

4. The patient moves the left crutch forward.
5. The patient moves the right foot forward.

STEP 5

6. Repeat procedure steps 3 through 5.
7. The patient ends in the tripod position.
The tripod position is relatively stable, and it ensures the patient's safety before moving and reduces the risk for falls.

Follow postprocedure steps I through VI.

Swing-To Gait

Follow preprocedure steps I through VIII and procedure steps 1 through 4 in the “Rising from a Chair by Using Crutches” section.

1. The patient starts in the tripod position with the crutch tips on the floor approximately 6 inches in front of and 6 inches to the side of the patient's feet.
The tripod position is relatively stable, and it ensures the patient's safety before moving and reduces the risk for falls.
2. The patient moves both crutches forward at the same time.
One leg (in the case of a patient who is non-weight bearing on one side) or both legs (in the case of a paraplegic) support the body weight while the crutches move forward.
3. The patient lifts the body and swings both legs to the crutches.
The crutches support the body weight while the legs swing forward to the crutches.
4. Repeat procedure steps 2 and 3.
5. The patient ends in the tripod position.
The tripod position is relatively stable, and it ensures the patient's safety before moving and reduces the risk for falls.

Follow postprocedure steps I through VI.

Sitting Down on a Chair While Using Crutches

Follow preprocedure steps I through VIII.

1. The patient backs up to a chair that has armrests and stands in the tripod position.
The tripod position is relatively stable, and it ensures the patient's safety before moving and reduces the risk for falls.
2. The patient makes sure that the stronger leg is against the back of the secure chair or locked wheelchair, balances, and then moves the crutches to the affected side, holding on to the hand bars.
This position ensures patient safety while the patient is preparing to sit and reduces the risk for falls.
3. The patient reaches for the armrest of the chair with the arm on his or her stronger side and sits down.
Using the stronger arm ensures safety and reduces the risk for falls.
4. The patient lowers his or her body to the chair while holding onto the crutches on the weaker side and armrest on the stronger side.
Holding onto the arm rest and crutches provide a wide base of support.

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

SKILL 28.4 Antiembolism Hose

Purpose

- Prevent edema to lower extremities
- Prevent deep vein thrombosis (DVT) and venous stasis
- Promote blood flow of venous return
- Ultimately, prevent pulmonary emboli

Resources

- Antiembolism hose (knee length or thigh length)
- Tape measure

Interprofessional Collaboration and Delegation

- Applying, removing, and cleaning antiembolism hose may be delegated to unlicensed assistive personnel (UAP) after proper fitting and skin assessment by the nurse.
- UAP should report any of the following:
 - Complaints related to pain, application, or fit
 - Sores, wounds, irritations, lesions, edema, redness, or localized warmth in the lower extremities
 - Difficulties in performing the procedure
- UAP should be instructed in the following:
 - Appropriate application methods
 - Appropriate cleaning methods
 - Appropriate documentation

Evidence-Based Practice

- Antiembolism hose reduce the risk of DVT by over 60%; this rises to 85% when other methods are used in conjunction with antiembolism hose. Opinions are

divided as to whether thigh high hose are more effective than knee high hose, which are cheaper, and more comfortable (Autar, 2009).

- One of the most life-threatening side effects of immobility is a pulmonary embolism (PE). A PE may develop as a result of untreated deep vein thrombosis (DVT). Homans sign (calf pain with flexion of the knee and dorsiflexion of the foot) was used in the assessment and diagnosis of DVT. It has been shown that Homans sign is not a reliable way to assess for DVT, and may actually cause dangerous clot dislodgment. More information on the prevention, diagnosis, and treatment of DVT and PE is available at:

<https://www.nhlbi.nih.gov/health-topics/venous-thromboembolism#Risk-Factors>

Special Circumstances

1. **Assess:** Did the initial fitting of hose and measurements fall outside the range listed in the manufacturer's size charts?
Intervention: Notify the primary care provider (PCP). Alternative compression devices, such as sequential compression devices (SCDs; see Skill 28.5) or elastic bandages, may be needed.
2. **Assess:** Has the patient been out of bed before hose application?
Intervention: Have the patient elevate the legs or lie down for 15 to 30 minutes. Having the legs in a dependent position promotes edema; if edema exists when the hose are applied, the desired outcome will not be achieved.
3. **Assess:** Is there pain, redness, or soreness in the patient's legs?
Intervention: Determine whether the pain is new or a preexisting problem.
 - Stop the procedure if the complaint is new, and assess for possible DVT or an incorrect fit.
 - Notify the PCP.
4. **Assess:** What is the patient's neurovascular status at baseline? Check for the following:
 - Toes are warm and pink.
 - The posterior tibial and/or dorsalis pedal pulses are palpable or audible with a Doppler.
 - Assess for edema or distended veins.**Intervention:** Determine whether any unusual

- neurovascular symptoms are new or preexisting.
 - Stop the procedure if the symptom is new, and assess for possible DVT.
 - Notify the PCP.
5. **Assess:** Does the patient have incisions or open wounds?
- Intervention:** Determine whether they are new or preexisting.
- If an incision or wound is draining, cover it with a bandage to avoid the spread of microorganisms to the hose.
 - Carefully apply the stocking over this area to avoid causing further trauma or injury.
 - If the wound is new, notify the PCP.
6. **Assess:** Do the hose apply easily?
- Intervention:** Determine whether they are the correct fit and size, and ensure that the legs are dry:
- Resize the patient. If the size is incorrect, discard the hose, and obtain a new pair.
 - Ensure that the hose were dried flat after washing; hanging hose to dry may cause stretching.
 - Determine whether the legs are wet or damp. If they are, application of the hose will be difficult, possibly causing trauma to the skin. Ensure that the legs are dry.
 - Ensure that the hose are washed frequently; the recommendation is every 3 days. Having two pairs of hose allows for the use of one pair while the other is being laundered.

Preprocedure

I. Check PCP orders and the patient care plan.

Knowledge of patient-specific orders is critical for safe patient care.

II. Gather supplies and equipment.

Preparing for the patient encounter saves time and promotes patient trust.

III. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

IV. Maintain standard precautions.

Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient, using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Fitting: Knee-High Hose

Follow preprocedure steps I through VIII.

1. Measure from the heel to the popliteal space (behind the knee).

STEP 1 (Copyright Mosby's Clinical Skills: Essentials Collection.)

This measurement is required for manufacturers' sizing charts. Accurate measurements ensure the correct fit, avoiding patient harm that can occur from estimating sizes.

2. Measure around the widest part of the calf.

STEP 2 (Copyright Mosby's Clinical Skills: Essentials Collection.)

This measurement is required for manufacturers' sizing charts. Accurate measurements ensure the correct fit, avoiding patient harm that can occur from estimating sizes.

3. Compare these measurements with the manufacturer's sizing charts. If a patient's measurements fall between two sizes on the charts, take both sizes of hose, and try them on the patient to see which has the better fit.

It is essential to have the correct fit to ensure positive patient outcomes. If a stocking is too small, it will constrict blood flow; if it is too large, it can cause skin irritation and will not promote venous return of blood.

4. Proceed to the "Application: Knee-High Hose" section.

Fitting: Thigh-High Hose

Follow preprocedure steps I through VIII.

1. Measure from the heel to the gluteal fold below the buttocks.
This measurement is required for manufacturers' sizing charts. Accurate measurements ensure the correct fit, avoiding patient harm that can occur from estimating sizes.
2. Measure around the widest part of the calf.
This measurement is required for manufacturers' sizing charts. Accurate measurements ensure the correct fit, avoiding patient harm that can occur from estimating sizes.
3. Measure around the widest part of the thigh.

STEP 3 (Copyright Mosby's Clinical Skills: Essentials Collection.)

This measurement is required for manufacturers' sizing charts. Accurate

measurements ensure the correct fit, avoiding patient harm that can occur from estimating sizes.

4. Compare these measurements with the manufacturer's sizing charts. If a patient's measurements fall between two sizes on the charts, take both sizes of hose and try them on the patient to see which has the better fit.

It is essential to have the correct fit to ensure positive patient outcomes. If a stocking is too small, it will constrict blood flow; if it is too large, it can cause skin irritation and will not promote venous return of blood.

5. Proceed to the "Application: Thigh-High Hose" section.

Application: Knee-High Hose

Follow preprocedure steps I through VIII.

1. Raise the bed to working height.
Setting the bed at the correct working height for the provider prevents provider discomfort and possible injury.
2. Roll the hose inside out around hands; the leg of the hose will be inside out, covering the foot of the hose.
Rolling the hose in this way allows easy application and prevents possible trauma to the skin during application.
3. Have the patient point the toes; put each stocking over the toes and heel, and smooth wrinkles away from the foot.

STEP 3 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Pointing the toes allows easy application of the hose; wrinkles and bunching of the hose can cause trauma to the skin and constrict blood flow, preventing venous return.

4. Unroll the remainder of each stocking over the lower leg, smoothing wrinkles as the hose are unrolled.
Wrinkles and bunching of the hose can cause trauma to the skin and constrict blood flow, preventing venous return.
5. Ensure that the top of each stocking is 1 to 2 inches below the knee.
Hose that fit correctly do not apply excessive pressure to the area or interfere with circulation.

Follow postprocedure steps I through VI.

Application: Thigh-High Hose

Follow preprocedure steps I through VIII.

1. Follow procedure steps 1 through 4 in the “Application: Knee-High Hose” section.
2. Have the patient bend the knee. Unroll each stocking over the knee, and have the patient straighten the knee. Smooth wrinkles.

STEP 2 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Bending the knee allows easy application of the hose and prevents possible trauma to the skin during application. Wrinkles and bunching of the hose can cause trauma to the skin and constrict blood flow, preventing venous return.

3. Unroll the remainder of each stocking on the upper leg, smoothing wrinkles.
Wrinkles and bunching of the hose can cause trauma to the skin and constrict blood flow, preventing venous return.
4. Ensure that the top of each stocking is 1 to 3 inches below the buttock.
Hose that fit correctly do not apply excessive pressure to the area or interfere with circulation.

Follow postprocedure steps I through VI.

Postprocedure

- I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.
Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.
- II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions. *Disinfection eliminates most microorganisms from inanimate objects.*

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

SKILL 28.5 Sequential Compression Devices

Purpose

- To prevent edema to the lower extremities
- To prevent deep vein thrombosis (DVT) and venous stasis
- To promote venous blood flow
- To prevent pulmonary emboli

Resources

- Sequential compression device (SCD)
- SCD sleeves (knee length or thigh length)
- Tape measure

Interprofessional Collaboration and Delegation

- Applying and removing SCDs may be delegated to unlicensed assistive personnel (UAP) after the nurse has verified proper fitting, completed skin assessment, and ensured proper device function. These checks by the nurse must be performed at least once per shift.
- UAP should report any of the following:
 - Complaints related to pain, application, or fit of the sleeves
 - Sores, wounds, irritations, lesions, edema, redness, or localized warmth in the lower extremities
 - Difficulties in performing the procedure
- UAP should be provided instructions about the following:
 - Appropriate application methods
 - Proper use of the mechanical device, tube connections, alarm settings, and inflation

- sequencing
- Restrictions on removal of SCD sleeves (i.e., SCD sleeves should not be removed for long periods of time)
- Appropriate documentation

Evidence-Based Practice

- Consistency of use of SCDs is important for the immobile patient. Inconsistent use of SCDs is an issue that nurses face. [Brady et al. \(2015\)](#) found adherence to use of SCDs to be approximately 58% even with nurse and patient education. Consistency of use worsened with each successive hospital day during a hospital stay.

Special Circumstances

1. **Assess:** Did the initial fitting of sleeves and measurements fall outside the range listed in the manufacturer's size charts?
Intervention: Notify the primary care provider (PCP); alternative compression devices may be needed.
2. **Assess:** Is there pain, redness, or soreness?
Intervention: Determine whether the sign is new or preexisting.
 - Stop the procedure if the sign is new, and assess for possible DVT or incorrect fit.
 - If the patient has a known DVT, do not apply SCDs.
 - Notify the PCP.
3. **Assess:** What is the patient's neurovascular status at baseline? Check for the following:
 - Toes are warm and pink.
 - The posterior tibial and dorsalis pedal pulses are palpable.
 - Assess for edema or distended veins.
Intervention: Determine whether any unusual neurovascular symptoms are new or preexisting.
 - Stop the procedure if the symptom is new, and assess for a possible DVT or incorrect fit.
 - If a DVT is detected, notify the PCP.
 - Two fingers should fit under the sleeve when it is not inflated; reapply the sleeve if it is too tight or too loose.

- If the sleeve is thigh length, re-measure and determine the correct fit.
4. **Assess:** Does the patient have incisions or open wounds?
Intervention: Determine whether they are new or preexisting.
 - If the incision or wound is draining, cover it with a bandage to avoid the spread of microorganisms to the SCD sleeves.
 - If the wound is new, notify the PCP.
 5. **Assess:** Has only one SCD sleeve been ordered (i.e., for one leg)?
Intervention: Keep the other sleeve in the package and attached to the machine for proper inflation and functioning of the device.
 6. **Assess:** Has the patient complained of warmth, or is there overt perspiration on the leg?
Intervention: Ensure that the cooling control on the device is activated (i.e., it resets to *off* each time the device is turned off). Place a stockinette on the leg to absorb perspiration if antiembolism hose were not ordered in conjunction with the SCDs.
 7. **Assess:** Is an alarm sounding?
Intervention: Ensure that the ankle pressure on the device is set at 35 to 55 mm Hg. Check that all tubing is connected and that the tubing has the arrows correctly aligned with the arrows on the machine at connection. If only one sleeve is being used, verify that the other sleeve is connected and remains in an enclosed space so that it can inflate against something.

Preprocedure

I. Check PCP orders and the patient care plan.

Knowledge of patient-specific orders is critical for safe patient care.

II. Gather supplies and equipment.

Preparing for the patient encounter saves time and promotes patient trust.

III. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

IV. Maintain standard precautions.

Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient, using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Fitting and Application: Knee-High Sequential Compression Device Sleeves

Follow preprocedure steps I through VIII.

1. Raise the bed to working height.
Setting the bed at the correct working height for the provider prevents provider discomfort and possible injury.
2. Measure from the heel to the popliteal space (behind the knee).
This measurement is required for manufacturers' sizing charts. Accurate measurements ensure the correct fit, avoiding patient harm that can occur from estimating sizes.
3. Measure around the widest part of the calf.
This measurement is required for manufacturers' sizing charts. Accurate measurements ensure the correct fit, avoiding patient harm that can occur from estimating sizes.
4. Compare these measurements with the manufacturer's sizing charts.
It is essential to have the correct fit to ensure positive patient outcomes.
5. Place the device on the foot of the bed.
The manufacturer's design prevents possible provider and patient injury.
6. Place the sleeve of the SCD under the patient's leg with the leg resting in the center of the sleeve.

STEP 6

Proper positioning of the SCD sleeve allows proper fit and application, which decreases the risk of constricting the blood flow or diminishing optimal outcomes.

7. Wrap the sleeve around the leg, and fasten it with Velcro straps. Verify that two fingers fit between the leg and the sleeve when the sleeve is not inflated.

STEP 7

The proper fit is necessary when the sleeve is inflated to maximize optimal outcomes and decrease the risk of constricting blood flow.

8. Repeat on the other leg if ordered. If a sleeve has been ordered for only one leg, leave the other sleeve in the package.
The proper fit is necessary when the sleeve is inflated to maximize optimal outcomes and decrease the risk of constricting blood flow.
9. Connect the sleeve tubing for both sleeves to the device. Verify that there are no kinks in the tubing and that the arrows on the tubing align with the arrows on the machine.
Proper connections are needed for the device to function correctly.
10. Turn on the device. Set the cooling control to *on*, and set the alarm to *on*. Ensure that the ankle pressure is 35 to 55 mm Hg.

STEP 10 (Copyright Mosby's Clinical Skills: Essentials Collection.)

The cooling control feature ensures patient comfort and decreases skin irritation and breakdown caused by excess perspiration. The alarm provides safety notification in the event of malfunction.

11. Ensure that sequential inflation is occurring and that the machine is functioning properly.

Proper function of the device optimizes patient outcomes.

Follow postprocedure steps I through VI.

Fitting and Application: Thigh-High Sequential Compression Device Sleeves

Follow preprocedure steps I through VIII.

1. Measure around the thigh at the gluteal fold below the buttocks.
This measurement is required for manufacturers' sizing charts. Accurate measurements ensure the correct fit, avoiding patient harm that can occur from estimating sizes.
2. Measure from the heel to the gluteal fold below the buttocks.
This measurement is required for manufacturers' sizing charts. Accurate measurements ensure the correct fit, avoiding patient harm that can occur from estimating sizes.
3. Measure around the widest part of the calf.
This measurement is required for manufacturers' sizing charts. Accurate measurements ensure the correct fit, avoiding patient harm that can occur from estimating sizes.
4. Compare the measurements to the manufacturer's sizing charts. If a patient's measurements fall between two sizes on the charts, take both sizes of sleeves, and put them on the patient to see which has the better fit.
The correct fit ensures positive patient outcomes. If a sleeve is too small, it will constrict blood flow; if it is too large, it can cause skin irritation and will not promote venous blood return.
5. Place the device on the foot of the bed.
The manufacturer's design prevents possible provider and patient injury.
6. Place the sleeve of the SCD under the patient's leg with the leg resting in the center of the sleeve.

STEP 6 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Proper positioning of the SCD sleeve allows proper fit and application, which decreases the risk of constricting the blood flow or diminishing optimal outcomes.

7. Wrap the sleeve around the leg, and fasten it with Velcro straps. Verify that two fingers fit between the leg and the sleeve when the sleeve is not inflated.

STEP 7 (Copyright Mosby's Clinical Skills: Essentials Collection.)

The proper fit is necessary when the sleeve is inflated to maximize optimal outcomes and decrease the risk of constricting blood flow.

8. Repeat on the other leg if ordered. If a sleeve has been ordered for only one leg, leave the other sleeve in the package.
The proper fit is necessary when the sleeve is inflated to maximize optimal outcomes and decrease the risk of constricting blood flow.
9. Verify that the knee is seen through the opening in the sleeve.
Proper application and fit of the sleeve are needed to decrease the risk of constricting blood flow or diminishing optimal outcomes.
10. Connect the sleeve tubing for both sleeves to the device. Verify that there are no kinks in the tubing and that the arrows on the tubing align with the arrows on the machine.

STEP 10 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Proper connections are needed for the device to function correctly.

11. Turn on the device. Set the cooling control to *on*, and set the alarm to *on*. Ensure that the ankle pressure is 35 to 55 mm Hg.
The cooling control feature ensures patient comfort and decreases skin irritation and breakdown caused by excess perspiration. The alarm provides safety notification in the event of malfunction.
12. Ensure that sequential inflation is occurring and that the machine is functioning properly.
Proper function of the device optimizes patient outcomes.

Follow postprocedure steps I through VI.

Postprocedure

- I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.
Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.
- II. Assess for additional patient needs and state the time of your expected return.
Meeting patient needs and offering self promote patient satisfaction and build trust.
- III. Properly dispose of PPE.
Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.
- IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.
Disinfection eliminates most microorganisms from inanimate objects.
- V. Perform hand hygiene.
Frequent hand hygiene prevents the spread of infection.
- VI. Document the date, time, assessment, procedure, and patient's response to the procedure.
Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Summary of Learning Outcomes

LO 28.1 *Describe the function of the musculoskeletal, neurologic, and cardiopulmonary systems in normal activity and movement:* The musculoskeletal, nervous, and cardiopulmonary systems work together to ensure a person's ability to move and maintain posture, alignment, and balance.

LO 28.2 *Identify changes in the musculoskeletal, neurologic, and cardiopulmonary systems that cause alterations in activity and movement throughout the life span:*

Impairment or injury of any component of the musculoskeletal, nervous, or cardiopulmonary system affects the body's ability to move. Immobility predisposes a person to weakness, decreased muscle tone, decreased bone and muscle mass, muscle atrophy, contractures, increased cardiac workload, decreased lung expansion, urinary stasis, and constipation.

LO 28.3 *Assess the effects of decreased activity and immobility on multiple body systems:* Initial assessment of mobility and patient activity includes observation (i.e., inspection) of the patient's gait and coordination. A fall risk assessment helps ensure patient safety. Neurologic, cardiovascular, nutritional, skin, and psychosocial assessment data as they relate to activity and mobility concerns must be collected.

LO 28.4 *Discuss nursing diagnoses for patients experiencing immobility and impaired levels of activity:* Nursing diagnoses related to activity, immobility, and safe patient movement include *Impaired Mobility, Risk for Fall, and Activity Intolerance*.

LO 28.5 *Generate nursing care goals and outcome criteria for patients with complications from inactivity or immobility:*

Nursing care plans should be developed in collaboration with patients and other health care

professionals to prevent potential complications of immobility.

LO 28.6 *List interventions to enhance patient activity, promote safety, and reverse negative effects of immobility that can be evaluated after implementation:* Specific nursing interventions to encourage exercise, promote safety, enhance lung expansion, prevent deep vein thrombosis, provide adequate nutrition and fluid, maintain skin integrity, and prevent social isolation are necessary to prevent the negative impact of immobility on patients. Safe patient-handling and mobility algorithms have been developed to assist the nurse in promoting safe patient positioning and transfers. Evaluation of treatment interventions for patients who have limited mobility or are confined to bed rest must be based on the attainment of goals and be an ongoing process.

Review Questions

1. An uncooperative 70-year-old male with right-sided paralysis from a recent cerebrovascular accident (CVA) has to be transferred from the bed to a wheelchair. Which action indicates the best method to transfer this patient?
 - a. A two-person lift is performed, with one person on each side of the patient.
 - b. The patient is steadied under the arms and pivoted on his left leg.
 - c. A full-body sling lift is used with the help of unlicensed assistive personnel (UAP).
 - d. A stand assist lift is used with the help of another nurse.
2. After instruction, which action by a patient who can bear weight on both feet indicates an understanding of the proper use of crutches?
 - a. Adjusting the crutches so that they rest directly under the axilla
 - b. Moving the opposing crutch and leg together for a two-point crutch walk
 - c. Using a four-point crutch walk when not weight bearing on the left leg
 - d. Placing the crutches 28 inches forward and then swinging both legs forward
3. What bony prominences are at greatest risk for skin breakdown on a patient who is restricted to bed rest and placed in the side-lying position? (*Select all that apply.*)
 - a. Sternum
 - b. Ears
 - c. Elbows

- d. Hips
 - e. Coccyx
4. Which area of the central nervous system has most likely sustained damage if a patient exhibits a lack of coordination and an unsteady gait after a traumatic head injury?
 - a. Medulla oblongata
 - b. Articular disk
 - c. Brainstem
 - d. Cerebellum
 5. A nurse is providing patient education on the prevention of osteoporosis. Which important fact should the nurse include in the teaching care plan?
 - a. Calcium should be taken with vitamin D to increase calcium absorption.
 - b. African American women are more prone to developing osteoporosis than are Asian American women.
 - c. Increased phosphorus metabolism may lead to bone fragility.
 - d. Aerobic exercise is more advantageous than weight-bearing exercise in preventing osteoporosis.
 6. What nursing intervention would be most effective in preventing flaccidity in a hospitalized patient?
 - a. Early ambulation after surgery
 - b. Administering calcium with vitamin D
 - c. Coughing and deep breathing exercises
 - d. Referring the patient to occupational therapy
 7. Identify all nursing interventions that are necessary when caring for a quadriplegic patient injured 2 years earlier in a motor vehicle accident. (*Select all that apply.*)

- a. Monitoring respiratory status and breathing difficulties
 - b. Assisting with feeding and activities of daily living (ADLs)
 - c. Developing a care plan with the patient's power of attorney
 - d. Using mechanical lifts to assist with transferring the patient
 - e. Placing a gait belt around the patient's waist before ambulation
8. Which discovery found during an admission assessment of a patient transferred from a long-term care facility does the nurse recognize as the result of immobility?
- a. Bilateral elbow contractures
 - b. Increased muscle tone
 - c. Decreased cardiac workload
 - d. Orthostatic hypertension
9. Which nursing diagnosis is a top priority for a patient who is one day status post hip replacement?
- a. *Impaired Health Maintenance*
 - b. *Activity Intolerance*
 - c. *Impaired Mobility*
 - d. *Self Care Deficit*
10. After application of sequential compression devices (SCDs) on a patient, what assessment finding is essential for the nurse to include in documentation?
- a. Warmth of bilateral upper extremities
 - b. Lower extremity circulatory status
 - c. Circumoral cyanosis
 - d. Bowel sounds

CHAPTER 29

Skin Integrity and Wound Care

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 29.1 Describe the normal structure and function of skin.
- LO 29.2 Review the factors that alter the skin's structure and function.
- LO 29.3 Discuss the components of a focused skin and wound assessment, including the use of risk assessment tools.
- LO 29.4 Identify appropriate nursing diagnoses for the patient with impaired skin integrity.
- LO 29.5 Develop measurable patient-centered goals for patients with impaired skin integrity.
- LO 29.6 Select interventions to prevent and treat impaired skin integrity that can be implemented then evaluated.

KEY TERMS

- abnormal reactive hyperemia, p. 599**
- acute wound, p. 594**
- approximated, p. 594**
- bioburden, p. 612**
- capillary closing pressure, p. 597**
- chronic wound, p. 594**
- clean contaminated wound, p. 594**
- clean wound, p. 594**
- closed wound, p. 593**
- colonized wound, p. 594**

Case Study

Patrick Jamison (P. J.) is a 64-year-old male with a 30-year history of multiple sclerosis (MS). He worked as a high school math teacher until 8 years ago, when his deteriorating health necessitated early retirement. His wife has taken a part-time job to supplement their income from his pension. P. J. is alert and oriented $\times 3$ and able to move all extremities with noted weakness. He is incontinent of urine and stool and uses adult briefs. With assistance from his son, who lives nearby, or his wife, P. J. can sit on a chair but tends to slide down. He requires assistance with meals, tires easily, and rarely finishes 50% of a meal. P. J. expresses sadness over his declining health and the “burden” that it places on his family, both physically and financially.

He is admitted to the unit with the diagnosis of a urinary tract infection (UTI). He has no known drug allergies. He is 177.8 cm (70 in) tall and weighs 60 kg (132 lb). His albumin is 2.5 g/dL, and his prealbumin is 15 mg/dL. Upon admission his vital signs are T 38.3° C (101° F), P 110 regular and thready, R 28 and labored, and BP 110/60, with a pulse oximetry reading of 94% on room air. Physical assessment reveals a wound on P. J.'s right hip that measures 5.5 cm in length and 5 cm in width, with bone palpable along the medial edge. The periwound skin is intact. The wound has been treated at home with normal saline-moistened gauze that is changed once or twice a day. P. J. states that the wound has been present for more than 3 months and “it just doesn't get better.” The gauze dressings are saturated by green-tinged exudate in 3 hours, with a slight foul odor. A 2 cm-by-2 cm area of redness also is present on his left heel that does not blanch when pressure is applied.

P. J. is diaphoretic and appears anxious. He states, “I can't turn myself! Who will take care of me here? I hurt all over but especially my hip!” He rates his pain at 6 of 10 in the right hip and states that the pain is sharp and continuous, but worsens with movement.

Treatment orders are as follows:

- Pressure-reducing bed surface; turn every 2 hours
- Regular adult diet
- Up in chair that has a gel pad seat twice daily with assistance
- Vital signs (VS) every 4 hours
- Dietary consult

Medication orders are as follows:

- Intravenous (IV) infusion of dextrose 5% (D₅) in 0.45% normal saline (NS) at 125 mL/hr
- Ceftriaxone 1 g intravenous piggyback (IVPB) once daily
- Acetaminophen 650 mg per os (by mouth; PO) every 6 hours as needed for a temperature >38° C (101° F) or mild pain

Refer back to this case study to answer the critical-thinking exercises throughout the chapter.

Knowledge and understanding of the structure and function of the skin and wound healing, as well as the factors influencing processes involved, are essential for the nurse. Alterations in skin integrity can have a tremendous impact on the physical and psychological well-being of the affected person. Although some changes to the skin structure are inevitable secondary to the aging process, the patient and the health care provider can implement measures to protect the skin from harm and to promote wound healing in the event of injury.

LO 29.1 Normal Structure and Function of Skin

Skin is a part of the body that many take for granted, yet it is a complex and vital organ. The skin, the largest organ of the body, weighing more than 6 pounds, has many important functions that are essential for overall health. It is involved in thermoregulation through its ability to dilate and constrict blood vessels, allowing for heat to be released or retained by the body. This ability of the skin to change the size of blood vessels and produce perspiration in response to changes in internal and external temperatures assists in the maintenance of a steady body temperature. The skin has a major role in sensation, giving tactile feedback from the surrounding environment. The sensitivity of the skin as a sensory organ allows us to feel something as personal as the touch of a loved one and identify objects without the aid of sight. The skin alerts us to potential danger through its ability to transmit the sensations of pressure, pain, and temperature extremes. The skin is involved in the production of vitamin D in the presence of sunlight, works to rid the body of waste products, and is essential in fluid and electrolyte regulation. Intact skin serves as an effective barrier to environmental hazards (such as ultraviolet light, chemicals, and the microbes or pathogens commonly on the skin surface), preventing them from entering the body. The skin's normally acidic pH provides a protective mechanism against pathogens. In addition to its physiologic functions, the skin is part of each person's self-perception and is intricately connected to personal and cultural identity, body image, and self-expression.

It is important to understand the normal anatomy of the skin. The skin is composed of three main layers: the epidermis, the dermis, and the subcutaneous layer (Fig. 29.1). Each layer has its own functions and unique characteristics.

FIGURE 29.1 Cross section of the layers and structures of the skin.

Epidermis

The **epidermis** is the outermost layer of the skin and the thinnest of the layers. Despite its lack of a blood supply, it has the ability to regenerate every 4 to 6 weeks. The epidermis can be subdivided into five more layers: the stratum corneum, stratum lucidum, stratum granulosum, stratum spinosum, and stratum germinativum or basale.

The outermost of the epidermal layers is the **stratum corneum**, which is made up of flattened dead cells. These are the flakes of skin that are seen being removed during normal bathing or with rubbing. Even though the cells themselves are dead, this layer is very important to the skin's roles of providing protection from outside dangers and regulation of fluids and electrolytes. The middle three layers, each of which is one to five cells thick, provide for a transition from the stratum germinativum, or basale, to the stratum corneum and help in the reduction of friction and shear. The innermost layer, the **stratum germinativum**, or basal layer, consists of a very active single layer of cells. This layer constantly produces new cells that are pushed upward through the other layers of the epidermis toward the stratum corneum, where they flatten, die, and are eventually sloughed off and replaced by new cells. The protein, keratin, is synthesized in the stratum germinativum and is found throughout the layers of the epidermis as the cells migrate outward. Keratin gives the skin strength and flexibility

and allows the skin to repair itself. Melanin, which gives the skin its distinctive and unique color and provides protection from ultraviolet light, and Langerhans cells, which are involved in the digestion of bacteria and in the immune system's response to foreign materials, are also found in the epidermis.

Dermis

The **dermis**, lying between the epidermis and the deeper subcutaneous layer, is much thicker than the epidermis, although this thickness varies depending on the part of the body. For example, the skin on the soles of the feet is thicker than that on the fingertip or eyelid. The epidermal and dermal layers are joined to each other by the basal membrane.

Extending up from the dermis are irregular, interconnected projections that link with the epidermis above (Fig. 29.2). These projections, known as **rete ridges**, or the **papillary dermis**, provide the “stick” that anchors these layers of the skin together, preventing them from sliding back and forth. The connective tissue contained in the dermis, with its elastin and collagen fibers, provides strength and elasticity that is characteristic of the skin, while its abundant vascular system provides the necessary oxygen and blood. Embedded in the dermis are sebaceous glands, sweat glands, hair and nail follicles, nerves, and lymphatics.

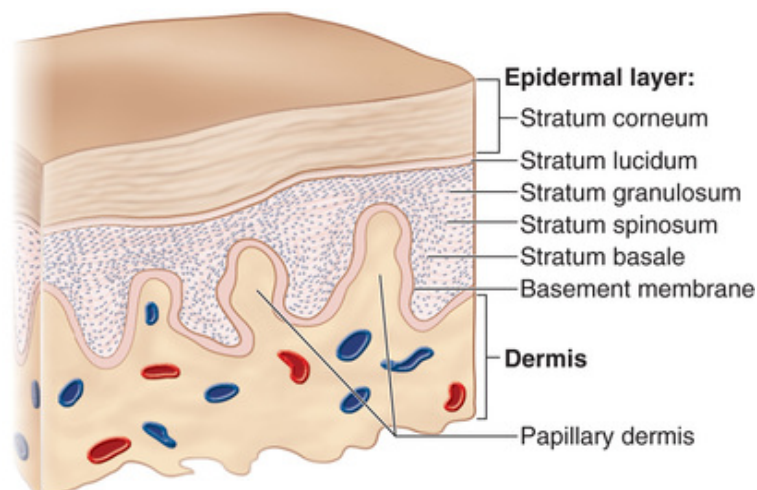

FIGURE 29.2 Epidermis and dermis.

Subcutaneous Layer

The **subcutaneous layer** is a layer of adipose tissue, or fat, that, in addition to attaching the dermis to the underlying muscles and bone, delivers the blood supply to the dermis, provides insulation, and has a

cushioning effect. The size of this layer varies depending on the body location and person's weight, sex, and age.

Factors Affecting Skin Integrity

Many different factors can affect the body's ability to maintain intact and healthy skin. **Wounds**, which are disruptions that may occur in the skin's integrity, lead to a loss of the skin's normal functioning. Other factors contribute to the development of wounds and lead to delays in wound healing. Vascular disease is a comorbid condition which impairs the skin's ability to obtain required oxygen and nutrients. Diabetes, another comorbid condition, affects not only the microvasculature but also the skin's normally acidic pH. Other examples of factors that contribute to wound complications are malnutrition involving inadequate proteins, cholesterol, fatty acids, vitamins and minerals; steroids, nonsteroidal antiinflammatory drugs (NSAIDs), anticoagulants, and other medications; excessive moisture; and external forces (such as, pressure, shear, and friction).

One significant factor influencing skin integrity and wound healing is the aging process. As people age, it is more likely that they will have some comorbidity (such as diabetes or cardiovascular disease), take medications that affect the skin, and exhibit damage to skin from ultraviolet light exposure over the years. Additionally, aging dramatically affects the appearance and functioning of the skin. Aging is associated with thinning of the epidermis, dermis, and subcutaneous layers, with a resultant reduction in elastin, collagen fibers, sweat glands, and sebaceous glands. These changes lead to sagging or wrinkling of the skin and to the dry, paper-thin appearance of skin often seen in elderly people. It contributes to a reduction in the skin's ability to serve as both insulation and cushioning, thereby increasing vulnerability to trauma and temperature extremes characteristic of this population. A loss of melanocytes after age 40 leads to the graying of hair and an increased susceptibility to the development of skin cancers. With the decrease in number of Langerhans cells with aging, a corresponding decrease occurs in resistance to infection. Finally, the rete ridges—those interconnected projections that keep the epidermal and dermal layers connected—begin to flatten, making the skin more susceptible to mechanical trauma, shearing forces, and tears from even minor injury. **Medical adhesive-related skin injuries (MARSIs)** occur when superficial layers of skin are removed by medical adhesive, in which erythema and/or other manifestation of skin trauma or reaction including formation of vesicles, bulla, skin erosion, and epidermal tears, persist longer than 30 minutes after removal of the adhesive. MARSIs not

only affects skin integrity but also causes pain, increases risk of infection, potentially increases wound size, and delays healing.

1. Identify risk factors for P. J. that may cause further pressure injury development or delayed wound healing.

Safe Practice Alert

Remove products with a strong adhesive backing, such as that found in tapes and adhesive dressings, carefully from the elderly person's skin to prevent stripping of the epidermis.

LO 29.2 Altered Structure and Function of the Skin

Given the many functions of the skin, any alteration in the integrity of the skin can have dramatic implications for general health and well-being. The nurse is in a unique position to assess skin, implement interventions designed to promote the integrity of the skin, and carry out actions to promote the healing of any wounds. If a wound is identified, an additional assessment of the wound takes place. It is important to understand the different ways in which wounds are classified and the normal phases of the wound healing process.

Wound Classification

There are many ways to classify wounds. They can be labeled according to the underlying cause; for example, the terms *diabetic ulcer*, *arterial ulcer*, and *pressure injury* are used to describe wounds. The same wounds could be classified more broadly by a basic description of the integrity of the skin and referred to as either *open* or *closed* wounds. Wounds are also classified on the basis of wound depth and are termed *superficial*, or *partial thickness*, versus *deep*, or *full thickness*. The presence of **infection** or contamination in the wound, or the length of time that it is taking for the wound to heal, results in the terms *chronic* and *acute*. For the nurse, it is important to understand what these terms mean and to see where they overlap to better communicate both with the patients and with other members of the health care team.

Skin Integrity

An **open wound** is characterized by an actual break in the skin's surface. For example, an abrasion, a puncture wound, and a surgical incision are types of open wounds. Some chronic wounds, like those frequently seen resulting from pressure or vascular diseases, can be open wounds. In a **closed wound**, as seen with bruising, the skin is still intact. Although any wound that is open puts the patient at greater risk for infection from outside organisms, a closed wound does not necessarily indicate a more benign condition. Some injuries first occur below the level of the skin, such as pressure-related injuries or fractured bones, and the integrity of the skin is not a good indicator of the severity of the underlying tissue damage.

Wound Depth

A **superficial wound** involves only the epidermis, whereas a **partial-thickness wound** involves the epidermis and the dermis but does not extend through the dermis to the subcutaneous layer. These wounds tend to heal quickly, leaving no scar, unless other outside factors delay the normal healing process. A deeper wound, or **full-thickness wound**, extends through the dermis to the subcutaneous layer and may extend farther, to the muscle, bone, or other underlying structures. Full-thickness wounds tend to heal slowly and leave scarring, and they are more likely to become chronic in nature.

Amount of Contamination

On the basis of the degree of contamination, wounds can be classified as clean, clean contaminated, contaminated, infected, or colonized. A **clean wound** is one in which there is no infection and the risk for development of an infection is low. For example, a closed surgical incision made in the controlled, sterile environment of the operating room that does not involve bacteria-containing organ systems is considered a clean wound. A **clean contaminated wound** is similar to a clean wound, but because the surgery involves organ systems that are likely to contain bacteria, the risk for infection is greater. **Contaminated wounds** result from a break in sterile technique during surgery; from the perforation of an organ (such as the colon, small bowel, or appendix) before surgery, which allows for spillage of bacteria-laden material into the wound; or from certain types of trauma or accidents, such as penetrating trauma or a fall. These wounds have a higher risk of infection than clean contaminated wounds. An **infected wound** shows clinical signs of infection, including redness, warmth, and increased drainage that may or may not be purulent (contain pus), and has a bacterial count in the tissue of at least 10^5 per gram of tissue sampled when cultured (Fig. 29.3). In a **colonized wound**, one or more organisms are present *on the surface* of the wound when a swab culture is obtained, but there is no overt sign of an infection in the tissue below the surface. Colonization is common in chronic wounds and may contribute to delayed wound healing.

FIGURE 29.3 An infected wound. (© Thinkstock.com.)

Healing Process

A wound that progresses through the phases of wound healing in a rapid, uncomplicated manner is an **acute wound**. Wounds such as surgical incisions or traumatic wounds in which the edges of the wound can be **approximated** (brought together) to heal are examples of acute wounds. This type of wound is said to heal by **primary intention**.

Wounds that heal by primary intention tend to heal quickly and result in minimal scar formation. By contrast, a **chronic wound** fails to progress to healing in a timely manner, often remaining open for an extended period of time. Chronic wounds commonly heal by **secondary intention**. When a wound heals by secondary intention, new tissue must fill in from the bottom and sides of the wound until the wound bed is filled with new tissue. Such wounds are often associated with disease processes (such as diabetes or vascular disease) or with other factors that have inhibited proper wound healing.

In some situations, it is necessary to initially leave a wound open for a period of time after an injury. For example, if contamination occurs during surgery, as can happen in surgeries involving the gastrointestinal tract, the wound may at first be left open to allow for observation and better wound drainage. Later, when the danger of infection is judged to be less, the edges of the wound may be pulled together to achieve closure. When a delay occurs between injury and closure, the wound healing is described as **tertiary intention**.

Phases of Wound Healing

The classification of a wound is important in selecting an appropriate treatment regime and in educating the patient on ways to better heal an existing wound or to prevent a recurrence. The actual phases of wound healing are the same for all full-thickness wounds regardless of type or causation. The three phases of healing are the inflammatory phase,

which includes the process of homeostasis, the proliferative phase, and the maturation phase.

Inflammatory Phase

The **inflammatory phase** of healing begins with the body's initial response to wounding of the skin and lasts about 3 days. With the initial injury to the skin, bleeding occurs, which triggers what is known as the *coagulation cascade* and the formation of a clot to stop the bleeding. This process is an important way of preventing blood loss because of the release of numerous growth factors by the platelets involved in clot formation. These growth factors, along with cytokines, which are released during the inflammatory phase, play an important role in wound healing. During the inflammatory phase, there is an increase in pain, redness, warmth, and swelling in the injured area as the blood vessels dilate and leak fluid to the tissue surrounding the injury. Macrophages and neutrophils are drawn to the site of injury and begin the process of cleaning the wound of bacteria and debris. At the end of this phase, the wound bed is clean and ready to begin the actual repair process.

Proliferative Phase

The events of the **proliferative phase** of healing are repair of the defect, filling in the wound bed with new tissue (called *granulation tissue*), and resurfacing the wound with skin. This phase usually lasts several weeks, but it can be shorter with a surgically closed wound—healing by primary intention—or significantly longer if the wound is large or left to heal by secondary intention. The proliferative phase involves the development of new blood vessels (a process known as *angiogenesis*) that are needed to support the new tissue, collagen synthesis, wound contraction, and epithelialization. The key cells in this phase of wound healing are the fibroblasts, which produce growth factors, synthesize the collagen and proteins needed to form granulation tissue, promote angiogenesis, and are thought to work to contract the edges of the wound, thereby reducing the amount of granulation that needs to be produced. **Granulation tissue**, the new tissue created to fill the wound, is beefy red in appearance because of the many newly created blood vessels. This new tissue bleeds easily and has a granular, or “bumpy,” texture (Fig. 29.4). It consists of an immature type of collagen, the strength of which is only about 20% of that of mature collagen, making it more susceptible to injury. Finally, in this phase, epithelial cells proliferate and migrate laterally from the edges of the wound, across the moist granulation tissue, until the wound has been resurfaced with

epithelial cells and the normal layers of the skin are reestablished. The need of epithelial cells to migrate across a moist, vascular wound bed is the basis for many of the moist wound dressings used today to support and promote wound healing.

FIGURE 29.4 Granulation tissue. (From Bryant, R. A., & Nix, D. P. [2016]. *Acute and chronic wounds* [5th ed.]. St. Louis: Elsevier.)

Maturation Phase

The last phase of wound healing, the **maturation phase**, is known as the *remodeling phase* and can last up to a year. During this time collagen continues to be deposited and remodeled, and scar tissue is formed and strengthens. **Scar tissue** is an avascular mass of collagen that gives strength to the repaired wound. However, the strength of the scar is never equal to that of unwounded tissue, achieving only about 80% of its previous tensile strength.

Factors Affecting Wound Healing

As stated earlier, many of the same factors that affect overall skin integrity will significantly affect the ability of the skin to heal once injured. Factors include disease processes, age, infections, and nutrition.

Oxygenation and Tissue Perfusion

All cells in the body need oxygen to function properly. Specifically, chronic tissue hypoxia is associated with a reduction in collagen formation, a decrease in the action and proliferation of fibroblasts, a reduction in leukocytes, and an impairment of the cell's ability to migrate. Any condition that affects the body's ability to perfuse the tissue with an adequate amount of oxygen will adversely affect wound healing. Therefore comorbid conditions (such as heart disease, peripheral vascular disease, and pulmonary disease) can lead to a

prolongation of the healing process. Smoking, even before lung damage has occurred, is a huge risk to successful wound healing. Smoking impairs the hemoglobin's ability to carry oxygen. The nicotine in cigarettes causes vasoconstriction and increased coagulability of the blood, reducing the body's ability to circulate oxygen.

Diabetes

According to the [American Diabetes Association \(2018\)](#), in 2015 more than 23.1 million people in the United States alone had been diagnosed with diabetes mellitus. An additional 84.1 million Americans were termed *prediabetic*, and an estimated 7.2 million had diabetes but had not yet been diagnosed. In view of the impact of diabetes on wound healing, this is a significant factor to consider in assessing a patient with a wound. Diabetes causes changes in the microvascular and macrovascular systems, leading to a thickening of the vessel wall and occlusion of blood flow with decreased supply of needed nutrients and oxygen. For a patient with diabetes, the presence of a wound is accompanied by a reduction in collagen synthesis, a decrease in the strength of that collagen, impaired functioning of leukocytes, and a reduction in the number and action of macrophages.

Nutrition

Adequate nutrition is essential for wound healing to occur. With any injury, including any surgical procedure, the body requires additional energy to recover and heal from the injury. Although overall caloric needs increase, sometimes by more than 100%, depending on the severity of the injury, the need for protein increases disproportionately. Protein is needed by the fibroblasts for the purpose of synthesizing collagen. In addition, deficiencies in vitamins C and A, and the trace minerals zinc and copper, have been found to have a significant impact on wound healing. Many patients enter the health care system in a malnourished state; others become depleted nutritionally because of illness, surgery, or medical treatments. An adequate, ongoing assessment of the patient's nutritional status is an essential component of the overall plan for wound healing. Refer to [Chapter 30](#) for more information on the importance of nutrition in wound healing.

Age

Although an older person can heal from wounds, the aging process affects all phases of wound healing. With increasing age, the entire inflammatory response is decreased or delayed; the action of the

macrophages and fibroblasts is reduced, resulting in a decrease in collagen synthesis and a slowing of the epithelialization of the wound. Due to these physiologic factors, in addition to the increased frequency of comorbid conditions, the elderly patient is at higher risk for poor outcomes related to wound healing.

Infection

Infection is both a cause of delayed wound healing and a complication of impaired wound healing. A wound that is left open, or is contaminated, is at increased risk for invasion by additional pathogens. (The signs of an infected wound are discussed earlier, in the “Amount of Contamination” section.) Once a wound is infected, the infection causes a prolongation of the inflammatory phase, delays collagen synthesis, prevents epithelialization, and can lead to additional tissue destruction. Infection contributes to failure of the wound to progress through the normal phases of healing and to the development of chronic wounds. Any wound that shows no progress toward healing despite appropriate treatment should be assessed for an underlying infection and treated aggressively for infection if present.

Complications of Wound Healing

Complications of wound healing, in addition to the failure to heal in a timely manner, include dehiscence, evisceration, and fistula formation. These complications lead to an increased length of stay in a health care setting, additional costs for both the health care system and the affected patient, and increased pain and suffering.

Dehiscence and Evisceration

Dehiscence, which usually occurs in connection with surgical incisions, is the partial or complete separation of the tissue layers during the healing process. **Evisceration** is the total separation of the tissue layers, allowing the protrusion of visceral organs through the incision. People at risk for these complications are the same patients who are at risk for delayed or impaired wound healing. In addition, coughing, vomiting, or straining puts additional stress on the healing tissue, increasing the risk of dehiscence and evisceration. These complications usually occur 5 to 9 days after surgery and are related to a delay in collagen synthesis. If a wound is healing properly, a 1-cm-wide ridge, or area of induration, can be palpated next to the incision line. This ridge is indicative of the new collagen being laid down in the wound. If this “**healing ridge**” is not felt, the wound is at increased risk for dehiscence and evisceration.

Symptoms include a “popping” sensation accompanied by an increase in drainage from the wound. Nursing interventions include teaching the patient to “splint” the incision with a pillow or folded blanket or to use an abdominal binder for comfort while coughing and deep breathing and during movement (Fig. 29.5). If dehiscence or evisceration occurs, cover the wound with gauze moistened with a sterile normal saline and notify the physician immediately. Although small areas of dehiscence can sometimes be treated without additional surgery, large dehiscent wounds and eviscerations can require emergency surgery. See [Chapter 37](#) for more information about dehiscence and evisceration.

FIGURE 29.5 A, Abdominal binder. B, Splinting. (A, Courtesy Dale Medical Products, Plainville, MA.)

Fistula Formation

A fistula is an abnormal connections between two internal organs or between an internal organ and, through the skin, the outside of the body. The organs involved can be identified by the name of the fistula. For example, an enterovaginal fistula involves an opening between the intestine (entero) and the vagina, allowing intestinal content to drain into the vagina. An enterocutaneous fistula is an opening between the intestine (entero) and the skin (cutaneous). Fistulas usually are the

result of a specific disease process such as that in certain cancers and Crohn disease, treatment modalities (such as radiation), or any of the factors implicated in poor wound healing. Fistulas predispose the affected person to fluid and electrolyte loss, nutritional deficits, and alterations in skin integrity. This is particularly true if the fistula is draining material that is naturally destructive to the skin's surface. For example, exposure to the digestive enzymes normally found in fluids from the small intestine or pancreas can cause extensive damage to the skin in a short time.

Burns

Burns are tissue injuries to the skin caused by heat, electricity, chemicals, radiation, extreme cold, or friction. Burns can be superficial, causing damage to only the epidermis, with resulting pain and erythema. Partial-thickness burns destroy the epidermis and part or all of the dermis, causing blistering and pain. Full-thickness burns destroy the epidermis, dermis, and part of the subcutaneous tissue. These severe burns cause the area to be white or brown, charred, and without sensation. They cannot heal without surgery. When burns occur over a large percentage of the body, the patient is at risk for severe fluid and electrolyte disturbances. These disturbances are considered further in [Chapter 39](#).

Pressure Injury

According to the [Agency for Healthcare Research and Quality \(2014\)](#), it is estimated that every year pressure injuries affect up to 2.5 million patients in the United States, with a total cost ranging from \$9.1 to \$11.6 billion per year. In addition to the pain and suffering incurred by affected patients, the injuries contribute to an estimated 60,000 deaths. In 2008, Medicare stopped reimbursing many hospitals and other health care facilities at higher reimbursement levels for conditions deemed “reasonably preventable” on the basis of existing evidence-based guidelines. One such condition is hospital-acquired pressure injuries. These facts are an impetus for developing effective prevention and treatment protocols. The development and implementation of these protocols are of great concern to nursing. Nursing plays a critical role in the identification of patients at risk for this complication, and many independent nursing actions have a direct impact on the prevention of pressure injuries and their ultimate resolution. Following three evidence-based practice steps is key to pressure injury prevention.

- Determine each patient's risk level through assessment with a reliable tool.
- Reduce pressure on bony prominences using nursing interventions discussed in the Intervention and Evaluation section of this chapter.
- Improve pressure tolerance of the patient's skin by ensuring that the patient is well nourished, and that the skin is dry, intact, padded, and perfused (Black, 2018).

Pressure injuries were previously known as pressure ulcers and are sometimes referred to as *bedsores* or *decubitus ulcers*. However, the term *pressure injury* more closely reflects the underlying etiology of the wound. A **pressure injury** is damage to the skin in an area that may include soft tissue damage and is usually found over bony prominences. It can also occur from pressure on the body from medical devices (European Pressure Ulcer Advisory Panel and National Pressure Ulcer Advisory Panel, 2014). The injury can present as intact skin or an open ulcer and may be painful. Although these lesions most commonly occur over bony prominences (such as the sacrum, ischium, trochanter, and heel) (Fig. 29.6), any part of the body that is subjected to pressure can be affected, including the areas under casts and wraps.

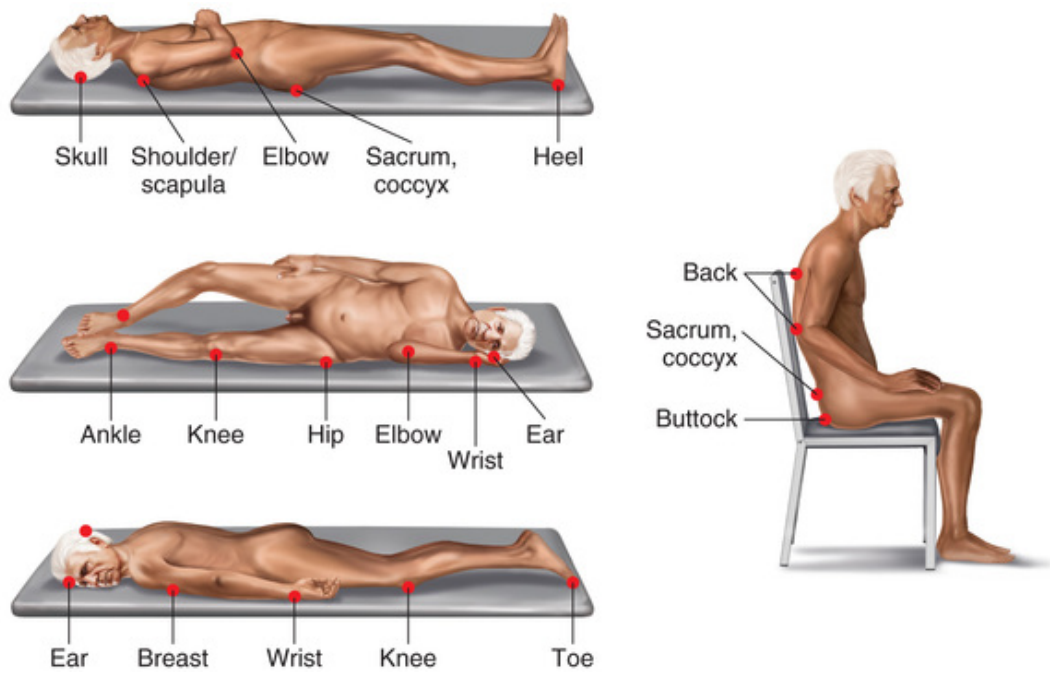

FIGURE 29.6 Sites of pressure injuries.

The primary cause of pressure injuries is, as the name suggests, pressure. The injury mechanism is more than just pressure, however; specific factors include the intensity of the pressure, the length of time that the tissue is subjected to the pressure, and intrinsic and extrinsic factors that affect the tissue's ability to withstand or tolerate that pressure.

Intensity of Pressure

The terms **capillary closing pressure** and **critical closing pressure** refer to the minimum pressure required to collapse a capillary. With the collapse of the capillary walls, blood flow to the tissue is impaired, leading to tissue hypoxia and cell death. Although the measurement of capillary closing pressure is difficult to achieve, it generally is accepted to be 12 to 32 mm Hg. This value usually is exceeded in anyone seated in a chair or lying on a hard surface, yet there is no tissue damage. Normally, pain is felt when tissue ischemia occurs, and this pain prompts a position shift, relieving the pressure and restoring the flow through the capillaries. If the pressure is not relieved, because the person is either unable to move or unable to sense the warning signal of pain, the ischemia leads to tissue damage and the development of an actual pressure injury. It has been found that subcutaneous and muscle tissues are more susceptible to the effects of pressure than other tissues, including the epidermis and dermis (European Pressure Ulcer Advisory Panel and [National Pressure Ulcer Advisory Panel, 2014](#); [Edsberg, Black, Goldberg, et al., 2017](#)). With pressure-related injuries, the damage

occurs first in the subcutaneous and muscle layers, and the degree of damage may not be readily observable on initial assessment of the skin condition.

Duration of Pressure

It has been found that low levels of pressure over long periods of time can be as damaging to the skin and underlying tissue as high levels of pressure over a short period of time. Pressure seems to have a cumulative effect on the tissue. Thus, once a tissue has been exposed to pressure, even if the pressure is then removed, later reexposure of that tissue to the same or even less pressure may result in considerable damage.

Medical Devices

Patients who have medical devices (such as oxygen tubing, a nasogastric [NG] tube, oxygen sensor probes, a continuous positive airway pressure [CPAP] mask, or trach ties) are at risk for **medical device–related pressure injuries**. These type of injuries result from the use of devices designed and applied for diagnostic or therapeutic purposes. The injury generally conforms to the pattern or shape of the device. Those at risk include anyone with a medical device but particularly those in acute care, critical care, long-term care, and home care. It is important to use medical devices according to manufacturer recommendations. Also, ask the patient if the device is too tight or if it hurts. Inspect the skin under the medical device at least twice daily, ideally more frequently. When not in use, remove devices that have pressure potential. If possible, place a prophylactic dressing under the device.

Friction and Shear

Friction is the rubbing together of two surfaces—in this case, the skin and the bed or some other surface that the skin is in contact with. Friction by itself damages the epidermal layer but does not cause damage to the deeper structures ([National Pressure Ulcer Advisory Panel, 2016a](#)). The real danger of friction comes from the relationship between friction and gravity and the resultant phenomenon of **shear**. The classic example of friction that results in shear is the clinical scenario in which a patient “slides” down in bed as the head of the bed is elevated. The friction encountered by the skin as it slides over the bed surface leads to a “sticking” of the skin to the bed linens while the body's weight continues to pull the person downward ([Fig. 29.7](#)). These

opposing stresses on the skin result in hyperangulation and stretching of the blood vessels, damaging them and their ability to transport blood. Shear is thought to significantly contribute to the development of pressure injuries, particularly in areas routinely subjected to both pressure and shear: the sacrum and coccyx. Use of mechanical lifts to move immobile patients, discussed in [Chapter 28](#), helps reduce injuries due to friction and shear.

FIGURE 29.7 Friction and shear.

Sensory Loss or Immobility

Patients who are unable to feel pain (the warning sign of tissue ischemia), unable to respond appropriately, or limited in their ability to move or maintain their position independently are at increased risk for the development of pressure injuries. This risk group includes patients with neurologic conditions (such as spinal cord injury or advanced multiple sclerosis); those with chronic conditions that lead to neuropathies, as seen in diabetes; patients with dementia or brain injury; and those who, because of medical interventions (such as the use of traction and restraints), are unable to reposition themselves independently.

Moisture

Moisture-associated skin damage (MASD) is the general term for inflammation or skin erosion caused by prolonged exposure to a source of moisture (such as urine, stool, sweat, wound drainage, saliva, or mucus). Incontinence is thought to contribute to the development of pressure injuries because of the effects of **maceration**, a condition in

which excessive moisture causes a softening of the skin. However, more recent studies show that while the skin may become macerated, and the enzymes found in stool can lead to perineal inflammation and dermatitis known as **incontinence-associated dermatitis (IAD)**, the damage from moisture is confined to the more superficial layers ([National Pressure Ulcer Advisory Panel, 2016a](#)).

Nutrition

Proper nutrition, as already discussed, is essential for wound healing. Inadequate nutrition is implicated in the development of pressure injuries. Patients at risk for nutritional deficits include those who are unable or unwilling to feed themselves or to take in enough nutrients to meet their metabolic requirements. When inadequate nutrition results in an unintentional weight loss of 5% or more; a low body mass index (BMI); deficiencies in vitamins A, C, and E and the minerals zinc and copper; and protein-calorie malnutrition, the ability of the tissue to withstand the forces of pressure and shear and to combat infectious agents is compromised ([Taylor, 2017](#)). A thorough nutritional assessment including an evaluation of weight and recent changes in weight, BMI, diet history, and pertinent laboratory findings (including serum albumin, serum prealbumin, nitrogen balance, and other measures) is an essential first step in preventing the development of pressure injuries while promoting healing of those already present. Collaboration with a registered dietitian and other members of the health care team, as well as the patient and family members, is needed in the development of a plan to address the nutritional needs of the at-risk patient. This plan must be consistent with the overall plan of care and the wishes of the patient and family.

For all of the reasons already discussed, the elderly population is at increased risk for developing pressure injuries, and such lesions, if they occur, will be slower to heal. The combination of comorbid conditions (such as diabetes and peripheral vascular disease), medication use, exposure to sun, and the changes in skin characteristics inherent in aging makes the elder population highly vulnerable to impaired wound healing.

Classification of Pressure Injuries

Pressure injuries are classified, or staged, according to the type of tissue visible in the wound bed. Although this classification system has been used for other types of wounds, it is designed for use in the description of pressure injuries. The system was first introduced in 1975 and most recently modified in 2016. There are slight differences in the way the

stages are defined by the European Pressure Ulcer Advisory Panel (EPUAP) and by the National Pressure Ulcer Advisory Panel (NPUAP). The injury classification system requires knowledge of the different tissue types seen in a wound and the ability to accurately identify those tissue types. Because this knowledge often is lacking in health care practitioners, confusion and disagreement may arise regarding the stage of the wound being evaluated. If the wound is filled with necrotic tissue, accurate identification of the underlying tissue type is not possible, so the wound cannot be staged. Questions also can arise about the underlying etiology of a wound. For example, it can be difficult to differentiate a superficial wound resulting from a tape tear, friction, or incontinence from a stage 2 pressure injury secondary to pressure. Despite these limitations, staging of pressure injuries is the accepted method for describing tissue damage caused by pressure.

Stage 1 Pressure Injury: Non-Blanchable Erythema of Intact Skin

A **stage 1 pressure injury** is characterized by *intact*, nonblistered skin with nonblanchable erythema, or persistent redness, in the area that has been exposed to pressure (Fig. 29.8). The redness is called **abnormal reactive hyperemia** and is due to excessive vasodilation caused by pressure. When the area is pressed lightly with a finger, it does not blanch but instead remains red. When the redness blanches, or turns white, with gentle fingertip pressure, normal reactive hyperemia is occurring owing to vasodilation, and the redness will disappear. Such changes can be difficult to see in darkly pigmented skin, so the definition was expanded to include an area that is painful and differs in firmness (either softer or firmer) or in temperature (warmer or cooler) from the surrounding tissue (EPUAP and NPUAP, 2014).

FIGURE 29.8 Stage 1 pressure injury. (Used with permission of the National Pressure Ulcer Advisory Panel. Copyright NPUAP.)

Stage 2 Pressure Injury: Partial-Thickness Skin Loss With Exposed Dermis

A partial-thickness wound that involves the epidermis and/or dermis but does not extend below the level of the dermis is called a **stage 2 pressure injury**. It is shallow and superficial, with a pink wound bed (Fig. 29.9). Intact or ruptured blisters that are the result of pressure also are considered to be stage 2 pressure injuries.

FIGURE 29.9 Stage 2 pressure injury. (Used with permission of the National Pressure Ulcer Advisory Panel. Copyright NPUAP.)

Stage 3 Pressure Injury: Full-Thickness Skin Loss

Stage 3 pressure injuries are full-thickness wounds that extend into the subcutaneous tissue but do not extend through the fascia to muscle, bone, or connective tissue (Fig. 29.10). There may be undermining or tunneling present in the wound. **Undermining** is an area of tissue loss

present under intact skin, usually along the edges of the wound, forming a “lip” around the wound. A **tunnel** or **sinus tract** is similar to an undermining but is a narrower passageway extending outward from the edge of the wound. Although a stage 3 pressure injury is described as a deeper wound than a stage 2 pressure injury, the degree of depth is dependent on the location of the wound and the amount of subcutaneous tissue present. For example, far less subcutaneous tissue is present on the heel or back of the head than on the hip or shoulder.

FIGURE 29.10 Stage 3 pressure injury. (Used with permission of the National Pressure Ulcer Advisory Panel. Copyright NPUAP.)

Stage 4 Pressure Injury: Full-Thickness Skin and Tissue Loss

Another full-thickness wound is a **stage 4 pressure injury**. This wound is deeper than a stage 3 pressure injury and involves exposure of muscle, bone, or connective tissue (such as tendons or cartilage) ([Fig. 29.11](#)). The considerable depth of the wound, particularly if the bone is palpable, makes osteomyelitis, or an infection of the bone, likely.

FIGURE 29.11 Stage 4 pressure injury. (Used with permission of the National Pressure Ulcer Advisory Panel. Copyright NPUAP.)

Unstageable Pressure Injury: Obscured Full-Thickness Skin and Tissue Loss

An **unstageable pressure injury** is a full-thickness wound in which the amount of necrotic tissue, or **eschar**, in the wound bed makes it impossible to assess the depth of the wound or the involvement of underlying structures (Fig. 29.12). Even if it is suspected that a wound is a stage 3 or 4 based on location and other characteristics, the wound cannot be staged until the necrotic tissue is removed, or debrided.

FIGURE 29.12 Unstageable pressure injury. (Used with permission of the National Pressure Ulcer Advisory Panel. Copyright NPUAP.)

Deep Tissue Pressure Injury: Persistent Non-Blanchable Deep Red, Maroon or Purple Discoloration

Suspected deep tissue pressure injury, a category of classification added in 2007, is seen as an area of intact skin that is purple or maroon or a blood-filled blister (Fig. 29.13). Like stage 1 pressure injuries, deep tissue pressure injuries may be difficult to detect in darker-skinned patients. The true depth of tissue damage is not readily apparent on initial inspection; however, these injuries can progress rapidly, exposing deeper layers of tissue even if treated quickly and appropriately.

FIGURE 29.13 Suspected deep pressure tissue injury. (Used with permission of the National Pressure Ulcer Advisory Panel. Copyright NPUAP.)

As a pressure injury heals, it does not travel in reverse in terms of staging; that is, a stage 4 pressure injury does not go from stage 4 to stage 3 to stage 2 to stage 1. Because the tissue will never be the same as it was before injury, the wound should be referred to as a *healed stage 4*. Some nursing issues related to wounds and wound healing are outlined in [Box 29.1](#).

Box 29.1

Diversity Considerations

Life Span

- Chronic wounds can result in an inability to work and a loss of independence in people of all ages. A significant financial burden may be incurred from costs associated with treatment of chronic wounds.

Ethnicity

- Full-thickness wounds, especially those allowed to heal by secondary intention, as with stage 3 and 4 pressure injuries, demonstrate a loss of certain epidermal structures, including hair follicles, sweat glands, and melanocytes. This loss can be permanent. Localized loss of skin pigment leads to a change in color at the wound site.
- Keloids (scars that grow larger than normal and have a smooth, rubbery appearance) and areas of hypo- and hyperpigmentation are more common in darker pigmented people ([American Osteopathic College of Dermatology, n.d.](#)).

Disability

- Patients with disabilities that cause difficulty with mobility or sensory perception are at risk for development of pressure injuries. Such disabilities include spinal cord injuries, peripheral neuropathies, and neuromuscular disorders.

Morphology

- Obesity is a risk factor for poor wound healing. Weight is not a good indicator of protein stores or nutritional health, so the obese patient can be deficient in the nutrients essential to wound healing. In addition, adipose tissue is poorly vascularized, compared with the epidermis and dermis, and therefore at greater risk for tissue ischemia. Because of the increase in mechanical forces that can be exerted on the edges of a healing wound, possible reduction in the ability to reposition oneself due to size, and common comorbid conditions (such as heart disease and diabetes) that may also be present, obesity increases the risk of chronic wounds and poor outcomes related to wound healing.

2. Stage P. J.'s right hip and left heel wounds.

LO 29.3 ♦ Assessment

Assessment of the skin is performed on every patient in both acute- and long-term care facilities, as well as those receiving home care. A thorough skin assessment by the nurse should occur on every patient upon admission, on every shift, with transfer of the patient to another unit or facility, and when the patient is discharged (Powers & Ames, 2018). It should include focused health assessment questions (Box 29.2) and an assessment of the skin's temperature, overall color and local variations in that color, presence of excessive moisture or dryness, odor, texture, turgor, and integrity (see Chapter 20). The presence of risk factors associated with skin breakdown or impaired wound healing and any actual wounds present are included in the assessment. After a baseline is obtained, regular reassessments should occur as indicated by the patient's risk factors, the presence and characteristics of wounds, and the clinical setting.

Box 29.2

Health Assessment Questions

General Skin Assessment Questions

- How would you describe your overall skin condition?
- Have you ever had problems with your skin? What kind of problems? Location? When?
- Describe your usual skin care regime.
- Describe your usual diet. Have you experienced any recent unintended weight loss?
- Are you ever incontinent of urine or stool?
- Have you been told that you have diabetes or problems with your circulation?
- Do you smoke?
- Do you drink alcohol or use illicit drugs?
- Have you noticed any numbness or tingling in your feet?
- Has it seemed to take a long time for a wound to heal in the past?

Focused Wound Assessment

- How long has this wound been present? What do you think caused this wound? Have you ever had a wound like this before?
- What are you doing for this wound at home? What are you using to clean the wound? What have you put on it?
- Have you noticed any changes in the appearance of the wound or the skin around it?
- How much wound drainage is there? Has the amount, color, or odor of the drainage changed? How often do you need to change the bandage at home?
- Do you live alone? Do you have anyone who helps you at home?
- Is the cost of caring for this wound difficult for you to manage?

If a wound is present, an accurate and detailed assessment is conducted to determine the most appropriate treatment, monitor healing progress, and adjust the treatment plan as needed. It includes close inspection of the wound, determination of the suspected etiology of the wound, a thorough patient history, and a head-to-toe physical examination. Additional testing may be required, such as vascular studies to assess arterial and venous status, blood work to evaluate chronic diseases (such as diabetes or malnutrition), or biopsy of the wound to rule out infection or malignancy.

Risk Assessment for Pressure Injuries

Several tools have been developed specifically to assist in the identification of patients at risk for the development of pressure injuries. Although risk assessment tools may not directly reduce the number of pressure injuries acquired, accurate and timely assessment of at-risk patients serves as a guide to the need for implementation of preventive strategies. Early identification of each person's risk factors allows health care facilities to focus available resources on the patients at greatest risk for pressure injuries. Two available tools are the Braden Scale (Fig. 29.14) and the Norton Scale (Fig. 29.15). Each tool ranks certain risk factors, the number of which varies, and the summation of the individual rankings determines the overall risk score. With both the Braden and Norton scales, the lower the score, the greater the overall risk.

BRADEN SCALE FOR PREDICTING PRESSURE SORE RISK					
Patient's name _____		Evaluator's name _____		Date of assessment _____	
SENSORY PERCEPTION Ability to respond meaningfully to pressure-related discomfort	1. Completely Limited Unresponsive (does not moan, flinch, or gasp) to painful stimuli due to diminished level of consciousness or sedation. OR Limited ability to feel pain over most of body.	2. Very Limited Responds only to painful stimuli. Cannot communicate discomfort except by moaning or restlessness. OR Has a sensory impairment that limits the ability to feel pain or discomfort over 1/2 of body.	3. Slightly Limited Responds to verbal commands, but cannot always communicate discomfort or the need to be turned. OR Has some sensory impairment that limits ability to feel pain or discomfort in 1 or 2 extremities.	4. No Impairment Responds to verbal commands. Has no sensory deficit that would limit ability to feel or voice pain and discomfort.	
MOISTURE Degree to which skin is exposed to moisture	1. Constantly Moist Skin is kept moist almost constantly by perspiration, urine, etc. Dampness is detected every time patient is moved or turned.	2. Very Moist Skin is often, but not always, moist. Linen must be changed at least once a shift.	3. Occasionally Moist Skin is occasionally moist, requiring an extra linen change approximately once a day.	4. Rarely Moist Skin is usually dry; linen only requires changing at routine intervals.	
ACTIVITY Degree of physical activity	1. Bedfast Confined to bed.	2. Chairfast Ability to walk severely limited or non-existent. Cannot bear own weight and/or must be assisted into chair or wheelchair.	3. Walks Occasionally Walks occasionally during day, but for very short distances, with or without assistance. Spends majority of each shift in bed or chair.	4. Walks Frequently Walks outside room at least twice a day and inside room at least once every 2 hours during waking hours.	
MOBILITY Ability to change and control body position	1. Completely Immobile Does not make even slight changes in body or extremity position without assistance.	2. Very Limited Makes occasional slight changes in body or extremity position, but unable to make frequent or significant changes independently.	3. Slightly Limited Makes frequent though slight changes in body or extremity position independently.	4. No Limitation Makes major and frequent changes in position without assistance.	
NUTRITION Usual food intake pattern	1. Very Poor Never eats a complete meal. Rarely eats more than 1/2 of food offered. Eats 2 servings or less of protein (meat or dairy products) per day. Takes fluids poorly. Does not take a liquid dietary supplement. OR Is NPO and/or maintained on clear liquids or IVs for more than 5 days.	2. Probably Inadequate Rarely eats a complete meal and generally eats only about 1/2 of any food offered. Protein intake includes only 3 servings of meat or dairy products per day. Occasionally will take a dietary supplement. OR Receives less than optimum amount of liquid diet or tube feeding.	3. Adequate Eats over half of most meals. Eats a total of 4 servings of protein (meat, dairy products) per day. Occasionally will refuse a meal, but will usually take a supplement when offered. OR Is on a tube feeding or TPN regimen that probably meets most of nutritional needs.	4. Excellent Eats most of every meal. Never refuses a meal. Usually eats a total of 4 or more servings of meal and dairy products. Occasionally eats between meals. Does not require supplementation.	
FRICTION and SHEAR	1. Problem Requires moderate to maximum assistance in moving. Complete lifting without sliding against sheets is impossible. Frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance. Spasticity, contractures, or agitation leads to almost constant friction.	2. Potential Problem Moves feebly or requires minimum assistance. During a move, skin probably slides to some extent against sheets, chair restraints, or other devices. Maintains relatively good position in chair or bed most of the time but occasionally slides down.	3. No Apparent Problem Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during move. Maintains good position in bed or chair.

FIGURE 29.15 Norton Scale. (Adapted from Norton, D., McLaren, R., Exton-Smith, A. N. [1962]. An investigation of geriatric nursing problems in hospital, London, Churchill Livingstone.)

The most valuable tool would be one that predicts with 100% precision those patients who will or will not develop a pressure injury. When comparing the predictive abilities of the Braden and Norton scales, researchers found them to be similar, with both scales overpredicting the risk of pressure injury development (Park & Lee, 2016). While this means that some people who will not develop pressure injuries receive unnecessary preventive interventions, it is thought that this is preferable to failing to intervene and having a pressure injury subsequently develop.

With each of these tools, it is essential to understand the definitions of the different categories in order to accurately arrive at a risk score that is reflective of actual risk. Too often, the risk score becomes just another number on a flow sheet instead of something that serves to guide practice. Although the overall risk score is important and may be the assessment finding that initiates prevention protocols, the scores in each of the tool's individual categories can help the nurse in the selection of interventions. By reducing the impact of these contributing risk factors, it is possible to reduce the person's overall risk for pressure injuries. The

Braden Scale ranks the patient on the risk categories of sensory perception, moisture, activity, mobility, nutrition, and friction and shear. A score lower than 18 places the person at risk for pressure injury development. If, on assessing that score, the nurse notes that the patient scored particularly low in one or more of the categories, preventive strategies can be directed more precisely at those specific areas as a way to decrease overall risk.

3. On the basis of the information in the case study, calculate P. J.'s score utilizing the Braden Scale.

Wound Assessment

A focused wound assessment includes an evaluation of the wound's location, size, and color; presence of drainage; condition of the wound edges; characteristics of the wound bed; and patient's response to the wound or wound treatment.

Location

The location of the wound is described using clear, anatomic terminology whenever possible. For example, referring to the left outer malleolus instead of the left ankle clarifies for those subsequently assessing the wound exactly where the wound is located. This distinction becomes more important if more than one wound is present. The use of anatomic diagrams to illustrate wound locations is now widely practiced in documentation. Wound care is documented in the electronic health record ([Fig. 29.16](#)).

Size

The nurse assesses the size of the wound. With the healing process, the edges of an open wound contract and the wound bed fills with new tissue. Consistency in wound measurements is important in accurately monitoring progression toward healing (Box 29.3).

Box 29.3

Nursing Care Guideline

Measuring a Wound

Background

- Wound size changes over time, and size can indicate healing or negative progression.
- Measuring a wound is considered assessment and therefore cannot be delegated to unlicensed assistive personnel (UAP).
- Measurement is performed using the metric system with a facility-provided ruler that has increments in centimeters or millimeters.

Sterile cotton-tipped applicators can be used to measure the depth of a wound.

Procedural Concerns

- Always wear clean or sterile gloves, depending on the type of wound and dressing-change orders.
- Take measurements in the following manner:
 - Width is measured laterally from the left to right sides at the widest open area of the wound.

- Length is measured vertically from the top to the bottom, or head to toe, at the widest open area of the wound.
- Depth of the visible wound is determined by inserting the tip of a sterile cotton-tipped applicator straight down into the deepest part of the wound. Mark the area on the stick portion of the applicator that is even with the level of the skin. Measure the distance from the tip of the applicator to the marked area on the stick to determine the depth of the wound.

- Depth of undermining is determined by laterally inserting the tip of a sterile cotton-tipped applicator into the widest section of the undermining. Mark the area on the stick end of the applicator that is even with the edges of the skin, and measure the distance from the tip of the applicator to the marked area to determine the depth of the undermining.

- Tunneling is measured using the same procedure as that used for undermining.
- When measuring depth, be sure to insert the sterile cotton-tipped applicator gently. The patient may require pain medication before the procedure.

Documentation Concerns

- Observe and document the color of the wound bed and periwound area; the amount, color, consistency, and odor of drainage; and the type of tissue present in the wound (granulation, slough, eschar, subcutaneous, muscle, bone, ligament).
- Observe and document any signs or symptoms of infection. Changes in the skin surrounding the wound (such as redness or breakdown) can indicate infection. These areas should be described and measured.
- Document all measurements by width, length, depth, and undermining or tunneling depth in appropriate metric units (such as cm or mm). Document where the undermining measurements were taken within the wound.
- A drawing or photograph may be necessary to fully document the shape of the wound.
- Document any pain or discomfort associated with the procedure reported by the patient.

Safe Practice Alert

The nurse should be cautious when palpating inside a wound with a sterile gloved finger. Exposed bone, if present, can be sharp, resulting in a cut in the glove and finger. Only wound care nurse specialists and those with special training in wound assessment should attempt palpation of a deep wound.

Presence of Undermining or Tunneling

Undermining can be present around the entire wound or only part of the wound and can vary in its depth. Undermining is often seen when the wound is a result of pressure and shear forces, and it is often present in sacral pressure injuries. The presence and location of undermining are determined by exploring the edge of the wound with a cotton-tipped applicator. The undermined area is part of the wound and is included in the treatment plan for the wound. Tunnels increase the actual size of the wound, are a part of the wound, and must be treated appropriately. Because wounds heal from the edges inward and from the bottom up, tunneled wounds usually are packed lightly with gauze or other dressing materials so that they can heal along with the rest of the wound, instead of prematurely closing, which would result in

pockets of dead space. Such pockets can predispose the patient to the development of an abscess or infection.

Drainage

During wound assessment, note whether drainage is present, the amount of drainage, and its color, consistency, and odor. **Serous** drainage contains clear, watery fluid from plasma. **Serosanguineous** drainage is pink to pale red and contains a mix of serous fluid and red, bloody fluid. **Sanguineous** drainage usually indicates bleeding and is bright red. Purulent drainage is thick and indicates infection. It can be yellow, greenish, or beige. The amount of drainage (small, moderate, or large) from a wound is difficult to ascertain and is determined somewhat subjectively by evaluators. Usually, knowledge of the exact amount of drainage is not required. Increases in the amount of drainage and the presence of purulence or a foul odor can indicate infection or the presence of a fistula. In cases in which infection is suspected, the nurse can seek an order for a wound culture. Common organisms causing wound infections include *Staphylococcus aureus* and *Streptococcus pyogenes*. Infectious organisms are discussed in [Chapter 26](#).

An important point to remember is that the production of drainage requires energy, and the drainage may have high protein content. Therefore excessive drainage can exacerbate the nutritional deficiencies that are common in this patient population.

Conditions of Wound Edges and Surrounding Tissue

Because wounds heal from the edges inward, wound edges should be examined for regeneration of epithelial tissue. A lack of epithelial tissue is an indication that something is preventing the wound from healing, so reassessment is needed to determine the cause. The surrounding tissue is inspected for maceration, which appears as pale, soft, or wrinkled skin; signs of infection (redness, warmth, induration); and further tissue breakdown or the development of new wounds. Maceration ([Fig. 29.17](#)) can provide a clue to the amount of drainage produced by a wound, serve as an indicator of an incorrectly applied dressing that allowed contact of a moist dressing with intact skin, or indicate the need for more frequent dressing changes or a more absorbent dressing.

FIGURE 29.17 Wounds with maceration. (From Bryant, R. A., & Nix, D. P. [2016]. *Acute and chronic wounds* [5th ed.]. St. Louis: Elsevier.)

The development of new wounds, or the expansion of old ones, may mean that the underlying cause of or associated risk factors for the wound have not been adequately addressed, allowing additional tissue damage to occur. For example, a sacral pressure injury with nonblanching tissue or bruising around the injured area warns of the presence of additional tissue damage.

Wound Bed

In addition to determining the type of tissue in the wound bed (granulation tissue, necrotic tissue, subcutaneous tissue, muscle, or bone), the nurse assesses the color of the wound. The wound bed should be beefy red and shiny or moist in appearance. A wound that is pale or dry (Fig. 29.18) may be reflective of conditions that are not optimal for wound healing, such as anemia, poor vascular status, nutritional deficiencies, or dehydration. Wounds are examined for the presence of foreign bodies, particularly in the case of traumatic injuries, because foreign bodies can serve as a source of infection and delayed wound healing.

FIGURE 29.18 Pale wound bed. (From Bryant, R. A., & Nix, D. P. [2016]. *Acute and chronic wounds* [5th ed.]. St. Louis: Elsevier.)

Patient Response

Wounds cause pain. This holds true for acute and chronic wounds, deep and superficial wounds, and wounds occurring in the young and the old, regardless of race or gender. Yet the pain associated with wounds, especially chronic wounds, often is not considered or treated appropriately. The skin is full of sensory nerves; therefore damage to the skin, and the presence of inflammation and infection in the wound, can cause intense pain. This pain affects the patient's self-image and ability to perform customary societal roles, decreases perceived quality of life, decreases appetite, and activates the stress response, which causes vasoconstriction and a reduction in wound healing.

Treatments used in the care of wounds can be additional sources of pain and anxiety, with reported pain levels ranging from mild to excruciating during dressing changes (Jackson, Durrant, Bishop, et al., 2017). The patient's report of the level of pain or distress is the most reliable indicator of the presence of pain in wounds or during dressing changes and needs to be acknowledged as real and assessed frequently. Although some studies have looked at the value of various topical, systemic, and alternative treatment modalities, additional research is needed to determine the most effective ways to manage the pain found in different types of wounds and across diverse patient populations (Jackson, Durrant, Bishop, et al., 2017). Some recommendations regarding the management of wound-related pain include the appropriate selection of dressings; protection of surrounding tissue from irritating wound drainage or dressing materials; aggressive treatment of infection, which is known to increase the presence of inflammation and pain; positioning of the patient in a way that avoids pressure over the wound; use of binders or other devices to splint the wound edges; and premedication before turning, dressing changes, and debridement (Hopf, Shapshak, Junkins, et al., 2016). In 2014, the NPUAP and the EPUAP included the management of pain in their

guidelines for patients with pressure injuries, emphasizing that these wounds cause pain both during procedures and at rest and that this pain adversely affects quality of life. Additional suggestions for the management of acute and chronic pain can be found in [Chapter 36](#).

QSEN Focus!

Patient-centered care is demonstrated when the nurse assesses for and treats the patient's pain before procedures (such as dressing changes), thereby integrating understanding of multiple dimensions of care (such as physical comfort and emotional support). The nurse should also collaborate with the wound ostomy continence nurse (WOCN) to assess, treat, and manage pressure injuries.

Tools for the Assessment of Wound Healing

Although the assessment and documentation of wound characteristics monitor progression toward healing, specific tools are used both in the clinical setting and in research to track wound healing over time. Some, such as the Wound Characteristic Instrument, are used to assess any open wound, whereas others, such as the Pressure Sore Status Tool (PSST) and the Pressure Ulcer Scale for Healing (PUSH), are specific for pressure injuries. The PSST assigns a numerical score based on 13 wound attributes; the PUSH tool's score is based on three characteristics. With both tools, the scores obtained from the serial observations of wounds allow the health care provider to track wound healing and more rapidly identify trends that may be positively or negatively affecting wound healing.

LO 29.4 ♦ Nursing Diagnosis

Many nursing diagnoses may be applicable for a patient with a wound. Identifying appropriate diagnoses is based on the assessment data obtained from a thorough history and physical examination, including an assessment of the risk factors associated with impaired wound healing and a focused assessment of the actual wound. Examples of International Classification for Nursing Practice (ICNP) nursing diagnoses related to skin integrity are:

Impaired Skin Integrity

- Supporting Data: Compromised nutritional status: albumin 2.5 g/dL, prealbumin 15 mg/dL, requires assistance to move from bed to chair, right hip and left heel pressure injuries

Impaired Tissue Integrity

- Supporting Data: Pressure, immobility, stage 3 pressure injury on the coccyx

Acute Pain

- Supporting Data: Trauma, pain in the area of the wound rated by the patient at 8 of 10

LO 29.5 ♦ Planning

Goals, or the desired outcomes for the nursing diagnoses chosen for a patient, are determined after collaboration with the patient and other members of the interprofessional health care team. These goals or desired outcomes are the driving force behind the selection of the interventions that will aid in the achievement of the goals. Goals include specific evaluation criteria on which to base the patient's response to care and achievement of the stated goal (Table 29.1). For example, the overarching goal for the nursing diagnosis *Impaired Skin Integrity* may be complete healing of the wound. However, a more complete goal statement for an alteration in skin integrity related to a pressure injury is:

TABLE 29.1
Care Planning

ICNP Nursing Diagnosis With Supporting Data	Nursing Outcome Classification (NOC)	Nursing Intervention Classification (NIC)
<i>Impaired Skin Integrity</i> Compromised nutritional status: albumin 2.5 g/dL, prealbumin 15 mg/dL Requires assistance to move from bed to chair Right hip and heel pressure injury	<i>Nutritional status:</i> <i>Nutrient intake</i> <i>Caloric intake</i>	<i>Nutrition therapy</i> Monitor food and fluid ingested, and calculate daily caloric intake, as appropriate

From Butcher, H. K., Bulechek, G. M., Dochterman, J. M., et al. (Eds.). (2018). *Nursing interventions classification (NIC)* (7th ed.). St. Louis: Mosby; Moorhead, S., Swanson, E., Johnson, M., et al. (Eds.). (2018). *Nursing outcomes classification (NOC)* (6th ed.). St. Louis: Mosby; ICNP is owned and copyrighted by the International Council of Nurses (ICN). Reproduced with permission of the copyright holder.

- Wound will show signs of healing with a decrease in size and depth on assessment within 2 weeks.

This statement includes a stated period for reevaluation, as well as the criteria needed to meet the stated goal. Other examples of goal statements for the nursing diagnoses listed in this chapter are:

- Patient will ingest 75% of each meal during hospitalization.
- Patient will be able to participate in position changes within 24 hours.
- Patient will report a decrease in pain while on the prescribed pain management regime.

Collaborative and professional concerns for patients with impaired skin integrity are outlined in [Boxes 29.4](#) and [29.5](#).

Box 29.4

■ Interprofessional Collaboration and Delegation

Patients With Wounds

- Assessment and evaluation of a patient's skin and wounds, and the effectiveness of the treatment plan, are the nurse's responsibility and cannot be delegated to unlicensed assistive personnel (UAP). UAP should report to the nurse any changes in skin condition or integrity, elevation in temperature, complaints of pain, increased wound drainage or incontinence, and observed changes in dietary intake.
- Depending on the setting and treatment, some dressing changes can be performed by a UAP. For example, application of nonsterile dressings for chronic wounds with an established treatment plan may be delegated in some situations. The nurse retains responsibility for the delegated task and must supervise the UAP. Care is taken to follow the policies of the facility and stay within the scope of practice.
- In view of the complexity of the patient with a chronic wound, collaboration among specialists in the fields of surgery, infectious disease, physical and occupational therapy, social work and discharge planning, nutrition, and nursing is essential for achieving optimal wound outcomes.
- Collaboration with a specialist in wound care and incontinence, such as a wound ostomy continence nurse (WOCN), should be considered in caring for an at-risk patient.

- A nursing representative is an important member of the purchasing committee charged with the selection of skin and wound care products. Effectiveness, as well as unit cost, must be considered in the selection process, making the role of nursing in product selection essential.
- Families should be included in the purchasing of supplies for home wound care, because the selection of products on the basis of insurance coverage may ease financial concerns.

Box 29.5

Ethical, Legal, and Professional Practice

Wound Care

- The development of a pressure injury often is seen as an indicator of neglect and inadequate care that reflects badly on the facility in which the care took place and on the personnel providing that care. Such wounds cause great pain and suffering for the patient and family and often result in litigation that is costly to all involved. Documentation of initial and ongoing assessments, including a risk assessment, initiation of appropriate prevention and treatment interventions, and the involvement of any specialty services needed to improve wound healing, is critical.
- As with all decisions regarding health care, how aggressively chronic wounds should be treated is a choice that needs to be made by the patient in collaboration with the family and health care providers. It is important for all to remember that the whole patient is the focus of care, not just the wound.
- Potential barriers to good wound care are many and may include a lack of knowledge, lack of access to consistent health care, lifestyle choices, and fiscal constraints at both the patient and facility levels. Many wound-related treatments, as well as the availability of acute, long-term, and home care, are dependent on financial resources. This creates great disparities in wound care among affected patients and in the outcomes of that care.

FIGURE 29.19 Partially completed conceptual care map based on P. J., the case study patient in this chapter.

The conceptual care map for P. J. provided in [Fig. 29.19](#) is partially completed to indicate how to use the map as a learning tool. Using it as an example, go to the website at <http://evolve.elsevier.com/YoostCrawford/fundamentals/> to complete Nursing Diagnoses 2 and 3.

LO 29.6 ♦ Implementation and Evaluation

Nursing care of all patients is aimed at protecting intact skin and promoting healing of existing wounds. Many devices exist to relieve and reduce pressure. Any of the numerous available forms of treatment for wounds may be used, depending on the type of wound and resources available.

Interventions to Preserve Skin Integrity

Interventions are selected to meet the related goals of promoting healing in existing wounds and preventing the development of additional wounds. Nurses, along with the interprofessional health care team, must provide care based on a critical appraisal of the most current available information and research using evidence-based practice (Box 29.6).

Box 29.6

Evidence-Based Practice and Informatics

Resources for Wound Care

The interprofessional health care team bases the selection of interventions on the strength of available evidence. Although the discussion of interventions presented in this text reflects evidentiary guidelines, research continues to produce new knowledge and new recommendations for treatments and products. Nurses have a responsibility to scrutinize the effectiveness of their practice, analyze research findings, use research-based guidelines whenever possible, and actively participate in the development and implementation of guidelines. Some resources for current wound care are:

- Guidelines developed by the National Pressure Ulcer Advisory Panel (www.npuap.org)
- Resources provided by groups, such as the Joanna Briggs Institute (<http://joannabriggs.org>)
- Research from the Agency for Healthcare Research and Quality (www.ahrq.gov)
- The Cochrane Library (www.cochrane.org)
- Wound Ostomy and Continence Nurses Society (www.wocn.org)

Turning and Positioning

The 2014 Pressure Ulcer Prevention and Treatment Guidelines, developed by the NPUAP and the EPUAP, recommend frequent position changes as a way of relieving the duration of pressure to which tissue is subjected, thereby reducing the development of pressure-related wounds. The current recommendations are to change the patient's position at least every 2 hours and to elevate the head of the bed no more than 30 degrees to reduce the effects of shear. When side-lying, patients should be positioned at 30 degrees (Fig. 29.20), as opposed to 90 degrees, to avoid direct pressure on bony prominences (such as the head of the trochanter). Folded towels, blankets, or a pillow are used to keep bony prominences from exerting pressure against each other (such as to keep the inner knees from pressing against each other in a side-lying position). Use of a posted turning schedule is helpful for the patient, family, and health care worker and serves as a visual reminder of the need to change the patient's position regularly.

Despite the need to reposition the patient frequently and reduce the impact of shear forces, it is important to consider the patient's overall medical condition and related health concerns, ability to be turned, support surface, and comfort level. A review of the literature related to the recommendations for position changes revealed that although position changes are important, more research is needed to better understand what frequency and type of positioning are most effective in the prevention of pressure injuries in different populations ([National Pressure Ulcer Advisory Panel, 2016a](#)).

FIGURE 29.20 Patient in a 30-degree side-lying position.

The skin over the heels is at a particularly high risk for breakdown because of the small surface area involved, the lack of a subcutaneous “cushion,” and the relatively large amount of underlying bone. Any discussion of proper positioning to relieve pressure must address the heels. Although many products designed to address the prevention of pressure injury to the heel are on the market, an effective intervention for prevention of pressure injury to the heel is positioning the leg with pillows so that the heel “floats” clear of the mattress surface, thereby relieving pressure ([Hopf, Shapshak, Junkins, et al., 2016](#)) ([Fig. 29.21](#)). There is evidence that the use of a comprehensive quality improvement initiative, including consistent assessment of the patient's heels, earlier use of heel protectors on high-risk patients, and staff education on the recognition of non-blanching erythema, prevention, treatment, and management of pressure injuries to the heel, results in improved patient safety and outcomes. A cost savings was also attributed to the increased awareness by staff ([Rajpal & Acton, 2016](#)).

FIGURE 29.21 Patient positioned with heels suspended off the mattress.

It is important to remember that the recommendations for frequent position changes also apply to the seated person. Patients who are seated in a chair for long periods and who are unable to sense the need to shift their weight or unable to do so independently need assistance in altering their position while seated. The amount of time spent in a chair without pressure relief should be limited to 2 hours or less to prevent pressure injuries ([National Pressure Ulcer Advisory Panel, 2016b](#)). Use a pressure redistribution chair cushion for individuals sitting in chairs or wheelchairs and patients who are weak or immobile to reduce pressure on bony prominences. These patients should also be repositioned hourly while sitting in a chair.

Skin Hygiene

Appropriate skin hygiene is important in the maintenance of healthy skin. Incontinence, wound drainage, and moisture from perspiration increase the risk of bacterial and fungal infections of the skin and contribute to a decrease in the strength of the skin. Such changes are thought to be a factor in skin tears, perineal injuries, and abrasions. The specific content of wound drainage may increase the severity of the damage to the skin. Regular cleansing of the skin with timely response to episodes of incontinence is an important component of nursing care. Use of soap and hot water can remove the oils from the skin, leading to excessive dryness. Overuse of many soaps, including antibacterial soaps, can change the skin's normally acidic pH and decrease its natural protective antimicrobial action. Some cleansers are marketed specifically for bathing and incontinence care, and use of any of several mild, pH-neutral soaps also may be appropriate. It is important to choose a product that preserves the normal pH of the skin and does not result in overly dry skin. One that combines a moisturizer with a cleanser is a good choice for cleansing and should be used with warm water as opposed to hot water. In the case of incontinence and wound drainage, the skin can be further protected after cleansing through the correct use of a moisture barrier ointment ([EPUAP and NPUAP, 2014](#); [Hopf, Shapshak, Junkins, et al., 2016](#)). Knowledge of the specific characteristics of different classifications of skin cleansers and barrier ointments aids in the selection of a suitable product.

Pressure-Reducing Mattresses and Support Surfaces

Many mattresses and seat cushions are specifically designed to reduce or relieve pressure and especially to decrease the risk for development of pressure injuries ([Fig. 29.22](#)). The selection of a suitable support surface is only one component of a prevention and treatment plan. It is critical to recognize that none of the specialty surfaces eliminates the need for a thorough assessment, identification and modification of known risk factors, and regular position changes. The erroneous belief that a specialty support surface eliminates the need for position changes is a common one, with potentially serious consequences for the patient.

FIGURE 29.22 Pressure-reducing or pressure-relieving support surfaces.
(Reproduced with permission from Hill-Rom. Copyright 2018.)

All support surfaces work to reduce pressure by redistributing or “spreading out” the body's weight over a greater surface area. By doing so, the resulting intensity and magnitude of the pressure on a given body surface area are decreased. Many different materials and technologies are used in support surfaces. They are made of foams or gels, can be fluid- or air-filled, and can be dynamic or static. Available as overlays, replacement mattresses, or specialty beds, they are designed for adults, children, or the obese and specifically for beds, chairs, operating room tables, and stretchers, as well as certain risk areas (e.g., heels). Although an in-depth discussion of the available support surfaces and their underlying technologies is beyond the scope of this textbook, it is important to recognize that different advantages, disadvantages, and costs are associated with each. These considerations and the need to use available resources judiciously have necessitated that health care facilities and insurers develop guidelines for the use of specialty support surfaces and that the users of these surfaces understand the indications for their use, as well as their strengths and limitations.

Interventions Related to Wound Care

Wound care depends on the type of wound, amount of drainage, presence of infection, and resources available. Wounds are assessed on an ongoing basis, because changes occur during the healing process. The type of wound care may change as the wound heals.

Wound Cleansing and Irrigation

Wound cleansing is important in removing surface contaminants or debris that can become a reservoir for bacteria, thereby allowing the bacteria to adhere to the wound and invade deeper tissue. The selected cleansing agent and method of cleansing must provide for balance between the need to clean the wound and the need to minimize further damage or trauma to the wound bed and allow wound healing to occur. For example, antiseptic solutions (such as Dakin's solution, povidone-iodine, acetic acid, and hydrogen peroxide), although cytotoxic to bacteria, are harmful to the cells needed for wound healing, and their use can actually delay wound healing. Although numerous wound cleansers are commercially available, 0.9% normal saline solution is an adequate wound cleanser and is readily available in most health care settings. Cold irrigation solutions (cooler than room temperature) decrease the activity of leukocytes and other cells for hours after irrigation, again delaying the ability of these cells to perform their necessary roles in wound healing. Therefore irrigation solutions should be room temperature or warmed. In irrigating a wound, the force of the irrigation must be sufficient to actually remove the surface contaminants yet not so strong that it damages the delicate new tissue of the healing wound (Skill 29.1).

QSEN Focus!

Safety requires that the nurse demonstrate effective use of strategies, such as use of personal protective equipment (PPE), that reduce the risk of harm to self or others when wound care may result in exposure to potentially infectious drainage.

Safe Practice Alert

Wound irrigation can result in splashing of the fluid and debris; therefore the use of PPE (such as gowns, masks, and goggles) is required.

Debridement

Debridement is the removal of necrotic tissue, which would otherwise prolong the inflammatory phase of wound healing and provide a reservoir for bacteria. The removal of necrotic tissue is necessary for the wound to be assessed adequately for viable tissue and staged in the case of pressure injuries. For some types of wounds, such as those on heels, debridement is not usually recommended if the necrotic tissue is dry and stable, with no evidence of infection. This is the exception, however. Several types of debridement may be used—sharp, mechanical, enzymatic, autolytic, and biologic. The selection of the type of debridement is based on an assessment of the wound, the patient's other health conditions, available resources, and the patient's concerns.

Sharp debridement is the use of a sharp instrument (scalpel, curette, or scissors) by health care personnel with appropriate training, to remove necrotic tissue. It is the fastest way of removing nonviable tissue and is the method of choice if an underlying infection is suspected or if a large amount of necrotic tissue needs to be removed rapidly. Caution is used in patients with bleeding disorders.

Mechanical debridement is a nonselective form of debridement in that it not only removes the necrotic tissue but also can remove or disturb exposed viable tissue that may be in the wound. The main forms of mechanical debridement are wet/damp-to-dry dressings and whirlpools. Wet/damp-to-dry dressings usually are saline-moistened dressing materials that are allowed to dry to the wound and are then removed, pulling the surface layer off the wound bed (Skill 29.2). Mechanical debridement often is painful for the patient, is harmful to viable tissue, can lead to bleeding and, in the case of wet/damp-to-dry dressings, is labor-intensive.

Enzymatic debridement is achieved through the application of topical agents containing enzymes that work by breaking down the fibrin, collagen, or elastin present in devitalized tissue, thus allowing for its removal. Although a slower method of debridement than mechanical or sharp, it is selective for nonviable tissue and is quite effective when used appropriately. The various enzymatic agents on the market differ in terms of action, application, and potential complications. Some examples are Santyl, Panafil, and Accuzyme.

Occlusive dressings (such as hydrocolloids and transparent films) are used for autolytic debridement, as are hydrogels. Autolytic debridement is based on the principle that wounds have an innate ability to clean themselves of debris and necrotic tissue through the action of the body's own enzymes and phagocytic cells. Because it is a normal part of the wound healing process, it requires a moist wound environment and the optimization of the other factors important for wound healing in order to be successful. This type of debridement is the slowest, and it is contraindicated in infected wounds. It is the most comfortable form of debridement for the patient.

Biologic debridement involves the use of sterile, medicinal larvae from green bottle flies (maggots), which secrete proteolytic enzymes that break down necrotic tissue,

digest bacteria, and stimulate the formation of granulation tissue. The use of maggots may cause pain, and the patient may find both the sight and sensation of the maggots to be disturbing. However, maggot therapy is an effective form of debridement in certain types of wounds.

Dressings

Dressings have multiple purposes: They are intended to keep the wound free of contamination, absorb drainage yet prevent overdrying of the wound bed, protect the periwound tissue, treat infection, and aid in the debridement of the wound. When selecting a dressing for a wound, the nurse must keep in mind the differences inherent in the various classifications of dressings, the assessment of the wound and surrounding tissue, and the goal of treatment (see [Skill 29.2](#)). No single dressing type is ideal for all wounds, and it is essential to match the wound to the dressing in order to select the best treatment. Reassessment of the wound as it heals may necessitate a change in the type of dressing used. Although many wound care products are available, there are certain broad classifications of dressings with which the nurse should be familiar: gauze dressings, transparent dressings, hydrocolloids, foams, alginates, and gels. The development of these dressing types, with the exception of dry gauze dressings, is based on the pioneering work of Dr. George D. Winter in the 1960s. He demonstrated in animal models that wounds heal faster in a moist skin environment than if allowed to become dry ([Hopf, Shapshak, Junkins, et al., 2016](#)). This discovery represented a radical departure from earlier beliefs about wound healing.

Many of these dressings are available impregnated or otherwise treated with antimicrobial agents, such as silver to reduce the bacterial load, or **bioburden**, in the wound and thereby improve wound healing. For wounds with signs of infection or chronic wounds that are not responding to appropriate treatment, use of this type of dressing may be indicated after a wound culture is obtained ([Skill 29.3](#)).

Gauze dressings are the oldest category of dressings, and both patients and health care workers may be familiar with their use. Gauze comes in many forms, shapes, and sizes, which makes it a versatile dressing. Although it is one of the most commonly used dressings, gauze as a primary dressing has many disadvantages. It is not an effective barrier to infection, particularly when moist; its removal often results in pain and inadvertent damage to the healing wound bed; fibers can be left in the wound; and its use is time-consuming and labor-intensive. The greatest disadvantage is its inability to maintain the moist wound environment required for healing even if moistened before being placed in the wound. Because of these disadvantages, its use often delays wound healing, thereby increasing overall costs. Despite this limitation, gauze remains a commonly used wound dressing and is preferable to allowing the wound to become dry ([Hopf, Shapshak, Junkins, et al., 2016](#); [EPUAP and NPUAP, 2014](#)). Gauze comes in many configurations and may be impregnated with antibiotics, petrolatum, or other materials. It is therefore useful as packing in all types of wounds, as a cover dressing, and for absorbing exudate from a heavily draining wound.

QSEN Focus!

Evidence-based practice demonstrates knowledge of basic scientific methods and processes. When selecting appropriate wound dressings, the nurse values the concept of evidence-based practice as an integral factor in determining best clinical practice.

Transparent films are made of adhesive-backed polyurethane that sticks to the periwound skin but not to the actual wound bed. Because polyurethane has no

absorbent capability, this type of dressing is inappropriate for wounds with more than a minimal amount of drainage. The films prevent bacteria and fluids from entering the wound but allow oxygen and water vapor to move through the dressing. They imitate the action of a blister by keeping the body's own wound fluid next to the wound bed, thus maintaining a moist environment. Transparent films come in a variety of shapes and sizes and can be used as a primary or secondary dressing. Their use is appropriate for autolytic debridement of a minimally draining wound that has no sign of infection.

Hydrocolloids are occlusive, adhesive dressings composed of gelling agents and carboxymethylcellulose. They absorb a small to moderate amount of drainage over a 3- to 7-day period, forming a gel as drainage is absorbed. This gel is sometimes mistaken for the purulent drainage suggestive of infection when the dressing is removed, so it is important to cleanse the wound before reassessment. Hydrocolloids provide a moist wound environment, and their absorbent capabilities prevent the wound bed and surrounding tissue from becoming too wet. Because of their occlusive properties and long wear time, they generally are not recommended for wounds suspected of being infected. Hydrocolloids are versatile dressings available in multiple shapes, sizes, and thicknesses and are appropriate for use with clean, uninfected wounds with small to moderate amounts of drainage.

Foams are able to pull fluid away from the wound bed yet maintain a moist wound environment. They are used for wounds producing moderate to heavy amounts of exudates and should not be used for wounds with only a small amount of drainage. They can be used over enzymatic debriding agents or gels, although the absorptive nature of the foam may cause these other materials to be absorbed into the foam dressing. Like transparent films and hydrocolloids, foams are available in a wide variety of sizes, shapes, and configurations, including sheets, rolls, and "pillows" designed to fill cavities. Although they sometimes are used as padding, important points are that they do not relieve pressure; this type of usage is not covered by insurers in the home care setting; and many less costly and more appropriate materials are available for this purpose (Box 29.7).

Box 29.7

Home Care Considerations

Wound Care Supplies in the Home

- The cost of wound care supplies in the home can be significant, and coverage for these supplies by insurers is not universal. If they are covered, the amount of the product provided is based on the documented assessment of the wound and the recommended usage of the product.
- Sterile supplies usually are not needed, and other, more readily available and sometimes more affordable products are utilized. For example, the use of sanitary napkins and disposable diapers as absorptive dressings can be acceptable on the basis of the assessment of the wound. Although further research is needed on the possible effects of these products on wound healing, their use remains common for many chronic wounds in the home care setting.
- A saline solution can be prepared in the home setting by boiling a quart of water for 5 minutes and then dissolving 2 teaspoons of salt in the water. Once the water has cooled, it can be used for wound cleansing or dressing changes.
- The solution can be kept for 1 week at room temperature if stored in a tightly closed container.

Like foams, alginates are useful in the highly exudative wound. They are made from brown seaweed fibers and are highly absorbent, capable of absorbing up to 20 times their weight. They are nonadhesive, nonocclusive, and usable in a variety of wounds. They can be combined with foam or another dressing type to increase the dressing's overall absorbent capabilities and decrease the frequency of dressing changes. Alginates should be avoided in dry wounds. They have a homeostatic property, meaning they have the ability to stop bleeding, so they are useful in bleeding wounds.

4. What type of dressings might be appropriate for P. J.'s wounds? State the rationale for your answer.

Gels, made in both tube and sheet versions, are used to add moisture to a wound, thus creating a moist environment and allowing autolytic debridement and wound healing to occur. Because of their high moisture content, they absorb very little wound drainage and thus are inappropriate for a highly exudative wound, and they can cause maceration of the periwound skin if used incorrectly.

5. Identify at least three nursing interventions that would be appropriate to address P. J.'s risk factors.

Drains

The placement of drains in or around surgical sites is thought to reduce the chance of infection by preventing excess blood, serum, or pus from collecting in the surgical area. The nurse is responsible for understanding the different types of drains and the care required by the patient with a drain. The amount, color, consistency, and odor of the drainage are assessed on a regular basis, with changes noted and reported to the surgeon or primary care provider (PCP). The skin around the drain is assessed for signs of infection (increasing warmth, drainage, erythema, pain) or damage from the drainage. Drainage from the small intestine, gallbladder, stomach, and pancreas is damaging to the skin, and protective action is taken in areas exposed to drainage from these sources. Effective strategies to prevent chemical damage to the skin from drainage include the use of barrier ointments designed for incontinence together with frequent dressing changes and the use of pouches similar to those used for ostomy management.

Drains can be closed or open systems and may or may not be sutured into place. Closed drainage systems (Box 29.8), such as **Jackson-Pratt (JP) drains** and **Hemovac drains**, are soft drains attached to a bulblike (JP) or springlike (Hemovac) suction device. When the drain is compressed and plugged, it provides suction by pulling

drainage from the wound as it reexpands. Although many closed drainage systems are placed during surgery, they can be inserted into fluid collections using ultrasound or computed tomography (CT) guidance.

Box 29.8

Nursing Care Guideline

Closed-Wound Drainage System: Hemovac and Jackson-Pratt

Background

- Closed-wound drainage most commonly is used for orthopedic and abdominal surgical patients.
- The system drains extra fluid from inside the surgical wound to the outside of the body and into a reservoir, or collection device, at the end of the tubing by maintaining constant mild to moderate suction.
- The system promotes healing, because granulation tissue (healing cells) can adhere to the surgical site when the wound is drained.
- The number of microorganisms entering the wound is reduced, because the system is closed (i.e., it has no open ends), and the drain usually is sutured in place in the sterile environment during surgery.
- The drain usually is disconnected by the surgeon or primary care provider (PCP) 3 to 5 days after surgery.

Emptying a Hemovac drainage system into a graduated cylinder. (Copyright © Mosby's Clinical Skills: Essentials Collection.)

Opening the plug on a Jackson-Pratt drainage system. (Copyright © Mosby's Clinical Skills: Essentials Collection.)

Procedural Concerns

- Always wear gloves, and do not touch the port or plug when emptying the reservoir.
- Use a marked, graduated measuring device to collect the drainage when emptying the reservoir to facilitate accurate measurement of the drainage. (A graduated cylinder or specimen cup can be used to drain a Hemovac device; a 30-mL plastic medication cup usually is used to drain a Jackson-Pratt [JP] device.)
- Empty the reservoir every 4 to 8 hours, depending on the surgeon or PCP orders and the amount of drainage.
- After emptying, recompress the device to maintain suction: With the port open, squeeze the reservoir, wipe the port and plug with an alcohol wipe, and close the port. The container should remain compressed to ensure that suction is applied.
- Secure the container(s) to the patient's hospital gown below the level of the wound, avoiding tension on the tubing.

Documentation Concerns

- Observe and document the amount, color, type (serous, serosanguineous, sanguineous), odor, and consistency of the drainage.
- Observe and document any signs of infection at the opening for the tubing or in the drainage.
- If multiple drains are in place, label them and document observations by the drain label.
- If no drainage is seen, check the tubing for kinks or blockage; make sure that the tubing is not dislodged. Notify the surgeon or PCP of any problems.

Closed drainage systems allow for a more accurate assessment of the drainage and prevent bacteria on the dressing from tracking up the drainage tube. Like open drains, closed drains often are removed before hospital discharge, but they can still be in place in a patient discharged to the home setting.

The **Penrose drain**, an open drain that is a flexible piece of tubing, usually is not sutured into place ([Box 29.9](#)). Care is taken to not inadvertently remove the drain during dressing changes. This type of drain usually is removed over a period of several days before discharge.

Box 29.9

Nursing Care Guideline

Open-Wound Drainage System: T-Tubes and Penrose Drains

Background

- Open-wound drainage is most commonly used in patients who have had abdominal surgery, particularly after incision and drainage procedures, gallbladder surgery, or other operative procedures involving the common bile duct.
- The system drains excess fluid through a passage created from an internal wound to the outside of the body and onto a wound dressing. The pressure inside the wound is greater than the pressure outside the body; therefore the drainage flows out of the tube onto the dressing.
- The drains typically are inserted through stab wounds a few centimeters away from the surgical incision line, to prevent any interference with healing of the main surgical site.

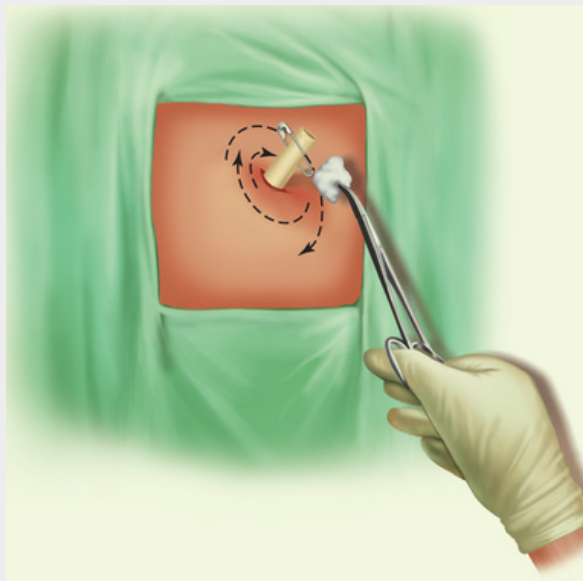

Procedural Concerns

- To prevent infection, always wear sterile gloves, and avoid touching the opening except with sterile forceps.
- Penrose drains are not sutured in place.

Penrose drains are not sutured in place. (From Williams P: *deWit's fundamental concepts and skills for nursing*, ed 5, St. Louis, 2018, Elsevier.)

- A sterile safety pin is placed through the portion of the drain outside the body during surgery to prevent the tube from slipping inside the wound.
- Care must be taken when changing dressings to keep the drain from becoming dislodged and to prevent the tube from being compressed.
- T-tubes or biliary draining tubes are T-shaped tubes. The top of the T is inserted into the bile duct during surgery with the straight end exiting the skin similar to a Penrose drain. They may or may not be sutured in place.
- A T-tube may remain connected to the drainage bag for approximately 1 week, at which time the bag may be disconnected and the tube tied or capped. The tube may be left in place for up to 6 weeks.
- Care should be taken to prevent drainage from coming into contact with the skin around the site, because the drainage is highly irritating to skin.
- Cleansing an open-wound drainage system is performed in a circular motion, working from the site of the drain outward and away from the drain. Drain sponges are applied after cleansing, and then sterile 4 × 4 gauze pads and an absorbent abdominal (ABD) pad are applied to absorb drainage.

Documentation Concerns

- Observe and document the amount, color, type (serous, serosanguineous, sanguineous), odor, and consistency of drainage.
- Observe and document any signs of infection at the opening for the tubing or in the drainage.
- If multiple drains are in place, label them, and document observations by drain label.
- If no drainage is seen, check the tubing for kinks or blockage; make sure that the tubing is not dislodged. Notify the surgeon or primary care provider (PCP) of any problems; for example, an abscess can be a common complication with this type of drainage system.

Negative-Pressure Wound Therapy

Negative-pressure wound therapy (NPWT), or vacuum-assisted closure (VAC), uses negative pressure to remove excess wound fluid, stabilize the wound edges, and stimulate granulation tissue (Skill 29.4). In some studies, this management technique has been shown to reduce the bacteria count in the wound. Although specific features vary among brands, application of the negative-pressure system generally consists of placing a foam sponge or other dressing into the wound, covering this dressing with a transparent adhesive drape, and applying a controlled amount of suction to the wound through the drape. The dressing usually is changed every 3 days but can be changed more frequently, depending on the wound assessment. It is used on acute and chronic wounds, including dehiscent wounds and fasciotomies, pressure injuries, venous stasis ulcers, and skin flaps, to promote wound healing. Although the cost of this device is absorbed by the prospective payment received from insurance in the acute care setting, it may not be fully covered in the home care setting.

Suture Care

Sutures are used to bring the edges of a wound together in order to speed wound healing and reduce scar formation (Box 29.10). The sutures can be threads or metal staples. Some are located deep within the tissue, usually dissolving over time; others

are visible from the skin surface and need to be removed later (Fig. 29.23). The timing of suture removal will vary, depending on the type of surgery and patient factors that might affect wound healing, but sutures generally are removed 7 to 14 days after insertion, when the formation of the healing ridge indicates that collagen synthesis has taken place. Special tapes, such as Steri-Strips, although not providing as strong a closure as with sutures, sometimes are used to close superficial or partially healed wounds.

Box 29.10

Nursing Care Guideline

Suture and Staple Care

Background

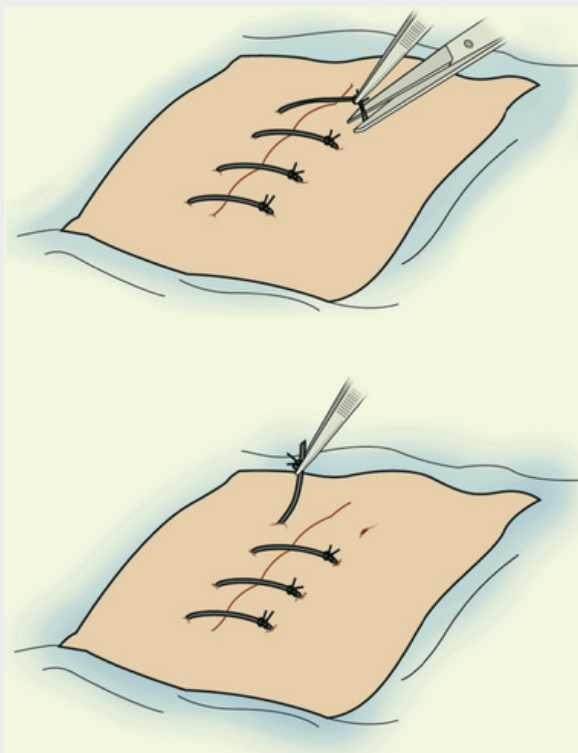

- Wounds may be closed with Steri-Strips, Dermabond glue, sutures, or staples. The choice is made by the surgeon or primary care provider (PCP), with the main goal of decreasing infection and minimizing scarring.
- Policies vary among facilities, regarding whether the nurse is allowed to remove sutures and staples. If the nurse is allowed to remove them, an order from the surgeon or PCP is required. This order should specify how many days after application the removal should occur and whether all staples or sutures should be removed.
- There are three primary methods of suturing:
 - In intermittent suturing, each suture is tied and knotted individually. Each suture is created from a single piece of material. Numerous pieces of suture material create the suture line.
 - In continuous suturing, the suture line is one continuous piece of material with a tie or knot at the beginning of the line and a second tie or knot at the end.
 - In retention suturing, stronger and deeper sutures are made and typically must be removed by the surgeon or PCP.
- Suture materials include silk, cotton, Dacron, linen, nylon, wire, and steel.
- The use of antimicrobial sutures is recommended to reduce the incidence of surgical site infections (SSIs) ([World Health Organization, 2016](#)).

Procedural Concerns

- The incision may or may not have to be cleansed on a regular basis, but it should be cleansed before and after removal of the sutures or staples.
- Some orders include that the site be covered with a dressing, whereas others require that the site be open to the air. Either way, some drainage is part of the normal healing process.
- Cleansing of the incision may be ordered. If signs of infection are noted, cleansing of the suture line may be required.
- Cleansing is always performed from the least contaminated area to the most contaminated area:

- Clean from the suture line outward (first on one side of the incision and then on the other).
- Alternatively, clean directly down the suture line and then to either side.
- For each cleansing stroke, use a new sterile gauze pad with the ordered cleansing solution applied.
- See [Skill 29.2](#), for further information.
- Sutures and staples typically are removed 7 to 14 days after insertion, depending on the PCP's order. Retention sutures are left in place longer (typically 14 to 21 days).
- Use sterile technique when removing sutures or staples
- When removing sutures or staples, skip every other one. This is a precaution to ensure that the incision is healed and the edges are approximated before completely removing all sutures or staples.
- To remove sutures:

(From Williams P: *deWit's fundamental concepts and skills for nursing*, ed 5, St. Louis, 2018, Elsevier.)

- Put on sterile gloves. To avoid sliding the scissors under the skin, use forceps to lift the suture material away from the skin. Then, using curved suture scissors, cut the material as close to the skin as possible.

- Use forceps to pull the suture material out of the incision. Make sure to pull the suture out from under the skin, rather than pulling exposed suture material through the skin. This prevents pulling microorganisms on the exposed suture material through clean tissues, possibly causing an infection.
- If the suture line is continuous, make a second cut as close as possible to the skin, and repeat the process.
- To remove staples:

(From Williams P: *deWit's fundamental concepts and skills for nursing*, ed 5, St. Louis, 2018, Elsevier.)

- Use a medical staple remover. It is important to recognize that removal of staples may be more painful for the patient than removal of sutures.
- Slide the tip of the staple remover under the center of each staple, and slowly squeeze the handles to bend the staple. The staple should not break.
- Free the staple from the skin and incision line. If necessary, use forceps to gently remove the staple.
- Discard removed staples in a sharps disposal container.
- Steri-Strips may be applied after suture or staple removal to support wound approximation and minimize scarring.

Documentation Concerns

- Observe and document the amount, color, type, odor, and consistency of any drainage at the incision site or on the dressing.
- Observe and document any signs of infection at or around the incision site or in the drainage.
- Document the type of suture line, material, and number of sutures, as well as any problems with the procedure and patient tolerance.
- Document the number of staples, as well as the ease of removal and patient tolerance.
- Notify the surgeon or PCP before removing sutures or staples if there are signs of infection or if the wound edges separate after removing the sutures or staples.

Evidence-Based Practice

Current guidelines strongly recommend that incisions be covered with a sterile dressing for 24 to 48 hours, but the evidence is inconclusive as to whether the incision should remain covered or be left open to the air after this time frame to avoid infection.

It is clear, however, that hand hygiene and the utilization of sterile technique when changing the dressing are imperative to prevent infection at the site (World Health Organization [WHO], 2016). Additionally, prolongation of prophylactic antibiotic therapy postoperatively is not recommended for the purpose of decreasing surgical site infections (SSIs) (WHO, 2016).

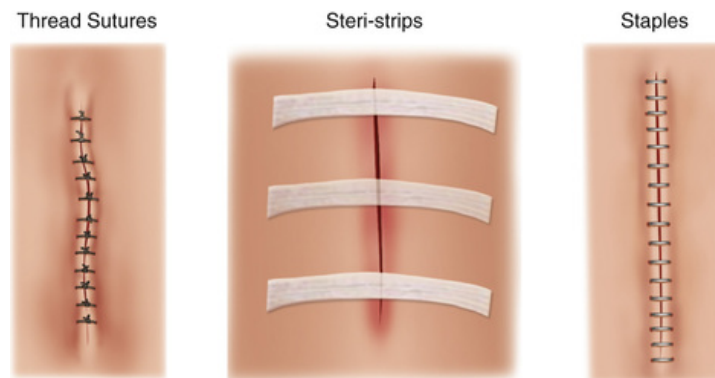

FIGURE 29.23 Types of wound closures.

Nursing care for the patient with sutures includes an assessment of the incision line and the tissue around each individual suture for changes in drainage, warmth, erythema, and pain. Although some erythema is a normal reaction to the presence of a foreign body, increasing redness, particularly when accompanied by an increase in pain, warmth, or drainage, can be an indication of infection.

Bandages and Binders

Bandages and binders are placed over wound dressings to secure a dressing or splint, to provide support and protection to the healing wound, to apply pressure to reduce bleeding, or to immobilize a body part (Skill 29.5). They come in many shapes, sizes, and compositions and may be intended for a single use, as in the case of rolls of gauze, or for multiple uses, as with elastic bandages, slings, and binders. An additional reason for their use is to reduce the amount of tape required during dressing changes by securing the underlying dressing with a bandage or binder. Use of this means of wound support reduces the incidence of skin tears due to tape. The bandage or binder is wrapped so that the underlying circulation is adequate and the patient is comfortable. Adjustments of the bandage or binder may be necessary after application. When a bandage is applied to an extremity, the nurse assesses the five *Ps* of circulation —*pain, pallor, pulselessness, paresthesia, and paralysis*—within 30 minutes of application. If any of the *Ps* are present, the bandage is removed and rewrapped so that it is less constricting.

Montgomery straps may be used instead of a binder. Montgomery straps are adhesive, multiholed straps placed on the skin on opposite sides of a wound. Gauze ties are then placed connecting the opposite holes of each piece of the paired tapes. This provides a means of securing a bandage, and subsequently changing it, without having to replace tape each time, thereby helping reduce the incidence of skin tears. See [Chapter 37](#) for more information.

Heat and Cold Application

The therapeutic application of heat or cold has been used for years as a complimentary or alternative therapy to reduce pain, improve circulation, and reduce swelling. In

many cases the use of these therapies requires a doctor's order, because serious complications related to their use have been documented. The order should specify the type of application, the length of the treatment, and its frequency, as well as the body part to be treated (Box 29.11).

Box 29.11

Nursing Care Guideline

Application of Heat and Cold Therapies

Background

- Heat causes vasodilation, improving blood flow and bringing oxygen, nutrients, and leukocytes to the area; it decreases edema, promotes muscle relaxation and decreases stiffness, helps debride wounds, and can be soothing for the patient. It can be applied through moist heat in compresses, soaks, or baths; through dry heat delivered using electric heating pads, disposable hot packs, or pads through which warm water is circulated; or through radiant heat from a heat lamp.
- Cold causes vasoconstriction, reducing the oxygen demands of the tissue; it decreases pain, decreases swelling, decreases blood flow, prevents edema, provides anesthesia, and relieves muscle spasms. It can be applied through the use of ice bags, cool compresses, cool soaks or baths, or pads through which cool water is circulated.

Procedural Concerns

Assessments

- Examine the baseline integumentary status in the area designated for application of heat or cold.
- Assess for sensory changes in the area to be treated. Assess for neuropathies.
- Check the condition of equipment: Do not use any equipment if there are questionable safety conditions.
- Assess extremity circulation. If circulation is impaired, do not apply cold; notify the primary care provider (PCP).

Patient Position

- Patient must never lie on a heat therapy device. Pressure intensifies the effects of heat, increasing the risk for burns.

Contraindications

- Heat should not be used in the presence of:
 - Bleeding (heat promotes vasodilation, so bleeding will continue)
 - Cardiovascular pathophysiology (heat should not be applied to large areas of skin because it disrupts blood flow to organs)
 - Local abscess, because rupture could occur

- Undiagnosed abdominal pain, because an inflamed appendix could rupture
- Cold should not be used if any of the following is present:
 - Edema (cold application slows reabsorption of the fluid)
 - Circulatory pathophysiology (cold application causes vasoconstriction, further reducing circulation to the area)
 - Shivering (this is a comfort concern)
- Application of heat or cold in the following situations results in altered sensory abilities and, ultimately, tissue damage. Frequent assessment of the patient is needed if treatment is applied under conditions of:
 - Neuropathy
 - Altered level of consciousness
 - Advanced age (skin thickness is a concern)

Specific Orders

- Application time for heat is as stated in the order; for cold, it is a maximum of 20 to 30 minutes.
- Moist heat/cold compress:
 - With this type of compress, sterile gauze or linens soaked with sterile solution typically are applied over the wound.
 - Cover the area with towels or a waterproof pad to maintain temperature.
- Moist heat/cold soak:
 - Completely submerge the extremity in the solution, which may be medicated if ordered.
- Maintain the temperature of the soak:
 - Cover the solution container and the extremity to minimize temperature change.
 - Check the solution and change it or add to it every 10 minutes, as needed.
 - Thoroughly dry the extremity to prevent tissue breakdown.
- Sitz bath:
 - Soak the pelvic area for 20 minutes.
 - Adjust the temperature according to facility policies and procedures.
 - Use a chair, tub, or toilet attachment (basin). A hose attached to it allows water to spray the pelvic area and gradually fill the basin.
 - Ensure that the patient is able to sit up.

Sitz bath. (From Theratherm, Chattanooga, TN, a DJO company.)

- Aquathermia (Aqua-K) pads (hot or cold):

(Courtesy Briggs Healthcare, West Des Moines, Iowa.)

- Each pad contains a control unit that regulates water flow and temperature through the channels in the pad.
- Use only distilled water.
- Place a towel between the patient's skin and the pad to prevent burns.
- Place the pad on top of the area being treated.
- Commercial hot/cold packs: Follow the manufacturer's instructions.
- Ice bags:

- Fill with water.
- Fill only two-thirds full if using crushed ice.
- Release air from the bag before sealing.

Documentation Concerns

- Document the equipment used and patient assessments.
- Assess and document any signs of infection at the site of application on the patient's skin or in the drainage.
- Note the time of application and application frequency. Document skin assessments throughout treatments.
- Treat and document adverse effects in accordance with facility policy and procedure. Note patient concerns and complaints, as well as interventions. Document patient education.

Evidence-Based Practice

- Heat and cold therapies have been shown to be safe adjuncts, after effective education, for treating and managing pain in pediatric patients (Lockett & Hays, 2013).
- Cold applications had a positive impact on postcardiac patients for pain relief from coughing when applied to the sternal incision in the form of a gel pack (Zencir & Eser, 2016).

The most serious complication that can result from the application of heat or cold arises secondary to the body's loss of its normally protective ability to sense temperature extremes through its adaptation to the change in temperature. With such deficits, after an initial sense of a change in temperature, the body then adapts and, within a short time, no longer senses the temperature as being unusually hot or cold. Damage to tissue, from either temperature extreme, can result. The nurse assesses the patient's age and ability to sense temperature and pain, the integrity of the skin, and the specific area to be treated and its size before applying either heat or cold. Patients who are more at risk for injury are the very young or very old; those with a history of cardiovascular or peripheral vascular disease, peripheral neuropathies, sensory changes, or open wounds; and those in whom a large area of tissue requires treatment. The skin of the neck, the inner aspect of the forearm, and the perineal area are less tolerant of temperature extremes and should be monitored carefully for changes (Box 29.12).

Box 29.12

Patient Education and Health Literacy

Heat and Cold Therapy

- Use of heat and cold therapies in the home requires patient and family education to maximize patient safety.
- Written instructions, photos, demonstration of the equipment needed, and videos all enhance the use of equipment for providing heat and cold therapies.

- A return demonstration by the patient or family member ensures understanding of the principles of safe use of these therapies.
- Patient education includes coordination with the social worker or the discharge planner to ensure that the teaching accomplished in the health care setting about all of the issues related to skin and wound problems can realistically translate to the home environment.

With both heat and cold therapies, it is important to have the patient report any pain or changes in sensation, to monitor the time that the tissue is exposed to the heat or cold source, to assess the skin before and after treatment, and to follow facility and manufacturer guidelines.

Safe Practice Alert

Warm compresses and water for soaks should not be heated in the microwave unless the product and microwave are specifically designed for this type of heating. The uneven heating and inability to measure the resultant temperature can result in serious burns to the patient.

Evaluation

It is essential to evaluate whether the patient has achieved the agreed-on goals. Although this often is considered the last step in the nursing process, it is really an integral part of an ongoing process whereby the effectiveness of interventions is assessed and the plan of care is revised as necessary. For example, if a wound is not showing signs of healing or new wounds have developed, the factors that can influence wound healing must be reassessed and the plan of care adjusted on the basis of the new information gleaned from the assessment.

SKILL 29.1 Irrigating a Wound

Purpose

Wound irrigation is used to:

- Clean a wound.
- Apply heat, which promotes healing.
- Apply medication (such as antibiotics).
- Remove debris and exudates.
- Remove bacterial colonizations.
- Prevent skin from healing over a deeper wound that must remain open.

Resources

- Solutions (may be warmed):
 - Sterile normal saline solution
 - Lactated Ringers solution
 - Ordered antibiotic solution
- Irrigation delivery system:
 - Deep wound: 30- to 50-mL piston syringe with an 18-gauge angiocath
 - Oral waterjet system
 - Sterile catheter
 - Sterile irrigation set
- Personal protective equipment (PPE):
 - Goggles
 - Gown
 - Mask
- Sterile drape
- Sterile gloves
- Sterile gauze pads
- Waterproof pads or towels
- Sterile basin
- Clean emesis basin

Interprofessional Collaboration and Delegation

- Irrigating a wound may not be delegated to unlicensed assistive personnel (UAP), but UAP can assist in the following tasks:

- Transporting specimens
- Positioning, comfort, and support of the patient
- Collaboration with the following professionals might occur before, during, and after wound irrigation:
 - A wound ostomy continence nurse (WOCN) specialist:
 - May perform the procedure
 - Coordinates assessment and timing of this procedure with other procedures
 - An infection control nurse:
 - Documents any confirmed infection
 - Places the patient on appropriate isolation precautions
 - Consults with the primary care provider (PCP) for appropriate actions
- The PCP provides appropriate orders, which are carried out by the nurse and other personnel.

Evidence-Based Practice

- The irrigation solution is delivered to the wound bed using a 30- to 50-mL syringe and an 18-gauge catheter. Unlike the 1 pound per square inch (psi) of pressure or less that is delivered by a standard bulb syringe, the use of a 30- to 50-mL syringe and an 18-gauge catheter has been shown to achieve an irrigation force that falls within the recommended 4 to 15 psi ([Ramundo, 2016](#)).
- Cleansing a wound with tap water has not been shown to increase infection rates as long as the water is drinkable. Some evidence has shown that tap water has been just as effective as sterile water or normal saline solutions in cleansing wounds. This has important implications for home care and emergency situations, because tap water is much more cost-effective and more readily available than other solutions ([Hillenbrand, Buhner, & Horch, 2016](#)).

Special Circumstances

1. **Assess:** Does the patient have signs of a systemic infection, such as fever and elevated heart rate?
Intervention: Notify the PCP; obtain orders for cultures; and document.
2. **Assess:** Is the patient in pain?
Intervention: Determine whether the pain is new or preexisting:

- Stop the procedure if the pain is a new complaint. Medicate the patient, and wait $\frac{1}{2}$ hour before resuming the procedure.
 - With known discomfort, premedicate the patient $\frac{1}{2}$ hour before the procedure.
 - Notify the PCP, if needed, and document as appropriate.
3. **Assess:** Was there bleeding during the procedure?
Intervention: Determine whether the bleeding is new or happened previously.
- Stop the procedure if new bleeding is evident. Assess the wound, and notify the PCP as appropriate.
 - Document.
4. **Assess:** What should be done if there is a bulb syringe in the irrigation kit?
Intervention: Obtain a piston syringe instead. Only limited control can be achieved with a bulb syringe, and it is not appropriate for wound irrigation.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct PPE is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.
- VI. Provide for patient privacy.
It is important to maintain patient dignity.
- VII. Identify the patient, using two identifiers.
Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.
- VIII. Explain the procedure to the patient.
The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Wound Irrigation

Follow preprocedure steps I through VIII.

1. Follow the steps in Skill 29.2 in the “Positioning/Preparation” section.
2. Follow the steps in Skill 29.2 in the “Removing an Old Dressing” section.
3. Place a waterproof pad and the clean basin beneath the wound.
Use the pad and basin to protect the bed linens from irrigation fluids.
4. Prepare a sterile field (see [Chapter 26](#), Skill 26.4). There are several variations for this skill:
 - a. Be aware that supplies vary depending on the wound type and assessment and on the PCP orders.
 - b. Place the sterile solution container on a clean work field. Do *not* touch the inside of the container.
 - c. Pour sterile normal saline solution or the PCP-ordered solution into the sterile basin (see Step 4 in the “Adding Sterile Supplies to a Sterile Field” section of Skill 26.4).
 - d. Drop other sterile items (such as gauze rolls, 2 × 2 pads, 4 × 4 pads, or foam) from their packages onto the sterile field (see Step 2 in the “Adding Sterile Supplies to a Sterile Field” section of Skill 26.4).
 - e. Put on sterile gloves (see [Chapter 26](#), Skill 26.2).
The sterile field and proper glove use reduce the number of microorganisms, thereby preventing or reducing further infection. Preparation of the field before the procedure provides organization to facilitate the procedure.
5. Fill the syringe with solution.
Avoids unnecessary interruption of the procedure once it has begun.
6. Irrigate the wound from the least contaminated area to the most contaminated.
 - a. If a syringe is used, keep it 1 inch above the wound.

STEP 6A (Copyright Mosby's Clinical Skills: Essentials Collection.)

- b. If a catheter is used, gently insert it until it meets resistance.

STEP 6B (Copyright Mosby's Clinical Skills: Essentials Collection.)

Irrigation should be from the least contaminated to the most contaminated area to prevent the spread of microorganisms from more contaminated areas.

7. If you run out of solution before completing the wound irrigation, pinch the catheter, remove it from the syringe, refill it with fresh solution, reattach the syringe to the catheter, and continue.
Maintains sterile procedure.
8. Stop when the solution flow is clear or the ordered amount has been administered.
9. Thoroughly dry the periwound area using sterile gauze and a patting motion; do *not* rub the wound to dry it. Dispose of gauze and waterproof pads in appropriate containers.
Proper drying prevents further skin breakdown from moisture. Patting (rather than rubbing) prevents healthy tissue from being removed and reduces trauma to the wound.
10. Re-dress the wound (see [Skill 29.2](#) or [Skill 29.4](#)).

Follow postprocedure Steps I through VI.

Postprocedure

- I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach of the patient.
Precautions must be taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.
- II. Assess for additional patient needs, and state the time of your expected return.
Meeting patient needs and offering self promote patient satisfaction and build trust.
- III. Properly dispose of PPE.
Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.
- IV. Clean or dispose of equipment that was in contact with the patient; see specific manufacturer instructions.
Disinfection eliminates most microorganisms from inanimate objects.
- V. Perform hand hygiene.
Frequent hand hygiene prevents the spread of infection.
- VI. Document the date, time, assessment, procedure, and patient's response to the procedure.
Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

SKILL 29.2 Changing a Sterile Dressing: Dry, Wet/Damp-to-Dry

Purpose

Sterile dressings are required for:

- Preventing infection
- Protecting a wound from injury
- Promoting wound healing

Sterile dressings may be removed to:

- Clean a wound
- Debride unhealthy tissue
- Apply a clean dressing
- Apply a new treatment
- Observe or assess wound healing
- Leave a wound open to the air

Resources

- Sterile normal saline solution
- Goggles
- Gown
- Sterile gloves
- Clean nonsterile gloves
- Waterproof pads or towels
- Sterile basin
- Waterproof trash bag or biohazard bag
- Sterile gauze pads:
 - The size of the gauze depends on the wound size
- Wet-to-dry dressings also may require a gauze roll
- Large, absorbent outer dressing or abdominal (ABD) pad
- Sterile cotton-tipped applicators
- Sterile forceps
- Tape
- Skin protectant
- Metric ruler
- Acetone-free adhesive remover, if appropriate

Interprofessional Collaboration and Delegation

- If allowed by facility policy, simple nonacute wound dressing changes may be delegated to unlicensed assistive personnel (UAP) without a nurse's assistance after assessment of the wound.
- UAP should report the following to the nurse:
 - Patient pain before, during, or after the procedure
 - Difficulties encountered while performing the procedure
- UAP should be instructed in:
 - Appropriate procedure and appropriate time to complete the procedure
 - Appropriate documentation
- Coordinate the procedure with a physical therapist if other wound treatments are required (such as whirlpool or electrical stimulation).
- Collaborate with the primary care provider (PCP) or the surgeon, and coordinate the procedure with the physician's rounds if the wound needs to be examined.
- It is important for interprofessional health care providers at the next level of care to be aware of the wound care treatment plan before patient transfer or discharge to home or another facility. It may be necessary to order supplies and equipment for home or the next facility before discharging the patient from the acute care facility.

Evidence-Based Practice

Promoting a moist wound environment has been shown to improve wound healing. In a wet/damp-to-dry dressing, the moistened gauze dries out, adhering to the surface of the wound. When the dressings are removed, debridement of the surface tissues occurs. However, wet/damp-to-dry gauze dressings are not selective, so they may remove healthy tissues, causing further damage to the wound bed. Wet/damp-to-dry dressings may be appropriate for short-term use for debridement; however, other types of debridement should be considered ([Ramundo, 2016](#)).

Special Circumstances

1. **Assess:** Is the patient complaining of pain?
Intervention: Determine whether the pain is new or preexisting.
 - Stop the procedure if the complaint of pain is new.
 - Medicate or premedicate the patient, according to orders.
 - Notify the PCP if no orders exist for wound pain.
2. **Assess:** Does the patient show signs or symptoms of infection?
Intervention: Consider culturing the wound (see [Skill 29.3](#)).

- Consult with a wound ostomy continence nurse (WOCN) specialist or the interprofessional health care team.
 - Notify the PCP.
3. **Assess:** Is the patient knowledgeable about the wound care procedures?
Intervention: Educate the patient and the patient's family. Include:
- The purpose of the treatment
 - An explanation of who will be changing the dressings and when
 - The procedure for dressing changes and their frequency
 - The signs and symptoms of infection or other complications, and guidance on when to notify the PCP if they occur
 - The appropriate disposal of soiled dressings
- Have the patient or caregiver perform a return demonstration.
4. **Assess:** Is assistance required for performing the procedure?
Intervention: Obtain assistance, if needed, from UAP or through collaboration with the wound care specialist or physical therapist. Consider the following when making this decision:
- The patient's ability to cooperate
 - The complexity of the required interventions
 - The support systems available
 - The facility policies, procedures, and requirements
5. **Assess:** Is the gauze sticking to the wound as the old dressing is being removed?
Intervention: Assess the type of dressing involved.
- If it is a wet/damp-to-dry dressing, do *not* moisten the dressing. Warn the patient of the discomfort, and continue to remove the dressing. The purpose is to debride the wound, so moistening the gauze would defeat this purpose.
 - If it is a dry dressing, moisten the dressing with normal saline solution and gently attempt to remove the gauze; this prevents further trauma to the wound.
6. **Assess:** What is a safe way to dispose of a small dressing?
Intervention: Fold the dressing inside the gloves as they are removed using the technique described in Skill 26.2.
- Dispose of the gloves with the dressing in an appropriate trash receptacle.
 - Keeping the dirty dressing inside gloves for disposal further reduces the spread of microorganisms.
7. **Assess:** Is an additional dressing needed on top of the dry dressing?
- An additional dressing can absorb excess drainage from a wound.
 - An additional dressing can ensure that the dressing is secure.
- Intervention:** Place an ABD pad or another dressing material on top of the sterile gauze, and tape it in place.
8. **Assess:** Did bleeding occur during the dressing change?
Intervention: Observe, monitor, treat, and document as appropriate.
- The wound may require pressure to stop the bleeding.
 - Notify the PCP if bleeding is excessive.

Preprocedure

- I. Check PCP orders and the patient care plan.

Knowledge of patient-specific orders is critical for safe patient care.

II. Gather supplies and equipment.

Preparing for the patient encounter saves time and promotes patient trust.

III. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

IV. Maintain standard precautions.

Use of the correct personal protective equipment (PPE) is required whenever contact with body fluids is possible in order to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient, using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Positioning/Preparation

Follow preprocedure Steps I through VIII.

1. Raise the bed to working height, and lower the side rails as appropriate and safe.

Setting the bed at the correct working height prevents provider discomfort and possible injury. Positioning should expose the wound but provide privacy and prevent overexposure.

2. Expose the wound, and position the patient appropriately:

- a. Treatments/solutions should flow from the least infected area to the most infected area.
- b. Towels and a waterproof pad must be under the patient/wound area before beginning the procedure.

Washing should proceed from the least contaminated to the most contaminated area to prevent the spread of microorganisms, and use of the proper solution should reduce the number of microorganisms and prevent infection. Towels and a pad protect linens and clothing. Preparing supplies in advance avoids

interruption during the procedure, promotes organization that facilitates the procedure, prevents patient discomfort due to repositioning, and ensures optimal care and dressing placement.

3. Place a waterproof trash bag or biohazard bag on the bed; fold the top of the bag over to make a cuff that will keep the bag open, and place the bag within reach.
Proper disposal of waste reduces the spread of microorganisms, protects linens, and provides organization to facilitate the procedure. Preparing supplies in advance avoids interruption of the procedure.

STEP 3 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Removing an Old Dressing

Follow preprocedure Steps I through VIII.

1. Follow Steps 1 to 3 in the "Positioning/Preparation" section, earlier.
2. Apply clean nonsterile gloves.
Using clean gloves reduces the spread of microorganisms.
3. Remove the old dressing:
 - a. Remove the tape by holding the skin taut and pulling the tape toward the dressing.

STEP 3A

- b. Gently remove one layer at a time of the gauze/packing/foam while observing the drainage on the dressing for color, quantity, and type.
 - c. Dispose of the dressing by folding it in on itself (soiled side of the dressing should be on the inside), and place it in the trash or biohazard bag.

STEP 3C

Careful tape removal reduces irritation of the wound edges. Removing layers of the dressing one at a time reduces the risk of infection and allows assessment of drainage and wound healing. Proper disposal of waste prevents the spread of microorganisms.

4. Remove excess adhesive on the patient's skin with an acetone-free adhesive remover.

Removing excess adhesive, if present, with each dressing change prevents build-up of adhesive, decreases skin irritation, and increases adherence of the new dressing.

5. Assess the wound:

- a. Observe for color and tissue type in the wound base.
- b. Observe the tissues around the wound.
- c. Measure the wound (see [Box 29.3](#)).
- d. Observe the drainage characteristics, including the amount visible.
- e. Assess the wound for signs and symptoms of infection.

The initial assessment provides a baseline that can be used to assist in determining whether the wound is healing, the need for any additional supplies, the best dressing type, and whether any changes are needed in the treatment plan concerning supplies or orders. If signs or symptoms of infection are noted, action taken at this time can prevent further infection and deterioration.

6. Remove the gloves, and dispose of them properly in the trash or biohazard bag. Perform hand hygiene.

Proper disposal of gloves and hand hygiene prevent the spread of microorganisms.

Follow postprocedure Steps I through VI.

Dressing Change: Dry Sterile Dressing

Follow preprocedure Steps I through VIII.

1. Follow Steps 1 to 6 in the “Removing an Old Dressing” section, earlier.
2. Prepare a sterile field (see [Skill 26.4](#)). Variations for this skill are as follows:
 - a. Be aware that supplies vary depending on the type and assessment of the wound and on PCP orders.
 - b. The sterile solution container should be placed on a clean work field. Do *not* touch the inside of the container.
 - c. Pour sterile normal saline solution into a sterile basin (see Step 4 in the “Adding Sterile Supplies to a Sterile Field” section of Skill 26.4).
 - d. Drop other sterile items (such as gauze rolls, 2 × 2 pads, 4 × 4 pads, or foam) from packages onto the sterile field (see Step 2 in the “Adding

Sterile Supplies to a Sterile Field” section of Skill 26.4).

e. Put on sterile gloves (see Skill 26.2).

Using a sterile field reduces the spread of microorganisms and prevents or reduces further infection. Preparation of the sterile field in advance of the procedure provides organization to facilitate the procedure.

3. Determine whether specific cleansing solutions or medications are indicated to treat the wound:

a. If specific products were ordered, follow the manufacturer instructions on the proper use of the product. You must comply with the Six Rights of Medication Administration (see [Box 35.4](#) before proceeding to Step 5 later).

b. If specific products were not ordered, proceed to Step 5.
Cleansing products remove excess drainage, reduce the spread of microorganisms, and prevent adverse events. Medications may be applied to a wound to debride or to prevent infection.

4. Determine whether irrigation of the wound was ordered:

a. If irrigation was ordered, see [Skill 29.1](#).

b. If irrigation was not ordered, proceed to Step 5.

Irrigation removes excess drainage and reduces the spread of microorganisms.

5. Clean the wound with sterile normal saline solution:

a. Depending on the size of the wound, use either a sterile cotton-tipped applicator (for small wounds) or gauze pads or sterile cotton balls (for large wounds; use with sterile forceps if needed).

STEP 5 (Copyright Mosby's Clinical Skills: Essentials Collection.)

b. Direction of cleaning should progress from the center of the wound toward the edges; cleaning should be performed using full- or half-circle motions.

c. Use a new applicator or gauze pad for each circle.

Proper application of sterile saline solution keeps the area of least contamination clean. Using a prescribed pattern ensures that all areas are cleaned. Frequent changes to new applicators or gauze pads will reduce the spread of microorganisms.

6. Clean the area around the wound (periwound area):

STEP 6

a. Use sterile normal saline solution.

b. Clean to at least 1 inch beyond the edges of the dressing.

Cleansing the area with sterile normal saline solution keeps the area clean, prevents infection, and reduces the spread of microorganisms.

7. Thoroughly dry the wound and periwound areas using sterile gauze and a patting motion; do not rub these areas.

Proper drying prevents further skin breakdown from moisture. Patting, rather than rubbing, prevents healthy tissue from being removed and reduces trauma to the wound.

8. Apply the dressing: Use an appropriate-size sterile gauze pad to cover the wound.

A dressing protects the wound from trauma and exposure to microorganisms.

9. Secure the dressing with the least amount of tape needed.

STEP 9

Removal of tape can cause skin damage; using less decreases the likelihood of tears when removing the tape.

10. Remove gloves, and dispose of them properly in the trash or biohazard bag. Perform hand hygiene.

Proper disposal of waste and hand hygiene reduce the spread of microorganisms.

Follow postprocedure Steps I through VI.

Dressing Change: Wet/Damp-to-Dry Dressing

Follow preprocedure Steps I through VIII.

1. Follow Steps 1 to 6 in the “Dressing Change: Dry Sterile Dressing” section, earlier.
2. Thoroughly dry the periwound area; pat the wound dry with sterile gauze (do not rub the wound); and apply skin protectant.

Dry the wound to prevent further skin breakdown from moisture and protect healthy tissue. Patting the wound and using a skin protectant prevents trauma to the skin and wound edges.

3. Prepare packing gauze:

- a. Use the ordered solution and packing material, or use sterile normal saline solution and gauze.
- b. Saturate the sterile gauze.
- c. Squeeze excess solution from the gauze.
- d. Open the gauze pads, or unravel the gauze rolls.
- e. “Fluff” the gauze by separating the layers.

Wet/damp-to-dry dressings should not be dripping wet; they should be moist.

Squeezing out excess moisture ensures that gauze is completely dry at the next dressing change. Proper preparation of the packing allows the gauze to absorb drainage.

4. Pack the wound:

- a. Pack the gauze gently and loosely into the wound to fill it.

STEP 4A (Copyright Mosby's Clinical Skills: Essentials Collection.)

- b. Use sterile forceps to insert the packing in most wounds.
- c. Use a sterile cotton-tipped applicator to insert the gauze or gauze strip if the wound is tunneled.
- d. Do not allow gauze to cover the wound edges.
- e. Use sterile scissors to cut the gauze roll, if used.

Packing too tightly increases pressure on the wound, leading to wound damage.

Loose packing allows the wound drainage to soak into the gauze or wick.

Using forceps or an applicator reduces the spread of microorganisms.

Avoiding moist gauze on healthy tissue prevents further skin breakdown from moisture.

5. Apply the primary dressing:
 - a. Use an appropriate size of sterile gauze.
 - b. Cover the wound.
A dressing protects the wound from trauma and exposure to microorganisms.
6. Apply a large, absorbent secondary dressing or ABD pad over the gauze.

STEP 6 (Copyright Mosby's Clinical Skills: Essentials Collection.)

A second layer of absorbent dressing absorbs excess drainage, promotes more secure dressing, and better protects the wound.

7. Secure all sides of the dressing with tape.
8. Remove gloves, and dispose of them properly in the trash or biohazard bag. Perform hand hygiene.
Proper disposal of waste and hand hygiene reduce the spread of microorganisms.

Follow postprocedure Steps I through VI.

Postprocedure

- I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach of the patient.

Precautions must be taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

- II. Assess for additional patient needs, and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment that was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

SKILL 29.3 Obtaining a Wound Culture Specimen

Purpose

Wound cultures are performed to:

- Determine whether infection exists
- Determine appropriate treatment for infection (by testing the sensitivity of the cultures to various medications)
- Evaluate the effectiveness of treatment for infection

Resources

- Sterile Culturette swabs
- Waterproof trash bags
- Patient labels
- Laboratory requisitions
- Clean or sterile gloves, depending on the wound
- Sterile normal saline solution
- Irrigation syringe
- Personal protective equipment (PPE), as needed

Interprofessional Collaboration and Delegation

Collecting a wound culture may not be delegated to unlicensed assistive personnel (UAP), but UAP can assist in the following tasks:

- Transporting specimens
- Patient positioning, comfort, and support

Collaboration with the following professionals might occur before, during, and after collection of a wound culture:

- A wound ostomy continence nurse (WOCN) specialist:
 - May note signs or symptoms of infection
 - May note improvement or deterioration of the wound
 - May request or collect a culture
 - Must ensure that appropriate cultures are obtained
- An infection control nurse:
 - Documents any confirmed infection
 - Places the patient on appropriate isolation precautions
 - Consults with the PCP for appropriate actions
- The PCP:

- Provides appropriate orders, which are carried out by the nurse and other personnel
- Consults with the nurse for any changes in medications based on the results of the culture

Evidence-Based Practice

Many health care providers are not educated regarding the proper techniques of collecting swab cultures of a wound, which is the specimen type that gives the least accurate results of wound culture (the gold standard is a tissue biopsy). It is imperative that nurses follow the facility's guidelines, based on standardized protocols, to collect a wound culture specimen via swab. This prevents unnecessary testing and/or treatment (Stotts, 2016).

In addition to understanding the assessment of signs and symptoms of localized and systemic infection, the nurse must recognize that patients with chronic wounds may not exhibit these clinical manifestations. The nurse needs to assess for foul-smelling drainage and pus, delayed healing, and increased wound breakdown; increased localized pain, warmth, redness, and swelling; and granulation tissue discoloration (Stotts, 2016).

Special Circumstances

1. **Assess:** Is the patient complaining of pain?
Intervention: If the patient has pain at the wound site:
 - Medicate the patient 30 minutes before the procedure.
 - Document the pain assessment and intervention.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible in order to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.
- VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient, using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Aerobic Culture: Swab

Aerobic means “needing or giving oxygen;” an aerobic culture would be available from a surface wound.

Follow preprocedure Steps I through VIII.

1. Remove the dressing (see [Skill 29.2](#)).
2. Cleanse or irrigate the wound (see [Skill 29.1](#)):
 - a. Use only sterile normal saline solution.
 - b. Ensure that exudates (drainage) are removed.

Irrigation removes noninfectious microorganisms (normal flora), as well as potentially infectious microorganisms; the exudate is considered contaminated because it contains microorganisms, whether they are infectious or not.
3. Collect the wound drainage sample:
 - a. Open the aerobic swab collection tube, while ensuring that the swab does not touch anything.

STEP 3A (Copyright Mosby's Clinical Skills: Essentials Collection.)

- b. Apply clean gloves.
- c. Moisten the swab with sterile normal saline solution.
- d. Insert the swab into actively draining tissue, *not* into necrotic tissue.
- e. Cover the swab with drainage material by rotating the swab and applying pressure.

STEP 3E (Copyright Mosby's Clinical Skills: Essentials Collection.)

f. Reinsert the swab in the Culturette tube making sure nothing touches the swab as it is replaced into the tube.

g. Secure the tubing top.

Using clean gloves prevents the spread of microorganisms and protects the provider from infection. Sterile gloves are used for irrigation and for sterile dressing changes and would be used to obtain a culture specimen only if the nurse needed to touch the wound area to obtain the culture. Proper preparation of the swab prevents contamination of the specimen, and covering the swab with exudate ensures the accuracy of the test by providing a sufficient quantity of sample for testing. Applying pressure produces wound fluid for sampling.

4. Crush an ampule of the collection medium within the Culturette tube if required by the manufacturer's instructions.

The ampule contains a chemical to preserve the specimen; such a medium is provided with most culture tubes.

5. Label the tube in accordance with facility policy and procedure; include the specific site from which the culture was drawn.

Proper labeling of samples prevents adverse events and medical errors.

6. Re-dress the wound (see [Skill 29.2](#) or [Skill 29.4](#)).

7. Place the tube in the resealable plastic bag or an appropriate transportation container.

Proper transport of specimens reduces the spread of microorganisms and protects providers from possible infections.

8. Transport the specimen to the laboratory.

Many tests are time- or temperature-sensitive, so avoid unnecessary delays.

Follow postprocedure Steps I through VI.

Anaerobic Culture: Swab

Follow preprocedure Steps I through VIII.

1. Follow Steps 1 through 3e in the “Aerobic Culture: Swab” section, earlier. Ensure that the special anaerobic culture swab is used.

Anaerobic means “without oxygen;” an anaerobic culture would be obtained from locations, such as deep within a tunneling wound.

2. Quickly remove the swab from the wound, and place it in the Culturette tube.

Minimize exposure of the sample to the air to ensure accurate results.

3. Label the tube in accordance with facility policy and procedure; include the specific site from which the culture was drawn.

Proper labeling of samples prevents adverse events and medical errors.

4. Place the tube in the resealable plastic bag or an appropriate transportation container, and transport it immediately to the laboratory.

Proper transport of specimens reduces the spread of microorganisms. Many tests are time- or temperature-sensitive, so avoid unnecessary delays.

5. Re-dress the wound (see [Skill 29.2](#), or [Skill 29.4](#).)

Follow postprocedure Steps I through VI.

Postprocedure

- I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach of the patient.

Precautions must be taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

- II. Assess for additional patient needs, and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

- III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

- IV. Clean or dispose of equipment that was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

- V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

- VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

SKILL 29.4 Negative-Pressure Wound Therapy, or Vacuum-Assisted Closure

Purpose

Negative-pressure wound therapy (NPWT):

- Promotes wound healing
- Provides a moist wound-healing environment
- Assists in development of granulation tissue
- Removes excess fluid
- Removes infectious materials

Resources

- Vacuum unit
- Evacuation canister
- Suction tubing
- Foam dressing
- Transparent occlusive dressing
- Sterile irrigation solution
- Normal saline solution
- Irrigation syringe
- Sterile scissors
- Sterile gloves
- Clean gloves
- Goggles
- Gown
- Waterproof pads or towels
- Waterproof trash bag or biohazard bag
- Skin protectant

Interprofessional Collaboration and Delegation

- The system setup for NPWT dressing changes and vacuum-assisted closure (VAC) therapy cannot be delegated to unlicensed assistive personnel (UAP). UAP may gather supplies and assist by handing the nurse supplies during dressing changes. UAP may assist with patient comfort, support, and positioning during and after the procedure at the nurse's discretion.
- UAP should report any of the following:

- Fever or a change in vital signs
- Mechanical problems with the VAC unit
- Loose dressings or alterations in the dressing
- Patient pain, discomfort, complaints, or concerns
- UAP should be instructed in appropriate:
 - Hygienic care for patients on VAC therapy
 - Equipment usage
 - Documentation
- Collaborate with the wound care specialist who may be responsible for dressing and system changes.
- Check the primary care provider (PCP) orders to make sure that correct supplies are readily available:
 - Ensure that the vacuum setting matches the PCP order.
 - Ensure that the vacuum is not disconnected for longer than 2 hours a day.
 - Coordinate dressing changes with PCP or surgeon rounds if possible. The PCP or the surgeon may want to assess the wound bed when the dressing is removed.
 - It is important for health care providers at the next level of care to be aware of the wound care treatment plan. It may be necessary to order supplies and equipment for the patient to take home or for the next facility before discharging the patient from the acute care facility.

Evidence-Based Practice

VAC therapy is used for acute and traumatic wounds, dehiscent wounds, partial-thickness burns, pressure injuries, and chronic open wounds such as diabetic ulcers, meshed grafts, and skin flaps. They aid in removing debris from the wound by using the vacuum action and pressure to gently draw the debris into the dressing and any wound drainage into the attached canister. The negative pressure also helps increase vascular perfusion to the wound site, which leads to reduced edema, reduced inflammation, and increased oxygenation. Localized subatmospheric pressure draws wound edges toward the center of the wound, leading to reduced edema and bacterial colonization and promotion of granulation tissue formation in the wound (Netsch, 2016).

VAC can be beneficial to both the nurse and the patient. For the nurse, VAC therapy requires fewer dressing changes. For the patient, VAC therapy has been shown to speed healing time, decrease expenses in terms of supplies and care, and shorten hospital stays (Netsch, 2016).

Special Circumstances

1. **Assess:** Are there any contraindications to VAC therapy?

Intervention:

- Do *not* proceed with therapy; contact the PCP for:
 - Wound tunneling (fistulas) that involve organs or body cavities
 - Necrotic tissue covered with eschar
 - Untreated infection of the bone (osteomyelitis)
 - Malignant wounds
 - Wounds with exposed arteries and veins
 - Use VAC cautiously in patients who:
 - Have active bleeding
 - Are on anticoagulant therapy
 - Have wounds with recurrent bleeding problems
2. **Assess:** Is the patient experiencing pain?
Intervention: Determine whether the pain is new or preexisting:
 - Nonpainful stinging is common on the initiation of therapy.
 - Stop the procedure if the pain is a new complaint.
 - Medicate or premedicate the patient, according to orders.
 - Notify the PCP if specific orders to address patient pain are lacking.
 3. **Assess:** Does the patient show any signs or symptoms of infection?
Intervention: Contact the PCP if there are signs and symptoms of local or systemic infection.
 4. **Assess:** Does the patient have knowledge of the VAC treatment modality?
Intervention: Educate the patient and family regarding the following:
 - Purpose of treatment
 - Who will be changing the dressings and when
 - Not to change vacuum settings
 - Not to remove the dressing unless directed
 - Not to disconnect the vacuum for longer than 2 hours a day
 - How to troubleshoot alarms
 5. **Assess:** Are the canister and vacuum system functioning appropriately?
Intervention: Educate the patient on appropriate inspection and safety techniques.
 6. **Assess:** Do the normal routines require modifications?
Intervention: Educate the patient on:
 - How to disconnect and reconnect the system for showering and bathing
 - How to monitor tubing, canister, and plug placement to minimize the risk of falls
 - How to appropriately dispose of soiled dressings
 7. **Assess:** Is an alarm sounding during treatment with a VAC?
Intervention: Troubleshoot the most common problems:
 - The canister has tipped more than 45 degrees.
 - The canister has been dislodged.
 - The canister is full, requiring change.
 - There is an air leak in the dressing.

Preprocedure

I. Check PCP orders and the patient care plan.

Knowledge of patient-specific orders is critical for safe patient care.

II. Gather supplies and equipment.

Preparing for the patient encounter saves time and promotes patient trust.

III. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

IV. Maintain standard precautions.

Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible in order to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient, using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Vacuum-Assisted Closure Device Preparation

Follow preprocedure Steps I through VIII.

1. Assemble a VAC device at the patient's bedside, following the manufacturer instructions.
The VAC setup varies according to different manufacturer specifications.
2. Set the negative-pressure setting according to the PCP order (usually 25 to 200 mm Hg).
Setting the machine ensures that PCP orders are followed. The VAC setting range promotes optimal, safe, high-quality patient care and prevents inadvertent errors.
3. Warm the irrigating solution to 90° to 95° F (32° to 35° C) if the wound is to be irrigated (see Skill 29.1).
Use a temperature range that promotes patient comfort and prevents tissue damage.
4. Proceed to "Vacuum-Assisted Closure Dressing Change" section next.

Vacuum-Assisted Closure Dressing Change

1. Refer to Skill 29.2, and follow Steps 1 through 6 in the “Dressing Change: Dry Sterile Dressing” section.
2. Thoroughly pat the wound dry with sterile gauze, dry the periwound area, and apply skin protectant.

Proper drying prevents further skin breakdown from moisture. Patting (rather than rubbing) prevents healthy tissue from being removed and reduces trauma to the wound.
3. Prepare the foam: Use sterile scissors to cut the appropriate type and size of foam material. More than one piece may be required.

Maintain sterile procedure to prevent the spread of microorganisms and reduce infection. Foam comes in a variety of types and shapes; the appropriate size depends on the size of the wound and treatment goals.
4. Place the foam in the wound.

Foam placement prepares the wound for a VAC dressing.
5. Place the transparent occlusive dressing over the foam, also covering 2 inches of intact skin around the wound. If the dressing supplied does not have a hole in the center, cut a hole with sterile scissors.

A proper seal is required to ensure that negative pressure is established.
6. Place the suction tubing in the center of the hole. *Note:* Tubing should not touch the wound bed. Place a second transparent dressing over the tubing and first dressing.

The suction tubing provides negative pressure to the wound, so it must be positioned properly.
7. Connect the other end of the suction tubing to the evacuation canister.

Once all tubing is in place, the system setup is complete.

STEPS 4 THROUGH 7 (Courtesy KCI, an Acclity Company. Used with permission.)

8. Remove gloves, and dispose of them properly in the trash or biohazard bag; perform hand hygiene.

Proper disposal of waste and frequent hand washing reduce the spread of microorganisms.
9. Turn on the vacuum unit to start the negative pressure; the transparent dressing should shrink and conform to the foam and skin.

Therapy begins once negative pressure is established. Shrinkage and conformation of the dressing to the foam and skin ensure a proper seal with no air leaks.
10. Maintain the unit by:
 - a. Measuring the drainage amount every shift
 - b. Changing the canister once a week or more frequently if it is full (follow facility policies and procedures)
 - c. Changing the dressing every 48 to 72 hours

Proper equipment maintenance provides optimal, safe, quality patient care.

Follow postprocedure Steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach of the patient.

Precautions must be taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs, and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment that was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

SKILL 29.5 Applying Wraps and Bandages

Purpose

The use of wraps, bandages, and binders:

- Promotes independence
- Secures dressings
- Promotes safety
- Decreases the risk of contamination
- Decreases the risk of further injury

Resources

- Appropriate-size wrap, bandage, or binder, as prescribed
- Tape measure
- Clean gloves
- Goggles
- Gown
- Mask
- Tape, pins, or self-closure devices (avoid metal clips)
- Gauze pads

Interprofessional Collaboration and Delegation

- Application of wraps, bandages, or binders may be delegated to unlicensed assistive personnel (UAP) without a nurse's assistance after assessment of the patient and any existing wounds, if allowed by facility policy and at the nurse's discretion.
- UAP should report any of the following:
 - Pain before, during, or after the procedure
 - Staining of underlying dressings
 - Difficulties in performing the procedure
- UAP should be instructed in:
 - Appropriate procedure and timing
 - Appropriate documentation
- Collaboration with the following professionals might occur before, during, and after the application:
 - A wound care nurse specialist:
 - May perform the procedure

- Coordinates assessment and timing with other procedures
- An infection control nurse:
 - Documents any confirmed infection
 - Places the patient on appropriate isolation precautions
 - Consults with the primary care provider (PCP) for appropriate actions
- Coordinate the procedure with a physical therapist if other wound debridement or stimulation treatments, such as whirlpool or e-stimulation, are required.
- Collaborate with the PCP or the surgeon and coordinate the procedure with the physician's rounds if the wound needs to be examined.
- It is important for health care providers at the next level of care to be aware of the wound care treatment plan. It may be necessary to order supplies and equipment for the patient to take home or for the next facility before the patient is discharged from the acute care facility.

Evidence-Based Practice

Wraps, bandages, and binders apply gentle, evenly distributed compression on a body part. Benefits include promoting venous return, decreasing blood pooling in lower extremities, increasing hemostatic pressure, and maintaining dressing placement.

Inconsistent patient use of bandages and wraps can be an issue that delays healing and well-being. The nurse needs to be aware of issues that interfere with proper use of bandages, such as pain, cost, discomfort related to heat or movement, and the patient's belief that the appliances do not help with underlying pathophysiology. The use of bandages and wraps is a proven best practice, and expertise in this modality will help the nurse provide effective patient education and encouragement. A wound care specialist may be of assistance ([Partsch & Mortimer, 2015](#)).

Special Circumstances

1. **Assess:** Is the patient experiencing pain?
 - Intervention:** Determine whether the pain is new or preexisting:
 - Stop the procedure if the pain is a new complaint.
 - Medicate or premedicate the patient, according to orders.
 - Notify the PCP if no orders exist to address patient pain.
2. **Assess:** Are there signs or symptoms of infection or overcompression?
 - Intervention:** Immediately remove any wrap, bandage, or binder.
 - Contact the PCP if there are signs and symptoms of local or systemic infection or any other complication.
 - Perform complete circulation checks of the distal portion of the affected limb to ensure presence of adequate circulation.
 - Never wrap the toes unless it is absolutely necessary.

3. **Assess:** Is the patient knowledgeable about wound care procedures?
Intervention: Educate the patient and the family. Include:
- The purpose of the treatment
 - An explanation of who will be changing the dressings and when
 - The procedure and frequency of dressing changes
 - Signs and symptoms of infection or other complications (and when to notify the PCP if they occur)
 - The cleaning, care, storage, and appropriate disposal of wraps, bandages, and binders
4. **Assess:** Is assistance required for performing the procedure?
Intervention: Obtain assistance, if needed, from UAP or through collaboration with the wound care specialist or physical therapist. Consider the following when making this decision:
- Identify the patient's ability to cooperate.
 - Determine the complexity of the required medical interventions.
 - Determine the support systems available.
 - Follow the facility's policies, procedures, and requirements.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible in order to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.
- VI. Provide for patient privacy.
It is important to maintain patient dignity.
- VII. Identify the patient, using two identifiers.
Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.
- VIII. Explain the procedure to the patient.

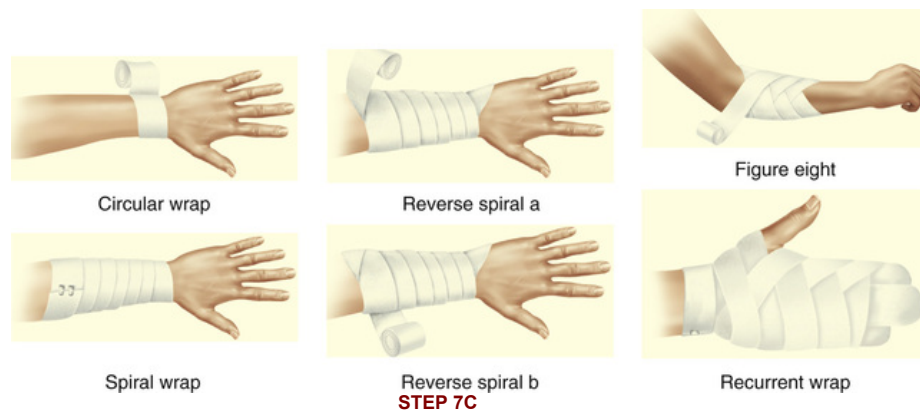

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Wraps and Bandages

Follow preprocedure Steps I through VIII.

1. Use a wrap or bandage that is an appropriate size for the body part—for example, narrower widths for the lower leg and wider widths for the upper leg.
Using the correct-size wrap or bandage promotes the appropriate distribution of pressure.
2. Ensure that the wrap or bandage is clean and rolled.
Cleanliness decreases the spread of microorganisms. Using a rolled wrap or bandage facilitates easy application.
3. Raise the bed to working height, and lower the side rails as appropriate and safe.
Setting the bed at the correct working height for the provider prevents discomfort and possible injury.
4. Expose the wound appropriately while maintaining the limb in a functional position. Ensure that the extremity is elevated for 15 to 30 minutes before applying the wrap or bandage.
Prepares the wound and limb to facilitate the procedure and prevent interruption of the procedure; prevents patient discomfort by avoiding repositioning. Proper limb position prevents complications. Elevation promotes venous return and reduces edema.
5. Assess the area to be wrapped or bandaged:
 - a. If a wound is noted, assess the wound (see [Skill 29.2, Step 5 in the “Removing an Old Dressing” section](#)).
 - b. Assess for signs and symptoms of infection.
 - c. Note any other skin lesion or abnormality.
 - d. Check circulation.
 - e. Apply a sterile dressing over the wound, if applicable (see [Skill 29.2](#)).
The initial assessment provides a baseline that can be used to assist in determining the progress of wound healing, the need for any additional supplies, and the best dressing type, as well as whether any changes are needed in the treatment plan concerning supplies or orders. Early detection and treatment of infection and lesions prevents further infection and deterioration and prevents injury.
6. Place gauze or cotton between the skin surfaces of toes and fingers.
Padding between the digits prevents injury and pressure injuries.
7. Apply the wrap:
 - a. Begin at the distal portion of the limb, and wrap around the limb twice (circular wrap).
 - b. Wrap up the limb from distal to proximal.
 - c. Directions of wrappings are spiral or reverse spiral for extremities, figure eight for joints, or recurrent wrap for the head or an amputated limb.

d. Overlap each wrap by half of the bandage.

A double circular wrap anchors the bandage. Proper wrapping promotes venous return and even compression.

8. Secure the wrap or bandage; ensure safety when applying tape, pins, or self-closure devices.

Securing the wrap maintains compression and anchors the bandage or wrap.

9. Elevate the extremity for 15 to 30 minutes.

Elevation promotes venous return and reduces edema.

10. Assess circulation:

a. Check the distal pulses.

b. Check for tingling, numbness, pain, and itching.

c. Loosen the bandage or wrap if a circulation problem is noted.

Assessing circulation prevents injury or other adverse events and promotes optimal, safe, quality patient care.

11. Maintain the bandage or wrap:

a. Remove every 8 hours.

b. Use a clean bandage or wrap daily or as needed (e.g., if it is soiled).

Removing the bandage or wrap facilitates skin assessment and skin care, allows maintenance of adequate compression, and prevents infection.

Follow postprocedure Steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach of the patient.

Precautions must be taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs, and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment that was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Summary of Learning Outcomes

LO 29.1 *Describe the normal structure and function of skin:* The skin is composed of the epidermis, dermis, and subcutaneous layers, each of which has its own role.

LO 29.2 *Review the factors that alter the skin's structure and function:* The functionality of the skin is affected by other disease processes, nutrition, the use of medications, external forces (such as pressure and shear), and aging. Alterations of skin integrity and complications of wound healing can occur as a consequence of many of these factors.

LO 29.3 *Discuss the components of a focused skin and wound assessment, including the use of risk assessment tools:* A focused skin and wound assessment includes an assessment of the overall integrity of the skin and risk factors for impaired skin integrity, as well as an assessment of the wound's location, size, and tissue type; the condition of the periwound skin; the presence of drainage, undermining, and tracts; and the patient's response to wound assessment and care. Risk assessment tools include the Braden Scale and Norton Scale.

LO 29.4 *Identify appropriate nursing diagnoses for the patient with impaired skin integrity:* Many nursing diagnoses are applicable for patients who have wounds or who are at risk for developing or incurring wounds. A determination of appropriate diagnoses must be based on a thorough assessment of the patient.

LO 29.5 *Develop measurable patient-centered goals for patients with impaired skin integrity:* Goals are developed in collaboration with the patient and other interprofessional health care providers to prevent development of wounds or promote wound healing, and they include measurable evaluation criteria and a time frame for completion.

LO 29.6 *Select interventions to prevent and treat impaired skin integrity that can be implemented then evaluated:* Interventions include those aimed at prevention (such as turning, pressure relief, nutritional support, and attention to moisture, friction, and shear) and those designed to promote wound healing (e.g., a variety of treatments and dressings).

Review Questions

1. On initial assessment of a patient, the nurse notices an area of redness over the right trochanter that, when pressed lightly, does not blanch. What does this assessment finding indicate to the nurse?
 - a. The presence of an infection in the area
 - b. The presence of a stage 1 pressure injury
 - c. An allergic reaction to the sheets
 - d. The need to apply a cold compress to reduce inflammation
2. Four days after abdominal surgery, the patient is getting out of bed and feels something “pop” in his abdominal wound. An increase in amount of drainage from the wound is seen, and further examination shows that the sutured incision is now partially open, with tissue protruding from the wound. Which are the priority nursing interventions? (Select all that apply.)
 - a. Apply Steri-Strips to close the wound edges.
 - b. Cover the wound with saline-moistened gauze
 - c. Apply a binder to pull the wound edges together and provide support to the edges.
 - d. Notify the physician.
 - e. Allow the area to be exposed to air until all the drainage has stopped.
3. Which features are characteristic of a closed drainage system, such as a Jackson-Pratt (JP) drain? (Select all that apply.)
 - a. Works by gravity
 - b. Provides for early discharge
 - c. Usually is inserted in surgery
 - d. Reduces the amount of antibiotics required
 - e. Allows for accurate measurement of wound drainage
4. Which skin-care interventions should be initiated by the nurse caring for a patient with urinary or fecal incontinence? (Select all that apply.)
 - a. Changing the adult brief every 8 hours
 - b. Cleansing frequently with hot water and a strong soap
 - c. Using an incontinence cleanser

- d. Frequent position changes
 - e. Applying a moisture barrier ointment
5. Based on knowledge of areas at greatest risk for development of a pressure injury in the bedridden patient, the nurse identifies which position to minimize this risk?
- a. 30-degree side-lying
 - b. Sitting with the head of the bed elevated 75 degrees
 - c. 90-degree side-lying
 - d. Lying supine with the bed flat at all times
6. A patient who has suffered a stroke is unable to maintain his position while seated in a chair without sliding down. His physician has ordered him to be up in a chair for part of the day. What does the nurse recognize as the patient's greatest risk factor for development of pressure injuries?
- a. Moisture from incontinence
 - b. Nutritional deficiencies
 - c. Pressure and shear
 - d. Aging
7. A patient has a stage 3 pressure injury on the coccyx. Which food will be most beneficial in improving the healing process?
- a. Food high in vitamin D
 - b. Whole-grain carbohydrates
 - c. High-calorie, high-protein drink
 - d. Food high in fat and water content
8. Which technique is used to collect an aerobic culture specimen from a wound?
- a. Collect the specimen immediately after removing the old dressing.
 - b. Apply sterile gloves, then open the culture tube.
 - c. Always be sure to culture any necrotic tissue.
 - d. Irrigate the wound before collecting the culture material.
9. Which patient is at highest risk for impaired wound healing?
- a. A 22-year-old with a pelvic fracture incurred in a motor vehicle accident

- b. A 49-year-old with a history of smoking two packs a day who just had abdominal surgery
 - c. A 72-year-old with diabetes and cardiovascular disease who had surgical repair of a broken hip
 - d. A 90-year-old with no chronic health conditions with a small blistered burn on the hand
10. Which statement best describes the healing process for a surgical wound that has been closed with the use of sutures?
- a. The edges of the wound are approximated.
 - b. New tissue fills the sides and base of the wound.
 - c. The proliferate phase is longer with surgical wounds.
 - d. Debridement aids in the surgical healing process.

CHAPTER 30

Nutrition

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 30.1 Describe the role of nutrition and food metabolism in achieving and maintaining normal body structure and function.
- LO 30.2 Identify nutritional imbalances that can result in physical alterations, psychological disturbances, and the development of disease.
- LO 30.3 Discuss critical aspects of a thorough nutritional assessment.
- LO 30.4 Identify nursing diagnoses for patients experiencing an alteration in nutrition.
- LO 30.5 Determine nursing care goals and outcome criteria for patients experiencing complications from an alteration in nutrition.
- LO 30.6 Explain the implementation and evaluation of interventions designed to address nutritional needs.

Case Study

Amy Kalista (A. K.) is a 17-year-old high school student admitted to the hospital for severe weight loss, nausea, vomiting, and blood-tinged emesis. She has a medical history of anorexia nervosa since the age of 15 and a surgical history of appendectomy at 11 years of age. She has no known drug allergies (NKDA).

A. K.'s vital signs are: T 97.2° F (36.2° C), P 90 and regular, R 16 and unlabored, and BP 98/68, with a pulse oximetry reading of 93% on 2 L of oxygen. She reports abdominal pain at a level of 2 to 3 on a 0-to-10 scale when vomiting. Her height is 167.6 cm (66 in) and her weight is 44.5 kg (98 lb), with an 18.1 kg (40 lb) weight loss in the past 6 months. Her Braden score is 19. She denies use of alcohol or recreational drugs.

Assessment reveals cachectic appearance; lungs are clear to auscultation, with prominent scapulae and clavicles. Skin is cool to touch, with poor turgor. Hair is dull, dry, and thin. Pallor is evident, with dark circles under the eyes and pale oral mucous membranes. Bowel sounds are hypoactive, and the abdomen is distended; the patient reports that her last bowel movement was “3 or 4 days ago” and that she has an increasing problem with constipation. The patient's mother reports, “Amy refuses to eat and is losing too much weight.” The mother also reports that her daughter is obsessed with exercising: “She exercises before and after meals and is exercising when I get up in the morning and when I go to bed.” A. K. states, “I don't exercise that much—I just don't want to be fat any longer!” She denies bingeing and purging but does admit to drinking 12 to 15 glasses of water and diet soda a day.

Refer back to this case study to answer the critical-thinking questions throughout the chapter.

Nutrition is the body's intake and use of adequate amounts of necessary nutrients for tissue growth and energy production. **Nutrients** are the necessary substances obtained from ingested food that supply the body

with energy; build and maintain bones, muscles, and skin; and aid in the normal growth and function of each body system.

Nutritional balance has a significant impact on the normal growth, development, function, and maintenance of the body. Health care professionals must be cognizant of the concepts of proper nutrition and be able to apply them in practice to enhance wellness, promote healthy lifestyle choices, and reverse negative effects of improper nutritional habits. Healthy eating can reduce the risk of chronic diseases across the life span ([U.S. Department of Health and Human Services \[HHS\] and U.S. Department of Agriculture \[USDA\], 2015](#))

With the prominence of fad diets and false advertising in the media claiming “quick weight loss,” the public needs accurate information for making nutritional decisions. Many people suffer from **malnutrition** (an imbalance in the amount of nutrient intake and the body's needs). Among them are those who are overweight or undernourished, lacking important nutrients due to poor food choices. To improve public health, health care professionals need to teach health care consumers how to do more than simply count calories. Choosing nutrient-rich foods helps people get the most benefit from calories ingested, resulting in better nutritional intake and fewer calories consumed. The [HHS \(2018\)](#) publishes *Healthy People 2020* topics and objectives, which focus on promotion of healthy lifestyles and decreasing the health variances across all cultures, races, and ethnic and socioeconomic groups. When patients and families are provided with dietary information and are educated to take a positive approach that focuses on the total nutritional quality of foods without calorie overconsumption, people can achieve better health.

LO 30.1 Normal Structure and Function

Overall health is dependent on a combination of appropriate nutritional intake, adequate exercise, weight management, and rest. Neglect of or improper emphasis on any of these factors places the person at risk for developing life-threatening conditions or premature death. Poor nutrition, lack of exercise, obesity, and stress contribute to health issues (such as heart disease, some cancers, strokes, hypertension, and diabetes or kidney disease). A strong relationship is recognized between infection and malnutrition. People who practice proper dietary habits have stronger immune systems, less illness, and better health. Healthy children learn more effectively. Healthy people are stronger, more industrious, and able to achieve a better quality of life.

Metabolism

Metabolism is the process of chemically changing nutrients, such as fats and proteins, into end products that are used to meet the energy needs of the body or stored for future use, thereby helping maintain homeostasis in the body. Body processes (such as repair and replacement of cells, elimination of waste through the kidneys, and functioning of the brain to maintain a pulse rate and respirations) are the results of metabolism. The **basal metabolic rate (BMR)** is the minimum amount of energy required to maintain body functions in the resting, awake state. Even during rest or sleep, the body requires a certain number of calories to support critical processes, such as cardiac function and breathing.

Metabolism is necessary to maintain life and is composed of two major biochemical processes: **anabolism** (the use of energy to change simple materials into complex body substances and tissue) and **catabolism** (the breaking down of substances from complex to simple, resulting in a release of energy). These two processes can be thought of as constructive and destructive, respectively. Anabolism permits cell growth, such as the mineralization of bone or development of muscle mass. An example of catabolism is the breaking down of proteins and their subsequent conversion into amino acids.

Metabolism is a continuous process within the body and is dependent on the intake of proper nutrients. The essential nature of each nutrient and its functions underscores the importance of nutritional balance and its impact on a healthy, properly functioning body. A deficiency of any major nutrient has an overwhelming effect on more than just one organ.

Nutrients

The major nutrients, often referred to as **macronutrients** (nutrients that are needed in large amounts), include carbohydrates (sugar, starches, and dietary fiber), which provide energy for cells, tissues, and organs; fats, which are major sources of energy and promote the absorption of vitamins; and proteins, which build, maintain, and repair muscles and tissue. Water also is a macronutrient, in that it is essential for proper functioning as well as for assisting the body with metabolic processes (metabolism).

Minerals (chemicals needed for energy, muscle building, nerve conduction, blood clotting, and immunity to diseases) and **vitamins** (organic compounds responsible for regulation of body processes, reproduction, and growth) are referred to as **micronutrients** (nutrients needed by the body in limited amounts). Failure of the body to properly use nutrients can result in diseases and other conditions, such as heart and kidney disease, renal disorders, diabetes, malnutrition, and obesity. **Obesity** is the result of the person's energy intake consistently exceeding energy use. The consequence is the excessive accumulation of body fat, which affects overall health. According to the Centers for Disease Control and Prevention (CDC, 2017), 71.6% of the United States population 20 years and older is considered overweight or obese. Worldwide obesity has more than tripled since 1975, with more than 1.9 billion individuals over the age of 18 identified as overweight and 650 million of those being obese (World Health Organization [WHO], 2018).

Carbohydrates

Carbohydrates are chemical substances composed of carbon, hydrogen, and oxygen molecules. Carbohydrates supply the body with 4 kilocalories (kcal) per gram. A **kilocalorie** is the amount of heat energy it takes to raise the temperature of 1000 grams of water 1 degree Celsius. Carbohydrates are major suppliers of energy and include sugars, starches, and fiber. They keep the body from using valuable proteins for energy, prevent ketosis, and enhance memory and learning capabilities. Carbohydrates are further classified as simple or complex. Simple carbohydrates are broken down and absorbed quickly, providing a quick source of energy. Examples are sugars, such as those derived from fruit (fructose), table sugar (sucrose), milk products (lactose), and blood sugar (glucose). Complex carbohydrates are composed of starches, glycogen, and fiber. They take longer to break down before absorption and use by the body's cells. Proper functioning of the brain and other tissues depends on a sufficient supply of carbohydrates in the form of glycogen. During physical activity, the need for carbohydrates

is increased to meet the energy demands of the muscles. A major portion of the glycogen from complex carbohydrates that is necessary for functioning is derived from stored “fuel.” Muscles store glycogen and use it during strenuous exercise. If glycogen supplies become depleted, the person may suffer from extreme fatigue.

Complex carbohydrates also provide the body with vitamins and minerals. Food sources include bread, rice, pasta, legumes (such as dried beans, peas, and lentils), and starchy vegetables (such as corn, pumpkin, green peas, and potatoes). It is recommended that adults consume approximately 50% of their calories from carbohydrates. People should be observant of overall nutritional content when selecting foods containing carbohydrates. Foods containing highly processed sugars (such as cakes, pies, and other pastries) should be avoided because they contain little or no nutrient value, adding only calories to the diet.

Fiber

Fiber is a complex carbohydrate and is classified as soluble or insoluble. *Solubility* refers to the disposition of the fiber when mixed with another substance, such as water. Soluble fiber mixes with water and forms a gel-like substance, which results in slower digestion. Insoluble fiber does not retain water but allows formation of bulk, resulting in the accelerated passage of the end products of food through the intestines and a slowing of starch absorption. Research indicates certain benefits of high-fiber diets, including promotion of cardiovascular health by lowering serum cholesterol levels, assistance in weight control, improvement of glycemic control in people with diabetes, and improvement of regularity (Pal, Khossousi, Binns, et al., 2012; McRorie & McKeown, 2017). Emerging research shows that the intake of certain soluble fibers enhances immune function in humans (McRorie & McKeown, 2017).

The lack of fiber can lead to bowel-related conditions, such as constipation, hemorrhoids, and formation of diverticula, which are protrusions of the intestinal membrane through the muscular layer of the intestine, most often in the large colon. The presence of these protrusions is referred to as *diverticulosis*. Older children, adolescents, and adults should consume 20 to 35 grams of fiber a day. Food sources include whole grains, wheat bran, cereals, fresh fruits, vegetables, and legumes (Fig. 30.1).

FIGURE 30.1 Soluble and nonsoluble fiber foods. (Copyright Thinkstock.com.)

Fats

Fats are composed of carbon, hydrogen, and oxygen and yield 9 kilocalories per gram when metabolized within the body. **Lipids** refer to any fat found within the body, including true fats and oils (such as fatty acids, cholesterol, and phospholipids). Fats are needed for energy and to support cellular growth. Total fat intake, as recommended by the [American Heart Association \(2017a\)](#), should be between 20% and 35% of caloric intake each day. Ideally, less than 5-6% should be from saturated fat. The *2015-2020 Dietary Guidelines for Americans*, 8th edition ([HHS & USDA, 2015](#)) encourages less than 10% of calories from saturated fats. Dietary fat takes longer to digest than other major nutrients and requires the presence of carbohydrates to associate with oxygen and produce energy for the body's use. **Triglycerides** are the most abundant lipids in food. An important point is that although the intake of a limited amount of triglycerides is important, an excess can be unhealthy, contributing to health problems (such as, coronary artery disease and obesity). Benefits of fat in the body include energy production, support and insulation of major organs and nerve fibers, energy storage of adipose tissue, lubrication for body tissues, vitamin absorption, and transportation of fat-soluble vitamins A, D, E, and K. Fat also plays a role in the development of the cell membrane structure.

Fats are composed of one (monoglyceride) to three (triglyceride) fatty acids, which consist of chains primarily made up of carbon and hydrogen atoms. The number of fatty acids contained in a fat has dietary and health implications. **Saturated fatty acids** contain as many hydrogen atoms as the carbon atoms can bond with and no double carbon bonds. **Monounsaturated fatty acids** have only one double bond

between carbon atoms, whereas **polyunsaturated fatty acids** have multiple pairs of double carbon bonds.

Monounsaturated fat sources include canola, olive, and peanut oils, as well as almonds, sesame seeds, avocados, and cashews.

Polyunsaturated sources include corn, safflower, sesame, soybean, and sunflower seed oils. Fish (such as halibut, herring, mackerel, salmon, sardines, fresh tuna, trout, and whitefish) are known sources of polyunsaturated fats. Saturated fats are found in hard margarines, vegetable shortenings, pastries, crackers, fried foods, cheese, ice cream, and other processed foods. Foods from animal sources, especially beef, lamb, and processed meat, remain major sources of total fat, saturated fat, and cholesterol in dietary intake. Typically, patients are encouraged to increase their intake of monounsaturated fats (which also contribute fiber and antioxidants to the diet) while decreasing intake of polyunsaturated and saturated fats.

Trans fats (**trans fatty acids**), composed of partially hydrogenated fatty acids, and saturated fats are known to raise the body's total **cholesterol**, a waxy, fatlike substance that is found in all cells of the body. Approximately 75% of cholesterol is produced by the liver and intestines; the remaining 25% is obtained from dietary intake ([American Heart Association, 2017a](#)). Cholesterol is an essential component of cell membranes, is necessary for the production of some hormones (such as adrenaline, estrogen and testosterone, and cortisone), and aids in digestion as a component of bile salts. See [Chapter 34](#) for an extensive discussion of cholesterol levels in the body.

Omega-3 (linolenic acid) and omega-6 (linoleic acid) are referred to as *unsaturated "essential" fatty acids* that need to be included in the diet, because human metabolism cannot produce them. They are necessary for a number of functions including blood clotting and normal brain and nervous system functioning. They help prevent atherosclerosis and lower triglyceride levels. Omega-3 fatty acids are believed to improve learning ability in children, enhance immune function, and relieve arthritis symptoms. Consuming one to two servings a week of fish, particularly fish that is rich in omega-3 fatty acids, appears to reduce the risk of heart disease, particularly sudden cardiac death. Dietary sources include fatty fish (such as, salmon, tuna, mackerel, and lake trout), nuts, seeds, and oils; flaxseed oil contains the highest amount of total omega-3 fatty acids. Linoleic acid plays an important role in lowering cholesterol levels. Omega-6 fatty acid is an unsaturated fat found in various types of seeds, nuts, and vegetable oils ([Mayo Clinic, 2018](#)). It is recommended that people learn to read nutrition labels and to avoid intake of *trans* fatty acids and saturated fats to minimize their adverse effects ([Box 30.1](#)).

Box 30.1

Patient Education and Health Literacy

Interpreting the Language of Food Labels

- Uniform nutrition labeling for packaged food was introduced in the United States in 1994, as part of the Nutrition Labeling and Education Act (NLEA)
- In May 2016, updated labeling guidelines were initiated to help consumers improve diet choices, including links between diet and chronic disease (FDA, 2017).
- Evidence indicates a link between eating healthier foods and reading nutrition labels (Garcia, Reardon, Hammond, et al., 2017).
- Studies indicate that the use of food labels to guide food selection is significantly lower among children, adolescents, older adults, ethnic minorities, and people of lower socioeconomic status (Zagorsky & Smith, 2017).
- Patients should be asked if they read food labels when shopping for groceries or food products. Evaluate their understanding of the main elements of a nutrient label (i.e., calories, fats, carbohydrates, sugar, and serving size).
- Assess patient understanding of the percentages of recommended daily allowances of fats, proteins, and carbohydrates listed on food labels.
- Assist patients with planning strategies for eating a well-balanced diet based on knowledge of caloric intake and nutrient content.
- Encourage patients to ask for dietary information at restaurants, including fast food establishments.

Protein

Proteins are active participants in the development, maintenance, and repair of the body's tissues, organs, and cells. Hemoglobin, the part of erythrocytes (red blood cells) responsible for transporting oxygen throughout the body, is one type of protein critical to regulating body function—as is prothrombin, the protein necessary for clotting blood. Proteins are involved in many other tasks throughout the body, including the production of hair and nails, muscle movement, nerve conduction, digestion, and defense against bacteria and viruses. They consist of organic compounds called **amino acids**, which often are

referred to as the “building blocks” of proteins. Unlike fat and carbohydrates, amino acids must be consumed in food every day, because the human body does not produce or store excess amino acids for later use. Most people consume enough protein in their diet. When the accumulation of protein exceeds the need for growth and repair of tissues, the protein is removed and excreted by the kidneys in urea. If the production of fat or carbohydrates is deficient, protein may assume the role of providing energy. This demand on protein stores can lead to a deficiency of protein in the body. Using a 2,000-calorie diet, the *2015-2020 Dietary Guidelines for Americans* (HHS & USDA, 2015) recommend $\frac{1}{2}$ ounces of protein per day. Like carbohydrates, proteins supply 4 kilocalories of energy per gram while supplying 15% of the total energy intake.

Proteins often are referred to as complete or incomplete. *Complete* proteins contain all essential amino acids. Sources of complete protein include animal-based foods (such as milk, eggs, cheese, fish, meat, and poultry). The only plant protein considered to be a complete protein is found in soybeans. *Incomplete* proteins lack one or more essential amino acids. Sources of incomplete protein include beans, peas, nuts, seeds, fruits, vegetables, bread, and bread products. The combination of two or more plant proteins can form a complete protein and provide all of the essential amino acids. Examples of this type of combination are pasta and broccoli, rice and beans, and peanut butter and whole wheat bread.

Water

Water plays a major role in the body and is necessary for processes (such as helping control body temperature, maintaining acid-base balance, regulating fluid and electrolytes, and transporting nutrient and waste products from the kidneys). Water is a component of intracellular and extracellular fluids within the body. Two-thirds of the body's fluids are contained within the cells (intracellular). The extracellular fluids are components of the blood, of the interstitial fluid between the cells, and within certain structures. When water loss continues without replacement, blood volume is diminished. When this happens, ample oxygen and nutrients cannot be furnished to body cells, and carbon dioxide and waste products cannot be efficiently removed. Every organ of the body is affected, including the brain and central nervous system. More important, water makes up approximately 60% of adult body weight; if it is not replaced after being lost through breathing, sweating, urination, or defecation, the ability of the body to function properly is affected. Water accounts for about 50% of the weight of elderly adults, making this age group at risk for dehydration. Some water may be obtained through most food sources or may be added in the preparation

of foods. Although fluid intake needs vary, most people obtain enough water through the food intake and liquids they drink ([USDA, 2017](#)).

Thirst is an indication that the body needs water or fluids. Even a slight decrease in water in the body, failure to meet the body's hydration needs, or loss of a disproportionate amount through excessive sweating, diarrhea, or vomiting can result in dehydration. Physical symptoms may include headaches and loss of concentration.

By contrast, excessive water intake or failure to excrete adequate amounts of urine, as seen in some renal conditions, can lead to water intoxication. Excessive amounts of fluid intake can dilute the amount of sodium in the body and cause hyponatremia. Fluid intake needs to be monitored closely in patients experiencing fluid overload, congestive heart failure, or a renal disease in which fluid intake is limited.

Vitamins

Vitamins are organic compounds that contribute to important metabolic and physiologic functions within the body. Vitamins are regarded as indispensable in proper dietary intake. Other characteristics include the body's inability to manufacture them or, often, limitation of production by environmental factors. They do not produce energy; however, they are crucial in chemical reactions within the body from nutrients such as fats, carbohydrates, and proteins. They typically are categorized according to their solubility in fat or water and their absorption, transportation, and storage processes within the body.

Fat-Soluble Vitamins

Fat is necessary in the diet to assist with the absorption of the **fat-soluble vitamins** A, D, E, and K. Excess fat-soluble vitamins are stored in the liver and fat tissue and are not excreted by the kidneys. Because of this storage, if an excessive amount of these vitamins is taken, toxicity may result, especially with vitamins A and D.

Vitamin A

Vitamin A is important for its ability to increase the resistance to infection, promote night vision through the development of normal visual pigment, develop and maintain normal function of epithelial tissue, and aid in the development of normal bones and teeth. Vitamin A and compounds created by its metabolism are responsible for maintaining the integrity and function of skin and mucosal cells, which are the body's first line of defense against infection ([Linus Pauling Institute, 2018](#)). Hemoglobin receives stored iron with the assistance of vitamin A. Deficiencies in vitamin A may cause night blindness (because of the inability of the cornea to adapt to darkness), poor

appetite, decreased immunity to infections, and impaired growth and development. Foods rich in vitamin A include liver, milk, egg yolk, and dark, leafy green vegetables. Yellow and orange vegetables and fruits (such as sweet potatoes, pumpkin, carrots, and apricots) also are good sources.

Vitamin D

Vitamin D has long been referred to as the “sunshine vitamin” because it is synthesized in the skin when exposed to sunlight. It is not found in most foods. Vitamin D is important for the development of bone and tissue formation because of its collaborative efforts with minerals (such as calcium and phosphorus) to develop and strengthen bones. It is recommended that people be exposed to direct sunlight for 15 minutes several times a week to promote the manufacture and storage of vitamin D, which assists in the development of collagen, a constituent of bone that aids in the bone strengthening. Dietary sources of vitamin D include dairy products, eggs, fortified food products, liver, and fatty fish (salmon and mackerel).

Vitamin E

Vitamin E is an antioxidant that protects cells from injury from **free radicals** (by-products that result when the body transforms food into energy). The accumulation of these by-products over time is mainly responsible for the aging process and can contribute to the development of numerous health conditions, such as cancer, heart disease, and various inflammatory conditions. Risk factors associated with formation of harmful oxygen free radicals include cigarette smoking, extensive exposure to the sun, and air pollution, which may result in damage to cells, tissues, and organs. Vitamin E is effective in maintaining a healthy immune system. Dietary sources may include nuts, seeds, and soybean, canola, corn, and other vegetable oils.

Vitamin K

Vitamin K is synthesized in the body by bacteria that are found in the large intestine. It is essential for the synthesis of proteins that promote the clotting, or coagulation, of blood. The liver produces a protein known as prothrombin and is dependent on vitamin K for this process. Deficiency of this vitamin can result in bruising and bleeding. Dietary resources include dark-green leafy vegetables such as broccoli, spinach, Brussels sprouts, and cabbage.

Water-Soluble Vitamins

Water-soluble vitamins dissolve in the body and are excreted in the urine. They are easily destroyed by air, light, and heat (cooking). Water-soluble vitamins must be ingested daily through dietary sources or supplements because they are not stored in the body.

Vitamin C

Vitamin C (ascorbic acid) is considered to be one of the most important vitamins because it plays a major role in promoting a healthy body. Among its functions is the synthesizing of the protein, collagen. Collagen is important in connective tissue, wound healing, and repair and maintenance of cartilage, bones, and teeth. Vitamin C is effective as an antioxidant that guards against cellular damage from toxic chemicals and pollutants in the environment. Vitamin C contributes to the development of a strong immune system by producing antibodies that fight bacteria and viruses to protect against infections and illnesses. Dietary sources include fresh yellow and orange fruits, papaya, kiwi, broccoli, and sweet and white potatoes.

Vitamin B Complex

The vitamin B complex contains eight principal water-soluble vitamins. The B vitamins help form red blood cells and act in part as *coenzymes*, small molecules that combine with an enzyme to make it active. They facilitate energy production in the body. **Enzymes** are proteins responsible for catalyzing most chemical reactions in the body, such as digesting food and synthesizing new compounds.

Vitamin B₁ (thiamine) is essential for the metabolism of protein, fat, and carbohydrates, including sugar to produce energy for the body's cells. It is important for normal growth and development and promotes normal heart, muscle, and nervous system functions. It also is necessary for the production of hydrochloric acid (which is necessary for proper digestion). Dietary sources include egg yolk, fruits, organ meat, lean pork, legumes, nuts, vegetables, and whole grains.

Vitamin B₂ (riboflavin) assists in the metabolism of protein and the function of other B vitamins, such as vitamin B₃ (niacin) and vitamin B₆ (pyridoxine). It assists in promoting visual adaptation to light and maintaining healthy skin. Dietary food sources include milk and dairy products, whole grains, enriched bread and cereals, legumes, dark-green vegetables (collard greens, spinach, and broccoli), and organ meats.

Vitamin B₃ (niacin), referred to as *nicotinic acid* or *nicotinamide*, is a coenzyme for energy production. It also has a critical role in the formation of fatty acids. Dietary sources are meats, poultry, fortified breads and cereals, brewer's yeast, fish (swordfish and salmon),

mushrooms, whole grains, green leafy vegetables, dried beans, and peanuts. Coffee contains a significant amount of niacin, which helps prevent deficiencies in cultures that consume little protein and large amounts of coffee.

Pantothenic acid and biotin are two B vitamins that are used by the body to produce energy. Biotin is necessary to form purines, which are essential components of DNA and RNA. It is found in liver, legumes, tomatoes, and egg yolk. Pantothenic acid, also known as vitamin B₅, is necessary for the metabolism of carbohydrates, fats, and protein, as well as the synthesis of acetylcholine. High amounts of pantothenic acid are found in whole-grain cereals, potatoes, legumes, broccoli, and egg yolks.

Vitamin B₆ (pyridoxine) assists as a coenzyme in the synthesis and catabolism of amino acids. Vitamin B₁₂ (cyanocobalamin) is essential for the production of red blood cells. It facilitates the entrance of folate into cells and maintains the protective sheath (myelin) that surrounds nerve fibers. It is necessary to make DNA, the genetic material in all cells. Vitamin B₁₂ is found in animal products, including meat, eggs, and dairy products.

Folic acid (vitamin B₉) is a water-soluble vitamin that must be provided in the diet or supplemented because it is not produced in the body. It is necessary for the synthesis of DNA (which controls heredity) and is used in red blood cell formation. Folic acid is especially critical to the formation of rapidly growing cells, such as those in blood and in fetal and gastrointestinal (GI) tissue. Its absorption may be affected by certain drugs, such as oral contraceptives and antibiotics. Folic acid supplements taken before and during pregnancy have been a major factor in the decline of neural tube defects in newborns. Dietary sources of folic acid include leafy green vegetables (kale, spinach, Brussels sprouts), oranges, strawberries, dried beans, peas and nuts, and enriched breads and cereals and other fortified grain products.

Additional information on vitamins and drug interactions may be found at the Linus Pauling Institute website (<http://lpi.oregonstate.edu/infocenter/contentnuts.html>).

Minerals

Minerals are considered to be micronutrients and are classified as macrominerals or microminerals, depending on their daily dietary requirements. Potassium, sodium, and chloride play a critical role in maintaining fluid balance in the body. They are important in nerve conduction and muscle contraction. If the body is able to maintain an adequate level of these nutrients, muscle tissue, including that of the

heart, can function properly. Dietary sources of potassium include milk, bananas, legumes, green leafy vegetables, and orange juice, tomatoes, vegetable juice, avocados, and cantaloupe. Dietary sources of sodium include table salt, smoked meat, fish, olives, and pickled foods. Sources of chloride include tomatoes, celery, seaweed, and olives.

Calcium, phosphorus, and magnesium are minerals that are important in the production and maintenance of bone tissue. Most of the body's calcium is found in the bones and teeth, with approximately 1% found in the blood ([National Institutes of Health, 2018](#)). Calcium is required for nerve conduction, muscle contraction, blood vessel expansion and contraction, and the secretion of hormones and enzymes. Dietary sources of calcium include milk and milk products, salmon with bones, spinach, kale, fortified whole wheat bread, tofu, and orange juice. Phosphorus, like calcium, plays a major role in the development of bone. It aids in the contraction of muscles, kidney function, nerve conduction, and maintenance of a regular heartbeat. It also plays an important role in the body's use of other major nutrients (such as, carbohydrates, fats, and proteins), all of which are crucial in the maintenance and repair of cells and tissues. Intake of phosphorus is considered adequate if intake of milk and meat products is sufficient.

Magnesium works in conjunction with calcium to promote structural support. The remaining amount is involved in a large number of chemical reactions, such as energy production and bone formation. Magnesium combined with calcium regulates blood pressure and maintains a regular heartbeat and nerve and muscle function. This nutrient is associated with the production of dopamine, norepinephrine (noradrenaline), and epinephrine (adrenaline). Increasing research focuses on the use of magnesium to treat conditions such as asthma, diabetes, cardiovascular disease, and attention deficit disorder in children. The mineral stimulates the production of the neurotransmitter gamma aminobutyric acid (GABA), which is believed to produce a calming effect ([Challem, 2015](#)). Magnesium deficiency may result from a dietary intake with little or no nutritional value, including additives, refined sugars, and foods high in calories and low in protein, vitamins, and minerals. An excessive amount of zinc intake may lower magnesium levels. Dietary sources of magnesium include halibut, seeds, nuts, tofu, Swiss chard, spinach, whole-grain wheat, brewer's yeast, and molasses. For more information on electrolytes, see [Chapter 39](#).

Antioxidants

Antioxidants are substances that may protect body cells against the effects of free radicals. Free radicals are molecules produced when the

body breaks down food or is subjected to environmental exposures to potential toxins, such as tobacco smoke and radiation. Antioxidants work by significantly slowing or preventing the oxidative process—or damage from oxygen—caused by free radicals, which can lead to cell dysfunction and the onset of problems such as heart disease, cancer, diabetes, and other diseases. Antioxidants also may improve immune function and perhaps lower the risk for infection and cancer. Antioxidants include beta carotene, lutein, lycopene, selenium, and vitamins A, C, and E. Food sources of antioxidants are listed in [Table 30.1](#).

TABLE 30.1

Antioxidant Food Sources

ANTIOXIDANT FOOD SOURCES	
Beta carotene	Dark-orange, red, yellow, and green vegetables and fruits, including red and yellow peppers, spinach, kale, sweet potatoes, carrots, broccoli, apricots, mangos, and cantaloupes
Selenium	Most vegetables and oatmeal, brown rice, chicken, dairy products, garlic, onions, seafood (salmon and tuna in particular), and whole grains
Vitamin C	Citrus fruits, dark-green vegetables and tomatoes, red and yellow peppers, pineapples, cantaloupes, guavas, and berries
Vitamin E	Olive, soybean, and corn oil; nuts, seeds, whole grains, legumes, and dark leafy vegetables

Digestion

The body is ultimately dependent on the digestive system for the processing of food and fluid taken in for nutritional purposes ([Fig. 30.2](#)). The body's metabolic processes rely on the *ingestion* or consumption of food. **Digestion** (the breaking down of food into smaller particles of nutrients) is dependent on physiologic and chemical changes within the body. These changes are necessary for the body to receive the nutritional benefits of food or fluid intake. As food enters the mouth, it becomes the target for enzymes. These are substances that chemically break down the food so that it can be used to build and nourish cells and provide energy. Enzymes are classified according to the type of chemical reaction they trigger, and they are reactive to temperature and the pH condition of the food (acid or alkaline). The first stage of digestion is performed by the salivary glands as food enters the mouth and chewing takes place. These glands secrete specific enzymes that break down certain components of the food. For example, salivary amylase (ptyalin) breaks down carbohydrates (starch) into maltose, which is then further broken down by enzymes in secretions from the pancreas and the lining of the small intestine. The enzyme in the lining

of the small intestine splits the maltose into glucose molecules as **absorption** (movement of the smaller elements through the walls of the digestive tract and into the blood) takes place. Glucose is then carried through the bloodstream to the liver, where it is stored or used to provide energy for the work of the body. As the food is being digested, it becomes a semiliquid mass as it travels through the intestines; this mass is referred to as **chyme**. The waste products are then propelled through the rest of the intestines, the rectum, and the anus by **peristalsis** (a wavelike muscular movement) for elimination to occur.

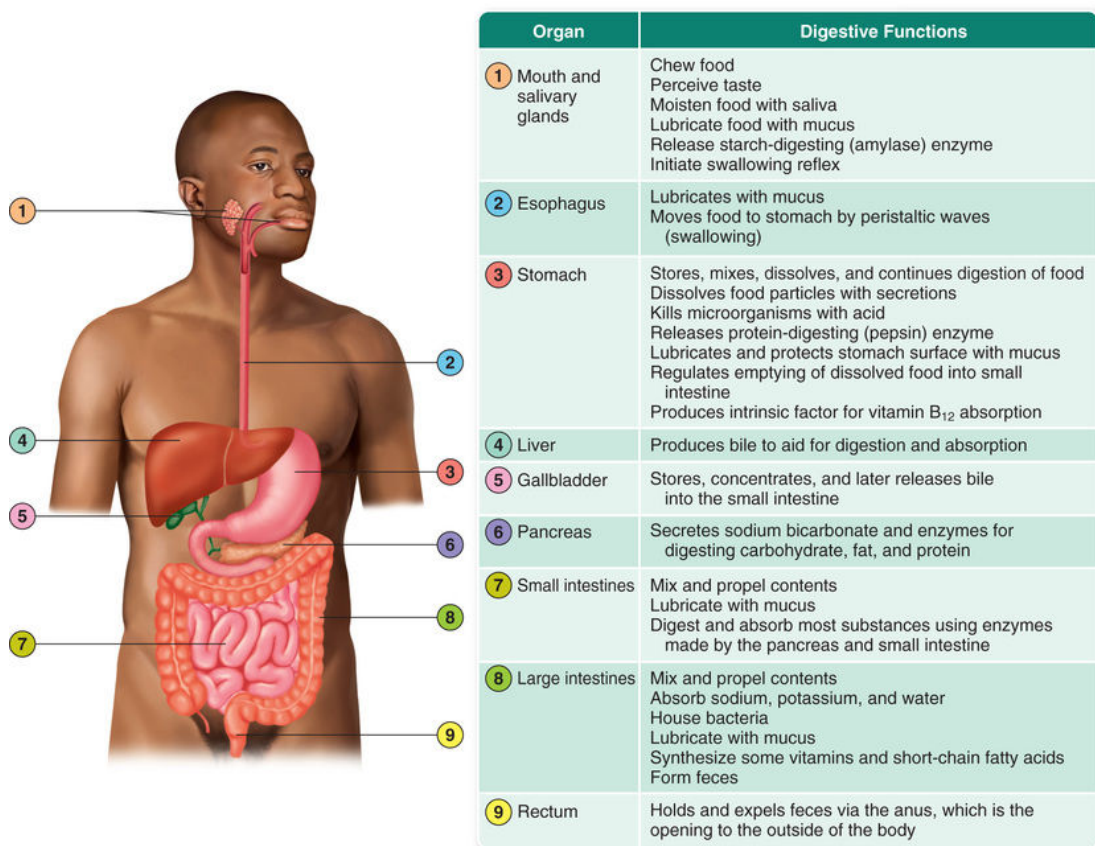

FIGURE 30.2 Essential components of the digestive system.

Ingestion, digestion of food, absorption of nutrients, and elimination of waste are the primary functions of the GI system. When digestion and absorption are completely undeterred, the necessary amounts of nutrients are delivered to the cells, tissues, and organs. During digestion, ingested foods are physically or chemically converted into a form that can be absorbed through the membranes of the intestines and enter the bloodstream. This process is known as *catabolism*, during which the body receives nutrients needed to provide energy for physical activity. These nutrients (such as proteins, carbohydrates, calories, and fat) are energy sources and substances needed to build and

repair muscle. As the body uses this energy to build tissues, it is in a state of anabolism. Another instance of the need for energy is the metabolism of fat. For fat to be adequately utilized by the body, the body has to have a sufficient supply of carbohydrates. If carbohydrate levels are deficient, an excessive amount of fat is rapidly metabolized for energy. This imbalance results in the production of **ketones** (from incomplete fat oxidation when carbohydrates are not available).

Chewing and moistening of the food with saliva produce a bolus of food that is swallowed and pushed along the esophagus by peristalsis into the stomach. In the stomach, the food is mixed with gastric juices to form chyme. As the food is pushed into the intestine by the peristaltic waves, the digested food makes contact with the intestinal mucosa, thus facilitating absorption and moving the food along the remainder of the digestive tract. Once the remaining contents are propelled into the sigmoid colon and rectum, elimination occurs. The actions of the digestive system promote health, prevent disease, and reduce preventable deaths and disabilities. The digestive system can be regarded as a major transportation system dependent on each structure to accomplish specific tasks.

Dietary Guidelines

The *Dietary Guidelines for Americans* are updated routinely by the USDA in collaboration with other federal agencies. These guidelines constitute a reliable resource and provide guidance for the intake of proper nutrients and the development of healthy dietary habits, which can promote health and reduce risk for major chronic diseases. According to the *2015-2020 Dietary Guidelines for Americans* ([HHS & USDA, 2015](#)), a healthy eating pattern is one that:

- Combines healthy choices from all food groups while paying attention to calorie limits
- Emphasizes fruits, vegetables, whole grains, and fat-free or low-fat milk and milk products
- Includes seafood, lean meats, poultry, beans, eggs, nuts, seeds, and soy products
- Is low in saturated fats, trans fats, sodium, and added sugars

People are encouraged to eat smaller portions and to drink water rather than sugary beverages.

Additional recommendations to meet caloric requirements include consuming less than 10% of calories per day from added sugar, less than 10% from saturated fats, and a sodium intake less than 2,300 mg. Serving sizes of fruits and vegetables are to cover half of a plate, as illustrated in Fig. 30.3. The MyPlate guide is intended for healthy people, not for those on a prescribed or specialized diet. Many people track fitness and eating electronically. Factors related to diet and nutrition are discussed in Box 30.2.

FIGURE 30.3 MyPlate dietary guidelines. (From U.S. Department of Agriculture. (2018). *Dietary guidelines for Americans*. Retrieved from www.choosemyplate.gov/MyPlate.)

Box 30.2

Diversity Considerations

Life Span

- The longer a woman breastfeeds her child, the lower her risk for serious diseases (such as diabetes, heart disease, and breast cancer) and the lower the child's risk for infections, obesity, diabetes, and other diseases and conditions. Medical experts agree with the U.S. Department of Health and Human Services (HHS) in recommending exclusive breastfeeding for 6 months and continued breastfeeding for the first year of life and beyond. Recent health care reform legislation promotes breastfeeding in the workplace. For more information, visit <http://usbreastfeeding.org>.

- Breastfeeding is not always an option. Some mothers do not breastfeed or choose to combine breastfeeding with supplemental formula feeding. Although formula-fed babies do not get all the complex nutrients or immune system benefits that are in breast milk, they do receive sufficient nutrients for growth and development.
- Some babies have milk allergies or significant medical conditions that impair normal digestion. For these infants, soy-based formulas and formulas with hydrolyzed (predigested) proteins are available. The content of infant formulas is regulated and is sometimes modified by the manufacturer with the intent to improve the overall health benefit to the consuming infant. The U.S. Food and Drug Administration (FDA) regulates formula companies to ensure that they provide all of the known necessary nutrients (including vitamin D) in their formulas.
- Infants require more essential nutrients than do adults to meet the demands of rapid growth. Infants typically double their birth weight at 5 to 6 months and triple it by the age of 1 year. Adolescents need additional calcium to meet the body's demand for mineralization of bone. Adolescent boys require an increase in iron to aid in the development of lean body mass; adolescent girls need to replenish iron lost during menstruation.
- Pregnant women and women of childbearing age are at high risk for development of iron deficiency anemia.
- Older adults are at risk for development of osteoporosis as a consequence of increased bone loss and low calcium intake in this age group (see [Chapter 28](#) for additional information on osteoporosis).
- Aging results in decreased functioning of all major organs. This creates the need for increased amounts of some vitamins and minerals such as vitamin D, calcium, and phosphorus.
- Specific concerns regarding the nutritional status of elderly people are well recognized. Calorie needs change owing to more body fat and less lean muscle. Less activity further decreases calorie requirements. Older adults may experience a decrease in the sense of smell or taste, difficulty chewing, impaired mobility, decreased motivation to cook for themselves, and financial limitations. Nurses should recommend including a variety of colors and textures of fruits and vegetables, adding whole-grain breads and cereals, and decreasing the amount of saturated fatty foods in the diet. The addition of spices and herbs may enhance the taste of foods.

- The challenge for older adults is to choose foods that are nutrient-dense. These foods are high in nutrients in relation to their calories. For example, an apple has approximately 80 calories plus vitamins and fiber. The fiber and water in the apple will fill the stomach. By contrast, a doughnut has more than 200 calories, contains less fiber, does not promote satisfaction, and usually does not satisfy hunger, leading to the consumption of additional food. Foods that are high in calories but have very few nutrients (such as colas, chips, cookies, and alcohol) should be avoided.
- Food selection by older adults also affects digestion. Eating whole-grain foods and a variety of fruits and vegetables and drinking water may minimize the risk of constipation.
- People with food allergies are advised to avoid the offending food, because the symptoms can be triggered any and every time a small amount of the food is consumed.
- Food intolerances are often related to the amount consumed. Symptoms are related to the quantity consumed and the frequency of consumption. For example, a person with fructose intolerance may be able to drink a single glass of fruit juice or regular soda but will become ill if several glasses are consumed.
- People who have symptoms after ingestion of certain foods should seek medical care to determine whether the cause is an allergy or intolerance and to establish a plan to help control the symptoms.
- Health care providers should determine the need for patient education on safe food handling and storage to promote the older adult's health. Some older adults are homebound and must rely on delivered food. For educational resources visit www.foodsafety.gov/blog/blog.html.
- According to the Meals On Wheels Association of America (MOWAA), one out of six seniors struggle with hunger (MOWAA, 2018). MOWAA plays a major role in investigating the causes and consequences of nutrient-related deficiencies and other health outcomes among older adults. For additional information, visit <http://mowaa.org>.

Gender

- Optimal caloric intake for both men and women depends on their level of exercise and body size.
- Women and men should avoid excess protein intake, to decrease calcium loss and help prevent osteoporosis and kidney stones.

- Excess calcium intake in men has been identified as a possible factor in the development of advanced prostate cancer (Markozannes, Tzoulaki, Karli, et al., 2016).

Culture, Ethnicity, and Religion

- Culture, ethnic background, and religion may affect individual food preferences. It is important that health care providers take this into consideration when selecting foods for someone who is incapable of making food decisions.
- Culture consists of all learned patterns of behavior passed down from one generation to the next. The patient's religious beliefs, language, communication skills or language barriers, traditions, and values influence the delivery of nursing care.
- Foods traditionally consumed by various ethnic groups may contribute to the development of chronic illnesses. People who consume large amounts of salted pork products may be prone to hypertension, whereas ethnic groups whose diet includes high levels of carbohydrates may experience an increased incidence of obesity and/or diabetes.
- Religious beliefs are individualized and may often affect patients' acceptance or refusal of traditional medical treatments. Health care providers should be cognizant of these differences and integrate them into the delivery of health care or assist patients to understand the impact of the decisions on their health status. For example, during the month of Ramadan, some people of Islamic faith will not eat or drink from sunrise to sunset.

Disability

- **Enteral feeding**, or tube feeding, as the only method of nutritional support poses certain challenges:
 - Selection of an appropriate formula to meet specific patient needs is based on the variables of nutritional adequacy, digestibility, viscosity, **osmolality** (ionic concentration), ease of use, and cost.
 - Patient-specific variables are current disease state, nutritional and hydration status, renal function, medication therapy, and digestive tract function. Existing chronic illnesses and factors that increase metabolic demands on the body (such as stress or fever) must be

considered if the patient's fluid and dietary needs are to be met.

- Patients with disabilities may be limited in the amount or degree to which they can participate in physical exercise, and this can lead to obesity. Nurses should encourage patients to exercise within their capabilities. Regular physical activity provides important health benefits for people with disabilities. The benefits include improved cardiovascular and muscle fitness, improved mental health, and better ability to do tasks of daily life. For more information on the Physical Activity Guidelines for Americans, visit www.health.gov/PAGuidelines.

Morphology

- Patients who have had surgery to help with their obesity (such as gastric bypass and banding) are at risk of nutritional deficiencies due to the altered state of digestion and absorption. Supplemental nutrients are necessary to minimize the effects of vitamin and mineral deficiencies.
- The challenge of adequate nutritional intake in patients with anorexia nervosa often is compounded by a patient's distorted self-perception and internal physical sensations. For example, patients with anorexia nervosa do not perceive hunger as hunger, or after eating a small amount of food, they report a feeling of fullness. Absence of internal physical sensations also may result in excessive, strenuous exercising without an awareness of fatigue.
- Nurses may be instrumental in helping anorexic patients overcome their nutritional deficiencies by contracting with the patient for the intake of a certain amount of food each day, establishing a target weight, and having the patient discuss any fears related to weight gain and loss of control.
- Exercise should be limited in people who are underweight as a result of an eating disorder. Excessive physical exercise can result in decreased estrogen levels and consequent thinning of bones, which are then easily broken.

LO 30.2 Altered Structure and Function

Poor nutritional intake, inadequate exercise, and lack of rest can result in improper growth and development in children and adolescents and serious health concerns in the adult. Alterations in the musculoskeletal, neurologic, cardiopulmonary, and digestive systems and disturbances in metabolism and in psychological well-being can adversely affect nutritional status and contribute to the development of disease processes and conditions that may decrease the patient's ability to lead an active and productive life.

Musculoskeletal Alterations

Poor nutritional intake affects the musculoskeletal system by placing the person at risk for bone defects as a result of an imbalance of vitamins, particularly vitamins A and D. One of these defects is a softening of the bone due to vitamin D deficiency, referred to as *osteomalacia*. Poor absorption of calcium, which is facilitated by vitamin D, may lead to osteopenia or osteoporosis, in which bone mass density decreases and bone tissue deteriorates. Decreased bone mass density increases bone fragility, which increases the risk of fractures.

Deficiencies of minerals (such as calcium, phosphorus, and magnesium) also affect bone mass density. When adequate calcium is consumed, absorption is higher in children versus adults, providing better protective benefits ([National Institutes of Health, 2018](#)). Decreased muscle size and strength (atrophy) limit the protection afforded to connective tissue and bones, as well as the ability of the body to produce heat.

Neurologic Alterations

Nutritional intake has an impact on physical, emotional, and cognitive behavior. Poor nutrition may result in increased or decreased body fat, slower mental problem solving, decreased alertness, and slower muscle response time. Excess dietary intake of sodium is of particular concern because of its role in hypertension, which can lead to an increased incidence of stroke (cerebrovascular accident [CVA]). Stroke ranks fifth after heart disease, cancer, chronic lower respiratory diseases, and unintentional accidents as a major cause of death in the United States ([CDC, 2017](#)). This condition killed more than 140,000 Americans in 2015 ([CDC, 2017](#)). [Box 30.3](#) highlights the importance of limited sodium intake.

Box 30.3

Evidence-Based Practice and Informatics

Sodium Intake and Its Effect on Health

- On average, Americans consume more than double the recommended intake of sodium. The [American Heart Association \(2017b\)](#) recommends that sodium intake should not exceed 1500 mg per day to lower blood pressure. This restriction can be accomplished by choosing foods that are prepared with little or no salt. Overall, the *2015-2020 Dietary Guidelines for Americans* encourage a sodium intake of less than 2,300 mg/day ([HHS & USDA, 2015](#)).
- In the United States, hypertension is the major cause of cardiovascular disease contributing to coronary heart disease and cerebrovascular events, including 410,000 American deaths in 2014 ([CDC, 2017](#)).
- Numerous health conditions (such as left ventricular hypertrophy, renal disease, obesity from excessive soft drink consumption, renal calculi, asthma, and stomach cancer) are linked to high salt intake.
- Salt reduction is one of the most cost-effective strategies to combat the epidemic of hypertension and associated cardiovascular disease and improve population health.
- The American Heart Association has joined with federal agencies to assist Americans to lower their consumption of sodium through strategies such as:
 - Reducing the amount of sodium in the food supply
 - Making more healthy foods available (e.g., more fruits and vegetables)
 - Providing consumers with education and decision-making tools to help them make better choices

A deficiency of folate contributes to the incidence of macrocytic or megaloblastic anemia. Folic acid deficiencies in the adult patient may be evident in symptoms such as depression, mental confusion, glossitis (inflamed tongue), loose stools, and a decrease in nerve function. Folic acid and some of the other B vitamins have been researched for the treatment of memory loss and Alzheimer disease, which is a neurologic disorder that affects cognitive, memory, and functional ability ([Linus Pauling Institute, 2018](#)).

Cardiopulmonary Alterations

Imbalanced nutrition has significant effects on the cardiopulmonary system. Substances secreted from fat cells produce most of the pathologic changes that result in conditions, such as atherosclerotic heart disease. Cholesterol and lipids combine with other substances and have the propensity to attach themselves to the walls of the arteries, leading to multiple forms of coronary artery disease. In atherosclerosis, blood flow to a part of the heart is occluded due to the presence of plaque or a piece of plaque that has broken off and entered the arteries. This condition may lead to cardiac damage as a result of an acute myocardial infarction, or heart attack, due to the lack of blood flow to the heart tissue.

Digestive System Alterations

Conditions that alter the digestive system affect the body's ability to metabolize and absorb nutrients. For digestion and absorption to occur properly, the ability to consume adequate amounts of food must be present. **Dysphagia** (difficulty in swallowing) may result from the presence of an obstruction from a mass or tumor, residual effects of a CVA, neurologic damage, or psychological disorders. **Malabsorption** (problematic or inadequate absorption of nutrients in the intestinal tract) may cause weight loss, fatigue, GI upset (as seen in celiac disease or gluten-sensitive enteropathy), and vitamin and mineral deficiencies such as rickets (vitamin D deficiency) and scurvy (a deficiency of vitamin C). Deficiencies of vitamin C interfere with normal tissue synthesis and may result in gingivitis, which produces swollen and bleeding gums with loosened teeth, and painful, stiff joints. Other problems associated with malabsorption include anemia (a deficiency of red blood cells), excessive bleeding, petechiae (bleeding under the skin), poor wound healing, and neural tube defects. According to the **WHO (2018)**, approximately 45% of the deaths of children younger than 5 years of age worldwide are attributed to malnutrition secondary to conditions, such as **marasmus**, resulting from both protein and calorie deficiency, and **kwashiorkor**, a lack of protein accompanied by fluid retention (**Fig. 30.4**). Although these conditions primarily affect children in developing countries, they may be seen in vulnerable populations anywhere, including abused or neglected children or older adults.

FIGURE 30.4 Children with malnutrition-related conditions: *left*, marasmus; *right*, kwashiorkor. (From Forbes, C., & Jackson, W. (2003). *Color atlas and text of clinical medicine* (2nd ed.). St. Louis: Mosby.)

Failure of the body to break down and properly use other nutrients may result in conditions such as phenylketonuria, a condition in which an infant's body fails to metabolize the amino acid phenylalanine. This inborn error of metabolism may result in impaired brain development, progressive cognitive delays, and irreversible damage. With any obstruction in the esophagus or GI tract, nausea, vomiting, constipation, diarrhea, and severe pain may occur. Inflammatory bowel diseases (such as Crohn's disease, diverticulitis, and ulcerative colitis) can have a significant impact on nutritional health. For additional information on conditions that contribute to malabsorption or elimination problems, see [Chapter 40](#).

Metabolic Alterations

The body's metabolism typically works effectively without a conscious awareness of the processes taking place. If metabolism is altered by an imbalance of enzymes or hormones or their malfunction, the subsequent excess or deficiency may lead to serious illness. Symptoms of metabolic alterations vary depending on the enzyme or hormone imbalance involved.

Diabetes Mellitus

Controlling excessive amounts of circulating glucose in the body is one of the responsibilities of the pancreas. The pancreas has a major role in

producing insulin. Insulin aids in regulating the use and storage of glucose, the end product of carbohydrate metabolism. Failure of the pancreas to produce adequate insulin to regulate glucose levels allows the accumulation of glucose in the circulatory system and its decreased diffusion, or entry, into the cells. This results in a condition known as *diabetes mellitus*. The two common types of diabetes are insulin-dependent, or type 1, and non-insulin-dependent, or type 2. Replacement of insulin through injections is necessary for the proper metabolism of glucose in patients with type 1 diabetes. Although injectable insulin used to be derived from the pancreas of pigs or cattle, it is now biosynthetic, eliminating concerns for people who do not consume pork or beef. Oral antiglycemic agents, diet, and exercise are most frequently effective in controlling glucose levels in type 2 diabetics. Patients with diabetes are at high risk for developing blindness (because of retinal changes), renal failure, neuropathy (loss of sensation) in the lower extremities, and poor wound healing.

Allergies and Intolerances

Patients may have allergies or intolerances to various foods or dietary supplements that should be noted. Food allergies are a response of the immune system that occurs when the body erroneously identifies an ingredient or food product as harmful and produces antibodies to fight it. The most common food allergens include peanuts, fish, shellfish, tree nuts (such as pecans or almonds), and wheat.

Food intolerances trigger a digestive system response, resulting in the irritation of the digestive tract or the inability to digest or break down food. Lactose intolerance, which may occur after consuming dairy products, is the most common food intolerance. Whereas food intolerance causes discomfort, food allergies are potentially life-threatening.

Obesity

Obesity in adults is defined as a **body mass index (BMI)** of 30 or higher. Obesity is prevalent throughout the world. According to the [HHS \(2017\)](#), obesity is “epidemic.” The following statistics support that health concern:

- More than thirty-nine percent of adults and 18.5% of youth in the United States were obese in 2015-2016.

- The prevalence of obesity in the United States went from 15% to 39.8% among adults and from 5% to 18.5% among children and adolescents from 1980 to 2017.
- Compared with a non-obese teenager, an obese teenager has more than a 70% greater risk of becoming an obese adult.
- Obesity is more common among Hispanic teenagers (25.8%), and non-Hispanic black teenagers (22%) than non-Hispanic white teenagers (14.1%).

Individuals are classified as morbidly obese when their BMI is greater than 40 or they are more than 50% above their ideal body weight. Morbid obesity is known to interfere with the normal activities of daily living. Overweight (BMI between 25 and 29.9) and obesity contribute to an increased incidence of health-related conditions such as diabetes, hypertension, heart disease, and other chronic diseases.

BMI is a helpful tool for determining the extent of obesity and its potential health complications. According to the National Institutes of Health (2016), as BMI levels rise, blood pressure and cholesterol levels also rise, and the average high-density lipoprotein (HDL), or good, cholesterol levels decrease. Men with a high BMI (above 31.3) are at greater risk for hypertension, hyperlipidemia, or both compared with men of normal weight. **Hyperlipidemia** (elevation of plasma cholesterol, triglycerides, or both) or low HDL levels contribute to the development of atherosclerosis (buildup of fat deposits on arterial vessel walls). Women with an elevated BMI (above 32.3) have four times the risk for development of either or both of these conditions. Nutrition and weight status objectives from *Healthy People 2020* are outlined in [Box 30.4](#).

Box 30.4

Nutrition and Weight Status Objectives From *Healthy People 2020*

Healthier Food Access

- Increase the number of states with nutrition standards for foods and beverages provided to preschool-age children in child care.
- Increase the proportion of schools that offer nutritious foods and beverages outside school meals.
- Increase the number of states that have state-level policies that incentivize food retail outlets to provide foods that are encouraged by the *Dietary Guidelines for Americans*.
- Increase the proportion of Americans who have access to a food retail outlet that sells a variety of foods that are encouraged by the *Dietary Guidelines for Americans*.

Health Care and Work Site Settings

- Increase the proportion of primary care physicians who regularly measure the body mass index (BMI) of their patients.
- Increase the proportion of physician office visits that include counseling or education related to nutrition or weight.
- Increase the proportion of work sites that offer nutrition or weight management classes or counseling.

Weight Status

- Increase the proportion of adults who are at a healthy weight.
- Reduce the proportion of adults who are obese.
- Reduce the proportion of children and adolescents who are considered obese. Prevent inappropriate weight gain in youth and adults.

Food Insecurity

- Eliminate very low food security among children.
- Reduce household food insecurity and, in doing so, reduce hunger.

Food and Nutrient Consumption

- Increase the contribution of fruits to the diets of the population age 2 years and older.
- Increase the variety and contribution of vegetables to the diets of the population age 2 years and older.

- Increase the contribution of whole grains to the diets of the population age 2 years and older. Increase the contribution of whole grains to the diets of the population age 2 years and older
- Reduce consumption of calories from solid fats and added sugars in the population age 2 years and older.
- Reduce consumption of saturated fat in the population age 2 years and older.
- Reduce consumption of sodium in the population age 2 years and older.
- Increase consumption of calcium in the population age 2 years and older.

Iron Deficiency

- Reduce iron deficiency among young children and females of childbearing age.
- Reduce iron deficiency among pregnant females.

From U.S. Department of Health and Human Services (HHS). (2018). *Healthy People 2020*. Retrieved from www.healthypeople.gov/2020/topicsobjectives2020/objectiveslist.aspx?topicId=29

Malnutrition

Just as obesity is seen worldwide, so is malnutrition. Malnutrition may result from absorption or digestive problems, illness, or an inadequate or imbalanced intake of calories. Sadly, although plenty of food is available to feed everyone on earth, it most often is a problem with distribution or access that leads to many cases of malnutrition.

Malnutrition may be mild and cause few or no symptoms, or it also may lead to starvation and death. As discussed earlier, the lack of just one vitamin can cause an individual to be malnourished. Children are especially vulnerable to malnutrition. Poverty, government discord, and natural disasters (such as drought) may lead to famines or epidemics of malnutrition.

Psychological Alterations

The term **anorexia** refers to a loss of appetite in patients experiencing illness or side effects from allergies, medications, or treatments, such as chemotherapy, that suppress the desire to eat. These symptoms

typically dissipate after resolution of the illness or treatment. Two major psychological alterations, however, are linked to improper nutritional intake, lack of absorption, and metabolism of nutrients—*anorexia nervosa* and *bulimia*.

Anorexia Nervosa

Anorexia nervosa is a serious disorder in which the person exhibits life-threatening practices as a result of an altered mental state. This disorder may be used to gain some sense of control, especially when diagnosed in adolescents and young adults. Adolescents and young adults may feel as though they have no control over their lives; they may experience hopelessness in establishing relationships or dealing with family conflicts. Strict dietary intake regulation seen in *anorexia nervosa* may be used as a means of gaining control. The disorder may begin as a result of the desire to be thin through strict dieting and then the desire becomes more of an obsession. There is a distortion of body image, with an intense fear of gaining weight or being viewed as “fat,” despite the fact that the individual's weight is less than healthy or normal, according to the National Association of Anorexia Nervosa and Associated Disorders (ANAD, 2018).

Many factors contribute to the eating disorder, such as limited caloric intake, omission of healthy foods, excessive exercise routines, and obsessive behaviors. These behaviors may include excessive use of laxatives or diuretics, self-induced vomiting, and refusal to socialize with friends or family when food is involved. Circulatory collapse, organ failure, or cachexia are the most common causes of premature death in patients with *anorexia nervosa* (Maximilian, Fichter, & Quadflieg, 2016). [Box 30.5](#) addresses some of the concerns associated with caring for adolescents suffering from *anorexia nervosa*.

Box 30.5

Ethical, Legal, and Professional Practice

Treatment of Adolescents With Eating Disorders

The issue of how best to treat adolescents suffering from eating disorders is a challenging one for health care professionals. Certain bioethical concepts must guide the decision making of nurses participating in and guiding patient care. This is especially true in cases of forced hospitalization.

- Involving adolescents in decisions about their care reinforces the ethical principle of autonomy.
- This becomes especially challenging when issues of competency arise regarding the young adolescent's ability to make sound treatment decisions.
- Determining the extent to which adolescents suffering from eating disorders may harm themselves must be a factor in deciding plans of care. This approach supports the ethical principle of beneficence, or doing no harm.
- Health care insurance policies that do not cover specialized inpatient treatment may be a challenge to the ethical concept of justice, or equity, of social and medical resources.
- Although most adolescents with eating disorders can be treated on an outpatient basis, those who exhibit severe depression, extreme physical complications secondary to electrolyte imbalances, or suicidal tendencies may require extensive inpatient treatment.
- Research indicates that although forced hospitalization is indicated in some cases of anorexia, compulsory tube feedings are not always the best option.
- Highly skilled nursing care with hospitalization is preferred before body mass index (BMI) drops below 13 kg/m².
- Ultimately, the decision on how best to ethically treat an adolescent suffering from an eating disorder needs to be one of collaboration among the child's physician, nurse, counselor, spiritual adviser, parents, and other concerned adults.
- All treatment decisions must be considered within the legal context of the country and/or state in which the child resides.
- Related issues include the age of consent, the age up to which parents are required to be informed of a child's medical issues, and the age limit up to which parents are permitted to access confidential information about a child.

From Michaud, P., Blum, R., Benaroyo, L., et al. (2015). Assessing an adolescent's capacity for autonomous decision-making in clinical care, *J Adolesc Health* 57(4), 361-366.

Bulimia Nervosa

Bulimia nervosa is another common eating disorder. This illness involves an obsession with **bingeing** (the intake of excessive amounts of food), as many as 2000 to 3000 calories at one time, followed by **purging** (vomiting). In an effort not to gain weight from the excessive amount of

food eaten, the person may use self-induced vomiting or excessive exercise. Bulimia may also result from the abuse of laxatives or diuretics. It is not known specifically what causes this eating disorder, but it is thought to be a combination of psychological, biologic, and sociocultural factors. Complications from bulimia nervosa may vary, ranging from tooth decay or mild GI symptoms to more serious ones, such as electrolyte imbalance, cardiac dysrhythmias, heart failure, and death. Identification of these problems is extremely important, and treatment must be expeditiously initiated to obtain a favorable patient outcome.

Early identification of people with the predisposition for such behaviors is essential to minimize the long-term effects of eating disorders. Assessing adolescents and understanding the vulnerability of this age group promote early intervention. Recognizing relationship pressures from peers or family is imperative. Each aspect of the person's life has to be assessed to determine the underlying factors that contribute to the disordered eating behavior. When providing patient education, the health care professional should focus on body weight, nutrition, and exercise while stressing the importance of avoiding behaviors that could result in eating disorders. The health care professional also should recognize the family's role in collaborating with the physician, psychologist, family therapist, and registered dietitian in clinical management of the person suffering from an eating disorder.

LO 30.3 ♦ Assessment

Assessment of a patient's nutritional status includes observation of the patient's general health and completion of a health history followed by physical assessment (Box 30.6). The process is time-consuming, yet it is essential for determining dietary needs and nutritional status.

Box 30.6

Health Assessment Questions

Nutrition Focus

- What was your dietary intake for the past 24 hours?
- Have you noticed any changes in appetite or food intake?
- Have you gained or lost weight in the past month?
- While eating, do you experience any difficulty chewing or swallowing?
- Are you taking any prescribed or over-the-counter (OTC) medication that may be affecting your sense of taste or smell?
- Do you experience any gastric distress after eating, such as nausea, vomiting, heartburn, increased flatulence (gas), or changes in your bowel pattern (e.g., loose stools or constipation)?
- Are you allergic to or unable to tolerate any foods, such as milk or other dairy products?
- When looking in a mirror, what parts of your body do you think are your best or worst features, and why?
- How do you feel about your weight?
- How often do you weigh yourself?
- Have you ever used diet pills, laxatives, diuretics (water pills), or vomiting to lose weight?
- Do you ever feel that your eating is out of control?

Nutrition History

The nurse should conduct a nutrition history, noting dietary intake and any changes in weight or appetite reported by the patient. Collection of a diet history allows the nurse to analyze data regarding the type and quantity of foods consumed, establish baseline values for identifying

any health problems that may adversely affect the patient's nutritional status, and identify the need for nursing interventions. When collecting data, the nurse should take into consideration the patient's culture and ethnicity. Recognizing these influences on the patient's nutritional intake allows the nurse to make informed decisions. The data analysis may reveal the need to refer the patient to a registered dietitian for further evaluation of nutritional status. The registered dietitian performs additional assessments that result in recommendations for an individualized program of exercise, diet, and behavior modifications designed to meet the patient's nutritional needs.

Two common practices for obtaining information regarding the patient's dietary patterns are the 24-hour recall and the food diary. The 24-hour recall is dependent on the ability of the patient to remember consumption of foods and their quantities from the previous day. It is vital to remember that the patient's recall may not be factual and the intake may not be that of a typical day. The other means of assessing a patient's usual dietary pattern is to have the patient keep a written journal of food intake for a certain amount of time. The food diary should encompass entries for 3 to 5 days and include dietary intake for a typical weekend. The patient should be encouraged to include the type and amount of food and how the food was prepared (i.e., fried, grilled, with gravies or sauces). The nurse reviewing the journal entries or discussing the patient's recall of foods eaten should be nonjudgmental to motivate the person to better understand and use the information in ways that will promote and maintain good health. With the evaluation of the dietary history and a collaborative approach, the needs of the patient are met holistically.

A full nutritional assessment may be performed on admission if the nurse suspects eating disorders or an altered nutritional status. It is important to recognize that altered nutritional states may include a variety of problems associated with physiologic, psychological, socioeconomic, cultural, and religious factors, among other health-related issues. All patients should be asked about their typical dietary intake, food preferences, and allergies.

Screening for Malnutrition in Older Adults

Nurses must be sure to consider the effects of nutrition on older adults. Assessment of the older adult (age 65 years of age and older) must include close attention to the mouth, teeth, and gums. Consideration must be given to the decrease in sense organ function related to aging, such as changes in the ability to smell, taste, chew, and digest food. Other physiologic changes may include increased fat stores, limited activity, decreased bone mass, decreased kidney function, and a decline

in the immune system. These changes place the older person at risk for obesity, poor tolerance of activity, fractures, renal failure, and increased susceptibility to infection. Tools, such as the Mini Nutritional Assessment (MNA) or the DETERMINE self-assessment, are helpful in screening for malnutrition in older adults. The acronym *DETERMINE* stands for “disease, eating poorly, tooth loss/mouth pain, economic hardship, reduced social contact, multiple medications, involuntary weight loss/gain, needs assistance in self-care, and elderly years above age 80” (The [National Resource Center on Nutrition and Aging, 2017](#)).

Physical Assessment

A thorough physical assessment with a focus on nutritional status includes height and weight measurements, determination of BMI, evaluation of laboratory values, notation of any adverse signs and symptoms typical of malnourished people (poor dentition, poor skin turgor, or dull, thinning hair), and recognition of any existing physical and psychological illness. Assessment of the person's waist circumference, vital signs, past medical history, current medications, and activity level is essential in identifying the potential risk factors for cardiovascular diseases related to imbalanced nutrition ([Box 30.7](#)).

Box 30.7

Waist Circumference and Risks for Cardiovascular Disease

- Waist circumference is a valuable tool in addition to body mass index (BMI) measurement in determining a patient's risk for cardiovascular disease. Waist circumference assesses fat distribution and indicates body shape.
- A correlation has been found between waist-to-hip ratio and the development of specific disease conditions.
- Research indicates that people with “apple-shaped” bodies, with more fat deposited around the waist, are at risk to develop hypertension, coronary heart disease, and type 2 diabetes ([Emdin, Khera, Natarajan, et al., 2017](#)).
- People with “pear-shaped” bodies (most of the accumulated fat is stored below the waist, in the buttocks and thighs) are at risk for increased inflammation, insulin resistance, and the development of metabolic syndrome ([Jialal, Devaraj, Kaur, et al., 2013](#)).

- An average waist size of 88 cm (35 inches) for women and 102 cm (40 inches) for men puts them in the high-risk category for heart disease (Song, Jousilahti, Stehouwer, et al., 2015).

Morphology

Determining the patient's BMI is helpful to establish the presence of obesity, malnutrition, or cachexia (Box 30.8). **Cachexia** (physical wasting) often is seen in patients suffering from terminal illnesses who are unable to consume an adequate intake of food; the effects of the disease are evident in weight loss and the loss of muscle mass. Malnutrition may result as a consequence of eating disorders, dysphagia (difficulty swallowing), irritable bowel syndrome, chronic alcoholism, celiac disease, and intestinal damage from radiation therapy. It also may result from unmet increased metabolic needs in patients with infection, sepsis, burn injury, or cancer.

Box 30.8

Nursing Care Guideline

Height and Weight Assessment and Body Mass Index Calculation

Background

- Height, weight, and body mass index (BMI) assessment is used to track weight trends, which can be an indicator of disease processes.
- BMI is not an independent diagnostic assessment. It is part of a full assessment of various body systems.

Procedural Concerns

Height

- Is the patient capable of weight bearing?
 - Instruct the patient to remove his or her shoes and stand erect.
 - Use a tape measure or scale measure.
 - Make sure there is a 90-degree angle from the top of the head to the measurement device for accuracy.
- Is the patient not capable of weight bearing?

- Instruct the patient to remove his or her shoes; assist if needed.
- Position the top of the patient's head against the headboard or measuring device for accuracy.
- Instruct the patient to straighten the body and legs; assist if needed. Measure from the top of the head to the bottom of the heel; some measuring devices have movable footboards.

Weight

- When repeated measurements of the patient's weight are needed, make sure the patient is weighed at the same time of day, on the same scale, and in the same clothing (if possible) for each measurement.
- Instruct the patient to remove his or her shoes; assist if needed.
- Follow the manufacturer's directions for the scale used (electronic, platform, stretcher, chair, bed).

Body Mass Index

- Standard BMI calculations are assessed for patients older than 20 years of age. Specific BMI charts are available for patients younger than 20 years.
- Calculation is the weight in kilograms/(height in meters)².
- Interpretations of BMI calculations are:
 - Less than 18.5 kg/m² = Underweight
 - 18.5 kg/m² to 24.9 kg/m² = Normal weight
 - 25.0 kg/m² to 29.9 kg/m² = Overweight
 - 30.0 kg/m² to 34.9 kg/m² = Obese (class 1)
 - 35.0 kg/m² to 39.9 kg/m² = Obese (class 2)
 - More than 39.9 kg/m² = Extreme obesity (class 3)

Documentation Concerns

- Document and graph the patient's height, weight, and BMI in accordance with facility policy and procedure.
- Notify the primary care provider (PCP) of unusual or unexpected changes in height or weight.

Evidence-Based Practice

- It is important to calculate and document a patient's BMI and educate the patient regarding the interpretation. Patients who do not perceive themselves as overweight are not likely to participate in weight-control behaviors. Research indicates that weight misperception is more pronounced among blacks and Mexican Americans than whites, and Latinos are more likely to underestimate their weight than those of Caucasian, Filipino, or Korean American background ([Gibbs, Pacheco, Yeh, et al., 2016](#)).
- There has been discussion on whether BMI is truly a reliable and valid instrument to determine weight-related health risks. Research findings of [Agbaedeng, Mahajan, Munawar, and colleagues \(2017\)](#) indicate that obesity, determined by BMI, is associated with an increased risk of sudden cardiac death.

Anthropometric Measurements

Nurses often use **anthropometry** (the study of measurements of the human body) when performing nutritional or growth and development assessments of infants and children. The measurements include height, weight, length (used in infants and toddlers because they are unable to stand), and head circumference. These measurements must be accurate to be valid.

Anthropometric measurements used for adults usually include height, weight, BMI, and waist-to-hip ratio. These findings are compared against reference standards to assess weight status (underweight, ideal weight, overweight) and the risk for various diseases.

The distribution of body fat is significant in determining health risk potential. A strong relationship is recognized between obesity and cardiovascular health. Waist circumference can be used as a strong diagnostic criterion for metabolic syndrome, which is a cluster of medical conditions characterized by insulin resistance and the presence of obesity, significant abdominal fat, elevated blood glucose, serum triglycerides and cholesterol, and hypertension. The increasing number of people with this condition is linked to the rise in obesity rates among adults. In the future, metabolic syndrome may overtake smoking as the leading risk factor for heart disease ([National Heart, Lung, and Blood Institute, 2018](#)).

Skinfold measurements are one means of determining a person's body composition and body fat percentage. The percentage of body fat is estimated by measuring skinfold thickness, using calipers, at specific locations on the body. The thickness of the folds is a measure of the fat under the skin, also called *subcutaneous adipose tissue*. Skinfold thickness

results rely on formulas that convert the numbers into an estimate of body fat stores and nutritional status for the person's age and gender.

Skin and Hair

The influence of improper nutrition on the skin is evident during the physical assessment. Poor nutrition is reflected by the presence of thinning hair that has a dry, stiff texture and lack of shine. In severe cases of malnutrition, hair may totally lose its color and appear pale. The lips can have a deep red appearance with open lesions and deep cracks in the corners of the mouth. The oral mucosa may be a darker red than normal, with oral lesions, and/or the tongue may reveal white irregular areas. In conditions such as pernicious anemia, a characteristic finding is a sore, smooth-surfaced, beefy-red tongue; the soreness may interfere with the person's ability to chew certain foods.

A dry, rough appearance of the skin, pallor, and changes in the pigmentation of the skin may be noted. Skin may be easily bruised or have small pinpoint hemorrhages under the skin (petechiae). Skin changes in the more severely malnourished person may range from loose, wrinkled skin (due to loss of underlying fat tissue) to deep wounds that will not heal.

Skin turgor is an indication of the patient's level of hydration. In dehydration, when the skin is pinched, the skin takes on the appearance of a tent and returns to its original position very slowly. See [Chapter 29](#) for further information on skin integrity and the use of skin assessment tools.

Dentition

Older adults can retain their teeth with proper care. Normal wear and tear occurs with the aging process, resulting in the loss of tooth integrity: decreased amount of enamel, shrinkage of the gum tissue, and lengthening of the teeth, with the diminished ability of the teeth to cut and chew efficiently. However, a high prevalence of tooth loss also has been documented in the older adult population. Loss of natural dentition affects nutrient consumption and may result in the increased development of cardiovascular disease. Edentulous (toothless) people have been found to have significantly higher BMI values ([Hu, Lee, Lin, et al., 2015](#)). The increase in BMI appears to occur from increased consumption of high-calorie foods with low-level nutrients, such as soft, sweet foods that promote obesity. Nutritional intake and chewing efficiency often are not significantly compensated in people with partial or complete dentures.

1. Identify three pieces of data that would be essential for the nurse to document while caring for A. K. on the nursing unit.

Swallow Studies

People who have residual effects of stroke or other injury may experience dysphagia or choking during meals. People who have difficulty swallowing are also at risk of aspirating food and fluids into their lungs. Inhaling oral secretions or stomach contents may result in complications that vary from aspiration pneumonia to respiratory distress to death. Factors responsible for these complications are the amount and the character of the aspirated contents.

Individuals at risk for **aspiration** (inhalation of fluid or foreign matter into the lungs and bronchi) should be monitored closely for coughing, wheezing, dyspnea, apnea, bradycardia, and hypotension. Depending on the patient's condition—level of consciousness, recent sedation, ability to reposition self, limited mobility, and/or restrictions—and if the patient has been intubated, aspiration precaution measures should be established (Manabe, Teramoto, Tamiya, et al., 2015) (Box 30.9). People with these risk factors may need a swallow study or dysphagia screening. Swallow studies are normally conducted by a speech therapist. A registered dietitian will help determine the most appropriate food textures and means of hydration. If the person is unable to take nutrition and hydration orally, the dietitian may make a recommendation to the patient's primary care provider (PCP) for a non-oral route such as an enteral feeding tube, total parenteral nutrition (TPN), or nasogastric (NG) tube (for short-term therapy).

Box 30.9

Nursing Care Guideline

Aspiration Precautions

Background

- Aspiration precautions are taken to prevent the following materials from entering the lungs of at-risk patients instead of being swallowed:
 - Food
 - Fluid
 - Saliva
 - Other foreign objects
- To determine whether there is a risk of aspiration, do any or all of the following:
 - Consult the nutritional therapist.
 - Consult the speech therapist.
 - Have a swallow study done on the patient.
- Conditions that place patients at risk include:
 - Seizures
 - Cerebrovascular accidents (CVAs)
 - Dementia
 - Gastroesophageal reflux disease (GERD)
 - Cerebral palsy, muscular dystrophy, multiple sclerosis, Parkinson disease, and other diseases affecting mobility
 - Endoscopy procedures
 - Medications with a sedative or muscle relaxant effect, including anesthesia
 - Feeding of the patient by another person or an eating pattern that is too fast

Procedural Concerns

- Follow orders for dietary consistencies and textures.
- Follow the manufacturer's instructions and facility policies and procedures for thickening of liquids as ordered.
- Elevate the head of the bed to 45 degrees or higher during eating and for a minimum of 45 minutes after eating.
- Keep the head of the bed elevated to 30 degrees at all other times, including during enteral feeding.
- Encourage slow eating patterns.
- Instruct the patient to avoid eating or drinking for 2 to 3 hours before sleep.
- Administer gastrointestinal (GI) medications as ordered.
- Inspect the patient's mouth for pocketing of food.
- Observe the patient for swallowing between bites of food and fluids.

- Instruct the patient to alternate between bites of food and sips of fluids to facilitate swallowing.
- Maintain patient NPO status after procedures in which the throat was anesthetized, until return of a gag reflex has been verified.

Documentation Concerns

- Document any gagging, choking, and/or coughing during meals.
- Monitor respiratory status.
- Note any intermittent fevers that may occur.
- Record hesitance or fear of eating.
- Include occurrences of nausea, vomiting, regurgitation, and/or reflux symptoms.
- Document any dehydration and/or weight loss.
- Describe the aspiration protocol and plan of care expectations and guidelines.

Evidence-Based Practice

Nurses often are the first health care provider to notice signs or symptoms of aspiration pneumonia. Although aspiration pneumonia is actually a rare occurrence, when it does happen, it has a high mortality rate. Aspiration is the underlying cause of 80% of pneumonia cases requiring hospitalization, and is the leading cause of death in older adults with pneumonia (Maeda & Akagi, 2017). As a result, it is imperative that nurses implement all precautions possible to decrease the risk of aspiration. Excellent nursing management of dysphagia can reduce mortality rates in stroke survivors (Kenny, Barr, & Laver, 2016).

Qsen Focus!

Recognizing the value of contributions from other members of the health care team demonstrates an understanding of each person's unique professional role in helping patients achieve their health care goals.

Laboratory Studies

Laboratory tests add objectivity to the nutritional assessment. No single laboratory value will specifically predict nutritional risk or measure the presence or degree of malnutrition or the response to nutritional

intervention therapy. However, some levels (such as serum protein or prealbumin levels) are affected by factors (such as fluid balance, liver and renal function, acute stress, and colloid administration). Normal values for tests performed vary with institutions, testing facilities, and authors. It is important that nurses monitor laboratory results ordered by the PCP to complement information obtained in a complete assessment of the patient.

Prealbumin

Prealbumin levels are a measure of the amount of protein contained in the internal organs. Protein is synthesized in the liver and broken down by the kidneys. Prealbumin assays are valuable for determining recent nutritional status. Prealbumin levels below 11 mg/dL indicate the presence of malnutrition (Table 30.2). Decreased prealbumin levels may result from stress, inflammation, surgery, and renal failure.

TABLE 30.2
Laboratory Values Indicating Degrees of Malnutrition

TEST	HALF-LIFE (DAYS)	NORMAL	MILD	MODERATE	SEVERE
Prealbumin (mg/dL)	2	16-30	10-15	5-10	<5
Albumin (g/dL)	21	3.5-5.0	2.8-3.5	2.1-2.7	<2.1
Transferrin (mg/dL)	8-9	200-400	150-200	100-150	<100

From Dawodu, S. (2015). *Nutritional management in the rehabilitation setting*. Retrieved from <http://emedicine.medscape.com/article/318180-overview#a5>.

Albumin

Assessment of plasma protein levels such as albumin often is used to determine liver function. Albumin is synthesized in the liver and accounts for almost half of the total serum protein in the human body. Albumin levels should be included on the initial chemistry profile for nutritional screening purposes and monitored during hospitalization to determine the presence of an ample supply of protein over an extended period of time. The synthesis of protein may be affected by nonnutritional factors such as cirrhosis, acute stress, congestive heart failure, and hypoxia. Decreased levels may be caused by renal and liver disorders, altered fluid status, medications, chronic diseases, and malnutrition. Elevated levels may result from decreased fluid balance (dehydration), exercise, or medications.

Transferrin

Transferrin transports iron in the body and is sensitive to a decrease in protein and iron stores, as seen in iron deficiency anemia and kwashiorkor. Transferrin levels may be elevated in acute fasting, chronic infection, inflammation, burns, or pernicious anemia. Transferrin levels become elevated as the deficiency worsens and decrease as the iron level responds to treatment and returns to within an acceptable range. See [Table 30.2](#) for key prealbumin, albumin, and transferrin levels.

Hemoglobin and Hematocrit

Hemoglobin and hematocrit laboratory values are used to identify the number and percentage of circulating erythrocytes, their ability to provide oxygen to the cells, and the body's iron store status. Iron is an essential portion of hemoglobin. It assists in gas exchange within the lungs and helps meet the oxygen demands of the body. If iron stores are depleted, less oxygen is available to meet the demands of the body, resulting in signs and symptoms such as fatigue, pallor, shortness of breath, and rapid respirations. Iron deficiency anemia indicated by low hemoglobin levels usually is treated by providing iron in the form of oral supplements or intramuscular injections. People with low hemoglobin should be encouraged to increase their intake of foods that are high in iron, such as liver, dark-green leafy vegetables, seafood, and bran.

The hematocrit indicates the number and size of the red blood cells found in whole blood and are expressed as the percentage of total blood volume occupied by the erythrocytes. A low hematocrit is indicative of anemia. The size and shape of the red blood cell can be related to the type of anemia from which a person is suffering.

Blood Urea Nitrogen and Creatinine

Blood urea nitrogen (BUN) and serum creatinine assays (tests) commonly are ordered together as part of a basic or comprehensive metabolic profile. These two tests are used primarily to evaluate kidney function in people with disease processes known to affect the kidneys, such as diabetes or hypertension. BUN and serum creatinine levels determine the extent of kidney dysfunction, its progression, and the effectiveness of treatment. Elevated levels may be a result of dehydration, atherosclerosis, or injury to the kidneys from infection or trauma. For further information on diagnostic tests and normal values, see [Chapter 34](#).

2. List three laboratory values (and give a rationale for each) that the nurse needs to monitor in relation to A. K.'s nutritional status.

Elimination Patterns

A thorough abdominal assessment should be performed, including attention to the presence of bowel sounds; bowel pattern; color, amount, and character of stools; and use of laxatives.

Good or poor nutrition can have a drastic impact on bowel elimination. Constipation (hard stools) results from the slow progression of digested food through the GI tract. Lack of fluids or fiber can create dry, hardened feces and make evacuation of the bowel difficult. Patients should be instructed to increase their intake of fluids and add foods with high insoluble fiber content to the diet unless contraindicated by conditions, such as diverticulitis.

Excessive bowel elimination, referred to as *diarrhea*, may be a result of high fat intake, use of artificial sweeteners, or excessive intake of insoluble fibers. Increasing the amount of soluble fiber, which absorbs excess water and firms the stools, aids in delaying gastric emptying and, as a result, eases the diarrhea. Loss of fluids through diarrhea or vomiting may result in fluid and electrolyte imbalance, as may overuse of laxatives. Accurate documentation of a patient's elimination patterns is an essential aspect of nutritional assessment.

LO 30.4 ♦ Nursing Diagnosis

Once patient information and assessment data (subjective and objective) are collected and the patient's problems are identified and clustered together, the nurse selects nursing diagnoses based on the findings. These nursing diagnoses are the foundation on which the patient's care plan is developed.

Common International Classification for Nursing Practice (ICNP) nursing diagnoses directly associated with altered nutritional intake:

Impaired Nutritional Intake

- Supporting Data: History of eating disorder, cachectic appearance, 18.1 kg (40 lb) weight loss in past 6 months

Impaired Swallowing

- Supporting Data: Residual effects of neurologic damage secondary to CVA, gagging and choking with oral intake attempts

Impaired Self Feeding

- Supporting Data: Sensory and motor deficits secondary to spinal cord injury, bilateral upper-extremity paralysis, inability to self-feed

Additional nursing diagnoses related to specific body systems may also be relevant for the individual patient.

LO 30.5 ♦ Planning

After prioritization of the patient's needs, appropriate goals or outcomes are identified, and decisions are made to perform specific nursing actions aimed at helping the patient achieve the identified goals or outcomes. Collaboration with the patient and with other members of the health care team is crucial to attain the best possible outcomes (Box 30.10).

Box 30.10

■ Interprofessional Collaboration and Delegation

Providing Comprehensive Nutritional Care

- A registered dietitian is helpful in providing nutritional education and services that may address the psychosocial and economic factors that affect patient care.
- Case managers are responsible for coordinating timely, cost-effective inpatient and outpatient services (such as provision of durable medical equipment, infusion therapy, and transportation for patients), and follow-up after discharge to promote quality care.
- Collaboration with a speech therapist is needed for patients who have impaired swallowing and/or require restorative therapy.
- Collaboration with a board-certified psychologist may be necessary if psychological factors might have an impact on the patient's recovery.
- Assistance with feeding can be delegated to unlicensed assistive personnel (UAP).

Goals may be short- or long-term and should be realistic and measurable. As nurses initiate the planning portion of the patient's plan of care (Table 30.3), they need to have specific objectives in mind for the patient to accomplish as a result of the individualized nursing care being delivered. Consideration must be given to the possible need for home care, referrals to community resources, or assistive devices upon discharge.

TABLE 30.3
Care Planning

ICNP NURSING DIAGNOSIS WITH SUPPORTING DATA	NURSING OUTCOME CLASSIFICATION (NOC)	NURSING INTERVENTION CLASSIFICATION (NIC)
<i>Impaired Nutritional Intake</i> History of eating disorder Cachectic appearance 18.1 kg (40 lb) weight loss in past 6 months	<i>Nutritional status: Food and fluid intake</i> Oral food intake	<i>Eating disorders management</i> Monitor patient for behaviors related to eating, weight loss, and weight gain.

From Bulechek, G., Butcher, H., Dochterman, J., et al. (Eds.). (2018). *Nursing interventions classification (NIC)* (7th ed.). St. Louis: Mosby; Moorhead, S., Johnson, M., Maas, M., et al. (Eds.). (2018). *Nursing outcomes classification (NOC)* (6th ed.). St. Louis: Mosby; ICNP is owned and copyrighted by the International Council of Nurses (ICN). Reproduced with permission of the copyright holder.

Examples of goals or outcome statements are:

- Patient will gain 0.45-0.9 kg (1 to 2 lb) each week until weight is within normal range.
- Patient will not exhibit any signs or symptoms of aspiration during this hospitalization (e.g., lungs clear, respiratory rate within normal range for patient).
- Patient will demonstrate the ability to use assistive devices for self-feeding before discharge.

FIGURE 30.5 Partially completed conceptual care map based on A. K., the case study patient in this chapter.

The conceptual care map for A. K. provided in [Fig. 30.5](#) is partially completed to indicate how to use the map as a learning tool. Using it as an example, go to the website at <http://evolve.elsevier.com/YoostCrawford/fundamentals/> to complete Nursing Diagnoses 2 and 3.

LO 30.6 ♦ Implementation and Evaluation

Proper nutrition is necessary to prevent the adverse effects associated with excessive or minimal intake of the proper nutrients. Patients suffering from physical and psychological diseases often require an alteration in their dietary intake, including an increase or decrease in calories, a specialized diet, or a change in fluid or food consistency (e.g., no added salt, low cholesterol, 1800-calorie American Diabetic Association diet, thickened liquids). Such diets often are used to control or minimize the effects of acute and chronic disease and promote health.

Dietary Preferences

Vegetarian diets and the reasons people may choose to follow them vary widely. Vegetarian diets and lifestyle have been associated with improved health outcomes. Vegans do not consume any animal products, whereas lacto-ovo vegetarians consume milk and eggs. Although not strict vegetarians, many people choose to consume only small or minimal amounts of animal products. Vegetarian and vegan diets need to include food sources that provide protein, iron, calcium, and zinc. By including cereals, dried beans and peas, and a variety of vegetables to their daily intake, vegetarians are able to acquire the daily essential amino acids necessary for growth and development. Vegans are at risk for development of pernicious anemia and should supplement the diet with vitamin B₁₂ to minimize this risk.

Food Patterns Based on Religion or Culture

Some people choose to follow dietary restrictions (such as kosher or vegetarian diets) based on religious traditions. It is important for nurses to be aware of these customs while remembering that not all people of a particular culture or religion adhere to similar dietary traditions. Patient-centered plans of care are best developed when the nurse asks about the patient's individual dietary preferences and demonstrates respect for cultural and religious nutritional needs.

For people adhering to a kosher diet, the consumption of pork, shellfish, rare meats, and blood is prohibited, as is the combining of milk or dairy products with meat. There are strict kosher food preparation laws, as well as cooking restrictions on the Sabbath. Certain Jewish holidays require eating only unleavened bread or fasting. Many Catholics observe holy days with fasting, especially on Fridays during the season of Lent.

Islamic tradition prohibits the consumption of alcohol, pork, and caffeine, and halal food preparation rules share similarities with kosher laws. The month-long holy season of Ramadan requires abstaining from food and drink until sundown. There are exceptions made for those with special dietary needs. Similarly, people who adhere to Mormon tradition avoid the use of alcohol, tobacco, and caffeine. Seventh-day Adventists encourage a vegetarian diet and exclusion of alcohol. Some cultural traditions identify foods as “hot” or “cold” on the basis of their healing quality, not their temperature or degree of spiciness.

Most devout Buddhists avoid the consumption of meat and meat by-products and follow vegetarian dietary guidelines, as do many Hindus. The cow is sacred to Hindus, so no beef is consumed; however, other products from the cow (such as milk, yogurt, and butter) are not prohibited.

In faith traditions where fasting is stressed, it typically is prohibited for young children and for older children and adults whose health status would be negatively affected by a decreased dietary intake. It is important to ask patients about dietary restrictions before administration of alcohol-based medications, such as antitussives (cough syrups).

The foods typically consumed by some ethnic groups may include items high in fat, sodium, or carbohydrates. These dietary preferences present a challenge when nutritional intervention is needed to avoid serious health complications.

Qsen Focus!

Patient-centered care is exhibited when nurses respect the dietary needs of people with cultural or religious traditions different from their own.

Special Diets

Collaboration with a registered dietitian is helpful when the nurse is providing nutritional support while addressing medical or surgical conditions such as hypertension, dysphagia, cardiac disease, diabetes, or recovery after GI surgery. The PCP typically orders a special diet for the patient. Advancement from one level of special diet to the next may be at the discretion of the nurse; however, provisions for this are often included in the patient's orders. Examples of special diets to address specific patient needs are:

- *Clear liquid* has limited nutrients and is used only for a short period of time. Clear juices that do not contain pulp (such as apple or cranberry juice, gelatin, popsicles, and clear broths) are examples of clear liquids. Clear-liquid diets most commonly are ordered for patients with GI problems, before surgery (preoperatively) and after surgery (postoperatively), and before some diagnostic tests.
- *Full-liquid* diets consist of foods that are or may become liquid at room or body temperature. Full-liquid diets include juices with and without pulp, milk and milk products, yogurt, strained cream soups, and liquid dietary supplements. Such diets are often used to advance patients who have GI disturbances, who have just had dental work performed, or who cannot tolerate solid food.
- *Pureed* diets, often referred to as *blended*, consist of food that is placed into a blender and made into a pulplike mixture. This type of diet is used for individuals who cannot safely chew or swallow solid food. The addition of raw eggs, nuts, and seeds should be avoided.
- *Mechanical soft* diets include food consistencies that have been modified, such as ground meat or soft-cooked foods. They are used for those who have difficulty chewing effectively.
- *Thickened liquids* are used for patients who have difficulty swallowing and are at risk for aspiration. Liquids can be thickened by adding a commercially prepared thickening agent. Nuts, seeds, and other hard or raw foods should be avoided, to decrease the risk of aspiration.

- *Regular diets*, or *general diets*, are commonly referred to as *diet as tolerated*. There are no dietary restrictions, but foods should supply patients with a balanced diet of essential nutrients.
- *Diabetic* (American Diabetic Association [ADA]) diets are prescribed to control the amount of calories by controlling carbohydrate intake. Foods that have a high glycemic index and rapidly raise the body's blood glucose concentration should be avoided. High-fiber complex carbohydrates from vegetables and fruits are preferred to simple carbohydrates, sugars, and starchy foods (such as bread or pie).
- *Cardiac* diets are used to control the dietary intake of foods that contribute to conditions affecting the cardiovascular system. They typically consist of low-cholesterol and low-sodium dietary items. Cardiac diets minimize the intake of animal products, which contain cholesterol, and soups and processed foods (such as pickles and lunchmeats), which are high in sodium. Patients with hypertension, high cholesterol, atherosclerosis, chronic renal failure, or similar diseases may be placed on some type of cardiac (low-cholesterol, low-sodium) diet.
- *Renal* diets restrict potassium, sodium, protein, and phosphorus intake. Fresh fruits (except bananas) and vegetables are excellent dietary choices for people on a renal diet. Meats, processed foods, and peanut butter, cheese, nuts, caramels, ice cream, and colas typically are allowed in limited quantities or contraindicated.

Assistance With Feeding

Patients who have limited mobility of their hands or arms, poor tolerance of activity, or a poor cognitive or physical state may require assistance with feeding (Box 30.11). If patients are confined to bed and require assistance with feeding, it is extremely important to elevate the head of the bed at least 30 to 45 degrees (unless contraindicated), closely observe the patient's ability to swallow, and watch for signs and symptoms of dysphagia. Signs may include coughing, incomplete lip closure, poor tongue control, excessive chewing, gagging before swallowing or failure to swallow, holding foods in the cheek (pocketing), or refusal to eat. Patients who normally must be maintained in a flat position should be logrolled to side-lying for meals to aid in swallowing and aspiration prevention.

Box 30.11

Nursing Care Guideline

Assisting an Adult With Feeding

Background

- Assisting an adult with feeding should never be rushed, or aspiration may occur (see Box 30.9).
- Delegation to unlicensed assistive personnel (UAP) is appropriate, but UAP should be instructed on proper techniques and dietary restrictions to avoid complications.
- Follow any dietary and nutritional orders, including food texture and use of thickening agents.
- Find food that the patient likes: Check the patient's chart, and ask the patient or family members about food preferences.

Procedural Concerns

- Provide oral care before and after feeding.
- If the patient has dentures, ensure that they are in place and well fitted (see Skill 27.6).
- The patient's head should be elevated at least 30 to 45 degrees unless contraindicated.

- Special caution should be taken if the patient has impaired swallowing:
 - If the patient has one-sided muscle weakness, have the patient turn the head to the affected side to assist in airway protection.
 - Chin-tucking may help prevent aspiration.
 - If assistive devices are in use, follow the occupational or nutrition therapy guidelines or the manufacturer's instructions for use.
- Position yourself so that the patient can see you.
- Allow at least 30 minutes for each meal. Offer small bites (½ to 1 teaspoon).
- Wait at least 10 seconds between bites.
- Alternate food with fluids.
- Avoid unnecessary use of straws to prevent air ingestion.
- Observe for the rise and fall of the patient's larynx to verify swallowing.
- Check the patient's mouth frequently to prevent retention of food in the cheeks (pocketing).

Documentation Concerns

- Note the intake of food (percentage of food eaten) and liquids (in milliliters).
- Document any aspiration symptoms (see [Box 30.9](#)) and/or patient or caregiver difficulties with the feeding procedure.

Evidence-Based Practice

- Research indicates that when nurses place a high priority on patient mealtimes and help with feeding, there is an improvement in clinical outcomes ([Edwards, Carrier, Hopkinson, 2017](#)).
- Mealtime social interaction is associated with increased food consumption, and increased energy and protein intake in adults over 65 years of age ([Edwards, Carrier, Hopkinson, 2017](#)).

The task of feeding patients who are unable to feed themselves can be delegated to unlicensed assistive personnel (UAP). The nurse is responsible for advising UAP of any pertinent information, such as risk factors for aspiration or indications that the patient is experiencing difficulty in chewing or swallowing.

Safe Practice Alert

Do not attempt to feed a patient food or liquids in the supine position. The head of the bed must be elevated 30 to 45 degrees, with the patient in an upright position, to minimize the risk for aspiration. Logroll the patient into side-lying position, if semi-Fowler position is contraindicated. Have a suction machine at the bedside at all times.

Patients With NPO Orders

Patients who are nil per os (NPO) cannot receive anything by mouth. This requirement often is in place before and after surgery, to allow the intestinal tract to rest and decrease the stimulation of nerves that can lead to vomiting of stomach contents. Conditions (such as GI bleeding or intestinal blockage) may warrant the patient's not receiving anything by mouth. When patients are on NPO status, mouth care is an important nursing intervention, to help keep the oral mucosa moist and aid in swallowing. Oral care should include brushing the teeth, flossing to remove plaque, and using mouthwash. Patients who are unconscious require special attention to their oral care, as well. It is important to place the patient in a position, such as on the side, to allow the drainage of secretions from the mouth. A padded tongue blade can be used to aid in holding the mouth open and allow the toothbrush to reach inside the cheeks and lips.

Enteral Feeding Tubes

Enteral feeding tubes are used to provide short-term nutritional support for patients who have a functional GI tract but cannot swallow, refuse to eat, or need additional nutrients to meet the body's needs. Nasogastric (NG) feeding tubes are placed through one of the nares and into the stomach and are also used for short-term nutritional therapy and bowel decompression. Percutaneous endoscopic gastrostomy (PEG) tubes are surgically placed through an incision in the upper-left quadrant of the abdomen ([Box 30.12](#)). This placement is for long-term nutritional therapy and is indicated in patients who are neurologically impaired (e.g., after a CVA) or have a condition that affects the stomach and its normal function. Patients who have had esophageal cancer or traumatic injury to the nose and mouth may be candidates for this type of nutritional support ([Skills 30.1](#) and [30.2](#)).

Box 30.12

Evidence-Based Practice and Informatics

Confirming Enteral Tube Placement

- Studies support the use of radiographic confirmation as the only reliable method to date of confirming enteral tube placement.
- Using only pH and the appearance of aspirate from the newly inserted tube is not a safe method of verifying proper gastric tube placement, especially in patients receiving antacid medications.
- Auscultation of an air bolus to assess tube placement is no longer recognized as a reliable source in determining gastric tube placement.

Data from American Association of Critical Care Nurses (AACN): Initial and ongoing verification of feeding tube placement in adults (applies to blind insertions and placements with electromagnetic device). *Critical Care Nurse* 36(2):e8–e13, 2016.

Feeding set/Syringe end Feeding tube end
FIGURE 30.6 ENFit enteral feeding tube connector.

Safe Practice Alert

Always check to make sure that tube feedings are properly connected to enteral tubes only! Accidentally hooking up an enteral feeding tube to a patient's intravenous line can be fatal. The Joint Commission now requires that all enteral tube feedings have an ENFit connector to prevent inadvertent connection of feeding tubes with tubes having different functions (Fig. 30.6). Take the extra time necessary to ensure safe practice by following each tube from its point of origin to its destination before initiating intravenous or enteral therapy.

If the patient is being discharged to home with a feeding tube, the role of the nurse is to assess the patient's understanding of this type of nutritional support, determine patient needs (Box 30.13), share information, and instruct the patient or caregiver in the proper manner of administering enteral feedings or formula. Return demonstrations by the patient or caregiver allow the nurse to reinforce information regarding preparation, including the safe handling of the equipment (Box 30.14). Instructions may include how to check for residual, as well as how to administer medication through the tube and how to prevent occluding the tube. The nurse should inform the patient of signs and symptoms to report that could indicate adverse effects of the formula (such as diarrhea, nausea, and vomiting) and abdominal cramps.

Box 30.13

Home Care Considerations

Addressing Enteral Feeding Concerns

The need for dietary education and assistance with nutritional planning is important when enteral feeding continues after patients are discharged to home. Questions that need to be considered include:

- Is the patient cognitively and physically able to perform the feeding independently, or is it necessary for a caregiver to provide the feeding on a predetermined schedule?
- Is the patient at risk of skin breakdown due to bed confinement?
- Has the patient or caregiver received instructions to minimize the risk of infection at the tube insertion site?
- Does a suction machine need to be ordered for the patient's home setting?
- Are referrals to community agencies or support groups in place?

Box 30.14

Nursing Care Guideline

Percutaneous Endogastric Tube Care

Background

- The percutaneous endogastric (PEG) tube is used to infuse food directly into the stomach. This method:
 - Bypasses the mouth
 - Bypasses the swallowing mechanisms
- The PEG tube is placed in the stomach (or stomach and small intestine) through the abdominal wall.
- It is placed as a long-term feeding option.
- Several types of PEG tubes are available:
 - Traditional gastrostomy (G) tube placed in the stomach
 - Double-lumen gastrojejunostomy (GJ) tube:
 - One lumen—the gastrostomy, or G, tube—is placed in the stomach for feeding.
 - The other lumen—the jejunostomy, or J, tube—is placed in the jejunum for decompression.
 - Low-profile MIC-KEY gastrostomy feeding tube
 - Low-profile MIC transgastric-jejunal feeding tube

Procedural Concerns

- Use surgical asepsis if PEG tubes are newly inserted.
- Clean the site with warm water and mild soap:
 - Occasional use of hydrogen peroxide or normal saline solution is permitted.
 - Cleansing should be based on the patient's routine and facility policy and procedure.
- Dry the site thoroughly to prevent skin breakdown.
- A split-drain dressing may be applied to provide comfort and to prevent or treat skin breakdown.
- If the tube becomes occluded, flush it with a small amount of air. If this is unsuccessful in removing the occlusion, flush the tube using a 30- to 60-mL syringe and warm water. If flushing the tube with water is ineffective, research now suggests using special enzyme solutions or declogging devices rather than carbonated beverages or juices (Hayes & Hayes, 2018).

Documentation Concerns

- Document results of the skin assessment.
- Include notes on patency of the tube.
- Record patient tolerance of feedings.

- Document patient and family teaching related to PEG tube care and maintenance.

Evidence-Based Practice

- Complications for which nurses should assess following PEG tube placement include pneumonia, bleeding, peritonitis, bowel perforation, and infection at the site of insertion (Thompson, 2017).
- If a patient experiences bleeding, pain during or after feedings or medication administration, or leakage around the PEG site, the feeding or medication pass should be stopped immediately and the underlying cause investigated (Thompson, 2017).

Safe Practice Alert

Monitor the patient's skin around the percutaneous endoscopic gastrostomy (PEG) tube insertion site for signs of skin breakdown or infection, including increased warmth, redness, edema, and drainage.

Medication Administration via Enteral Tube

Special care should be taken in administering medications by way of an enteral tube. Compatibility, medication solubility, and possible reduction in effectiveness or increase in toxicity must be considered. Medications are never added directly to a tube feeding; rather, they are given in liquid form or ground into powder (as permitted, depending on the medication) and dissolved in 15 to 30 mL of sterile water before instillation into the tube. The enteral tube placement is verified, the tube is flushed with a minimum of 15 mL of sterile water, and the diluted medication is then allowed to flow into the tube by gravity or pushed in gently by plunger, followed by 15 to 30 mL of sterile water to flush the tube after medication administration. Tube feeding may continue immediately unless the contents would interfere with absorption of the medication, in which case the feeding is delayed for a designated time period, determined by medication administration guidelines, before it is resumed.

Total Parenteral Nutrition

Total parenteral nutrition (TPN) may be given through a peripherally inserted central catheter (PICC) line or central venous catheter (CVC) by means of an infusion pump. Typically, infusions with greater than 10%

dextrose concentration require a CVC rather than a peripheral intravenous site for infusion. TPN may be the only feasible option for patients who do not have a functioning GI tract, or it may be given when patients are unable to ingest, digest, or absorb essential nutrients due to conditions, such as some stages of Crohn's disease or ulcerative gastritis, GI obstruction, diarrhea unresponsive to treatment, abdominal trauma, burns, or postoperative status. The disadvantage of TPN is that it should not be used routinely in patients with an intact GI tract. Compared with enteral nutrition, it causes more complications, does not preserve GI tract structure and function as well, and is more expensive. TPN formula is individualized to meet the patient's needs, and its composition often has to be recalculated until the patient's nutritional status improves and stabilizes. This adjustment requires collaboration of the interdisciplinary team responsible for the patient's care, most likely consisting of physicians, dietitians, nurses, and pharmacists.

Monitoring the patient's progress and documenting the patient's assessment should be done consistently and communicated to all members of the health care team. Assessment of patients receiving TPN should include weight, complete blood count (CBC), electrolytes, and BUN (i.e., daily for inpatients). Measurement of plasma glucose and electrolytes helps determine tolerance to the solution. Glucose levels should be checked at least every 6 hours or more frequently until they stabilize. Fluid intake and output should be monitored continuously. When patients become stable, blood tests can be done much less often (Thomas, 2017). The TPN administration system should be monitored regularly to prevent complications. The formula and the tubing should be assessed daily for evidence of contamination. Tubing should be marked and clearly identified so that no other solution is infused through it. Tubing should be changed every 24 hours, with aseptic technique used to minimize the risk of contamination, and the dressing over the site should be changed every 48 hours, with assessment for signs and symptoms of infection (redness, swelling, or drainage).

Numerous potential complications may result from parenteral nutrition, including site infections, air embolism, catheter-related infections, and dislodgment or occlusion of tubing. Metabolic complications can range from common glucose abnormalities to adverse reactions to the lipid formula, liver dysfunction, metabolic bone disease, gallbladder dysfunction (cholelithiasis, cholecystitis), and other metabolic abnormalities (Thomas, 2017).

Nurses unfamiliar with the administration and monitoring of TPN should review the facility policies and procedures before assuming care of patients receiving parenteral nutritional support.

3. Describe at least four nursing interventions necessary to prevent A. K. from experiencing further complications from inadequate nutritional intake.

Evaluation

During the last phase of the nursing process, nurses should clearly evaluate whether or not patients have achieved short- and long-term goals and met established outcome criteria. Evaluation of the patient experiencing nutritional concerns should focus on the patient's response to the nursing interventions. Nutrition is a complex aspect of patient care that must be addressed on an individual basis. Assessing patient dietary needs and providing meals that meet the medical, surgical, cultural, and spiritual concerns of each patient are critical aspects of patient-centered care designed to promote positive patient outcomes.

Skill 30.1 Insertion, Placement, and Removal of Nasogastric and Nasojejunal Tubes

Purpose

Nasogastric (NG) and nasojejunal (NJ) tubes:

- Provide a short-term feeding method for nutritional intake and hydration
- Facilitate suction of stomach contents, which can be used to monitor gastrointestinal (GI) disorders
- Allow irrigation of the stomach
- Decompress the stomach
- Permit the GI system to rest
- Promote healing

Resources

- NG or NJ tube: 8 to 12 French (Fr)
- Water-soluble lubricant
- Irrigation kit:
 - 60-mL syringe
 - Graduated container
 - Tap water or sterile normal saline solution for irrigation
 - 1-inch tape or tube fixation device with clamp
 - Skin prep and/or skin adhesive
 - Emesis basin
 - Towels and/or paper towels
 - Tissues
 - Penlight
 - Suction equipment

- Pulse oximeter
- Water and straw (if the patient is able to swallow)
- Permanent marker
- pH test strips, if required by facility policy
- Waste container
- Clean gloves and other personal protective equipment (PPE), as needed

Interprofessional Collaboration and Delegation

- Insertion of an NG or NJ tube may not be delegated to unlicensed assistive personnel (UAP). UAP may assist with patient comfort, support, and positioning during and after the procedure, at the nurse's discretion.
- UAP should report any of the following to the nurse:
 - Patient complaints of difficulty breathing
 - Fever or change in vital signs
 - Tube displacement
 - Vomiting
 - Loose tape or a loose tube fixation device
 - Any other patient complaints or concerns
- UAP should be instructed in:
 - Essential oral care for patients with NG or NJ tubes
 - Appropriate use of equipment if the patient is connected to a suction or feeding pump
 - Required documentation
- Collaborate with the primary care provider (PCP) and/or surgeon on appropriate tube choice.

- Collaborate with appropriate radiology department staff to verify tube placement before the initial feeding with an NG or NJ tube.

Evidence-Based Practice

- Auscultation was previously taught as the standard for checking and verifying placement of an NG tube. This practice is extremely unreliable and should be discontinued. The gold standard for tube placement is radiology verification before the initial feeding. This may be combined with testing aspirated secretions for pH levels and consistently verifying exit location placement markings ([American Association of Critical Care Nurses \[AACN\], 2016](#)).
- The fact that a patient has a cuffed tracheostomy tube is not a reliable guarantee that the NG or NJ tube will not enter the airway during insertion. A tracheostomy tube with a cuff is not sufficient to protect the airway, because the cuff may deflate slightly throughout placement, leaving room for the tube, especially a small-bore feeding tube, to enter the airway ([AACN, 2016](#)).
- Capnography (measuring the carbon dioxide level) has been shown to have promise as an effective secondary measure for tube verification but should not be used as an independent placement verification method ([AACN, 2016](#)).

Special Circumstances

1. **Assess:** Was resistance encountered during the insertion of the tube?

Intervention: Stop the procedure.

- Rotate the tube, because this may enable easier insertion.
- Ensure that the patient is swallowing when the tube is being inserted.
- Ensure proper positioning of the patient and the tube.
- Withdraw the tube, and reapply water-soluble lubricant.
- Attempt insertion in the other naris.
- If indicated, the tube may be placed orally.
- Notify the PCP if the tube cannot be placed properly.

2. **Assess:** Is the patient gagging with insertion of a tube?

Intervention: Stop briefly.

- Do not immediately remove the tube completely; withdraw it until the nasopharynx (back of the throat) is reached.
- Support and encourage the patient.
- Provide water for swallowing if the patient is able to swallow and allowed oral intake.
- Use a penlight to inspect the tube in the back of the throat:
 - If the tube is coiled, withdraw it until it straightens or withdraw it completely and start again.
 - If the tube is straight, reassure the patient and proceed with the insertion.
- If the patient is showing signs of respiratory distress, withdraw the tube and start again.
- If necessary, use an anesthetic or analgesic spray. An order may need to be obtained from the PCP; check facility policy and procedure.

3. **Assess:** Has verification of placement been done by appropriate radiology evaluation?

Intervention: Ensure that radiology staff have verified proper tube placement.

4. **Assess:** Does the tube have a vent lumen, such as that found in a double-lumen (Salem sump) tube?

Intervention: Secure the vent above the level of the stomach.

- Do not use a safety pin because of the risk of injury.
- Tape the vent lumen to the patient's gown.
- Leaving some slack in the tube allows for patient movement.

- Securing the vent lumen prevents accidental displacement or dislodgment.
5. **Assess:** Are you unable to obtain an aspirate for pH level testing, if facility policy requires it?
- Intervention:** Try again 30 minutes after placing the patient in the side-lying position.
- Check the exit location marking; if the mark is outside the naris, advance the tube to the mark.
 - If there is no aspirate after *two* attempts:
 - Assume that the tube position is incorrect.
 - Do not use the tube for any procedures.
 - Notify the PCP.
 - Obtain an x-ray order to recheck the tube placement.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct PPE is required whenever contact with bodily fluids is possible in order to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.
- VI. Provide for patient privacy.
It is important to maintain patient dignity.
- VII. Identify the patient, using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Insertion

Follow preprocedure steps I through VIII.

1. Raise the bed to working height, and lower the side rails as appropriate and safe.

Setting the bed at the correct working height for the provider prevents provider discomfort and possible injury.
2. Assess the patient's cough and gag reflexes. Raise the head of the bed to the high Fowler position (or as far as the patient can tolerate up to that position). Affix a pulse oximeter and check the patient's vital signs.

Assessing the patient's ability to swallow before insertion of the tube and monitoring vital signs throughout the procedure helps ensure patient safety. Raising the head of the bed allows gravity to assist with proper insertion and decreases patient discomfort during the procedure.
3. Choose a naris on the basis of which one is most intact and has the greatest airflow; try to avoid placement in a naris that has undergone previous surgery or injury. Verify nares patency by asking the patient to hold the naris closed one at a time, while breathing through the other.
 - a. Examine skin and tissue integrity with a penlight; note any breaks in the skin or tissue.

STEP 3 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- b. As a safeguard, tell the patient to raise a finger to let you know if he is gagging or feels uncomfortable during the procedure.

Skin and tissue integrity issues can worsen with placement of a tube. Eliminate difficulties with placement by detecting obstructions or septal defects before insertion of the tube. Establishing a method to communicate during the procedure will help decrease patient anxiety.

4. Prepare the bedside setup.

- a. Prepare the setup on whichever side of the bed allows the dominant hand to be closest to the patient.
- b. Place a towel over the patient's chest.
- c. Ensure that the patient can reach tissues, the emesis basin, and a cup of drinking water (if allowed).
- d. Place the following on the bedside table: NG or NJ tube, water-soluble lubricant packet, tape or tube fixation device, and skin prep or skin adhesive (if needed).

Preparing supplies in advance facilitates efficient actions, avoids interruptions during the procedure, and thus promotes patient comfort. Tube insertion may cause natural tearing and trigger the gag reflex; drinking through a straw during insertion facilitates accurate placement and patient comfort. Skin prep or adhesive may be needed to ensure adhesion and prevent tube dislodgment.

5. Prepare the NG or NJ tube:

- a. Open the package.
- b. For an NG tube, measure the length of tube needed for the patient by placing the tip of the tube at the tip of the patient's nose and extending it to the patient's earlobe and then to the patient's xiphoid process.

STEP 5B

- c. For an NJ tube, follow step b, and add another 20 to 30 cm.
- d. Document the length of the tube to be used if the tube has a preprinted measurement scale. For any tube (with or without a preprinted scale), mark the measurement on the tube using a small piece of tape to ensure proper placement of the tube; fold the ends of the tape for easy removal.
- e. Continue preparing your supplies. Set up your syringe with water. Squeeze the water soluble lubricant out for the tubing. Apply clean gloves, and inject 10 mL of water through the tube prior to insertion using a 30 to 60 mL irrigation syringe to facilitate stylet insertion, if one is recommended. If there is a stylet, ensure that it is properly fitted. If the tube has a surface lubricant, dip the tube into a glass of room temperature water to activate it.
- f. Lubricate 4 inches of the tube tip with a water-soluble lubricant.

STEP 5F (Copyright Mosby's Clinical Skills: Essentials Collection.)

This measuring technique estimates the insertion length appropriately; placing tape at the location provides a visual reminder of the measurement that is used during insertion to promote safety (avoiding overinsertion or underinsertion). Lubricant facilitates insertion and promotes patient comfort; it also prevents trauma to the nasal and pharyngeal passages, and, because it is water-soluble, it dissolves and will not harm the lungs if the lubricated tube tip is inadvertently inserted into a lung.

Correct patient position promotes facilitation of insertion, as does following the nasal passage direction and rotating the tubing. Careful insertion of the tubing reduces patient discomfort and prevents mucosal trauma; swallowing helps occlude the trachea, so it reduces the likelihood of inserting the tube into a lung.

6. Prepare the tape or tube fixation device:
 - a. Using 1-inch-wide tape, cut a piece of tape 4 inches long, and then cut 2 inches of that piece lengthwise; fold the ends of the two pieces created by the lengthwise cut; keep the tape within reach.
 - b. The tube fixation device is usually a winged adhesive bandage with a connection clamp: Unwrap the patch, but do not remove the backing; ensure that the clamp is open. (If using another type of fixation device, follow the manufacturer's instructions.)

Prevent interruption of the procedure by ensuring that all resources are ready before beginning the procedure itself. Prior preparation of the tube fixation device allows it to be applied quickly once the tube is in place; thereafter, the device prevents displacement of the tube.

7. Insert the tube. Do not force it.
 - a. The patient's neck should be hyperextended.
 - b. Direct the tube down and back.

STEP 7B (From Pfenninger, et al, 2011.)

- c. When the tube has reached the nasopharynx (back of the throat), have the patient tilt the chin forward to rest on the chest.
- d. Advance the tube while the patient is swallowing; provide water to the patient (if the patient is able to swallow and allowed to drink fluids).

STEP 7D (Copyright Mosby's Clinical Skills: Essentials Collection.)

- e. Encourage the patient to mouth-breathe.
- f. Advance the tube as gently, quickly, and calmly as possible, rotating the tube if needed and stopping when the tape marking is at the naris. Once the tube has been advanced 25 to 30 cm, stop and listen for air escaping from the tubing. The presence of air indicates that the tube might be in the trachea rather than the esophagus. If air is present, withdraw the tube and start again. If there is no air, continue to advance the tube to the distance marker.

Correct patient position promotes facilitation of insertion, as does following the nasal passage direction and rotating the tubing. Careful insertion of the tubing reduces patient

discomfort and prevents mucosal trauma; swallowing helps occlude the trachea, so it reduces the likelihood of inserting the tube into a lung.

8. Secure the tube.

- a. If using tape, apply a skin prep or adhesive if needed. Attach one end of the prepared piece of tape at a time to secure the ends of the tape on the bridge of the nose, forming a sling for the tube. Secure the tube away from nasal mucosa by wrapping each of the split ends in opposite directions where it exits the nose.
- b. If using a tube fixation device (a winged adhesive bandage is described here), apply a skin prep or adhesive if needed; remove the backing from the Band-Aid, and place it over the bridge of the nose. If using a membrane dressing to secure the tube, apply tincture of benzoin or another skin adhesive to the patient's cheek and to the section of the tube you wish to secure. Place the tube against the patient's cheek, and use the membrane dressing to anchor it out of the patient's line of sight. Insert the tube into the clamp of the fixation device, and close the clamp. Fasten the end of the tube to the patient's gown using a clip or piece of tape. Do not use a safety pin to fasten the tube to the patient's gown.

STEP 8B (From Lilley, et al, 2017.)

Securing the tube appropriately prevents displacement or inadvertent dislodgment; securing it away from the nasal mucosa prevents trauma to tissues from pressure. If the skin is oily, using a skin preparation or adhesive ensures adherence.

9. Keep the tube clamped until placement of the tube is verified.
To prevent aspiration or other adverse events, the tube should not be used until placement is verified by radiology.
10. Check the initial tube placement with an x-ray; checking pH may be permitted or required by facility policy to confirm correct placement after verification by x-ray. (See “[Intermittent Placement Verification: pH Testing](#)” next.)
Radiology is the only reliable method of determining accurate placement; however, the placement may be re-verified with an alternative method that is facility policy.
11. Placement verification:
 - a. If placement of the tube is incorrect, remove the tube, obtain new equipment, and begin the procedure again.
 - b. If placement of the tube is correct, remove the measurement marking tape, mark the exit location on the tube with permanent marker, and proceed with the ordered treatment.
The tube should not be used until placement is verified. This prevents aspiration and other adverse events.
12. Provide oral hygiene.

Follow postprocedure steps I through VI.

Intermittent Placement Verification: pH Testing (If Required by Facility Policy)

Follow preprocedure steps I through VIII.

1. Raise the bed to working height, and lower the side rails as appropriate and safe.
Setting the bed at the correct working height for the provider prevents provider discomfort and possible injury.
2. Raise the head of the bed to the semi-Fowler or high Fowler position, as tolerated by the patient. Place the patient in the side-lying position.
Allow gravity/positioning to aid aspiration of fluid.
3. Check placement via pH levels just before intermittent feedings, as indicated. If the patient is on continuous feedings and is not experiencing any difficulties, x-ray evaluation has confirmed tube placement, and the tube exit location marking is stable, continuous feedings may run without interruption for pH

testing. Testing pH levels may need to be delayed following medication administration orally or via tube.

Nutritional feedings and medication administration will interfere with pH levels, if testing is required.

4. Prepare the bedside setup:

- a. Place a towel or disposable sheet over the patient's chest, under the tube connection.
- b. Place the following on the bedside table: irrigation kit, the pH test paper (placed on a paper towel), and the pH color results chart (available on the bottle or in the box that the test paper came in). Check the expiration date for the test paper, and verify that the paper is *not* litmus paper.

Preparing supplies in advance facilitates efficient actions, avoids interruptions during the procedure, and thus promotes patient comfort. Towels protect the bed linens and gown and prevent the spread of microorganisms.

5. Assess exit location marking:

- a. Verify that the exit location marking has been made in permanent ink *and* is at the naris. If the mark is present and correctly located, continue with the procedure.
- b. If the mark is not there or is not at the naris, stop the procedure and order an x-ray to verify tube location.

This is the primary check for verification of placement before beginning the procedure with an NG or NJ tube.

Proceeding without verification can cause trauma, aspiration, and other adverse events.

6. Withdraw aspirate:

- a. Apply clean gloves.
- b. Draw up 30 mL of air into a 60-mL syringe. Attach the syringe to the NG or NT tube. Flush the tube with 30 mL of air before attempting to aspirate stomach contents.
- c. Slowly pull the plunger back to obtain at least 1 mL of aspirate (5 to 10 mL is ideal).

Using gloves prevents the spread of microorganisms. Using a large syringe allows sufficient negative pressure to withdraw aspirate. Most pH test papers need at least 1 mL of aspirate for testing.

STEP 6C (Copyright Mosby's Clinical Skills: Essentials Collection.)

7. Complete the basic steps to test the pH level of aspirate. Follow the manufacturer's instructions for the test paper strip.
 - a. Apply a drop of aspirate to the pH test paper, following the manufacturer's instructions:
 - i. While ejecting the aspirate from the syringe into a 30-mL plastic medication cup, allow the pH test paper to become covered with aspirate.
 - ii. If not enough aspirate covers the pH test paper, the paper should be dipped into the 30-mL plastic medication cup.

STEP 7AII (Copyright Mosby's Clinical Skills: Essentials Collection.)

- b. Compare the color on the test strip to the color chart provided by the manufacturer.
- c. After checking gastric pH, irrigate the tubing with 30 mL of water. Remove gloves, and dispose of supplies properly.
 - *The pH level is one means of verifying correct tube placement.*

Correct placement of the tube in the stomach is verified if the pH is lower than 5.

If the tube has been inadvertently placed in a lung or the intestines, the aspirate pH is 6 or higher.

 - *Owing to the high risk of adverse events, a pH above 6 is reason to stop the procedure and*

again verify placement through radiologic methods.

- *Aspirate pH may be altered because of medications or feedings (pH value of 4.5 to 6). If other indicators verify correct placement, waiting and retesting is recommended, rather than radiologic exposure.*

Follow postprocedure steps I through VI.

Removal

Follow preprocedure steps I through VIII.

1. Raise the bed to working height, and lower the side rails as appropriate and safe. Raise the head of the bed to the high Fowler position unless contraindicated.
Setting the bed at the correct working height for the provider prevents provider discomfort and possible injury.
2. Prepare the bedside setup:
 - a. Place a towel over the patient's chest.
 - b. Ensure that the patient can reach tissues, an emesis basin, and a cup of drinking water with a straw (if allowed).
Preparing supplies in advance facilitates efficient actions, avoids interruptions during the procedure, and thus promotes patient comfort. Tube removal may cause natural tearing and trigger the gag reflex.
3. Disconnect the tube from the pump or wall suction, if connected:
 - a. Apply clean gloves.
 - b. If feedings are running (see [Skill 30.2](#)), stop the flow, flush the tube, and then disconnect *and* clamp the tube.
 - c. Stop wall suction, if connected, and then disconnect, flush, *and* clamp the tube.
The tube must be disconnected in order to be removed.
Clamping the tube ensures that secretions do not reenter the tube.
4. Apply clean gloves and remove any tape securing the tube to the patient's gown, and remove the tape from the patient's nose.
Removing the tape facilitates easy removal of the tube and avoids interruption of the procedure.

5. To remove the tube, instruct the patient to take a deep breath and hold it; pinch the tube, and pull it out smoothly and quickly. Immediately dispose of the tube, and remove and discard gloves.

The risk of having gastric secretions from the tube enter the respiratory tract is removed by having the patient hold his or her breath and the caregiver pinch the tube. Smooth, quick removal facilitates patient comfort and reduces the spread of microorganisms.

STEP 5 (Copyright Mosby's Clinical Skills: Essentials Collection.)

6. Provide mouth care for the patient. Offer the patient a drink (if allowed) and tissues. Use soap and water or adhesive remover to clean the bridge of the patient's nose.

Promotes patient comfort: Mouth care clears mucous secretions or inadvertent gastric secretions from the tube, while a drink soothes the throat. Tissues assist with nasal secretion removal. The bridge of the nose may be sticky from tape or a tube fixation device.

Follow postprocedure steps I to VI.

Postprocedure

- I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.

Precautions are taken to maintain patient safety.

Top side rails aid in positioning and turning.

Raising four side rails is considered a restraint.

- II. Assess for additional patient needs, and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Photos under "Insertion" are from Pfenninger, J. L., & Fowler, G. C. (2011). *Pfenninger and Fowler's procedures for primary care* (3rd ed.). Philadelphia: Elsevier, and Lilly, L. L., Collins, S. R., & Snyder, J. S. (2017). *Pharmacology and the nursing process* (8th ed.). St. Louis: Elsevier.

Skill 30.2 Enteral Feedings via Nasogastric, Nasojejunal, and Percutaneous Endoscopic Gastrostomy Tubes

Purpose

Enteral feedings are indicated for patients who are unable or not permitted to ingest oral feedings because of their level of consciousness, inability to swallow, or esophageal obstruction.

Enteral feedings may be used to:

- Provide sole nutritional intake
- Provide supplemental nutritional intake
- Ensure adequate hydration

Resources

- Irrigation kit:
 - 50- to 60-mL catheter-tip syringe
 - Graduated container
 - Tap water or sterile normal saline solution for irrigation
 - Feeding pump
 - Feeding bag and tubing
 - Appropriate labels for bag and tubing
 - Prescribed enteral formula
 - Alcohol swabs
 - Graduated container
 - pH test strips
 - Waste container
 - Clean gloves and other personal protective equipment (PPE), as needed

Interprofessional Collaboration and Delegation

- Administering an enteral feeding may be delegated, at the nurse's discretion, to unlicensed assistive personnel (UAP) in accordance with state regulations and facility policies and procedures.
- The nurse should verify tube placement and assess the patient before delegating this procedure.
- UAP should report any of the following to the nurse:
 - Patient complaints of difficulty breathing
 - Fever or change in vital signs
 - Tube displacement
 - Vomiting
 - Loose tape or a loose tube fixation device
 - Other patient complaints or concerns
- UAP should be instructed in:
 - Essential oral care for patients with nasogastric (NG) or nasojejunal (NJ) tubes
 - Appropriate use of equipment
 - Required documentation
- UAP should understand:
 - The ordered nutritional supplement
 - Ways to reduce medication errors
 - The rights of medication administration (see [Box 35.4](#))
- Collaborate with the primary care provider (PCP) and/or the surgeon on the appropriate nutritional choice.

Evidence-Based Practice

- Throughout continuous feedings, and before intermittent feedings, it is imperative that aspirated secretions be tested for pH levels. In addition,

routine aspiration precautions should include strict adherence to standard practices, such as residual volume checks, elevated head of bed during feedings, and verification of tube exit location markings (AACN, 2016).

- The feeding tube should be flushed with 30 mL of water every 4 hours, before and after medication administration, and following any interruption in feedings to ensure that the tube remains patent, unless contraindicated by fluid restrictions (Hayes & Hayes, 2018).

Special Circumstances

1. **Assess:** Is the feeding solution for the facility in a prefilled bottle?
Intervention: Replace the original cap on the prefilled bottle with a new, prepackaged cap with the special tubing that is required for the procedure (see Step 6 in the “Procedure” section).
2. **Assess:** Was bolus gravity feeding ordered?
Intervention: Feeding is administered without tubing or a pump (see Step 6 in the “Procedure” section).
 - A syringe without a plunger is connected to the tube.
 - The syringe is held slightly above the patient's stomach level to allow the feeding solution to flow slowly through the tubing by means of gravity.
 - Pour the feeding solution into the syringe while avoiding overflow; add solution to the syringe as the fluid level decreases.
 - Gravity allows the feeding solution to flow through the tube and into the stomach.
 - If the patient is not to receive the complete contents of the feeding bottle or can, refrigerate any unused portion for up to 24 hours.
3. **Assess:** Does the patient have discomfort or cramping with feeding?
Intervention: Slow or stop the feeding. If necessary, check the amount of residual gastric content (stomach contents remaining from the preceding feeding).

- Follow the facility policy or PCP orders regarding residual volume.
4. **Assess:** Is there a percutaneous endoscopic gastrostomy (PEG)/gastrostomy/MIC-KEY button?
 - Intervention:** An extension may have to be placed for intermittent feedings to connect to the pump tubing or syringe.
 5. **Assess:** Are any special precautions indicated if the patient is on intermittent feedings?
 - Intervention:** Clean the tubing and bag thoroughly after feeding to prevent growth of microorganisms.
 - Use warm water only.
 - Use a new feeding set every 24 hours.
 6. **Assess:** Is the patient showing signs or symptoms of dumping syndrome? Look for:
 - Nausea, vomiting, and/or diarrhea
 - Pallor and sweat
 - Heart palpitations and/or increased heart rate
 - Abdominal cramping
 - Fainting
 - Intervention:** Notify the PCP if these signs or symptoms occur during jejunostomy feedings.
 - They may be due to distention of the jejunum.
 - The ordered nutritional therapy may need to be changed.
 7. **Assess:** What if there is no clamp on the tubing?
 - Intervention:** Pinch the tubing instead.
 8. **Assess:** Are there any assessments that should be made to monitor for hydration status?
 - Intervention:** Monitor patient intake and output to assess hydration status.
 9. **Assess:** What specific laboratory values should be monitored for a patient on enteral feedings?
 - Intervention:** Monitor glucose, blood chemistries, and electrolytes as ordered; enteral feedings can cause electrolyte and fluid imbalance.
 10. **Assess:** Are there any special precautions that must be taken if the patient is on continuous feeding?
 - Intervention:** Check residual gastric content every 4 to 6 hours, as ordered or in accordance with facility policy.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct PPE is required whenever contact with bodily fluids is possible in order to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.
- VI. Provide for patient privacy.
It is important to maintain patient dignity.
- VII. Identify the patient by using two identifiers.
Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.
- VIII. Explain the procedure to the patient.
The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Administering a Tube Feeding

Follow preprocedure steps I through VIII.

1. Raise the bed to working height, and lower the side rails as appropriate and safe. Apply clean gloves. Auscultate for bowel sounds and assess the patient's abdomen.

Setting the bed at the correct working height for the provider prevents provider discomfort and possible injury.

Conducting an abdominal assessment determines the patient's ability to tolerate the tube feeding.
2. Raise the head of the bed to the high Fowler position, or at least 30 degrees and preferably to 45 degrees for continuous feeding; the bed must be raised to a similar degree during and for at least 1 hour after bolus or intermittent feedings. If the patient must remain supine, place the patient in the reverse Trendelenburg position.

Elevation of the patient's head prevents aspiration and promotes the flow of the feeding solution via gravity into the stomach.
3. Prepare an irrigation kit:
 - a. Fill the graduated container with tap water or sterile normal saline solution as specified in the order or the facility policy and procedure for irrigation.
 - b. Ensure that the syringe and tube are compatible.
 - c. Ensure that the syringe is functioning correctly.

An adaptor may be needed if the syringe and tube locks are not compatible (Luer-Lok versus catheter tip). Preparing supplies in advance and verifying that they are functioning avoids interruption during the procedure.
4. Verify tube placement (see [“Intermittent Placement Verification: pH Testing”](#) in Skill 30.1).
5. For tubes placed in the stomach and used for bolus or intermittent feeding, checking residual volume (stomach contents remaining from the preceding feeding) may be required. If facility policy or PCP orders require checking residual volume:
 - a. Use a 50- to 60-mL or larger syringe. Draw up 30 mL of air.
 - b. Connect the syringe to the feeding tube.
 - c. Unclamp the tube. Inject the air into the feeding tube.
 - d. Pull back the plunger of the syringe.

STEP 5D (Copyright Mosby's Clinical Skills: Essentials Collection.)

- e. Continue aspirating until the fluid stops.
- f. Typically, if the residual amount is less than 250 mL or half the amount of the last feed, proceed with the new feeding. Do not feed the patient if any single gastric residual volume (GVR) measurement exceeds 500 mL or if two consecutive measurements taken 1 hour apart each exceed 250 mL.
- g. Instill the fluid that was aspirated back into the tube.
- h. Instill 30 mL of tap water or ordered irrigation solution into the tube.

STEP 5H (Copyright Mosby's Clinical Skills: Essentials Collection.)

- i. Remove the syringe.
- j. Clamp the tube.

Note that this procedure does not ever apply to intestinal placement; that content cannot be aspirated. New evidence indicates that checking residual volume may not be necessary, nor is it a true reflection of the patient's tolerance of the feeding. Replacing the aspirated fluid maintains homeostasis, because the stomach contents also contain electrolytes and other chemicals.

6. Prepare for feeding:

- a. Ensure that the nutritional feeding solution is as ordered. Check the expiration date. (Follow the principles given in [Box 35.4](#).)
- b. Ensure that the feeding solution is room temperature. Shake the container thoroughly and clean the top of

- the can with an alcohol swab before opening it.
- c. Measure the feeding amount: For continuous feeding, use not more than the amount required for 4 hours plus the amount needed for priming the tubing. For intermittent feeding, use the ordered amount plus the amount needed for priming the tubing.
 - d. Open the pump tube and bag package.
 - e. Close all clamps on the pump tubing.
 - f. Open the cap on the top of the bag.
 - g. Pour the appropriate amount of feeding solution into the bag.

STEP 6G (Copyright Mosby's Clinical Skills: Essentials Collection.)

- h. Reapply the cap to the top of the bag.
 - i. Hang the bag on the feeding pump pole.
Knowledge of patient-specific orders is critical for safe patient care. Cold solutions can cause cramping.
7. Squeeze the drip chamber, if present, and allow the suction to fill it one-third to one-half full with irrigation solution.
Squeezing the drip chamber prevents air in tubing and creates suction.
 8. Fill the pump tubing with irrigation solution to prime the tubing. (Note: Some pumps prime the tubing automatically when the tubing is placed in the pump. Follow the manufacturer's instructions.)
 - a. Remove the cap on the end of the tubing but do *not* discard it; place the end of the tubing over the sink.
 - b. Open the clamp slowly.
 - c. Allow the solution to run through the tubing.
 - d. Close the clamp when the tubing is full.
 - e. Replace the cap on the tubing.

Use proper procedure to prevent contamination and prevent air from entering the tubing. Clamping prevents loss of irrigation solution.

9. Flush the tubing with irrigation fluid before initiating feeding:
 - a. Draw 15 to 30 mL of irrigation solution into the syringe.
 - b. Connect the syringe to the feeding tube.
 - c. Unclamp the feeding tube.
 - d. Instill the irrigation solution.
 - e. Clamp the feeding tube.
 - f. Disconnect the syringe.

Instilling irrigation fluid through the tube ensures that the feeding tube is patent, prevents air from entering the tubing, prevents loss of solution, and provides hydration for the patient.

10. Label the administration set "Tube feeding only." Label the bag with the type, strength, and amount of the tube feeding. Mark the date, time, and your initials on the label, per facility policy. A new set should be used every 24 hours.

STEP 10 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Correct labeling prevents adverse events and promotes safety. Frequent replacement of equipment prevents contamination and the spread of microorganisms.

11. Attach the pump tubing and bag to the pump, following the manufacturer's instructions.

Proper use of equipment prevents adverse events and promotes safety.
12. Connect the pump tubing to the feeding tube, and start the feeding via the pump:

STEP 12 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Make sure the feeding and pump tubes are securely connected.
 - b. Unclamp the pump tubing.
 - c. Unclamp the feeding tube.
 - d. Start the pump, following the manufacturer's instructions and the PCP order.
 - e. Ensure that the feeding solution is flowing appropriately.
Proper use of clamps prevents adverse events and promotes safety.
13. When feeding is to be stopped, it should be stopped by means of the pump:
- a. Stop the pump; follow the manufacturer's instructions and the PCP order.
 - b. Clamp the feeding tube.
 - c. Clamp the pump tubing.
Prevents adverse events; promotes safety.
14. Disconnect the pump tubing and the feeding tube:
- a. Disconnect the feeding tube from the pump tube.
 - b. Recap the pump tubing.
Disconnecting the feeding tube ensures that it remains patent.
15. Flush the feeding tube:
- a. Draw 15 to 30 mL of irrigation solution into the syringe.
 - b. Connect the syringe to the feeding tube.
 - c. Unclamp the feeding tube.
 - d. Instill the irrigation solution.
 - e. Clamp the feeding tube.
 - f. Disconnect the syringe.
The irrigation solution prevents obstruction of the feeding tube by any residual nutritional feeding solution and provides hydration.

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.

Precautions are taken to maintain patient safety.

Top side rails aid in positioning and turning.

Raising four side rails is considered a restraint.

II. Assess for additional patient needs, and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Summary of Learning Outcomes

LO 30.1 *Describe the role of nutrition and food metabolism in achieving and maintaining normal body structure and function:* Normal body structure and function are dependent on the adequate intake of nutrients, their metabolism, and their absorption.

LO 30.2 *Identify nutritional imbalances that can result in physical alterations, psychological disturbances, and the development of disease:* Various vitamin

deficiencies contribute to the development of diseases such as osteoporosis, scurvy, and rickets. Malnutrition may occur as a consequence of lack of protein or inadequate dietary intake and may lead to diseases such as kwashiorkor, marasmus, and anorexia nervosa. Imbalanced or excess intake of certain foods may promote development of coronary artery disease, hypertension, or diabetes.

LO 30.3 *Discuss critical aspects of a thorough nutritional assessment:* Assessment of nutritional status includes observation of the patient's general health and completion of a health history followed by physical assessment. The process is time-consuming yet essential in determining dietary needs and nutritional status.

LO 30.4 *Identify nursing diagnoses for patients experiencing an alteration in nutrition:* Some alterations in nutrition are described by the nursing diagnoses of *Impaired Nutritional Intake, Overweight, Impaired Swallowing, Impaired Self Feeding.*

LO 30.5 *Determine nursing care goals and outcome criteria for patients experiencing complications from an alteration in nutrition:* Goals and outcomes should

focus on alleviating nutritional deficiencies or excesses and be formulated in collaboration with the patient, PCP, and others directly involved in the patient's care.

LO 30.6 *Explain the implementation and evaluation of interventions designed to address nutritional needs:*

Specific nursing interventions to encourage the intake of essential nutrients and fluid, prevent food-nutrient-drug interactions, and manage impaired swallowing are necessary to enhance wellness.

Evaluation focuses on patient progress made toward attaining the agreed-on goals and outcomes.

Review Questions

1. What snack choice would be the best suggestion by the nurse for a patient on a renal diet?
 - a. Peanut butter
 - b. Bananas
 - c. Diet cola
 - d. Carrot sticks
2. A patient recovering from major abdominal surgery is to be progressed from a clear liquid diet to the next diet level. Which statement by the nurse would be most appropriate in this circumstance?
 - a. "You will progress from a clear liquid diet to a mechanical soft diet."
 - b. "If you can tolerate the clear liquid diet, your next meal will be a full liquid."
 - c. "You will receive a regular diet tray with anything you want at the next meal."
 - d. "It is important that you eat a pureed diet after you are able to tolerate the clear liquids."
3. What nursing intervention would be most beneficial to implement in an effort to prevent aspiration by a patient receiving tube feedings?
 - a. Check the pH of residual before starting each feeding.
 - b. Hold prescribed medications until after each feeding.
 - c. Elevate the head of the patient's bed at least 45 degrees.

- d. Slow the delivery of the tube feeding to 15 mL/hour.
4. Which action should the nurse take first when caring for a patient receiving a continuous enteral feeding through a percutaneous endoscopic gastrostomy (PEG) tube if the feeding tube becomes occluded?
- Use 15 mL of cranberry juice in a 20-mL syringe to clear the tubing.
 - Ask to have the PEG tube replaced to prevent rupture of the gastrostomy.
 - Flush the PEG tube with 60 mL of cold tap water, using gravity.
 - Try using enzyme solution if a 30-mL warm-water flush is ineffective.
5. The nurse is caring for an elderly patient who has weakness on the right side as the result of a cerebrovascular accident (CVA). The nurse is correct in reporting dysphagia when the patient exhibits which symptoms? (*Select all that apply.*)
- Incomplete lip closure
 - Presence of a normal gag reflex
 - A change in voice quality after eating
 - Difficulty speaking, with a slow, weak voice
 - Abnormal movements of the mouth, tongue, and lips
6. A young adult female is considering becoming pregnant and is not taking any multivitamins. Which nursing action would best help reduce the potential for development of neural tube defects in the fetus?
- Discuss taking selenium supplements with meals.

- b. Stress the importance of prenatal exercise.
 - c. Recommend folic acid dietary supplements.
 - d. Inquire about the patient's diet and birth control method.
7. A patient tells the nurse that he needs to increase his intake of potassium because he has been taking large doses of diuretics. To minimize complications from hypokalemia, the nurse should instruct the patient to include which of the following foods as a part of his diet?
- a. Cheese and crackers
 - b. Peanut butter and jelly sandwich
 - c. Tomatoes and spinach
 - d. Apples and grapes
8. A Jewish patient who adheres to a kosher diet is diagnosed with type 1 diabetes. What would be the best response of the nurse when the patient refuses to take insulin, stating, "Insulin contains pork and I do not eat pork"?
- a. "There is only a tiny amount of pork by-product in insulin."
 - b. "All of the insulin used today is made synthetically."
 - c. "I will notify your physician to change the insulin order."
 - d. "You really do not have the option of not taking insulin."
9. A female Muslim patient is admitted to the hospital and informs the nurse that it is the month of Ramadan. Which action should be taken by the nurse

to address possible dietary concerns while caring for this patient?

- a. Provide a vegetarian diet for the patient on Friday throughout her hospitalization.
 - b. Ask the dietitian to visit the patient to ensure that fruit and cheese are not combined.
 - c. Check on the potential effect fasting until sundown will have on the patient's condition.
 - d. Document that milk and milk products cannot be prepared with meat or meat products.
10. A 15-year-old female gymnast is hospitalized with the diagnosis of bulimia nervosa. Which data would the nurse anticipate finding in the patient's admission history and physical assessment?
- a. Excessive intake of food, self-induced vomiting, and use of laxatives
 - b. Refusal to eat, body image disturbance, constipation, and amenorrhea
 - c. Excessive exercise, refusal to eat, poor muscle tone, and social isolation
 - d. Hair loss, BMI of 27, occasional use of diuretics, calorie intake 2200/day

CHAPTER 31

Cognitive and Sensory Alterations

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 31.1 Describe the normal structure and function of brain and body regions involved in cognition and sensation.
- LO 31.2 Identify how alterations in structure and function associated with impaired cognition and sensation affect patients' abilities.
- LO 31.3 Perform assessments of patients' cognitive and sensory function.
- LO 31.4 Choose nursing diagnoses for patients who need assistance or modifications in care because of cognitive or sensory deficits.
- LO 31.5 Articulate goals for patients with cognitive or sensory alterations.
- LO 31.6 Carry out nursing care plans, including interventions to enhance patients' cognitive and sensory function that can be evaluated after implementation.

Case Study

Cynthia Matson (C. M.) is a 67-year-old married mother of three and grandmother of five. She was admitted 2 days ago with symptoms of slurred speech and weakness on her right side. A magnetic resonance imaging (MRI) study, done in the emergency department, showed a clot in her left frontal lobe. She was given a clot-dissolving drug, alteplase. C. M.'s condition has been improving since she was hospitalized. She has no allergies. She has a history of hypercholesterolemia and moderate hearing deficits, which have been worsening over the past 5 years. She is a full code. Her Braden score is 21.

C. M.'s vital signs are: T 36.7° C (98.1° F), P 68 regular and strong, R 18 and unlabored, and BP 128/76, with a pulse oximetry reading of 96% on room air. She is alert and oriented to person but confused about place and time. Her lungs are clear. Her abdomen is soft and nontender, with bowel sounds present $\times 4$. She denies pain. She has mild weakness on her right side and is slightly unsteady on her feet, requiring the assistance of one person. The intravenous (IV) access site in the left antecubital space is without redness or swelling. She demonstrates mild difficulty finding some words but has been able to express her needs. Since admission, C. M.'s speech has become clearer, and the strength on the right side of her body has improved. She has slight difficulty hearing when spoken to in a conversational tone but does not wear a hearing aid. In her laboratory results today, complete blood count (CBC) showed hemoglobin 13.2 g/dL and hematocrit 39%, and prothrombin time (PT)/international normalized ratio (INR) was 23.4/2.1. All other laboratory values were within normal limits.

C. M.'s husband visits daily and spends most of the day with her. He appears to be alert and oriented and has no obvious physical problems. Two of their children live out of state, but a daughter who lives locally has visited.

Treatment orders are as follows:

- Vital signs every 4 hours
- Low-cholesterol diet
- IV access saline lock
- Up with assistance
- Intake and output
- Physical therapy
- Speech therapy
- Fall precautions

Medication orders are as follows:

- Warfarin; call physician with PT/INR results daily for dosage
- Atorvastatin 10 mg daily
- Acetaminophen 650 mg every 6 hours as needed (PRN) for pain

Refer back to this case study to answer the critical-thinking questions throughout the chapter.

Sensory input and cognitive ability allow humans to react to their environment. When alterations occur in any of the cognitive areas or sensory pathways of the central nervous system, the person's ability to respond is affected. Alterations are caused by a variety of factors, including traumatic injuries, illnesses, metabolic imbalances, and aging. Patients may come to the health care setting with previously known alterations in cognition or sensation, or they may develop changes due to a current illness or injury.

LO 31.1 Normal Structure and Function of Brain and Body Regions Involved in Cognition and Sensation

Knowledge of the normal structure and function of the brain and nervous system helps the nurse to recognize alterations in cognition and sensation when they occur. Helping patients with deficits deal with the unfamiliar health care environment is an essential nursing responsibility.

Cognition is knowing influenced by awareness and judgment; it is composed of skills that include language, calculation, memory, attention, reasoning, learning, problem solving, and decision making. **Sensation** is a feeling, within or outside the body, of conditions resulting from stimulation of sensory receptors. Although the brain has the ability to change and relocate functions if damage occurs, which is a phenomenon called *plasticity*, specific areas of the cerebrum are responsible for cognition and the processing and integration of information from sensory input (McCance & Huether, 2019).

Cognition

Each hemisphere of the cerebrum is divided into four main lobes: frontal, parietal, temporal, and occipital. The frontal lobes of the cerebrum are the areas of the brain responsible for voluntary motor function, short-term memory, goal-oriented behaviors, and eye movements. The parietal lobes are responsible for receiving, analyzing, and responding to somatic sensory input from different parts of the body. The temporal lobes are concerned with auditory stimuli, as well as long-term memory, balance, taste, and smell. The occipital lobes process visual information (McCance & Huether, 2019). See Chapter 20 for further information on and illustrations of the structure and function of the central nervous system and cranial nerves.

Sensation

When a **stimulus**, which is a change in the environment sufficient to evoke a response, occurs, sensory receptors trigger a response, which results in nerve impulses ascending sensory pathways to the central nervous system for processing. The way the brain perceives the information is called **perception**. The person must be in a state of alertness to recognize and respond to stimuli. The area of the brain that

controls alertness and attention is the reticular activating system (RAS). During times of alertness, some impulses are ignored by the brain, because they are not assigned priority as more important than others. This process is called **sensory adaptation**.

Sensory receptors that detect touch, pressure, pain, heat, and cold are located throughout the body. As these impulses travel through sensory pathways up the spinal cord, they cross over, or **decussate**, to the other side of the body before reaching the brain (Fig. 31.1). Specialized receptors are located in groups on our sensory organs and detect the senses of smell, taste, hearing, equilibrium, and vision (Patton, 2012).

FIGURE 31.1 Sensory pathways ascend the spinal cord and cross to the other side of the body before reaching the brain.

General Senses of Touch, Pressure, Temperature, and Pain

Tactile receptors, or those detectable by touch, are located in the dermis and subcutaneous tissue. These nerve fibers supply the brain with information regarding touch and pressure by way of sensory pathways.

Two types of nerve endings supply the brain with information regarding temperature: warm receptors and cold receptors. These skin receptors respond to moderately warm (more than 35° C or 77° F) or cold (10° to 20° C or 50° to 68° F) temperature changes (Patton, 2012). Special receptors in the body perceive pain. They are discussed in [Chapter 36](#) in the context of pain management.

Special Senses of Smell, Taste, Hearing, Equilibrium, and Vision

Olfaction is the sense of smell. Scents are detected by **chemoreceptors**, or sensory nerve endings that react to chemicals. The chemoreceptors for smell are located in the upper nasal passages. Once the olfactory chemoreceptors are stimulated by an odor, the right and left first cranial nerves carry the impulses to the brain, where interpretation in the temporal lobe takes place.

Closely related to olfaction, the sense of taste, or **gustation**, requires that chemoreceptors come in direct contact with the stimulus. These sensory receptors are located in taste buds on the tongue, the roof of the mouth, and the throat. They are stimulated by food when it is consumed. The right and left seventh cranial nerves and right and left ninth cranial nerves transfer taste information to the brain, where it is analyzed. All of the cranial nerves are discussed in [Chapter 20](#) in the context of physical assessment.

The sense of hearing occurs through the workings of the outer, middle, and inner ears. Sound waves are collected by the outer ear, or **auricle**, causing the eardrum (the membrane dividing the outer and middle ears) to vibrate. The vibrations of the eardrum cause the three small bones, or **ossicles**, in the middle ear to vibrate. This vibration transmits the sound to the fluid-filled inner ear via a membrane-covered opening called the *oval window*. The inner ear is composed of a complicated set of **labyrinths**, which are intricate communicating passageways. Receptor cells pick up the sound waves and send messages to the brain by way of the right and left eighth cranial nerves, the vestibulocochlear nerves. Auditory impulses are interpreted in the temporal lobe of the cerebrum.

A second set of labyrinths in the inner ear, the **semicircular canal**, has receptor cells that interpret the head's position and maintain

equilibrium, or state of balance. Different receptors detect when the head is still and when it is in motion. This information is sent to the brain via the vestibulocochlear nerves.

The eye is the sense organ of vision. Light stimuli enter the eye through the cornea and then the lens. Photoreceptors in the **retina** (innermost layer of the eye) detect visual images by perceiving light waves, which are different lengths for different colors. Two types of photoreceptors, rods and cones, are present in the retina. **Rods** help with vision in the periphery and in dim light. **Cones** detect color and detail (**McCance & Huether, 2019**). Visual impulses travel from the receptors on the retina to the brain by way of the right and left second cranial nerves, the optic nerves, to the occipital lobes of the cerebrum.

LO 31.2 Alterations in Structure and Function Associated With Impaired Cognition and Sensation

Knowledge of the location and function of the lobes of the cerebral hemispheres enables the nurse to anticipate cognitive and sensory alterations on the basis of the location of disease or damage in the cerebrum. Understanding the mechanism of the sensory pathways and the function of the special senses helps the nurse decide which focused assessments are necessary for each patient. The nurse needs to be alert to changes in cognitive abilities and sensory perception in patients and respond accordingly.

The number of neurons decreases with aging, along with other changes in the central nervous system. This decrease causes a gradual decline in the ability to interpret sensory stimuli that reach the brain (McCance & Huether, 2019). As aging progresses, changes in the tactile and special senses occur. Loss of neurons affects cognition, causing response times to be slower. Aging may cause a person to forget a word or the last place where he or she put the car keys. In most people, however, the change is gradual and does not affect judgment, language, or the ability to live independently. Many factors affect cognition and sensation (Box 31.1).

Box 31.1

Diversity Considerations

Life Span

Children are more prone to otitis media because of the shorter, more horizontal eustachian tube in this age group.

Infants who are not touched and cuddled or who do not bond with a caregiver often suffer from the effects of sensory deprivation.

Each newborn's hearing is tested, before the infant leaves the hospital, for early assessment and intervention.

Hearing alterations with aging lead to social isolation in many patients. The person with a hearing deficit often feels embarrassed by the impairment, which draws unwanted attention and prevents easy interaction with others.

Sensory perceptual changes with aging may lead to less discriminating taste and smell or to problems with equilibrium in older adults.

The risk of dementia increases with age.

Gender

Postmenopausal women receiving hormone replacement therapy are at increased risk for cerebrovascular accidents (CVAs) caused by clots.

Disability

Sensory deprivation can occur in patients who have sensory deficits, especially those with visual or auditory impairment.

Morphology

Obesity predisposes patients to development of hypertension, putting them at a higher risk for CVAs.

Cognitive Alteration

Symptoms of cognitive impairment include disorientation, loss of language and/or simple arithmetic skills, poor judgment, and memory loss. If the patient exhibits these symptoms, further investigation is needed. Although some decline in cognitive ability occurs with aging, these symptoms are not a normal part of aging.

Delirium

Delirium is a reversible state of acute confusion. It is characterized by a disturbance in consciousness or a change in cognition that develops over 1 to 2 days and is caused by a medical condition. Fluctuating awareness, impairment of memory and attention, disorganized thinking, hallucinations, and disturbances of sleep-wake cycles are signs and symptoms of delirium ([U. S. National Library of Medicine, 2017](#)). Some causes of delirium are drug or alcohol use, the side effects of medication, infections, fluid and electrolyte imbalances, low oxygen level, and pain. Delirium may occur in patients in the intensive care unit (ICU) because of sensory overload. Once the underlying cause of delirium is identified and treated, the confusion subsides.

Depression

Depression is a mood disorder characterized by a sense of hopelessness and persistent unhappiness. Signs and symptoms of depression are loss of interest, sadness for an extended period of time, decreased self-esteem, sleeping too much or insomnia, and changes in eating patterns. Major depression is characterized by symptoms on most days for 2 weeks. This type of depression is often triggered by a life situation. Persistent depressive disorder is when symptoms are present for at least 2 years, but might vary in severity. With both types of depression, the symptoms interfere with daily living ([National Institutes of Mental Health, 2016](#)).

Patients taking a variety of medications may experience drug side effects that mimic depression. Social circumstances often trigger depression, especially in elderly people who are isolated from activity because of their living situations. **Sensory deprivation** (decreased stimulation from the environment) from lack of contact with others can lead to depression. Depression usually has a rapid onset, and the affected person's mood typically is constant. It usually is reversible with treatment by eliminating the underlying cause, providing counseling, or prescribing antidepressive agents.

Dementia

Dementia, which is a permanent decline in mental function, has a subtle onset. It is characterized by the decline in many cognitive abilities, including reasoning, use of language, memory, computation, judgment, and learning. Dementia is not reversible and worsens over time. Although the percentage of people with dementia increases with increasing age, it is not a normal part of aging. However, up to half of people age 85 and older may have some signs of dementia ([National Institutes of Health News in Health, 2014](#)).

The most common type of dementia is called *Alzheimer disease*. Pathologic changes occur in the brain due to **Alzheimer disease**. One change noted is **amyloid plaques**, which are protein fragments that build up between the nerve cells of the brain, blocking electrical impulses and chemical connections between neurons. Another change is the development of **neurofibrillary tangles**, which are twisted fragments of protein within the cells that clog nerve cells and interrupt nutrient delivery to the brain cells. An additional change noted is the brain shows marked cerebral **atrophy**, a decrease in the size of the brain ([Fig. 31.2](#)). All these changes cause problems within the cells that lead to diminished nerve conduction and cell death ([National Institute of Neurologic Disorders and Stroke, 2018](#)). These damaging alterations

interfere with the communication between nerve cells, causing the person with Alzheimer disease to lose cognitive function and, eventually, basic functions, such as breathing. Although genetics and environment both are believed to play a role in Alzheimer disease, no specific cause has been identified.

FIGURE 31.2 Magnetic resonance imaging (MRI) cross-sectional appearance. A, Normal brain. B, Marked atrophy of the brain associated with Alzheimer disease. (Copyright Thinkstock.com.)

Behavioral problems that arise in dementia patients include wandering, agitation, repetitive behaviors, **sundowning** (worsening of agitation and confusion in the evening) (**Box 31.2**), and verbal or physical outbursts. These behaviors can result from frustration, confusion, fear, anxiety, or lack of control.

Box 31.2

Sundowning

Several factors may contribute to increased confusion and behavior problems that occur in many Alzheimer patients later in the day and into the night:

- Changes in the brain causing a mix up between day and night
- Exhaustion at the end of the day of both the patient and the caregiver
- Reduced ability to see due to dim lighting
- Inability to distinguish between dreams and reality

Strategies to deal with sundowning:

- Keep the home well-lit during awake hours

- Keep on a consistent schedule
- Avoid alcohol, caffeine, and nicotine
- Approach the patient in a calm, reassuring manner
- Make sure needs are cared for, such as toileting, thirst, and hunger
- Reorient the patient to person, place, and time of day

From Alzheimer's Association. (2018). Sleep issues and sundowning. Retrieved from <https://www.alz.org/care/alzheimers-dementia-sleep-issues-sundowning.asp?gclid=CMfAt6uCtNQCFVG5wAodsK0Lig>

Brain Injuries and Illnesses

Traumatic brain injuries and infections, such as meningitis, impair cognitive and sensory functioning. Other infections can cause delirium. A **cerebrovascular accident (CVA)** occurs when an area of the brain is deprived of blood flow and also is called a *stroke*; it causes damage to an area of the brain. The resulting impairment depends on the area of the cerebrum involved. CVAs are of two types: (1) ischemic stroke caused by narrowing of a vessel or embolism (blood clot) blocking a vessel; and (2) hemorrhagic stroke caused by bleeding in the brain from a burst aneurysm or traumatic injury. Any of these events can cause temporary or permanent damage.

The first hours after an acute ischemic stroke are crucial, so early recognition is key. The **National Stroke Association (2018)** recommends the use of FAST (face, arm, speech, time) to educate the public in stroke recognition. One or more of the symptoms: *Face* weakness, *Arm* weakness, and problems with *Speech* are usually present in the early minutes of a stroke. Recognizing a stroke in a short amount of *Time* and placing a call to 9-1-1 immediately is crucial. Stroke protocols are in place at major health centers, and the patient is transported to the nearest available center if possible.

CVAs can cause altered balance and coordination. If the damage is on the left side of the brain, loss of sensation and motor function is seen in the extremities on the right side of the body, and problems with speech occur. If the damage is on the right side of the brain, the loss of sensation and motor function affects the extremities on the left side of the body, and visual–spatial problems occur.

Some speech problems that occur after a stroke or other traumatic brain injury include different types of **aphasia**, or speech or language impairment. The patient with receptive aphasia, also known as *Wernicke aphasia* (named for the area of the temporal lobe that interprets language), cannot comprehend written or spoken language. The auditory pathway is intact, but words do not make sense. In expressive

aphasia, or *Broca aphasia*, the damage is to the motor speech area of the frontal lobe. In this type of aphasia, patients understand language but are unable to answer questions, name common objects, or express simple ideas.

Meningitis is an infection of the lining of the brain caused by a virus or bacteria. In addition to signs of infection, meningitis can cause mental changes. Other infections, especially in elderly people, can cause changes in cognitive abilities that are temporary. When the patient exhibits sudden or rapid changes in behavior or cognition, a urinary tract infection or pneumonia are possible causes. The patient's cognitive ability will revert back to the pre-infection level after successful treatment of the underlying condition.

Sensory Deficits

Patients with sensory deficits have difficulty interacting with the environment. Hospitalized patients with any alterations in sensory reception or perception depend on the nurse to provide a safe environment, which adapts to each patient's special needs.

Tactile

Damage to sensory nerve fibers in the arms and legs leads to [peripheral neuropathy](#), nerve damage away from the center of the body. Patients may not be able to feel sharp objects or discern extreme hot and cold temperatures, leaving them vulnerable to injury. Peripheral neuropathy occurs in patients with diabetes mellitus and renal disease.

Smell

Olfactory chemoreceptors decline in number and lose their sensitivity with age, causing a decreased ability to detect odors. Infections, smoking, and cocaine use can damage chemoreceptors and cause a decline in or loss of the ability to smell. [Anosmia](#) is the complete loss of the sense of smell.

Taste

The number of gustatory cells declines after the age of 50 years, resulting in a decreased ability to distinguish taste in later life. Upper dentures, if present, cover part of the roof of the mouth, making detection of some tastes difficult. Injury to the tongue, cheeks, or roof of the mouth, or exposure to extremely hot or cold food can temporarily damage taste buds.

Hearing

Partial or complete hearing loss can occur at any age. Congenital hearing loss is due to genetic factors in more than one half of all cases. Other causes of congenital hearing loss are maternal diseases, such as rubella or diabetes, and lack of oxygen at birth.

Otitis media may cause temporary hearing loss from a buildup of fluid behind the eardrum. In cases of repetitive or chronic infection, permanent damage to the eardrum or ossicles can occur. A buildup of cerumen, which blocks sound in the outer-ear canal, also may cause temporary hearing loss. Both simple otitis media and blockage with cerumen cause a type of hearing deficit called *conductive hearing loss*, because the problem occurs in the portion of the ear that conducts sound waves. Another type of hearing loss is sensorineural, or damage to the receptor nerves or nerve pathways. Potential causes include loud noises, adverse reaction to ototoxic drugs, head injuries, or certain types of infection.

Age-related hearing loss is called [presbycusis](#). It usually comes on slowly and affects the hearing in both ears. It seems to exhibit a familial pattern ([National Institute on Aging, 2017](#)). Loss does not occur at the same rate with all people, or even in both ears in the same person.

Equilibrium

Motion sickness is a common equilibrium problem associated with mixed signals that the brain is receiving. If a person is in motion in an airplane, boat, or car, for example, and views only stationary objects, such as the seat in front of the person, the eye is seeing stillness while the inner ear is detecting movement. Signs and symptoms are dizziness, nausea, and vomiting. It is unknown why some people experience this problem and others do not.

Ménière disease is associated with [vertigo](#), or the sensation that objects are moving around the person; [tinnitus](#), or a ringing or other abnormal sound in the ear; and progressive hearing loss. It is caused by excess fluid accumulation in the labyrinth in the inner ear. Patients with fluid buildup or infections of the inner ear may describe dizziness, lightheadedness, unsteadiness, or vertigo. The symptoms disappear if the underlying cause is successfully treated.

Vision

Many changes in the structure and function of the eye and related structures cause problems with vision. Some of these problems are easily corrected with lenses, whereas others lead to permanent damage.

Myopia, or nearsightedness, causes the affected person to be able to see clearly only a short distance. This is because the image is focused in front of the retina instead of on the retina. In most cases, the eye is elongated, but the cause of the elongation is unknown. Myopia is corrected with use of a concave lens (eyeglasses or contact lenses) or through refractive surgery.

Presbyopia, manifesting as farsightedness, is an age-related decrease in the ability to focus on near objects. This loss of near vision occurs gradually, usually beginning after the age of 40 years. The cause is unknown, but the lens of the eye appears to become less flexible and loses its ability to change shape in order to focus. Reading lenses are worn to correct presbyopia.

Clouding of the lens of the eye is called a **cataract**. Cataracts cause blurring of vision and usually occur with aging. The visual deficit can be corrected with surgery, which usually is performed only if vision is severely affected. The clouded lens is removed, and a new lens is placed in the eye.

Glaucoma is a serious medical condition of the eye. It causes increased intraocular pressure, which puts pressure on the optic nerve, leading to loss of peripheral visual fields and possibly blindness. Because there are no early symptoms of glaucoma, screening is done during routine eye examinations.

Diabetic retinopathy is a complication of diabetes mellitus in which the blood vessels of the retina become damaged. Because the retina is the area of the eye that contains the photoreceptors, destruction of these cells leads to loss of vision. Usually, visual loss starts with distortion of the image, but the condition can lead to blindness.

The macula is the area of the retina that provides central vision. **Macular degeneration** is the leading cause of visual defects in the United States. It typically begins after the age of 50 years; loss of vision occurs in the central visual fields. Visual acuity is diminished. Causes include diabetes, genetics, smoking, and hypertension; however, some affected patients do not have these risk factors.

Fig. 31.3 depicts changes in vision associated with cataracts, glaucoma, diabetic retinopathy, and macular degeneration.

FIGURE 31.3 Normal vision (A). Loss of visual fields in cataracts (B), glaucoma (C), diabetic retinopathy (D), and macular degeneration (E). (Courtesy National Eye Institute, National Institutes of Health.)

Sensory Deprivation

Any of the sensory alterations discussed can lead to sensory deprivation. A person who cannot see, hear, feel, or respond to the environment may feel socially isolated. Sensory deprivation is a concern in the acute care setting because of decreased sensory input, lack of stimuli or ability to receive stimuli, and decreased meaning of stimuli due to the strange environment. Restrictions within the environment, such as isolation precautions, contribute to deprivation. The patient may appear bored, restless, and disinterested and complain of a decreased ability to think.

Sensory Overload

The best example of [sensory overload](#) in a hospitalized patient is that encountered in the environment of the ICU. The cause is an overabundance of stimuli—noise from machines, pressure from tubes, frequent interactions with health care personnel throughout a 24-hour day, constant lighting, and pain. When the brain is overly stimulated, it ceases to make sense of the incoming stimuli. Susceptibility to sensory overload varies from person to person, depending on tolerance levels. Signs and symptoms of sensory overload are anxiety, attention deficit, and confusion.

LO 31.3 ♦ Assessment

Cognitive and sensory alterations can cause problems with socializing, performing activities of daily living (ADLs) independently, working, or driving. The nurse's assessment helps to identify patients who are at risk for alterations, are experiencing alterations, or need special interventions for managing deficits (Box 31.3). Knowing the causes of cognitive and sensory deficits helps the nurse to quickly assess areas that are possible problems for individual patients.

Box 31.3

Health Assessment Questions

Cognitive Focus

When the patient has cognitive problems, the nurse may need to obtain the health history from a family member or other reliable person.

- Do you have trouble sleeping or do you sleep too much?
- Have you noticed difficulty adding numbers or doing your banking?
- Are you able to have conversations with others, either in person or on the phone?
- Are you able to drive to the store or do errands?
- Do you ever feel sad?
- Do you read the newspaper?
- Do you live with anyone? If so, with whom?
- What medication do you take every day?

Sensory Focus

- Can you feel the difference between hot and cold water?
- Have you ever had a sore on your leg or foot that wouldn't heal?
- Do you have any pain, numbness, or tingling in your hands, legs, or feet?
- Are you able to smell different foods?
- Can you taste salty foods? sweet? sour?
- Have you noticed changes in your hearing?

- Have you ever had a hearing examination?
- Do you wear hearing aids?
- Do you ever lose your balance or feel like the room is spinning?
- When was your last eye examination?
- Do you wear glasses or contacts?
- Can you see to read the newspaper?
- Can you see objects to your left and to your right?
- Is your vision blurry?

Health History

A thorough history and physical assessment of the patient with cognitive or sensory deficits is essential to determine the extent and cause of the deficit. The nurse starts by asking general questions about the patient's health history, followed by specific questions aimed at discovering whether the patient is at risk for or is experiencing cognitive or sensory deficits.

Effects of Lifestyle on Cognition and Sensation

Certain lifestyle choices put patients at higher risk for cognitive or sensory problems. Smoking, obesity, a high-cholesterol diet, and excessive alcohol use can cause hypertension and drastically increase the risk of stroke. Cocaine use can destroy olfactory receptors in the nasal passages, causing a decrease in the sense of smell. Smoking decreases the senses of smell and taste.

High stress levels in a patient's life can lead to alterations in a patient's physical status. Stress is one of the risks associated with hypertension, which can cause dizziness and stroke. In patients experiencing extremely high levels of stress, symptoms (such as anxiety and confusion) can be similar to those of sensory overload. The patient is interviewed regarding family, work, and personal stressors, including recent job loss, divorce, death of a loved one, illness in the family, and pressure to succeed at work.

Metabolic syndrome consists of a group of specific risk factors that together are associated with a greatly increased risk for development of coronary artery disease, stroke, and diabetes mellitus type 2. Metabolic syndrome is considered to be present if three or more of the defining features are documented. The patient is at a higher risk for developing the sensory deficits associated with the diseases. The features of metabolic syndrome are ([U. S. National Library of Medicine, 2018](#)):

- High blood pressure
- High blood glucose
- Excess fat around the waist
- Low levels of high-density lipoprotein (HDL) cholesterol
- High levels of triglycerides

Lack of sleep may cause problems with concentration, judgment, and mental abilities, as well as blurred vision and decreased response to auditory stimuli. The nurse obtains a thorough sleep history from any patient with a change in cognitive or sensory awareness. For more information on sleep deprivation, see [Chapter 33](#).

Effects of Environment on Cognition and Sensation

Exposure to environmental toxins poses a variety of health risks, including damage to some of the special sense organs. Hearing is adversely affected if loud noises have been a part of the patient's environment. Excessive exposure to ultraviolet light contributes to cataract development and other visual problems in some patients.

Safety in the home and hospital environments is a concern in patients who have sensory alterations. Home assessment can be accomplished through questioning the patient and family about the home environment, with referral to home health agencies when necessary.

Effects of Medical Conditions on Cognition and Sensation

Knowledge of the patient's past and current medical conditions is essential for the nurse who is planning patient care. Certain illnesses and infections cause sensory or cognitive changes. Diligence in monitoring the patient's condition decreases the detrimental effects of these changes. For example, the patient with diabetes is at risk for eye problems, such as diabetic retinopathy, glaucoma, and cataracts, which can lead to visual loss and blindness. Yearly dilated-eye examinations are essential to monitor these conditions. Keeping weight, blood sugar, and cholesterol levels under control will decrease the complications of diabetes.

Effects of Medications on Cognition and Sensation

Certain over-the-counter, prescription, and street drugs have side effects that alter sensory or cognitive status, and some symptoms are traced back to medication use. For example, aspirin can cause tinnitus. Narcotics and some street drugs can cause confusion, dizziness, and hallucinations. Pupils may be dilated from medication used to view the retina or from other drugs. The nurse asks the patient about all medications, including prescription drugs and over-the-counter medications, such as herbal preparations, and alternative medications, vitamins, and minerals.

Physical Assessment

A thorough physical assessment is necessary for all patients exhibiting a change in cognitive or sensory status. The nurse obtains vital signs and performs a complete head-to-toe assessment to determine the extent of sensory or cognitive alterations, as well as problems that could lead to deficits.

Vital Signs

The nurse monitors the patient's vital signs on a regular basis and notes changes or abnormal findings. Hypertension is a leading cause of stroke. If orthostatic hypotension is present, dizziness and loss of consciousness may occur when the patient changes position too quickly. Cognitive changes, such as confusion or disorientation, may be effects of a high fever. Hypoxia leads to dizziness and changes in levels of cognition and consciousness. For more information on normal vital signs, see [Chapter 19](#).

Neurologic Assessment

A neurologic assessment is completed for any patient experiencing changes in cognitive or sensory awareness. The patient's orientation is assessed during the health history. While talking with patients, the nurse assesses cognitive abilities, such as reasoning, judgment, and language. For patients with suspected deficits in cognition, the nurse can use a screening tool, such as the Mini-Mental State Examination (MMSE), developed by [Folstein, Folstein, and McHugh \(1975\)](#). This examination is simple and quick to administer and tests the patient's cognitive orientation, attention, calculation, recall, language, and spatial orientation. Periodic reassessment is necessary for patients who have been diagnosed with dementia to determine progression of cognitive impairment over time.

Cranial nerves are assessed if problems with the special senses are suspected. Assessing only the cranial nerve or nerves involved in the sensory alteration is acceptable. For a complete description of cranial nerve assessment, see [Chapter 20](#).

Laboratory Tests

Screening blood work is obtained for patients with complaints indicating sensory or cognitive changes. A complete blood count (CBC) should be performed in any patient who exhibits a sudden change in behavior, to rule out infection.

Electrolytes, such as sodium, potassium, chloride, calcium, and magnesium, are monitored. Both high and low levels of certain electrolytes in the body can cause problems with level of consciousness, cognition, and sensation. Patients with either hypernatremia or hyponatremia have central nervous system–related symptoms. Tactile disturbances, such as tingling and numbness around the mouth and in the fingers, are signs of hypocalcemia. Mental changes are associated with both hypercalcemia and hypocalcemia. For a complete description of electrolyte disturbances and related signs and symptoms, see [Chapter 39](#).

Blood glucose levels are monitored as part of routine blood work. Patients with diabetes are monitored several times daily. Patients experiencing hypoglycemia may exhibit symptoms of irritability and have difficulty concentrating. If the level of glucose in the blood becomes extremely low, loss of consciousness, coma, and even death can occur. If glucose levels are extremely high, diabetic ketoacidosis or diabetic coma may develop. Close monitoring of glucose levels in diabetic patients helps to prevent complications of hyperglycemia that may contribute to cognitive and sensory deficits, such as diabetic retinopathy, peripheral neuropathy, and stroke.

A urinalysis with culture and sensitivity testing is obtained for any patient exhibiting a change in cognition, to rule out a urinary tract infection. Presence of bacteria, nitrates, and white blood cells in the urine indicates an infection. Culture and sensitivity results specify the type of bacteria and indicate which antibiotics can be used to treat the infection. When the infection is treated successfully, behavior should return to the patient's baseline level.

Effects of Age, Illness, Stress, and Trauma on Cognition and Sensation

The nurse's knowledge of symptoms of cognitive and sensory alterations caused by age, illness, and trauma enables appropriate

assessment of patients. These alterations cause changes in the patient's ability to function independently, communicate, and carry out ADLs.

Mental Status and Cognitive Function

The normal aging process causes neurons to decrease in numbers. This loss of neurons causes a decrease in the number of synapses in the brain, leading to a decreased ability to identify sensations, such as pain, touch, pressure, and postural changes. As aging occurs, reflexes decrease; muscles atrophy; taste, smell, and vision decline; neuromuscular control of gait and posture decreases; and memory and cognitive impairment may occur. All of these changes may impair cognitive abilities and the person's response to sensory stimuli (McCance & Huether, 2019).

Qsen Focus!

Safety is maximized when the nurse uses strategies to reduce the risk of harm to self or others, especially in patients who have cognitive and sensory impairments. The nurse notes the cognitive and physical limits of each patient.

Any illness or trauma that involves the central nervous system can alter mental status and cognition. Brain injuries, as well as any damage to cranial nerves, inhibit stimuli from reaching the proper part of the brain and being interpreted correctly. The nurse's thorough assessment of the nervous system, including cranial nerve assessment if indicated, localizes the impairment and discovers its extent. To assess cognitive abilities, the nurse asks the patient to add simple numbers. Having the patient draw the face of a clock gives the nurse information about spatial perception and cognitive function.

Safe Practice Alert

Assess the patient's ability to stand and walk independently before permitting activities, such as ambulation or transferring.

Ability to Communicate

The patient's ability to communicate affects all aspects of care. If a brain insult has caused expressive aphasia, the patient will understand the spoken or written word but will not be able to respond correctly to

questions or statements. The nurse assesses the patient daily to monitor for changes and improvements in language expression. If the brain deficit results in receptive aphasia, the nurse continues to assess the patient's ability to understand simple directions.

Communication can be a challenge in patients with degenerative brain disorders, such as dementia. The patient's ability to communicate is assessed using simple conversation and directions. Testing communication skills is part of the MMSE discussed earlier, which screens for communication difficulties and shows progression of problems over time.

Hearing, Vision, Touch, Smell, and Taste

Hearing ability can be determined by observing the patient's conversation and responses and by talking with the patient in a normal conversational tone while standing slightly behind the patient. If the patient does not respond appropriately, a hearing impairment may exist. The nurse questions the patient about previous hearing examinations and the use of hearing aids. If the nurse suspects a hearing impairment, hearing acuity is assessed (see [Chapter 20](#)).

In the decade between the ages of 40 and 50 years, most people begin to exhibit presbyopia. The affected patient needs to hold reading materials at a distance or becomes unable to read normal-size or small print. Other age-related vision changes that can occur, such as cataracts, macular degeneration, and diabetic retinopathy, cause the patient to be unable to see in certain visual fields or to have blurred vision. Visual ability is assessed by testing vision in central and peripheral visual fields.

Safe Practice Alert

The nurse ensures the safety of a hospitalized patient who has visual changes by describing the room environment and identifying the location of needed objects. As with all patients, it is imperative that a call light be within reach.

Detection of touch and pressure stimuli diminishes with age. In some patients, this change is insignificant; in others, the change is more severe. Diseases (such as diabetic neuropathy) decrease the patient's ability to discern touch, especially in the lower extremities. The nurse assesses the patient's ability to feel light touch and pressure by touching the patient's legs and feet ([Fig. 31.4](#)). A thorough peripheral sensory

assessment is completed in any patient who exhibits diminished sensation in the extremities.

FIGURE 31.4 Assessment of the lower extremities for light-touch and light-pressure sensations. (Copyright [shutterstock.com](https://www.shutterstock.com).)

The special senses of smell and taste decline with age, altering the taste of food. Patients with diminished smell and taste either prefer a bland diet or add too much salt or seasoning to foods. Some lose interest in food, leading to poor nutritional status. The nurse facilitates provision of appealing, nutritious meals by determining the patient's food preferences and eating patterns while the patient is in the hospital or long-term care facility.

Ability to Perform Activities of Daily Living

The nurse assesses the patient's understanding of and ability to perform ADLs. Patients who have damage to the brain due to illness or trauma may have decreased motor functions. The patient who has had a CVA or a head injury may have weakness or paralysis on one side of the body, making it difficult to ambulate or perform tasks of self-hygiene or toileting. Observing the patient's abilities during care and assisting the patient with tasks that cannot be performed independently help the nurse determine the plan of care.

1. List two focused assessments that the nurse should perform for C. M.. Give rationales for each.

LO 31.4 ♦ Nursing Diagnosis

Nursing diagnoses related to cognitive and sensory alterations are numerous, and the diagnoses identified for a particular patient depend on the specific deficit. A thorough assessment is conducted, and diagnoses are based on the objective and subjective data that are collected. They are chosen to coincide with patient problems for which nursing interventions can be outlined. Unique patient care plans are written that are intended to address specific patient goals. Some common nursing diagnoses associated with cognition relate to the patient's thought processes, communication, and the appropriateness of the patient's interaction with the environment. Sensory nursing diagnoses include those associated with the special senses, as well as tactile alterations.

The following are some examples of relevant International Classification for Nursing Practice (ICNP) nursing diagnoses:

Acute Confusion

- Supporting Data: Cerebral hypoxia, clot in the cerebral artery, oriented to person but confused about place and time

Impaired Verbal Communication

- Supporting Data: Alterations of the central nervous system, cerebrovascular accident (CVA), inability to recognize words or understand questions

Risk for Social Isolation

- Supporting Data: Alterations in mental status, dementia, sad affect, states "I feel so alone"

2. Identify three cognitive, sensory, or psychosocial nursing diagnoses for C. M. with supporting data.

LO 31.5 ♦ Planning

The third phase of the nursing process is the planning phase. After nursing diagnoses are identified and prioritized for the patient, desired outcomes and patient-centered goals are established. Nursing care plans are developed for each nursing diagnosis, with interventions aimed at meeting the patient goals. Careful consideration is given to the patient's abilities, the resources available, and the time frame for goal attainment.

For patients with cognitive and sensory alterations, collaboration with families or significant others is imperative. Often, other health care providers are consulted to ensure continuity of care and maximization of cognitive and sensory function for the patient (Box 31.4).

Box 31.4

Interprofessional Collaboration and Delegation

Patients With Cognitive or Sensory Alterations

- Family and friends of the patient with dementia will be involved in the day-to-day care of the affected person and therefore need to be included in the planning process.
- Ensure that full-time caregivers have a support system, to avoid caregiver burnout.
- The patient with cognitive alterations needs an interdisciplinary team to assess deficits and provide ongoing treatment.
- A speech therapist is consulted for patients with hearing deficits or aphasia.
- A patient who has had a stroke benefits from consultation with an occupational therapist for adaptations necessary to maintain activities of daily living (ADLs) and with a physical therapist for ambulation training.
- For the patient with cognitive or sensory alterations, care may be delegated to unlicensed assistive personnel (UAP) after assessment by the nurse.
- Consultation with social services to arrange home care specialists may be needed for patients with cognitive or sensory alterations that preclude safe self-medication.

After identifying specific nursing diagnoses, the nurse writes goal statements that are patient centered, set measurable goals, and include a time frame (Table 31.1). The following are some examples of goal statements that coincide with each of the nursing diagnoses listed in the previous section:

TABLE 31.1
Care Planning

ICNP NURSING DIAGNOSIS WITH SUPPORTING DATA	NURSING OUTCOME CLASSIFICATION (NOC)	NURSING INTERVENTION CLASSIFICATION (NIC)
<i>Acute Confusion</i> Cerebral hypoxia Clot in cerebral artery Oriented to person but confused about place and time	<i>Cognitive orientation</i> Identifies current place	<i>Reality orientation</i> Engage patient in concrete “here and now” activities, which focus on something outside self that is concrete and reality oriented.

From Butcher, H.K., Bulechek, G.M., Dochterman, J.M., et al. (Eds.). (2018). *Nursing interventions classification (NIC)* (7th ed.). St. Louis, MO: Mosby; Moorhead, S., Swanson, E., Johnson, M., et al. (Eds.). (2018). *Nursing outcomes classification (NOC)* (6th ed.). St. Louis, MO: Mosby; ICNP is owned and copyrighted by the International Council of Nurses (ICN). Reproduced with permission of the copyright holder.

- Patient will respond appropriately to questions about place and time within 48 hours.
- Patient will communicate basic needs through the use of photos within 1 week.
- Patient will interact with other nursing home residents during planned activities.

3. Write a short-term goal for this nursing diagnosis: *Impaired Verbal Communication*; Supporting data: Alterations of the central nervous system, cerebral vascular accident, mild difficulty finding words.

The conceptual care map for C. M. provided in [Fig. 31.5](#) is partially completed to indicate how to use the map as a learning tool. Using it as an example, go to the website at <http://evolve.elsevier.com/YoostCrawford/fundamentals/> to complete Nursing Diagnoses 2 and 3.

LO 31.6 ♦ Implementation and Evaluation

The final two steps in the nursing process are dynamic. The nurse delivers care through appropriate interventions and continuously evaluates the effects of that care. Patients who have experienced a change in cognitive or sensory status need ongoing reevaluation and adjustment of the plan of care to maximize their functional potential.

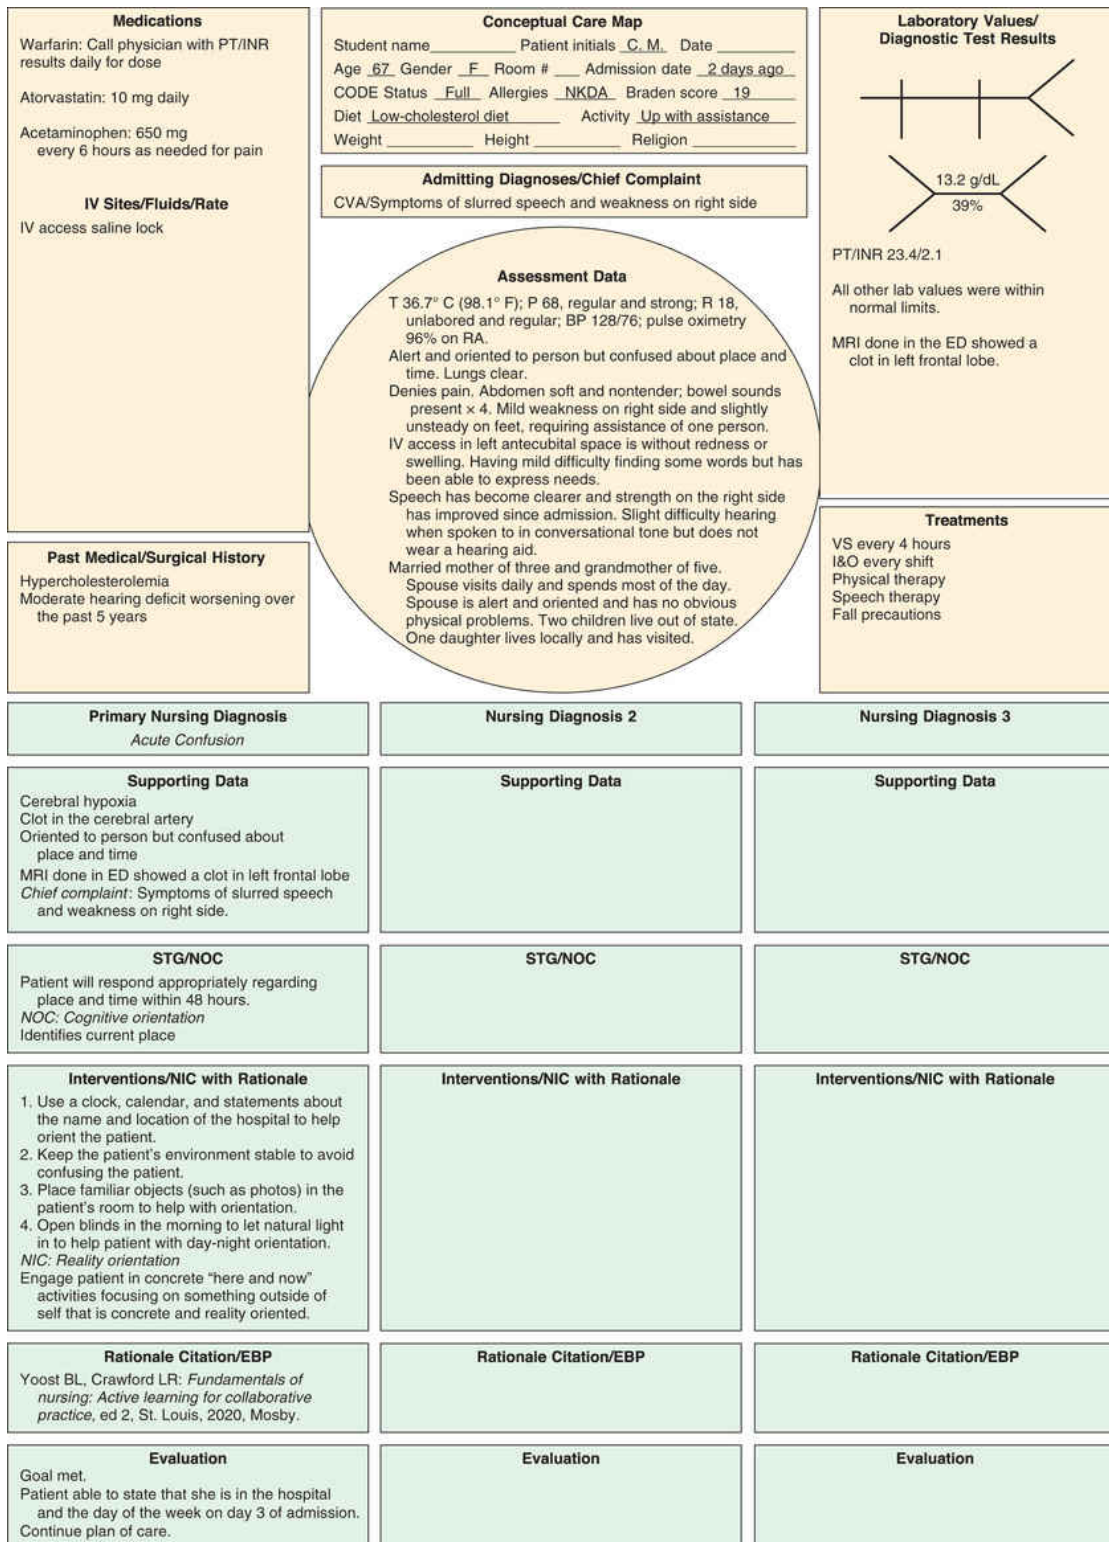

FIGURE 31.5 Partially completed conceptual care map based on C. M., the case study patient in this chapter.

Interventions

Nursing care plans for patients with cognitive or sensory alterations are individualized, depending on the clinical problem and the nursing diagnosis. Patient-centered care plans specify interventions focused on maximizing the patient's capabilities.

Patients With Cognitive Alterations

The nurse in consultation with the primary care provider (PCP) ensures that any patient with cognitive changes has had a thorough workup, including a history, physical, blood work, urinalysis, and other diagnostic studies as necessary. Ruling out the presence of infection and differentiating among dementia, delirium, and depression are important diagnostic steps. The nurse functions as an advocate for the patient during the diagnostic process and collaborates with other specialists as needed.

Safe Practice Alert

When the patient is in bed, leave the bed in the lowest position and the two side rails at the head of the bed in the up position. The side rails are a reminder to the patient that he or she is near the edge of the bed. Check facility policy regarding use of side rails.

The hospitalized patient with cognitive alterations is oriented by use of a clock, a calendar, and statements about the location or name of the hospital. Monitoring orientation to person, place, and time is ongoing. Staff members always identify themselves by name, both verbally and nonverbally (with a name tag) so that the patient knows who is caring for them. The patient's environment is kept as consistent as possible, and moving the patient from room to room is avoided to prevent confusion. Some familiar objects, such as a family photo, are placed near the patient to provide comfort if the hospital stay is longer than a few days. The environment is kept free of distractions (such as loud noises and bright lights) to decrease the possibility of overstimulation. Natural lighting to provide the patient with orientation to time of day can be accomplished by opening blinds or curtains during the day and darkening the room at night. The nurse talks with the patient while completing the assessment and care and explains all changes and procedures in simple terms to help the patient understand what is happening. If a family member or significant other has a health care power of attorney, that person is involved in decisions about care.

Qsen Focus!

Through patient-centered care, the nurse understands the importance of involvement of family and friends. The nurse communicates patient values, preferences, and expressed needs to other members of the health care team.

Safe Practice Alert

The nurse always reminds the patient about the location and proper use of the call light each time the patient will be left alone.

Maintaining a safe environment is essential for patients who are confused. Floors are kept dry and free of cords and tubes to avoid tripping hazards. The call light is placed within reach of the patient to decrease the chance of the patient getting up unassisted. The room should be lit so that the patient can see the surroundings. Patients who are unable to use the call light are checked frequently so that needs are met. Pressure-sensitive alarms may be used to alert the nurse of patient attempts to get out of bed.

Safe Practice Alert

The nurse checks the room for clutter and makes sure the floor is clear, clean, and dry. Nonskid footwear is provided for all patients.

Caring for the patient with dementia poses special challenges. Communication needs to be kept clear and simple to facilitate understanding. If negative behavior occurs, the patient is redirected or distracted. Reminiscing about the past provides a distraction. The patient often remembers details from many years ago even when he or she cannot remember what just occurred. The nurse must be flexible and creative when planning care for the patient with dementia. A gentle, caring approach shows the patient that the nurse is there to help.

If the patient has damage to the speech centers of the brain, special communication methods are needed to enhance communication. The nurse uses simple phrases and questions and speaks clearly without shouting. If the patient has expressive aphasia, asking questions that can be answered with yes or no and using a communication board with pictures may help the patient communicate. For patients with receptive aphasia, the nurse can point to pictures that represent food, drink, or

use of the bathroom so that basic needs are met. In dealing with patients who have either type of aphasia, the nurse is calm and unrushed so that the patient feels relaxed. The environment is without distractions, and the nurse should stand or sit somewhere that enables the patient to watch facial expressions. Gestures, facial expressions, and other cues help the patient to understand what is being said. A notepad or whiteboard may enhance communication.

Safe Practice Alert

Communication is key to all nursing interactions. Modifications are made for patients with deficits to enable meaningful communication.

The patient may be able to physically perform self-care but may need to be reminded to take a bath or brush the teeth. If the patient has motor damage that makes self-care difficult or if the patient's cognitive status is such that self-care cannot be completed independently, assistance with hygiene, toileting, and ambulation may be necessary. After doing a thorough assessment, the nurse may delegate some care to UAP. Patients with cognitive deficits depend on the nurse for reminders to eat and drink adequate amounts. Caffeine is discouraged because it can contribute to sleeplessness. Regular exercise helps decrease restlessness and wandering.

Social interaction facilitates orientation and is important for the patient with cognitive changes. The nurse facilitates interaction with family members and friends in person or by phone. Reading newspapers or magazines of interest, or engaging in other activities that stimulate the brain, is encouraged.

Patient education is needed to ensure a safe home environment and adaptation within the community for patients with cognitive alterations. Safety is a primary concern with discharge of the patient to home. Providing adequate social interaction is another priority.

The dementia patient needs a simple environment and a consistent routine to minimize confusion. The environment is adapted to the patient. Adequate nutrition and rest are important to maintain health. Harmful substances, such as chemicals and medications, are kept under lock because the patient may not be able to judge danger. The patient is supervised, to minimize the chance of wandering. Activities that are enjoyable are made available to the patient. Reality orientation involves helping the patient stay as aware as possible of his or her circumstances, through use of clocks, calendars, notes, and other reminders, thereby

minimizing confusion. Providing activities that the patient enjoys can help prevent boredom and deter negative behavior (Fig. 31.6).

FIGURE 31.6 Talking with a patient with dementia about the past can help make the person feel loved and accepted.
(Copyright [shutterstock.com](https://www.shutterstock.com).)

Because patients with dementia gradually lose the ability to reason and make decisions, a guardian often is necessary. A loving family member or friend typically fills this role to protect the patient from injury and abuse. If no one is available, the court will appoint a guardian (Box 31.5).

Box 31.5

Ethical, Legal, and Professional Practice

Patients With Dementia

- For dementia patients who do not establish a guardian in the early stages of the disease while still capable of reasoning and making decisions, the court can declare a patient incompetent in the later stages of the disease and appoint a guardian or authorize a person through a health care power of attorney to make health care decisions for the patient. Often the person appointed or authorized is a family member.
- Ethical issues arise for patients with dementia, such as how much they should be told about their illness and who should make care decisions if no one has been appointed.

Patient and family education about dementia is an ongoing process. Educating family members on how to relate to their loved one reduces caregiver frustration and burnout. Resources available for caregivers include respite care, household help, support groups, books, and workshops. Caregivers should manage their own stress through relaxation, exercise and pursuit of hobbies, and care for their health needs with regular doctor visits (Robinson, Wayne, & Segal, 2018).

Patients With Tactile Alterations

Numerous safety concerns are recognized for the patient with tactile deficits. The nurse tests the temperature of bath water to reduce the risk of burns in patients who cannot feel differences in temperature. Frequent monitoring of the extremities is indicated. Any changes indicating decreasing sensation or circulation are reported to the PCP. If the patient can move the affected extremities, active range-of-motion exercise is encouraged to stimulate circulation.

The patient who is unable to move in bed independently should be turned and repositioned at least every 2 hours to prevent damage to tissue from unrelieved pressure. Sharp objects (such as pins and clips) are kept away from the affected extremity or area and are not used to hold bandages. The patient who has limited sensation may not feel pressure or pain leading to development of a pressure injury or damage to tissue from a sharp object.

Patients With Olfactory and Gustatory Alterations

Some patients have a decreased sense of smell and taste because of aging, smoking, or infections. The nurse encourages intake of a well-balanced diet during hospitalization while taking into account the patient's specific dietary preferences. Serving highly aromatic foods stimulates the sense of smell. Enhancing the flavor and smell of foods to make them more appealing encourages intake. Diligent oral hygiene at least twice per day to keep the oral cavity pleasant tasting and hydrated has a positive impact on appetite.

The environment is kept clean, and noxious odors are eliminated as quickly as possible. Stimulation with pleasant odors, such as fresh flowers or room deodorizer, enhances the sense of smell.

The patient is encouraged to eat a variety of foods and to enhance the flavor with spices and herbs. Different flavors appeal to different patients depending on specific deficits. Nutrition education encourages healthy lifestyles. Other health promotion interventions are outlined in [Box 31.6](#).

Box 31.6

Patient Education and Health Literacy

Health Promotion

- Promoting healthier lifestyles to older adults is an important nursing consideration. Hearing and vision examinations are part of health promotion.
- Interventions to encourage healthy lifestyles include education regarding nutrition, exercise, smoking cessation, and the importance of health screening.
- Knowledge and preparation help to reduce frustration and give caregivers of dementia patients realistic expectations (Robinson, Wayne, & Segal, 2018).
- Health education and promotion of healthy lifestyles in older adults should be a key nursing intervention in the inpatient setting, as well as in the outpatient and community settings.

Patients With Auditory Alterations

Many hospitalized patients have hearing impairments. If the patient uses an assistive device at home (such as a hearing aid), its use in the hospital is encouraged. Care is taken to keep the hearing aid in good working order and prevent it from getting lost. See [Chapter 27](#) for a discussion on the use and care of hearing aids. Communication is facilitated when the nurse is positioned so that the patient can see the nurse's mouth, because many hearing-impaired patients read lips and watch facial expressions to assist hearing. The nurse speaks clearly and slowly without shouting. Background noise makes it harder for the patient to hear so is kept to a minimum. Hearing loss may not be equal in both ears. Ask the patient if hearing is better in one ear than the other, and stand on the patient's stronger-hearing side to converse. If the patient is cognitively and visually able to read, the use of written instructions and information is helpful. Paper and pencil, a whiteboard, or a computer can be kept at the bedside. A sign language interpreter is used when a patient communicates through sign language.

Closed captioning on television for the patient with hearing impairment provides a way to keep up with current events and a means of distraction while hospitalized. A light on the telephone that signals an incoming call, and an amplified receiver will enable the patient to use the phone to make and receive calls.

Patients With Equilibrium Alterations

The patient with equilibrium alterations is instructed to call for assistance when ambulating to prevent injury. If the patient is experiencing nausea or vomiting, a basin is kept on the bedside stand within easy reach so that the patient doesn't try to get out of bed unassisted. Keeping the lights dim and noise at a minimum may relieve some of the symptoms. Balance and coordination diminish with age, so obstacles are kept off the floor to prevent tripping and falls.

Safe Practice Alert

Patients experiencing problems with equilibrium or those taking over-the-counter medication to combat motion sickness should not drive.

Patients With Visual Alterations

The patient with a visual alteration is oriented to the placement of items in the hospital room. It is best to limit the amount of change in the environment. Furniture is kept in the same place, because the patient can memorize its position. Items that the patient needs are left within easy reach, and the nurse confirms that the patient knows the location. The call light is placed within reach so that the patient can call for assistance with ambulation, especially in the first few days of hospitalization. If eyeglasses or other visual assistive devices (such as contact lenses) are used, they should be kept in good working order and be available on the bedside table. For information about the care of these devices, see [Chapter 27](#). Adequate lighting without glare is provided if the patient needs to read print ([Box 31.7](#)).

Box 31.7

Evidence-Based Practice and Informatics

Care for Visually Impaired Patients

Care for the visually impaired patient involves some simple steps that can enhance the patient's experience and facilitate the nurse–patient relationship:

- Maintain adequate lighting, and minimize glare.

- Make sure the patient is wearing eyeglasses or contact lenses if prescribed.
- Use large print or clear handwriting with a bold tipped marker or pen when giving written instructions.
- Use photos, pictures, diagrams, or audiotaped instructions if necessary.

From [National Institute on Aging. \(2017\). Aging and your eyes.](https://www.nia.nih.gov/health/aging-and-your-eyes)
Retrieved from <https://www.nia.nih.gov/health/aging-and-your-eyes>.

When a visually impaired patient is served a meal tray, the nurse describes the placement of food on the tray in terms of the numbers on a clock so that the patient knows where to find each item (Fig. 31.7). For example, the nurse may say, “Your peas are at the 8 o'clock position.” [Box 31.8](#) outlines discharge planning considerations for patients with cognitive or sensory deficits.

FIGURE 31.7 The nurse identifies position of food on the patient's plate or tray by referring to the numbers on a clock face.

Box 31.8

Home Care Considerations

Patients With Cognitive and Sensory Alterations

Patient With Cognitive Alterations

- If 24-hour supervision and assistance with care are needed, provisions are made with loved ones or a day care service, or placement in a long-term care facility is arranged.
- If the patient is cared for at home, information on day care and respite care is provided.
- Simple, calm environments help to optimize function in the patient with dementia.
- Use of door locks that require a key may be necessary if the patient wanders.
- The environment is kept free of hazards, such as sharp objects.
- Referral to home health agencies is made if assistance with care is needed.

Patient With Tactile Alterations

- A simple kitchen thermometer is used to verify that bath water temperature is approximately 37.8° C (100° F).
- Hot water heaters are set so that scalding is not possible.
- The patient is instructed not to use heat or cold therapy on an affected extremity or region.
- Wearing gloves in the winter to prevent frostbite is especially important in patients with decreased sensation in the fingers.
- Sturdy shoes can prevent foot injuries when the patient has decreased sensation in the lower extremities.
- Any decrease in sensation, change in the color of the skin, and wounds or other lesions are reported to the health care provider.

Patient With Olfactory and Gustatory Alterations

- The patient may not be able to smell noxious odors, such as from gas or spoiled food. The home should be checked for safety of gas stoves, hot water heaters, and furnaces.
- The patient is reminded to use other senses to detect spoiled food.
- Smoke detectors need to be in good working order.
- Use of noxious cleaning and other chemicals is avoided, because the patient is at risk for being overcome by fumes.

Patient With Auditory Alterations

- The patient is instructed on the use and care of hearing aids and encouraged to wear them in the home environment.
- Family members are given communication tips. such as speaking in a slow, distinct voice and standing in good lighting 3 to 5 feet in front of the hearing-impaired person.
- If the patient uses sign language, family members are encouraged to become proficient in this modality.
- Smoke detectors, doorbells, and telephones should have visual signals for a severely hearing-impaired person or amplification for the patient with some hearing.
- An amplified telephone or a [telecommunications device for the deaf \(TDD\)](#)—an electronic device that sends text communications through a telephone line—is a helpful adaptive tool.
- Electronic communication (such as email or texting) helps keep the patient in touch with loved ones.

Patient With Equilibrium Alterations

- The patient experiencing dizziness or vertigo should change positions slowly and cautiously.
- Installation of a secure grab bar in the tub or shower at home gives the patient stability when getting in and out of the tub.
- Use of a tub chair may be necessary.
- Keeping rooms well lit and instructing the patient to focus ahead when walking will help with equilibrium.
- Use of a cane or walker to provide further stability is advised, especially when the patient is walking in unfamiliar areas.
- Anyone with a current symptom of dizziness or vertigo is cautioned not to drive or operate machinery.
- The patient suffering from motion sickness should ride in the front seat of the car and look far ahead through the car windshield. Over-the-counter motion sickness medications, such as dimenhydrinate and meclizine, are available. These medications inhibit vestibular stimulation but may cause drowsiness and dizziness.

Patient With Visual Alterations

- If the patient is living independently, care is taken to rid the home of safety hazards. Furniture is placed to allow wide passageways.

Throw rugs, which are a tripping hazard, are removed. Nonskid mats are used in bathrooms and kitchens. Grab bars placed in the tub or shower, and stair railings are kept in good repair.

- Bright lighting in hallways and stairways prevents falls by the patient who has limited vision.
- The patient is oriented to the environment and the location of specific items.
- If vision is severely limited, use of a cane or walking stick held slightly in front helps the patient feel objects in his or her path.
- The patient with severe visual impairment may use Braille or voice recognition equipment in the home.
- The patient may use a seeing-eye dog.

Patient With Sensory Deprivation

- The patient who is discharged with sensory alterations is at risk for sensory deprivation.
- Use of sensory aids, such as glasses and hearing aids, promotes social interactions.
- Information on support groups and public transportation helps the patient maintain independence.
- Activities that the patient enjoys are encouraged.
- Referral to community agencies or use of home health aides may be necessary if the patient needs assistance with activities of daily living (ADLs).

Patients With Sensory Deprivation

Any hospitalized patient who has a cognitive or sensory deficit, especially auditory or visual, is at risk for sensory deprivation. Providing social interaction for the hospitalized patient with a sensory deficit prevents feelings of isolation. Engaging in meaningful interactions with the patient and encouraging enjoyable activities (e.g., watching television, doing crossword puzzles, and reading) are ways to avoid sensory deprivation. For the visually impaired patient, listening to audiobooks or music is stimulating and provides diversion.

Tactile stimulation is provided when the nurse touches the patient. Giving a backrub during the bath, holding the patient's hand while conversing, or gently touching the shoulder conveys a caring attitude. Patients who are ambulatory and not at risk for falling are encouraged to walk in the hospital room or in the hallway.

The patient in isolation for medical reasons is at risk for sensory deprivation due to the restricted environment. The nurse uses proper personal protective equipment and enters the room as often as necessary to provide patient care, including emotional support. Family can visit the patient as long as proper protocol for the type of isolation is followed (Fig. 31.8).

FIGURE 31.8 The nurse provides emotional support for a patient in isolation. (From Williams, P. [2018]. *deWit's fundamental concepts and skills for nursing* (5th ed.). St Louis, MO: Elsevier.)

Patients With Sensory Overload

Sensory overload is common in ICU patients. To prevent or alleviate overload, the nurse reduces sensory stimuli, dimming unnecessary lights and turning the sound down on alarms if possible. Nursing care is planned so that the patient is not constantly disturbed. Internal stimuli (such as pain and nausea) can contribute to sensory overload. Pain medication decreases unpleasant stimuli for the patient. Nursing interventions (such as soothing music or a backrub) help some patients. For other patients, these interventions may add to the overload. Visits from family members serve as reality orientation and provide a soothing, recognizable presence for some patients experiencing overload.

4. Identify at least four nursing interventions for C. M. designed to meet the short-term goal written for Critical-Thinking Question 3.

Evaluation

Ongoing evaluation of short- and long-term goal attainment is necessary to document patient progress. Changes in the patient's condition and goal attainment require updating the care plan and setting new goals. Improvement in sensory or cognitive abilities enables the patient to perform more self-care. A decline in the patient's condition necessitates more assistance from the nursing staff.

Goal statements are patient centered and identify ways to move the patient toward independence, if possible. Monitoring goal attainment is a nursing responsibility and helps the nurse to evaluate the patient's progress. Evaluation of the plan of care includes information gathered from the patient and family.

Summary of Learning Outcomes

LO 31.1 *Describe the normal structure and function of brain and body regions involved in cognition and sensation:* Cognitive abilities and nervous system interpretation of sensory input enable individuals to respond to their environment.

LO 31.2 *Identify how alterations in structure and function associated with impaired cognition and sensation affect patients' abilities:* Illness, trauma, stress, and aging may cause alterations in cognitive and sensory function. When alterations occur, thought processes may be affected and sensory loss may occur.

LO 31.3 *Perform assessments of patients' cognitive and sensory function:* A thorough assessment is crucial for all patients at risk for or experiencing cognitive or sensory alterations.

LO 31.4 *Choose nursing diagnoses for patients who need assistance or modifications in care because of cognitive or sensory deficits:* Nursing diagnoses are based on the specific deficit and may include *Acute Confusion*, *Impaired Verbal Communication*, and *Risk for Social Isolation*.

LO 31.5 *Articulate goals for patients with cognitive or sensory alterations:* When planning care for patients with cognitive or sensory alterations, the nurse establishes goals that are aimed at the patient's reaching his or her full potential. The patient's abilities and specific deficits are taken into consideration when the nurse establishes outcome criteria.

LO 31.6 Carry out nursing care plans, including interventions to enhance patients' cognitive and sensory function that can be evaluated after implementation:

Nursing care plans are individualized for patients with specific cognitive or sensory alterations to maximize each patient's capabilities. Evaluation of the plan of care is ongoing.

Review Questions

1. A visually impaired diabetic patient states that he has lost the call light. What is the next step the nurse should take?
 - a. Clip the call light closer to the patient.
 - b. Tell the patient that the call light is clipped to the bed.
 - c. Describe the call light location, and take the patient's hand and guide it to that location.
 - d. Instruct the patient to verbally call for a staff member because "someone is always nearby."
2. When caring for a hearing impaired patient, use of which technique by the nurse would facilitate communication?
 - a. Speaking clearly with distinct words
 - b. Talking slowly to facilitate understanding
 - c. Sitting behind the patient to decrease distractions
 - d. Standing near the patient's affected ear to balance sound
3. The nurse is caring for a patient with decreased sensation in the lower extremities. Which precaution does the nurse advise the patient to take?
 - a. Use heat to warm hands during cold weather.
 - b. Go barefoot at home to prevent blisters from shoes.
 - c. Soak feet in cold water daily to decrease swelling.
 - d. Test the bath water temperature to prevent burning injuries.
4. Which statement by the patient with vertigo lets the nurse know that the patient has understood the

- home-going instructions?
- a. "I will buy a visual signal for my smoke detectors."
 - b. "I will have grab bars installed in my bathtub."
 - c. "I will change positions quickly to avoid vertigo."
 - d. "I will get a home phone with amplified sound."
5. Which nursing intervention is appropriate for a patient with sensory overload?
- a. Dimming the lights
 - b. Performing care a little at a time
 - c. Leaving the patient's door open
 - d. Rushing to get care done quickly
6. Which recommendation in the home-going instructions is appropriate for a patient with damage to the chemoreceptors of the upper nasal passages?
- a. Arranging for lighted signals on doorbells and telephones
 - b. Obtaining a thermometer for testing bath water temperature
 - c. Installing amplification devices on televisions, doorbells, and telephones
 - d. Scheduling yearly safety checks of gas hot water heaters and furnaces
7. When caring for an elderly patient who presents with acute confusion of sudden onset, which test would the nurse expect to be ordered?
- a. Urine culture and sensitivity testing
 - b. Mini-Mental State Examination (MMSE)
 - c. Swallow evaluation

- d. Magnetic resonance imaging (MRI) with contrast
8. Which nursing diagnosis is most appropriate for a patient with expressive aphasia?
- a. *Impaired Verbal Communication*
 - b. *Acute Confusion*
 - c. *Self-Care Deficit*
 - d. *Impaired Mobility*
9. Which nursing interventions would be necessary in caring for a patient with cognitive alterations who is hospitalized? (*Select all that apply.*)
- a. Apply wrist restraints for combativeness.
 - b. Place a clock in the room for orientation.
 - c. Keep floor free of clutter for safety.
 - d. Identify staff with each interaction.
 - e. Play loud music for distraction.
10. Which goal statement is appropriate for a patient with the nursing diagnosis of *Acute Confusion*?
- a. Patient will remember nurse's name.
 - b. Nurse will remind patient of his or her name each shift.
 - c. Patient will state name and date with each nursing encounter.
 - d. Nurse will remind patient of name and date with each nursing encounter.

CHAPTER 32

Stress and Coping

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 32.1 Identify the key concepts associated with the body's physiologic and psychological responses to stress.
- LO 32.2 Describe psychological and physiologic responses of the nervous, endocrine, and immune systems to stress.
- LO 32.3 Describe the effects of stress on health.
- LO 32.4 Demonstrate assessment techniques for recognizing signs and symptoms of stress.
- LO 32.5 Identify stress-related nursing diagnoses.
- LO 32.6 Articulate stress reduction goals and patient outcomes.
- LO 32.7 Develop patient-centered care plans with interventions designed to address stress-related conditions and guide evaluation criteria.
- LO 32.8 Discuss the potential impact of stress on nurses.

Case Study

Roland Hastings (R. H.) is a 60-year-old retired architect who is financially comfortable. His medical history includes a heart attack 5 years ago and a second heart attack just 4 weeks ago. R. H. lives with his wife in their two-story home, which they own. The bedrooms and bathroom are upstairs.

During the intake interview at his first clinic visit, R. H. states that his wife “hovers” over him, taking care of him physically and seeing that he does not overexert himself. He denies any chest pain but mentions that he occasionally experiences slight shortness of breath when climbing the stairs. R. H. looks downcast and somewhat depressed, despite being given permission by the cardiologist to begin driving again. He states, “I am going to die from this heart condition, so why treat it?” He states that he has difficulty falling asleep and remaining asleep, because he feels anxious and jittery.

The nurse takes Mrs. H. aside and asks how she is feeling. Mrs. H. states that she is afraid her husband will have another heart attack if he exerts himself doing routine daily tasks and feels that she must take on his responsibilities. She knows that he is frustrated and stressed, and she does not know what to do to help him.

Refer back to this case study to answer the critical-thinking questions throughout the chapter.

Stress is ever-present in life, affecting every person regardless of socioeconomic status, age, gender, lifestyle, education, or occupation. Unrelieved stress has a negative impact on health. The stress response can directly cause damage to body tissues by increasing heart rate and blood pressure and causing the release of powerful stress hormones. Nurses need to recognize stress in their patients and themselves to facilitate appropriate and effective interventions to improve these responses.

Stress is a complex concept that has been identified historically in several ways. Physiologic stress is the body's potentially harmful reaction to a stimulus (Selye, 1976). Psychological stress comprises the emotional and cognitive factors involved in the appraisal of threat (Lazarus, 1966). When the affected person interprets an event as a threat, the physiologic stress response is activated. A third form of stress, sociocultural stress, occurs when social systems are challenged by factors such as racism, economic hardship, or political upheaval. All three types may interact and are related.

Stress is an autonomic psychologic or emotional response to an internal or external environmental challenge, which is automatic and typically beyond a person's resources or ability to respond (Bystritsky & Kronemyer, 2014). Selye (1976) defines stress as "a nonspecific response of the body to any demand made upon it." *Stress* may refer to the physiologic response pattern itself. A **stressor** is an event or stimulus that disrupts the person's sense of equilibrium. People react to stress in different ways, which are determined by their appraisal of the stressful event and their self-perceived ability to respond to the stressor. **Stress appraisal** is the process by which the person interprets a stressor as either a threat or a challenge (Folkman, Lazarus, Dunkle-Schetter, et al., 1986). The way a person responds to stress determines its impact on the person's attitude and physiologic response. Stress may lead to creative changes that enhance the person's life and well-being. Stress also may trigger inflammatory bowel disease, cardiovascular disease, chronic pain, and autoimmune diseases, such as rheumatoid arthritis (Slavich & Auerbach, 2018).

Knowledge of stress, coping, and adaptation is important for health care personnel because of the link between health and stress. The stress and coping components of this knowledge base are especially relevant for nurses because of their primary concern with the human responses to stressful conditions. The negative effects of stressful circumstances may be minimized if the stress is recognized early, resources for coping are identified, and appropriate interventions are implemented.

Sister Callista Roy's **Adaptation Model (1970)** provides a solid theoretical foundation for nursing care of patients facing stressful situations. In Roy's theory, people adapt to stress by meeting their physiologic needs, developing a positive identity, performing social role functions, and balancing dependence and independence. Stressors disrupt the person's equilibrium, resulting in illness. Nursing care is directed at altering stimuli that are stressors to the patient. In Roy's model, the nurse's role is to help patients adapt to illness or develop positive adaptive behaviors.

LO 32.1 Scientific Foundation

The concept of **homeostasis**, the body's regulation of systems to maintain a steady state, was first described by Walter Cannon in 1932. Seventeen years earlier, **Cannon (1915)** identified the **fight-or-flight response** to excitement or threat. This physiologic response to stress, whether physical or psychological, is activation of the autonomic nervous system, resulting in an increase in heart rate, blood pressure, and respirations along with pupil dilation and a decrease in gastric motility and blood flow to the skin (**Fig. 32.1**). When experiencing the fight-or-flight response, people report symptoms of rapid heartbeats, palpitations, and nausea, as well as anxious feelings.

FIGURE 32.1 Fight-or-flight response. *GI*, Gastrointestinal.

LeDoux (2015), a neurobiologist, identified subcortical survival circuits and a pause preceding fight-or-flight readiness, modifying the

response to be “freeze, flight or fight.”

General Adaptation Syndrome

Hans Selye (1976) named the physical response to stress the **general adaptation syndrome (GAS)**. He noted that the body responds in the same way to any demand, whether it is physical, emotional, pleasant, or unpleasant. The GAS is evoked when the stimulation or stressor is strong enough to activate the autonomic nervous branch of the central nervous system, eliciting an adaptive response. Selye referred to the demands that produce the adaptive response as *stressors* and noted that stress is unavoidable. He labeled negative stress as **distress** (stress that is beyond the ability of the affected person to cope with or adapt to effectively), which can cause physical illness or emotional dysfunction. He identified positive stress as **eustress** (motivational stress), which is associated with effective coping and adaptation. Eustress is thought to be essential for normal growth and development.

The GAS consists of three stages: alarm reaction, resistance, and exhaustion. Most stressful events involve only the first two, but some ongoing demands can exceed the body's resources and lead to the final stage of exhaustion (Fig. 32.2).

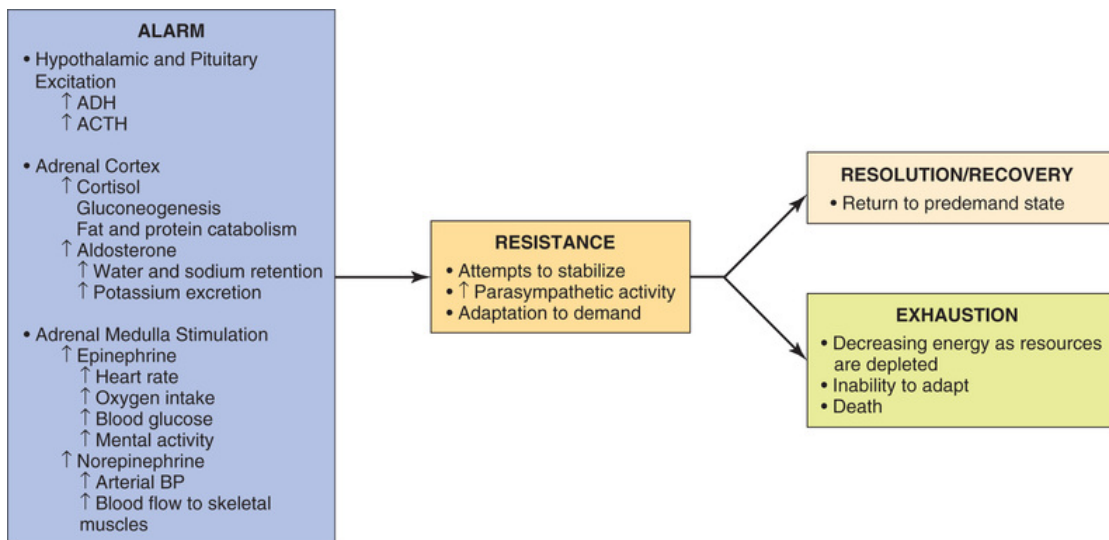

FIGURE 32.2 The general adaptation syndrome (GAS). *ACTH*, Adrenocorticotrophic hormone; *ADH*, antidiuretic hormone; *BP*, blood pressure.

When the level of stress from a stressor reaches a threshold that threatens homeostasis, it is strong enough to activate the *alarm* stage of the stress response. In the alarm stage, the hypothalamic-pituitary-adrenal and autonomic nervous systems are activated, successively

triggering responses in the sympathetic nervous system and the endocrine and immune systems. In the *resistance* stage, the body attempts to adapt to the stressor, and some of the initial responses are lessened as the parasympathetic nervous system reverses the sympathetic stimulation and stabilization occurs. The body begins to repair damage and restore resources. However, if the stress is not relieved or the resources are inadequate to meet persistent demands, the body advances to the third stage, *exhaustion*.

When resources are depleted, and the body is unable to continue the efforts of adaptation, the body cannot maintain physical function, and death may result at a cellular or systemic level. This stage may be reversed by augmentation of the body's resources from the outside, such as through medication, nutritional support, or other therapies. Chronic, prolonged, unrelieved stress (such as that typical of the exhaustion stage) may cause disease.

Local Adaptation Syndrome

Selye noted that tissues of the body more directly affected by stress demonstrate a **local adaptation syndrome (LAS)**, which may manifest as inflammation, reflexive response to pain, or hypoxia secondary to catecholamine release. Hypoxia can negatively affect wound healing as well as the ability to think clearly at times of severe anxiety. The GAS and the LAS are closely related, but the effects of the LAS are most notably manifested by activities in the immune system.

Allostasis

McEwan and Lasley proposed *allostasis* as an alternate term for the stress response. According to these researchers, **allostasis** is how homeostasis is reestablished, and the purpose of allostasis is to assist the body in maintaining stability (McEwan & Lasley, 2002). A sustained stress response is potentially damaging. Allostatic responses (such as the fight-or-flight response) should terminate when no longer needed, reducing the allostatic load. The physiologic responses caused by physical and psychological stress are adaptive in the short term, but the body does not tolerate prolonged periods of sympathetic arousal. Chronic, high levels of stress have been shown to produce atrophic changes in the brain (Yoshii, Oishi, Ikoma, et al. 2017).

Stress Appraisal

Richard Lazarus and his colleagues developed a theory of cognitive mediation within emotion. An important concept within that theory is

appraisal, or the automatic, often unconscious assessment of a demand or stressor. This evaluation of threat occurs in two stages, which may occur almost simultaneously. In the first stage, the immediacy of the threat and the degree of ambiguity of the threat are factors. The person measures what is at stake in the stressful encounter. In the second stage, coping options are evaluated. Primary and secondary appraisals determine whether the stressful situation or transaction is a threat or a challenge. A threat invokes the possibility of harm or loss, whereas a challenge holds the possibility of benefit (Folkman, Lazarus, Dunkel-Schetter, et al. 1986). Current related research is focused on the concepts of conscientiousness and responsibility as they relate to the appraisal of daily stressors.

Sense of Coherence

The fact that some people experience considerable stress but do not develop physical illness or prolonged emotional distress was of interest to stress researchers after World War II. In studying the survivors of concentration camps, they noted that personality factors, cultural and other support systems, and the timing and clustering of events affected the person's response to life events. Antonovsky (1979) developed the concept of **sense of coherence (SOC)** to help explain this variation in response to stress.

SOC is a characteristic of personality that references one's perception of the world as comprehensible, manageable, and meaningful. *Comprehensible* means that the demands of the internal and external environments are understandable and predictable; *manageable* means that the person recognizes resources that are available to meet these demands; and *meaningful* is the person's interpretation of the demands as worthy of engagement. Persons with strong SOC are likely to recognize and utilize resources in a stressful situation, whereas those with low SOC are likely to be overwhelmed and have difficulty coping.

Coping

Coping has been defined as the dynamic cognitive and behavioral efforts to manage demands (internal or external) that are appraised as exceeding immediately available resources (Lazarus & Folkman, 1984). Coping is recognized as a dynamic process that changes over time and does not guarantee success or healthy behavior. Some coping responses may have little or no effect, and some may be damaging to health, especially if used inappropriately. Examples of potentially damaging responses are defense mechanisms, such as denial and suppression, or the excessive use of alcohol and other drugs.

Defense Mechanisms

Defense mechanisms are predominantly unconscious, protective coping methods that people may apply in response to a perceived threat. Use of defense mechanisms on a short-term basis initially may prevent harm to the person in distress. However, long-term coping strategies that are based on defense mechanisms can prevent healthy growth and development. Examples of defense mechanisms are presented in [Table 32.1](#).

TABLE 32.1

Defense Mechanisms

MECHANISM	DESCRIPTION
Compensation	Focusing on strengths rather than perceived weaknesses
Denial	Ignoring aspects of reality that induce anxiety or contribute to a loss of self-esteem
Displacement	Redirecting negative emotions perceived as unacceptable or threatening to a safer focus
Intellectualization	Overthinking a challenging situation or impulse to avoid dealing with the emotions it elicits
Projection	Attributing one's own motives, values, desires, situational responses, and personality traits to another person
Rationalization	Explaining personal actions in a way that enhances one's own self-image
Reaction formation	Responding to negative thoughts or feelings by demonstrating opposite emotions and actions
Regression	Reverting to behavior associated with an earlier stage of development when challenged by thoughts and stressors
Repression	Blocking unacceptable thoughts and feelings from consciousness
Sublimation	Channeling unacceptable emotions or impulses into acceptable actions or responses

Coping Strategies

Problem-focused coping techniques are aimed at altering or removing the stressor. In circumstances in which the problem may not have a solution, emotion-focused coping strategies work to ease the emotional distress associated with a stressful condition. For example, a person with a new diagnosis of diabetes may use strategies such as information gathering (seeking information about diabetes) and direct action (learning how to manage diet and medications), which are problem-focused. For another person, a new diagnosis of diabetes may be overwhelming, leading to feelings of helplessness or despair. That person may use avoidance or other emotion-focused strategies to relieve the stress associated with what is perceived to be a threat.

Studies have shown that successful coping usually involves both problem-focused and emotion-focused efforts. Coping strategies may be chosen on the basis of personal experience of success with various mechanisms, the degree of threat, and the availability of social resources. Persons who are able to apply different strategies in varying stressful situations generally are found to cope more effectively (Folkman, Lazarus, Dunkel-Schetter, et al., 1986).

LO 32.2 Normal Structure and Function

The physiologic responses to stress may be understood if the responses of the three major systems of the body are recognized. The nervous, endocrine, and immune functions of an individual are all interrelated and affected by stress, and the stress response may activate other physiologic systems indirectly. Because all systems are connected, a stressor has the potential to affect any or many body systems.

Nervous System Responses to Stress

The physical signs of stress are those of sympathetic nervous system stimulation. When a demand is perceived, a stimulus in the form of sensory impulses from any of the sensory organs (such as the skin, eyes, or ears) is transmitted along spinothalamic pathways in the peripheral nervous system. These afferent impulses activate the reticular formation located in the brainstem, relaying the stimulus to the thalamus. The reticular activating system (RAS) and the thalamus are a primitive part of the brain that functions to maintain alertness.

From the thalamus, the impulses are sent to the cerebral cortex, the seat of higher brain functions, including conscious thought and reasoning. The cerebral cortex interprets the somatic, auditory, visual, and other sensory input. In the frontal areas of the cerebral cortex, the brain evaluates the information, considering past experience and future implications. The temporal areas of the cerebral cortex, when stimulated, produce a sensation recognized as fear. Fear can modify the perception of a stressor.

The hypothalamus, located superior to the pituitary gland, has many functions useful in the adaptation to stress. Baroreceptors in the carotid sinuses transmit information to the hypothalamus about blood pressure. Emotional stimuli activating the limbic system also may activate the hypothalamus and the sympathetic nervous system. Corticotropin-releasing hormone (CRH) released by the hypothalamus stimulates the pituitary to release adrenocorticotrophic hormone (ACTH).

These hormones increase the heart rate, resulting in increased cardiac output and elevated blood pressure. There is an increase in the flow of blood to muscles at the expense of the digestive and other systems not immediately needed in the fight-or-flight response. Smooth muscle in the bronchi relax and dilate the bronchi and smaller airways, and the respiratory rate increases, allowing for an enhanced flow of well-oxygenated blood to muscles and other organs. The motility of the digestive tract is decreased, slowing digestive processes, but glucose and fatty acids are mobilized from the liver and other stores to support

increased mental activities (alertness) and skeletal muscle function. Pupillary dilation produces a larger visual field. Some of these changes result from direct nervous system stimulation and some from the secretion of hormones and other neurotransmitters (such as cortisol, ACTH, aldosterone, testosterone, and catecholamines) stimulated by the autonomic system activation. These changes occur within the first minutes of exposure to a stressor and may be experienced as the sensations of palpitations, light-headedness, nausea, and anxiety.

Immune System Responses to Stress

The immune system coordinates the body's defense against infection and injury. This system's white blood cells, created in bone marrow and circulated by the bloodstream, determine what is healthy body, or "self," and what is foreign, or "not self." Foreign cells or proteins are destroyed.

The first immune response to infection or injury is pain, a signal to the brain that something is wrong, followed by inflammation. Immune cells at the local site of the injury trigger changes in adjacent blood vessels that cause redness (vasodilation) and swelling (increased capillary permeability). Phagocytes and macrophages migrate to the area and ingest the infecting agents. Other white blood cells, the T and B lymphocytes, are aggressively cytotoxic to infected cells. If the local responses cannot neutralize the invader, the hypothalamus is signaled and a general response is triggered.

Endocrine System Responses to Stress

A consequence of hypothalamic activation is sympathetic stimulation, which triggers epinephrine and norepinephrine release from the adrenal medulla. The combined effect of these catecholamines is known as the *sympathoadrenal response*. Psychological, as well as physiologic, stressors can activate the hypothalamic-pituitary-adrenal complex. The secretion of CRH by the hypothalamus initiates release of a precursor of ACTH and a neuropeptide, beta-endorphin. Endorphins are known to act as analgesics, reducing the sensation of pain. ACTH stimulates the secretion of corticosteroids and aldosterone.

Corticosteroids are important in the stress response, because they increase serum glucose levels and inhibit the inflammatory response. Catecholamines also have an effect on blood vessels. Alterations in blood flow include the shunting of blood flow to muscles, at the expense of some internal organs, and increased clotting time functions that protect circulation to vital organs when blood loss occurs.

Inhibition of the stress response by corticosteroids can mediate the negative effects of a prolonged stress response.

Stress-induced hyperglycemia may result from various stressors. Gestational diabetes during pregnancy, hyperglycemia experienced after acute myocardial infarction, and postoperative hyperglycemia must be addressed to avoid serious complications. Increased infection rates and poor wound healing, similar to those seen in patients with type 1 diabetes mellitus, are associated with untreated stress-induced hyperglycemia.

Psychological Responses to Stress

Although research initially focused on the physiologic changes caused by stress, specific factors including age, nutritional status, and genetic inheritance were identified to affect a person's response, and great variation among individual responses to the same stressor was recognized. Stress appraisal, the affected person's attribution of meaning to a stressful event, also influences the expression of this stress response and reflects the complex psychological processing involved.

One perspective suggests that the frequency and intensity of stress exposure account for differences in adaptive responses, explaining why some people appear to be more resistant to stress-related illness. [Holmes and Rahe \(1967\)](#) developed the classic measurement tool called the *Social Readjustment Rating Scale* to identify stressors and estimate a person's degree of stress. Major stressors are assigned a numeric value, and an individual's total score may be used to predict the likelihood of illness. Other stress measurement tools include the Everyday Hassles Scale of [Lazarus and Folkman \(1989\)](#) and the Perceived Stress Scale (PSS)-14 by Cohen ([Cohen and Janicki-Deverts, 2012](#)). Most stress assessment tools are limited due to their perceived insensitivity to age, gender, or sociocultural differences, but they can be useful if these limitations are taken into account. At the present time, stress assessment tools are being translated into many languages, which should improve their accuracy when used in a variety of cultural settings.

Another point of view is that personality factors (such as resilience, hardiness, and SOC) can buffer the impact of stress, reducing the negative consequences. Resilience is the ability to cope in adverse or challenging situations ([Slater, 2018](#)). Resilient people bend but do not break under stress and use a variety of coping strategies. Positive personal and professional relationships, positivity, emotional intelligence, life balance, spirituality, and self-reflection are some of the characteristics of resilient people ([Slater, 2018](#)).

Coping style refers to a pattern of measures taken to relieve stress. Effective coping is validated when adaptive mechanisms maintain stress

within manageable limits, enhance physical recovery, and preserve psychological well-being. How well each person copes will vary and may be influenced by the number of and intensity of stressors, the duration of exposure, past experiences, personality factors, and availability of resources.

Anxiety

Anxiety is a response to stress that causes apprehension or uncertainty. It differs from fear, which has an identifiable source of impending danger. Anxiety may manifest as vague nervousness or as a feeling of dread. Various levels and types of anxiety have been identified.

Mild anxiety can be motivational, foster creativity, and actually increase the ability to think clearly. For example, a person who experiences mild performance anxiety when acting in a play may have a heightened ability to remember lines or cues, which keeps the person at top performance level. *Moderate* anxiety narrows focus, dulls perception, and may challenge the person to pay attention or use appropriate problem-solving skills. Both mild and moderate anxiety are considered normal and are experienced by everyone on a regular basis.

Severe anxiety results in the inability to make decisions or solve problems, whereas *panic* (the highest level of anxiety) is associated with a multitude of physiologic changes, as well as subjective feelings of extreme dread or terror. Panic causes the affected person to become immobilized, unable to concentrate, communicate, or think in a rational manner. Panic attacks may be manifested as physical signs, such as diaphoresis, chest pain, difficulty breathing, and palpitations.

Many types of anxiety are recognized, including **generalized anxiety disorder (GAD)**, social anxiety disorder, obsessive-compulsive disorder, and **post-traumatic stress disorder (PTSD)**. GAD is characterized by unrealistic levels of worry and tension with or without an identifiable cause. Social anxiety involves fear of being judged by others and overwhelming self-consciousness in social situations. Obsessive-compulsive disorder can be immobilizing or interfere with daily activities by causing the affected person to repeat ritualistic behaviors in an effort to avert unrealistic concerns about harm. PTSD is a very serious mental health condition characterized by flashbacks and erratic behaviors that results from exposure to a horrifying experience. PTSD may develop when the person's ability to cope is exceeded by the trauma that was experienced.

Anger

Anger is an emotion that involves antagonism toward another person or situation. It is evoked by a feeling of being wronged in some way. Anger actually prepares the affected person to “attack,” physically or otherwise. Healthy people seek ways to effectively channel or resolve feelings of anger through conflict resolution strategies, counseling, or active exercise. Unresolved anger may be expressed through violent, abusive behavior, whereas chronically suppressed anger may lead to physiologic changes, such as high blood pressure and gastrointestinal upset, or depression.

Depression

Depression sometimes is described as “anger turned inward.” Typically, depression results from an experience of loss—loss of a loved one, relationship, or job; failure of a professional goal; or diminished physical health or appearance. People experiencing depression may feel worthless, guilty, or hopeless. A depressed person may have difficulty getting out of bed, experience insomnia, lack energy for activities of daily living (ADLs), display a flat affect, act chronically tired or withdrawn, or appear disheveled. If initial feelings of depression are not addressed, clinical depression may develop, leading to suicide attempts or loss of life. Psychotherapy and medication are recommended methods of treatment for people experiencing any form of depression. Ideally, feelings of depression serve as a motivator for change, leading to a healthier, happier lifestyle.

LO 32.3 Altered Structure and Function

Prolonged or severe stress can have significantly detrimental physical effects on the body. In certain stressful situations, parasympathetic, rather than sympathetic, stimulation is the primary event. In these circumstances, increased gastrointestinal motility and bronchial constriction may occur, resulting in stress-induced conditions, such as irritable bowel syndrome or asthma.

The ability of the body's immune system to respond to infections is significantly altered by stress. Lymphocytes are created in response to particular infective agents after initial exposure; this is the principle behind the formation of antibodies and vaccinations. If exposed to those same infectious agents at a later time, antibodies recognize and react to the agent as foreign. However, antibody concentrations in vaccinated people and animals have been found to be lower under conditions of stress, and stress decreases the activity of some lymphocytes (Sandvik, Bartone, Hystad, et al., 2013). Stress has accelerated the progression of human immunodeficiency virus (HIV) infection toward active acquired immune deficiency syndrome (AIDS) (Weinstein & Li, 2016), and stress has a positive correlation with high viral loads, making highly active antiretroviral therapy (HAART) less effective.

High stress levels are known to exacerbate multiple sclerosis and other autoimmune diseases. Herpes simplex and zoster viruses have the ability to become latent within an infected cell and show an affinity for neurons. Periodic reactivation of herpes infections commonly occurs with stress, especially with herpes simplex virus type 1 and type 2 (HSV-1 and HSV-2) infections, producing skin lesions on the mouth or genital areas.

The unrelieved exposure to some stress hormones can lead to organ failure. Aldosterone secretion increases sodium reabsorption in the kidney, and stimulation of the posterior pituitary in stress results in increased secretion of antidiuretic hormone (ADH); both contribute to increased extracellular volume. These hormonal stress responses result in retention of sodium and loss of potassium and calcium from the body.

Measurement of cortisol, found in the blood, urine, and saliva, is the standard for laboratory assessment of physiologic stress. Testosterone levels are known to rise in physically stressful conditions in males. The hormonal milieu for females is more complicated before menopause, but studies have demonstrated that stress can delay ovulation and suppress menstruation (Hillman, 2015). Box 32.1 highlights the impact

of stress on males and females of various ages and cultural backgrounds.

Box 32.1

Diversity Considerations

Each person responds to stress slightly differently. However, some commonalities have been noted in research that assist health care providers in adapting care to meet the unique needs of specific populations.

Life Span

- Stressors that are significant for children include all forms of abuse (i.e., physical, emotional, sexual), parental mental instability and substance abuse, marital conflict and divorce, and aggressive or neglectful relationships (Chen, Brody, & Miller, 2017).
- Emotionally supportive relationships in childhood are linked to more positive physical health across the lifespan (Chen, Brody, & Miller, 2017).
- Stressors in children before age 5 and social stress in adolescents ages 14-17 have been found to cause decreased gray matter development in the brain which impacts resilience and may affect mental health (Tyborowska, Volman, Niermann et al., 2018).
- Job stress; family stress; and health, economic, political, and cultural stressors significantly impact the level of anxiety experienced by adults (Scott, Sliwinski, & Blanchard-Fields, 2013).
- Research indicates that younger adults experience more interpersonal stressors and are more reactive to them than are older adults (Scott, Sliwinski, & Blanchard-Fields, 2013).
- Studies have shown that younger adults, people with a poor self-concept, and those with a perceived lack of situational control demonstrate greater reactivity to stress (Scott, Sliwinski, & Blanchard-Fields, 2013).
- Stress is as much a fact of life for older adults as it is for younger persons, but there are differences in the amount of stress and the nature of their stressors. Most stressors for older adults involve loss and grieving. The changes of aging reflect a loss or decrease in physical function, which may be distressing in and of itself, as well as represent a potential loss of independence and dignity (Byun & Jung, 2016).

- The allostatic load in the older adult may be overwhelming because of diminished physical capabilities. Loss of appetite, sleep disturbances, and depression may be symptoms of stress in the older adult (Byun & Jung, 2016).
- Cognitive changes may affect the older adult's ability to cope. Anger or withdrawal as a coping strategy may be used more frequently than in the past (Hvalvik & Reiersen, 2015).

Culture, Ethnicity, and Religion

- Personal beliefs and culture will have an impact on the patient's conceptualization of health and illness, willingness to seek health care assistance, and adherence to therapies (Hamilton, Stewart, Thompson, et al., 2017).
- Religious practices (such as prayer, attendance at services, liturgy, and pastoral visits) are reported as very important to chronically ill patients facing an uncertain future. Spiritual concerns complicate the patient's ability to cope and manage stressors (Hamilton, Stewart, Thompson, et al., 2017).
- Cultural factors that affect health care include language and communication, social and family organization, perceptions of environmental control, and spatial and time orientation (Spector, 2017).

1. List a minimum of three factors that are contributing to R. H.'s stress level.

LO 32.4 ♦ Assessment

A trusting relationship permits the nurse to pursue assessment of personal and sensitive information regarding stress and the coping skills used by patients. The use of open-ended questions assists in obtaining accurate information regarding specific stressors and coping skills (Box 32.2). Identifying the ability of the patient to successfully use problem-focused (changing or removing a stressor) and emotion-focused (modifying one's reaction to a stressor) coping skills assists in planning appropriate interventions. Coping strategies can be individually tailored on the basis of past successful use.

Box 32.2

Health Assessment Questions

Present Stressors

- What personal stress are you currently experiencing?
- Have you experienced any changes in your life recently?
- Have you experienced changes in your stress level due to these changes?

Coping Skills

- How have you dealt with stressful situations in the past?
- Were your techniques of handling stress effective?
- Whom can you ask for assistance during stressful times?

Symptoms of Stressors

- Are you experiencing feelings of anxiety or nervousness?
- Are you experiencing feelings of depression, irritability, or anger?
- Are you experiencing your heart racing and pounding?
- Have you experienced episodes of hyperventilating?
- Does stress cause you to experience muscle tension in your neck, back, and head?
- Do you experience migraine headaches when you are under stress?

- Have you experienced diarrhea or constipation during stressful times?
- Are you having trouble sleeping?
- Have you had any changes in weight?

Adults

- Have you recently experienced any social, physical, emotional, or financial losses?
- Do you feel safe in your home?
- Do you suffer from physical illnesses?
- Have there been any major changes in your life recently?

Children

- What has been bothering you lately?
- Do you have any specific concerns?
- Do you feel safe at home and school?

Support Network

- Whom do you turn to when you need help?
- Whom do you talk to about your feelings and problems?

Additional Considerations

- Does your cultural or spiritual background provide you with certain beliefs that are helpful in times of stress?
- Do you see someone other than a doctor or nurse for health care, such as a psychologist, social worker, faith healer, folk healer, or medicine man?

Observations During the Assessment

- How would you describe the patient's physical appearance, facial expression, behavior, and mood?
- What are the patient's posture and gait?
- Can the patient sit still? Is the patient experiencing tremors or muscle tension?

- Does the patient appear to be depressed or withdrawn?
- Is the patient agitated, aggressive, or angry?

Physical Assessment

- What are the patient's vital signs? Are the patient's heart rate and blood pressure elevated? Are the patient's respirations shallow? Does the patient report any pain?
- Is the patient experiencing any shortness of breath, dry mouth, or gastrointestinal upset?

Cultural competence of the nurse is essential in assessing patients from other cultures for stress. With patients from cultural backgrounds different from that of the nurse, the nurse needs to obtain a knowledge base for each patient's culture, as well as to identify health beliefs and cultural values from that patient's world view. The patient's world view provides insight into how illness is interpreted and possibly treated. In such situations, the nurse may need to conduct a cultural assessment. For more information on the many cultural and spiritual aspects of health care, refer to [Chapters 21](#) and [22](#), respectively.

Stress can be manifested both physically and psychologically, and assessment should include appropriate questions to address both spheres. The nurse needs to closely observe the verbal responses, as well as the nonverbal behaviors exhibited by the patient. Nonverbal behaviors (such as irritability, agitation, anxiety, and poor eye contact) may prove more revealing than verbal responses. Lack of congruence between nonverbal behavior and verbal responses requires further exploration. See [Chapter 3](#) for additional information on congruence.

Stress may be caused by the loss of a job, the death of a family member or friend, the diagnosis of an illness, finances, and relationships. Many adults are in the “sandwich generation,” which means they are caring for their own children as well as their parents. Meeting the daily needs of their children as well as those of ill or aging parents while holding down full-time employment creates both physical and psychological stressors. Caregivers experience stress while providing assistance to others. The nurse should observe caregivers for symptoms of stress to determine the strength of patient support systems.

Symptoms of stress are manifested in multiple ways. Stressors may be exhibited as physical or psychosocial symptoms or through denial. Identifying the stressors and finding resolution will facilitate the patient's recovery. Stressors for one person are not necessarily stressors

for another. A stressor for one hospitalized patient may be concern that a pet is not receiving daily care. For another, absence from work may mean no income while hospitalized, with corresponding concern about food for the family.

The coping skills of the patient will determine whether positive or negative responses occur in these situations. Ineffective coping skills may lead to physical or psychological responses in reaction to the stressor and be manifested as symptoms in the nervous system, immune system, or endocrine system. It is necessary to assess for cardiovascular, respiratory, neurologic, musculoskeletal, gastrointestinal, urinary, cognitive, and emotional signs of stress.

Stress assessment tools, such as the Holmes-Rahe Social Readjustment Rating Scale (Fig. 32.3), are helpful for identifying stressors in the daily lives of patients. The nurse needs to examine stress assessment tools for cultural appropriateness before use.

Social Readjustment Rating Scale (SRRS)	
1. Death of a spouse	100
2. Divorce	73
3. Marital separation	65
4. Jail term	63
5. Death of a close family member	63
6. Personal injury or illness	53
7. Marriage	50
8. Fired at work	47
9. Marital reconciliation	45
10. Retirement	45
11. Change in health of family member	44
12. Pregnancy	40
13. Sex difficulties	39
14. Gain of a new family member	39
15. Business readjustments	39
16. Change in financial state	38
17. Death of a close friend	37
18. Change to different line of work	36
19. Change in no. of arguments with spouse	35
20. Mortgage over \$100,000	31
21. Foreclosure of mortgage	30
22. Change in responsibilities at work	29
23. Son or daughter leaving home	29
24. Trouble with in-laws	29
25. Outstanding personal achievements	28
26. Wife begins or stops work	26
27. Begin or end school	26
28. Change in living conditions	25
29. Revision of personal habits	24
30. Trouble with boss	23
31. Change in work hours or conditions	20
32. Change in residence	20
33. Change in school	20
34. Change in recreation	19
35. Change in religious activities	19
36. Change in social activities	18
37. Loan less than \$100,000	17
38. Change in sleeping habits	16
39. Change in no. of family get-togethers	15
40. Change in eating habits	15
41. Vacation	13
42. Holidays	12
43. Minor violation of laws	11

SCORING

Each event should be considered if it has taken place in the last 12 months. Add values to the right of each item to obtain the total score.

Your susceptibility to illness and mental health problems:

Low <149 Mild 150–200 Moderate 200–299 Major >300

FIGURE 32.3 Holmes-Rahe Social Readjustment Rating Scale. (From Holmes, T. H., & Rahe, R. H. (1967). The Social Readjustment Rating Scale, *J Psychosom Rese* 11(2), 213-218. Adjusted to reflect inflation.)

Safe Practice Alert

Verbalization of suicidal ideation or a suicide plan must be taken seriously. In the case of a hospitalized patient, one-on-one observation should be implemented to ensure patient safety, and referral to psychiatric services also should be implemented. Do not leave the patient alone.

LO 32.5 ♦ Nursing Diagnosis

People use coping skills to deal with stressors that threaten their physical and mental well-being. If people have poor or no coping skills, they generally use denial as a defense mechanism (Gagani, Gemao, Relajo, & Pilao, 2016).

International Classification for Nursing Practice (ICNP) nursing diagnoses for stress and coping include:

Difficulty Coping

- Supporting Data: Lack of confidence in ability to cope, reports of fatigue, lack of sleep, anxiety, negative attitude toward recovery

Anxiety

- Supporting Data: Change in health status, fatigue, difficulty concentrating

Caregiver Stress

- Supporting Data: Complexity of caregiver activities, fatigue, gastrointestinal upset, weight change

LO 32.6 ♦ Planning

Once the assessment data are analyzed, nursing diagnoses are identified and ranked in order of priority. Highest-priority nursing diagnoses are those of a life-threatening nature.

Examples of goals that address concerns related to stress and coping are:

- Patient will discuss possible coping strategies during weekly office visits.
- Patient will report increased ability to concentrate on care instructions before discharge.
- Caregiver will use respite care for his loved one once a week for the next month.

Collaboration among members of the health care team often is incorporated into the plan of care (Table 32.2) for a patient experiencing stress. Depending on the patient's situation, consultation with professionals from various health care and other specialties may be appropriate (Box 32.3).

TABLE 32.2
Care Planning

ICNP NURSING DIAGNOSIS WITH SUPPORTING DATA	NURSING OUTCOME CLASSIFICATION (NOC)	NURSING INTERVENTION CLASSIFICATION (NIC)
<i>Difficulty Coping</i> Lack of confidence in ability to cope Reports of fatigue, lack of sleep, and anxiety Negative attitude toward recovery	<i>Coping</i> Identifies multiple coping strategies	<i>Coping enhancement</i> Encourage the patient to identify own strengths and abilities.

From Bulechek, G., Butcher, H., Dochterman, J., et al. (Eds.). (2018). *Nursing interventions classification (NIC)* (7th ed.). St. Louis, MO: Mosby; Moorhead, S., Johnson, M., Maas, M., et al. (Eds.). (2018). *Nursing outcomes classification (NOC)* (6th ed.). St. Louis, MO: Mosby; ICNP is owned and copyrighted by the [International Council of Nurses \(ICN\)](#). Box 32.3

Interprofessional Collaboration and Delegation

Approaching Stress-Related Concerns Holistically

- A dietitian can be consulted to assess the patient's nutritional needs and develop a nutritional plan.
- To identify appropriate services and resources, a social worker is incorporated into the plan of care.
- Family members and assistive personnel may be involved in care planning to ensure a comprehensive approach.
- Pastoral care plays a significant role in addressing stress and anxiety issues when the patient has a preferred religion or strong faith background.
- If coordination of care between multiple health care disciplines is needed, a case manager is used.
- Patients with mental health issues related to current health problems or with chronic mental health or psychiatric issues need referral to a psychologist, psychiatrist, or advanced practice psychiatric nurse.

Addressing the needs of patients experiencing extreme levels of stress requires interventions by health care professionals, as well as family members, significant others, and friends who can play a vital role in assisting patients with coping skills. Nurses and other members of the patient's support system provide social support and encouragement, which prevents the patient from giving up or failing to try potential coping strategies. Encouragement from others prevents discouragement if there are relapses. Including patients in the development of their own individualized plans of care promotes the best chance of achieving positive outcomes. Nurses play a vital role in alleviating the potential damage that stress can cause to a person's physical and emotional health.

The conceptual care map for R. H. provided in Fig. 32.4 is partially completed to indicate how to use the map as a learning tool. Using it as an example, go to the website at <http://evolve.elsevier.com/YoostCrawford/fundamentals/> to complete Nursing Diagnoses 2 and 3.

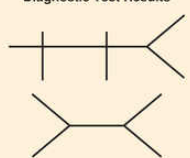

Medications	Conceptual Care Map Student name _____ Patient initials R. H. Date _____ Age _60_ Gender _M_ Room # _____ Admission date _____ CODE Status _Full_ Allergies _NKDA_ Diet _____ Activity _____ Braden score _____ Weight _____ Height _____ Religion _____		Laboratory Values/ Diagnostic Test Results 
	Admitting Diagnoses/Chief Complaint Follow-up visit 4 weeks after myocardial infarction		
IV Sites/Fluids/Rate	Assessment Data Retired architect owns home, financially stable. Recovering from second heart attack in the past 5 years. Lives in a two-story home with his wife; states that his wife "hovers" over him, taking care of him physically and protecting him from overexertion. Denies chest pain; notes minimal shortness of breath when climbing stairs. Appears downcast and somewhat depressed, and states, "I am going to die from this heart condition, so why treat it?" Complains of difficulty falling asleep and remaining asleep due to feeling anxious and jittery. Wife notes that her husband is stressed and frustrated; shares that she feels like she must take on her husband's responsibilities to avoid his overexerting himself and having another heart attack.		Treatments May resume all normal activities, including driving Cardiac rehabilitation three times a week
Past Medical/Surgical History Myocardial infarction 5 years ago			
Primary Nursing Diagnosis <i>Difficulty Coping</i>	Nursing Diagnosis 2	Nursing Diagnosis 3	
Supporting Data Appears downcast and somewhat depressed Reports lack of sleep and anxiety Fatalistic attitude toward recovery	Supporting Data	Supporting Data	
STG/NOC Patient will identify a minimum of three activities that he will take responsibility for immediately without his wife's assistance. <i>NOC: Coping</i> Identifies multiple coping strategies	STG/NOC	STG/NOC	
Interventions/NIC With Rationale 1. Assess patient's level of activity before the myocardial infarction to provide a baseline for establishing realistic rehabilitation goals. 2. Discuss physical, psychological, and sleep benefits of increased exercise to encourage active participation in rehabilitation and address identified patient stressors. 3. Establish gradual rehabilitation goals that the patient views as attainable to promote success and progressive improvement. <i>NIC: Coping enhancement</i> Encourage patient to identify own strengths and abilities. LO 32.7 ♦ Implementation And Evaluation

Interventions for stress management focus on decreasing stressors and improving or mobilizing coping strategies. Interventions need to be agreed on by the patient and the nurse to achieve the desired outcomes. Social support and emotional support from family members, significant others, or friends have been found to decrease stress ([Wolf, Warner Stidham, & Ross, 2015](#)) and influence adaptation to stressful situations ([Zeidner, Matthews, & Shemesh, 2016](#)). Psychosocial and physical symptoms of stress decrease with social support. Social support interventions also may focus on the family and community.

Managing stress and developing coping skills involve identification of both internal and external strategies. Internal strategies address the person's feelings associated with stress. External strategies seek to provide relief through social networking and mobilization of support systems. Working with patients, families, and communities to identify their general resistance resources when they are faced with stressors helps people use sources of support that already exist. [Antonovsky \(1979\)](#) identified general resistance resources as physiologic, tangible, emotional, attitudinal, interpersonal, and relational, as well as cultural, in nature. Examples of general resistance resources are the body's fight-or-flight response, money, health insurance, a positive attitude, hope for the future, adaptability, family, and social service agencies.

2. Identify five general resistance resources that R. H. has as sources of support.

Stress Management

Stress management is a holistic approach to stress reduction that incorporates a variety of individualized interventions to address specific sources of stress and complementary and alternative therapies, including relaxation therapies and mind-body therapy, to address the

negative emotional and physiologic effects of stress. Integrating relaxation and mind-body techniques into one's daily routine has been found to decrease pain, decrease blood pressure, increase a sense of well-being, improve quality of life, and increase the SOC (Clayton, Luxford, & Stupans, 2016; Sabourin, Watt, Krigolson, & Stewart, 2016; Wang, Ying, Wong, & Li, 2016).

Strategies for stress management must focus on the principles of balance, relaxation, and nutrition. To maximize the effectiveness of these strategies, a balance must exist between activity and rest. An imbalance of activity and rest contributes to further physiologic and physical signs of stress. The attainment of relaxation is accomplished through interventions, such as active and passive activity, exercise, yoga, biofeedback, and guided imagery. An optimal state of nutrition provides adequate nutrients for body functioning.

Time Management

When stress results from overwhelming perceived work and/or personal responsibilities, time management may be an effective intervention to help people address identified issues. Multitasking facilitated by technology has been identified as a significant source of stress that actually increases the time required to complete a task by as much as 25% (Schwartz, 2012). Research over the past two decades suggests that switching from task to task may reduce worker productivity as much as 40% and reduce cognitive ability (Goldfarb, Frobose, Cools, & Phelps, 2017; Plessow, Kiessel & Krischbaum, 2012). Loh and Kanai (2014) found a link between media multitasking and decreased gray matter density in the area of the brain responsible for cognitive and emotional control. Repetitive multitasking reduces a person's cognitive capability and may result in earlier mental decline and decreased acuity (Newland, 2016). Strategies such as prioritizing tasks, setting goals, increasing concentration skills, decreasing distractions, avoiding procrastination, setting boundaries, and maintaining self-discipline are time management interventions that people may use to address certain types of stressors.

Anger Management

Anger management strategies can help people deal with anger in a positive way, thereby reducing stress and potentially destructive actions and emotions that lead to compromised health and fractured relationships. Some anger management interventions include expressing feelings in a calm and nonconfrontational manner, exercising, identifying potential solutions, taking a time-out, forgiving,

diffusing the situation with humor, “owning” the negative feelings, and doing deep-breathing exercises (Mayo Clinic, 2018). These strategies may require appropriate training or counseling for effective application. People whose stress is exacerbated by feelings of anger should be encouraged to enroll in anger management classes or to seek professional counseling to identify and address concerns.

Nutrition

Research has revealed that stress often leads to unhealthy food choices that affect mood and impact a person's response to inflammation. Stress puts people at a greater risk for infection and delayed wound healing (Brown, 2016). Because inflammation plays a role in diseases (such as cancer, diabetes, depression, and cardiovascular disease), encouraging people to eat a balanced diet can facilitate stress reduction and improve physical well-being. Increasing the intake of fruit, vegetables, legumes, fish, poultry, and whole grains can enhance both psychological and physical responses to stress. Collaboration among the patient, the primary care provider (PCP), and a registered dietitian should be implemented by the nurse to identify a diet that will promote stress reduction while adhering to limitations, such as food exclusion, as required by specific health problems.

Support Groups

For some people, attending a support group is an effective intervention to reduce stress related to specific life circumstances. Patients who share a common disease process or loss often find solace in knowing they are not alone in their struggle. Nurses should consult with the patient's PCP to discuss the possibility of referral to a community- or facility-based support group. Often, the patient's assigned social worker can suggest available support groups in the person's local area.

More recently, online support services have become increasingly popular. If patients choose to become involved in online support groups, the nurse should provide guidance on how to evaluate the legitimacy of an online group. Support groups facilitated through national agencies (such as the American Cancer Society), research and health care institutions (such as the Cleveland Clinic and the Mayo Clinic), or professionals directly affiliated with health care or academic institutions should take priority over informally led or configured groups.

Complementary and Alternative Therapies

Complementary therapies frequently are used in conjunction with medical therapies. Alternative therapies are used in place of medical treatment. These types of interventions are useful when patients are experiencing physiologic and psychological responses to stress, such as increased heart rate, increased respiratory rate, and gastrointestinal symptoms. When coping mechanisms are ineffective or nonexistent, stress-related illnesses (such as gastrointestinal problems, pain, and heart disease) may occur. Relaxation techniques decrease the physiologic response by decreasing heart rate, respiratory rate, and gastrointestinal motility. Psychological responses to relaxation techniques include an increased sense of well-being and a decrease in depression and anxiety.

Some complementary and alternative therapies (such as, therapeutic touch, Reiki, biofeedback, and massage therapy) require additional certification and training, whereas muscle relaxation and guided imagery do not. Benefits of mind-body therapies include improved sleep, relaxation, and decreased pain (Mehi-Madrona, Mainguy, & Plummer, 2016; Wang, Ying, Wong, & Li, 2016). Mind-body therapies are also effective in reducing adolescent anxiety disorders, the most common adolescent mental health conditions in the United States (Fulweiler & John, 2018).

Relaxation Therapy

Relaxation therapy incorporates the use of nonpharmacologic techniques to reduce psychological or physiologic distress. The development of cognitive skills for use in stressful situations provides patients with the ability to recognize potential stressors and initiate relaxation techniques. Relaxation therapy increases awareness of muscle tension and incorporates interventions to decrease tension. Research findings indicate that it is an effective intervention in a variety of patient-care situations (Box 32.4). Progressive relaxation is implemented by having patients focus on muscles that are tensed and then intentionally relax those muscle groups. Typically, relaxation progresses from head to toe. With practice, the patient visualizes an image of the relaxed muscles and will be able to relax muscles from the mental image.

Box 32.4

Evidence-Based Practice and Informatics

Effectiveness of Relaxation Therapies

Research supports the use of relaxation therapies to treat a variety of conditions including:

- Anxiety associated with biopsy procedures, dental treatment, cancer, and chronic illnesses, such as heart disease
- Insomnia
- Pain during labor and cancer treatment
- Nausea during chemotherapy treatment
- Chronic headaches
- Chronic pain in children and adolescents
- Anxiety in older adults

National Institute of Health. (2017). National Center for Complementary and Integrative Health: *Relaxation Techniques for Health*. Retrieved from <https://nccih.nih.gov/health/stress/relaxation.htm#hed1>

Exercise

Exercise has been found to decrease stress level and cortisol levels and increase a sense of well-being in patients of all ages (Sabourin, Watt, Krigolson, & Stewart, 2016). Other benefits of exercise include improved muscle tone, weight management, and improvement of cardiovascular and pulmonary functioning. Increasing daily exercise may decrease the risk of physiologic as well as psychological issues, such as depression (Sabourin, Watt, Krigolson, & Stewart, 2016). Exercise does not need to be formal. Increasing exercise can begin as a daily walking program.

Sleep

Sleep is essential to engage in ADLs. Sleep is a restful state during which metabolism is reduced. Sleep disturbances resulting from stress and worry may be seen as difficulty falling asleep and/or remaining asleep, poor quality of sleep, frequent night awakenings, difficulty awakening, and daytime tiredness (Lee, Wuertz, Rogers, & Chen, 2013). Disturbances in sleep patterns can lead to irritability, fatigue, depression, tiredness, decreased ability to concentrate, and immunosuppression (Lee, Wuertz, Rogers, & Chen, 2013; Sabourin, Watt, Krigolson, & Stewart, 2016). Quiet music played at bedtime for older adults and hospitalized patients improves perceived sleep quality and daytime functioning (Shaw, 2016; Wang, Ying, Wong, & Li, 2016). Nurses can implement interventions to facilitate sleep, including limiting interruptions during the night and controlling the environment, such as lighting, noise, and room temperature.

Guided Imagery

Guided imagery focuses on positive external images, such as a patient's favorite vacation spot, to create a relaxed state. Guided imagery is a verbal form of instruction by the nurse or another clinician that directs the patient's attention away from upsetting thoughts. Well-conducted guided imagery improves physiologic functions, such as heart rate, respiratory rate, blood pressure, gastrointestinal motility, and hormonal levels (Lewandowski & Jacobson, 2013). Guided imagery can be incorporated into care to boost the immune system, decrease pain, and develop positive feelings.

Yoga

The practice of yoga includes physical exercises, breathing, and meditating to strengthen the body, mind, and soul. Engaging in yoga increases flexibility, improves endurance, decreases blood pressure, enhances breathing, promotes relaxation, and reduces stress (Thiyagarajan, Pal, Pal, et al., 2015). The benefits of yoga are attainable by patients across the life span, from children to older adults (Fig. 32.5). Yoga has been found to decrease inflammatory processes and increase the cortisol awakening response (which is known to increase stress resilience) (Cahn, Goodman, Peterson, et al., 2017).

FIGURE 32.5 Yoga combines physical exercise, breathing, and meditation to promote relaxation and reduce stress. (© thinkstock.com.)

Meditation

Meditation involves relaxing the body and quieting the mind by directing one's focus on a specific word, sound, or image. During

meditation, breathing is deep, slowed, and relaxed. Meditation can be used to decrease stress and anxiety in adults. Meditation affects the sympathetic nervous system by creating a state of relaxation, thereby lowering blood pressure, heart rate, breathing, metabolism, and blood flow to the muscles.

Mindfulness

Mindfulness-based stress reduction has become increasingly popular in recent years, especially within the medical community. It is a form of therapy that helps people become more aware of their thoughts, emotions, and motivating behaviors; this awareness has been shown to reduce levels of anxiety, pain, insomnia, and depression (Nascimento, Oliveira, & DeSantana, 2018; Yeung-shan Wong, De-xing, Ling, et al., 2017). Mindfulness combines the practices of meditation, body scan (progressive attention to various areas of the body), and yoga.

Biofeedback

Biofeedback involves the use of electronic devices to help the patient develop a learned awareness of the body's physiologic responses to unconscious, involuntary stressors. The learned awareness enables the patient to engage in voluntary actions to decrease the stress response. The patient learns the correlation between feelings, thoughts, and physiologic responses to stressors. Biofeedback requires a referral. Techniques are taught under the guidance of a biofeedback therapist with specialized training. It generally requires 8 to 10 sessions to master these skills. Biofeedback is used to treat problems, such as stress, addictions, and back pain.

Energy Therapy

Energy therapy uses the hands of the practitioner as a conduit to manipulate the negative energy fields of the patient and move the congestion or obstruction of the negative energy away from the energy field. Energy therapy has been shown to decrease stress, anxiety, and acute and chronic pain and to promote a sense of well-being. This technique enhances and promotes comfort in children, older adults, cancer patients, and dying patients. Therapeutic touch and Reiki are types of energy therapy, both of which require training.

Reiki

The hands of the practitioner transfer energy from the practitioner to the patient, thus restoring balance and harmony to the body during times of health issues.

Therapeutic touch

The use of touch through hand motions enhances energy fields to promote healing. Therapeutic touch decreases pain and anxiety, increases the sense of well-being, enhances the functioning of the immune system, promotes relaxation, and reduces depressive symptoms.

Eastern Medicine

Traditional Chinese medicine (TCM) originated more than 2000 years ago and is based on the balance of harmony and equilibrium of humans as they exist within a continually changing environment ([National Institute of Health, 2018](#)). In TCM, health is a balance of yin and yang (two opposite forces of nature). Imbalance between yin and yang causes illness and disease. Herbal medicine, massage, acupuncture, and Feng Shui are several of the many TCM modalities.

3. Name three stress management therapies that could benefit R. H. Discuss the best way to incorporate these therapies into R. H.'s plan of care.

Crisis Intervention

Crisis intervention is short-term assistance provided at a time of physical or emotional upheaval with the goal of helping the person in distress to regain equilibrium. Crisis intervention involves immediate action to help reduce the impact of a traumatic event in the affected person's life. When people are overwhelmed by the circumstances confronting them, crisis intervention strategies can help them adapt and restore their ability to function. Crisis intervention involves simple, innovative, accessible, practical, and immediate actions that ensure a person's safety and mental well-being, such as providing counselors for school students after the sudden death of a classmate or encouraging a person to drive as soon as possible after involvement in a fatal accident that took the life of a friend. Nurses, doctors, clergy, counselors, and community workers (such as firefighters and police) often are called on to provide crisis intervention at times of natural disasters, tragic

accidents, or unexpected loss. Lack of appropriate assistance for a person in crisis to help reestablish a sense of equilibrium may lead to development of mental illness. Crises should be approached by professionals as teachable moments in which people have great openness to change and growth.

QSEN Focus!

Implementing strategies that empower patients and their families to make healthy decisions to address identified stressors is central to patient-centered care.

Evaluation

It is the nurse's responsibility to evaluate the outcome of interventions that are implemented into a patient's plan of care. A point to keep in mind is that situations of acute stress resolve more quickly than those of chronic stress. Once stress decreases, patients typically report feeling better, sleeping more soundly, and feeling less anxious. It is important to observe patient behaviors and compare them with self-reported accounts. Patients should be reminded to continue using stress reduction techniques to maintain a feeling of well-being. Patients may require continued care for stress management after discharge from a health care setting. Because modification of coping skills for stress management is a slow process, sometimes requiring months or years, referrals may need to be made for long-term follow-up assessment and treatment.

4. What suggestions should the nurse make to Mrs. H. regarding her husband's care?

LO 32.8 Stress and Nursing

The profession of nursing requires a constant vigilance to the needs of others. The demands of workplace stress can lead to depression, compassion fatigue, **burnout** (mental or physical exhaustion due to constant stress or activity), and decreased job satisfaction. Researchers note that nurse burnout results from a variety of factors including excessive workload, perceived powerlessness, and incivility in the workplace (Fida, Laschinger, & Leiter, 2018; Dyrbye, Shanafelt, Sinsky, et al., 2017). Research has demonstrated a relationship among nurse burnout and patient safety, patient dissatisfaction, and healthcare-associated infections (Ross, 2016; Berkowitz, 2016; Cimiotti, Aiken, Sloane, et al., 2012).

Compassion fatigue occurs when deeply caring and empathetic nurses become overwhelmed by the constant needs of patients and families. Research indicates that nurses with less experience and younger nurses (born between 1988 and 2000) are at high risk for compassion fatigue compared with more experienced, older colleagues (Kelly, Baker, & Horton, 2017). Reported manifestations include mood swings, avoidance of working with some patients, frequent sick days, irritability, reduced memory, poor concentration, and a decreased ability to show empathy. Physical signs of compassion fatigue are similar to those exhibited by nurses experiencing burnout, including headaches, digestive upset, muscle tension, fatigue, and in some cases chest pain or palpitations. Interventions designed specifically to prevent nurse burnout and address compassion fatigue include mentoring programs, availability of quiet areas on the nursing unit for relaxation, mind-body therapies, availability of pastoral care, the sharing of feelings with trusted colleagues, and promotion of work-life balance (Kelly, Baker, & Horton, 2017; Lombardo & Erye, 2011).

To care most effectively for others, nurses must first take time to care for themselves. Many of the stress reduction interventions incorporated into patient care plans can be effective in addressing the stressors faced by nurses. Exercise, balanced nutrition, and mindfulness therapy have been shown to help health care professionals in coping with the demands of patient care. Some hospital systems offer worksite fitness facilities or health club memberships and Employer Assistance programs that include counseling services, to help their employees cope with work stress.

The **American Nurses Association (ANA)** declared 2017 as the Year of the Healthy Nurse with an emphasis on nutrition, exercise, sleep, and overall wellbeing. The Healthy Nurse, Healthy Nation Grand Challenge

focuses on five wellness indicators including: rest, nutrition, physical activity, quality of life, and safety (ANA, 2017). ANA's Health Risk Appraisal in 2016 indicated that within the population of nurses and nursing students:

- The average body mass index (BMI) was 27.6 (overweight)
- 12% nodded off while driving in the previous month
- Fewer than 20% consumed the recommended daily amount of fruits and vegetables
- Less than 50% engaged in recommended muscle-strengthening exercise (ICG & ANA, 2016)

Resources related to stress reduction and work-life balance, available at <https://www.nursingworld.org/practice-policy/hnhn/2017-year-of-the-healthy-nurse>, support efforts for nurses to improve their individual emotional, spiritual, and professional well-being.

Reducing daily stressors through the use of healthy coping strategies promotes wellness and emotional stability that enhance a nurse's ability to care. In situations in which stressors may become overwhelming, such as the occurrence of multiple patient deaths on a unit within a short period of time, it is important for nurses to collaborate with their professional counseling colleagues, who can help guide the healing process. Taking the time to cope effectively with stress will ultimately strengthen the nurse's ability to provide empathetic patient care and thrive in the stressful health care environment.

Summary of Learning Outcomes

LO 32.1 *Identify the key concepts associated with the body's physiologic and psychological responses to stress:* The fight-or-flight response is a physiologic response to physical or psychological stress that activates the autonomic nervous system. The body's GAS consists of three stages: alarm reaction, resistance, and exhaustion. Allostasis is how homeostasis is reestablished. Stress appraisal, SOC, and general resistance resources all contribute to a person's response to stress.

LO 32.2 *Describe psychological and physiologic responses of the nervous, endocrine, and immune systems to stress:* Stress appraisal influences the unique response of each person and reflects the complex psychological processing in the stress response. Increased cardiac output, elevated blood pressure, and increased blood flow to muscles result from direct nervous system stimulation and from the secretion of hormones during stress. Endocrine responses to stress include alterations in blood flow to muscles, at the expense of some internal organs, and increased clotting time to protect circulation to vital organs when blood loss occurs. Pain and inflammation, are the initial responses to stress by the immune system.

LO 32.3 *Describe the effects of stress on health:* In certain stressful situations, parasympathetic, rather than sympathetic, stimulation is the primary event. In such circumstances, increased gastrointestinal motility and bronchial constriction may occur,

resulting in serious stress-induced physical conditions.

LO 32.4 *Demonstrate assessment techniques for recognizing signs and symptoms of stress:* Interviewing patients and observing for nonverbal signs of stress are critical assessment strategies that the nurse can implement during the assessment phase. The use of stress assessment tools adapted for specific populations may also be helpful.

LO 32.5 *Identify stress-related nursing diagnoses:* *Difficulty Coping, Anxiety, and Caregiver Stress* are some nursing diagnoses that may be used in addressing patient needs associated with stress.

LO 32.6 *Articulate stress reduction goals and patient outcomes:* Goals for stress reduction should include realistic and measurable patient outcomes that reflect increased patient control of situational stress.

LO 32.7 *Develop patient-centered care plans with interventions designed to address stress-related conditions and guide evaluation criteria:* Including interventions (such as exercise, improved dietary intake, and a variety of stress management strategies in stress-related care plans) is most effective when patients have major input in choosing which treatments should be implemented.

LO 32.8 *Discuss the potential impact of stress on nurses:* The demands of workplace stress can lead to depression, compassion fatigue, burnout, and decreased job satisfaction.

Review Questions

1. The nurse has been assigned the same patients for the past 4 days. Two of the patients demand a great deal of attention, and the nurse feels anxious and angry about being given this assignment again. What action would demonstrate the most effective way for the nurse to cope with the patient care assignment?
 - a. Share complaints about the assignment with the nurse manager.
 - b. Prioritize the patients' needs, and identify a specific time period for care for each patient.
 - c. Talk with the patients, and explain that they cannot expect so much personal attention.
 - d. Trade assignments with another nurse who is unaware of the concerns regarding the patient assignment.
2. A patient is newly diagnosed with diabetes and requires insulin injections. He requests information about classes offered by the diabetes educator. Which type of coping technique is this patient using?
 - a. Emotion-focused
 - b. Problem-focused
 - c. Avoidance
 - d. Denial
3. Which statements by a patient would indicate the use of effective coping strategies? (*Select all that apply.*)
 - a. "Each month, my wife and I attend a support group for parents of children with autism."

- b. "Talking with my spiritual adviser may challenge my thinking on how best to handle this situation."
 - c. "I've invited my son to join me for drinks at the bar each night on his way home from work so that we can spend more time together."
 - d. "We are looking into joining the new health club facility in our neighborhood."
 - e. "After working all day, I eat dinner in front of the television while my family sits at the kitchen table."
4. When using a stress assessment tool with a patient from another culture, what factors must the nurse take into consideration? (*Select all that apply.*)
- a. Specific methods of managing stress are revealed in using stress assessment tools.
 - b. Stress assessment tools should be used only for persons living in North America.
 - c. Stress assessment tools may not be appropriate for all people of all ages.
 - d. Resistance resources become evident when stress assessment tools are analyzed.
 - e. Adaptations may need to be made to the assessment tool based on circumstances.
5. Two adult siblings are caring for their ill mother, who requires 24-hour care. She needs assistance with feeding, bathing, and toileting. One of the siblings takes time to exercise after work, whereas the other goes directly to the mother's home before and after work each day. The nurse recognizes that people may react differently to the same stressors depending on which factors? (*Select all that apply.*)

- a. Individual coping skills
 - b. Type of identified stressor
 - c. Amount of perceived stress
 - d. Personal appraisal of the stressor
 - e. Hair color, gender, and skin type
6. A male patient is told that he may have colon cancer. Which response by the patient best indicates that his initial appraisal of the situation is primarily a challenge to be met?
- a. Requesting information on various treatment options
 - b. Demanding to see another physician immediately
 - c. Storming out of the gastroenterologist's office
 - d. Yelling at the nurse who is scheduling his colonoscopy
7. A 25-year-old female patient demands that her mother or father be present during all blood testing. Which defense mechanism could the nurse document as being used by this patient?
- a. Sublimation
 - b. Repression
 - c. Projection
 - d. Regression
8. In the immediate postoperative period after open-heart surgery, a patient who is not a diabetic has elevated blood glucose levels. What physiologic stress response best describes the rationale for the patient's increased blood sugar?
- a. Release of epinephrine

- b. Circulation of endorphins
 - c. Increase in corticosteroids
 - d. Secretion of corticotropin-releasing hormone (CRH)
9. Which short-term goal would be most appropriate for a patient with the nursing diagnosis *Anxiety* with supporting data, including upcoming diagnostic tests, expressions of concern, and pacing around the room?
- a. Patient will discuss specific aspects of concern.
 - b. Nurse will administer prescribed antianxiety medication.
 - c. Patient will understand diagnostic test procedures.
 - d. Nurse will describe test procedures in detail to allay concerns.
10. Which intervention would be most appropriate for the nurse to include in the care plan for a patient who is experiencing constipation and increased heart and respiratory rates?
- a. Time management
 - b. Decreased grain intake
 - c. Relaxation therapy
 - d. Regimented exercise

CHAPTER 33

Sleep

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 33.1 Explain the physiology and functions involved in sleep.
- LO 33.2 Discuss characteristics of common sleep disorders.
- LO 33.3 Summarize assessment techniques for determining sleep patterns.
- LO 33.4 Identify nursing diagnoses for patients with sleep disturbances.
- LO 33.5 Determine patient goals based on specific sleep problems.
- LO 33.6 Implement, and evaluate nursing care related to sleep promotion.

KEY TERMS

- bruxism, p. 728**
- cataplexy, p. 724**
- circadian rhythms, p. 722**
- dyssomnias, p. 724**

Case Study

Jack Barnes (J. B.) is a 51-year-old male who owns a small business. All of his employees are family members. He recently had to lay off two of his five employees and increase his own working hours. The stress of dealing with the financial losses and laying off of family members has caused a change in his overall health and sleep habits. His day-to-day work involves managing all aspects of the business and employees and handling customer relations. He drinks approximately six cups of coffee a day, smokes two packs of cigarettes a day, has three or four alcoholic drinks at night to “relax,” and has gained more than 30 pounds in the last year. He arrives at the clinic, accompanied by his wife, requesting “something to help me sleep.”

Assessment data for J. B. reveal a man who looks older than his stated age, has dark circles around puffy eyes, and yawns frequently during the assessment. His height is 180.3 cm (71”) and his weight is 117.7 kg (259 lbs.), body mass index (BMI) 36.1. Vital signs are: T 36.3° C (97.4° F), P 96 and regular and steady, R 26 and slightly labored, and BP 174/96, with a pulse oximetry reading of 90% on room air. He has no complaints of pain or discomfort at this time.

J. B. reports daytime sleepiness, trouble falling asleep, headache when awakening in the mornings, difficulty concentrating, and two minor car accidents recently. His wife states that he is irritable, goes to bed late, sleeps for only 4 or 5 hours at night, is very restless in bed, and has periods of not breathing followed by periods of loud snoring. He currently is taking no prescription medications.

Refer back to this case study to answer the critical-thinking questions throughout the chapter.

Sleep is a naturally occurring altered state of consciousness regulated by the central nervous system. Without healthy sleep, concentration and judgment become impaired, and participation in daily activities

decreases. People who experience an acute or chronic illness often need more rest and sleep. To promote adequate sleep and rest for patients, the nurse needs to understand the characteristics of sleep, factors that influence sleep, the way to assess for sleep disorders, and the use of interventions to support the practice of good sleep habits, known as *sleep hygiene*, for patients of all age groups.

Lo 33.1 Normal Structure and Function Involved in Sleep

Physical and emotional health depend on proper nutrition, adequate exercise, and the right type and amount of sleep and rest. Sleep is a universal human need. Many Americans suffer from sleep disorders.

During sleep, both awareness of and reaction to the environment are decreased. Historically, it was thought that sleep was a period of time during which the body was at complete rest and activity was dormant. However, sleep has several stages, all of which are important to a person's health and restoration of cells, as well as processes, such as memory and concentration ([National Sleep Foundation, 2018](#)).

Physiologic and Psychologic Changes Surrounding the Sleep Cycle

Although the effects of sleep on the body are not well understood, well-recognized physiologic and psychologic changes occur with adequate sleep. The heart beats 10 to 20 fewer times per minute when sleeping, and respirations, blood pressure, and muscle tone all decrease during sleep ([McCance & Huether, 2017](#)). **Rapid eye movement (REM) sleep** occurs during deep sleep and is manifested by quick scanning movements of the eyes that are associated with dreaming. REM sleep is associated with memory storage, learning, increased cerebral blood flow, and epinephrine release ([McCance & Huether, 2017](#)). During **non-rapid eye movement (NREM) sleep**, in which REM does not occur, physiological activity is reduced; brain waves, breathing, and heart rate slow; and blood pressure drops ([National Sleep Foundation, 2018](#)). The effect of sleep on psychologic well-being is best illustrated by the diminished mental functioning associated with sleep deprivation. People with too little sleep have difficulty making decisions, experience decreased concentration, and become emotionally irritable. Accidents and injuries are common in people who drive or operate heavy machinery while sleep-deprived.

Many physiologic rhythms fluctuate in preparation for activity or rest. Body temperature, cortisol, and melatonin levels change in preparation for waking or sleeping. For example, in anticipation of daytime activity, cortisol levels increase around 4 a.m. and peak around 6 a.m. Core body temperature, which typically is coupled closely with activity rhythm, starts to increase after the minimum core temperature level is reached between 2 a.m. and 4 a.m., in anticipation of activity.

Activity and core temperature peak at approximately 4 p.m. Conversely, a rapid decline in core temperature normally occurs approximately 2 hours before sleep onset. Melatonin is the hormone believed to induce sleep in humans. Although core temperature and cortisol levels decrease with the onset of darkness, melatonin levels increase. Eight hours of uninterrupted sleep are more easily achieved when sleep begins approximately 6 hours before the minimum temperature is reached (Berger & Hobbs, 2006).

Neurotransmitters and the Reticular Activating System

Sleep is a complex process regulated by the reticular activating system (RAS) and neurotransmitter interactions. The RAS receives sensory impulses from the spinal cord and relays motor impulses to the thalamus and all parts of the cerebral cortex. As messengers of the nervous system, neurotransmitters provide communication between neurons. The neurotransmitters, acetylcholine and norepinephrine, influence REM sleep; the neurotransmitters, serotonin and gamma aminobutyric acid (GABA), affect NREM sleep.

Circadian Rhythms

Biologic rhythms exist in plants, animals, and humans. In humans, these biorhythms, along with internal and external factors, affect sleep. The most familiar rhythm is the day-night, 24-hour circadian rhythm cycle. **Circadian rhythms** influence patterns of biologic and behavioral functions. Some creatures are diurnal, or primarily active during the day, whereas others are nocturnal, with most of their activity during the night.

Nerve cells within the hypothalamus control the 24-hour circadian rhythms, which affect body temperature, endocrine functions, blood pressure, sleep, and other functions. Factors such as daily routines, work schedules, social commitments, alarm clocks, and noise affect the circadian rhythm and sleep-wake cycle. Melatonin, synthesized in the pineal gland, regulates the circadian phase of sleep and is closely related to light conditions. The sleep-wake circadian rhythm is further affected by the light-dark cycle of the natural environment as input of surroundings is received by the retina of the eyes (Carley & Farabi, 2016).

Sleep Cycles

Humans spend approximately one-third of their lives asleep. At night, an adult normally falls asleep within 10 minutes and then goes through a sequence of four sleep stages. **Polysomnography** is the recording of brain waves and other physiologic variables, such as muscle activity and eye movements, during sleep. A normal polysomnograph shows a sleep sequence of three NREM stages and one REM stage. NREM sleep alternates with REM sleep in time intervals of approximately 90 minutes, and a normal sleep pattern consists of three to five cycles of sleep each night (Table 33.1). Quality of sleep is affected by frequent waking, pain, and shortened REM stage of sleep.

TABLE 33.1
Sleep Stages

STAGE IN SLEEP CYCLE	DESCRIPTION
Non-rapid eye movement (NREM) 1	<ul style="list-style-type: none"> • Lightest level of sleep, between sleep and wakefulness • Vital signs and metabolism begin to decrease/slow down • Easy arousal by external stimuli, such as noise • Feeling of drowsiness • Lasts a few minutes • May occur during the day as “resting my eyes”
NREM 2	<ul style="list-style-type: none"> • Relaxation increases • Sleep becomes deeper • Snoring may occur • Relatively easy arousal • Physiologic functions continue to slow • Accompanied by occasional small muscle jerks • Lasts 10-20 min
NREM 3	<ul style="list-style-type: none"> • Deepest stage of sleep, called slow-wave or delta wave sleep for the type of brain waves seen during this type of sleep • More difficult arousal and rare movement • Muscles relaxed • Vital signs decrease, but regular rhythms/patterns maintained • Restorative processes (such as the release of growth hormone) occur • Sleep walking, somnambulism, and nocturnal enuresis may occur • Strong stimuli needed for arousal • Amount of time spent in slow wave sleep depends on how long since a person slept. • Lasts approximately 30-60 min
Rapid eye movement (REM)	<ul style="list-style-type: none"> • Occurrence of vivid, colorful dreaming (less vivid dreaming may occur in other stages) • Starts approximately 90 min after sleep is initiated • Autonomous response causes rapid eye movements, fluctuating heart rate and respirations, and increased blood pressure • Muscle tone decreased • Gastric secretions increased • Very difficult arousal • Duration of REM sleep increases with each sleep cycle and averages 20 min

Sleep Rhythms

Polysomnography recordings of sleep show recurring patterns of sleep lasting approximately 90 minutes. The usual sleep sequence for a person is a fairly rapid progression through NREM stages 1 through 3, back through NREM stage 2, and then into REM sleep (Fig. 33.1). During the early hours of sleep, NREM stage 3 is longer; in the later hours of sleep, REM sleep may last as long as 45 minutes of the cycle. If someone is fully awakened and goes back to sleep, the cycle begins again with NREM stage 1.

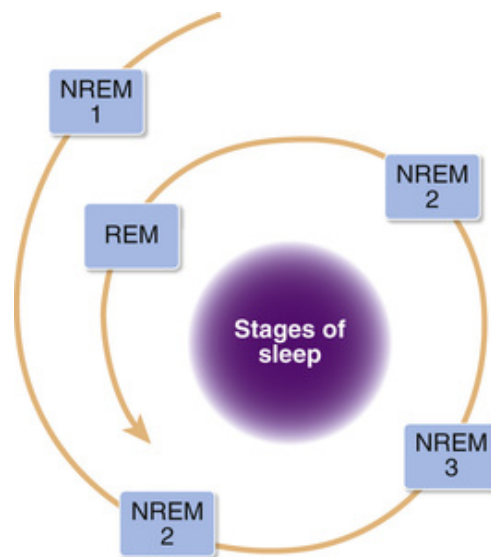

FIGURE 33.1 The sleep cycle. *NREM*, Non-rapid eye movement; *REM*, rapid eye movement.

Patterns of Sleep Throughout the Life Cycle

The overall amount of time spent sleeping and the amount of time spent in each stage of sleep vary among people, especially with age. Although sleep is affected by several variables, sleep changes follow a predictable age-related pattern (Box 33.1). Newborns require the most sleep of all age groups, and elderly people require the least sleep.

Box 33.1

Diversity Considerations

Life Span

Newborn

- Newborns should sleep in 2- to 4-hour blocks between feedings resulting in 14- to 17-hour sleep duration each day.
- Teach parents to position newborns and infants on the back for sleeping, to decrease the risk of sudden infant death syndrome (SIDS) ([Box 33.2](#)).

Infant

- Infants sleep 12 to 15 hours at night, with naps during the day.
- Half of their sleep is in lighter stages.
- Sleep patterns are unique for each child. The general pattern consists of sleeping, awakening to eat, and sleeping again.
- Caution against using blankets, pillows, and bumpers in cribs, to decrease suffocation risk.
- Teach that eye movements, grimacing, and body movement are normal features of sleep at this age.
- Encourage parents to have infants sleep in their own cribs. According to the [American Academy of Pediatrics 2011](#) revised guidelines on SIDS, the infant may sleep in the parents' room for the first year of life if the infant sleeps in his or her own crib and not with parents or siblings.
- Older infants may safely roll to their stomachs during sleep, because they have developed good head control.

Toddler and Preschooler

- Children in this group sleep 11 to 14 hours a day.
- The sleep-wake cycle usually is established by the age of 2 to 3 years.
- Sleep needs fluctuate with growth spurts.
- A nap during the day can restore energy.
- Toddlers and preschoolers may exhibit resistance to going to bed.
- They may be moved out of the crib to a bed at approximately 2 years of age.
- Bedtime rituals are important. Teach parents to establish a regular bedtime routine and consistently follow it.
- Address safety needs that arise when children are able to get out of bed. For example, a safety gate across a doorway may be needed to protect a child from stairs or other hazards should the child get up.

- Educate parents on how to address a child's fear of the dark (by using a nightlight) or nightmares (by soothing the child but allowing the child to return to sleep).

School-Age Child

- School-age children sleep 9 to 11 hours a night. Naps are rare.
- The occurrence of nightmares decreases with age.
- The stress of starting school may disrupt the sleep pattern.
- Less sleep is needed by the age of 11 to 12 years, so bedtime may be extended.
- The bedtime routine is still important.

Adolescent

- Adolescents need 8 to 10 hours of sleep each night.
- Sleep patterns may change to waking later in the morning, with occasional naps.
- Males may experience nocturnal emissions (“wet dreams”).
- Adolescents who use technology prior to sleep may experience daytime sleepiness with impaired alertness and functioning (Johansson, Petrisko, & Chasens, 2016).
- Complaints of tiredness or poor school performance may be related to inadequate sleep.

Adult

- Adults sleep 7 to 9 hours a night.
- Most adults tend to continue sleep patterns established when younger.
- Adults may begin to have more night awakenings.
- Teach adults about sleep hygiene and nonpharmacologic measures (especially stress reduction) to enhance sleep patterns.
- Discourage the long-term use of sleep medications.

Older Adult

- Older adults sleep approximately 7 to 8 hours a night.
- Deeper stages of sleep are shortened, resulting in less restorative sleep.

- The first rapid eye movement (REM) stage is longer.
- Older adults awaken more at night and take longer to go back to sleep.
- A decline in health or the use of medications may interfere with sleep.
- Encourage older adults to maintain the usual bedtime and routines as much as possible.
- Older adults should exercise caution when using sleep medications.
- When hospitalized, an environment that is warm and safe (night light, call light) encourages relaxation for the older adult.
- Resolving underlying health issues, if possible, will enhance sleep (Hirshkowitz, Whiton, Albert, et al., 2015).

Gender

- Adult males are at higher risk for development of obstructive sleep apnea (OSA). Children and adult females are at lower risk for the disorder.

Culture and Ethnicity

- In some cultures, a family bed in which children sleep with parents is common. Instruct families about the dangers of infants sleeping with adults.

Morphology

- People who sleep less than average are more likely to be overweight, develop diabetes, and eat a high-calorie, high-carbohydrate diet (NIH, 2011).
- Obesity predisposes affected people to obstructive sleep apnea (OSA).

Box 33.2

Evidence-Based Practice and Informatics

Sudden Infant Death Syndrome

Sudden infant death syndrome (SIDS) was first formally defined in 1969 as the sudden unexpected death of an infant younger than 1 year of age that remains unexplained after a thorough postmortem investigation.

- SIDS is the leading cause of death among infants 1 to 12 months of age ([National Institute of Child Health and Human Development, n.d.](#)).
- It has a devastating impact on surviving family members.
- The etiology remains largely unknown.
- Risk factors include the infant's sleeping on the stomach, being exposed to cigarette smoke, and/or sleeping in the same bed as the parents, as well as premature and multiple-birth babies, soft bedding in cribs, a sibling with SIDS, poor or no prenatal care, and drinking and drug use during pregnancy ([National Institute of Child Health and Human Development, n.d.](#)).
- The most important modifiable SIDS risk factor appears to be prone sleeping.
- Dramatic decreases in SIDS rates (reaching 50%) have been observed in countries that actively discourage prone sleeping and emphasize the supine (back) sleeping position.
- Instructions from health care providers about prone sleeping are essential. Recommendations on creating a safe sleep environment include ([American Academy of Pediatrics, 2011](#)):
 - Placing the baby on his or her back on a firm sleep surface (such as a crib or bassinet with a tight-fitting sheet)
 - Avoid use of soft bedding, including crib bumpers, blankets, pillows and soft toys
 - Share a bedroom with parents, but not the same sleeping surface for at least the first 6 months and preferable the first 12 months
 - Avoid baby's exposure to smoke, alcohol, and illicit drugs
- Parent and caregiver information, "About SIDS and Safe Infant Sleep," is available from National Institute of Child Health and Human Development at <https://www1.nichd.nih.gov/sts/about/Pages/default.aspx>

Infant supine in safe sleeping position.

Lo 33.2 Altered Sleep

Sleep alterations, if left unaddressed, can cause disturbed sleep, resulting in insomnia, abnormal movements or sensations during sleep, or excessive daytime sleepiness. People deprived of REM sleep become agitated and impulsive; deprivation of NREM sleep results in withdrawal and vague physical complaints. Sleep disorders are classified into dyssomnias, parasomnias, and secondary sleep disorders on the basis of their underlying cause (Table 33.2).

TABLE 33.2
Sleep and Sleep-Related Disorders

CATEGORY	SPECIFIC DISORDER/UNDERLYING CAUSE
Dyssomnias	<ul style="list-style-type: none">• Insomnia• Obstructive sleep apnea (OSA)• Shift-work sleep disorder• Time zone change (jet lag)• Hypersomnia• Restless legs syndrome• Narcolepsy• Sleep deprivation
Parasomnias	<ul style="list-style-type: none">• Nocturnal enuresis• Somnambulism• Sleep terrors• Bruxism
Secondary sleep disorders	<ul style="list-style-type: none">• Physiologic effect of medical conditions: heart failure, chronic obstructive pulmonary disease, pain, or gastric reflux disease• Hospitalization with a serious illness• Mental health disorders:<ul style="list-style-type: none">• Depression• Anxiety• Fear

Dyssomnias

Dyssomnias are disorders associated with getting to sleep, staying asleep, or being excessively sleepy. Decreases in the amount or changes in the timing of sleep result in daytime sleepiness, poor concentration, and a feeling of not being rested. Causes of dyssomnias include too much napping, anxiety, depression, high levels of stimulation at bedtime, medication use, shift work, and hyperthyroidism.

Circadian Rhythm Sleep Disorders

A disruption of the normal circadian sleep pattern occurs when the person cannot sleep when sleep is wanted, needed, or expected. This disorder is common in shift work and time zone change (jet lag) situations (Box 33.3). The potential consequences of circadian rhythm disturbances include depression, sexual dysfunction, memory difficulties, high blood pressure, obesity, and an increased risk for accidents.

Box 33.3

Ethical, Legal, and Professional Practice

Effects of Shift Work on Safety

Shift work generally is defined as work hours that are other than the day shift. The definition includes lengthy (e.g., 12-hour) and extended shifts.

Since the 1960s, scientists have been examining the effect of conditions, such as air travel and shift work, on biological functions, activity, and rest. The body's internal clock is cued by the light–dark cycle, and shift work disrupts the pattern. Possible results may include sleep disturbances, increased accidents and injuries, and social isolation. Complications of fatigued nurses include slowed reaction time, medication errors, poor teamwork and compromised problem solving. For example, after a 12-hour nursing shift, the risk of making a medication error or incurring a needlestick can be double that associated with an 8-hour shift.

Nurses working various shifts can adopt countermeasures, such as taking power naps, eliminating overtime on 12-hour shifts, and completing challenging tasks early in the shift to reduce patient care errors. Other strategies that can help adaptation to shift work include:

- Take responsibility for obtaining a minimum of 6 hours of sleep each 24-hour period.
- Maintain a regular sleep schedule when working and on nights off.
- Include a 4-hour “anchor” sleep time during which sleep is scheduled whether on or off work. For example, after working, sleep from 8:30 a.m. to 4:30 p.m., and on days off, sleep from 4:30 a.m. to 12:30 p.m. The anchor sleep time is from 8:30 a.m. to 12:30 p.m.
- Wear dark glasses that block blue light when driving home after night work.

- Seek exposure to bright light (sunlight is best) as soon as possible after waking.
- Before the first night shift, power-nap 30 to 90 minutes before leaving for work.

Adapted from Berger, A. M., & Hobbs, B. B. (2006). Impact of shift work on the health and safety of nurses and patients, *Clin J Oncol Nurs* 10(4):465-471; Kelton, D., Kingsley, E., Davis, C., et al. (2014). Running on empty? The facts about nursing fatigue, *Nurs Made Incred Easy!* March/April: 45-49.

Insomnia

Insomnia is the most common dyssomnia and is characterized by difficulty in falling asleep or staying asleep, sleep that is too light, or early-morning awakenings. Concern with the problems related to not getting enough sleep further interferes with sleep, contributing to an ongoing cycle of sleep disturbance. The occurrence of insomnia increases with age, and the disorder affects more women than men ([National Institute of Neurological Disorders and Stroke \[NINDS\], 2018b](#)). Short-term insomnia usually can be traced to acute stress or lifestyle changes and often is self-limiting. Insomnia can lead to symptoms of sleep deprivation and daytime fatigue, which can cause impairment in work, social, and other areas of functioning. Medications for insomnia do not deal with the cause of the sleep problem, and prolonged use can create drug dependency.

Narcolepsy

Narcolepsy is a chronic neurologic disorder caused by the brain's inability to regulate the sleep-wake cycle normally, resulting in an uncontrollable desire to sleep. This sleep starts with the REM phase. At various times throughout the day, people with narcolepsy experience overwhelming sleepiness and fall asleep for periods of seconds to several minutes. These sleep episodes can occur at any time; accordingly, the disorder can be very disabling. People may involuntarily fall asleep while at work or at school, or when having a conversation, playing a game, eating a meal, or, most dangerously, driving an automobile or operating other types of potentially hazardous machinery. In addition to daytime sleepiness, three other major symptoms frequently characterize narcolepsy: **cataplexy**, or the sudden loss of voluntary muscle tone; vivid hallucinations during sleep onset or on awakening; and brief episodes of total paralysis at the beginning or end of sleep.

Scientists now believe that narcolepsy results from disease processes affecting brain mechanisms that regulate REM sleep. For normal sleepers, a typical sleep cycle begins with NREM sleep and undergoes transition to REM sleep. People with narcolepsy frequently enter REM sleep within a few minutes of falling asleep. The diagnosis of narcolepsy is confirmed by sleep diagnostic tests—the polysomnogram and the multiple sleep latency test.

Hypersomnia

Hypersomnia is excessive daytime sleepiness lasting at least 1 month that causes impairment in the ability to function in occupational or other areas of the affected person's life. Even after 8 to 12 hours of sleep each night, the person still experiences trouble awakening in the morning. Hypersomnia can be caused by medical conditions, such as some kidney or liver disorders, diabetic acidosis, central nervous system damage, or hypothyroidism.

Sleep Apnea

Sleep apnea is a condition in which the person experiences the absence of breathing (apnea) or diminished breathing during sleep between snoring intervals. It is characterized by a lack of airflow through the mouth and nose for at least 10 seconds, lasting up to 2 minutes, during sleep. The most common type is **obstructive sleep apnea (OSA)**, which affects 12 million to 18 million people in the United States.

OSA involves collapse of the upper airway despite respiratory effort (Fig. 33.2). The affected person continues to try to breathe, evidenced by chest and abdominal movements with loud snoring or snorting sounds. Diaphragmatic movements become stronger until the obstruction is relieved. Increased carbon dioxide levels in the blood that accumulate during the apneic episodes cause the person to awaken, and these awakenings can occur hundreds of times each night. Prolonged sleep apnea can cause an increase in blood pressure, leading to cardiac arrest. Cardiac arrhythmias, pulmonary hypertension, and left-sided heart failure can result from prolonged sleep apnea. The affected person's sleep partner's sleep may be disrupted by the snoring or by the abrupt cessation of breathing occurring with periods of apnea. Sleep partners often report staying awake to be sure the patient starts breathing again after each apnea period.

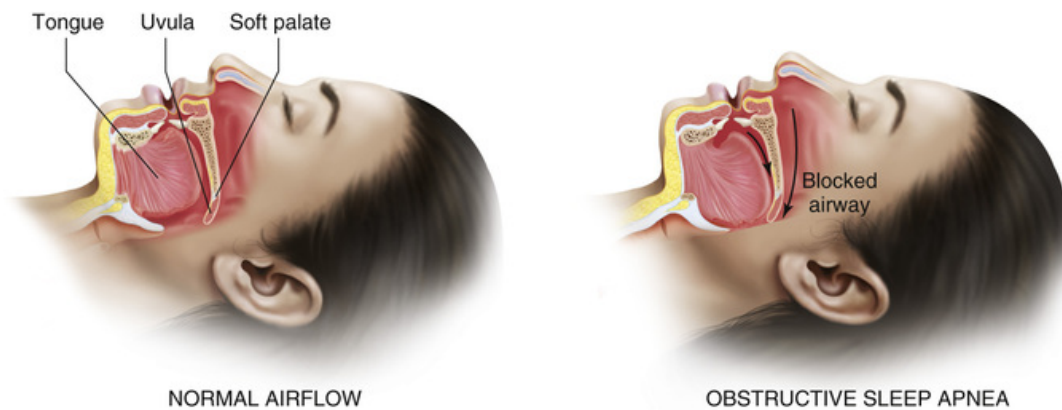

FIGURE 33.2 Changes occurring in obstructive sleep apnea (OSA).

Qsen Focus!

Through patient-centered care, the nurse values an active partnership with patients, their families, or designated surrogates in planning, implementation, and evaluation of care. This approach is especially important in assessing the patient's sleep, because the significant other or family member often can describe what is happening with the patient during sleep.

Risk factors for OSA include being male, overweight or obese, large neck circumference (43.2 cm [17 in] or more for men; 40.6 cm [16 in] or more for women), smoking, alcohol use before bedtime, middle-aged or older, and a family history of OSA (Morton, 2012). Structural abnormalities (such as a recessed chin, abnormal upper airway structures, deviated septum, nasal polyps, or enlarged tonsils) can predispose the affected person to OSA (Dugan, 2007; Morton, 2012). The gold standard for diagnosis of OSA is confirmed with polysomnography to measure respirations, heart rate, and muscle movements.

1. What signs and symptoms does J. B. exhibit that are indicative of obstructive sleep apnea (OSA)?

Safe Practice Alert

Obstructive sleep apnea (OSA) can cause fragmented sleep and low blood oxygen levels to the body, including the heart, leading to hypoxia, acidosis, and hypercapnia (increased carbon dioxide).

Sleep Deprivation

Sleep deprivation occurs from prolonged lack of sleep of good quality and adequate quantity. Disturbances of sleep leading to deprivation can be associated with aging or may result from hospitalization, drug and substance abuse, emotional stress, medications, factors in the environmental (e.g., noise, light), and disruption of normal sleep patterns, such as with shift rotations or changes in lifestyle patterns. Sleep deprivation can cause symptoms of fatigue, headache, nausea, increased sensitivity to pain, decreased neuromuscular coordination, irritability, and difficulty concentrating. Eventually, disorientation and hallucinations may occur. Sleep deprivation can have negative health effects on blood pressure (hypertension), glucose metabolism, and hormone regulation (type 2 diabetes), and may lead to inflammation, increased frequency of seizures in patients with seizure disorders, and increased weight gain contributing to obesity (Dashti, Scheer, Jacques, et al., 2015; Miller, 2015). Florence Nightingale's nursing theory work discussed environmental adaptation with appropriate noise, hygiene, light, comfort, socialization, hope, nutrition, and conservation of patient energy. Many of these adaptations have been found to promote sleep and rest. See [Chapter 1](#) for more on Nightingale's theory. People respond differently to sleep deprivation. The most effective treatment is correction of the factors interrupting the sleep patterns.

Hospitalization, especially in acute care units (such as intensive care or cardiac care units), puts patients at risk for sleep deprivation. This is secondary to the unfamiliar noises from staff and equipment, necessary care by medical staff, constant light, and poor physical condition.

Restless Legs Syndrome

Restless legs syndrome (also known as *Willis-Ekbom disease*) is a familial sleep disorder characterized by disagreeable-feeling leg movements resulting from intense, abnormal, lower-extremity sensations of crawling or tingling. The sensations cause delay in sleep onset leading

to daytime sleepiness and difficulty concentrating. This disorder affects up to 10% of the population (Cuellar, 2010). Restless legs syndrome can occur at any age but is more common in elderly people.

Parasomnias

Parasomnias are disorders associated with abnormal sleep behaviors, rather than disorders of sleep itself. The behaviors come from activation of the autonomic nervous system, motor system, or cognitive processes during sleep or during the transitions between sleep and wakefulness. These disorders are more common in children and adolescents.

Attempts to awaken the person from a parasomnia should be discouraged. Although safety needs must be met, help should be given to the extent the person will accept it, which includes encouraging the person to return to sleep as the event ends.

Somnambulism

Somnambulism, or “sleepwalking,” affects 2% to 3% of adults and up to 15% of children. It can result in trauma that may be potentially life-threatening (Sauter, Veerakatty, Haider, et al., 2016). Sleepers may sit up with glassy eyes and get up and walk around; generally, they will avoid anyone who attempts to talk to them.

Nocturnal Enuresis

Nocturnal enuresis (bedwetting at night) is a socially disruptive and stressful condition that is common, but underreported, in childhood. Bed alarms are the treatment that currently appears to work best in the long term. These alarms sound when moisture is present, waking the child. Behavioral therapy or medications may be used either alone or in conjunction with a bed alarm (Traisman, 2015).

Sleep Terrors and Nightmares

Sleep terrors, or night terrors, are a parasomnia in which a person quickly awakens from sleep in a terrified state. Sleep terrors occur during deep sleep, usually during the first third of the night. The cause is unknown, but they may be triggered by fever, lack of sleep, use of alcohol, or periods of emotional stress or conflict. Night terrors are fairly common in children 3 to 7 years of age, but they are most common in boys 5 to 7 years old. Night terrors may run in families. By contrast, nightmares are more common in the early morning. They may occur after the affected person watches a frightening movie or television program or has a strong emotional experience. The person may

remember the details of a dream on awakening and will not be disoriented after the episode ([U.S. National Libraries of Medicine, 2018b](#)).

Bruxism

Bruxism is the clenching of teeth or the grinding of teeth from side to side. This often occurs during sleep and may be due to stress. Pain can result if the clenching is tight or occurs over an extended period of time ([U.S. National Library of Medicine, 2018a](#)).

Secondary Sleep Disorders

Secondary sleep disorders can be disabling symptoms of underlying medical or psychiatric disorders. The physiologic effect of medical conditions affects the sleep–wake cycle. For example, heart failure, chronic obstructive pulmonary disease, pain, and gastric reflux disease all may affect sleep. Mental health disorders cause changes in sleep–wake regulation. Up to 90% of patients with depression report disturbed sleep. Anxiety, which is common in people who are hospitalized or who have a serious illness, also interferes with sleep.

Factors Causing Sleep Alterations

Many factors in a person's life can alter sleep patterns. Some of these factors are within a person's control, such as diet and exercise. Others are outside factors that the person cannot control, such as an illness or hospitalization.

Lifestyle

A work schedule that does not match the person's biologic rhythms (as can occur with rotating shifts or periodic assignment to a night shift) frequently interferes with sleep. Younger adults may adjust to shift work more easily than older adults who are more set in sleep patterns. Accumulated sleep loss may affect decision making, as well as patient safety in health care. The stress of a fast-paced life with multiple demands can prevent a person from relaxing and falling easily asleep.

Diet and Exercise

Both the type and amount of food and liquid consumed are recognized to affect sleep. Highly caffeinated substances (such as coffee, cola, and chocolate) are central nervous system stimulants that can disrupt the sleep cycle. Going to bed hungry or eating a large, heavy, or spicy meal

just before going to bed can interfere with sleep. Bedtime snacks that contain complex carbohydrates are recommended to promote calmness and relaxation.

Sleep and rest are important in addressing the rise in obesity in the United States. Both children and adults who sleep less than the recommended number of hours each night are more likely to be overweight ([National Institutes of Health \[NIH\], 2011](#)). Exercise can assist with weight loss efforts and promote relaxation, but excessive exercise, especially in the evening, interferes with sleep.

Smoking

Nicotine has a stimulating effect, and smokers may have more trouble falling asleep and arouse more easily once asleep. Long-term smoking can lead to permanent lung damage, which in turn is associated with hypoxia, requiring an increased need for rest. People who quit smoking usually report improved sleep, although temporary sleep disturbance may occur immediately after complete withdrawal from nicotine.

Alcohol

Small amounts of alcohol may help some people fall asleep, but alcohol increases wakefulness in the last half of the night. Ingesting large quantities of alcohol creates difficulty falling asleep and limits REM sleep. These effects may cause a restless sleep, contributing to a “hangover” experienced on arising. Alcohol ingested when taking sleeping pills can cause dangerous side effects.

Stimulants and Other Medications

Many prescription and over-the-counter medications can affect the quality of sleep, causing sleepiness, restlessness, or insomnia. Medications that decrease REM sleep include barbiturates, amphetamines, and some antidepressants. Other medications that affect sleep patterns include diuretics, antiparkinsonian medications, antihypertensives, steroids, decongestants, and asthma drugs. Beta blockers have been reported to cause nightmares and insomnia. Narcotics suppress REM sleep, cause frequent awakening, and may cause excessive daytime sleepiness.

Short-term use of medications, such as zaleplon (Sonata) and zolpidem (Ambien), may be indicated to improve sleep patterns. Eszopiclone (Lunesta) has been approved by the U.S. Food and Drug Administration (FDA) for longer-term treatment of insomnia.

Environmental Factors

People tend to sleep best in familiar settings where they feel comfortable and secure. Sleeping in new environments influences both NREM and REM sleep stages. People accustomed to the noise associated with living in a city may not rest well in country locales, whereas those accustomed to the quiet of the country may find it difficult to sleep in a city. Temperature and light are other variables that affect the ability to sleep.

Illness and Hospitalization

Illness and hospitalization are both physiologic and psychologic stressors that influence sleep. Any illness that results in pain, discomfort, or mood changes can result in sleep problems. Sleep disturbances are more common with certain illnesses ([Box 33.4](#)).

Box 33.4

Sleep Disturbances Associated With Illnesses

- Peptic ulcers cause pain at night, which may be related to the normal increase in gastric secretions during rapid eye movement (REM) sleep. Antacids that neutralize gastric acidity may relieve the pain and help sleep patterns.
- Pain associated with coronary artery disease is more likely to occur during REM sleep.
- Hypertension often causes early morning awakening and fatigue.
- Epileptic seizures are more likely in non-rapid eye movement (NREM) sleep stages.
- Hypothyroidism tends to decrease the amount of NREM sleep.
- Hyperthyroidism makes it difficult for a person to fall asleep.
- Low estrogen levels in women cause daytime fatigue, hot flashes, or night sweats, any of which may interfere with sleep.
- End-stage renal disease disrupts sleep and leads to daytime sleepiness.
- Shortness of breath impairs the ability to sleep, and sinus drainage may cause difficulty breathing.
- Any illness or injury associated with pain may disrupt sleep.
- Anxiety, fear, or stress may cause problems with falling and staying asleep.

Hospitalization is a stressor that disrupts sleep. Hospitals and residential care facilities usually do not adapt care routines to the person's sleep–wake cycle. When possible, health care providers should cluster care activities to provide 90- to 120-minute blocks of uninterrupted sleep time. This schedule allows for completion of all sleep stages. Maintaining a regular routine as much as possible enhances sleep for the hospitalized patient. When the sleep–wake cycle is disrupted, the patient may experience anxiety, restlessness, impaired judgment, and irritability, along with other negative effects on overall health. During a hospitalization, factors that affect sleep include unfamiliar surroundings, sounds, and smells; proximity to other patients; lack of privacy; increased light levels; medical technology; and underlying medical illnesses.

Anxiety and Stress

Psychologic stress decreases REM sleep and can prevent a person from getting enough sleep. Anxiety, including the stress associated with work, finances, illness, and family, can cause intrusive thoughts, muscular tension, and increased norepinephrine levels, all of which may interfere with being able to go to sleep and stay asleep.

Relationships

New parents often report sleep disturbance as they adjust to the parenting role and associated frequent nightly awakenings. The sleep disturbance may become chronic if young children in the home do not establish regular sleep patterns or have ongoing care needs. Similarly, caregivers of persons with chronic illnesses living at home may become sleep-deprived.

People whose primary relationships are disrupted often suffer from sleep disorders. A person going through the grieving process after a loss commonly may have difficulties sleeping; children away from home and suffering from homesickness often have trouble sleeping as well. Marital problems contribute to sleep disorders in both the involved adults and the children in the home. Sleep also is disrupted for those with a partner who has a sleep disorder. This can lead to sleep deprivation consequences for both partners.

Lo 33.3 ♦ Assessment

All patients should be assessed periodically for the presence of sleep disturbances. Assessment can occur during regular health checks or on admission to a health care facility. A sleep history starts with asking the patient to describe his or her usual sleeping pattern, sleeping and waking times, typical hours of sleep, and satisfaction with sleep. Bedtime routines, the use of sleep medications and other medications, the normal sleep environment, and any recent changes in sleep patterns should be assessed. An introductory assessment question could be “How have you been sleeping?” followed by “Do you feel rested when you arise in the morning, and do you have enough energy to do your expected tasks during the day?” If the patient does not identify any sleep difficulties, this history may be brief, allowing time for reinforcement of good sleep practices. If any sleep difficulties are identified, further questioning will help the nurse identify specific issues related to the patient's sleep (Box 33.5).

Box 33.5

Health Assessment Questions

Sleep

- How have you been sleeping?
- Do you have any bedtime routines?
- What time do you usually go to bed?
- What time do you usually awaken?
- Do you feel rested when you awaken?
- How long does it take for you to fall asleep?
- Do you awaken during the night? How often? What do you do?
- Do you have enough energy to complete your tasks during the day?
- Do you take naps during the day? For how long?
- What is your normal eating pattern?
- Do you drink beverages with caffeine, such as colas, coffee, or tea?
- Does your sleep partner comment about your sleep? Snoring? Pauses in breathing?

- What do you do to help yourself sleep? Use of over-the-counter meds? Prescription medications?

Health History

A sleep assessment should be completed when a patient is admitted to a health facility. The nurse assesses the patient's usual sleeping and waking times, medications, illnesses, bedtime routines, and sleeping environment preferences and incorporates the information into the plan of care when possible. The nurse should assess current life events and emotional status. Sleep instruments that can be used as part of the sleep assessment include the Epworth Sleepiness Scale, a self-reported 8-item questionnaire that can differentiate between sleep disorders and sleep deprivation; the Pittsburgh Sleep Quality Index, a self-reported 19-item instrument that assesses sleep quality and sleep disturbance over a 1-month period; and the Sleep Hygiene Index, a 13-item self-reported assessment that examines sleep hygiene behaviors (Dugan, 2007; Smyth, 2008).

A more focused assessment may need to be done if sleep problems are identified (Box 33.6). Information that should be obtained if a sleep disturbance is present includes:

Box 33.6

Focused Health Assessment Questions

Sleep Disorders

- Why do you think you are having sleep problems?
- Have you recently had any changes at home or at work?
- Have you started any new medications?
- Is there anyone else at home who does not sleep well?

Insomnia

- How long does it take you to go to sleep?
- How often do you have trouble falling asleep?
- Do you have trouble staying asleep? Waking up early and not getting back to sleep?
- What time do you wake up in the morning? Do you use an alarm clock?

- What do you do to prepare for sleep?
- What have you tried to improve your sleep?

Sleep Apnea

- Has anyone told you that you snore loudly or stop breathing while you sleep?
- Do you have headaches when you wake up?
- Do you have trouble staying awake during the day?
- Do you feel tired all the time?

Narcolepsy

- Do you fall asleep unexpectedly at random times? (Family or co-workers may report such episodes.)
- Do you have episodes of weakness, causing you to fall to the floor?
- Do you have vivid dreams when falling asleep?

- The type of problem
- Any potential causes
- Identified signs and symptoms
- When the disturbance started
- The effect on daily roles and activities
- How the patient copes with the problem
- The ability of the nurse to treat the problem or the need for a referral to another professional

Physical Assessment

Findings from a physical assessment can be used to validate the presence or absence of sleep disturbances. Key assessment findings include an adequate energy level for tasks, physical weakness, fatigue, lethargy, decreased affect, and behavioral signs, such as yawning or slow speech. Physical signs that may indicate potential sleep problems include obesity, thick neck, nasal polyps or deviated septum, or shortness of breath. Other signs that can be assessed during hospitalization include the presence of muscle contractions and jerks that arouse the patient from sleep, snoring, sleep apnea, or the irregular periods of silence followed by an abrupt snort indicative of OSA.

Diagnostic Tests

Objective data regarding sleep characteristics are obtained in a sleep disorder laboratory and are interpreted by a sleep specialist.

Polysomnography records eye movements, muscle movement and activity, heart and respiratory rates, oxygen levels, airflow, and brain activity while the patient sleeps. The results of polysomnography include the apnea-hypopnea index, or the number of apneic or hypopneic episodes per hour. The normal number of these episodes for an adult is fewer than 5 per hour; mild OSA ranges from 5 to 15 episodes per hour; moderate OSA ranges from 15 to 30 episodes per hour; and severe OSA is more than 30 apneic or hypopneic episodes per hour ([Morton, 2012](#)).

Another test is the multiple sleep latency test. The patient is monitored for brain waves, heartbeat, and eye movement during several 20-minute naps during the day. This test is used for patients suspected of having narcolepsy, and it shows whether they enter REM sleep shortly after falling asleep.

Lo 33.4 ♦ Nursing Diagnosis

When a sleep problem is identified that is amenable to nursing interventions, an appropriate nursing diagnosis is chosen. Some International Classification for Nursing Practice (ICNP) nursing diagnoses related to sleep disturbances and based on data clustered for each patient are shown below:

Sleep Deprivation

- Supporting Data: Poor sleep patterns, daytime sleepiness, snoring, sleeps 4 to 5 hours per night

Impaired Sleep

- Supporting Data: Lighting and noise in the hospital, reports of being awakened at night, changes in normal sleep pattern

Fatigue

- Supporting Data: Sleep deprivation, daytime drowsiness

Lo 33.5 ♦ Planning

The major goal for a patient with a sleep disorder is to develop and maintain sleeping patterns that provide appropriate energy for daily activities. Care planning and outcomes for patients with a sleep disorder need to be individualized (Table 33.3). Interventions and outcomes should be identified in collaboration with the patient to increase success in implementation.

TABLE 33.3
Care Planning

ICNP NURSING DIAGNOSIS WITH SUPPORTING DATA	NURSING OUTCOME CLASSIFICATION (NOC)	NURSING INTERVENTION CLASSIFICATION (NIC)
<i>Sleep Deprivation</i> Poor sleep patterns Daytime sleepiness Snoring Sleeps 4 to 5 hours per night	<i>Sleep</i> Hours of sleep	<i>Sleep enhancement</i> Encourage the patient to establish a bedtime routine to facilitate transition from wakefulness to sleep

From Butcher, H. K., Bulechek, G. M., Dochterman, J. M., et al. (Eds.). (2018). *Nursing interventions classification (NIC)* (7th ed.). St. Louis, MO: Mosby; Moorhead, S., Swanson, E., Johnson, M., et al. (Eds.). (2018). *Nursing outcomes classification (NOC)* (6th ed.). St. Louis, MO: Mosby; ICNP is owned and copyrighted by the International Council of Nurses (ICN). Reproduced with permission of the copyright holder.

Goals and Outcome Statements

The primary goal for the patient with a sleep disorder is to improve the quality and quantity of sleep. It should be recognized that it may take weeks to achieve outcomes for sleep problems.

Potential goals that support the nursing diagnoses related to sleep and rest include the following:

- Patient will remain asleep for 6 to 7 hours consistently within 1 month.
- Patient will sleep for at least 90 minutes at a time during hospitalization.
- Patient will take two 20-minute naps daily.

2. Write a short-term goal for the nursing diagnosis: *Sleep Deprivation*; Supporting Data: Poor sleep patterns, daytime sleepiness, snoring, sleeps 4 to 5 hours per night.

	Admitting Diagnoses/Chief Complaint Requesting "something to help me sleep"	Assessment Data Vital signs: T 36.3°C (97.4° F), P 96, regular and steady; R 26, slightly labored; BP 174/96; and SaO2 90% on room air; no complaints of pain or discomfort at this time. Gained over 30 lb in the last year. BMI 36.1. Looks older than his stated age, has dark circles around puffy eyes, and yawns frequently during the assessment. Reports daytime sleepiness, trouble falling asleep, headache on waking, difficulty concentrating, and two recent car accidents. Wife states that he is irritable, goes to bed late, sleeps only 4-5 hours, restless in bed, and has periods of not breathing and periods of loud snoring. He is currently on no prescription medications. Owns a small business and all employees are family members. Recently laid off two employees and increased his own working hours. The stress of the financial losses and laying off family members changed his overall health and sleep habits. Manages all aspects of the business and employees, and handles customer relations. Drinks approximately six cups of coffee a day, smokes two packs of cigarettes a day, has three or four alcoholic drinks at night to "relax."

FIGURE 33.3 Partially completed conceptual care map based on J. B., the case study patient in this chapter.

The conceptual care map for J. B. provided in [Fig. 33.3](#) is partially completed to indicate how to use the map as a learning tool. Using it as an example, go to the website at <http://evolve.elsevier.com/YoostCrawford/fundamentals/> to complete Nursing Diagnoses 2 and 3.

Lo 33.6 ♦ Implementation and Evaluation

Nursing interventions to improve sleep quality are based on health promotion principles. During illness, sleep is important for recovery. The nurse should have a caring attitude when implementing strategies to improve sleep. Addressing the sleep environment, maintaining sleep routines, providing light snacks if allowed, instituting relaxation measures, and carefully using medications can enhance sleep in both hospital and home settings. Medications do not reset the circadian rhythms. These rhythms can be adjusted by progressing through shift rotation in a forward motion (days to evenings to nights), implementing sleep hygiene practices (evening routine; diet, alcohol, tobacco, and activity restrictions), and arising at the same time each day. Each of these measures helps the body adjust to the change in sleep schedules.

Interventions for Specific Sleep Disorders

Treatment for insomnia should include interventions, such as stimulus control (using the bedroom for only sleep and sex), sleep restriction (staying in bed only if asleep), sleep hygiene, and cognitive therapy (relaxing and changing thought patterns). A combination of nonpharmacologic methods is often necessary to change sleep patterns. Treatment for hypersomnia is aimed at correcting any underlying conditions contributing to the hypersomnia.

There is no cure for narcolepsy at present. Treatment that may improve the symptoms includes a regular exercise routine, a regular sleep routine, daytime naps if possible, light meals high in protein to maintain alertness, and vitamins. Avoiding alcohol, heavy meals, long-distance driving, and long periods of sitting are helpful. Medications for narcolepsy include central nervous system stimulants, the nonamphetamine wake-promoting drug modafinil, and tricyclic and selective serotonin reuptake inhibitor antidepressants. In 2002, the FDA approved Xyrem, which is the trade name for gamma hydroxybutyrate (GHB), for treating people with narcolepsy who experience episodes of cataplexy ([NINDS, 2018c](#)).

Lifestyle changes for good sleep practices recommended in the treatment of sleep apnea include weight loss, and avoiding alcohol, ([American Sleep Apnea Association, 2017](#)). Additional treatment consists of surgical procedures to correct abnormalities of the soft tissue or bone structure that is obstructing the patient's airway, use of an oral appliance while sleeping to keep the airway open, or continuous positive airway pressure (CPAP). CPAP is noninvasive and consists of a

face or nasal mask, connected to an air pump, that is worn during sleep and maintains pressure to hold the airway open (Fig. 33.4). Some patients report discomfort, skin irritation, or claustrophobia sensations; however, continued use of CPAP should be encouraged. Correcting sleep apnea through lifestyle changes or use of CPAP will enable the patient to have a more restful night's sleep and decrease the risks associated with OSA.

FIGURE 33.4 Patient with continuous positive airway pressure (CPAP) device. A, Patient wearing nasal pillows (positive pressure only through nose). B, Patient wearing a full face mask (positive pressure to both nose and mouth). (From Goldman, L., & Schafer, A. I. [2016]. *Goldman-Cecil medicine* [25th ed.]. Philadelphia: Elsevier.)

3. A sleep study with polysomnography is performed, and it verifies the diagnosis of obstructive sleep apnea (OSA). After discussing treatment options with his primary care provider, J. B. decides to try continuous positive airway pressure (CPAP). How would the nurse explain the function of CPAP to J. B. and his wife?

4. The nurse plans to counsel J. B. regarding lifestyle factors that affect sleep in general. Identify at least four lifestyle factors that J. B. might work on to improve his sleep patterns.

Treatment for restless legs syndrome includes lifestyle changes of decreased caffeine, alcohol, and tobacco use, as well as maintaining a regular sleep pattern. Massaging the legs, walking, or doing deep knee bends may temporarily relieve symptoms. Use of supplements as a complimentary and alternative therapy to correct deficiencies in iron, folate, and magnesium may be helpful. No one medication is effective for restless legs syndrome, but drugs such as dopaminergic agents (largely used to treat Parkinson disease), ropinirole (Requip), benzodiazepines, opioids, and anticonvulsants may be prescribed (Cuellar, 2010; Morton, 2012; NINDS, 2018a).

Nonpharmacologic Interventions

Feeling comfortable and safe when attempting to sleep is important. A comfortable bed with linens that are not wrinkled and allow freedom of movement helps promote relaxation. Body alignment should prevent muscle strain and discomfort. A quiet, darkened room with privacy is helpful for most people, but a night light may be needed in unfamiliar surroundings. Infants and older adults may sleep best in softly lit rooms, but not with light shining directly in their eyes. Noise is a common sleep disrupter in the hospital; equipment sounds and staff conversations should be modified, as possible, to decrease noise (Box 33.7). Room temperature and the use of extra clothing or blankets should be at the discretion of the patient.

Box 33.7

Ways to Control Noise in the Hospital

- Provide visual cues to decrease noise by dimming lights and closing curtains, but provide a night light for safety.

- Provide privacy by drawing curtains between patients or closing room doors if possible.
- Negotiate times to mute television, radios, and music on hospital units.
- Limit overhead pages to only emergencies at night.
- Lower volume of telephone ringtones.
- Limit staff conversations in hallways and at nursing stations.
- Conduct shift reports in areas away from patient rooms, unless the facility requires bedside reporting. If the patient is asleep during change-of-shift rounds, the nurses can check the patient and then step away and speak in soft voices.
- Move equipment quietly, without hitting other objects.
- Monitor equipment frequently to prevent alarm tones as much as possible.

It is not unusual for hospitalized patients to be awakened for sleeping pills or long before it is time for a meal or procedure. When possible, treatments and care should be scheduled for when a patient normally is awake. Scheduling of medications and treatments that can disrupt sleep (e.g., nebulizer treatments) should be carefully considered. It is best to reserve at least 90 to 120 minutes of “sleep windows” to allow progression through all stages of sleep.

Bedtime Routines

Bedtime routines relax patients in preparation for sleep (Box 33.8). The nurse should make every effort to allow the patient to follow his or her regular sleep schedule. Normal daytime nap patterns that do not interfere with nighttime sleep should be considered in planning and administering care.

Box 33.8

Interprofessional Collaboration and Delegation

Care of Patients Before Bedtime

Evening care, or h. s. (“hour of sleep” — at bedtime) care, is provided to prepare the patient for an uninterrupted period of sleep. Activities to

prepare for sleep that the nurse may delegate to unlicensed assistive personnel (UAP) include:

- Providing oral care
- Doing partial bathing, to cleanse the face and hands
- Providing skin care
- Giving a backrub
- Straightening or changing bed linen
- Offering the opportunity for toileting
- Offering a light snack or water

Most people follow a bedtime routine. Such routines are important in promoting relaxation and mental preparation for sleep (Box 33.9). Reading, watching the news, praying, meditating, and doing physical hygiene procedures (such as washing the face, bathing, and brushing teeth) are common components of bedtime routines. Some children and adults have a light snack as part of their bedtime ritual. Children may have a very specific routine that includes bathing, stories, music, *good-nights* to everyone, prayers, and presence of a specific toy or blanket for sleep time.

Box 33.9

Bedtime Routines That Promote Sleep

- Take a warm bath.
- Eat a light snack that contains carbohydrates.
- Drink warm milk.
- Avoid caffeine, tobacco, and excessive alcohol.
- Get a back massage.
- Relax using aromatherapy and music therapy.
- Adjust the environment for temperature, noise, and light.
- Elevate the head of the bed for patients diagnosed with gastroesophageal reflux disease (GERD).
- Avoid large meals and certain medications in the evening.

Bedtime Snacks

Going to bed hungry or eating a large, heavy, or spicy meal just before going to bed can interfere with sleep. A snack with complex

carbohydrates seems to promote sleep for some people, so a piece of whole grain toast, crackers, or a glass of juice may help initiate sleep if allowed in the patient's plan of care. Tryptophan, an amino acid found in milk, stimulates the production of serotonin, which promotes sleep. Alcohol after dinner may help some people sleep, but in general it interferes with sleep cycles and should be avoided. Likewise, caffeine in foods (such as chocolate) and drinks should be avoided for several hours before bedtime owing to its central nervous system stimulation. Fluids may be decreased in the evening if the person often awakens during the night with the need to void. Large, heavy, or spicy meals close to bedtime should be avoided because they can lead to discomfort and increase the likelihood of gastroesophageal reflux disease (GERD).

Exercise

Physical activity can promote fatigue and relaxation and can increase both NREM and REM sleep. Vigorous exercise within 2 hours of normal sleep time, however, can hamper sleep and should be avoided. Excessive exercise and exhaustion can hinder normal sleep.

Relaxation

Sleep rarely occurs until a person feels relaxed. Coping mechanisms that decrease stress include enlisting the help of friends, family, or clergy to deal with problems, learning to deal with problems only at certain times of the day, and using relaxation techniques.

Aromatherapy, music therapy, and spiritual supportive measures, when correctly used, can be especially effective for patients experiencing stress or anxiety that contributes to sleep disorders. A backrub, warm shower or bath, oral care, and face wash help most patients relax. Adequate clothing or bedding prevents feeling cold and increases relaxation, especially in children and elderly people. Pain, which commonly occurs in illness or with surgery, is a major deterrent to sleep. Measures to relieve pain can include administering medication as appropriate, staying with a frightened child or adult, providing a warmed blanket, or offering a backrub. For other methods of treating pain, see [Chapter 36](#).

Qsen Focus!

Patient-centered care requires that the nurse provide physical comfort and emotional support. When addressing sleep disturbances, the nurse elicits the patient's preferences and expressed needs as part of the

clinical interview, implementation of the care plan, and evaluation of care.

A backrub provides the comfort of human touch, promotes relaxation, decreases pain, and stimulates the immune system. The use of the therapeutic massage as a complimentary and alternative therapy in nursing practice has declined through the years in favor of high-tech interventions, yet it is one of the simplest ways to improve patient sleep patterns (see [Skill 27.4](#)). The time spent on giving a backrub can be simultaneously used to reinforce goals reached by the patient during the day, activities accomplished, visits from friends and families, or positive thoughts of other events of the day that will help calm the patient's mind in preparation for sleep.

Sleep Medications

After nonpharmacologic methods have been tried, medications to assist with sleep are prescribed for some patients with chronic, ongoing sleep disturbances that interfere with daily life. For medications prescribed on an as-needed basis, the nurse must assess the need for medication and understand how the drug works. Nonpharmacologic measures, including patient teaching, should be used as appropriate in addition to any prescribed medications to assist with the initiation of sleep.

Antianxiety medications reduce anxiety and tension, but they can cause physical and psychologic dependence. Antihistamines, such as diphenhydramine (Benadryl), have mild sedative effects that can promote sleep. Tricyclic antidepressants, such as amitriptyline (Elavil) or doxepin (Sinequan), or trazodone may be prescribed at a lower dose than that needed to alleviate depression, for their beneficial effect on sleep patterns. Sedative-**hypnotics** induce sleep, but it is an unnatural sleep that is associated with disturbances in REM and NREM sleep patterns. With this group of agents, tolerance may develop after several days, and the patient may then increase the dose of medication to obtain the same effect, which creates specific safety concerns. Withdrawal symptoms (weakness, tremors, restlessness, insomnia, increased pulse rate, and death) can occur if barbiturate sedative-hypnotics are stopped abruptly. Some medications have adverse effects in elderly people and must be used with caution in this population.

Medications used to induce sleep can cause daytime drowsiness. Long-term use of antianxiety, sedative, or hypnotic medications further disrupts sleep and may cause additional problems. In 2007, the FDA mandated that the product labels of sleep medications include new safety warnings that provide information related to potential severe

allergic reactions, severe facial swelling, and complex sleep behaviors, such as sleep-driving or preparing and eating food while asleep.

Safe Practice Alert

When administering medications that affect sleep, be sure beds are in the low position, night lights are on, and call lights are within reach to help prevent patient falls. No alcohol products should be ingested with sleeping medications.

Home Care Considerations

Patients may underestimate their need for rest while recuperating from illness or surgery. Discharge planning should include recommendations for rest and activity to encourage self-care. Patients should be taught about normal variations in sleep patterns along with common measures to promote relaxation and sleep when at home (Box 33.10). Caregivers should receive education on how they can best meet their own energy and sleep needs so that they are able to provide the necessary care for the patient in addition to meeting self-care needs.

Box 33.10

Home Care Considerations

Sleep Hygiene Practices for Home

Activity

- Activity promotes sleep. Find physical activity that can be done daily, such as walking, swimming, or exercising.
- Relaxation is difficult after vigorous exercise. Avoid vigorous exercise within 2 hours of bedtime.
- Multiple interventions increase sleep success by promoting physical and mental relaxation. Implement complementary relaxation strategies before attempting sleep, including music, massage, or aromatherapy.

Diet

- Carbohydrates affect serotonin levels in the brain, inducing relaxation. Therefore eat a light bedtime snack with carbohydrates if hungry in the evening.
- Heavy meals interfere with sleep. Avoid heavy meals within 3 hours of bedtime.
- Central nervous system stimulants interfere with sleep. Limit caffeine, alcohol, and tobacco use, especially in the evening.

Sleep Pattern

- Using the bedroom only for sleep and sex helps the mind associate the room with these activities. Do not watch television, read, study, or eat in this space.
- Getting out of bed if unable to sleep trains the mind to sleep when in bed. If unable to fall asleep within 20 minutes, get out of bed and engage in a relaxing activity (such as reading or listening to music) until sleepy.
- Maintaining a regular sleep pattern helps maintain circadian rhythms. Continue the regular sleep pattern on weekends and on holidays.
- A consistent bedtime routine signals to the mind and body that it is time to go to sleep. Follow a consistent routine.
- Identify lifestyle factors (e.g., long work hours, late meals, family stress) that may interfere with sleep, and change those factors.

Environment

- Comfort and security, along with decreased sensory input, promote sleep. Adjust the environment to enhance sleep: Darken the room; decrease noise or wear earplugs; adjust the temperature to a comfortable level; and wear loose, comfortable clothing.

Interventions to enhance sleep in the home are similar to those used in the hospital. Patients may be taught to keep a sleep diary to record sleep patterns at home: The patient records data over the course of several days and nights, including information about sleep quality, sleep patterns, and interventions to improve sleep (Box 33.11). If the sleep diary adds to the stress of trying to improve the quality of sleep, the diary should be discontinued and the data obtained by interview.

Box 33.11

Patient Education and Health Literacy

Sleep Diary

Information to be recorded daily in the sleep diary includes:

- Activities and food within 2 hours of going to bed
- Time of retiring
- Time of awakening
- Required time to fall asleep
- Number of times aroused during the night
- Length of time awake if aroused during the night
- Degree of restfulness in the morning
- Use or nonuse of an alarm
- General comments regarding sleep

Evaluation

The effectiveness of the plan of care to promote sleep is evaluated by determining whether the identified outcomes have been reached.

Outcomes are likely to be achieved if the patient is able to:

- Rest in an environment that promotes sleep
- Follow bedtime rituals as much as possible
- Report feeling rested after sleeping
- Maintain adequate energy and mental alertness to complete necessary tasks
- Identify factors that interfere with sleep and measures to improve sleep habits
- Use a variety of techniques to promote sleep

Follow-up assessment of the effectiveness of the interventions is an important step in ensuring healthy sleep patterns for patients in hospital and home settings.

Summary of Learning Outcomes

LO 33.1 *Explain the physiology and functions involved in sleep:* Sleep is a reversible and naturally occurring altered state of consciousness during which awareness, responsiveness, and perception of the environment are decreased. It is restorative, protective, and necessary for optimal health. Sleep occurs in a predictable cycle of specific stages.

LO 33.2 *Discuss characteristics of common sleep disorders:* Common sleep disorders fall into the major categories of dyssomnias (insomnia, OSA, narcolepsy, restless legs syndrome, circadian rhythm disorders), parasomnias (sleepwalking, nightmares), and secondary sleep disorders resulting from underlying medical or psychiatric illnesses.

LO 33.3 *Summarize assessment techniques for determining sleep patterns:* Assessment of sleep may be brief if no problems are discovered or more extensive if issues surrounding the patient's sleep patterns are identified. A detailed history, physical examination, and specialized tests will help determine the nature of the sleep problem.

LO 33.4 *Identify nursing diagnoses for patients with sleep disturbances:* Nursing diagnoses for patients with sleep problems include *Sleep Deprivation*, *Impaired Sleep*, and *Fatigue*.

LO 33.5 *Determine patient goals based on specific sleep problems:* Goals are individualized in accordance with the specific sleep disturbance and its effects on the patient's daily life.

LO 33.6 *Implement, and evaluate nursing care related to sleep promotion:* Nursing interventions that promote sleep include pharmacologic measures, such as the use of hypnotics, and nonpharmacologic measures to improve sleep habits, or sleep hygiene (bedtime rituals, relaxation, regular exercise, and diet changes). Nursing interventions for promoting sleep in the hospitalized patient include reducing noise and lighting, ensuring a period of uninterrupted sleep, and controlling pain.

Review Questions

1. An elderly, tense patient is having trouble relaxing enough to sleep. Which measures should be implemented by the nurse to help promote sleep? *(Select all that apply.)*
 - a. Give the patient a back rub.
 - b. Take the patient for a brisk walk right before bedtime.
 - c. Provide a warm, quiet environment.
 - d. Encourage the patient to eat a large meal in the evening.
 - e. Give the patient a diet cola.
 - f. Play soft music during the 30 minutes before bedtime.
2. A nurse who was hired to work in a sleep lab understands that the most common type of sleep apnea is caused by which factor?
 - a. Airway collapse
 - b. Lack of exercise
 - c. Dietary factors
 - d. Medication use
3. A patient has been referred for polysomnography to confirm a diagnosis of narcolepsy. What behavior would the nurse expect the patient to be exhibiting?
 - a. Excessive use of sleeping medications
 - b. A lack of dreaming during sleep
 - c. Consistent use of relaxation techniques
 - d. Unexpected daytime sleeping episodes

4. A mother brings her toddler for a well-child checkup and mentions that she is having a lot of trouble getting the child to go to bed. Which intervention can the nurse teach the mother to help her toddler establish good sleep habits?
 - a. Establish and maintain a consistent bedtime routine.
 - b. Put the child to bed immediately after the evening meal.
 - c. Allow the child to stay up as long as desired to increase sleepiness.
 - d. Allow the child to sleep with the parents until the child is older.
5. An elderly patient complains of difficulty sleeping after the death of his spouse of 56 years. What would be an appropriate nursing assessment for this patient?
 - a. Assess the patient for possible use of sedatives.
 - b. Obtain a health history regarding sleep hygiene.
 - c. Assess the patient's weight over the past year.
 - d. Request a sleep study to rule out sleep apnea.
6. The nurse is completing a sleep assessment for a newly admitted patient. Which data reported by the patient would cause the nurse to suspect obstructive sleep apnea (OSA)? (*Select all that apply.*)
 - a. Morning headaches
 - b. Sudden weight loss
 - c. Loud snoring during sleep
 - d. Daytime sleepiness
 - e. Deep sleep during the night

- f. Increased blood pressure problems
7. A patient complains of not being able to sleep while in the hospital. What action would be a priority for the nurse to implement?
- Administer a sleeping medication with the evening meal.
 - Restrict visitors for the patient in the evening.
 - Decrease noise around the patient during the night.
 - Offer a hot drink of regular tea at bedtime.
8. A patient reports that the prescribed sleeping medication is no longer effective. What information would be appropriate for the nurse to recommend to the patient? (*Select all that apply.*)
- Take the medication with an alcoholic drink.
 - Use relaxation techniques before sleep.
 - Do not study in the bedroom before bedtime.
 - Adjust sleep temperature for comfort.
 - Sleep in a different room of the home.
9. A nurse is working a night shift after several months of working day shift. What action does the nurse take to protect patient safety?
- Take a meal break at midnight.
 - Plan critical tasks for early in the shift.
 - Ask another nurse to administer all medications.
 - Turn up lights on the unit to maintain alertness.
10. At a routine clinic visit, an athlete training for a major sports event reports difficulty sleeping that is affecting the training schedule. What would be the best recommendation by the nurse for this patient?

- a. Increase the use of electrolyte-enriched drinks to increase stamina.
- b. Obtain a short-term prescription for sleeping medications.
- c. Plan to arise later in the morning to accommodate sleep changes.
- d. Avoid vigorous exercise for at least 2 hours before bedtime.

UNIT VI

Nursing Care

OUTLINE

- Chapter 34 Diagnostic Testing
- Chapter 35 Medication Administration
- Chapter 36 Pain Management
- Chapter 37 Perioperative Nursing Care
- Chapter 38 Oxygenation and Tissue Perfusion
- Chapter 39 Fluid, Electrolyte, and Acid-Base Balance
- Chapter 40 Bowel Elimination
- Chapter 41 Urinary Elimination
- Chapter 42 Death and Loss

CHAPTER 34

Diagnostic Testing

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 34.1 Recall the types of cells found in blood and their functions.
- LO 34.2 Identify common blood tests, their purposes, and their normal values.
- LO 34.3 Discuss other laboratory tests, such as urine and stool studies, and their purposes and normal values.
- LO 34.4 Explain the purpose of common diagnostic tests.
- LO 34.5 Describe assessment procedures for patients undergoing diagnostic tests.
- LO 34.6 Choose appropriate nursing diagnoses associated with diagnostic testing.
- LO 34.7 Select goals to meet individual patient problems.
- LO 34.8 Describe the nurse's role in implementation and evaluation of the plan of care before, during, and after diagnostic tests and procedures.

Case Study

Margaret Rees (M. R.), a 68-year-old female, was admitted to the hospital with loss of appetite and fatigue and was evaluated to rule out gastrointestinal (GI) bleeding. She says that her “stools have been darker than they normally are.” She has a medical history of osteoarthritis, diabetes mellitus, and hypertension. She has no known drug allergies (NKDA) and has full-code status. “I don't have the energy to do anything anymore. I don't know what's wrong with me.” Her vital signs on admission are: T 36.8° C (98.2° F), P 110 regular and bounding, R 26 and labored, and BP 106/62, with a pulse oximetry reading of 91% on room air. Admitting blood work was normal except for the following: RBC 3.8 cells/mm³, Hgb 8.6 g/dL, Hct 34%, and glucose 210 mg/dL.

During the assessment, M. R. says, “I'm worried about that test tomorrow. I just know they're going to find cancer. My father died of stomach cancer, and it was horrible.” She denies having pain, but says she is very tired.

The patient states that she takes a regular aspirin every day. She says, “I saw on TV that it's supposed to prevent heart attacks.” She is scheduled for an esophagogastroduodenoscopy (EGD) tomorrow.

Medications are as follows:

- Sliding-scale insulin for Humulin R subcut with dose based on fingerstick blood glucose result:

Less than 150 mg/dL	No insulin
150-200 mg/dL	4 units
200-249 mg/dL	6 units
250-299 mg/dL	8 units
300 mg/dL or higher	Call primary care provider

- Intravenous (IV) 1000 mL D₅ 0.45% normal saline (NS) at 50 mL/hr
- Midazolam 2.5 mg IV on call for the EGD

She takes the following medications on a daily basis, which are currently on hold:

- Humulin N 10 units/Humulin R 5 subcut units every A.M.
- Humulin N 5 units subcut every P.M. before dinner

- Naproxen 500 mg PO BID
- Aspirin 81 mg PO daily
- Lisinopril 10 mg PO every A.M.

Treatment orders are as follows:

- Vital signs, including pulse oximetry, every 4 hours
- 2 to 4 L of O₂ per nasal cannula; titrate to keep SpO₂ >92%
- Clear liquids; nothing by mouth (NPO) after midnight
- EGD in A.M.
- Fingerstick blood sugar before meals and at bedtime
- Bed rest with bathroom privileges
- Complete blood count (CBC) every A.M.
- Stools × 3 for occult blood

Refer back to this case study to answer the critical-thinking questions throughout the chapter.

An essential aspect of patient care is identifying diseases and disorders. Diagnostic test results are examined and combined with patient assessment data to identify, determine the severity of, and evaluate therapy effectiveness for a disease or disorder. Diagnostic tests are used to examine different aspects of the body and assess indicators that the body may not be healthy. Whether it is a fractured ankle seen on an x-ray or low blood glucose level determined from a fingerstick blood sample, diagnostic tests assist primary care providers (PCPs), surgeons, and specialist physicians in determining the best possible treatment for the patients in their care. Nurses must be able to perform, understand, and communicate the results of diagnostic tests to their patients.

LO 34.1 Normal Structure and Function of Blood Cells

On average, a person has approximately 5 liters of blood circulating throughout the body. Approximately 3 liters are plasma, the fluid portion, and 2 liters are cells.

Cell Types

Three types of cells are found in blood: erythrocytes, thrombocytes, and leukocytes (Fig. 34.1). The **erythrocytes** (red blood cells [RBCs]) contain **hemoglobin (Hgb)**, which is a protein primarily responsible for oxygen transport to and carbon dioxide transport from the erythrocytes. The RBCs have an important role in maintaining normal acid–base balance. Development of new erythrocytes occurs in the bone marrow.

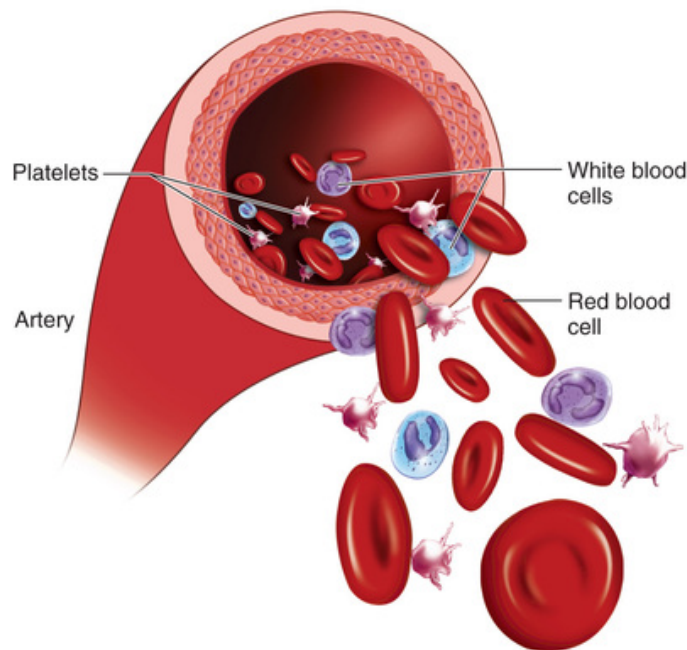

FIGURE 34.1 Formed elements of blood.

Thrombocytes, also called *platelets*, are an integral part of blood clotting. When a blood vessel ruptures, platelets clump together to form a plug to seal the vessel. Platelets are formed in the bone marrow.

The **leukocytes** (white blood cells [WBCs]) are primarily responsible for the inflammatory and immune response in the body (Table 34.1). Leukocytes are classified as **lymphocytes** (T and B), **monocytes**, **eosinophils**, **neutrophils**, and **basophils**. Leukocytes are formed primarily in the bone marrow, except for T lymphocytes, which are produced in the thymus.

TABLE 34.1**Normal White Blood Cell Count Differential**

Type	Proportion of 100 White Blood Cells (%)	Function
Neutrophils	55-70	Are first defenders against bacterial and fungal infections, foreign antigens, and cell debris
Lymphocytes	20-40	Recognize foreign antigens; produce antibodies; create memory cells
Monocytes	2-8	Involved in phagocytosis; become macrophages
Eosinophils	1-4	Destroy parasites; involved in allergic reactions
Basophils	0.5-1.0	Involved in the inflammatory response to injury; release histamine

Adapted from Pagana, K. D., & Pagana, T. J. (2018). *Mosby's manual of diagnostic and laboratory tests* (6th ed.). St. Louis: Elsevier.

Plasma

Plasma is the fluid portion of the blood. It contains various substances vital to homeostasis, and water is the primary carrier of these substances. Electrolytes (such as, sodium, potassium, calcium, magnesium, chloride, and bicarbonate) are transported to and from the cells in the plasma. [Chapter 39](#) provides an in-depth discussion of electrolytes.

Plasma proteins include albumin, fibrinogen, and globulins. **Albumin** is the major plasma protein, primarily responsible for maintaining fluid balance by providing colloidal osmotic pressure in the blood. **Fibrinogen** plays an integral part in blood coagulation by converting into fibrin threads in the presence of ionized calcium. Fibrin is the essential component of blood clots. **Globulins** are classified as alpha, beta, and gamma globulins. Some globulins function as antibodies, and others are responsible for enzymatic functions and the transport of lipids, iron, and copper in the blood.

Plasma contains various nutrients, primarily glucose, amino acids, fatty acids, and vitamins. Hormones are transported throughout the body in blood plasma. The blood also transports waste products (such as, urea and creatinine) to be excreted by the kidney.

LO 34.2 Laboratory Tests: Blood

A venous blood sample can be tested for many different components. Blood tests are common diagnostic tools that are used frequently in inpatient and outpatient settings. Venous blood is the primary source of sampling for these tests. Arterial blood samples are used for determination of arterial blood gases (ABGs). Capillary blood samples are often used for fingerstick glucose tests.

Complete Blood Count

A complete blood count (CBC) is a frequently ordered diagnostic test designed to provide information about oxygen and carbon dioxide transport capabilities. A differential blood cell count can provide information about the status of the immune response.

CBC components include the RBC count, hemoglobin level, hematocrit, RBC indices, WBC count, and differential WBC count. Hematocrit is the packed cell volume; it measures the proportion of RBCs in a volume of whole blood. The RBC indices include the mean corpuscular volume (MCV), which is the average size of an individual erythrocyte; the mean corpuscular hemoglobin (MCH), which is the average amount of hemoglobin in an individual erythrocyte; and the mean corpuscular hemoglobin concentration (MCHC), which is the proportion of an individual erythrocyte occupied by hemoglobin. The WBC count is the number of WBCs in a cubic millimeter of blood. The differential WBC count is the proportion of each type of WBC in a sample of 100 WBCs (see [Table 34.1](#)). [Table 34.2](#) lists the CBC components, normal values, and common explanations for abnormal levels.

TABLE 34.2**Complete Blood Count**

Component	Normal Value	Clinical Significance of Abnormal Values	
		Decreased Levels	Increased Levels
RBCs (cells/mm ³)	Adult male: 4.7-6.1 Adult female: 4.2-5.4 Newborn: 4.8-7.1 Child 1-18 yr: 4.0-5.5	Anemia Bone marrow suppression Chronic infection Hemorrhage Renal disease Vitamin B ₆ , B ₁₂ , or folic acid deficiency	Major burns Cardiovascular disease Chronic lung disease Congenital heart defect Polycythemia vera
Hemoglobin (g/dL)	Adult male: 14-18 Adult female: 12-16	Anemia Bone marrow suppression Chronic infection Hemorrhage Renal disease Vitamin B ₆ , B ₁₂ , or folic acid deficiency	Major burns Cardiovascular disease Chronic lung disease Congenital heart defect Polycythemia vera
Hematocrit (%)	Adult male: 42-52 Adult female: 37-47	Anemia Bone marrow suppression Chronic infection Hemorrhage Renal disease Vitamin B ₆ , B ₁₂ , or folic acid deficiency Overhydration	Major burns Cardiovascular disease Chronic lung disease Congenital heart defect Polycythemia vera Dehydration
Red Blood Cell Indices			
Mean corpuscular volume (cells/mm ³)	80-95	Iron-deficiency anemia Lead poisoning Thalassemia minor and major	Pernicious anemia Folic acid deficiencies Chronic liver disease
Mean corpuscular hemoglobin (pg/cell)	27-31	Iron-deficiency anemia Lead poisoning Rheumatoid arthritis Sickle cell anemia	Alcohol abuse Chronic liver disease Folic acid deficiency Hypothyroidism
Mean corpuscular hemoglobin concentration (g/dL)	32-36	Iron-deficiency anemia Lead poisoning	Normal finding in infancy
WBCs (cells/mm ³)	Adult: 5000-10,000 Child >2 yr: 5000-10,000 Newborn: 9000-30,000	Chronic leukemia Aplastic anemia	Acute leukemia Infections Surgery Trauma
Differential White Blood Cell Count ^a			

Component	Normal Value	Clinical Significance of Abnormal Values	
		Decreased Levels	Increased Levels
Neutrophils (cells/mm ³)	Segmented: 2500-8000	Anaphylactic shock Anorexia nervosa Leukemia Rheumatoid arthritis Septicemia Stress Viral infection (measles, rubella, infectious mononucleosis, hepatitis)	Acidosis Acute hemolysis of RBCs Acute pyogenic infections Cancer of liver, GI tract, or bone marrow Emotional stress Physical stress Hemorrhage Septicemia Tissue necrosis (surgery, major burns, myocardial infarction)
Lymphocytes (cells/mm ³)	1000-4000	Acute tuberculosis AIDS Congestive heart failure Hodgkin disease Myasthenia gravis Renal failure Systemic lupus erythematosus	Crohn disease Drug hypersensitivity Infectious mononucleosis Ulcerative colitis Viral disorders (mumps, rubella, rubeola, hepatitis, varicella)
Monocytes (cells/mm ³)	100-700	Acute stress reaction Overwhelming infection	Chronic inflammatory disorders Chronic ulcerative colitis Syphilis Tuberculosis
Eosinophils (cells/mm ³)	50-500	Severe infection Shock Stress Trauma	Allergic disease Cancer of lung, stomach, or ovary Hodgkin disease Parasitic infection Polycythemia Ulcerative colitis
Basophils (cells/mm ³)	25-100	Acute infection Graves disease Pregnancy Shock Stress	Chickenpox Chronic sinusitis Measles Ulcerative colitis

^aProportion of each type of white blood cell observed on the blood smear.

AIDS, Acquired immune deficiency syndrome; *GI*, gastrointestinal; *RBC*, red blood cell; *WBC*, white blood cell.

Adapted from Pagana, K. D., & Pagana, T. J. (2018). *Mosby's manual of diagnostic and laboratory tests* (6th ed.). St. Louis: Elsevier.

1. Explain the relationship between M. R.'s laboratory results and her vital signs. Provide possible explanations for the abnormal results.

Coagulation Studies

Three mechanisms are activated by injury to a blood vessel: vascular spasm, plug formation, and blood clotting (Fig. 34.2). In an attempt to prevent additional blood loss, the injured vessel constricts. This vasoconstriction lasts only a few minutes but provides the needed time and decreased surface area to facilitate platelet aggregation. The platelets clump together and form a temporary plug to seal the injured vessel. The final mechanism to protect against blood loss is coagulation, or clotting, of the blood. This complex process involves the conversion of fibrinogen to fibrin. The fibrin then adheres to the platelets and other blood cells to form a more permanent seal to the injured blood vessel (Fig. 34.3). The animation “[Hemostasis](#)” illustrates the three mechanisms following blood vessel injury[®].

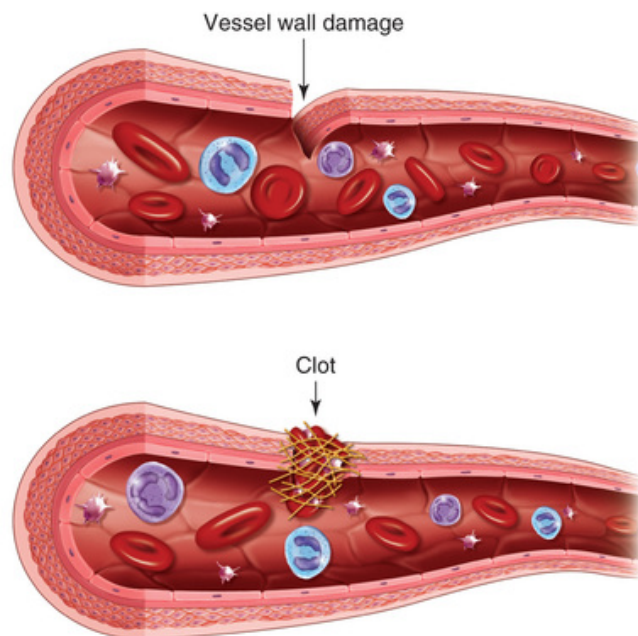

FIGURE 34.2 Blood clotting.

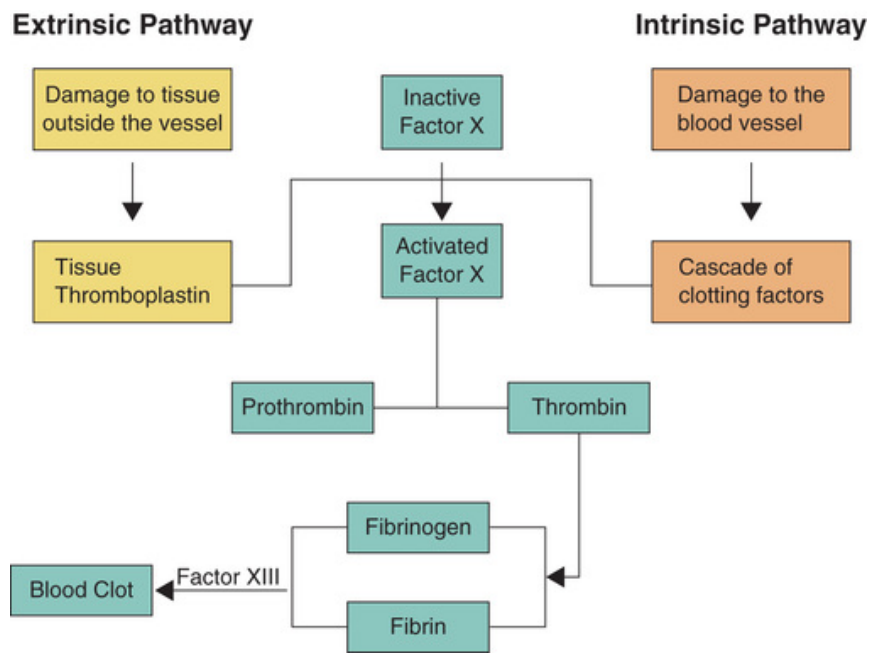

FIGURE 34.3 Pathways of coagulation.

Five diagnostic tests are used to monitor hemostasis, the blood's ability to stop bleeding. They measure (1) platelets, (2) bleeding time, (3) **prothrombin time (PT)** or **international normalized ratio (INR)**, (4) **activated partial thromboplastin time (APTT)**, and (5) fibrinogen. These tests, the normal values, and abnormal findings are summarized in [Table 34.3](#).

TABLE 34.3**Coagulation Studies**

Component	Function	Normal Value	Clinical Significance of Abnormal Values	
			Decreased Levels	Increased Levels
Platelets (cells/mm ³)	Measures number, size, and shape of cells	150,000-400,000	Pernicious, aplastic, and hemolytic anemias Multiple transfusions of packed RBCs HIV infection Result of chemotherapy and radiation therapy	Leukemias Splenectomy Iron-deficiency anemia Rheumatoid arthritis Acute infection or inflammatory diseases
Prothrombin time	Can detect bleeding disorders caused by abnormalities of the extrinsic clotting system Used to monitor effectiveness of warfarin therapy	11-12.5 sec Therapeutic level for anticoagulant therapy: 1.5-2.0 times the control value	N/A	Acute leukemia Congestive heart failure Chronic pancreatitis Hepatitis Liver disease Oral anticoagulant therapy (warfarin)
International normalized ratio (INR)	Used to monitor effect of anticoagulant therapy	0.8-1.1 for patient not on anticoagulant 2.0-3.0 for therapeutic prophylaxis or treatment of venous thrombosis 3-4 for prosthetic cardiac valve replacement	N/A	Acute leukemia Congestive heart failure Chronic pancreatitis Hepatitis Liver disease Oral anticoagulant therapy (warfarin)
Activated partial thromboplastin time	Can detect bleeding disorders caused by abnormalities of the intrinsic clotting system Used to monitor effectiveness of heparin therapy	30-40 sec Therapeutic level for anticoagulant therapy: 1.5-2.5 times the control value	Acute hemorrhage Advanced stages of cancer	Hemophilia Cirrhosis Hemodialysis Liver disease Heparin therapy Vitamin K deficiency

Component	Function	Normal Value	Clinical Significance of Abnormal Values	
			Decreased Levels	Increased Levels
Fibrinogen (mg/dL)	Used to identify suspected bleeding disorders Used to monitor progressive liver disease	200-400	Anemia Cirrhosis Hemophilia Leukemia Liver disease Malnutrition	Acute infection Major burns Heart disease Hepatitis Nephrosis Cancer (breast, kidney, stomach) Myocardial infarction

HIV, Human immunodeficiency virus; *N/A*, not applicable; *RBC*, red blood cell.

Adapted from Pagana, K. D., & Pagana, T. J. (2018). *Mosby's manual of diagnostic and laboratory tests* (6th ed.). St. Louis: Elsevier.

Newer anticoagulants are being used in some patients. Some of these drugs are monitored by the CBC and others by clotting factors, depending on the medication and its action within the body.

Blood Chemistry

When electrolytes are dissolved, they become electrically charged particles known as *cations* (positively charged) or *anions* (negatively charged). The most commonly monitored cations include sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and magnesium (Mg^{2+}). Anions that are commonly monitored include chloride (Cl^-), bicarbonate (HCO_3^-), and phosphate (HPO_4^-). [Chapter 39](#) discusses the functions of these intracellular and extracellular electrolytes, the normal values, and the common causes of abnormal values. A **basic metabolic panel (BMP)** is a commonly ordered diagnostic test that measures electrolytes, carbon dioxide, glucose, and renal function. [Table 34.4](#) lists the BMP components, normal values, and common explanations for abnormalities.

TABLE 34.4**Basic Metabolic Panel**

Component	Normal Value	Clinical Significance of Abnormal Values	
		Decreased Levels	Increased Levels
Sodium (mEq/L)	136-145	Hypovolemic hyponatremia Diuretic use GI fluid loss Profuse diaphoresis Water intoxication Prolonged use of hypotonic IV solutions SIADH	Excessive sodium intake Hypertonic IV solutions Hypertonic enteral feedings without adequate water Excessive loss of water due to diarrhea Inadequate intake of water Insensible loss due to fever
Potassium (mEq/L)	3.5-5	Loss of potassium due to vomiting, gastric suction, diarrhea Laxative abuse, frequent enemas Use of potassium-wasting diuretics Inadequate intake seen in anorexia, alcoholism, debilitated patients Hyperaldosteronism	Renal failure Massive trauma, crushing injuries, burns Hemolysis IV potassium Potassium-sparing diuretics Acidosis, especially diabetic ketoacidosis
Chloride (mEq/L)	98-106	Overhydration Heart failure SIADH Vomiting or gastric suction Addison disease Burns Metabolic alkalosis Certain medications	Dehydration Anemia Excessive normal saline infusion Cushing syndrome Kidney disease Metabolic acidosis Respiratory alkalosis or hyperventilation
Carbon dioxide (mEq/L)	23-30	Renal failure Salicylate toxicity Diabetic ketoacidosis Metabolic acidosis Shock	Severe vomiting Severe diarrhea Aldosteronism Metabolic alkalosis Emphysema/COPD
Glucose (mg/dL)	74-106	Anxiety Excessive exercise Malabsorption Excessive insulin	Diabetes mellitus Obesity Liver disease Pancreatitis Trauma Corticosteroid therapy
Blood urea nitrogen (mg/dL)	10-20	Alcohol abuse Diet inadequate in protein Hepatitis Liver failure Malnutrition	Acute glomerulonephritis Congestive heart failure Diabetes mellitus High-protein diet Nephrotic syndrome Renal disease Severe dehydration Severe infection Shock
Serum creatinine (mg/dL)	Females: 0.5-1.1 Males: 0.6-1.2	Atrophy of muscle Pregnancy	Congestive heart failure Dehydration Diabetes mellitus Glomerulonephritis Renal failure Rheumatoid arthritis Shock Uremia

COPD, Chronic obstructive pulmonary disease; *GI*, gastrointestinal; *IV*, intravenous; *SIADH*, syndrome of inappropriate antidiuretic hormone secretion.

Glucose, an energy source necessary for cellular metabolism, is an end product of carbohydrate metabolism. Excess glucose is converted to glycogen and is stored in the liver. Normal glucose levels are controlled by the release of two hormones: glucagon and insulin. Glucagon raises blood levels of glucose by facilitating the breakdown of glycogen. Insulin lowers blood glucose levels by acting as a carrier to transport glucose into the cells, where it is available for use.

Monitoring serum levels of glucose is useful in detecting abnormal glucose metabolism. Although there are several causes for abnormal glucose metabolism, the most common is diabetes mellitus. Blood glucose levels can be monitored with a venous sample, but it is most frequently monitored using a capillary blood sample before meals and at bedtime for patients with diabetes.

Hemoglobin A_{1c} (Hgb A_{1c}), or glycosylated hemoglobin, testing evaluates blood sugar levels over a period of 2 to 3 months. This blood test is performed to provide the PCP with information about long-term blood sugar control. The normal value of Hgb A_{1c} in patients without diabetes is 4% to 5.9%. The [American Diabetes Association \(2016\)](#) states that diabetes is diagnosed for Hgb A_{1c} levels more than 6.5%. A level of < 7% indicates a diabetic in good control; > 9% indicates that the patient has had poor blood glucose control during the past few weeks, and increases the patient's risk of long-term complications from hyperglycemia.

Kidney Function Tests

Two blood tests included in the BMP are used to monitor renal function and assess damage: **blood urea nitrogen (BUN)** and serum creatinine. Urea is a by-product of protein metabolism. It is excreted by the kidneys and measured as BUN. Elevated BUN levels may indicate decreased renal glomerular function. BUN levels also may be elevated as a result of a high-protein diet or with dehydration. Serum **creatinine** is a waste product of skeletal muscle metabolism. It is excreted by the kidneys. Because creatinine is excreted at a more consistent rate than BUN, serum-level values tend to be more sensitive in detecting renal impairment. The normal ratio of BUN to creatinine is between 6 and 25. The ratio can assist in determining whether a patient is volume depleted.

The glomerular filtration rate (GFR) is another essential test of renal function and measures the milliliters filtered by the kidneys each minute. A level less than 60 mL/min/1.73 m² is a sign of renal impairment. The creatinine clearance is a test of renal function that uses a serum creatinine blood test and a 24-hour urine collection test to measure the GFR. Because the 24-hour urine collection can be time consuming and costly, more institutions are now estimating the GFR (eGFR) using a prediction calculation ([Pagana, Pagana, & Pagana, 2019](#)). A level below 60 mL/min/1.73 m² indicates renal impairment.

Lipid Profile

A lipoprotein profile is used to diagnose hyperlipidemia and monitor treatment effectiveness. It usually consists of four tests: total cholesterol, **low-density lipoprotein (LDL)** cholesterol, **high-density lipoprotein (HDL)** cholesterol, and triglycerides. **Cholesterol** is a sterol (i.e., modified steroid) that is mostly synthesized in the liver from dietary fats. It can be found in cell plasma membranes and is a precursor for vitamin D, steroid hormones, and sex hormones.

LDLs transport cholesterol from the liver to various parts of the body. LDL cholesterol is considered “bad cholesterol” because of its role in atherosclerotic disease. HDLs transport excess cholesterol from the tissues back to the liver, where it is broken down and excreted in bile. HDL cholesterol is considered “good cholesterol,” because high levels reduce the risk of heart disease.

Triglycerides are composed of fatty acids, proteins, and glucose. They are synthesized in the liver and stored in adipose tissue and muscle. They can be retrieved when additional energy is needed to meet metabolic demand. Measurement of triglycerides is used to calculate LDL cholesterol levels with the following formula (Pagana & Pagana, 2018):

$$\text{LDL cholesterol} = \text{Total cholesterol} - (\text{HDL cholesterol} + [\text{Triglycerides} \div 5])$$

Normal values for lipid levels and the disorders that lead to abnormal values are summarized in [Table 34.5](#).

TABLE 34.5
Lipid Studies

Component	Normal Value	Clinical Significance of Abnormal Values	
		Decreased Levels	Increased Levels
Total cholesterol (mg/dL)*	<200	Acquired immunodeficiency syndrome (AIDS) Chronic anemia Liver disease Malabsorption Malnutrition Sepsis Stress	Atherosclerosis Cardiovascular disease Hyperlipidemia Nephrotic syndrome Obesity Uncontrolled diabetes mellitus
High-density lipoprotein cholesterol (mg/dL)*	Males: >45 Females: >55	Chronic inactivity Diabetes mellitus End-stage liver disease Obesity Renal failure Smoking Stress	Alcoholism Chronic liver disease Long-term aerobic exercise
Low-density lipoprotein cholesterol (mg/dL)*	<130	Cancer Malabsorption Malnutrition	Chronic renal failure Diabetes mellitus High-cholesterol diet Hyperlipidemia Nephrotic syndrome
Triglycerides (mg/dL)*	Males: 40-160 Females: 35-135 Critical value: >400	Chronic obstructive pulmonary disease Low-fat diet Malabsorption Malnutrition	Alcohol abuse Cirrhosis Diabetes mellitus Low-protein, high-carbohydrate diet Familial hyperlipoproteinemia Gout Hypertension Nephrotic syndrome Pancreatitis

*Test requires fasting.

Liver Function Tests

A liver profile usually consists of serum levels of albumin, bilirubin, and the following four liver enzymes: **alanine aminotransferase (ALT)**, **alkaline phosphatase (ALP)**, **aspartate aminotransferase (AST)**, and **gamma-glutamyl transpeptidase (GGTP)**.

Albumin is one of the plasma proteins synthesized by the liver. It is an essential component of fluid balance, responsible for maintaining colloidal oncotic pressure in the vascular and extravascular spaces. Low levels of albumin may indicate malnutrition.

Prealbumin is another plasma protein synthesized by the liver. It has a much shorter half-life than albumin and is therefore considered a more precise measure of current nutritional status.

Bilirubin, one of the components of bile, is synthesized in the liver, spleen, and bone marrow. Bilirubin is also a by-product of **hemolysis**, or RBC destruction. Total bilirubin levels are increased in jaundice.

ALT is an enzyme found primarily in the liver, but it also is found in the kidneys, heart, and skeletal muscle. It is a catalyst for amino acid production. Serum levels are used to monitor liver disease progression and the effect of hepatotoxic drugs.

ALP is an enzyme found primarily in the liver. It also is found in the bone, placenta, intestine, and kidneys. Serum levels are useful indicators of liver and bone disease.

AST is an enzyme found primarily in the heart, liver, and muscle. It is released after cell death or injury. Serum levels are measured primarily to assess the severity of liver damage and disease.

GGTP is found primarily in the liver and biliary tract. This enzyme assists the transportation of amino acids across cell membranes. Elevated serum levels may indicate liver disease.

Normal values for liver function test results and disorders that lead to abnormal values are summarized in [Table 34.6](#).

TABLE 34.6**Liver Function Tests**

Component	Normal Value	Clinical Significance of Abnormal Values	
		Decreased Levels	Increased Levels
Albumin (g/dL)	3.3-5	Diabetes mellitus Glomerular protein loss Hepatic disease Malnutrition Renal disease Rheumatoid arthritis Stress	Acute pancreatitis Dehydration
Bilirubin (mg/dL) ^a	0.3-1.0	N/A	Biliary obstruction Cirrhosis Hepatitis Hemolytic transfusion reaction Tissue hemorrhage
Alanine aminotransferase (units/L)	4-36	N/A	Biliary obstruction Cirrhosis Hepatitis Muscle inflammation Pancreatitis Shock Trauma
Alkaline phosphatase (units/L)	30-120	Chronic nephritis Hypothyroidism Malnutrition Excessive vitamin D intake	Biliary obstruction Cirrhosis Hepatitis High-fat intake Pancreatitis Vitamin D deficiency
Aspartate aminotransferase (units/L)	0-35	Diabetic ketoacidosis Pregnancy Uremia	Acute renal disease Biliary obstruction Cirrhosis Hepatitis Pancreatitis Trauma
Gamma-glutamyl transpeptidase (units/L)	Males and females >45 yr: 8-38 Females <45 yr: 5-27	N/A	Acute pancreatitis Alcoholism Biliary obstruction Cirrhosis Congestive heart failure Hepatitis Myocardial infarction

Cardiac Markers

Cardiac markers are proteins that leak out of injured heart muscle cells into the bloodstream. A series of tests is used to detect abnormal levels of these markers, which can indicate myocardial damage due to coronary artery occlusion. These tests are usually done over the course of a day, usually every 3-6 hours to track trends. Testing may include the following markers: **creatinine kinase (CK)** and the CK-MB isoenzyme, myoglobin, and troponin I and troponin T.

CK is an enzyme found primarily in skeletal muscle, cardiac muscle, and brain tissue. Elevated CK levels usually indicate damage in one of these three areas. CK is further broken down into three isoenzyme forms. CK1 (CK-BB) is found primarily in brain tissue. CK2 (CK-MB) is found in cardiac tissue. CK3 (CK-MM) is found primarily in skeletal tissue. Normal levels of CK consist primarily of the CK-MM isoenzyme. Elevated levels of isoenzymes can be useful in diagnosing and differentiating between myocardial damage and skeletal and inflammatory disorders. Correct timing of these tests is essential for accurate diagnosis.

Myoglobin is an oxygen-transporting and storage protein found in cardiac and skeletal muscle. When damage to a muscle cell occurs, myoglobin is released, and blood levels of the protein rise. Because myoglobin is found primarily in cardiac and skeletal muscles, elevated levels can be diagnostic of myocardial infarction (MI) or skeletal muscle trauma.

Troponin is a complex of three proteins found in cardiac and skeletal muscle. Two of the proteins, **troponin I** and **troponin T**, are found exclusively in cardiac muscle. These proteins are released during myocardial damage and can be detected as early as 4 hours after an MI, even with small areas of cardiac muscle injury. Tests for troponins are much more sensitive to the early onset of an MI and are used much more frequently in the clinical setting to detect an MI than CK-MB or myoglobin. [Table 34.7](#) lists the onset, peak, and return-to-normal times for the cardiac markers previously discussed.

TABLE 34.7
Cardiac Markers

Marker	Normal Value	Abnormal Value	Begins to Rise (hrs)	Peak (hrs)	Returns to Normal (days)
Total creatine kinase (units/L)	Females: 30-135 Males: 55-170	Females: >150 Males: >174	6	18	2-3
CK-MB (%)	<0%	>3%	4	18	2
Myoglobin (ng/mL)	<90	>90	3	8-12	Within 1
Troponin I (ng/mL)	<0.03	>0.04	4-6	10-24	4
Troponin T (ng/mL)	<0.1	>0.1	4-6	10-24	10

Homocysteine is an amino acid formed in the conversion of methionine to cysteine. Folate and vitamins B₆ and B₁₂ are necessary for the body to

metabolize homocysteine. Normal levels for homocysteine are 4 to 14 $\mu\text{mol/L}$. High levels of homocysteine are associated with an increased risk of cardiovascular disease, although it is not known whether increased levels are a precursor to or a result of the disease. Smoking and vitamin deficiencies, specifically folate and vitamins B₆ and B₁₂, seem to play a role in elevating levels. Adding these vitamins to the diet can lead to lower serum levels of homocysteine.

Brain natriuretic peptide (BNP) is a hormone produced by myocardial cells. It is released from the ventricle during times of increased pressure or overload. BNP causes vasodilation by opposing the action of angiotensin II and increases sodium excretion and urine output. Elevated levels are often found in patients with heart failure, and plasma concentrations reflect the severity of cardiac failure. Normal levels are below 100 pg/mL.

C-reactive protein (CRP) is produced by the liver in response to inflammation, tissue damage, and infection. Blood levels of CRP have been used as a marker for inflammatory and autoimmune disorders, such as rheumatoid arthritis, lupus, and inflammatory bowel syndrome. CRP is a marker for vascular inflammation—an important factor in atherosclerosis. The high-sensitivity CRP (hs-CRP) blood test is used to measure the CRP level. Levels below 1 mg/L indicate a low risk, levels between 1 and 3 mg/L indicate average risk, and levels above 3 mg/L indicate high risk. CRP is now used as a screening for coronary artery disease and as a predictor of future cardiac events.

The **arterial blood gas (ABG)** diagnostic test is used to examine arterial blood and assess a patient's oxygenation status and acid–base balance. [Chapter 39](#) provides more information on this topic.

LO 34.3 Laboratory Tests: Urine and Stool

Tests are commonly ordered for urine, stool, and other bodily fluid specimens. In many circumstances, it is the nurse's responsibility to collect these specimens or to delegate the collection to unlicensed assistive personnel (UAP).

Urinalysis

Urinalysis is a common diagnostic test. It is frequently ordered on admission to the hospital and as part of a routine physical examination. It is used to diagnose urinary tract infections (UTIs) and is helpful in detecting diseases and disorders unrelated to the renal system. Sometimes a quick reagent strip is used for urinalysis (Fig. 34.4). Skill 34.2 explains the use of the quick reagent strip. An overview of the components of the urinalysis, the normal values, and the disorders related to abnormal values can be found in Table 34.8.

FIGURE 34.4 (A) and (B), Quick reagent strip for urinalysis. (From Brunzel, N. A. [2018]. *Fundamentals of urine and body fluid analysis*. St. Louis: Elsevier.)

TABLE 34.8**Urinalysis Findings**

Component	Normal Value	Abnormal Values
Color	Light yellow to amber	Dark yellow to amber: <ul style="list-style-type: none"> • Concentrated urine • Presence of bilirubin Blue/green: <ul style="list-style-type: none"> • Pseudomonas UTI Light straw/very pale yellow: <ul style="list-style-type: none"> • Alcohol ingestion • High fluid intake • Dilute urine Orange: <ul style="list-style-type: none"> • Presence of bile • Fever • Several drugs known to alter the color of urine
Clarity	Clear to slightly hazy	Cloudy: may indicate bacteria and RBC or WBCs
Specific gravity	1.005-1.030	Increased: <ul style="list-style-type: none"> • Acute glomerulonephritis • Congestive heart failure • Dehydration • Diabetes mellitus • Low fluid intake • Liver failure • Vomiting and diarrhea Decreased: <ul style="list-style-type: none"> • Antidiuretic hormone deficiency • Chronic pyelonephritis • Diuretics • High fluid intake
Potential hydrogen (pH)	4.6-8.0	Increased: <ul style="list-style-type: none"> • Bacteriuria • Chronic renal failure • Metabolic alkalosis • UTI • Starvation Decreased: <ul style="list-style-type: none"> • Dehydration • Diabetes mellitus • Diarrhea • Fever • UTI
Glucose	Negative	Increased: <ul style="list-style-type: none"> • Diabetes mellitus • Infection • Stress
Ketones	Negative	Increased: <ul style="list-style-type: none"> • Alcoholism • Anorexia • Diabetes mellitus • Diarrhea • Fasting • Fever • High-protein diet • Postanesthesia • Starvation • Vomiting

Component	Normal Value	Abnormal Values

Stool

The excreted waste products of digestion are known as *stool* or *feces*. Stool analysis is useful in identifying disorders of the gastrointestinal (GI) tract, liver, and pancreas. Analysis is commonly ordered to test for occult blood, fecal fat, urobilinogen levels, and ova and parasites.

Bleeding anywhere along the GI tract results in blood in the stool. Bleeding that occurs in the upper GI tract produces stools that are black and tarry in appearance. Bleeding from the lower tract results in stools with bright red blood. The testing for occult blood in the stool can detect very small amounts of blood, as little as 5 mL per day. Results that are positive for occult blood may indicate several disorders, including peptic ulcer disease, inflammatory bowel disease, hemorrhoids, and trauma to the GI tract. Positive occult blood findings also can indicate gastric or colon cancer. The [American Cancer Society \(2018\)](#) recommends screening for colorectal cancer using fecal occult blood testing, sigmoidoscopy, or colonoscopy in adults with average risk factors beginning at age 45 years.

Examination of the stool can provide diagnostic information about the effectiveness of the digestive system. Fecal fat, or **steatorrhea**, indicates a failure to digest and absorb dietary fat. Steatorrhea is usually a result of malabsorption syndrome, deficiency of pancreatic enzymes, or deficiency of bile (usually due to biliary obstruction).

Urobilinogen is produced by the breakdown of bilirubin and is responsible for the brown color of stool. Normal levels are 50 to 300 mg per 24 hours. Increases in urobilinogen result from increased RBC destruction, as in

hemolytic anemia. Decreased levels are seen in biliary obstruction or in severe liver disease.

Parasites and their eggs (ova) in the stool can lead to GI symptoms, such as diarrhea. Common parasites are roundworm, pinworm, hookworm, tapeworm, and *Trichinella spiralis*. With the exception of pinworms, common parasites are ingested by consuming contaminated food or water. Stool collected for ova and parasite examination must be delivered to the laboratory while still warm.

Culture and Sensitivity

When an infection is suspected, culture specimens can be obtained from body fluids to identify the pathogen responsible. Common sources of specimens are blood, throat, sputum, stool, urine, and wounds. The collected specimen is sent to the laboratory, where a portion is placed on a culture medium. A culture is considered positive when sufficient bacteria are found growing on the medium. After the pathogen has been identified, it is exposed to various antibiotics, and the bacterial growth is monitored to determine *sensitivity*, or which antibiotic therapy would be most effective in treating the infection. Bacteria are considered susceptible when the antibiotic kills or inhibits growth, whereas resistant bacteria continue to grow despite the presence of the antibiotic.

LO 34.4 Diagnostic Examinations

In addition to having their blood and body fluids tested in the laboratory, patients may have orders for diagnostic tests, such as radiography, computed tomography (CT), magnetic resonance imaging (MRI), electrocardiography, endoscopy, ultrasound, and needle aspirations and biopsies. Nursing responsibilities for these tests depend on the setting and the particular test.

Radiography

Radiography is the use of x-rays to visualize bones, organs, and soft tissues for abnormalities. X-rays are electromagnetic vibrations that travel in a straight line. When the x-ray passes through matter, some of the intensity is absorbed; the denser the matter, the higher the degree of absorption. This absorption can be captured on film, with the differences in density appearing as various shades of darkness. High-density matter, such as bone, appears to be white, and air-filled areas appear to be black.

Noncontrast Studies

X-rays are routinely ordered as diagnostic examinations for the chest, bones, abdomen, and breasts. These x-rays are considered noncontrast studies because they do not require administration of contrast material before the examination.

Chest x-rays are one of the most frequently ordered radiographs. A chest x-ray can be used to diagnose several pulmonary disorders, such as tuberculosis, cancer, and pneumonia. Chest x-rays are also used to determine the correct placement of treatment devices, such as chest tubes, central line infusion catheters, and pacemakers.

X-rays are used to diagnose fractures in bones and joints. Other disorders that can be diagnosed with orthopedic x-rays include osteoporosis, osteomyelitis, arthritis, and tumors. A frontal supine x-ray of the abdomen is called a *KUB*, which stands for kidneys, ureters, and bladder.

Mammograms are soft tissue x-rays that allow visualization of the underlying breast tissue. Mammography is used primarily as a screening tool for the early detection of tumors or cysts. The [American Cancer Society \(2018\)](#) recommends annual mammograms for average risk women without symptoms starting at 45 years of age.

Contrast Studies

In some situations, visualization requires the use of contrast media to highlight the details not seen on a noncontrast x-ray. The ideal contrast material has low toxicity, is nonallergenic, has no effects on normal physical function, and is relatively low in cost. All contrast materials have the potential for causing allergic reactions, ranging from mild responses (e.g., nausea, vomiting, localized rash) to severe anaphylaxis. Nurses should assess for patient allergies

to seafood, iodine, and contrast dye, as well as lab values (such as BUN, creatinine, and creatinine clearance) that can help determine kidney function, which is needed to excrete the contrast dye.

Disorders of the genitourinary and GI system commonly use contrast x-rays. An intravenous pyelogram is a contrast x-ray exam that examines the kidneys, ureters, and bladder and is useful for diagnosing kidney stones and other abnormalities of the urinary tract. The upper GI series consists of a series of x-rays of the esophagus, stomach, duodenum, and upper portion of the jejunum. It is useful for diagnosing gastric ulcers, pyloric stenosis, hiatal hernias, and carcinoma of the stomach. Before the examination, the patient drinks a contrast agent, usually barium sulfate; the upper GI series is sometimes referred to as a *barium swallow*. The contrast medium outlines the organs seen on x-ray, thereby aiding in identification of any abnormality.

The lower GI tract can be visualized using barium sulfate, sometimes known as a *barium enema*. The contrast medium is introduced through a rectal tube or an enema. Examination of the ascending, transverse, and descending colons, as well as the sigmoid colon and rectum, is useful in diagnosing colon cancer, obstructions, and chronic disorders (such as ulcerative colitis). For the upper and lower GI barium studies, it is the nurse's responsibility to monitor the patient until the barium is expelled. Patients should increase their fluid intake afterward, and some may need a mild laxative to aid in the elimination of the barium. The patient should be aware that barium can cause white stools for a few days as it is expelled.

Computed Tomography

Computed tomography (CT) is a radiologic procedure in which the use of a special scanner allows cross-sectional images of an organ to be visualized (Fig. 34.5). CT scans can be done with or without the use of a contrast medium. Table 34.9 lists specific examinations and abnormal findings.

FIGURE 34.5 Computed tomography (CT) scan. (From Lewis, S. L., Bucher, L., Heitkemper, M. M., et al. [2017]. *Medical-surgical nursing: Assessment and management of clinical problem* [10th ed.]. St. Louis: Elsevier.)

TABLE 34.9
Computed Tomography Findings

Site	Abnormal Findings
Abdomen	Abdominal aortic aneurysm Appendicitis Bile duct dilation Gallstones Hemorrhage Infection Tumors
Brain	Abscess Cerebral infarction Aneurysms Hemorrhage Hydrocephalus Tumors
Chest	Aortic aneurysm Enlarged lymph nodes Esophageal tumors Hiatal hernia Pleural effusion Pulmonary embolism
Kidneys, ureters	Urinary calculi Tumors

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is the most common diagnostic examination for brain pathology and joint visualization (Fig. 34.6). It involves the use of a superconducting magnet and radiofrequency waves that cause hydrogen nuclei to emit signals. A computer translates the signals into a well-defined image of the structure.

FIGURE 34.6 Magnetic resonance imaging (MRI) scan. CSF, Cerebrospinal fluid. (From Mettler, F. A. [2019]. *Essentials of radiology* [4th ed.]. Philadelphia: Elsevier.)

MRI produces a cross-sectional image of the body, similar to a CT scan, but without radiation exposure. It allows better visualization of blood vessels and signs of hemorrhage within hours of the event. It can be used with or without contrast media. [Table 34.10](#) lists the most common sites studied with MRI and examples of abnormal findings.

TABLE 34.10**Magnetic Resonance Imaging Findings**

Site	Abnormal Findings
Abdomen, pelvis	Cancers in the peritoneal area Abdominal aortic aneurysm Acute tubular necrosis
Brain	Acute head injury Stroke Subarachnoid hemorrhage Cerebral abscess Hydrocephalus Tumors
Breast	Cancer Benign lesions
Heart	Congenital heart disease Atherosclerotic plaques Myocardial infarction
Spine	Spinal cord lesions Spinal cord compression Disk herniation Spinal stenosis
Bones, joints	Abnormalities or injuries Joint deterioration

MRI has some disadvantages. It tends to be more expensive than CT. The magnet can affect the functioning of computerized equipment, such as IV infusion pumps and mechanical ventilators. Because the magnet can move metal objects implanted in the body, it is contraindicated for patients with pacemakers, implanted medication pumps, inner ear implants, fragments from gunshot wounds, or other metal objects in the body. It is the nurse's responsibility to assess for these before an MRI. All jewelry must be removed before the test. Some patients experience claustrophobia, because the test is often performed in a tunnel-like machine for 30 to 90 minutes, and these patients may require a sedative. Rarely, people with a tattoo have reported burning and swelling in the area of the tattoo after MRI ([Food and Drug Administration, 2017](#)).

Positron Emission Tomography

Positron emission tomography (PET) is a nuclear study performed after injection of radioactive chemicals intravenously. These chemicals are used metabolically by the organs being studied and emit positrons, which appear as color-coded images that can be analyzed. PET scans are commonly used to study the brain, heart, and in oncology to identify pathologic tissue ([Pagana, Pagana, & Pagana, 2019](#)).

Electrocardiogram

An **electrocardiogram (ECG)**, also called EKG, is a recording of the electrical current generated by the heart during depolarization and repolarization of the cardiac muscle. The ECG is composed of several waveforms that reflect

different aspects of cardiac contraction: P wave (atrial depolarization), QRS wave (ventricular depolarization), and T wave (ventricular repolarization).

The ECG is recorded on special paper that allows measurement of the waveforms in terms of time and shape. Increases in the duration of any waveform can indicate injury to or disorders of the cardiac conduction system. [Chapter 38](#) provides more information on ECGs.

Endoscopy

Endoscopy is a general term used to describe the examination of the interior of an organ or cavity by means of a fiberoptic video endoscope ([Fig. 34.7](#)).

Fiberoptics is a system in which flexible glass or plastic fibers are used to transmit light around curves and corners. This allows direct visualization of the area of interest. Separate ports allow instillation of drugs, suction, and insertion of instruments for tissue or foreign object removal. Some of these procedures are considered “minimally invasive” and use IV sedation rather than general anesthesia, reducing risks. Nurses should ensure that informed consent has been signed by the patient ([Box 34.1](#)). Endoscopic examination is often used to identify tumors and to remove tissue samples for biopsy ([Box 34.2](#)). [Table 34.11](#) summarizes the most common types of tests and the significance of abnormal findings. The “[Endoscopy](#)” animation depicts this procedure[®].

FIGURE 34.7 State-of-the-art video endoscope. (Courtesy Olympus America, Inc., Melville, NY.)

Box 34.1

Ethical, Legal, and Professional Practice

Informed Consent and Communication of Examination Results

- Many diagnostic examinations require informed consent. It is the nurse's responsibility to ensure that the physician has explained the procedure and the consent form has been signed before the procedure begins. Obtaining informed consent is the responsibility of the physician, but the nurse can witness the patient's signature.
- The nurse communicates test and diagnostic examination results to the appropriate interprofessional health care team members in a timely manner.
- The Health Insurance Portability and Accountability Act (HIPAA) protects the patient by requiring that testing results be shared only with health care professionals who need the information to provide treatment and with individuals designated in writing by the patient. [Chapter 11](#) provides more information on HIPAA.

Box 34.2

Evidence-Based Practice and Informatics

Colorectal Cancer Guidelines

The American Cancer Society has recommended the following examinations for early detection of colorectal cancer for people of average risk who are asymptomatic:

- Fecal occult blood test annually starting at age 45 (if the test is positive, a colonoscopy should be performed)
- Flexible sigmoidoscopy every 5 years, starting at age 45 (if the test is positive, a colonoscopy should be performed) *or* colonoscopy every 10 years starting at age 45 *or* double-contrast barium enema every 5 years *or* virtual colonoscopy (CT colonography) every 5 years

Patients considered at higher risk undergo the examinations at more frequent intervals.

From American Cancer Society. (2018). *Guidelines for early detection of cancer*.

TABLE 34.11**Endoscopy Findings**

Examination	Site	Abnormal Findings
Arthroscopy	Joint structure	Cysts Degenerative joint changes Fractures Meniscal injury or disease Osteoarthritis Rheumatoid arthritis Synovitis
Bronchoscopy	Larynx, trachea, and bronchi	Cancer Foreign body Hemorrhage Infection Lung abscess Tracheal stenosis
Colonoscopy or Sigmoidoscopy	Large intestine Distal sigmoid colon and rectum	Colon cancer Crohn disease Diverticulosis Hemorrhoids Polyps Ulcerative colitis Irritable bowel syndrome
Cystoscopy	Bladder and urethra	Calculi Diverticula Prostatic hypertrophy Tumors Urethral stricture
Esophagogastroduodenoscopy (EGD)	Esophagus, stomach, and upper duodenum	Diverticula Esophageal hiatal hernia Esophageal stenosis Gastritis Pyloric stenosis Tumors Varices Ulcers
Laparoscopy	Abdominal and peritoneal cavity	Appendicitis Cholecystitis Infection Tumors or cysts Endometriosis

Ultrasound

Ultrasound is a procedure that provides visualization of soft tissue organs by recording and measuring the reflection of ultrasonic waves. The reflected waves are received by a transducer that converts them into electrical signals. A computer translates these signals into a visual image. This allows a direct view of various organ structures and soft tissues, such as muscles and tendons. Fetal ultrasound is commonly used to determine fetal age, growth, and presence of congenital abnormalities. Abnormal organ growth, lesions or tumors, and

structural damage can also be seen with ultrasound. [Table 34.12](#) summarizes the most common examinations done with ultrasound and the significance of abnormal findings.

TABLE 34.12
Ultrasound Findings

Examination	Site	Abnormal Findings and Uses
Abdominal	Hepatobiliary system	Organ enlargement Presence of masses Tumors Calculi Cirrhosis
	Pancreas	Tumor Pseudocysts Inflammation
	Kidneys	Cysts Calculi Masses Hydronephrosis
	Aorta	Aneurysms Clots Tumors
	Spleen and lymph nodes	Organ enlargement Metastatic spread of cancer
Pelvic (gynecologic)	Bladder, uterus, and ovaries	Organ enlargement Follicle development and oocyte retrieval during infertility treatments Tumors
Pelvic (obstetric)	Uterus	Fetal health, age, and size Level of amniotic fluid Placenta abnormalities
Heart (echocardiogram)	Heart	Heart size, shape, position, and thickness Heart valve abnormalities Abnormal blood flow

Needle Aspirations and Biopsies

Needle aspirations are procedures that are used to remove fluid and tissue for testing. Fine-needle aspiration is a method for obtaining samples with minimal trauma to the underlying organ or structure. A **paracentesis** involves removing fluid from the peritoneal cavity; a **thoracentesis** removes fluid from the pleural space. A **biopsy** involves removing a larger collection of cells, as in a tumor or mass, and may be used to detect cancer in the skin, breast, or liver. Samples can be obtained from any part of the body that can be accessed by the needle. Bacteriologic examination may be conducted on the samples aspirated. [Table 34.13](#) summarizes four of the more common types of aspirations ordered. The animations “[Bone Marrow Aspiration and Biopsy](#),” “[Lumbar Puncture](#),” “[Abdominal Paracentesis](#),” and “[Thoracentesis](#)” depict how these procedures are performed[Ⓜ].

TABLE 34.13**Needle Aspiration Findings**

Examination	Site	Abnormal Findings
Bone marrow aspiration	Iliac crest, sternum	Agranulocytosis Cancer Infection Iron-deficiency anemia Leukemia Lymphoma Platelet dysfunction
Lumbar puncture	Lumbar vertebrae	Infection Brain infarction Meningitis Tumor
Paracentesis	Peritoneal cavity	Cirrhosis Congestive heart failure Nephrotic syndrome Malignancy Peritonitis Pancreatitis
Thoracentesis	Pleural cavity	Infection Malignancy Metastasis Chest trauma Hemothorax

LO 34.5 ♦ Assessment

The nurse begins a preprocedure assessment by collecting basic health history information. Some example questions can be found in [Box 34.3](#).

Box 34.3

Health Assessment Questions

Diagnostic Test Focus

- What medications do you take on a daily basis (include prescription, herbal, and over-the-counter medications)?
- Do you have any allergies to food or medications? What happens if you take them?
- What is your understanding of the test? Do you have any questions?
- What medications did you take before the examination? Prescriptions? Over-the-counter medications?
- Have you smoked or consumed alcohol in the past 24 hours?
- When was the last time you had anything to eat or drink?
- For females: Is there any chance that you may be pregnant? When was your last menstrual period?
- What preparation did you make for this test (e.g., laxatives, nothing by mouth [NPO])?

Several factors need to be assessed before a patient undergoes a diagnostic test. [Table 34.14](#) summarizes some aspects that are applicable to most diagnostic tests. The nurse should check the facility's procedure manual or a diagnostic handbook for care specific to each test.

TABLE 34.14**Assessment Factors and Interventions Associated With Diagnostic Testing**

Focus	Nurse's Responsibility
Identification (ID) band	Check for the presence of an ID band. Ensure that the band is on the patient and is correct.
Database, medical history	Review the medical record for a history of medical disorders that may signal a high risk for complications (e.g., bleeding disorders, hypertension) and/or implanted metallic devices (e.g. pacemakers, ear implants).
Allergies	Check for allergies to food or medications. If the patient is undergoing an examination that involves an iodine contrast medium, check for a history of adverse reactions or allergies to iodine-containing food (e.g., shellfish, cabbage, kale, iodized salt).
Consent	Check that the consent form has been signed and witnessed.
Baseline vital signs	Obtain and document a complete set of vital signs. This provides a baseline for comparison during the procedure.
Medications	Consult with the primary care provider (PCP) about whether regularly scheduled medications should be administered before the diagnostic test.
Nothing by mouth (NPO)	When appropriate, ensure that the patient has maintained NPO status.
Preparations	Determine whether the ordered preparations (e.g., laxatives, cathartics) were taken by the patient. Document the results.
Intravenous (IV) access	If the procedure requires IV access for the administration of medications or contrast media, be sure the IV line is patent and well secured.
Preprocedure medications	If a preprocedure sedative or analgesic has been ordered, ensure that the medication is given at the appropriate time, and emergency equipment is nearby.

It is common for diagnostic procedures to be scheduled on an outpatient basis. This means that the patient is not hospitalized but comes in for the procedure before the scheduled time. As a result, the patient may be required to follow certain instructions at home. [Box 34.4](#) describes some of these instructions.

Box 34.4**Patient Education and Health Literacy****Preparation for Procedures**

Patients often need to complete preprocedure preparation at home. These preparations may include the following:

- A special diet (e.g., clear liquids, nothing by mouth [NPO])
- Laxatives, cathartics, or enemas
- Cessation of certain daily medications (e.g., a patient who takes a daily aspirin may need to stop taking it 1 week before the scheduled examination)

The nurse should employ “universal health literacy precautions,” assuming that all patients may have difficulty comprehending health information, and

aim to simplify communication and confirm comprehension of instructions to ensure that preprocedure preparations are followed properly ([Agency for Healthcare Research and Quality \[AHRQ\], 2018](#)).

2. List at least three focused assessments for M. R. before her esophagogastroduodenoscopy (EGD).

LO 34.6 ♦ Nursing Diagnosis

Nursing diagnoses are based on subjective and objective assessment information, and are used to develop an effective plan of care. The following are common International Classification for Nursing Practice (ICNP) diagnoses related to diagnostic testing:

Ready to Learn (i.e., diagnostic test purpose, procedure, and care required)

- Supporting Data: Patient's statement about wanting to know what is wrong

Risk for Injury

- Supporting Data: Preprocedure medications that cause changes in the sensorium

Anxiety

- Supporting Data: Actual or perceived threat to biologic integrity due to invasive procedure, fidgeting, insomnia

3. Identify two nursing diagnoses appropriate for M. R. Include supporting data.

LO 34.7 ♦ Planning

During the planning phase, the assessment data and nursing diagnoses are used to develop individualized goals and interventions (Table 34.15). The following examples of goal statements reflect the desired outcomes of patients undergoing diagnostic testing:

TABLE 34.15
Care Planning

ICNP Nursing Diagnosis With Supporting Data	Nursing Outcome Classification (NOC)	Nursing Intervention Classification (NIC)
<i>Ready to Learn</i> (i.e., diagnostic test purpose, procedure, and care required) Patient's statement about wanting to know what is wrong	<i>Knowledge: Health behavior</i> Health promotion services	<i>Health education</i> Determine current health knowledge and lifestyle behaviors of individual, family, or target group.

From Butcher, H. K., Bulechek, G. M., Dochterman, J. M., et al. (Eds.). (2018). *Nursing interventions classification (NIC)* (7th ed.). St. Louis: Mosby; Moorhead, S., Johnson, M., Swanson, M., et al. (Eds.). (2018). *Nursing outcomes classification (NOC)* (6th ed.). St. Louis: Mosby; ICNP is owned and copyrighted by the International Council of Nurses (ICN). Reproduced with permission of the copyright holder.

- Patient will state how and why the procedure is performed before the test.
- Patient will remain free from injury in the preprocedure time period.
- Patient will sleep 6 to 7 hours the night before the diagnostic procedure.

The conceptual care map for M. R. can be found at <http://evolve.elsevier.com/YoostCrawford/fundamentals/>. It is partially completed to indicate how to use the map as a learning tool. Complete the nursing diagnoses using the example conceptual care maps shown in Chapters 8 and 25 to 33.

LO 34.8 ♦ Implementation and Evaluation

The nurse's responsibility during a diagnostic procedure is to monitor the patient and assist the PCP. A time-out must be called prior to any procedure to properly identify the correct patient with the correct procedure and correct site. It is not uncommon for a mild antianxiety or analgesic medication to be administered before and during the procedure. The nurse should monitor the vital signs and oxygenation and provide supportive interventions as needed (e.g., oxygen). Post procedure, the nurse's responsibility is to monitor vital signs and assess for any complications that may arise from a procedure (such as, hemorrhage, pain, allergic reaction, and infection).

Many diagnostic procedures require that the patient be positioned in a certain way. Often, the nurse needs to assist the patient in maintaining this position throughout the procedure. When positioning the patient, make sure that bony prominences are protected and the patient is as comfortable as possible.

During some procedures, patients are conscious, although somewhat drowsy. When needed, the nurse should provide emotional support by explaining the procedure and answering questions. Never underestimate the support provided by simply holding the patient's hand.

Many diagnostic procedures involve the risk of exposure to the patient's blood and body fluids. Universal or standard precautions and medical asepsis should always be maintained. When sterile technique is required, it is the nurse's responsibility to assist in maintaining the sterile field.

4. List at least five nursing interventions for this diagnosis: *Risk for Injury*; Supporting data: Effects of midazolam on the sensorium. Include focused assessment interventions and teaching points.

It is common for biopsies or specimens to be collected during procedures, or as part of routine care. The nurse makes sure that each specimen is placed in the appropriate container and clearly labeled with the patient's identification information. The date and time of the collection and site/location should also be noted on the label.

Specimen Collection

Some specimens are collected routinely, and it is the nurse's responsibility to schedule the timing of the collection and coordinate instructions for specimen

collection with the patient and other staff (Box 34.5). Although many of the specimens can be collected by UAP, it remains the nurse's role to ensure that the samples are collected correctly and in a timely manner. Before the start of any procedure, the nurse must ensure that consent forms are signed and the patient has been correctly identified with the correct specimens being collected. Certain types of specimen collection can be performed at home; it is important that the nurse assess the ability of the patient or the caregiver to carry out the collection following the correct technique (Box 34.6).

Box 34.5

Interprofessional Collaboration and Delegation

Specimen Collection and Diagnostic Tests

- Many specimens are collected by trained unlicensed assistive personnel (UAP). It is important for the nurse to understand which specimen collection can be delegated and to whom (i.e., UAP, laboratory technicians). Nurses should also communicate specimen needs with all team members who may assist patients with toileting.
- The nurse is responsible for ensuring that the specimen is collected correctly and sent to the laboratory in a timely manner. The nurse documents the appropriate information in the patient record and on the collection container (date, time, initials, site, location, method of collection).
- It is important for the nurse to communicate to other members of the health care team when preprocedure medications or treatments may alter the plan of care. For example, if the nurse has administered a preprocedure sedative, the other members of the interprofessional health care team should be aware of an increased risk for sedation, breathing difficulties, or injury related to falls.
- When multiple tests are ordered, the nurse is responsible for coordinating and scheduling the tests. For example, if a patient is ordered to have a chest x-ray and a colonoscopy, it would be important to wait until after the chest x-ray is completed before administering the pre-procedure bowel laxatives.

Box 34.6

Home Care Considerations

Specimen Collection at Home

Often the patient is asked to collect a specimen at home and transport it to the health care center. To ensure accurate test results, the nurse should assess the following factors:

- Does the patient understand the collection instructions? They include timing of the collection, cleansing procedures, and contamination precautions.
- Does the patient have the appropriate equipment and containers to collect the specimen?
- How is the specimen to be transported?
- Does it need to be kept warm or cold?
- When does it need to be transported? Immediately or within a few hours?

Safe Practice Alert

The nurse must check that the consent form has been signed *before* any preprocedure sedatives or narcotics are administered.

An essential component of the collection process is obtaining the specimen from the correct patient (Box 34.7). The National Patient Safety Goals established by The Joint Commission (2019) address patient safety concerns. Goal 1, *identify patients correctly*, using at least two identifiers, such as name and date of birth. Another national patient safety goal is to improve staff communication by getting important test results to right person on time.

Box 34.7

Evidence-Based Practice and Informatics

National Patient Safety Goals

- Identifying patients correctly continues to be a top National Patient Safety Goal.
- Two patient identifiers are used when collecting blood samples and other specimens for clinical testing.
- The patient's room number or physical location is not used as an identifier.
- Containers used for blood and other specimens are labeled in the presence of the patient.
- Although technology and informatics systems may flag abnormal test results, nurses must ensure test results are communicated and received by the responsible provider in a timely fashion.

Modified from The [Joint Commission](https://www.jointcommission.org/standards_information/npsgs.aspx). (2019). National Patient Safety Goals. Retrieved from https://www.jointcommission.org/standards_information/npsgs.aspx

Blood Collection

Blood specimens can be collected by venipuncture, which accesses a vein; arterial puncture, which accesses an artery; or fingerstick, which collects capillary samples. Venipuncture is performed by nurses in some settings but is commonly performed by phlebotomists. This skill is discussed later in this chapter and in [Chapter 39](#), where it is covered in Skill 39.1 in relation to starting a peripheral IV line. Arterial samples are usually collected by a phlebotomist or respiratory therapist but can also be drawn by a nurse who has been specially trained. Capillary samples are routinely obtained by the nurse and sometimes by UAP, according to facility policy.

Venipuncture

Some of the most frequently ordered diagnostic tests require a sample of the patient's blood. This sample is usually obtained by **venipuncture**, insertion of a needle directly into the vein and withdrawal of the needed amount of blood ([Box 34.8](#)). When venipuncture is required, the timing of the test may be important. For example, some tests require the patient to fast for a specified time period. If the purpose of the test is to monitor blood levels of a medication, venipuncture must be done at a precise time after the medication is administered.

Box 34.8

Diversity Considerations

Life Span

- Obtaining a blood sample from infants and children can be difficult due to the small size of the veins. Having parents or caregivers present may help calm the child.
- Capillary blood from heel sticks is sometimes used for testing in newborns and infants.
- Elderly people commonly have veins that are fragile, increasing the risk of hemorrhage and bruising after venipuncture, especially in those taking aspirin or anticoagulants.

Morphology

- It is often difficult to visualize and access veins in people who are obese. Vein visualization devices can improve venipuncture success.

Safe Practice Alert

Venipuncture is an invasive procedure that may expose the nurse to blood-borne organisms and contaminated needles. The nurse must wear gloves throughout the procedure and properly dispose of the collection needles in the sharps container immediately after the specimen is obtained.

Other factors that can influence test results include hemoconcentration and hemolysis. Hemoconcentration, which is an increased concentration of RBCs compared with plasma volume, can result from the tourniquet being applied for too long. The nurse should minimize the time that the tourniquet is on the patient's arm and release it as soon as the specimens are collected.

Hemolysis is the breakdown of RBCs and the subsequent release of hemoglobin. Hemolysis occurs when the needle used for venipuncture is too small and the RBCs are damaged as a result of the negative pressure.

Certain blood collection tubes are specific for venipuncture. These tubes are made of glass or plastic and are attached to a needle and a holder. The tubes are sealed with a partial negative vacuum (i.e., the pressure within the tube is less than that outside the tube). The needle is inserted into the vein, with the collection tube attached in the holder; the negative pressure causes blood to flow into the tube to a predetermined point. The rubber stopper seals are different colors based on the additive contained inside. [Table 34.16](#) lists the most common stopper colors, the additive contained in the tube, and the corresponding test. The ordered serum samples must be collected in a specific order to avoid cross-contamination of the additives from one tube to another. The chart lists the tubes in the order of collection. Nurses should be aware of facility policy regarding the collection of blood and containers available. Although venipuncture is commonly performed by certified phlebotomists, there are situations and times when it is the nurse's responsibility to obtain the blood sample.

TABLE 34.16**Blood Collection Tubes**

Stopper Color	Additive	Specimen Use
Yellow	SPS	Blood culture
Light blue	Sodium citrate	Coagulation studies: PT, PTT, and fibrinogen
Red	No additive	Most blood chemistries and serology tests Blood bank testing
Red/black	Silicone	Most blood chemistries and serology tests
Green	Heparin	Stat (immediate) blood chemistries
Lavender	EDTA	Hematology studies
Gray	Potassium oxalate and sodium fluoride <i>or</i> Lithium iodoacetate and heparin	Glucose Blood alcohol levels Lactic acid

From Warekois, R. S., & Robinson, R. (2016). *Phlebotomy* (4th ed.). St. Louis: Elsevier.

EDTA, Ethylenediaminetetraacetic acid; PT, prothrombin time; PTT, partial thromboplastin time; SPS, sodium polyanethol sulfonate.

QSEN Focus!

A high amount of variance in blood collection practices causes concern for quality and patient experience outcomes. Standardization in blood collection processes will improve safety.

QSEN Focus!

When collecting blood samples, the nurse must use evidence-based practice and demonstrate knowledge of scientific methods and standardized processes.

Safe Practice Alert

It is important to assess the venipuncture site in patients who are on anticoagulant therapy (e.g., warfarin, heparin, enoxaparin) or take aspirin on a daily basis. They are at higher risk for continued bleeding.

Blood Glucose Monitoring Device

Frequent monitoring of blood glucose levels by the nurse or self-monitoring by the patient is easily done with the use of a glucose monitoring device (Box 34.9). A drop of capillary blood is obtained by puncturing the end of a finger with a sterile lancet. A test strip with a specific reagent is placed in the monitoring device and the drop of blood is placed on the test strip. The devices use a light beam or an electric charge to interpret the changes on the test strip (Skill 34.1). The accuracy of the capillary reading can be influenced by hypoxia, markedly abnormal hemoglobin levels, or a glucose level higher than 800 mg/dL (Corbett & Banks, 2013). Most monitors cannot detect glucose levels greater than 600 mg/dL. Test strip factors and contaminants on the patient's hand can also have an impact on the accuracy of capillary readings.

Box 34.9

Home Care Considerations

Blood Glucose Monitoring

Patients with diabetes mellitus are asked to monitor their blood glucose levels on a daily basis at home. It is important to assess their ability to comply with this testing regimen.

- Does the patient understand the procedure and frequency of testing? A return demonstration is helpful in assessing the patient's level of understanding.
- Are there financial concerns regarding testing? Although testing supplies may be expensive, most insurance companies cover the cost. For uninsured patients, there are programs that assist with the costs.
- Is the patient compliant with the testing? Frequent testing can be an essential component of blood glucose control.

Urine Collection

Urinalysis is one of the most frequently ordered diagnostic tests. Urine samples are relatively easy to obtain and are inexpensive. Testing components of urine can provide diagnostic information about renal function, fluid balance, and the existence of infection and other disorders. The nurse is responsible for ensuring that the urine sample is collected accurately. Urine tests can require a one-time voided sample or a timed collection in which all the urine within a specific time period (e.g., 24 hours) is collected and saved.

Safe Practice Alert

It is essential that the nurse maintain standard precautions when collecting urine and stool specimens. These precautions include washing hands before and after collection, wearing gloves during the procedure, and storing the specimen in a biohazardous material container or plastic bag during transport to the laboratory.

A random (clean-voided) specimen is usually adequate for routine urinalysis and random drug testing. Most patients are able to obtain a specimen independently and with minimal direction. The clean specimen can be collected in a new urinal or bedpan or directly into the specimen container (Fig. 34.8).

FIGURE 34.8 Sterile specimen container. (Copyright [istock.com](https://www.istock.com).)

When a urine sample is needed for culture and sensitivity, a clean-catch (midstream) collection method is used. The clean-catch process requires cleaning of the urethral meatus and surrounding area with antiseptic wipes. After cleansing, the patient begins voiding, allowing the first part of the stream to pass. The container is placed under the stream to collect the urine midstream (Skill 34.2). With a random or clean-catch specimen, it is essential that the specimen be free from fecal matter. If a woman is menstruating, that information should be included on the test requisition slip and communicated to the laboratory. If a urine culture is to be done, the specimen container may require a preservative. Hospitals are now required to report catheter-associated urinary tract infections (CAUTIs), and prevention strategies are key, such as reducing unnecessary catheters and minimizing their duration (Lo,

Nicolle, Coffin, et al., 2014; Shapiro & Yaney, 2015). If a patient has an indwelling Foley catheter, a sterile urine specimen can be obtained through the collection port of the catheter tubing.

A timed specimen requires all urine to be collected within a specified time period, which can range from 1 to 24 hours. The patient is instructed to discard the first voiding of the morning and then collect all subsequent urine for the time period (Fig. 34.9). Depending on the test ordered, the urine may require refrigeration or a special container with preservatives. If unsure, the nurse should check with the laboratory personnel for specific instructions. Signs should be posted in the bathroom, instructing health care personnel to save all urine for the required time period.

FIGURE 34.9 24-hour urine specimen collection container.

Stool Collection

The amount of stool collected depends on the purpose of the test. A specimen to be tested for occult blood requires only a small amount of stool, which is placed on a **Hemoccult** test strip. A Hemoccult strip contains chemically altered filter paper that changes color when stool containing blood is placed on it. Specimens that are cultured to detect, for example, bacterial or viral infection require only a small amount of stool. Testing for ova and parasites usually requires a larger sample, typically 1 inch of solid stool or 15 to 30 mL of liquid stool (Skill 34.3). Specimens should be obtained from different areas in the stool.

When handling stool, the nurse must always maintain medical asepsis. The nurse wears gloves throughout the specimen collection and makes sure that there is no stool on the outside of the container. After the stool is in the container, the lid is firmly applied, and the container is placed in a biohazard

bag. The specimen is transported to the laboratory immediately after collection.

Sputum Collection

Sputum is the mucus that is found in the lungs, bronchial tubes, and trachea in cases of inflammation or infection. A sputum culture is often ordered when an infectious disease (such as pneumonia or tuberculosis) is suspected. Subsequent sputum specimens can be used to evaluate the effectiveness of antibiotic or antiviral therapy. Sputum analysis can identify abnormal cells that may indicate a tumor or malignancy (Box 34.10).

Box 34.10

Nursing Care Guideline

Sputum Specimen Collection

Background

- A sputum specimen is a sample of mucus used for diagnostic testing to look for specific microorganisms and to determine optimal treatment options.
- Unless suctioning techniques are used, obtaining a sputum specimen can be delegated to unlicensed assistive personnel (UAP) who have been educated and trained in the procedure, according to the patient's care plan, the nurse's judgment, or the facility policy and procedure.
- UAP education includes appropriate collection and handling of the specimen and reporting of procedural or physiologic difficulties.

Procedural Concerns

- The specimen cup is sterile so that bacteria from the environment are not introduced into the sample. Do *not* touch the inside of the cup. Wear clean gloves when handling the sputum cup.
- Obtain the sample first thing in the morning if possible.
- Provide oral care (see Skill 27.6).
- Instruct the patient to breathe deeply and cough to expectorate sputum into the cup.
- If a sample cannot be obtained in this manner, alternative procedures may be used, for which an order from the primary care provider (PCP) may be needed. The following are alternative methods:
 - Expectorants
 - Chest physiotherapy
 - Aerosols or nebulizers

- Suctioning, using tracheostomy suctioning or nasotracheal suctioning (see Skill 38.1) or a sputum trap
- Obtain 2 to 10 mL of sputum for routine testing to ensure accurate results.
- Provide oral care.
- Label the container, place it in a biohazard bag, and transport the sample to the laboratory.

Documentation Concerns

- Document assessment of the sample for quantity, color, type, odor, and consistency of the sputum.
- Document assistance required by the patient or caregiver in obtaining the sample.
- Describe the patient's reaction to the procedure.
- Note that the procedure has been completed.

The nurse should provide clear instructions to the patient to ensure that the specimen is sputum and not saliva. Normally, the patient is instructed to expectorate the sputum directly into a sterile container (see Fig. 34.8). When sputum is being tested for tuberculosis, a special container may be required.

Throat Culture

A throat culture is obtained in a variety of settings. The nurse may collect a culture in a medical office or in the hospital setting. Guidelines for obtaining a throat culture are outlined in Box 34.11.

Box 34.11

Nursing Care Guideline

Throat Culture

Background

- A throat culture is used for diagnostic testing to look for specific microorganisms, to determine whether an infection exists and the source of that infection, and to determine optimal treatment options.
- Obtaining a throat culture should *not* be delegated to unlicensed assistive personnel (UAP).

Procedural Concerns

- Wear gloves.

- The swab end of the Culturette is sterile. Touch only the potentially infected areas of the oropharynx and tonsils with the swab to avoid cross-contamination.
- Depress the tongue, and use a light to see the interior of the mouth and throat. Run the swab over reddened or draining areas.
- The procedure may cause gagging, which can be alleviated by several measures:
 - Instructing the patient to sit upright and say “ahhh”
 - Placing the swab off center
 - Swabbing quickly
- Place the swab in its tube, and seal it immediately. Specialized chemicals in the tube promote the growth of microorganisms.
- Label the container, place it in the biohazard bag, and transport it to the laboratory.

Documentation Concerns

- Document assessment of the throat, including swelling, redness, presence and color of discharge, and pustules.
- Document that the culture has been completed.
- Note pain, discomfort, or other patient concerns.

Evidence-Based Practice

- Rapid antigen detection testing (RADT) has been developed for use in outpatient and emergency department settings. The test is performed in the manner described in the “Procedural Concerns” section and does not require a wait time to retrieve results.
- There is slightly conflicting evidence regarding the validity of the results, but most studies have found a high correlation for positive and negative results. A patient with a positive RADT result should begin treatment without having a follow-up culture sent to the laboratory. If the RADT result is negative and clinical symptoms suggest pharyngitis, the primary care provider (PCP) may consider ordering a follow-up throat culture, which is more sensitive, to be sent to the laboratory so that strep infections are not missed. The PCP may withhold treatment until the results are received which may take up to 2 days ([American Association of Clinical Chemistry, 2017](#)).

Wound Drainage Collection

Wound infections can occur as a complication of surgery, trauma, or underlying disease processes. Infection slows the healing process by prolonging the inflammatory phase of healing, increasing the need for

nutrients and energy, and producing enzymes that are damaging to surrounding tissues.

The nurse assesses the wound on a frequent basis, looking for signs of infection. Changes in the appearance and amount of drainage can indicate an underlying wound infection. Obtaining a sample of the drainage for culture is an important step in identifying the presence of an infection and determining appropriate treatment (see Skill 29.3).

Interventions After Invasive Procedures

Most invasive procedures require ongoing nursing assessment and care. After the procedure, it is important to continue to monitor the patient's vital signs, airway, and oxygenation status. There are specific responsibilities for postprocedure care, depending on the type of procedure. [Table 34.17](#) describes postprocedure care and possible complications for the various types of endoscopy discussed in [Table 34.11](#).

TABLE 34.17**Care After Endoscopy and Possible Complications**

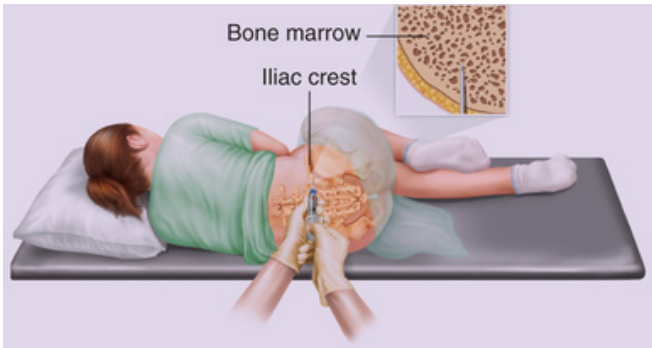

Examination	Postprocedure Care	Possible Complications
Arthroscopy	Assess the neurovascular status of the affected limb, including pain, pallor, paresthesia, paralysis, and pulse. Elevate the extremity and apply ice. Administer analgesics PRN. Instruct the patient to avoid alcohol for 24 hrs.	Thrombophlebitis Compartment syndrome
Bronchoscopy	Keep patient NPO until swallow, gag, and cough reflexes have returned. Provide gargles for mild pharyngitis. Monitor respiratory status, including lung sounds and sputum. Maintain oxygen as ordered.	Shock Bleeding from biopsy Hypoxemia Bronchospasm/laryngospasm Infection Pneumothorax
Colonoscopy, sigmoidoscopy	Monitor vital signs until the patient is fully awake. Encourage a liquid diet or light meal for the first 6 hrs after the procedure. Observe stools for visible blood. Instruct the patient to report any abdominal pain.	Perforation of bowel Hypotension Hemorrhage
Cystoscopy	Monitor voiding patterns. Inspect urine for blood or clots. Instruct the patient that frequency, dysuria, and pink to light red urine are common after the procedure.	Bladder edema or perforation Infection Hematuria Urinary retention
Esophagogastroduodenoscopy (EGD)	Maintain NPO until the gag reflex returns. Position the patient on the left side until fully awake to prevent aspiration.	Perforation Bleeding Aspiration Infection

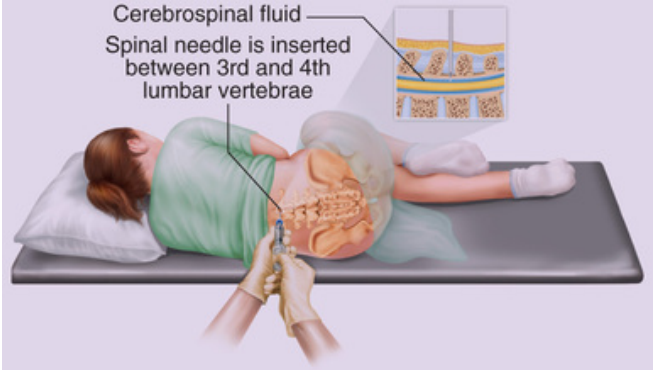

NPO, Nothing by mouth; *PRN*, as needed.

Needle aspirations require patient positioning and special care during and after the procedure. [Table 34.18](#) summarizes the essential aspects that the nurse should consider. For detailed information on the care during and after specific procedures, the nurse should consult the facility procedure book or a diagnostic testing handbook.

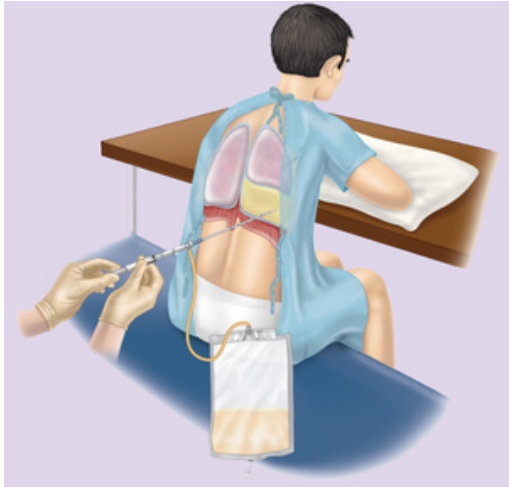

TABLE 34.18

Care During and After Needle Aspirations and Biopsies

Examination	Care During Procedure	Postprocedure Care
<p data-bbox="252 398 542 432">Bone marrow aspiration</p> 	<p data-bbox="1038 398 1201 1124">Position the patient in the prone or lateral position. Maintain sterile technique throughout the procedure. Provide emotional support during the procedure. Label the specimen in the presence of the patient, and transport it to the laboratory.</p>	<p data-bbox="1227 398 1393 913">Observe the site for bleeding. Assess for signs of infection: Erythema and tenderness at the site and fever. Maintain bed rest for at least 1 hr. Administer analgesics PRN.</p>

Examination	Care During Procedure	Postprocedure Care
<p>Lumbar puncture</p> 	<p>Assist the patient to a side-lying position with knees pulled up to the abdomen and with chin to chest (lateral recumbent). Maintain sterile technique throughout the procedure. Provide emotional support during the procedure. Label the specimen in the presence of the patient, and transport it to the laboratory.</p>	<p>Instruct the patient to lie flat for 4-8 hrs. Encourage fluids. Perform neurologic assessment as ordered. Assess the puncture site for drainage. Administer analgesics PRN.</p>

Examination	Care During Procedure	Postprocedure Care
<p data-bbox="252 259 400 286">Paracentesis</p> 	<p data-bbox="1038 259 1198 472">Weigh the patient and measure abdominal girth before the procedure.</p> <p data-bbox="1038 472 1198 685">Assist the patient to a high Fowler (sitting) position with feet on the floor.</p> <p data-bbox="1038 685 1198 864">Maintain sterile technique throughout the procedure.</p> <p data-bbox="1038 864 1198 1021">Limit the amount of fluid drained to 1000 mL.</p> <p data-bbox="1038 1021 1198 1290">Assess for signs of shock, such as hypotension, tachycardia, and changes in mental status.</p> <p data-bbox="1038 1290 1198 1447">Provide emotional support during the procedure.</p> <p data-bbox="1038 1447 1198 1680">Label the specimen in the presence of the patient, and transport it to the laboratory.</p>	<p data-bbox="1230 259 1385 371">Monitor vital signs every 15 mins until stable.</p> <p data-bbox="1230 371 1385 506">Check the dressing frequently for drainage.</p> <p data-bbox="1230 506 1385 663">Assess for hemorrhage and abdominal pain.</p> <p data-bbox="1230 663 1385 752">Monitor for signs of shock.</p> <p data-bbox="1230 752 1385 864">Administer IV fluid and/or albumin as ordered.</p> <p data-bbox="1230 864 1385 1021">Reweigh the patient and remeasure abdominal girth.</p> <p data-bbox="1230 1021 1385 1133">Compare results with pretest numbers.</p> <p data-bbox="1230 1133 1385 1245">Monitor strict intake and output.</p>

Examination	Care During Procedure	Postprocedure Care
<p>Thoracentesis</p> 	<p>Assist the patient to a sitting position, leaning forward with arms resting on the over-the-bed table. Use a pillow to provide support. Maintain sterile technique throughout the procedure. Limit the amount of fluid drained to 1000 mL. Provide emotional support during the procedure. Label the specimen in the presence of the patient, and transport it to the laboratory.</p>	<p>Position the patient to the <i>unaffected</i> side for at least 1 hr. Monitor vital signs until stable. Check the dressing frequently. Assess the puncture site for bleeding or crepitus. Assess respiratory status, including breath sounds and symmetry during respirations, and monitor for signs of distress. Arrange for a chest x-ray if ordered.</p>

IV, Intravenous; PRN, as needed.

Communication of Results

A primary responsibility of the nurse is communicating the test results to the ordering PCP in a timely manner. One of The [Joint Commission's \(2019\)](#) National Patient Safety Goals is to *improve the effectiveness of communication among caregivers*. Promptly communicating test results to the right health care professionals is part of this goal.

QSEN Focus!

Informatics is used when technology and information management tools are applied to support safe processes of care, such as the flagging or alerts of

abnormal results. Nurses should ensure prompt communication of results to appropriate interprofessional health care team members.

Although it may be the ordering PCP who discusses the results with the patient, the nurse may receive questions from the patient regarding the significance of the test findings. The tests described in this chapter are used to diagnose illnesses, determine prognoses, and evaluate the effectiveness of treatments. The patient may have questions or concerns about the meaning of the test results and their impact. The nurse is in a unique position to address these concerns through further education and emotional support.

Evaluation

Evaluation of the care plan for each patient is ongoing. The plan of care for a patient undergoing diagnostic tests changes on the basis of the setting, when the tests are performed, the type of tests, the postprocedure care, and the results. Updating the plan of care to include teaching and information pertinent to the results enables the patient to learn about preventive health measures, available treatments, and prognoses for specific diseases.

SKILL 34.1 Blood Glucose Testing

Purpose

- Monitoring glucose levels in blood
- Monitoring the response to insulin therapy
- Gauging the amount of insulin needed for a sliding scale

Resources

- Blood glucose monitor, properly calibrated
- Sterile lancet or automatic lancing device
- Blood glucose testing reagent strips
- Blood glucose meter
- Soap and warm water or alcohol wipes
- 2- × 2-inch gauze sponges
- Adhesive bandage
- Sharps container
- Clean gloves
- Personal protective equipment (PPE) as needed

Interprofessional Collaboration and Delegation

- Blood glucose testing may be delegated to unlicensed assistive personnel (UAP) without a nurse's assistance after appropriate training and certification in accordance with state and institutional guidelines.
- UAP should report the following:
 - Completion of the procedure
 - Timely notification of results to professional personnel
 - Difficulties in the procedure or other concerns verbalized by the patient
- UAP should be instructed in the following:
 - Timing of the procedure according to orders (frequently before meals and at bedtime)

- Avoidance of extremities on which cuts or bruises are observed
- Preferred sites are fingers or forearms, depending on the testing meter
- Specificities of techniques (such as, milking, massaging, using alcohol wipes, and not wasting the first drop) vary for different glucometers. Check the manufacturer's instructions for further information.

Special Circumstances

1. **Assess:** Is there difficulty obtaining the specimen?
Intervention: Warming the extremity increases vasodilation.
2. **Assess:** Is the reagent strip discolored?
Intervention: Obtain a new bottle and strip.
 - Check the expiration date.
 - Label the date of opening with initials.
 - Calibrate the meter.
 - Always cap the container immediately after taking the strip, because humidity and light can affect strip validity.
3. **Assess:** Is the result out of normal range for the patient?
Intervention: Assess the patient; troubleshoot the meter.
 - Ensure that hands were washed.
 - Assess for signs and symptoms of hypoglycemia or hyperglycemia.
 - Verify the time of the last meal or insulin dose.
 - Ensure that an adequate sample was obtained.
 - Check that strip codes match the meter.
 - Verify the last calibration. Check the meter with control samples.
 - Make sure that batteries are charged.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.

III. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

IV. Maintain standard precautions.

Use of the correct PPE is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient, using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Blood Glucose Testing

Follow preprocedure steps I through VIII.

1. Raise the bed to working height and lower the side rails as appropriate and safe.

Proper positioning of equipment prevents provider discomfort and possible injury.

2. Select the site, which depends on the meter:

- a. Use the middle or ring finger, along either side about halfway between the end of the finger and the first joint.
- b. Follow the manufacturer's instructions for other sites.
- c. Avoid nonintact skin.

Correct site selection promotes patient comfort, provides accurate results, and prevents nerve, skin, or bone injury.

3. Apply clean gloves.

Use of gloves prevents the spread of microorganisms and protects caregivers from injury.

4. Remove the reagent strip from the container and recap:
 - a. Ensure that the strip is not expired.
 - b. Ensure that the strip is intact.
 - c. Check that the code on the container matches the code programmed in the meter.
 - d. Follow the manufacturer's instructions on when to place the strip in the glucometer.

Performing the procedure properly ensures accurate results.

5. Cleanse the site: Have the patient wash hands with soap and warm water, or wipe the finger with an alcohol wipe. Allow the finger to dry thoroughly before testing. Lower the hand below the heart to facilitate capillary blood flow.

Disinfection prevents microorganisms or other particulates from contaminating the site. Warm water increases vasodilation, and thorough drying prevents contamination of the sample.

6. Quickly puncture the capillary site. Use a lancing device, following the manufacturer's instructions and facility policy and procedures.

STEP 6 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Correct technique reduces pain, promotes patient comfort, and promotes safe, quality patient care.

7. Using a 2 × 2 gauze pad, wipe off the first drop of blood and any remaining alcohol.

This method ensures accurate results because the first drop of blood may contain higher amounts of serous fluids, and alcohol may change the results.

8. Place blood on reagent test strip according to the manufacturer's instructions.

STEP 8 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Following instructions ensures accurate results. A full sample is required.

9. The meter calculates results and displays them when complete.
Automatic computation ensures accurate results. The time needed to produce results depends on the manufacturer; most meters are automatically timed.
10. Apply gauze and pressure to the site.
The risk of bleeding and complications is decreased.
11. Discard the lancet into the sharps container. Most lancets have an automatic safety mechanism.
Safety mechanisms and proper disposal prevents an accidental needlestick.
12. Check the site; apply an adhesive bandage if needed.
Covering the site decreases the risk of bleeding and complications.
13. Remove gloves.

Follow postprocedure steps I through VI.

Postprocedure

- I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach of the patient.
Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.
- II. Assess for additional patient needs, and state the time of your expected return.
Meeting patient needs and offering self promote patient satisfaction and build trust.
- III. Properly dispose of PPE.
Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

SKILL 34.2 Urine Specimen Collection

Purpose

- Collecting a urine sample for diagnostic testing
- Testing a urine sample for specific substances
- Determining whether specific microorganisms are growing in the urinary system
- Determining the optimal treatment options for urinary system infections

Resources

- Appropriate collection container:
 - Sterile specimen cup
 - Nonsterile, large, 24-hour collection container (may contain a chemical preservative)
- Diagnostic test reagent strips (specified for substance testing)
- Washbasin with ice (for 24-hour collection)
- Syringe with Luer-Lok tip or blunt, needleless cannula (for catheter collection)
- Antiseptic/disinfectant towelettes
- Toilet paper
- Biohazard bag for laboratory transport
- Patient identification labels
- Clean, nonsterile gloves
- Personal protective equipment (PPE) as needed

Interprofessional Collaboration and Delegation

- Voided urine specimen collection (not collection from a catheter) may be delegated to unlicensed assistive personnel (UAP) without a nurse's assistance after appropriate training in accordance with state and facility guidelines.
- UAP should report the following to the nurse:

- Completion of the procedure
- Sample color, odor, and consistency
- Blood, mucus, or foul odors in the specimen, or any breaks in specimen collection technique
- Difficulties in performing the procedure or other concerns verbalized by the patient
- UAP should be instructed in the following:
 - Timing of the specimen collection
 - Sterile technique
 - Midstream clean-catch process
 - Appropriate documentation

Special Circumstances

1. **Assess:** Is a random urine sample being obtained by using the nonsterile or clean-catch technique?
Intervention: Document which technique was used; contamination may have occurred, causing inaccurate or unexpected results.
2. **Assess:** Was there a urine specimen that missed collection or a spilled urine specimen during a 24-hour collection period?
Intervention: Document the problem, and start the procedure over.
3. **Assess:** Is a 24-hour urine collection being obtained from an indwelling catheter?
Intervention: Replace the drainage collection bag at the start of the procedure, and keep the bag on ice.
4. **Assess:** Is the test strip for reagent testing discolored or otherwise not intact?
Intervention: Obtain a new container of test strips:
 - Check the expiration date on the container.
 - Label the container with the date of opening and your initials.
 - Always cap the container immediately after removing a strip; humidity and light can affect strip validity.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.

Preparing for the patient encounter saves time and promotes patient trust.

III. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

IV. Maintain standard precautions.

Use of the correct PPE is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient, using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Urinalysis (Clean Catch): Female

Follow preprocedure steps I through VIII.

1. Assist the patient to the bathroom, onto a bedside commode, or onto a new bedpan.
Prepare the patient for the procedure in a safe and proper environment. Precautions must be taken to maintain patient safety and prevent provider injury.
2. If the patient will be collecting the sample, have her wash her hands.
Handwashing prevents microorganisms from contaminating the specimen and ensures accurate results.
3. Remove the lid from a sterile specimen cup, and place it on a flat surface with the inside of the lid facing up.

Proper technique avoids contamination of the specimen with microorganisms and ensures accurate results.

4. Instruct the patient to separate the labia with the second and third fingers on the non-dominant hand.

Spreading the labia exposes the urinary meatus and prevents microorganisms from contaminating the specimen; it ensures more accurate results.

5. Have the patient cleanse the perineum using an antiseptic wipe or swab while keeping the labia spread (depending on the facility-provided kit or supplies). Instruct the patient to use the following method:

STEP 5 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Wipe from the front to the back (toward the rectum)
- b. Use a new wipe or swab for each wipe
- c. Wipe one side of the labia, then cleanse the other side, and then the center of the perineum

Proper cleaning should be used to prevent the spread of microorganisms and to prevent microorganisms from contaminating the specimen. Washing should be done from the least contaminated area to the most contaminated area (i.e., from the area of fewer microorganisms to the area of more microorganisms) to ensure accurate results.

6. While keeping the labia spread, instruct the patient to urinate a small amount but not into the specimen cup.

Urinating a small amount before taking the specimen flushes contaminants from the urethra and prevents microorganisms from contaminating the specimen, ensuring more accurate results.

7. Instruct the patient to place the cup into the urine stream; the cup must not touch skin or the perineum.

STEP 7 (Copyright Mosby's Clinical Skills: Essentials Collection.)

This method prevents microorganisms from contaminating the specimen and ensures accurate results.

8. Collect 90 to 120 mL of urine if possible. A minimum of 30 mL is needed for some tests.

Routine urine testing requires at least 30 mL to ensure accurate results. Check with the laboratory for amounts necessary for specific tests.

9. Instruct the patient to remove the cup from the urine stream before she has finished urinating.

Avoiding collection of the last quantity of urine eliminates contamination from skin flora.

10. Instruct the patient to finish urinating and immediately cap the container.

Completing urination avoids complications from not emptying the bladder. Immediate capping of the container prevents microorganisms from contaminating the specimen and ensures accurate results.

11. The nurse should handle the container with gloves. Wipe and dry the outside of the container with a paper towel.

STEP 11 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Precautions must be taken to protect caregivers and prevent the spread of microorganisms.

12. Label the container according to facility policy and procedure. A note should be placed on label if patient is menstruating.

Proper labeling of samples prevents adverse events and medical errors.

13. Place the container in a biohazard bag. Remove gloves, and perform hand hygiene.

STEP 13 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Precautions must be taken to protect caregivers and prevent the spread of microorganisms.

14. Transport the specimen to the laboratory. If it is not possible to get the specimen to the laboratory within 15 minutes of collection, place the specimen in the refrigerator.

Many tests are time or temperature sensitive; urine tests are especially temperature sensitive. Refrigeration slows microorganism growth.

15. Communicate in a report and in the chart or electronic health record that the test is complete.

Communicate essential information to provide safe, timely, and efficient quality patient care and to prevent adverse events and medical errors.

Follow postprocedure steps I through VI.

Urinalysis (Clean Catch): Male

Follow preprocedure steps I through VIII.

1. Follow procedure steps 1 through 3 in the “[Urinalysis \(Clean Catch\): Female](#)” section.
2. If the patient has not been circumcised, have him retract the foreskin and *not* release it.

Retracting the foreskin exposes the urinary meatus and prevents microorganisms from contaminating the specimen, ensuring more accurate results.
3. Have the patient cleanse the top of the penis using an antiseptic wipe or swab (depending on the facility-provided kit or supplies). Instruct the patient to use the following method:

STEP 3A (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Clean from the meatus to the base of the glans using a circular outward motion
 - b. Use a new wipe or swab for each cleansing
 - c. Repeat the cleansing a total of three times
- Proper cleaning should be used to prevent the spread of microorganisms and to prevent microorganisms from contaminating the specimen. Washing should be done from the least contaminated area to the most contaminated area (i.e., from the area of fewer microorganisms to the area of more microorganisms) to ensure accurate results.*
4. Instruct the patient to urinate a small amount but *not* into the specimen cup.

Urinating a small amount before obtaining the specimen flushes contaminants from the urethra and prevents microorganisms from contaminating the specimen, ensuring more accurate results.

5. Instruct the patient to place the cup into the urine stream; the cup must *not* touch skin or the penis.

STEP 5 (Copyright Mosby's Clinical Skills: Essentials Collection.)

This prevents microorganisms from contaminating the specimen and ensures accurate results.

6. Collect 90 to 120 mL of urine if possible. A minimum of 30 mL is needed for some tests.

Routine urine testing requires at least 30 mL to ensure accurate results. Check with the laboratory for amounts necessary for specific tests.

7. Instruct the patient to remove the cup from the urine stream *before* he has finished urinating.

Avoiding collection of the last quantity of urine eliminates contamination from skin flora.

8. Instruct the patient to finish urinating and then immediately cap the container.

Completing urination avoids complications from not emptying the bladder. Immediate capping of the container prevents microorganisms from contaminating the specimen and ensures accurate results.

9. Follow procedure steps 11 through 15 in the “[Urinalysis \(Clean Catch\): Female](#)” section.

Follow postprocedure steps I through VI.

Urinalysis: Quick Reagent Strips and Urine Culture and Sensitivity

Follow preprocedure steps I through VIII.

1. Follow procedure steps 1 through 7 in the “[Urinalysis \(Clean Catch\): Female](#)” section or steps 1 through 5 in the “[Urinalysis \(Clean Catch\): Male](#)” section.
2. Depending on the test, do *not* allow the cup to touch the skin, perineum, or penis. Collect an appropriate quantity of urine. Depending on the test and results, the sample may be sent for a

urinalysis and culture and sensitivity. The total amount of urine needed is 13 to 35 mL:

- a. Urinalysis requires 10 to 30 mL.
- b. Urine culture and sensitivity requires 3 to 5 mL.

Avoid touching the patient with the cup to prevent microorganisms from contaminating the specimen and to ensure accurate results.

Accurate testing requires the minimum quantity specified.

3. Follow procedure steps 10 through 11 in the “**Urinalysis (Clean Catch): Female**” section. For urinalysis using a quick reagent strip, proceed to step 4. For urine culture and sensitivity, skip to step 6.

For Urinalysis Using Quick Reagent Strips

4. Obtain a quick reagent test strip for the ordered test, and dip it in the urine sample. Follow the manufacturer's instructions on the test strip container for the amount of time to wait between immersing the strip in urine and reading the result, the minimum quantity of urine that must be used for accuracy, and result interpretation.

The use of proper equipment for a specific test ensures the accuracy of the reading.

5. Compare the colors on the quick reagent strip with those from the testing bottle after the designated time for results has elapsed. Document the results, and notify the PCP if needed.

STEP 5 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Obtaining a quick and accurate test result facilitates diagnostic decision making. Proper record keeping is essential because it communicates important information needed for patient care and provides legal evidence of care. Ensure quality patient care by communicating promptly with the PCP if needed.

For Urine Culture and Sensitivity

6. Transfer the urine to a special culture collection container. The method used depends on facility policies and procedures.

Following the manufacturer's instructions ensures accurate results.

7. Follow procedure steps 11 through 15 in the “**Urinalysis (Clean Catch): Female**” section.

Follow postprocedure steps I through VI.

Foley Catheter Urine Specimen Collection

Follow preprocedure steps I through VIII.

1. Ensure that the urine in the tubing is emptied into the drainage bag.
Emptying the tubing provides an accurate baseline assessment, and it prevents microorganisms from contaminating the specimen, which can interfere with obtaining accurate results.
2. Clamp the catheter tubing below the specimen port.
Fresh urine will collect but not drain into the bag. Microorganisms grow quickly in urine at room temperature.
3. Wait 10 to 30 minutes to allow urine to accumulate in the tubing.
The specimen cannot be obtained from the drainage bag, because the urine in the bag is not sterile. Allowing urine to accumulate in the upper part of the tubing ensures a sterile specimen.
4. When the appropriate amount of urine has accumulated, begin collecting the specimen using aseptic technique.
Proper aseptic technique should be used to prevent the spread of microorganisms and ensure accurate results.
5. If there is a sufficient length of catheter tubing to work with from the anchoring device to the injection port, leave the catheter anchored; otherwise, remove the catheter from the anchoring device, and be careful when working with it to avoid inadvertent dislodgement.
Avoiding inadvertent dislodgement of the catheter maintains patient safety and comfort.
6. Place a waterproof pad under the catheter at the injection port.
The pad protects linens from moisture and maintains skin integrity.
7. Put on clean gloves. Clean the specimen port or injection port with an antiseptic wipe in accordance with facility policy and procedure.
Proper antiseptic procedures should be used to prevent the spread of microorganisms and reduce the risk of infections.
8. Connect a syringe to the specimen port:

STEP 8 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. If a needleless catheter system (Luer-Lok) is in place, twist a syringe onto the port.
- b. If an access port is in place, insert a blunt, needleless cannula at a 30-degree angle with the bevel in the direction of the

- bladder.
- c. Pull back on the syringe plunger to obtain a sample.
The specimen port and needleless syringe are used to prevent possible provider injury. A 30-degree angle allows urine to be withdrawn easily and prevents puncture of the catheter and specimen port.
9. Withdraw the syringe, and transfer the urine directly from the syringe to an appropriate sterile collection container.
Proper technique avoids contamination of the specimen from microorganisms and ensures accurate results.
 10. Remove the clamp, and secure the catheter before leaving the bedside.
Removing the clamp allows drainage to occur by gravity and prevents back-up of urine into the bladder. Securing the catheter reduces the risk of damage to urinary tissues and inadvertent removal of the catheter.
 11. Follow procedure steps 11 through 15 in the “[Urinalysis \(Clean Catch\): Female](#)” section.

Follow postprocedure steps I through VI.

24-Hour Urine Specimen Collection

Follow preprocedure steps I through VIII.

1. Label a special 24-hour collection container according to facility policy and procedure.
Proper labeling of samples prevents adverse events and medical errors.
2. Ensure that all samples are collected:
 - a. Place a sign in the patient's bathroom and on the patient's chart or a notation in the electronic health record.
 - b. Remind the patient of the necessity of collecting all urine samples for the 24-hour period.
 - c. Communicate testing in a report at the end of the shift and in the chart or electronic health record.
Proper communication of instructions enhances patient cooperation, prevents adverse events and medical errors, and ensures accurate results. Proper record keeping is essential because it communicates important information needed for safe, efficient, and timely quality patient care and provides legal evidence of care.
3. Prepare for the procedure by placing a basin filled with ice in the bathroom or ensuring that a designated refrigerator is available for storing the specimens. Collect the urine in a new container (i.e., urinal, graduated hat, or bedpan). Always wear clean gloves when handling urine specimens.
Urine tests are especially temperature sensitive; refrigeration slows microorganism growth and ensures accurate results.
4. If possible, begin the test in the morning:

- a. Have the patient void. Document the quantity, color, and clarity of urine for the first morning void.
 - b. Discard the first morning void.
 - c. Note the time of day that the test was started.
Discard the first morning void to provide an accurate baseline assessment; the urine in the first morning void was produced before the 24-hour test period.
5. Immediately empty each specimen completely into a special collection container:
- a. Do *not* splash the urine.
 - b. Depending on the test, separate containers may be required; document the time and quantity on each container.
 - c. Document the time, quantity, color, and clarity of the urine for each void in the chart or electronic health record. Record the quantity of intake and output on the patient's flow sheet.
 - d. Ensure that the specimen is labeled and on ice or refrigerated.
Splashing causes loss of specimen volume, which may result in inaccurate results. Proper labeling of samples prevents adverse events and medical errors. Refrigeration or use of ice decreases the growth of microorganisms.
6. At the end of the 24-hour collection time:
- a. Obtain the last urine sample.
 - b. Remove the signs from the patient bathroom and from the patient chart or the notation in the electronic health record.
 - c. Communicate that the testing is complete in a report and in the patient's health record.
Proper communication of instructions prevents adverse events and medical errors and ensures accurate results. Proper record keeping is essential because it communicates important information needed for safe, efficient, and timely quality patient care and provides legal evidence of care.
7. Follow steps 11 through 15 in the “[Urinalysis \(Clean Catch\): Female](#)” section.

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach of the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

SKILL 34.3 Stool Specimen Collection

Purpose

- Use for diagnostic testing
- Testing for specific agents
- Determining the specific microorganisms growing in the gastrointestinal (GI) system
- Determining optimal treatment options for GI system infections
- Testing for blood in the GI system

Resources

- Stool collection container with a lid (for stool culture)
- Hemoccult cardboard test slide and developing solution per facility policy (for occult blood)
- New bedpan, graduated specimen hat, or bedside commode
- Tongue blades
- Biohazard bag for laboratory transport
- Patient identification labels
- Clean gloves and other personal protective equipment (PPE) as needed

Interprofessional Collaboration and Delegation

- Collecting a stool specimen and testing stool for occult blood may be delegated to unlicensed assistive personnel (UAP) without a nurse's assistance after appropriate training in accordance with state and facility guidelines.
- UAP should report any of the following to the nurse:
 - Positive results of occult blood (immediate report to the nurse)
 - Completion of the procedure
 - Sample color, odor, and consistency

- Difficulties encountered in the procedure or other concerns verbalized by the patient
- UAP should be instructed in the following:
 - Timing of the procedure
 - Necessity of ensuring that the sample is free of other bodily fluids and toilet paper
 - Appropriate documentation

Evidence-Based Practice

When patients are being tested for occult blood with a guaiac-based fecal occult blood test (gFOBT), it is important that “patients ... adhere to a 72-hour diet free of ... [foods such as] meat, poultry, fish, and leafy green vegetables before testing to avoid false-positive results. Medications ..., such as aspirin and antiinflammatory agents, iron and oxidizing drugs, and potassium preparations, may cause false-positive results, and ascorbic acid use may result in false-negative results” (Jessee, 2010, p. 134).

After age 45, the [American Cancer Society \(2018\)](#) recommends a multiple stool gFOBT yearly or a stool DNA test every 3 years to detect cancer. If either of these tests is positive, a colonoscopy should be performed.

Special Circumstances

1. **Assess:** Has measurement of intake and output been ordered?
Intervention: Two graduated collection hats are needed in the patient's bathroom: one for urinary collection and measurement and the other for collection of stool samples.
2. **Assess:** Is the sample contaminated with bodily fluids, toilet paper, or toilet water?
Intervention: Obtain a new sample.
3. **Assess:** Are multiple specimens required? The test is often ordered in sets of three.
Intervention: Communicate and document information:
 - Place a sign in the patient's bathroom and on the patient's health record.
 - Remind the patient that samples are needed, and provide other procedural information.
 - Communicate information in the report and the patient's health record.
 - Ensure that valid samples are not discarded.
 - Remove the signs when the last sample has been obtained.
4. **Assess:** Is the patient on antimicrobial therapy?
Intervention: Note the medication and dose on the laboratory slip; medication may affect test results.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct PPE is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.
- VI. Provide for patient privacy.
It is important to maintain patient dignity.
- VII. Identify the patient, using two identifiers.
Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.
- VIII. Explain the procedure to the patient.
The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Stool Culture

Follow preprocedure steps I through VIII.

1. Assist the patient to the bathroom, where a new collection hat has been placed in the toilet, onto the clean bedside commode, or onto a new

bedpan. Inform the patient to use the call light when finished defecating.

Prepare the patient for the procedure in a safe and private environment. Precautions must be taken to maintain patient safety and prevent provider injury.

2. Instruct the patient to perform hand hygiene after defecating.
Hand hygiene prevents the spread of microorganisms.
3. Assist the patient back to bed.
Assistance promotes comfort and dignity.
4. Apply clean gloves.
Using gloves prevents the spread of microorganisms and protects caregivers from injury.
5. Remove the lid from the specimen cup and place it on a flat surface with the inside of the lid facing up.
Proper technique avoids contamination of the specimen from microorganisms and ensures accurate results.
6. Use a wooden tongue blade or applicator stick to collect a 1-inch diameter specimen of solid stool or 15 to 30 mL of liquid stool. Samples should be collected from different areas of the specimen. The nurse should handle the container or specimen only while wearing gloves.
A minimum quantity of stool is required to ensure accurate test results. Using a wooden tongue blade or applicator stick prevents microorganisms from contaminating the specimen.
7. Cap the container when finished. The nurse should handle the container and/or specimen only while wearing gloves.
Immediate capping of the container prevents microorganisms from contaminating the specimen and ensures accurate results.
8. Clean the outside of the container with a paper towel. The nurse should handle the container or specimen only while wearing gloves.
Precautions must be taken to protect caregivers and prevent the spread of microorganisms.
9. Label the container in accordance with facility policy and procedure.
Proper labeling of the sample prevents adverse events and medical errors.
10. Place the container in a biohazard bag. Remove gloves and perform hand hygiene.
Precautions must be taken to protect caregivers from infection and to prevent the spread of microorganisms.
11. Transport the specimen to the laboratory. If it is not possible to get the specimen to the laboratory within 15 minutes of collection, check the facility or laboratory policy and procedure for storage recommendations.
Many tests are time or temperature sensitive; stool samples undergo changes due to normal bacterial flora that affect test results.
12. Communicate in a report, and document, that the test is complete.
Communicate essential information to provide safe, timely, and efficient quality patient care and to prevent adverse events and

medical errors.

Follow postprocedure steps I through VI.

Occult Blood Testing (Guaiac-Based Fecal Occult Blood Test)

Follow pre-procedure steps I through VIII.

1. Follow procedure steps 1 through 3 in the “Stool Culture” section.
2. Apply clean gloves.
Using gloves protects the provider, prevents the spread of microorganisms, and prevents microorganisms from contaminating the specimen, ensuring more accurate results.
3. Open a Hemocult test slide.
Prepare needed equipment before beginning the test.
4. Use a wooden tongue blade or applicator stick to collect a thin smear from the center of the specimen, and apply a smear of the stool sample to the center of the first test window of the Hemocult test slide.
Samples taken from the edge of the stool specimen may be contaminated from straining or hemorrhoids; using a sample from the center of the specimen ensures more accurate results.
5. Use a new tongue blade or applicator stick to collect a thin smear from a different area of the specimen (avoiding the edges of the sample), and apply a smear of the stool sample to the center of the second test window.

STEP 5 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Samples taken from the edge of the stool specimen may be contaminated from straining or hemorrhoids. Sampling different areas of the fecal specimen ensures more accurate test results; blood may not be in every area of the sample.

6. Close the Hemocult test slide. Follow facility policy for development of fecal occult. If your facility permits the testing of fecal occult on the nursing unit, follow steps 7 to 10. If not, skip to step 10.
Closing the slide protects the provider and prepares the test for processing.
7. Wait 3 to 5 minutes; see the manufacturer's instructions.

The stool must have sufficient time to adhere to the slide for processing to ensure accurate results.

8. Develop the results:

STEP 8 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Open the reverse side of the Hemoccult test slide.
- b. Apply 2 drops of developing solution to each of the three windows (i.e., first and second test windows and the control window).
- c. Wait 30 to 60 seconds, according to the manufacturer's directions.

The developing solution chemically reacts with the blood; the solution soaks through the paper to the stool; and proper timing ensures accurate results. The control window ensures valid testing of the solution and the slide.

9. A bluish color indicates the presence of blood. Document the test results according to facility policy and procedure, and notify the PCP if needed.

The solution chemically reacts with blood, producing a blue color when blood is present. Proper record keeping is essential because it communicates important information needed for patient care and provides legal evidence of care.

10. Label the test slide, and send it to the laboratory in a biohazard bag in accordance with facility policy and procedure.

Proper labeling of samples prevents adverse events and medical errors.

11. Remove gloves and perform hand hygiene.

12. Communicate in a report and document that the test is complete.

Communicate essential information to provide safe, timely, and efficient quality patient care and to prevent adverse events and medical errors. Because blood may not be in all areas of the sample, performing multiple tests optimizes the chances of identifying occult blood.

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach of the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Summary of Learning Outcomes

LO 34.1 *Recall the types of cells found in blood and their functions:* Three types of cells are found in blood: erythrocytes, which contain hemoglobin; thrombocytes, which are necessary for blood clotting; and leukocytes, which are responsible for the inflammatory and immune responses.

LO 34.2 *Identify common blood tests, their purposes, and their normal values:* Complete blood counts, coagulation studies, blood chemistries, liver and kidney function tests, and cardiac markers are the most common blood tests ordered for diagnostic and treatment purposes.

LO 34.3 *Discuss other laboratory tests, such as urine and stool studies, and their purposes and normal values:* Urine and stool studies provide additional diagnostic information that is not always available with blood tests. They include urinalysis and stool analysis for occult blood. Culture and sensitivity analysis can be performed on blood, stool, urine, the throat, sputum, and wounds.

LO 34.4 *Explain the purpose of common diagnostic tests:* Common radiographic studies are useful in visualizing structural abnormalities and disorders in the skeletal system, GI tract, and other body systems. Other studies that visualize structure include computed tomography, magnetic resonance imaging, ultrasound, and endoscopy. Electrocardiograms measure the electrical activity of the heart.

LO 34.5 *Describe assessment procedures for patients undergoing diagnostic tests:* The nurse assesses baseline information before the patient undergoes diagnostic tests, including any preparation the patient has performed at home before the test.

LO 34.6 *Choose appropriate nursing diagnoses associated with diagnostic testing: Ready to Learn, Risk for Injury, and*

Anxiety are common nursing diagnoses associated with diagnostic testing.

LO 34.7 *Select goals to meet individual patient problems:*

Goals are written to meet individual patient problems, and they depend on the diagnostic tests being performed and the patient's level of knowledge and particular nursing diagnosis.

LO 34.8 *Describe the nurse's role in implementation and evaluation of the plan of care before, during, and after diagnostic tests and procedures:* The nurse's role before, during, and after diagnostic procedures includes conducting the baseline assessment, monitoring patient status, assessing for potential complications, and evaluating the plan of care. The nurse may be responsible for collecting some specimens.

Review Questions

1. Which laboratory result should immediately be reported by the nurse to the primary care provider (PCP)?
 - a. Hemoglobin: 15.6
 - b. Hematocrit: 32%
 - c. Red blood cells: 5.3
 - d. White blood cells: 6000
2. The patient states that she has been taking warfarin, an anticoagulant, for several years. The nurse notices several bruised areas on her arms. Which of the following laboratory results is the most clinically significant for this medication?
 - a. Platelets: 450,000
 - b. Prothrombin time: 24.2 seconds
 - c. Activated partial thromboplastin time: 30 seconds
 - d. Fibrinogen: 350 mg/dL
3. The patient tells the nurse that she has been on a high-protein, low-carbohydrate diet for the past 6 months. Which blood test results could be influenced by her diet?
 - a. Bilirubin
 - b. Creatinine
 - c. Blood urea nitrogen
 - d. Creatine kinase
4. The nurse is working at a health fair and providing information about reducing the risk of heart disease. A male asks what his ideal numbers should be for cholesterol and triglycerides. Which of the following are recommended levels for lipid?
 - a. Total cholesterol: >200 mg/dL
 - b. HDL: >45 mg/dL
 - c. LDL: >100 mg/dL

- d. Triglycerides: >160 mg/dL
5. The nurse is preparing a patient for a barium swallow test. Which statements by the patient indicate that the patient has understood the nurse's teaching? (*Select all that apply.*)
- a. "The doctor will be able to view my stomach and intestines during the test."
 - b. "I should increase fluids after the test."
 - c. "I will have to drink a contrast agent."
 - d. "Barium can cause constipation and I may need a mild laxative."
 - e. "I will be NPO for 8 hours after the test."
 - f. "My stools may turn black for a few days afterward."
6. A patient has a 24-hour urine specimen ordered for creatinine clearance. Which instruction is correct?
- a. "Collect all urine from the time the collection begins until it ends."
 - b. "Save only a sample from each voiding."
 - c. "Clean the perineal area three times before you begin to urinate."
 - d. "Discard the first urine specimen, and then collect all urine until the time period expires."
7. Which specimens should be collected using sterile technique in a sterile container? (*Select all that apply.*)
- a. Clean-catch urine
 - b. Stool for occult blood
 - c. Wound drainage
 - d. Sputum
 - e. Urine from a Foley catheter
8. Which blood test is used to monitor renal function?
- a. Creatine kinase
 - b. Triglycerides

- c. Creatinine
 - d. Alkaline phosphatase
9. For which patient is magnetic resonance imaging (MRI) contraindicated?
- a. A patient with an allergy to latex
 - b. A patient with an infection
 - c. A patient with a pacemaker
 - d. A patient with a head injury
10. The nurse is caring for a patient after a lumbar puncture to obtain a cerebrospinal fluid specimen. Which are appropriate post procedure interventions? (*Select all that apply.*)
- a. Position the patient with head of bed up at least 90 degrees for 4 hours.
 - b. Assess the puncture site for drainage or bleeding.
 - c. Encourage PO fluids.
 - d. Maintain NPO until the gag reflex returns.
 - e. Encourage ambulation immediately after the test is complete.

CHAPTER 35

Medication Administration

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 35.1 Verbalize how government, facility, and professional regulations affect medication administration by nurses.
- LO 35.2 Explain the physiologic outcomes of medication actions.
- LO 35.3 Identify differences between prescription and nonprescription medications.
- LO 35.4 Summarize common medication forms and routes.
- LO 35.5 Describe measures for administering medications safely.
- LO 35.6 Discuss assessments necessary for safe medication administration.
- LO 35.7 Choose nursing diagnoses related to safe medication administration.
- LO 35.8 Determine individual patient goals.
- LO 35.9 Implement guidelines and essential nursing actions for safely administering medications and evaluating patient outcomes.

Case Study

Carol Petros (C. P.) is a 77-year-old female admitted to the hospital 4 hours earlier after a fall at home caused by dizziness and weakness. She was initially brought to the emergency department by her daughter, who checked on her after not reaching her by phone. Her medical history includes hypertension, osteoarthritis, and a hysterectomy at age 50. She states that she has an allergy to penicillin, and she is full-code status. The patient has lived alone since the death of her spouse 3 months ago. She brought a small plastic bag with multiple medications in it because, as she said, "I can't open my medication bottles easily because of my arthritis."

C. P.'s vital signs are: T 36.5° C (97.7° F), P 92 and regular, R 20 and unlabored, BP 172/92, with a pulse oximetry reading of 98% on room air. She reports a pain level of 8 of 10 in her left hip. She also reports a pain level of 5 of 10 in her hands from her arthritis. As the nurse completed the admission assessment, C. P. stated, "I forgot to take my furosemide in the morning, so I took both tablets before bed. I was up and down to the bathroom a lot, and fell because I was dizzy and my legs gave out early this morning. My daughter came to get me. Right now my hip and leg hurt when I move."

She further reported, "I always have some pain in my hands and have to take medicine for that sometimes, but I don't like to because then I get constipated. I take a tablet of the over-the-counter herb, feverfew, every day to help with my arthritis pain." The nurse notes a 4 × 5 cm bruise on the left hip. The patient's Braden score is 20, and her Morse Fall score is 40. Her left hip x-ray on admission showed no acute fracture. Serum potassium level is 3.3 mEq/L.

Treatment orders are as follows:

- Vital signs every 4 hours
- No-added-salt diet
- Activity as tolerated with assistance

- Intake and output
- Electrolyte panel in a.m.

Medication orders are as follows:

- Continue home medications of:
 - Furosemide 40 mg PO bid
 - Hydrocodone 5 mg PO every 4 hours PRN for pain
 - K-Lor 8 mEq daily
- Start docusate sodium 50 mg PO daily
- Start intravenous (IV) infusion of 5% dextrose in half normal saline (D₅ ½NS) with 20 mEq of KCl to run at 75 mL/hr

Refer back to this case study to answer the critical-thinking exercises throughout the chapter.

Historically, nurses administered prescribed medications at scheduled times by the prescribed route with minimal assessment and documentation. Today, the nurse's role and responsibility in medication administration are much more complex. Safe nursing practice includes knowledge about medication actions; side effects; interactions with foods, herbs, and other medications; associated assessment and evaluation; ethical considerations; and legal aspects of medication therapy. Patients with acute and chronic illnesses seek treatment for their symptoms, with medications often prescribed to help diagnose, treat, or prevent illness; relieve symptoms; or cure illness. The nurse must integrate into the plan of care the self-prescribed medications and herbs that patients use to prevent or treat self-identified illnesses.

Medication management requires the collaborative efforts of many health care team members, such as the prescribing primary care provider (PCP), pharmacist, respiratory therapist, and dietician. Nurses, however, have the specialized knowledge, clinical judgment, and skills employed in health care and community settings that are needed for the essential role of educating patients about medications, administering medications according to accepted protocols, and evaluating the patient's response to medications. Patient education by nurses on the correct use of medications is an important responsibility to prevent illness relapse, new medical problems, and patient injury. Often, family members or caregivers are included in medication teaching to meet the patient's needs. Clinical judgment is needed before, during, and after administering medications to patients as assessments are made about the effectiveness of medications in restoring or maintaining health.

Continuing education of nurses is needed to ensure that standards of practice are met, new or unfamiliar medications are administered properly, and medication administration technology is used correctly.

LO 35.1 Medications and Regulations

Medications are substances that can prevent, improve, or reduce the symptoms of a medical condition, and the objective of drug therapy is to provide maximum benefit with minimum harm to the patient. Ongoing research provides the scientific foundation for the use of medications. The chemical makeup of the medication determines its actions in the human body.

Drugs and Medications

A **drug** is any substance that positively or negatively alters physiologic function. A **medication** is a drug specifically administered for its therapeutic effect on physiologic function. Medications and preparations may be researched by using drug textbooks or point-of-care software.

Medications can have up to four designations: chemical name, official name, generic name, and trade (brand) name. The chemical name describes the elements of the medication's molecular structure. The official name is assigned by the U.S. Adopted Names Council, and it is usually the **generic name**, which is simpler than the chemical name. The generic name is not capitalized and often contains a prefix or suffix that helps identify the drug class. For example, beta blockers are drugs that are prescribed for cardiac conditions; their generic names frequently end in *-olol*: propranolol, metoprolol, labetalol. The **trade name**, or brand name, is a registered name assigned by the drug manufacturer. Because one type of medication can be manufactured by several companies, it can have several different trade names while having a common generic and chemical name:

Chemical Name	Generic Name	Trade Names
2-(4-isobutylphenyl)propionic acid	ibuprofen	Motrin, Advil, Nuprin

Medication Standards and Regulations

Medications are synthesized in a laboratory or developed from plant, mineral, or animal sources. Because medications vary in purity, potency, efficacy, safety, and toxicity, the United States (U.S.) and many other governments have developed standards to ensure uniform quality so that the effects are predictable. In the U.S., official medication lists have been reported in the *United States Pharmacopeia* (USP) since 1820 and the *National Formulary* (NF) since 1898. These sources help protect

public safety by identifying medication properties that show an appropriate range of quality and purity.

Medication administration in the United States is regulated by law. The Pure Food and Drug Act of 1906 designated the USP and NF as the only official authorities to establish drug standards, including the requirement that medications be free of impurities. Subsequent legislation has continued to set standards related to the safety, potency, sales, distribution, and efficacy of medications. **Controlled substances** are types of medications that have government-regulated manufacturing, prescribing, and dispensing requirements. [Table 35.1](#) summarizes U.S. drug legislation. Enforcement of medication legislation in the United States is the responsibility of the U.S. Food and Drug Administration (FDA), which mandates that all medications undergo safety testing before being released to the public.

TABLE 35.1**United States Drug Legislation**

YEAR	LEGISLATION
1912	<i>Sherley Amendment</i> : Prohibits labeling of medicines with false therapeutic claims intended to defraud the purchaser. (Mrs. Winslow's Soothing Syrup for teething and colicky babies, laced with morphine, killed many infants.)
1914	<i>Harrison Narcotic Act</i> : Classified medications thought to be habit-forming as narcotics; regulates the use of narcotic substances, including increased record keeping for physicians and pharmacists who dispense narcotics.
1938	<i>Federal Food, Drug, and Cosmetic (FDC) Act</i> : Requires that labels be accurate and that all drugs be tested for harmful effects; added the <i>Homeopathic Pharmacopeia</i> as a third medication standard.
1951	<i>Durham-Humphrey Amendment</i> : Defines the kinds of drugs that cannot be safely used without medical supervision; restricts their sale to prescription by a licensed practitioner (before this amendment, all medications could be purchased over the counter).
1962	<i>Kefauver-Harris Drug Amendments</i> : Require proof of drug safety and efficacy before marketing and greater controls on investigational medications (passed in response to birth defects associated with thalidomide).
1970	<i>Patient package insert requirement</i> : Mandates that oral contraceptives contain information for the patient about specific risks and benefits. <i>Comprehensive Drug Abuse Prevention and Control Act</i> : Replaces previous laws and categorizes drugs on the basis of their abuse and addiction potential compared with their therapeutic value (i.e., controlled substances addiction potential); made it illegal to possess a controlled substance without a prescription.
1997	<i>Food and Drug Administration Modernization Act</i> : Contains the most wide-ranging reforms in agency practices since 1938. Provisions include measures to accelerate the review of devices, regulate advertising of unapproved uses of approved drugs and devices, and regulate health claims for foods.
2004	<i>Project BioShield Act of 2004</i> : Expediates new review procedures to enable rapid distribution of treatments as countermeasures to chemical, biological, and nuclear agents that may be used in a terrorist attack against the U.S., among other provisions.
2013	<i>Drug Quality and Security Act</i> : Outlines steps for an electronic and interoperable system to identify and trace certain prescription drugs throughout the U.S.

From U.S. Food and Drug Administration (FDA). (2018). *Milestones in U.S. Food and Drug Law History*. Washington, DC: U.S. Department of Health and Human Services.

Controlled Substances

A specific aspect of nursing practice governed by law is the use of controlled substances. In the United States, the Comprehensive Drug Abuse Prevention and Control Act (1970), known informally as the *Controlled Substances Act (CSA)*, established five categories of scheduled drugs, referred to as *controlled substances* (Table 35.2). One objective of the CSA is to reduce opportunities for drugs to be diverted from legitimate sources to drug abusers. In working toward this goal, the CSA mandates regulations for the handling and distributing of

controlled substances by manufacturers, distributors, pharmacists, nurses, and care providers. Compliance with these regulations is monitored by the Drug Enforcement Administration (DEA), an office within the U.S. Department of Justice.

TABLE 35.2
Controlled Substances

CATEGORY	DESCRIPTION	EXAMPLES
Schedule I	High potential for abuse No currently accepted medical use in treatment in the United States	Heroin, lysergic acid diethylamide (LSD), and methaqualone
Schedule II	High potential for abuse; may lead to severe psychological or physical dependence Has a currently accepted medical use with severe restrictions	Morphine, cocaine, methadone, and methamphetamine
Schedule III	Lower potential for abuse compared to the drugs in schedules I and II in regard to moderate dependence Has a currently accepted medical use	Anabolic steroids, narcotics such as codeine or hydrocodone with aspirin or acetaminophen, and some barbiturates
Schedule IV	Lower potential for abuse relative to the drugs in schedule III; may lead to limited dependence Has a currently accepted medical use	Pentazocine, meprobamate, diazepam, and alprazolam
Schedule V	Low potential for abuse relative to the drugs in schedule IV Has a currently accepted medical use in treatment in the United States.	Over-the-counter (OTC) cough medicines with codeine

From U.S. Department of Justice, Drug Enforcement Administration (DEA). (n.d.). *Mid-level practitioners authorization by state*. Washington, DC: U.S. Department of Justice.

A written record is required to track all transactions involving controlled substances that originate from legitimate sources. Every time a controlled substance is purchased or dispensed, an accurate record must be documented. An inventory must be kept of all controlled substances in stock, and this inventory must be reported to the DEA every 2 years. Although not required by the CSA, many hospitals and clinics require that floor stock of controlled substances be accounted for at the beginning and end of each nursing shift.

If a controlled drug needs to be wasted (e.g., only a partial amount is needed for the prescribed dose), two licensed clinical staff members must witness the appropriate disposal of the substance and document the wasting of the drug.

State and Local Medication Regulations

Health care facilities develop policies and procedures that must be in compliance with federal, state, and local regulations and may be more restrictive than government controls. The goal of these regulations is to prevent adverse patient outcomes. The functions and professional responsibilities of nurses are defined by each state's nurse practice act. Health care facilities cannot modify or expand the nurse practice act. It is the nurse's responsibility to understand and follow the nurse practice act and policies of the facility when administering any medication, particularly controlled substances. Violations of regulations can result in fines, imprisonment, and the loss of nurse licensure.

LO 35.2 Principles of Drug Actions

The nurse should understand how a drug exerts its effects on the body. **Pharmacokinetics** is the study of how a medication enters the body, moves through the body, and ultimately leaves the body.

Pharmacodynamics is the process in which a medication interacts with the body's cells to produce a biologic response. Understanding these processes helps the nurse evaluate the *therapeutic*, or intended, response and *adverse*, or unintended, effects caused by the administered medication.

Pharmacokinetics

The **therapeutic effect**, or intended effect, is the desired result or action of a medication. To achieve a therapeutic effect, the medication must be taken into the body, be absorbed and distributed in cells and tissues, and alter physiologic functioning. Effectiveness is influenced by the medication dose, route of administration, frequency of administration, function of metabolizing organs (such as the liver or kidneys), and age of the patient (Box 35.1). Prescribing practitioners and nurses providing care monitor the patient's response to the medication. Laboratory and diagnostic studies measure medication effects. Medication actions depend on absorption, distribution, metabolism, and excretion properties.

Box 35.1

Diversity Considerations

Life Span

- *Pregnancy*: Nurses must take extreme care when administering, recommending, or prescribing medications to pregnant women, especially in the first trimester, due to the risk of harm to the developing fetus.
 - The U.S. Food and Drug Administration (FDA) has established categories for pregnant women for each drug.
 - Category A drugs have no demonstrated risk, whereas category D or X drugs have documented evidence of risk or harm to a fetus.

- *Infants*: Infants require small doses because of their body size and immature organs.
- *Infants and children*: Medication doses are often based on weight.
- *Older adults*: Age-related changes, such as increased fat deposits, decreased gastric motility, decreased renal and liver function, and changes in the blood–brain barrier; can lead to increased side effects of medications.
- Comorbidities, polypharmacy, potential drug interactions, and adverse drug side effects (such as falls and delirium) increase dramatically in older adults ([Woods, Mentes, Cadogan, et al., 2017](#)).

Gender

- Differences in body weight, plasma volume, cardiac output, and hormones in men and women have an impact on drug metabolism and clearance.
- Women have slower gastric motility than do men, which affects plasma concentration and absorption of oral medications ([Chu, 2014](#)).
- Glomerular filtration rate and renal blood flow are higher in men than in women, which contributes to faster clearance of medications eliminated via the kidneys in men ([Chu, 2014](#)).

Culture, Ethnicity, and Religion

- Genetic factors affect drug metabolism and influence therapeutic and adverse effects ([Woods et al., 2017](#)).
- Research indicates that medication adherence rates are typically lower among individuals with lower socioeconomic status and racial/ethnic minority backgrounds ([McQuaid & Landier, 2018](#)).
- Herbal medicines used by persons of a specific culture or ethnicity may affect the action of prescribed medications. Assessing patients for use of herbal medicines is vitally important to prevent potentially serious adverse interactions.
- Certain cultural and religious groups have beliefs that discourage the use of medications other than natural remedies.
- Differences in drug responses that are often attributed to lack of adherence may actually be due to complex genetic differences, cultural-based food preferences, or gene–environment interactions ([Woods et al., 2017](#)).

Absorption

Absorption is the passage of a drug from the administration site into the bloodstream. Several factors affect absorption: route of administration, ability of the drug to dissolve or become soluble, blood flow to the administration site, body surface area, and patient age. Administration of a medication intravenously, or directly into a blood vessel, results in the quickest rate of absorption, followed in descending order by intramuscularly, subcutaneously, and orally administered medications.

Distribution

Distribution is the process of delivering the medication to tissues and organs and ultimately to the specific site of action. Distribution is affected by the chemical properties of the drug, the effectiveness of the cardiac system, the ability to pass through tissue and organ membranes, and the extent to which the drug binds to proteins or accumulates in fatty tissue.

Metabolism

Metabolism is the process by which a drug is altered to a less active form to prepare for excretion. The products of this process are called *metabolites*. Most metabolism takes place in the liver, and it may be slowed in elderly individuals or anyone with impaired liver function. Care is taken in administering medications to these populations, because toxic levels of a medication can build up if the liver is not able to break the drug down to a less active form.

Excretion

The **excretion** process removes the less active drug or its metabolites. Most metabolites exit the body through the kidneys, but some may be excreted in feces, breath, saliva, sweat, and breast milk. The drug may accumulate to unwanted levels in elderly individuals and people with impaired kidney function, necessitating prescription of smaller doses or longer durations between doses.

Pharmacodynamics

Drug activity results from chemical interactions between a medication and the cells of the body, causing a biologic response. The biochemical response can be systemic, such as the effects seen when an administered pain medication affects the nervous system (sedation), respiratory

system (change in respiratory rate), and gastrointestinal system (constipation). The response can be local, as occurs when an antipruritic lotion is applied to an insect bite. The biochemical response is typically evaluated on the basis of changes in the patient's clinical condition. Improvement is seen when a therapeutic effect is achieved with the medication, but unexpected or unwanted effects may occur, and different patients may respond differently to the same medication.

The desired drug action is produced by maintaining a constant drug level in the body and is based on the **half-life** of the drug. A drug's half-life is the expected time it takes for the blood concentration to measure one-half of the original drug dose due to drug metabolism and excretion. For example, if a drug has a half-life of 12 hours, 50% of the drug's original dose remains in the bloodstream 12 hours after administration. Repeated doses are usually required to maintain the desired drug level. Correct spacing of doses to maintain consistent drug levels and obtain therapeutic effects is based on the drug's half-life and is an important consideration when medications are prescribed.

Nurses must account for other drug action factors. **Onset of action** is the time the body takes to respond to a drug after administration. Onset is affected by the administration route, drug formulation, and pharmacokinetic factors. For example, the onset of action for insulin varies greatly, depending on the route (intravenous versus subcutaneous) and on the type of insulin (e.g., lispro versus glargine). **Peak plasma level** indicates the highest serum (blood) concentration. After the peak is reached, serum levels decrease until another dose is administered. Conversely, the **trough** is the lowest serum level of the medication. The peak and trough levels of a medication are measured with serum laboratory tests, and results are used to adjust dose amounts and monitor for toxicity. Blood samples for peak serum levels are drawn at specified times after administration on the basis of the drug half-life; samples for trough levels are drawn just before the administration of a scheduled dose.

Side Effects, Adverse Effects, and Interactions

Side effects are predictable but unwanted and sometimes unavoidable reactions to medications. Side effects may be minor and harmless, or they may cause patient injury. Patients may refuse to continue a medication because of side effects. Patient education regarding how to handle expected side effects can offset these reactions. For example, if nausea is a frequent side effect of a medication, the drug can be taken with a light meal to reduce this sensation. Nurses must be particularly alert for side effects when a new medication is started or the dose is increased.

Adverse effects are severe, unintended, unwanted, and often unpredictable drug reactions. An adverse effect may occur after one dose, such as a severe allergic response, or it may develop over time, such as the development of anemia associated with a medication. When an adverse reaction occurs, the medication is immediately stopped. Adverse reactions are reported by primary care providers to the FDA by using the MedWatch program (FDA, 2018).

Toxic effects result from a medication overdose or the buildup of medication in the blood due to impaired metabolism and excretion. Toxic levels of a drug can lead to serious physiologic effects that may be lethal. For example, toxic levels of a pain medication (such as morphine sulfate) may cause respiratory depression, leading to respiratory arrest. Other organs that can be damaged from drug toxicity include the kidneys (nephrotoxicity), liver (hepatotoxicity), organs of hearing (ototoxicity), and heart (cardiotoxicity). Most drug toxicity is avoidable with careful patient monitoring, especially of kidney and liver function.

Allergic reactions are unpredictable immune responses to medications. When a patient is first exposed to a foreign substance (antigen), the body produces antibodies. The medication, a chemical preservative, or one of the metabolites can initiate the immune response. On exposure, the patient reacts to the antigen with an allergic reaction that ranges from minor to severe. Minor allergic reactions include a rash, itching of the skin, inflammation of the nasal passages causing swelling and a clear discharge, and raised skin eruptions (hives).

A severe allergic reaction is called an **anaphylactic reaction**, and it is a medical emergency. Anaphylaxis can occur immediately after the administration of medication and can be fatal. Treatment includes immediate discontinuation of the drug and administration of epinephrine (an antagonist), intravenous (IV) fluids, steroids, and antihistamines while providing respiratory support. Patients who have experienced a severe allergic reaction to a medication need to wear an identification bracelet or tag identifying the drug or substance (Fig. 35.1). The bracelet or tag alerts medical staff to the allergy if the patient is unable to communicate.

FIGURE 35.1 Patient allergy necklace. (Copyright Thinkstock.com.)

Safe Practice Alert

Many community-based health facilities require patients to remain in the facility for 20 to 30 minutes after receiving medications to be monitored for a severe allergic reaction. Treatment can be initiated immediately if a reaction occurs.

Safe Practice Alert

To avoid initiating an allergic response, always check for patient allergies before administering medication.

An **idiosyncratic reaction** is an unpredictable patient response to medication. This response can be an overresponse, underresponse, or abnormal reaction to the medication. For example, a patient receiving an antihistamine may become overly alert and be unable to sleep rather than being drowsy, as expected.

Medication interactions occur when the drug action is modified by the presence of a certain food or herb or another medication. The interaction can alter the way the medication is absorbed, metabolized, or eliminated. A **synergistic effect** occurs when the combined effect is greater than the effect of either substance if taken alone. Alcohol, for example, is a central nervous system depressant that has an increased effect when taken with antihistamines, antidepressants, or barbiturates. A synergistic effect may be specifically sought by the primary care provider; for example, a patient with hypertension may receive a diuretic and a vasodilator to achieve a greater antihypertensive response than would be achieved by either drug alone. **Antagonism** occurs when the drug effect is decreased by taking the drug with

another substance, including herbs. For example, antibiotics can lessen the effect of birth control medications, and grapefruit juice alters the absorption of statins, a class of lipid-lowering drugs.

Special care is taken when administering parenteral medications. Mixing medications in a solution that causes precipitation or combining a drug with another drug that causes an adverse chemical reaction is called **drug incompatibility**. Compatibility must be verified before mixing or administering medications with a syringe or through IV tubing. If medications that are not compatible are prescribed, they must be administered separately with appropriate safety measures, such as flushing the IV tubing between medications.

LO 35.3 Nonprescription and Prescription Medications

Medications are classified as those that require a legal prescription and those that can be obtained without a health care provider's authorization. Nurses need to assess patient use of both nonprescription and prescription substances and provide teaching on possible interactions among the substances.

Nonprescription Medications

Many medications, vitamins, herbs, and supplements can be obtained without a prescription from a health care provider. They are referred to as *over-the-counter (OTC)* medications. Examples are cold medicines, mild analgesics, diet and nutrition supplements, and sleep aids. The FDA regulates OTC medications relative to safety and recommended dosage, but it does not regulate all supplements. Most people take OTC medications responsibly, but there is potential for misuse, including inappropriate dosing, delay in seeking evaluation by a primary care provider (PCP), and lack of knowledge about interactions with prescription medications. It is important for the nurse to educate patients about following the package directions and notifying the PCP that OTC medications are being used.

Factors to consider when selecting an OTC medication include: 1) clearly understanding the desired effect and potential side and adverse effects of all ingredients in the medication, 2) possible allergic reactions, 3) potential interactions with other medications and herbs, 4) warnings, 5) directions and dosage, and 6) features (such as safety caps). The FDA developed Choosing the Right Over-the-Counter Medicine, which is a checklist for use when selecting OTC medications

(<https://www.fda.gov/Drugs/ResourcesForYou/Consumers/BuyingUsingMedicineSafely/UnderstandingOver-the-CounterMedicines/Choosingtherightover-the-countermedicineOTCs/ucm150299.htm>).

Vitamins

Vitamins needed by the body are usually acquired from food that is eaten. The body uses vitamins for the biologic processes of growth, digestion, and nerve function. Water-soluble vitamins are excreted by the body through the kidneys. The water-soluble vitamins are the B complex and C vitamins. Fat-soluble vitamins are stored by the body for

use as needed; however, excess can build up in the liver, so they must be used with caution. The fat-soluble vitamins are the A, D, E, and K vitamins. There are certain conditions in which vitamins should be considered for use. They include pregnancy, breastfeeding, a vegetarian or vegan diet, an illness or condition that prevents oral consumption of foods, and the need for dietary supplements.

Vitamin use should be recorded as part of the patient history. They can have side effects, such as anticoagulation and interfering with the results of medical tests (Table 35.3). Vitamin products are regulated by the FDA as dietary supplements, with testing for purity, strength, and composition.

TABLE 35.3

Vitamins and Adverse Effects

VITAMIN	ADVERSE EFFECTS
Water-Soluble Vitamins	
B ₃ (niacin)	Flushing, redness of the skin, upset stomach
B ₆ (pyridoxine, pyridoxal, and pyridoxamine)	Nerve damage to the limbs, which may cause numbness, trouble walking, and pain
C (ascorbic acid)	Upset stomach, kidney stones, increased iron absorption
Folic acid (folate)	At high levels, especially in older adults, may hide signs of B ₁₂ deficiency
Fat-Soluble Vitamins	
A (retinol, retinal, retinoic acid)	Nausea, vomiting, headache, dizziness, blurred vision, clumsiness, birth defects, liver problems, possible risk of osteoporosis
D (calciferol)	Nausea, vomiting, poor appetite, constipation, weakness, weight loss, confusion, heart rhythm problems, deposits of calcium and phosphate in soft tissues

From U.S. Food and Drug Administration (FDA). (2018). *Fortify your knowledge about vitamins*. Washington, DC: U.S. Department of Health and Human Services.

Alternative Therapies

Many people take herbal supplements to support and maintain their health. Herbal therapy has roots that date back to ancient times. In a 2012 survey conducted by the National Center for Complementary and Integrative Health (NCCIH), more than 17% of adults in the United States reported using an herb or supplement. Among the top 10 were fish oil, glucosamine or chondroitin, probiotics, melatonin, coenzyme Q-10, echinacea, cranberry, garlic, ginseng, and ginkgo biloba (Clarke, Black, Stussman, et al., 2015).

Herbal medications come from plants or a plant part and are found in many foods. Herbs can be dried and processed to make a more

concentrated product that is delivered in a capsule or pill. Many commercial herbal preparations contain more than one herb. Many nonprescription and prescription drug formulations include a plant or plant extract. Common examples are aspirin (willow tree bark), morphine (opium poppy), and digitalis (foxglove).

The FDA regulates herbs and dietary supplements through the Dietary Supplement Health and Education Act (DSHEA). This form of regulation is different from that for prescription medications, despite the fact that herbs and prescription medications can act in the human body in the same way. The effects of herbals and dietary supplements necessitate that PCPs be informed about these products so that they can educate consumers. More detailed information on labeling and health claims can be found on the FDA website (<http://www.fda.gov/Food/DietarySupplements/>).

Herbs are often taken for specific symptoms and for a limited period of time. Because they act in the body similar to the way that prescription medications act, they should be used with caution, and many need to be discontinued several days before a surgical procedure. Many consumers are reluctant to inform or do not understand the importance of telling their PCP about their use of herbal supplements, and this increases the possibility of an adverse reaction among prescribed medications and the supplements (Table 35.4).

TABLE 35.4**Common Herb Side Effects and Drug Interactions**

HERB	USES	SIDE EFFECTS AND DRUG INTERACTIONS
Echinacea	Stimulates the immune system; facilitates wound healing; fights flu and colds	Possible liver inflammation and damage if used with anabolic steroids or methotrexate
Garlic	Lowers blood pressure and cholesterol and triglyceride levels	Increased bleeding; potentiates action of anticoagulants
Ginkgo biloba	Improves memory and mental alertness	Increased bleeding; potentiates action of anticoagulants
Ginseng	Increases physical stamina and mental concentration	Can increase heart rate and blood pressure; decreases effectiveness of anticoagulants; may cause hypoglycemia in patients taking oral hypoglycemics or insulin
Saw palmetto	Helps with enlarged prostate and urinary inflammation	Interacts with other hormones
St. John's wort	Alleviates mild to moderate depression, anxiety, and sleep disorders	Interacts with anti-anxiety medications, antidepressants, anticoagulants, birth control pills, cyclosporine, digoxin, statins, and human immunodeficiency virus (HIV) and cancer medications

From National Center for Complementary and Integrative Health. (2018). *Herbs at a glance*. Bethesda, MD: National Institutes of Health.

Herbs can be grown in many regions with different soil, water, and atmospheric conditions. For this reason, standardization and quality control are difficult. The nurse must be vigilant in obtaining an accurate patient medication history that includes the use of herbs, extracts, teas, tinctures, and dietary supplements. Because many herbs have the same properties as prescription medications, the patient taking an herb and prescription medication for the same effect could experience a toxic reaction. To determine specific side effects and possible drug interactions, each preparation needs to be researched individually.

Prescription Medications

Medications are usually dispensed by a pharmacist on receipt of electronically transmitted PCP orders, or via written directions, or **prescription** (Fig. 35.2). Legally, prescribing medications is limited to physicians, dentists, specially qualified nurse practitioners or other advanced practice nurses, and physician assistants. It is illegal to dispense medications without a legal prescription. A medication order

from any health care setting must have several components to be a legally valid medication prescription:

John Jones, M.D. EastWest Medical Group 1234 Main Street Chicago, IL 60619	
Phone: (312) 949-7000	Fax: (312) 949-7001
LICENSE#: IL 93824	DEA#: RF20398678
Name: MARY SMITH	DOB: 10/20/1965
Address: 2663 HAPPY DRIVE CHICAGO, IL 60649	Date: 2/27/20
RX: Procardia 10 mg #90	
ROUTE: Oral	
QUANTITY: Three times daily	
REFILLS: 2	
<i>John Jones</i>	
THIS PRESCRIPTION WILL BE FILLED GENERICALLY UNLESS PRESCRIBER WRITES 'd a w' IN THE BOX BELOW	
<input type="checkbox"/>	
Dispense As Written	

FIGURE 35.2 Sample prescription.

- Patient's name
- Date and time the order is written
- Name of drug to be administered
- Dosage of the drug
- Route of drug administration
- Frequency of drug administration
- Signature of the person writing the order

1. C. P. has requested medication for pain in her bruised hip. When the nurse accesses the locked narcotic cabinet, she finds a discrepancy between the expected amount and actual amount of the prescribed pain medication. What action should the nurse take?

2. The primary care provider electronically transmits an order for C. P. for “docusate sodium daily, PRN.” What additional actions are needed before the nurse can safely administer this medication?

Each patient in a health care facility has a medication administration record (MAR). The MAR includes the patient's name, full name of medication, administration time, dose, route, frequency, site of administration for parenteral medications, and the nurses' initials and signatures. The prescribing PCP may also be identified. The MAR shows when previous routine doses were administered and by whom, along with any as needed (PRN) or intermittent (one-time) medications. [Fig. 35.3](#) shows a legal medication order for inpatient settings. Computerized charting meets all of these requirements. Specific documentation is needed when a medication is not administered as prescribed, such as when a patient refuses a medication or the nurse purposefully does not administer, or “holds,” a medication before a procedure. Refer to [Chapter 10](#) and [Fig. 10.4](#) for handwritten medical documentation requirements.

Medication Name	1500	1600	1700	1800	1900	2000	2100	2200
hydrochlorothiazide (MICROZIDE) capsule 12.5 mg Freq: DAILY Route: Oral Order Dose: 12.5 mg Admin Amount: 1 capsule (1 × 12.5 mg capsule) Order Start Time: 08/15/20 1230 Disp Location: MAIN PHARMACY Last Admin Given: 08/16/20 1540 References: lexicomp Last 3 Actions: 08/15 1230, 08/16 0900, 08/17 0900 Next 3 Scheduled: 08/18 0900, 08/19 0900, 08/20 0900	Given 1540 JS 12.5 mg							
morphine injection 2 mg Freq: EVERY 4 HOURS PRN Route: Intravenous Order Dose: 2 mg Admin Amount: 1 mL = 2 mg of 2 mg/mL Dispensed Volume: 1 mL Order Start Time: 08/15/20 1213 Disp Location: MAIN PHARMACY Last Admin Given: 08/16/20 1937 Recent Admin Within 36 Hours: 08/16/20 1937 PRN Reasons: Pain References: lexicomp Last 3 Actions: none Next 3 Scheduled: none					Given 1937 JS 2 mg

QSEN Focus!

Using informatics, the nurse applies technology and information management tools to support safe processes of care. The nurse values technologies that support error prevention in medication administration.

Nurses need to know why a medication is ordered for certain times and whether the times can be altered. For example, there is a difference between medications ordered every 6 hours (q 6 hr) and those ordered four times per day (qid), even though the four doses of medication are administered in a 24-hour period. A medication ordered q 6 hr is given at regular intervals around the clock (e.g., at 6 a.m., 12 p.m., 6 p.m., and midnight) to maintain a constant blood level. A medication given qid (e.g., at 9 a.m., 1 p.m., 5 p.m., and 9 p.m.) is administered during waking hours.

Medication orders can change on the basis of the status of the patient. For example, a sudden change in condition, an adverse reaction to a medication, or a patient transfer to a different care unit can necessitate a change in medication orders. Medication orders may need to be adjusted by the prescriber after surgical procedures or on discharge.

Insulin is often prescribed to be taken at a specific time before meals; other medications may be ordered to be taken after meals to ensure that they are not taken on an empty stomach.

The five common types of medication orders in acute care settings are based on administration frequency or urgency: routine, PRN (as needed), one-time or on-call, stat, and now orders (Table 35.5). Stat medications are given immediately. The instructions regarding when to give an on-call medication are included in the order; the time is based on when a treatment or procedure is scheduled to start, such as when the operating room staff is ready to transport a patient to the surgical department for surgery. A PRN medication is administered as needed but still within identified time constraints. Each facility's pharmacy has guidelines for medication administration times. It is not within the scope of practice for a nurse to determine medication administration times. The hours of administration per pharmacy protocol must be adhered to, unless ordered differently by the PCP.

TABLE 35.5
Types of Medication Orders

TYPE	DESCRIPTION	EXAMPLES
Routine order	Administered until the health care provider discontinues the order or until a prescribed number of doses or days have occurred.	digoxin 0.125 mg PO daily amoxicillin 250 mg PO q 8 hr × 10 days
PRN order	Given only when the patient requires it. Use determined by objective and subjective assessment and clinical judgment of the nurse.	morphine sulfate 4 mg IV q 2 hr PRN pain
One-time or on-call order	Given only once at a specified time, often before a diagnostic or surgical procedure.	lorazepam 1 mg IV on call surgery
Stat order	Given immediately and only once in a single dose; frequently given for emergency situations.	diazepam 10 mg IV stat for seizure
Now order	Used when a medication is needed quickly but not as immediately as a stat medication; given one time.	vancomycin 1 g IV now, on admit

LO 35.4 Forms of Medication and Routes of Administration

Medications are formulated for a specific route of administration. The route of administration is specified on the prescribed order and refers to how the drug is absorbed.

Forms of Medication

Nurses must administer the correct form of a medication ([Table 35.6](#)) by the correct route for optimal effectiveness and patient safety. Patient education on correct administration by the correct route is an important responsibility for nurses.

TABLE 35.6**Common Forms of Medication**

FORM	DESCRIPTION AND USES
Tablets	Medication is compressed with binding substances and disintegrating agents; may have flavoring added to improve taste; used for oral, sublingual, and buccal routes. <i>Enteric-coated tablets</i> have a special outer covering that delays absorption as it dissolves in the intestines.
Capsules	Medications are enclosed in cylindrical gelatin coatings. <i>Time-release capsules</i> have medication particles encased in smaller casings that deliver medication over an extended period.
Powders	Ultrafine drug particles in a dry form; depending on the medication, may be inhaled, mixed with food, or dissolved in liquids immediately before administration.
Troches or lozenges	Medications prepared to dissolve in the mouth.
Solutions	Medications already dissolved in liquid. <i>Syrups</i> are mixed with sugar and water. <i>Suspensions</i> are finely crushed medications in liquid. <i>Elixirs</i> are medications dissolved in alcohol and water with glycerin or other sweeteners. <i>Drops</i> are a sterile solution or suspension administered directly into the eye, outer ear canal, or nose or sublingually. <i>Injectable solutions</i> are sterile suspensions supplied in ampules, vials, prefilled syringes, bags, or bottles.
Inhalants or sprays	Medications inhaled or sprayed into the mouth or nose; may have local or systemic effects. Some are delivered in fixed doses.
Skin preparations	Ointments (spreadable, greasy preparations), creams (not greasy but used on skin only), and lotions (solutions or suspensions used on skin and not as sticky as creams or ointments). <i>Transdermal patches</i> contain medication absorbed through the skin over an extended period.
Suppositories	Bullet-shaped gelatin tablets commonly administered rectally or vaginally, depending on the medication. Urethral preparations are used for erectile dysfunction.

Routes of Medication Administration

Although the pharmacy should dispense the correct form, the nurse ensures that the medication is the correct form for the route of administration. Medication preparations are not interchangeable for alternate routes. For example, if a patient has difficulty swallowing a medication tablet, the nurse cannot substitute a liquid form without consulting the health care provider. A liquid form may be a different concentration or have a different absorption rate, which requires a change in dose or time of administration.

Common routes of administration include **oral** (by mouth), **buccal** (against the cheek), **sublingual** (under the tongue), **parenteral** (by injection or infusion), **topical** (on skin or mucous membranes), by inhalation, and through a medical tube (e.g., a nasogastric tube, percutaneous endoscopic gastrostomy [PEG] tube). Each route has advantages and disadvantages ([Table 35.7](#)).

TABLE 35.7**Medication Administration Routes**

ROUTE	ADVANTAGES	DISADVANTAGES
Oral	Convenient, cost-effective, and comfortable, with low stress for the patient. Certain oral tablets formulated to dissolve on contact with the tongue	Inappropriate for patients with nausea or vomiting; contraindicated for patients with swallowing difficulty Can irritate gastrointestinal lining, have unpleasant taste, or discolor teeth Patient must be alert and oriented to safely administer Cannot be used with simultaneous gastric suctioning or before various diagnostic or surgical procedures Possible irregular or slow absorption
Sublingual or buccal	As above plus more potent because the drug bypasses the liver and enters the bloodstream directly	May be inactivated by gastric juices if swallowed
Topical	Local effect with few side effects	Absorption may be irregular if skin breaks are present, and it may be slow
Transdermal	Prolonged systemic effects without gastrointestinal absorption problems	May leave residue on clothes
Mucous membranes (eyes, ears, nose, vagina, rectum, ostomy)	Local effects to involved sites with systemic effects possible; readily absorbed; may be used if the oral route is contraindicated	Mucous membranes are highly sensitive to concentrated medications Dose absorption may be unpredictable Procedure may be messy
Inhalation	Rapid localized effect; may be administered to unconscious patients	May cause serious systemic effects; can be administered only through the respiratory system
Parenteral (intradermal, subcutaneous, IM, IV)	Can be used if the oral route is contraindicated; more rapid response than the oral or topical route; can be used for critically ill patients or for long-term therapy IV route can decrease discomfort and can better control absorption if peripheral perfusion is compromised	Sterile technique must be used as the skin barrier is compromised More costly to formulate and administer; useful for small volumes only, except by IV route; affected by circulatory status; can produce patient anxiety

IM, Intramuscular; *IV*, intravenous.

Oral Administration

Medication is most commonly administered by the oral route, abbreviated as *PO* (Latin: *per os*, which means “by mouth”). These

medications are designed to be swallowed with fluid, which is the safest, most convenient, and least expensive method for administration. Medications given by the oral route have a slower onset of action than parenteral medications. Nurses are responsible for ensuring that all medications taken by the oral route are swallowed. Patients with difficulty swallowing may hold medications in their mouths, or patients with cognitive or mental health issues may pocket medications in the cheeks.

The sublingual and buccal oral routes are used for absorbing small amounts of medications quickly through the oral mucosa; this prevents destruction of the medication by gastric or intestinal secretions. For the sublingual route, medications are placed under the tongue to dissolve (Fig. 35.4). Nitroglycerin for chest pain is administered by this route. For the buccal route, medications are placed against the mucous membrane of the cheek until completely dissolved (Fig. 35.5). Medications administered by the buccal route include antiemetics and opiate pain medications.

FIGURE 35.4 Sublingual placement of a tablet.

FIGURE 35.5 Buccal placement of medication.

Oral medication can often be administered through nasogastric, gastric, intestinal, and jejunal tubes when they are ordered to be given via that route. Tube placement is checked before medication administration. [Chapter 30](#) provides more information about checking tube placement before medication administration. Special safety precautions need to be taken to prevent aspiration or clogging of the tube when administering medications through feeding tubes.

Topical Medications

Medications formulated for topical application are applied to a specific skin surface or mucous membrane of a body cavity. Nurses administer medications to the skin and mucous membranes in a variety of ways. Liquids and ointments can be directly applied to the eyes. Suppositories can be inserted into the rectum or vagina. Fluids can be instilled into a body cavity such as the ear, nose, bladder, or rectum. Body cavities such as the eye, ear, vagina, bladder, and rectum can be flushed with a medicated solution. A spray can be applied to the throat. Lotions and ointments can be applied to any skin surface.

Safe Practice Alert

Remember that not all medications can be crushed for administration through a tube. Enteric-coated, time-release, sublingual, buccal, and other medications with special coatings cannot be administered through a tube. Contact the PCP to safely change the prescribed

medication to an alternate administration route or formulation, if needed.

Absorption is affected by the vascularity of the application site and typically requires additional applications each 24-hour period. A **transdermal patch** is a topical preparation designed to deliver medication slowly for systemic effects (e.g., nicotine for smoking cessation, pain medication such as fentanyl, nitroglycerin for angina).

Inhaled Medications

Medications for **inhalation** are taken into the body through the respiratory tract. The deeper passages of the respiratory tract provide a large surface for medication absorption. Inhaled medications are effectively used to induce anesthesia and to treat respiratory disorders. Nurses administer inhaled medications through nasal passages, oral passages, an endotracheal tube, or a tracheostomy tube. Means of delivery include small amounts of fluids, metered-dose inhalers (MDIs), turbo-inhalers, and nebulizers (Fig. 35.6).

FIGURE 35.6 Inhaled Medication Delivery Systems. (A) Nebulizer. (B) Metered-dose inhaler (MDI) and spacer. (A, From Lilley, L. L., Collins, S. R., & Snyder, J. S. [2017]. *Pharmacology and the nursing process* [8th ed.]. St. Louis: Elsevier. B, Copyright Mosby's Clinical Skills: Essentials Collection.)

Parenteral Medications

Parenteral medications are administered by injection into tissue, muscle, or a vein. Absorption is usually faster and more complete by a parenteral route than the oral route. Aseptic technique is used because the protective skin barrier is bypassed with this route, resulting in infection risk. Safe injection practices maintain basic levels of patient safety and provider protection by combining aseptic technique with standard precautions (Centers for Disease Control and Preventions [CDC], 2018a). Tissue damage is another risk when medications are administered parenterally. There are four major sites of injection:

1. **Intradermal**: Shallow injection into the dermal layer just under the epidermis
2. **Subcutaneous** (subcut; subcutaneously): Injection into the subcutaneous tissue just below the skin
3. **Intramuscular (IM)**: Injection into a muscle of adequate size to accommodate the amount and type of medication

4. **Intravenous (IV):** Injection or infusion directly into the bloodstream via a vein

Parenteral Medication Preparation

Various supplies are needed to administer parenteral medications. Syringes are usually made of plastic and have a barrel, plunger, and syringe tip (Fig. 35.7). The plunger fits within the barrel. Moving the plunger in and out of the barrel allows fluid or air to move in or out of the syringe. With a Luer-Lok syringe, the needle is secured onto the end of the syringe with a twisting motion. A Luer-Lok syringe can be directly attached to an access port on the IV tubing or saline lock without the use of a needle. Other syringes have needles that slide onto the end. The nurse may touch the outside of the syringe barrel and the handle of the plunger, but a nonsterile object should not touch the tip of the barrel, inside of the barrel, shaft of the plunger, or needle. Common syringes range from very small, 0.5 mL sizes for intradermal and subcutaneous injections to 60 mL for irrigations and tube feeding. Larger syringes are available for special uses. The three common types of syringes are standard, tuberculin, and insulin (Fig. 35.8).

FIGURE 35.7 Parts of a syringe.

FIGURE 35.8 Types of syringes (*left to right*): tuberculin, insulin 50 units, insulin 100 units, standard 3 mL, standard 10 mL.

Most needles are made of stainless steel. The hub of the needle fits onto the tip of the syringe, the shaft of the needle is metal, and the bevel is the slanted tip of the needle. The needle diameter, or gauge, is identified by a number. Common gauges range from 18 to 30; the larger gauges, such as 16 or 14, are used in emergency departments or operating rooms (Fig. 35.9). As the gauge number decreases, the diameter of the needle increases. For example, an 18-gauge needle has a larger diameter than a 25-gauge needle. The nurse selects a needle gauge based on the viscosity, or thickness, of the medication to be injected and the route of administration. Long-acting medications formulated in an oil base for sustained release require a larger gauge needle than thinner, water-based medications.

FIGURE 35.9 Needle sizes.

Needle length varies from $\frac{1}{4}$ to 3 inches. Proper needle length depends on the age and size of the patient and the route of administration. Shorter needles are used for children and thin adults.

Standard syringes are 1, 3, 5, and 10 mL sizes. Subcutaneous injections are typically administered with a 1 mL syringe and a $\frac{3}{8}$ to $\frac{5}{8}$ inch, 25 to 31 gauge needle. IM injections are usually administered with a 3 mL syringe and a 1 to 3 inch, 19 to 25 gauge needle. Intradermal injections require a 1 mL tuberculin syringe with a short, $\frac{1}{4}$ to $\frac{5}{8}$ inch needle. U-100 (meaning there are 100 units per mL) insulin syringes are calibrated in units and millimeters and are supplied in three sizes: 30 units (0.3 mL), 50 units (0.5 mL), and 100 units (1 mL), each with a 26 to 31 gauge needle. Insulin may be administered by a prefilled insulin pen (see [Box 35.13](#)), which combines the insulin container and syringe. [Table 35.8](#) lists route, site selection, and appropriate syringe and needle sizes.

TABLE 35.8**Syringe and Needle Sizes**

PARENTERAL ROUTE	SYRINGE SELECTION	NEEDLE SELECTION	SITE SELECTION
Subcutaneous	$\frac{1}{2}$ -3 mL Insulin syringe: U-100, U-50, or U-30	25-31 gauge, $\frac{3}{8}$ - $\frac{5}{8}$ inch (up to 1 inch for an obese patient) Preattached to Insulin syringe: 29-33 gauge, $\frac{1}{8}$ - $\frac{5}{16}$ inch (4-8 mm) ^a	Abdomen, lateral aspects of the upper arm and thigh, scapular area of the back, and upper ventrodorsal gluteal area
Intradermal	1-mL tuberculin syringe	Preattached 25-27 gauge, $\frac{1}{4}$ - $\frac{5}{8}$ inch	Inner forearm, upper arm, and across the scapula
Intramuscular (IM)	Adults: 1-5 mL depending on site and muscle mass ^b Infants, small children: 0.5-1 mL	19-25 gauge, 1-3 inch (adult) 22 to 25 gauge, $\frac{5}{8}$ to 1 inch (pediatric) Oil-based solutions: 18-20 gauge	Ventrogluteal, vastus lateralis, and deltoid Age of patient and corresponding site [†] : Infant: Vastus lateralis Children: Vastus lateralis or deltoid Adult: Ventrogluteal or deltoid
Intravenous (IV)	Depends on amount of medication to be infused	Typically, a large-gauge, 1-inch needle; needleless, blunt-tip cannula or Luer-Lok used with associated IV ports. (Do not use needles in a needleless system to access IV ports.)	Vein

^aFrom Worldwide Injection Technique Questionnaire Study. (2016). *Mayo Clinic Proceedings* 91(9): 1212-1223.

^bFrom Shepherd, E. (2018a). Injection technique 1: administering drugs via the intramuscular route. *Nurs Times* 114(8): 23-25.

There are other parenteral routes (e.g., epidural, intrathecal, intraosseous, intraperitoneal, intraarterial) that only advance practice nurses in specialty areas or physicians can use to administer medication. The nurse is responsible for monitoring the integrity of the delivery system, understanding the desired outcome of the medication, and evaluating the patient response to the medication for all routes of delivery.

Filter needles or straws are used when medications are being withdrawn from a glass ampule. The filter traps glass fragments. A filter needle or straw must be replaced with a regular needle before injecting the medication into the patient.

Needleless delivery systems significantly decrease needlestick injuries and exposure to blood-borne pathogens. Needleless systems are available for IV medication administration and require special tubing ports and blunt-tip cannulas that attach to the syringe in place of a needle. Some needleless systems allow syringes to connect directly to the IV tubing port. Adapters are available for vials that allow access to the contents of the vial by needleless cannulas. Needleless devices are disposed of in the same manner as regular needles.

LO 35.5 SAFE Medication Administration

The nurse is accountable for adherence to professional standards that apply to medication administration. Accountability is based on facility policies and procedures and on the [American Nurses Association's *Nursing: Scope and Standards of Practice* \(2015\)](#) for medication protocols and legal expectations. Before administering a medication, the nurse should check the patient's MAR or the primary care provider's prescription, review diet and fluid orders, review relevant laboratory values, and perform a brief physical assessment.

To decrease medication errors, safe practice standards dictate that the nurse should follow only written orders. In an emergency situation, a verbal order from a PCP may be given to the nurse or pharmacist, but the order must be put in writing as soon as possible. In most settings, student nurses are not allowed to transcribe written orders or accept verbal orders.

Safe Practice Alert

Nurses are legally accountable for medications they administer and for recognizing side effects and adverse reactions. Questions regarding the purpose, dose, route, time, abbreviations, relation to laboratory values, potential interactions, allergies, or patient response must be resolved with the PCP or pharmacist before the nurse administers the medication. The nurse has the right and responsibility to refuse to administer a medication if he or she feels that the prescribed medication endangers the safety of the patient, but the PCP must be notified of the refusal to administer the medication.

Interpreting the Order

Special care is taken by the nurse to correctly read and interpret the initial medication order. The order must be clearly written or entered correctly into an electronic system. Clinical judgment is

needed to evaluate whether the medication, amount prescribed, and route are safe for the patient. The nurse must understand the purpose, typical dosage, route, and side effects of the medication before administration. Interpreting the order is a step that should not be overlooked, because the nurse assumes legal responsibility for all medications he or she administers. The nurse should clarify orders with the prescriber that are difficult to read, do not contain all of the critical information needed for safe administration, or contain prohibited or unfamiliar abbreviations (Box 35.2).

Box 35.2

Ethical, Legal, and Professional Practice

Consulting the Primary Care Provider About a Medication Order

The nurse is preparing the prescribed daily dose of warfarin for Mr. Andrews. As part of the nurse's assessment, the nurse reviews the international normalized ratio (INR) in the laboratory results obtained earlier in the morning. The INR level is 4.2, and the nurse recognizes that it would be unsafe to administer the prescribed warfarin. Additional investigation reveals that, unknown to the nursing staff, Mr. Andrews's wife has been administering his prehospitalization prescribed medications while he has been in the hospital. These medications include warfarin. The situation is reported by the nurse to the primary care provider using the SBAR format:

- S:** Situation. Mr. Andrews's warfarin dose was held today because his INR result is 4.2.
- B:** Background. Mr. Andrews, age 79, was admitted 2 days ago with a third occurrence of deep vein thrombosis. His wife has been giving him his home medication of warfarin without telling the nursing staff. He has a history of gastrointestinal (GI) bleeding requiring transfusions.
- A:** Assessment. The warfarin was held today based on Mr. Andrew's INR results, the fact that Mrs. Andrews has been giving him his home medication including warfarin

without the knowledge of the nursing staff, and his history of GI bleeding. Mr. Andrews's home medications have been sent to the pharmacy for safekeeping until he is discharged to prevent duplication of medications. He shows no signs of GI bleeding.

R: Recommendation. Do you want to monitor the INR daily and guaiac stools? What INR parameters do you want used for resuming administration of the warfarin and at what dose? We will monitor for bruising, bleeding gums, and bloody urine or stools and and continue to have the patient use a soft toothbrush and safety razor.

Medication Errors

Prevention of medication errors is the first step in medication safety. The FDA indicates that medication errors injure 1.3 million Americans each year and kill at least one patient each day. The common causes of errors include poor communication, misinterpretation of writing, and the use of improper techniques (FDA, 2017).

The National Coordinating Council for Medication Error Reporting and Prevention (NCCMERP, 2018) defines a **medication error** as “any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the health care professional, patient, or consumer. These events may be related to professional practice, health care products, procedures, and systems, including prescribing; order communication; product labeling, packaging, and nomenclature; compounding; dispensing; distribution; administration; education; monitoring; and use.”

QSEN Focus!

An understanding of safety is evident when the nurse delineates general categories of errors and hazards in care. The nurse values his or her own role in preventing errors.

Medication errors can occur anywhere in the medication system, from the manufacturer to patients and their families.

Mistakes can occur during any of the many steps in the process of medication administration. Fortunately, mistakes can be caught at any of the preadministration steps. Multidisciplinary collaboration for medication administration helps safeguard against errors (Box 35.3). Because the nurse is typically the last person in the sequence of administering medications in a health care facility, the nurse is the patient's last line of defense against mistakes. Many facilities have a No Interruption Zone policy for medication administration, requiring the nurse to prepare medications in a quiet setting without interruptions by other staff, patients, or phone calls. Focusing only on preparing the correct medications helps decrease errors (Williams, King, Thompson, & Champagne, 2014).

Box 35.3

Interprofessional Collaboration and Delegation

Medication Administration in the Acute Care Setting

- Collaboration with the patient and family or support person promotes the proper use of medications.
- Family members who may be assisting a patient with medication use after discharge need to understand how to monitor for therapeutic and adverse effects.
- Care providers, pharmacists, and case managers or social workers can ensure that the patient has the resources to obtain needed medications.
- Pharmacists participate in the review of medication orders for accuracy including dosage, laboratory values, and interactions. They can be consulted for additional information about preparations and specific administration questions. Nurses should consult with pharmacists prior to administering any newly developed medications for which there is no reference information available in drug guides.

- Dietitians may consult with patients taking medications that are effected by specific food intake. Patients with diabetes, cardiac disorders, undergoing chemotherapy, or taking anticoagulants are some examples of individuals who would benefit from meeting with dietitians.
- Medication administration cannot be delegated to unlicensed assistive personnel (UAP) in the acute care setting. UAP usually are informed of any medication effects that are anticipated or being monitored. For example, UAP are told to expect that the patient may be dizzy when getting up after taking an antihypertensive medication that lowers the blood pressure.

There are several types of medication errors. Some can cause harm to the patient directly (e.g., giving an excessive dose of medication). Others fail to treat the patient's illness (e.g., giving too little medication). Other errors include giving the wrong drug, giving a medication to the wrong patient, or using the wrong route. Human factors include knowledge or performance deficits (e.g., administering a drug intravenously rather than intramuscularly), miscalculation of dosage, stress, and lack of sleep. Name confusion arises from medications with names that look or sound alike.

If a medication error occurs, the nurse's priorities are to determine the effect on the patient and intervene to offset any adverse effects of the error. Actions include immediate and ongoing assessment, notification of the prescribing PCP, initiation of interventions as prescribed to offset any adverse effects, and documentation related to the event. Error reporting is an essential component of patient safety and should be completed as soon as the patient is assessed and stable. The nurse should follow facility guidelines for medication error reporting.

QSEN Focus!

Creating a culture of safety, the nurse describes factors such as open communication strategies and organizational error reporting systems. The nurse uses organizational error reporting systems for any medication error.

Measures that can be especially effective in reducing errors include replacing handwritten medication orders with a computerized provider order entry (CPOE) system and using a barcode system when administering medications. Barcodes verify that the patient and drug match and that adverse interactions are unlikely (Fig. 35.10). Technological advances such as barcodes, electronic medication administration records (eMARs), CPOE, IV smart pumps, and automated dispensing systems help eliminate nearly all medication errors (Lapkin, Levett-Jones, Chenoweth, & Johnson, 2016). The Institute for Safe Medication Practices has compiled a list of error-prone abbreviations, symbols, and dose designations that should be avoided to decrease errors (see Chapter 10, Fig. 10.2).

FIGURE 35.10 Scanning the barcodes on a patient's armband and medication helps prevent medication errors. (Copyright Mosby's Clinical Skills: Essentials Collection.)

Abbreviations

The safe use of abbreviations is important in preventing medication errors. The National Patient Safety Goals developed by The Joint Commission emphasize prevention of medication errors. From this effort came The Joint Commission's Do Not Use list of abbreviations that were identified as contributing to medication errors. This list is included in Chapter 10, Table 10.1. Some commonly approved abbreviations used in medication administration are found in Table 35.9.

TABLE 35.9**Common Abbreviations Related to Medication Administration**

ABBREVIATION	MEANING
ac	Before meals
pc	After meals
h or hr	Hour
bid	Two times per day
tid	Three times per day
qid	Four times per day
q	Every
g or gm	Gram
mcg	Microgram
mg	Milligram
mL	Milliliter
IM	Intramuscular
IV	Intravenous
PO or po	By mouth, orally
NPO or npo	Nothing by mouth
PRN or prn	As needed
SL	Sublingual
STAT	Immediately

QSEN Focus!

When administering medications, the nurse examines medication administration factors, basic safety design principles, and commonly used unsafe practices (such as dangerous abbreviations).

Dosage Calculation

Three types of measurement systems are used in medication calculations: metric, apothecary, and household. The nurse must understand all three to accurately administer the prescribed medication. A nurse may need to convert the ordered dose from what is dispensed by the pharmacy.

Basic measures of the metric system include gram (weight), liter (volume), and meter (linear). The metric system has a basic unit of 10, and calculations are performed by dividing or multiplying in increments of 10. Because 1 g is equal to 1000 mg, to change

milligrams to grams, the number of grams is multiplied by 1000. An example is $0.5 \text{ g} = 500 \text{ mg}$.

Safe Practice Alert

When noting a metric dose, always place a zero in front of the decimal point, and never have a trailing zero. For example, doses are identified as 0.5 mL instead of .5 mL and as 5 mL instead of 5.0 mL.

The apothecary system is older than the metric system. It has a basic measure called the *minim* (volume). The minim is followed in increasing order by the dram, ounce, pint, quart, and gallon. Weight in the apothecary system is based on 1 grain of wheat, which is abbreviated as *gr*. The apothecary system is no longer used on any drug labels. Medications should be prescribed and calculated using the metric system. Occasionally, the nurse may find a prescription written in terms of fluid ounces or grains.

The household system is the one with which most people in the United States are familiar. It is the most inaccurate of the three systems. The base unit of measurement is the drop (gtt). The drop is followed in increasing order by the teaspoon (tsp), tablespoon (Tbsp), and cup (c). The use of the teaspoon as a measurement is familiar and widely practiced by many. If strictly accurate dosing is needed, it is important to convert to a metric equivalent. These conversions are done by memorizing equivalents and then calculating the conversion. For example, a teaspoon is 5 mL and a tablespoon is 15 mL.

Calculation Methods

Several formulas or methods can be used to calculate the dosage of medications. Regardless of the method chosen, it is important to identify the available quantity of medication and the desired (prescribed) quantity.

Although a ratio proportion or formula method of dosage calculation may be used, the dimensional analysis method removes the need for multiple-step calculations and provides a consistent method for calculating medication dosages. This

formula can be used in all situations, from doing basic calculations to determining pediatric doses to calculating titration of potent drugs in critical care units.

The nurse begins a dosage calculation by identifying the units of measure (e.g., mg, capsule) needed for the answer to the problem. The unit used in the answer must have the same unit as the numerator, or top of the equation, and the denominator, or bottom of the equation. Start the equation with the dose to be given, then the concentration or supply available. For example, the prescribed medication is “amoxicillin 0.5 g every 8 hours,” and the available quantity is amoxicillin 250 mg per 1 capsule. A unit conversion is needed from grams to milligrams. Notice that *capsule* must be in the numerator in the problem because it is the unit needed in the answer; the nurse needs to figure out how many capsules to administer per dose.

$$\frac{0.5 \text{ g}}{1 \text{ dose}} \times \frac{1 \text{ capsule}}{250 \text{ mg}} \times \frac{1000 \text{ mg}}{1 \text{ g}} =$$

In dimensional analysis, the first step is to cross off units that appear in both the numerator and denominator:

$$\frac{0.5 \cancel{\text{ g}}}{1 \text{ dose}} \times \frac{1 \text{ capsule}}{250 \cancel{\text{ mg}}} \times \frac{1000 \cancel{\text{ mg}}}{1 \cancel{\text{ g}}} =$$

After the units occurring in both numerator and denominator are crossed off, the only units left in the equation are the correct ones for the answer to the nurse's question. Next, the numbers on the top of the equation are multiplied, and the numbers on the bottom are multiplied. The final step is to divide the numerator by the denominator and add the correct units to the numeric answer:

$$\frac{500 \text{ capsules}}{250 \text{ doses}} = 2 \text{ capsules/dose}$$

Using a consistent approach in calculating medication dosages can greatly reduce the potential for medication errors resulting from miscalculations.

Administering Medications by Using the Six Rights

The Six Rights of Medication Administration were developed to help the nurse prevent mistakes. Confirming that the medication label matches the prescribed order and is a safe dosage, reviewing patient allergies, and verifying the expiration date of the medication, in addition to following the Six Rights during each patient interaction, can prevent medication errors. The **Six Rights of Medication Administration** are the right drug, right dose, right time, right route, right patient, and right documentation (Box 35.4).

Box 35.4

Nursing Care Guideline

Six Rights of Medication Administration

Background

- Six Rights of Medication Administration:
 - The right drug
 - The right dose
 - The right time
 - The right route
 - The right patient
 - The right documentation
- Additional checks before medication administration:
 - Check prescriber order
 - Check patient allergies
 - Check medication expiration date
- Never administer medication that you did not prepare. This task cannot be delegated, even to other professionals.

- Unlicensed assistive personnel (UAP) may not administer medications unless they are in a state that allows designation of certified medication technicians in certain facilities.
- These technicians may administer certain medications. Check with the state's nurse practice act and the facility's policies and procedures.
- The task is not being delegated; the technician is assuming responsibility.
- If there is any question regarding the medication order by the nurse or the patient, do not administer the medication. Contact the primary care provider or pharmacist for clarification.
- Never leave the medication unattended at the bedside.

Procedural Concerns

Verification

- The Six Rights require that verifications be completed.

(Copyright Mosby's Clinical Skills: Essentials Collection.)

- Verify that the drug is the right drug at each of these three points:

- When taking the drug out of the drawer or dispensing unit
- When comparing it with the MAR as the drug is being prepared
- At the bedside immediately before administration
- Verify that the right dose will be given by confirming the following:
 - The calculation of the dose is correct.
 - Its strength is correct.
 - The dose prescribed is appropriate for the patient.
- Additional verification is provided by the following:
 - Have another nurse check critical dosage calculations.
 - Be aware that unit-dose systems were developed to decrease errors related to dose amounts.
 - Use standard measurement devices such as graduated medication cups, syringes, and calibrated droppers when preparing medications.
- Verify that the medication will be administered at the right time:
 - Administer medications within the appropriate time frame (usually between the half hour before and the half hour after the scheduled time for oral medication; check facility and state policy) or administer as specified (e.g., before meals).
 - Make sure it will be administered with the correct frequency (especially important with PRN, or as-needed medications, as the patient may meet the indications for administration but the correct amount of time has not elapsed between doses).
 - Use the correct time system. Many health centers use military time to avoid the confusion that can result when using A.M. and P.M.
- Verify that the medication will be administered by the right route to ensure compatibility:
 - Possible routes of administration are oral (PO), sublingual (SL), buccal, rectal (PR), vaginal, topical, transdermal, subcutaneous, intramuscular (IM), intradermal, intravenous (IV), and inhalation.

Medications can only be administered via the prescribed route.

- Before administering parenteral medications, check compatibility, need for dilution, and rate of administration.
- When medications are mixed in the same syringe, there may be a time limit between when the drugs are mixed and when they are administered. Always verify timing of administration.
- When more than one syringe is needed, as in giving 2 parenteral medications, label the syringes with the drug name and dose.
- Some medications may be cut or crushed.
- Verify that the medication will be administered to the right patient by using one of the following:
 - A barcode scanning system or by verifying at least two identifiers (such as full name of the patient, date of birth, and current photograph) against the MAR. Never use the patient's room or physical location to verify identity.

(Copyright [istock.com.](https://www.istock.com/))

- Complete the right documentation after administration:
 - Documentation is completed after administration to reflect the administration, refusal, or with holding of prescribed medication.
 - Verify that it is accurate and complete according to facility policy and procedure.

- It should account for adverse effects.
- It should include communication with other health care providers.
- It must include the indications that necessitate administration of PRN medications and the patient's response to medication.

Other Considerations

- Verify that the medication is being given for the right reason (i.e., medication is correct for the patient's condition). Know what outcome from the medication is expected for the patient.
- Complete an assessment, and verify the observations:
 - The appropriate vital signs are taken before and after administration.
 - The patient has no allergies to the drug.
 - The appropriate laboratory data are obtained.
 - The appropriate physical assessment data are collected.
 - The patient's pain levels are known.
- When the nurse is administering a medication, patient teaching is essential and should include the name of the drug, what it is for, the dosage, and potential side effects.
- Complete an evaluation of medications, and verify that required follow-up assessments are performed.

Patient Concerns

- If the patient questions or refuses the medication, stop the administration, verify the information, and proceed accordingly.
- The patient has the right to refuse medications.
- The nurse investigates the patient's reasons for refusing the medication and provides, reinforces, or clarifies information to ensure that the patient understands the risks of refusing the medication.

- The prescriber needs to be notified of the patient's refusal of the ordered medication.
- Documentation of refusal of medication should include the patient's concern, the information provided by the nurse, and the name of the prescriber who was notified of the patient's refusal.

Documentation Concerns

- Do not document administration of the medication until it is given to the patient.
- Documentation using paper charting may be necessary if the situation is an emergency or the computer system is not operational for some reason. The following are special considerations for paper charting:
 - Ensure the legibility of orders and documentation.
 - The appropriate ink color, depending on facility policy, must be used. Some facilities require black ink so that documents can be scanned and stored electronically. Other facilities require that each shift document in a different ink color.
 - Never leave blanks or spaces in documentation.
 - [Chapter 10](#) further discusses paper charting and correction of errors.
- Documentation using computerized charting:
 - Ensure that the entries are in the appropriate location.
 - Ensure that the actual caregiver is logged on and that entries are submitted or saved.
 - If a manual override is used, document the reason for using it.
- Documentation using both computerized and paper charting:
 - Use appropriate abbreviations, avoiding abbreviations as listed in the following references:
 - The Do Not Use list published by The Joint Commission (see [Fig. 10.2](#))
 - The Error-Prone Abbreviations, Symbols, and Dose Designations list published by the

Institute for Safe Medication Practices (ISMP)
(see [Table 10.1](#))

- Use correct grammar and spelling.
- Record the correct time.
- Chart promptly.
- Document adverse effects reported by the patient or observed during evaluation.

Evidence-Based Practice

- The [ISMP \(2017\)](#) independently collects data and promotes educational tools to prevent medication errors. The institute collaborates with multiple agencies to assist facilities with implementing the best evidence-based practices in regard to medication administration.
- Use of evidence-based practices has reduced medication errors and prevented adverse events.

Before administering a medication, the nurse carefully reads the medication record to confirm the prescriber's order and make sure it is a safe dosage, then does three safety checks with the labeled medication. The first safety check consists of confirming that the label of the medication matches the MAR, performing any necessary dosage calculations, reviewing patient allergies, and verifying the expiration date of the medication. The second safety check consists of preparing the medication and again checking the medication label against the MAR. The safety third check is a recheck of the medication label a final time against the MAR before opening the package at the bedside *or* a recheck of the label on the medication before returning the medication to its storage place.

High-Risk Situations for Medication Administration

Many situations can increase the risk of making a medication error and causing patient injury ([Table 35.10](#)). Safeguards for preventing medication errors include following facility policies

regarding patient identification, giving medications prepared by the person administering them, double-checking doses, verifying high-risk drug doses with a second nurse, addressing patient questions about medication, and understanding why the patient is receiving a specific medication.

TABLE 35.10**High-Risk Situations for Medication Administration**

MEDICATION ADMINISTRATION HIGH-RISK SITUATIONS RIGHTS	
Right drug	<p>Incorrectly dispensing and giving a medication with a name similar to the one prescribed</p> <p>Administering a medication that the nurse did not prepare</p> <p>Incorrectly identifying a medication</p> <p>Not listening to a patient who reports that the medication looks different from that given previously</p>
Right dose	<p>Needing multiple tablets, capsules, or medication cups to prepare a single dose</p> <p>Having a large change in prescribed dosage</p> <p>Having a unit dose or dose supplied by the pharmacy that does not match the prescribed dose</p> <p>Not listening to a patient who states that the dose being offered is different from that normally taken</p> <p>Using nonstandardized measuring devices, such as a plastic spoon</p> <p>Breaking tablets that are not scored into pieces or not using an accepted cutting device to split a tablet</p> <p>Leaving part of crushed medication behind in the crushing device or the patient's not eating all of the food or liquid in which the crushed medication is mixed</p> <p>Not knowing the usual, or safe, dosage range</p> <p>Incorrectly calculation of dose ordered compared to supplied medication</p>
Right time	<p>Giving all medications at convenient times for the nurse instead of at the times they will be most effective or are specifically prescribed</p> <p>Not administering medications according to specific needs, such as with food or on an empty stomach</p> <p>Missing doses and needing to reschedule times</p> <p>Not adhering to the prescribed frequency for PRN doses (giving more frequently than permitted)</p>
Right route	<p>Not knowing the medication's usual route</p> <p>Not looking up unfamiliar medications</p> <p>Preparing parenteral doses that are not designed for the parenteral route</p>

MEDICATION ADMINISTRATION HIGH-RISK SITUATIONS RIGHTS	
Right patient	Incorrectly identifying patients with similar names (who often require additional safety measures such as flagging the medication administration record [MAR]) Bypassing the identification process and relying on memory of previous patient interactions Preparing medications for more than one patient at a time Relying on unsafe identification means, such as a room number Using a smudged or illegible name band as an identifier
Right documentation	Using incomplete, inaccurate, or illegible medication information Lacking documentation of the assessment data required for the medication, such as laboratory values or apical heart rate Documenting administration before medication is administered Failing to document the medications administered, which is especially dangerous for medications scheduled at shift-change times (e.g., morning insulin doses) Failing to document notification of provider when a dose is not administered Failing to document the patient response to medications

3. The nurse accidentally administers C. P.'s prescribed diuretic, potassium, and stool softener to Charlotte Peters (C. P.), the patient in the next room. Identify at least four safety measures that can prevent medication errors when properly followed, and list the actions the nurse needs to take now.

Patient Rights

In 2003, the American Hospital Association developed the Patient Care Partnership program to help patients understand their rights

while in the hospital. Patient rights related to medication administration include the following:

- The right to be informed of the name, purpose, and potential side effects of medications
- The right to refuse a medication
- The right to have an accurate medication history taken by a qualified person
- The right to receive medications in accordance with the Six Rights of Medication Administration

If the medication is part of a research study, the nurse should be informed of this fact. Patients' questions or concerns regarding medication need to be treated respectfully and questions should be answered. The nurse uses knowledge and caring to answer questions and follows through appropriately if a patient refuses medication or has an adverse effect.

LO 35.6 ♦ Assessment

To safely administer medications, the nurse gathers patient assessment data. Information about a patient's allergies to drugs and food and the patient's pregnancy or breastfeeding status is especially critical. The initial assessment produces baseline data, and medication-specific assessment is part of ongoing care by the nurse (Box 35.5).

Box 35.5

Health Assessment Questions

Drug History and Current Use

- What food or drug allergies do you have? Describe the reaction.
- What prescribed medications are you currently taking? Do you have them with you?
- Which over-the-counter (OTC) medications and herbs do you take on a regular basis (e.g., antacids, laxatives, aspirin, creams, or lotions)?
- How many alcoholic beverages do you consume each day? How many caffeinated beverages do you drink each day?
- What medications have you stopped taking recently?
- Do you use any other methods to relieve your symptoms? What home remedies have you tried?
- Do you have any cultural or religious considerations regarding medications?

Medical History

- Do you have any ongoing illnesses?
- What surgeries have you had?
- Are you up to date on your immunizations?

- Are you pregnant or breastfeeding?
- Have you been hospitalized? For what? When?

Medication Schedule

- What times do you take your medications?
- Do you prepare your medications in a special way (e.g., crushed in applesauce, taken with a meal)?
- How do you remember to take your medications on schedule?

Medication Response

- What response have you had to your medications?
- Have you had any side effects or adverse reactions from medications?

Medication Adherence

- Can you tell me why you take this medication?
- Are there problems that prevent you from taking your medications (e.g., cost, access at work or school, irregular meal schedules)?
- Do you have vision problems? Hearing problems? Difficulty opening medication containers? Mobility difficulties? Trouble remembering to take medications? Trouble swallowing?
- How do you feel about taking medications?

Medication Safety

- Where are your medications kept at home?
- Do others have access to your medications? Any children?
- Do you have medications at home that you no longer take regularly? How long do you keep your medications?
- How do you dispose of medications that you are no longer taking?

- Do you do any special monitoring for these medications (e.g., blood levels, blood glucose monitoring)?

Ongoing assessment evaluates medication effectiveness and enables early identification of adverse effects. Important data to be collected are the patient's medical history; allergy information; medication history, including any prescription, OTC, or alternative therapies; physical examination results, with a focus on medication effects on the body; and relevant laboratory results. Assessment questions are adapted to meet the patient's needs and are asked in terms that the patient can understand. Responses to medication assessment questions should be documented in the appropriate sections of the health record.

Safe Practice Alert

Patient allergies to foods, drugs, and other substances are noted in the medical record in the history and physical section and on the medication administration record (MAR). The pharmacy and dietary departments are notified about allergies, and an allergy band is placed on the patient's wrist.

The body's response to some medications is monitored over time to establish therapeutic effects or watch for adverse effects. Common laboratory tests monitored to assess medication responses include electrolytes, serum glucose, complete blood count (CBC), white blood cell (WBC) count, bleeding time, blood urea nitrogen (BUN), creatinine, and serum levels of specific medications.

The nurse completes a physical assessment to identify body systems that may be affected by prescribed medications. For example, a respiratory assessment is performed before the administration of a bronchodilator treatment for a patient having an asthma attack. This assessment includes respiratory rate, auscultation of lung sounds, use of accessory muscles, and oxygen saturation levels. The assessment is repeated after medication administration to determine the effectiveness of the intervention.

Because medications may affect temperature, pulse, respirations, and blood pressure, vital signs that may be affected

should be measured before and after administering a medication. For example, the apical pulse for 1 minute is obtained before administering digoxin (i.e., cardiac medication that slows the heart rate), because it is common to withhold administration if the patient's heart rate is less than 60 beats/min; blood pressure is monitored before and after an antihypertensive is administered; the patient's temperature is measured before and after an antipyretic (medication to decrease fever) is administered; and respiratory rate and blood pressure are measured before administration of an opiate (narcotic) that can decrease these vital signs.

Assessing the patient's ability to swallow is important before administration of an oral medication. Adequate muscle mass is needed for proper absorption of IM medications, and functioning IV access must be available for intravenously administered medications. The skin site for topical medications must be inspected.

The most important steps for the nurse to take when preparing to administer medications are assessment of the patient and adherence to the Six Rights of Medication Administration (see [Box 35.4](#)).

LO 35.7 ♦ Nursing Diagnosis

The nurse analyzes subjective and objective assessment data to identify actual or potential problems to choose an applicable nursing diagnosis. It is important to have thorough data before determining the nursing diagnosis, which leads to developing the appropriate nursing interventions. The following are examples of common International Classification for Nursing Practice (ICNP) nursing diagnoses related to medication administration:

Lack of Knowledge

- Supporting Data: Lack of exposure to information, patient took a double dose of furosemide, patient unaware of possible side effects

Constipation

- Supporting Data: Opioid pain medication use, reported hard stools, painful defecation

Impaired health maintenance

- Supporting Data: Verbalized misunderstanding of therapeutic regimen, refusal to continue prescribed medications

LO 35.8 ♦ Planning

The nurse develops patient goals and plans care based on the nursing diagnoses, assessment of the patient's ability to perform needed tasks, and realistic expectations for achieving the goals (Table 35.11). The following are patient goals based on the nursing diagnoses:

TABLE 35.11
Care Planning

ICNP NURSING DIAGNOSIS WITH SUPPORTING DATA	NURSING OUTCOME CLASSIFICATION (NOC)	NURSING INTERVENTION CLASSIFICATION (NIC)
<i>Lack of Knowledge</i> Lack of exposure to information Patient took a double dose of furosemide Patient unaware of possible side effects	<i>Knowledge: Medication</i> Medication adverse effects	<i>Teaching: Prescribed medication</i> Instruct patient on possible adverse side effects of each medication.

From Bulechek, G., Butcher, H., Dochterman, J., et al. (Eds.). (2018). *Nursing interventions classification (NIC)* (7th ed.). St. Louis: Mosby; Moorhead, S., Johnson, M., Maas, M., et al. (Eds.). (2018). *Nursing outcomes classification (NOC)* (6th ed.). St. Louis: Mosby; ICNP is owned and copyrighted by the International Council of Nurses (ICN). Reproduced with permission of the copyright holder.

- The patient will verbalize side effects of medications before discharge.
- During outpatient visit, the patient will verbalize understanding of the need for adequate fluid and fiber intake to prevent constipation.
- The patient will take medications daily until the next appointment.

The conceptual care map for C. P. can be found at <http://evolve.elsevier.com/YoostCrawford/fundamentals/>. It is partially completed to indicate how to use the map as a learning tool. Complete the nursing diagnoses using the example conceptual care maps shown in **Chapter 8** and **Chapters 25 to 33**.

LO 35.9 ♦ Implementation and Evaluation

The nurse implements the plan of care through identified nursing interventions based on the nursing diagnoses, goals, and desired outcomes. Evaluation of the effectiveness of those interventions occurs within the specific time frames that the nurse established in the plan. Using the goals and outcomes provides an objective, measurable way to conduct the evaluation.

Medication Administration

Each medication that a nurse administers must be prescribed by a primary care provider and be appropriate for the patient. The order may be electronically entered into the medication system (or in rare or emergency occasions handwritten on a patient chart), from where it is transcribed onto the electronic health record (EHR) or MAR. The nurse uses the MAR when preparing and administering all medications.

Safe Practice Alert

The National Institute for Occupational Safety and Health (NIOSH) has identified multiple drugs as hazardous to nurses who administer or prepare them. Most of the hazardous drugs require special handling by health care workers to avoid exposure to potentially serious health outcomes (such as skin rashes, infertility, spontaneous abortion, and cancer). Consult the *NIOSH List of Antineoplastic and Other Hazardous Drugs in Healthcare Settings* available at <https://www.cdc.gov/niosh/topics/hazdrug/default.html> for further information.

Medications are administered through several different routes, and nurses must follow established protocols for administering medications safely by each route. Clinical judgment acknowledges that special techniques be used for children and elderly individuals to facilitate the administration of medications (Box 35.6).

Box 35.6

Diversity Considerations

Life Span

Children

- Liquid forms of oral medications are preferred for children younger than 5 years of age.
- Parents or caregivers may need instruction with pictures and written directions about home medication administration.
- A calibrated dropper is used for infants or very young children. Place the medication between the gum and cheek to prevent aspiration.
- Uncoated tablets or soft capsules may be crushed and sprinkled over a small amount of food. Do not use a favorite food or formula, because the child may avoid food associated with medicines in the future.
- Warn the child if the medication has an unpleasant taste; this helps increase future trust in the nurse.
- Praise the child after the medication is swallowed.

Older Adults

- Do not rush medication administration. Allow time for understanding of treatment and slower swallowing.
- Crushed or liquid forms of medications may be easier to swallow.
- Normal aging processes (e.g., decreased renal and hepatic function) may affect the dosage needed, because drugs may be metabolized slower. Adverse effects may be increased in elderly individuals.
- Patients may need instruction on medications to be taken at home. Focus on the name and purpose of the drug, explain that the appearance and color of the medication may vary by manufacturer.
- Loss of dexterity and the ability to open pill bottles, visual impairment, and cognitive impairment in the elderly can affect safe medication administration.

Oral Medications

The easiest and most convenient administration route is by mouth (PO), which is discussed in [Skill 35.1](#). Drugs administered by this route are intended to be absorbed in the stomach and small intestine. The patient's ability to swallow, level of consciousness, gag reflex, and whether the patient is experiencing nausea and vomiting are assessed to ensure the patient's ability to take medications by the oral route and to prevent aspiration (i.e., inhalation of gastric contents into the respiratory system). If a patient should receive nothing by mouth (**NPO**), an alternate route is used or an order is obtained for the patient to be NPO except for medications. After oral medication has been taken, the nurse verifies that the medication was swallowed and encourages the patient to drink fluids to ensure that medication has not lodged in the esophagus. If the patient feels that medication is stuck in the throat, eating a small amount of soft food, such as oatmeal or a slice of bread, helps the medication move through the esophagus.

Special techniques are used for the patient who has difficulty swallowing large tablets. Some capsules may be opened and the contents added to a small amount of applesauce, pudding, or ice cream. Certain tablets may be crushed and added to food in a similar manner. Use a small amount of food so that the entire dose is administered if the patient eats only a small amount.

Safe Practice Alert

Enteric-coated or sustained-release tablets should never be crushed. The enteric coating protects the oral and gastric mucosa from irritating medications. Crushing a sustained-release medication allows absorption to occur all at once rather than the desired absorption over time.

Liquid medications often come in premeasured packages. If not, a calibrated syringe or medication cup is used to accurately measure the prescribed amount. Antifungal liquid medications (e.g., nystatin) may need longer contact with mucous membranes and be prescribed as “swish and swallow.” The patient swishes the medication back and forth in the mouth several times and then swallows it. This should be the last oral medication administered so that additional use

of fluids to swallow the other medications does not rinse the medication from the mucous membranes.

Medication is never given from a container with a label that is missing or difficult to read. Unused medication is not returned to a multidose container and should not be placed in unlabeled containers. Medication that has changed color or does not stay in solution is discarded. Offer oral hygiene after medication with an unpleasant taste.

Safe Practice Alert

Never return unused medication to a multidose container. Never administer medication that is not labeled.

Medication may be administered by the enteral route (i.e., through a gastrointestinal tube). Liquid medication is preferred, although some tablets may be finely crushed and dissolved in sterile water. Care is taken that the tube is flushed before and after administration with 15 mL of sterile water (or in accordance with facility policy) to clear the tube of medication and prevent clogging of the tube. Having the patient sit as upright as possible decreases the risk of aspiration. The patient should remain with the head elevated for at least 30 minutes after administration. To allow absorption time, gastric suction should not be used for 20 to 30 minutes after administration (Boullata, Kirby, & Krzywda, 2016). Water intake associated with medication administration is counted as intake on the intake and output record.

Sublingual and Buccal Medications

The sublingual and buccal routes allow rapid absorption of medications, such as nitroglycerin for chest pain. A sublingual medication is placed under the tongue and allowed to dissolve. The patient should not eat or drink anything until the medication is completely dissolved. A medication given by the buccal route (e.g., antiemetic, sedative, opiate) is placed in the side of the mouth against the inner cheek. Patients are taught to alternate cheeks to avoid mucosal irritation. Buccal medication should not be chewed, swallowed, or taken with liquids. Standard precautions are used by the nurse administering medications by the sublingual or buccal

route, because the nurse's hand may come in contact with oral secretions.

Topical Medications

Topical medications are placed on the skin surface, on mucous membranes, or in body cavities (Box 35.7). Placement sites in addition to the skin include eyes, ears, nose, rectum, vagina, and lungs. Drugs applied directly to skin for a local effect include lotions, creams, powders, and aerosol sprays. Cleanse the skin before applying topical medications to remove body oils or dry skin, which can impair medication absorption. Gauze dressing may be applied over the medication to prevent removal of the medication by clothing. Gloves and applicators are used to avoid absorption through the nurse's skin during placement of topical medications.

Box 35.7

Nursing Care Guideline

Topical Medication Administration

Background

- Always follow the Six Rights of Medication Administration.
- Medications are applied to skin for many reasons:
 - Hormone treatment
 - Administration of cardiac medications
 - Application of narcotic analgesics
 - Assistance with overcoming nicotine addiction
 - Treatment of pruritus
 - Provision of a protective coating on the skin
 - Treatment or prevention of infection
- The following are types of topical medications:
 - Creams or oils (for lubrication)
 - Lotions (to protect and soothe)
 - Powders (for drying surface moisture and decreasing friction)
 - Ointments (to provide prolonged contact with the medication and to soften)

- Transdermal patches or disks (for continuous medication administration for several hours to several days)
- Absorption of medication through the skin is called *inunction*.

Procedural Concerns

All Topicals

- Apply gloves to avoid being exposed to the patient's medication that is absorbed through the skin.

Transdermal Patches

Remove the old patch from the patient's skin; fold it so that it sticks to itself instead of having exposed adhesive surfaces.

- Assess, clean, and dry new and old sites:
 - Rotate application sites.
 - Ensure that each site is free from hair and is not located over a bony prominence.
 - Note any redness, irritation, or skin breakdown; do not apply a new patch to an area of skin irritation or breakdown.
 - Never apply a patch over a pacemaker or implanted port.
- Put on clean gloves.
- Remove the new patch from the package; write your initials, date, and the time of day it was applied directly on the patch, or on a piece of tape to be placed on or near the patch after it is applied, if the manufacturer recommends against writing directly on the patch (Durand, Alhammad, & Willett, 2012).
- Remove the covering, and apply the patch to the skin:

- Apply gentle pressure with the palm of your hand for 10 to 15 seconds.
- Do not massage the patch.
- After removing the previous patch, the new patch should be applied at the same time of day and on the days ordered.
- Remove gloves and perform hand hygiene.

Documentation Concerns

- Follow all documentation procedures discussed in [Box 35.4](#).
- Document the removal of the previous patch and the body site where the topical medication was applied and skin changes observed at old or current application sites.

Evidence-Based Practice

- If the patient is in a cardiac emergency, remove transdermal patches before defibrillation. Many patches have an aluminum backing that can cause second-degree burns with defibrillation.
- Prior to magnetic resonance imaging (MRI), transdermal patches should be removed according to facility protocols.

Transdermal Medications

Medications designed to be absorbed through the skin for systemic effect are administered transdermally, usually in the form of a patch. The skin site is cleansed because skin oils may interfere with the adhesive on these products. A previously placed patch and

remaining medication must be removed. Patches are disposed of according to facility policy, especially if the patch contains a controlled substance. Placement sites are rotated to avoid skin irritation. Placement of the new patch and removal of the old patch are recorded in the MAR.

Ophthalmic Instillation

Ophthalmic medications (i.e., eyedrops and ointments), including OTC preparations, are used to treat eye irritation, infections, or disorders, such as glaucoma (Box 35.8). Eyedrops can be used for diagnostic procedures or to anesthetize the eye for procedures. Cross-contamination is a potential problem with eye medications. Each patient has an individual bottle of eye medication. Care is taken not to touch the tip of the dropper or tube to the patient's eye, because infection can be transferred from one eye to the other if the applicator touches the eye.

Box 35.8

Nursing Care Guideline

Ophthalmic Medication Administration

Background

- Always follow the Six Rights of Medication Administration.
- Because the cornea is sensitive, most eye medications are placed inside the lower eyelid.
- Types of ophthalmic medication:
 - Eyedrops (for treatment of eye diseases or irritations)
 - Ointments (for infections or irritations)
 - Irrigations (to remove secretions or foreign bodies or to cleanse and soothe the eye)
 - Disks (for continuous medication administration up to a week), which are similar to a contact lens, usually placed in the eye at night because they may cause blurriness of vision, and may stay in place for a week

Procedural Concerns

- Always wear gloves.
- Do not let anything touch the applicator (i.e., maintain medical asepsis).
- All types of ophthalmic medications:
 - Hand the patient tissues (to blot eye overflow from the face).
 - Tilt the patient's head back.
 - Have the patient look up.
 - Pull the patient's lower eyelid down to form a pouch.
- Eyedrops
 - Hold the bottle above the eye that is to be treated.
 - Place drops into the pouch formed by the lower eyelid in the lower conjunctival sac.
 - Have the patient blink several times. Maintain slight pressure on the inner canthus to prevent loss of medication through the tear duct and reduce systemic effects of the medication.

(Copyright Mosby's Clinical Skills: Essentials Collection.)

- Ointments:
 - Squeeze a $\frac{1}{2}$ -inch strip of ointment from the tube into the lower eyelid, moving from the inner canthus to the outer canthus being careful to not allow the tip of the tube to touch the eyelid (maintain medical asepsis).
 - Instruct the patient to close and roll the eyes around.
 - Inform the patient that the medication may temporarily blur vision.
- Irrigations:
 - Fill a sterile irrigation syringe with warmed sterile irrigation solution.

- Place a basin below the patient's face, and offer the patient a towel.
 - Hold the patient's eye open with the nondominant hand.
 - Hold the syringe 1 inch above the eye and at an angle from the inner canthus toward the outer canthus.
 - Flush the eye until the solution exiting the eye is clear or the foreign particle is removed.
- Disks:

- Position the medicated disk on a gloved fingertip.
- Place the disk in the conjunctival sac, and position the lower eyelid over the top of it. The disk should not be visible.
- Remove the disk at the designated or ordered time:
- Expose the disk by lowering the lower eyelid.
- Use a gloved index finger and thumb to pinch the disk and break the suction with the eye, and remove the disk.
- Do not allow the patient to rub the eye after medication has been inserted.

Documentation Concerns

- Follow all documentation procedures discussed in [Box 35.4](#).
- Document the eye or eyes in which medication was instilled and the patient's response to the medication.

Otic Instillation

Solutions administered to the ear canal are otic medications ([Box 35.9](#)). Eardrops are used to treat ear infections and associated pain, soften earwax to ease removal, apply a local anesthetic, and remove foreign particles trapped in the ear canal. The internal ear is very sensitive to temperature changes, and it is important to use eardrops at room temperature to prevent nausea, pain, and dizziness. If the tympanic membrane has been damaged, all procedures are performed with sterile technique to prevent infection. Medication should not be forced into the ear canal because forcing may rupture the tympanic membrane.

Box 35.9

Nursing Care Guideline

Otic Medication Administration

Background

(Copyright Mosby's Clinical Skills: Essentials Collection.)

- Always follow the Six Rights of Medication Administration.
- Medications are placed in the ear to soften cerumen (earwax), destroy insects, organisms, or foreign particles inside the ear, relieve pain, or act as a local anesthetic.
- Types of otic medications:
 - Eardrops (to treat infections or soften cerumen)
 - Irrigations (to remove secretions or foreign bodies and clean the ear)

Procedural Concerns

- Do not let anything touch the applicator (maintain medical asepsis).
- All types of otic medications:
 - Hand the patient tissues to blot overflow from the ear.
 - Clean the ear if needed.
- Eardrops:
 - Have the patient lie with the ear to be treated in the uppermost position.
 - Hold the medication bottle above the ear.
 - Straighten the auditory canal of an adult patient by gently pulling the pinna up and back.
 - Place the specified number of drops into the ear canal.
 - Release the pinna, and press on the tragus several times to prevent loss of medication and reduce systemic effects from the medication.
 - If ordered, place cotton loosely in the auditory canal.
 - Wait 5 minutes before administering medication in the other ear (if bilateral administration is ordered).
- Irrigations:
 - Fill a sterile irrigation syringe with warmed sterile irrigation solution.
 - Place a basin at face level and under the ear, and offer the patient a towel.
 - Clean the pinna and meatus of the ear canal.
 - Straighten the auditory canal of an adult patient by gently pulling the pinna up and back.
 - Hold the syringe at an upward angle at the entrance to the ear.
 - Flush the ear until the solution exiting the ear is clear or the foreign particle is removed.
 - Place cotton loosely in the ear, and offer the patient a towel.
 - Have the patient lie down on another towel placed under the head; the patient should be in a side-lying position with the affected side down to help drain excess fluid by gravity.
 - Remove the cotton in 10 to 15 minutes to allow fluid to flow freely outward.
 - If the patient complains of pain or dizziness during the procedure, stop and assess the complaint.

Documentation Concerns

- Follow all documentation procedures discussed in [Box 35.4](#).
- Document the ear or ears in which medication was instilled and the patient's response to the procedure.

Nasal Medications

Nasal medications are administered by drop or nebulizer formulations into the nose ([Box 35.10](#)). The nose is a clean, not sterile, cavity, but the nurse uses medical asepsis when administering nasal preparations because of the connection of the nose to the sinuses. Decongestant sprays or drops to relieve symptoms of sinus congestion are the most common medications administered through nasal instillation. When these medications are used in excess, they may have systemic effects such as increased heart rate and a rebound effect that increases congestion.

Box 35.10

Nursing Care Guideline

Nasal Medication Administration

Background

- Always follow the Six Rights of Medication Administration.
- Nasal medications are used to treat allergies, sinus infections, nasal congestion, and inflammation. Chronic use of nasal decongestants may lead to rebound effect (i.e., increased nasal congestion).

Procedural Concerns

- Have the patient blow the nose first.
- Medication administration:
 - Tilt the patient's head slightly back, or have the patient lie in the supine position with the head tilted backward.
 - Have the patient breathe out through the mouth.

- Insert the end of the delivery device $\frac{1}{8}$ inch into one nostril. Have the patient plug the opposite nostril. Do not touch the insides of the nares with the device, because doing so may cause sneezing and contamination.

(Copyright [Thinkstock.com.](#))

- Administer the drops or spray as the patient inhales through the nose.
- Have the patient exhale through the mouth.
- Keep the patient's head tilted back for several minutes while the patient continues to breathe through the mouth.

Documentation Concerns

- Follow all documentation procedures discussed in [Box 35.4](#).
- Document whether medication was instilled into one or both nares and the patient's response to the procedure.

Inhaled Medications

The nose and mouth provide entry to the lower respiratory system. MDIs and dry powder inhalers (DPIs) are small, hand-held devices that a patient activates before inhaling ([Skill 35.2](#)). Each time the device is pressed, a specific dose is released. Medication absorption is very rapid. Spacers can be used with the MDI to trap the medication

and allow inhalation over several breaths. A spacer is especially helpful for children or a patient who cannot inhale slowly.

Nebulizers are used to aerosolize medication into a fine droplet or gas form that is then inhaled for delivery to the lungs, where the particles are absorbed almost immediately. Common uses for inhaled medications are to induce anesthesia during surgery and to treat respiratory disorders, such as asthma or chronic lung disease. Bronchodilation is a desired local effect from inhaled medications for respiratory disorders. Some medications, such as inhaled steroids for inflammation, can cause systemic effects.

Safe Practice Alert

Rinsing the mouth and oral care should be performed by the patient receiving steroids by inhalation. This prevents irritation to the oral mucosa and tongue and prevents oral fungal infections.

Assessment before and after administration of inhaled medications includes assessment of breathing status, breath sounds, respiratory rate, and use of accessory muscles. The nurse assesses the patient's use of inhalers, because the MDI is often used incorrectly ([Press, Arora, Trela, et al., 2016](#)). Important patient education includes determining when the inhaler is empty and needs to be replaced. It is recommended that the number of doses in the container be divided by the number of doses the patient takes in a day. The patient should keep a record of doses to obtain a refill of the medication canister before it runs out ([American Thoracic Society, 2014](#)). Proper use of the medication ensures optimal outcomes. The ability to compress the inhaler is affected by hand strength, flexibility, and the hand size of a child or adult.

Vaginal Medications

Creams, foams, tablets, liquids (i.e., douche), suppositories, and gels can be administered vaginally ([Box 35.11](#)). They are used for infection, itching, antibacterial preparation before surgery, contraception, or induction of labor. Proper placement often requires a special applicator. Vaginal suppositories are typically refrigerated until use because they melt at body temperature. Patients should be offered an absorbent pad and a comfortable undergarment to collect medication drainage. Tampons should not be used after vaginal

medication instillation, because the tampon can absorb the medication intended for mucosal absorption.

Box 35.11

Nursing Care Guideline

Vaginal Medication Administration

Background

- Always follow the Six Rights of Medication Administration.
- Medications are placed in the vagina to maintain the normal acidity of secretions and normal pathogens and to combat or treat infections.
- Types of vaginal medications include creams, foams, tablets, liquids, suppositories, and gels.

Procedural Concerns

- Have the patient empty her bladder.
- Instruct the patient to lie on her back with knees flexed (i.e., dorsal recumbent position), or, if unable to tolerate the dorsal recumbent position, have her lie in the Sims position.
- Put on gloves.
- Lubricate the applicator or suppository using a water-soluble gel.
- Separate the labia with the nondominant hand to expose the vaginal opening.
- Cleanse the vaginal opening (see [Skill 27.2](#)).
- Fully insert the applicator or suppository. Use a rolling motion, inserting downward and backward.
- Remove gloves, turning them inside out to prevent the spread of microorganisms.
- Instruct the patient to remain on her back, in a side-lying position, or with hips elevated on a pillow for 5 to 10 minutes.
- Offer the patient a perineal pad.

Documentation Concerns

- Follow all documentation procedures discussed in [Box 35.4](#).
- Document the patient's response to the procedure.

Rectal Medications

Rectal suppositories are thinner than vaginal suppositories. Medication effects from this route can be local (e.g., laxative or stool softener effect) or systemic (e.g., antiemetic or antipyretic effect). Rectal suppositories are often stored in the refrigerator. Clean, disposable gloves are used when administering suppositories. The unwrapped suppository is placed above the internal anal sphincter and against the mucous membrane for proper retention and absorption ([Box 35.12](#)). For a laxative effect, the suppository needs to remain in the rectal vault for 15 to 45 minutes or until the patient feels the urge to defecate.

Box 35.12

Nursing Care Guideline

Rectal Medication Administration

Background

- Always follow the Six Rights of Medication Administration.
- Medications are placed in the rectum when a patient is unable to take a medication by mouth or when a more rapid effect is required.
- Types of rectal suppositories are antipyretics, antiemetics, and laxatives.

Procedural Concerns

- Position the patient on the left side, with the upper knee flexed (i.e., Sims position) (see [Fig. 28.20](#)).
- Unwrap the suppository and lubricate it and a gloved index finger, using water-soluble gel.

(Copyright [Thinkstock.com.](https://www.thinkstock.com/))

- Separate the buttocks to expose the anus.
- Have the patient breathe slowly and deeply.
- Insert the suppository with the rounded end inserted first.
- Gently push the suppository along the rectal wall; avoid embedding it in feces.
- Continue until the suppository is inserted past the internal sphincter (approximately 3 to 4 inches).
- Cleanse excess lubricant or stool from the patient's perirectal area.
- Instruct the patient to remain in left lateral position with buttocks pressed together for 5 to 10 minutes; if a laxative was inserted, the patient should remain supine for 35 to 45 minutes.
- Remove gloves, turning them inside out to avoid possible contamination with microorganisms.
- Wash hands thoroughly.

Documentation Concerns

- Follow all documentation procedures discussed in [Box 35.4](#).
- Document the patient's response to the procedure and, in the case of a laxative, how long the patient was able to retain the medication.

Liquid medications are instilled in the rectum using an enema solution. An enema solution can be used to treat patients with high potassium levels or to rid the bowel of stool before a procedure. Small-volume enemas contain approximately 100 mL of fluid and need to be retained for a minimum of 5 minutes and preferably longer. Large-volume enemas contain up to 1000 mL of fluid and need to be retained as long as possible for maximum benefit.

Parenteral Medications

Parenteral medications are administered by injection into tissue, muscle, or a vein. Patients may refer to any parenteral medication as a *shot*. Standard precautions and sterile technique are followed when using the parenteral route because the skin barrier is broken. The effects of parenterally administered medications occur rapidly, depending on the rate of absorption, and the nurse must closely observe the patient for medication responses.

Equipment needed to administer parenteral medications includes syringes, needles, or another injection mechanism and the vial or ampule from the pharmacy that contains the medication. Many types of syringes and needles are available. The nurse must select the correct syringe and needle to administer the type and amount of medication solution into the prescribed site. Syringes may come packaged with a needle attached, but needles also come packaged individually to allow the nurse to select the best needle size for the patient and medication. All needles have safety mechanisms to help prevent needlestick injuries. Immediately following use, the safety mechanism is activated and the needle and syringe are disposed of in an approved puncture-resistant container in accordance with facility policy.

QSEN Focus!

The nurse demonstrates safety by the effective use of strategies to reduce the risk of harm to self or others by immediately activating the safety mechanism on a needle after administering an injection.

Safe Practice Alert

After use, a needle should not be recapped (placing the protective cap back over the needle). Most needlestick injuries occur during recapping. Needlesticks expose health care workers to blood-borne pathogens, such as human immunodeficiency virus (HIV) and hepatitis B and C viruses.

Safe Practice Alert

The needle safety mechanism is activated immediately after the syringe and needle are used for medication administration. This step is critical in preventing a needlestick injury.

Preparing Parenteral Medications

Parenteral medications may be premixed and packaged as a unit dose, or they may have to be prepared by the nurse. Medications may be prepared from ampules or vials and may come in a powder form that needs to be reconstituted before it is administered ([Skill 35.3](#)).

Ampules and vials

An ampule is a small glass container that holds a single liquid dose of medication ([Fig. 35.11](#)). Ampules range in size from 1 mL to 10 mL (or larger), but all have a constricted neck area that is snapped off to allow access to the medication. A colored ring around the narrow neck identifies where the glass is pre-scored to be broken. The ampule neck is cleaned with an alcohol swab. A protective sleeve or sterile 2 × 2 inch gauze is used when breaking the ampule top to protect the nurse from being cut by the glass. After the needed dose of medication has been drawn using a filter needle or filter straw, the ampule is discarded in a sharps container along with any unused medication.

FIGURE 35.11 A vial (left) and an ampule (right).

A vial is a glass or plastic container holding one or more doses of a solution or medication (see [Fig. 35.11](#)). It has a self-sealing rubber seal at the top and a soft metal or plastic cap that is easily removed to access the rubber seal. A needle attached to a syringe is used to pierce the rubber seal, and the proper amount of fluid is drawn into the

syringe. Alternatively, an adapter for use with a needleless cannula may be used if multiple doses are to be drawn from the vial. If more than one dose is to be used from the vial, the vial must be labeled with the date and time it is opened and the initials of the nurse opening it. The medication is stored in a locked medication cart or room and used or discarded within a designated time to protect from possible microbial growth in the vial. Multidose vials should be dedicated to one patient whenever possible. The rubber seal is cleaned with alcohol each time the vial is accessed for additional doses. The vial is a closed system, and air equivalent to the amount of liquid to be withdrawn is injected into the vial. Injecting air prevents a vacuum from forming in the vial, which would make withdrawing the medication difficult.

Reconstituting powdered medications

Some medications are supplied as a powder in a vial. They are reconstituted by adding a liquid, or diluent, to the powder. Powdered medications are carefully reconstituted by adding only the proper amount and type of diluent identified by the manufacturer. Sterile normal saline and sterile distilled water are common diluents used for reconstituting medications. Specific directions printed on the vial or package insert identify the type and amount of diluent needed for reconstitution and the resulting concentration of medication.

An Act-O-Vial system (i.e., dual-compartment vial) is another approach for administering powdered medication. In this system, the medication powder (e.g., methylprednisolone sodium succinate) and diluent are in two compartments of a single vial, separated by a rubber stopper. To prepare the Act-O-Vial for administration, the nurse depresses the stopper to combine the diluent and medication, gently mixes the solution, and withdraws the prescribed dose.

Prefilled cartridge or syringe

A single dose of medication may be supplied in a prefilled cartridge or syringe. A cartridge is placed into a reusable injection device or holder. Care is taken to lock the cartridge into the injection holder to stabilize it during administration. Before injection, the cartridge is cleared of air and excess medication because products may be overfilled, risking overdose, or the dose ordered may be smaller than the amount of medication contained in the cartridge. After administration, the cartridge is removed from the holder and placed in the appropriate disposal container. The holder is retained and is

reusable. Examples of prefilled cartridge holders include Tubex and Carpuject appliances.

Some medication supplied in cartridges is withdrawn using a different syringe and is then administered with that syringe. The transfer of medication from a prefilled cartridge to a different syringe is done if a needleless system is in place or a safety needle is available for use instead of the needle supplied with the cartridge.

Withdrawing medication from a cartridge is similar to using a vial, except that no air is injected into the cartridge before the medication is withdrawn.

Prefilled syringes are similar to prefilled cartridges. A single dose of medication is in a syringe with a needle attached. Excess air or medication may need to be expelled from the syringe; however, some prefilled medication syringes, such as enoxaparin, contain air that should not be removed before administration.

Mixing medications in one syringe

If two medications are compatible, they can be mixed in one injection if the total amount of fluid is within the guidelines for administration into a parenteral site (see [Skill 35.3](#)). Incompatible medications may become cloudy or form a precipitate when mixed. Compatibility is determined through drug information and pharmacy resources.

When preparing medication from a vial and an ampule, the nurse prepares the medication from the vial first and then uses the same syringe and a filter needle or straw to withdraw the medication from the ampule. When mixing medications from two vials ([Skill 35.4](#)), the nurse takes care to ensure that the final dose is correct. Aseptic technique is used.

Administering Parenteral Medications

The depth of insertion, needle angle, and site selection determine whether the medication is an intradermal, subcutaneous, or IM dose ([Skill 35.5](#)). [Fig. 35.12](#) illustrates the angle of insertion into tissue levels for parenteral injections.

FIGURE 35.12 Insertion angles for parenteral injections.

Intradermal administration

Intradermal injections are given into the dermis, the layer of tissue just below the skin surface. The intradermal route is often used to administer local anesthetics, to test for allergies, and to test for tuberculosis exposure. Drugs are absorbed slowly through the dermal tissue, and only small amounts of medication (0.01 to 0.1 mL) can be instilled. Common sites for injection are the inner forearm, the upper arm, and the scapular area. A 1-mL tuberculin syringe with a 25 to 27 gauge, $\frac{1}{4}$ to $\frac{5}{8}$ inch needle is used to provide accurate measurement of the small dose and shallow penetration through the epidermis layer of the skin. Pressure should not be applied to the site, and the site should not be massaged after injection. The location of the injection is documented.

Subcutaneous administration

Subcutaneous tissue is the layer of fat located below the dermis and above muscle tissue (see [Skill 35.5](#)). Insulin and heparin are medications commonly administered by the subcutaneous route. Absorption is slow, with a sustained effect. Because the subcutaneous area is less vascular, injection into a blood vessel is rare. Aspiration is therefore not required for subcutaneous injections ([Shepherd, 2018b](#)). The volume of medication administered should not exceed 1 mL by this route.

Common subcutaneous sites include the abdomen, lateral aspects of the upper arm and thigh, scapular area of the back, and upper

ventrodorsal gluteal area (Fig. 35.13). The injection site should be rotated to avoid the development of hard, painful areas where injections are given. A 0.5 to 3 mL syringe with a 25- to 31-gauge, $\frac{3}{8}$ - to $\frac{5}{8}$ -inch needle is used. Typically, the nurse pinches approximately 2 inches of tissue between two fingers and inserts the needle at a 90-degree angle. If less tissue is available, the nurse pinches 1 inch of tissue and inserts the needle at a 45-degree angle.

FIGURE 35.13 Subcutaneous injection sites.

Some types of insulin are supplied in special multidose devices called *insulin pens* (Box 35.13). These pens are easier for some patients to use at home, because the medication does not have to be drawn up. Instruct the patient to use caution when more than one kind of insulin is supplied in pen form. The pens look very similar, and double-checking that the correct insulin is being administered is recommended.

Box 35.13

Nursing Care Guideline

Medication Administration With Multidose Insulin Pens

Background

- Always follow the Six Rights of Medication Administration.
- A specialized device that looks like a large pen contains the prescribed insulin in a multidose syringe.
- Injection sites should be rotated.
- Patients must dial the correct dose and attach a new needle for each injection.

Procedural Concerns

- Remove the pen cap.
- If a previously used cartridge is to be used, check the insulin reservoir:
- If there is enough insulin remaining for a complete dose, proceed with the following steps:
- If there is not enough insulin remaining for a complete dose, replace the pen with a new one, or in pens with replaceable cartridges, replace the cartridge.

(Copyright [Thinkstock.com.](https://www.thinkstock.com/))

- Clean the pen tip with alcohol.
- If an insulin suspension is prescribed, invert the pen 20 times to mix a suspension.
- Remove the protective tab on a new needle.
- Attach the needle to the pen; needles usually screw onto the pen.
- Remove the cap on the needle.
- Prime the pen:
 - Dial the dose to 2 units.

- Hold the pen with the needle pointing up, making sure all air rises to the top of the pen.
- Depress the plunger slightly to deliver the 2-unit dose of insulin to the air.
- If the insulin appears at the needle tip, proceed to the next step.
- If the insulin does not appear at the needle tip, repeat the 2-unit dose to the air.
- Verify that the dial is at 0 units.
- Dial the needed dose.
- Clean the injection site with alcohol, and allow it to air-dry.
- Hold the pen as you would a dart, directed at the chosen site.
- Insert needle into the tissue with a quick motion.
- Depress the plunger, and hold it down while counting to 10 seconds.
- Remove the pen.
- Remove the needle from the pen.
- Dispose of the needle in a sharps container.

Documentation Concerns

- Follow all documentation procedures discussed in [Box 35.4](#).
- Document the site of the injection.

A child may require a shorter needle, whereas an obese adult may require a longer one. The angle of insertion for the needle is 45 to 90 degrees, depending on the weight of the patient. A 45-degree angle may be used to give a subcutaneous injection to a very thin patient to ensure that the medication is injected into fatty tissue. A 90-degree angle can be used in a patient with adequate subcutaneous tissue. The length of the needle should be approximately half the depth of the pinched skin fold.

Intramuscular administration

Because there are more blood vessels in muscles than in subcutaneous tissue, IM injections are absorbed rapidly if the patient has adequate circulation. When preparing to administer an IM injection, the nurse considers the volume of fluid to be injected, medication being administered, injection technique, site selection,

and syringe and needle selection. Other factors include the patient's age and condition (Ogston-Tuck, 2014).

The three common IM injection sites are ventrogluteal, vastus lateralis, and deltoid (Fig. 35.14). IM injection volume varies from 1-5 mL depending on the site of the injection, and body muscle mass (Shepherd, 2018a). In 2004, the World Health Organization (WHO) recommended that a fourth site, the dorsogluteal muscle, *not* be used routinely for IM injections due to the proximity to the sciatic nerve and superior gluteal artery and the increased risk of injecting into the thick layer of fat present. If the dorsogluteal site is used because no other site is available, slow aspiration for blood over 5–10 seconds before administration of medication should be performed to prevent inadvertent injection into the gluteal artery or venous circulation (Mraz, Thomas, & Rajcan, 2018). Aspiration for blood is no longer recommended for other IM sites. The primary site for administering an IM injection for patients older than 7 months of age is the ventrogluteal site, which is free of major blood vessels, nerves, and fat and is associated with lower rates of injury (Kara, Uzelli, & Karaman, 2015; Coskun, Kilic, & Senture, 2016). The vastus lateralis site has no large blood vessels or nerves and can safely be used for most patients. The deltoid site lies close to the radial nerve and brachial artery; care must be taken to properly locate the muscle for safe injection. Each IM site is located according to specific anatomic landmarks.

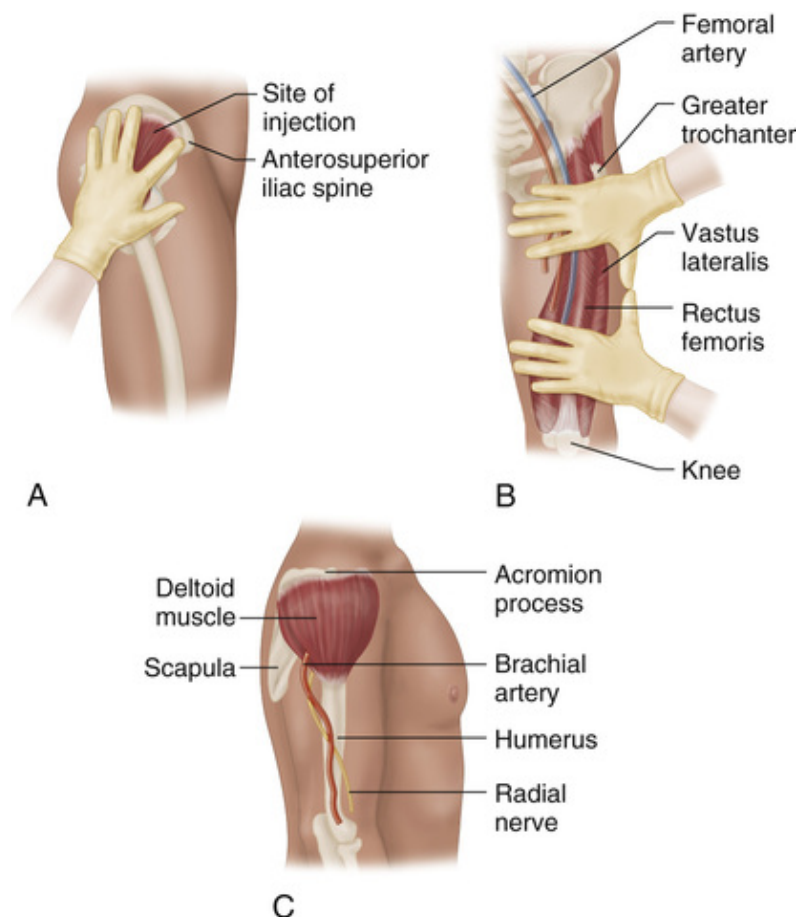

FIGURE 35.14 Intramuscular (IM) injection sites. (A) Ventrogluteal. (B) Vastus lateralis. (C) Deltoid.

Safe Practice Alert

Failure to find the correct injection site by using anatomic landmarks before injecting medication can result in tissue, bone, or nerve damage.

Intramuscular injections of medications that discolor tissue (e.g., iron) or are irritating to tissue (e.g., hydroxyzine) are administered by the Z-track method. This technique seals the medication into the muscle tissue, with no tracking of medication into the subcutaneous tissue when the needle is withdrawn. After the medication dose is prepared, a new needle is placed on the syringe so that no medicine is on the outside of the needle. A large muscle site, such as the ventrogluteal area, is selected. The site is prepared with an antiseptic cleanser, and the overlying skin and subcutaneous tissue are then pulled approximately 1 inch laterally to the side (Fig. 35.15). The skin

is held taut in this position with the nondominant hand, the needle is inserted deep into the muscle, and the medication is injected. The needle is held in place approximately 10 seconds to allow medication dispersion. The needle is then withdrawn, and the skin is immediately released. A zigzag path is left that seals the medication into the muscle.

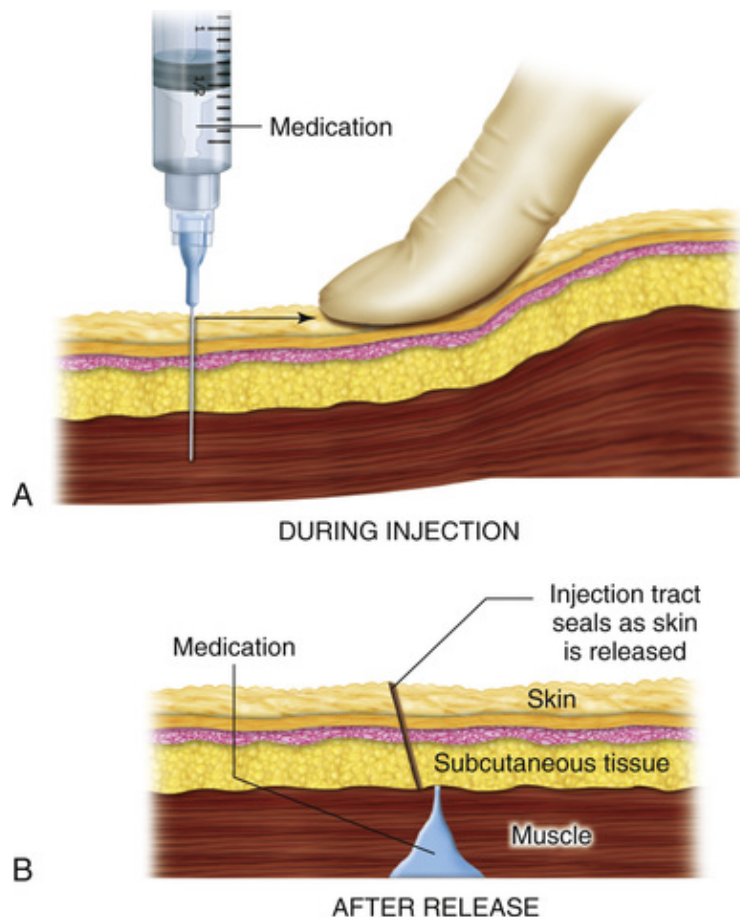

FIGURE 35.15 Z-track injection technique. (A) During injection. (B) After release.

Special IM medication administration devices include epinephrine auto-injectors, which are used to treat severe allergic reactions. An EpiPen or Adrenaclick IM injection is given in the vastus lateralis muscle by means of the special technique described in [Box 35.14](#).

Box 35.14

Nursing Care Guideline

Medication Administration With EpiPens and Adrenaclick Auto-Injectors

Background

- Always follow the Six Rights of Medication Administration.
- The EpiPen and Adrenaclick are specialized devices that look like a large pen and consist of a needle and a syringe; both contain one dose of epinephrine.

(From Proctor, D., Niedzwiecki, B., Pepper, J., et al. (2017). *Kinn's the medical assistant*, 13th ed., St. Louis: Elsevier.)

- They are used for the emergency treatment of severe allergic reactions, or anaphylaxis, caused by allergens, exercise, or unknown triggers and for patients who are at increased risk for these reactions.
- Two doses are available:
 - An adult dose (0.3 mg) for individuals weighing more than 66 lbs
 - A junior dose (0.15 mg) for individuals weighing 33 to 66 lbs
- The injection site for the patient is the lateral aspect of the thigh, the vastus lateralis (see the “[Injections: Intramuscular](#)” section of [Skill 35.5](#)).
- EpiPens and Adrenaclick auto-injectors are stored at room temperature in their plastic storage tubing.

Procedural Concerns

- Inspect the epinephrine auto-injectors for expiration date and solution color. The solution should be clear.
- Remove the auto-injector from its plastic storage tubing.
- Remove the blue or gray safety top(s) from the auto-injector.
- Wrap your hand around the device.
- Point the orange or red pen tip against the patient's thigh. The dose can be administered through the patient's clothes.
- Quickly dart the device into the thigh.
- Hold the pen in place for approximately 10 seconds.
- Remove the pen. Massage the area for 10 seconds.
- Depending on which auto-injector is used, the needle may automatically retract or require careful one-hand replacement into the safety top.
- Seek emergency medical attention for the patient.

Documentation Concerns

- Follow all documentation procedures discussed in [Box 35.4](#).
- Document whether the injection was given in the left or right thigh.
- Document the patient's vital signs and response to the injection.

Intravenous administration

The IV route is used when a rapid drug effect is desired or when the prescribed medication is irritating to tissues. Medication is given through a catheter inserted into a vein. Larger fluid amounts may be administered by this route than by other parenteral routes, but it may take a few minutes to several hours to fully administer the correct dose. IV medications are delivered by intravenous push (IVP) or bolus, intermittent small-volume administration or intravenous piggyback (IVPB), or volume control administration set (IV pump or controller) ([Skill 35.6](#)). Disadvantages of the IV route include the cost of preparation and administration, difficulty administering medications anywhere other than a health care facility, difficulty maintaining access into a vein, and increased complication risks of infection, extravasation (medication leaking from the vein into tissue), and thrombophlebitis (inflammation of the vein from medication).

Because the medication is released directly into the bloodstream, extra care is taken in preparing and administering medication by the IV route. Assessment data needed before administration include patient allergies, medication or IV solution incompatibilities, the amount and type of diluent needed for the medication, and the rate of medication administration. The IV access site is assessed for signs or symptoms of infiltration (swelling and discomfort at the site) and thrombophlebitis. Medications are prepared in a sterile manner. Some medications have pH or osmolarity levels that are extremely irritating to the tissues, and the nurse ensures that the IV catheter is still in place in the vein to avoid inadvertent injection into tissue. Special care is taken to assess for medication incompatibilities when medications are administered into an IV tubing port of a primary solution that already has medication added, such as potassium chloride or multivitamins.

Safe Practice Alert

High-risk medications require the use of an electronic infusion pump. Follow facility policy.

For safety reasons, most medications are mixed into intravenous (IV) solutions in the pharmacy. However, in certain settings, the nurse has to prepare a solution for IV use ([Box 35.15](#)).

Box 35.15

Nursing Care Guideline

Adding Medications to an Intravenous Solution

Background

- Always follow the Six Rights of Medication Administration.
- Medications may be added to an intravenous (IV) solution for diluted delivery.
- Addition of medications should be performed only under sterile, aseptic, specialized conditions by licensed personnel with specialized knowledge.

- The nurse should be uninterrupted, strictly adhere to aseptic technique, and be extremely familiar with the principles of reducing and preventing medication errors.
- Most facilities require that nurses demonstrate competency to perform this skill.

Procedural Concerns

- Inspect the medication and the IV solution for expiration date and solution color.
- Verify compatibility between the medication and the IV solution.
- Clean the port on the IV bag and vial top with an alcohol swab.
- Follow the medication reconstitution and dilution instructions carefully.
- Use the proper equipment and procedure to draw the medication from the ampule or vial (see [Skill 35.3](#)).
- After ensuring that the proper technique has been used and the correct dosage has been drawn into the syringe, clean the port on the IV bag again with an alcohol swab, and allow it to dry completely.
- Inject the medication from the syringe into the IV bag. The IV flow clamp should be closed to prevent the medication from infusing into the patient in its concentrated dose and to allow the medication to properly dilute in the IV solution.
- Label the IV bag immediately! Check facility policies and procedures for specifics.
- Verify the medication vial, ampule, or container against the IV bag label and against the primary care provider's order before hanging the medication.
- Regulate the flow rate according to dosage requirements.
- Monitor the patient and the infusion.

Documentation Concerns

- Follow all documentation procedures discussed in [Box 35.4](#).
- Document the patient's response to the medication.

Safe Practice Alert

Complications associated with intravenous (IV) medication administration include infection of the IV site from a break in aseptic technique; administration of medication into surrounding tissue from cannula dislodgement, resulting in tissue damage; thrombophlebitis in the vein from trauma or irritation to the vein; and speed shock from administration of medications too rapidly. Frequent assessment of the IV site for infection and infiltration is essential, as is knowledge of appropriate speed of administration.

Medications and Home Care

Patient education regarding medications is an important responsibility for the nurse. Education may be directed to the patient, a family member, or a caregiver. When providing medication instruction, it is important to prioritize what the patient, family member, or caregiver needs to know about each medication and supplement being taken.

Oral medications have long been administered in the home. Long-term transdermal, peritoneal dialysis and IV treatments with infusion pumps are now being administered in the home under supervision of an interdisciplinary team that includes equipment providers, pharmacists, care agencies, care providers, and nurses ([Box 35.16](#)).

Box 35.16

Home Care Considerations

Medication Administration in the Home

- Discharge planning should include teaching patients, family members, and caregivers how to safely administer medications in the home.
- Patients should be encouraged to keep an updated list of medications and bring this list with them anytime they have an encounter in the health care system.
- Nurses must follow the state nurse practice act and comply with laws relevant to the storage, use, and disposal of medications in the home, especially in regard to controlled substances.

- A medication regimen for each patient must account for lifestyle, be easy to remember, and be convenient for the patient. Assistive devices, such as a pill organizer or an automated phone reminder system, can help patients remember to take medications (Fig. 35.16).
- Linking medication times to normal events in the day, such as meals or bedtime, increases accurate and continued use of medications. These events must be assessed carefully because patients may have schedules that vary from the expected, such as eating only two meals per day.
- Nurses should carefully assess for factors that may affect the safe use of medications, such as poor memory or poor vision.
- Referrals to social services for financial assistance programs and drug company assistance programs can help address financial needs for obtaining medications.
- Medications disposed of in the trash or flushed down the toilet can leak into the water supply and contaminate it. Many pharmacies have designated specific days when patients may safely dispose of expired or unused medications by returning them to the pharmacy.
- Patients need to be educated about proper disposal of needles. Sharps disposed of in the trash have the potential of injuring sanitation workers.

FIGURE 35.16 Weekly medication organizer. (Copyright Thinkstock.com.)

When providing patient education, the nurse must use language that the patient can understand. The patient, family, or caregiver should be able to repeat to the nurse the following information for each medication being taken: the name of the medication; the reason

for taking it; how and when to take it; food, drinks, OTC medications, and herbs that can affect the action of the drug; safety concerns, such as activities affected by use of the drug (e.g., driving a car); usual side effects; usual adverse reactions; and special instructions about the prescribed route of the medication (Box 35.17).

Box 35.17

Patient Education and Health Literacy

Self-Administration of Medications

- Patients who understand medication instructions make fewer mistakes, get well sooner, and better manage chronic health conditions than those who lack understanding.
- It is essential that patients be assessed regarding their ability to understand these materials.
- Large pharmacies can provide patients with written medication instructions translated into their native language.
- The National Patient Safety Foundation has developed the Ask Me 3 program, which emphasizes questions patients should ask during each health care encounter:
 - What is my main problem?
 - What do I need to do?
 - Why is it important for me to do this?

From National Patient Safety Foundation. (2018). Ask me 3. Retrieved from: <https://npsf.site-ym.com/default.asp?page=askme3>

The nurse must emphasize that the patient should take medications in the amounts and for the length of time prescribed. It is important to discuss with the patient and family what action should be taken if a dose is missed, the importance of not sharing medications with others, and how to dispose of unused or outdated medications. The patient should demonstrate new skills, such as self-administering insulin, to the nurse after teaching is completed. Documentation of teaching the patient and family and of the planned outcomes is the last step of patient teaching.

4. C. P. verbalizes the concern that she will not take her medications correctly when she returns home. What plan can the nurse implement to help the patient safely take her medications?

Evaluation

Clinical observation is an important way to evaluate the effectiveness of medications. Subjective data (e.g., “My pain is a level 2”) and objective data (e.g., patient's apical pulse is regular and 88 beats/min) show evaluation of medication responses. The nurse assesses for adverse effects of medications, such as nausea, rash, change in vital signs, and difficulty breathing. Laboratory tests indicate the patient's response to some medications. Monitoring drug levels in the blood determines whether they are within the therapeutic range desired or if dose adjustments are needed. Electronic monitoring can reflect outcomes from medication treatment, such as the oxygen saturation of a patient after respiratory medications are administered or a change in heart rate or rhythm on a cardiac monitor after medication treatment for arrhythmias. Significant deviations from normal response must be reported to the primary care provider.

Safe medication administration, including the evaluation of prescribed drug effectiveness, is one of the most critical aspects of nursing care. Nurses must stay focused when preparing and giving medications. Before administering medications, it is essential for nurses to know the:

- classification of each prescribed drug,
- expected and adverse effects,
- potential interactions,
- safe dosage, and
- assessment requirements.

Nurses should be aware of possible allergic reactions and educate patients as to why they are receiving prescribed medications. By always following medication administration protocols, nurses can avoid errors and ensure patient safety.

Skill 35.1 Oral Medication Administration

Purpose

- The administration of oral medications must be done appropriately and safely and should follow the Six Rights of Medication Administration:
 - The right medication
 - The right dose
 - The right time
 - The right route
 - The right patient
 - The right documentation

Resources

- Medication cup:
 - Plastic graduated cup for liquid medication
 - Paper soufflé cup for tablets and capsules
- Oral syringe for liquid medication doses less than 10 mL
- Water or another drink, as appropriate, with medication
- Food or a snack, as appropriate, with medication
- A straw, as appropriate, for the medication or for the patient
- Medication administration resource guide or software or a drug handbook
- Pill crusher (i.e., commercial, industrial, or mortar and pestle), as needed

- Pill splitter, as needed

Interprofessional Collaboration and Delegation

- Refer to [Box 35.4](#).
- Medication administration may not be delegated.
- Unlicensed assistive personnel should report the following to the nurse:
 - Changes in vital signs or patient complaints or discomfort
 - Medication found in the patient's room
 - Patient questions regarding medication
- The timing for administering many medications in regard to meals is important. Ensure proper administration and collaboration with the dietary staff.
- Collaborate with the pharmacist on medication questions before administration.
- Collaborate with physical or occupational therapists to appropriately time analgesic medication administration before therapy sessions.

Evidence-Based Practice

- Medication errors can be prevented by having as much data available as possible when preparing and administering medications.
- Data gathering includes observation and assessment of the patient, the patient's chart, and traditional book resources.

- Implementing new technological innovations can further reduce the risk of medication errors by providing additional resources and prompts to assist the licensed professional in ultimately providing safe, quality patient care ([Lapkin, Levett-Jones, Chenoweth, & Johnson, 2016](#)).

Special Circumstances

1. **Assess:** Does the patient have an aspiration risk or difficulty swallowing?

Intervention: Medication may have to be crushed and mixed with fluid or food.

- Verify that the patient's required medication may be crushed or the capsule opened.
- When crushing tablets:
 - Clean the compartment of the pill crusher by following the manufacturer's instructions.
 - Place the pill into the container following the manufacturer's instructions.
 - Place the powder in an appropriate food or fluid.
 - Following the manufacturer's instructions, clean the compartment to remove any pill residue.
- For medication that is in capsule form:
 - Gently hold the two ends of the capsule.
 - While holding the capsule above the appropriate food or fluid, twist the ends in opposite directions.
 - Empty the powder from the capsule into the food or fluid.
 - If all powder does not release from the capsule, gently pinch and twist the capsule or tap the edges of the capsule with your finger.
 - Discard the empty capsule in accordance with facility policies and procedures.

2. **Assess:** Is the pill dosage larger than what was ordered?

Intervention: The medication should be divided appropriately.

- Capsules cannot be divided for any reason. Call the pharmacist or primary care provider (PCP) to obtain a different dosage or form of the medication.
- Check with the pharmacist before dividing medication to verify whether the exact dosage is available; dividing medication is not as accurate as obtaining whole tablets or liquids.
- If a tablet or pill is enteric coated, it *cannot* be split or crushed. Call the pharmacist or PCP for an alternate route or form of medication.
- If a tablet or pill is extended-release, it *cannot* be split or crushed. Call the pharmacist or PCP for an alternate route or form of medication.
- If the medication surface is scored to facilitate splitting, it can be split.
- To use a pill splitter:
 - Clean the pill splitter by following the manufacturer's instructions.
 - Place the tablet on the pill splitter with the scoring aligned with the blade.
 - Bring the handle down.
 - Remove the two halves. Follow facility policies and procedures for safe disposal of the second half of the pill.
 - Clean the pill splitter by following the manufacturer's instructions.
- To break a pill:
 - Apply new nonsterile gloves.
 - Grasp half of the pill on one side of the scored line between the thumb and forefinger of one hand, and grasp the other half of the pill on the other side of the scored line between the thumb and forefinger of the other hand.
 - Bend the pill. The pill should break evenly along the scored line.
 - Follow facility policies and procedures for safe disposal of the other half of the pill.

- If the medication surface is *not* scored:
 - Call the pharmacist or use electronic or printed resources to determine whether the medication may be split.
 - If the pill may be split, use only a commercial pill splitter.
3. **Assess:** Has the medication been dropped on the floor or other unclean surface?
- Intervention:** Discard the medication appropriately, and document in accordance with facility policies and procedures. Repeat the preparation with a new pill.
4. **Assess:** Is the patient questioning or refusing the medication?
- Intervention:** Stop the administration.
- The patient has the right to refuse medication.
 - If the patient continues to refuse although the medication is correct, document this in accordance with facility policies and procedures and notify the PCP.
5. **Assess:** Does the medication require special administration?
- Intervention:** Use drug resources, or consult with a pharmacist.
- Some medications require administration with food.
 - Some medications require administration on an empty stomach.
 - Some liquid medications require administration through a straw to avoid staining the teeth.
 - Some medications cannot be crushed. Refer to the Institute of Safe Medication Practice's Do Not Crush list (www.ismp.org/Tools/DoNotCrush.pdf).
 - Some medications cannot be split.
 - Some medications cannot be given with other medications.
 - Some medications cannot be given with certain foods or fluids.
6. **Assess:** Is the liquid medication from the unit-dose container the incorrect dosage for the patient?
- Intervention:** Measure the correct dosage of medication, and dispose of the excess as waste in accordance with facility policies and procedures.
- If the needed dosage is less than 10 mL, use an oral syringe to draw up the medication.

- If the needed dosage is more than 10 mL, use a plastic graduated medication cup.
 - Measure the dosage in a medication cup at eye level to ensure accuracy.
7. **Assess:** What is the proper method of disposing of excess medication that is a controlled substance?
Intervention: Follow facility policies and procedures; disposal requires witnessing by a second licensed professional.
8. **Assess:** Has the medication expired?
Intervention: Do not administer expired medication.
- Notify the pharmacy of any expired medication.
 - Follow facility policies and procedures for disposal of expired medication.
 - Obtain new medication to administer to the patient, and restart the procedure.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient by using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Oral Medication: Tablets and Capsules

Follow preprocedure steps I through VIII.

1. Ask the patient whether a preferred drink or snack is desired, if appropriate, or obtain it before preparing the medication.
*Asking about the patient's preferences promotes adherence.
Preparing supplies in advance avoids interruption during the procedure and possible medication errors.*
2. Prepare medications in a No Interruption Zone according to facility policy. Obtain the medication. Verify that the label of the medication matches the medication administration record (MAR), perform any dosage calculation, and check the expiration date of the medication.

STEP 2 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. If an automated dispensing system is used, enter the appropriate information, and remove the medication. Verify the correct dose, but do not pour or open.
 - b. If bar coding is used, scan the MAR and medication. Verify the correct medication and dosage, but do not prepare or open.
 - c. If a medication cart is used, unlock the cart, locate the correct patient drawer, pull the medication, and verify the correct dose. Do not prepare or open.
- Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times. Most medication is prepared at the bedside.*
3. Prepare the medication and check the medication label against the MAR a second time.
 - a. If a multidose bottle is used, pour the medication onto the open lid of the bottle until the appropriate number of tablets or capsules has been counted out, and then pour them into a medication cup.
 - b. If a unit dose is used, verify the correct dose. Split whole tablets if needed and appropriate, but otherwise do *not* remove the medication from the wrapping until ready to administer at the patient's bedside.

STEP 3B (Copyright Mosby's Clinical Skills: Essentials Collection.)

Verification ensures the accuracy of the dose. Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times. Pouring into the lid avoids touching the medication, preventing the spread of microorganisms. Not removing medication from the wrapping allows another check and patient education at the bedside.

4. Enter the patient's room, perform patient identification, check patient allergies, assess patient knowledge, and educate the patient as needed.

Communication with the patient facilitates cooperation.

Avoid possible medication errors by adhering to the Six Rights of Medication Administration.

5. Recheck the label on the medication with the MAR a third time before returning the medication to its storage place *or* before opening the package at the bedside. Prepare or open unit-dose medication.
 - a. Perform premedication assessments as needed including the patient's ability to swallow.
 - b. If using a barcoding device, scan the medication and the patient identification, and enter any pertinent information (see [Fig. 35.10](#)).
 - c. Open the medication packages one at a time, and place them in a medication cup. Do *not* touch the tablets or capsules.

STEP 5C

Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times. Avoid direct contact with the medication to prevent the spread of microorganisms.

6. Administer medication with water while the patient is sitting or has the head of the bed elevated. Assist as needed (see [Box 30.11](#)), and ensure that all the tablets or capsules are swallowed.

STEP 6 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Patient position is important to prevent aspiration. Providing assistance to the patient promotes adherence, avoids medication errors, and promotes safety and quality care.

7. If a medication requires a follow-up assessment of the patient, return to obtain information within an appropriate time frame. Educate the patient about the expected effect of the medication and the time of your return.

Completing the necessary follow-up prevents adverse effects and promotes patient adherence. Communication with the patient eases anxiety and gives the patient control.

Follow postprocedure steps I through VI.

Oral Medication: Liquids

Follow preprocedure steps I through VIII.

1. Follow procedure step 2 in the “Oral Medication: Tablets and Capsules” section.
2. Verify the needed medication dosage. Prepare the medication and check the medication label against the MAR a second time:
 - a. If using a multidose bottle and if less than 10 mL is needed, use a syringe to measure the dosage. If more than 10 mL is needed, use a graduated medication cup. Shake the bottle gently if doing so is not contraindicated on the label, and remove the lid, placing it upside down on the counter. Pour or draw the dose at eye level. When pouring, hold the bottle with the label in your palm; wipe the lip of the bottle as needed with a paper towel, and replace the lid.

STEP 2A(1)

STEP 2A(2)

- b. If using a unit dose, verify the correct dose; gently shake the container but do *not* open it.

Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times. Shaking mixes

the medication and ensures the accuracy of the dose. Lid placement prevents the spread of microorganisms. Measuring at eye level ensures accuracy. Positioning the label in the palm ensures that the medication does not spill onto the label and promotes safety for the person pouring the medication. Not opening the unit-dose container allows another check to be performed, along with patient education, at the bedside, thus further promoting patient safety and cooperation.

3. Enter the patient's room, perform patient identification, check patient allergies, assess patient knowledge, and educate the patient as needed.

Communication with the patient facilitates cooperation.

Avoid possible medication errors by adhering to the Six Rights of Medication Administration.

4. Recheck the label on the medication with the MAR a third time before returning the medication to its storage place *or* before opening the package at the bedside. Prepare the medication for administration:

- a. Perform premedication assessments as needed.
- b. If using a barcoding device, scan the medication and the patient identification, and enter pertinent information.
- c. If using a unit dose, open the medication, and administer from the original container. Do *not* touch the medication.

Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times. Avoid direct contact with the medication to prevent the spread of microorganisms.

5. Administer medication while the patient is sitting or has the head of the bed elevated. Assist as needed (see [Box 30.11](#)), and ensure that all medication is swallowed.

Patient position is important to prevent aspiration.

Providing the patient assistance promotes adherence, avoids medication errors, and promotes safety and high-quality care.

6. If a medication requires a follow-up assessment of the patient, return to obtain information within an appropriate time frame. Educate the patient about the expected effect of the medication and the time of your return.

Completing the necessary follow-up prevents adverse effects and promotes patient adherence. Communication with the patient eases patient anxiety and gives the patient control.

Follow postprocedure steps I through VI.

Oral Medication: Sublingual and Buccal

Follow preprocedure steps I through VIII.

1. Follow procedure steps 2 and 3 in the “Oral Medication: Tablets and Capsules” section.
2. Enter the patient's room, perform patient identification, check patient allergies, assess patient knowledge, and educate the patient as needed.

*Communication with the patient facilitates cooperation.
Avoid possible medication errors by adhering to the Six Rights of Medication Administration.*

3. Recheck the label on the medication with the MAR a third time before returning the medication to its storage place *or* before opening the package at the bedside. Prepare unit-dose medication.
 - a. Perform premedication assessments as needed and explain how sublingual or buccal medication is absorbed to the patient.
 - b. If using a barcoding device, scan the medication and the patient identification, and enter pertinent information.
 - c. Open medication, and place in a medication cup.
Do *not* touch the medication.
 - d. Put on clean gloves.
 - Place sublingual medication under the tongue until dissolved.
 - Place buccal medication between the cheek and gums until dissolved.
 - Do *not* administer either form of medication with food or fluid. Instruct the patient *not* to chew or swallow the medication.

Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times. Avoid direct contact with the medication to prevent the spread of

microorganisms. Gloves should be worn whenever contact with mucous membranes or bodily fluids is possible. Foods, fluids, and stomach acid can diminish the effectiveness of the medication. If sublingual or buccal medications are to be administered at the same time as oral medications, give the oral medications first and the sublingual or buccal medications last.

4. Administer medication while the patient is sitting or has the head of the bed elevated. Assist as needed (see [Box 30.11](#)), and ensure that all medication is dissolved.

Patient position is important to prevent aspiration.

Providing the patient assistance promotes adherence, avoids medication errors, and promotes safety and quality care.

5. If any medication requires a follow-up assessment of the patient, return to obtain information within an appropriate time frame. Educate the patient about the expected effect of the medication and the time of your return.

Completing the necessary follow-up prevents adverse effects and promotes patient adherence. Communication with the patient eases anxiety and gives the patient control.

Follow postprocedure steps I through VI.

Postprocedure

- I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.

Precautions are taken to maintain patient safety.

Top side rails aid in positioning and turning.

Raising four side rails is considered a restraint.

- II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

- III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document immediately after medication administration. Include the medication, dose, route, date, time, assessment, and the patient's response to the medication in the documentation.

Accurate documentation is essential to communicate medications administered and to provide legal evidence of care. Avoid possible medication errors by adhering to the Six Rights of Medication Administration.

Skill 35.2 Inhaled Medication Administration

Purpose

- The administration of inhaled medications must be done appropriately and safely and should follow the Six Rights of Medication Administration:

Administration:

- The right medication
 - The right dose
 - The right time
 - The right route
 - The right patient
 - The right documentation
- Inhaled medication is administered to improve or maintain the patient's underlying pathophysiology. Nebulizers allow medication to reach smaller airways by delivering finer particles:
 - They promote bronchodilation and inhibit inflammation by delivering various pharmacologic agents.
 - They promote expectoration of pulmonary secretions by delivering aerosolized mucolytic agents or humidity.
 - They treat and prevent pulmonary-specific infections by delivering antiinfective agents.

Resources

- Spacer, if required, for a metered-dose inhaler (MDI)
- An MDI
- Warm water to rinse the patient's mouth after administration, depending on the pharmacologic agent
- Emesis basin
- Nebulizer setup and tubing for nebulizer administration

Interprofessional Collaboration and Delegation

- Refer to [Box 35.4](#).
- The administration of medication may not be delegated; however, the patient may self-administer medication under the supervision of the nurse. Supervision cannot be delegated.
- Unlicensed assistive personnel should report any of the following to the nurse:
 - Changes in vital signs or any patient complaints or discomforts
 - Medication found in the patient's room
 - Patient questions regarding medication
- The timing of inhaled medication is important:
 - Ensure that the proper administration takes place and is performed in collaboration with a respiratory therapist as appropriate or indicated.
 - Ensure that the order of administration of inhaled medication is appropriate (e.g., use rescue inhalers before maintenance).

- In many facilities, a respiratory therapist is responsible for inhaled medication administration. Collaborate and consult with the respiratory therapist as necessary and in accordance with facility policies and procedures.
- Collaborate with the pharmacist about medication questions before administration.

Special Circumstances

1. **Assess:** What is the patient's respiratory status?
Intervention: Document the patient's preadministration and postadministration status, including the following:
 - Auscultation of lung fields
 - Respiratory and heart rates
 - Pulse oximetry
 - Patient report of breathing status
 - Patient complaints and discomfort
2. **Assess:** Is a spacer being used?
Intervention: Properly insert the spacer:
 - Ensure that the spacer is clean.
 - Fit the mouthpiece of the MDI into the end of the spacer or into the MDI cradle port, depending on the brand of spacer.
 - Have the patient use the mouthpiece of the spacer instead of that of the MDI.
 - Clean the spacer:
 - Once each day with warm running water
 - Once each week with mild soap and water
3. **Assess:** Has the medication expired?
Intervention: Do not administer expired medication.
 - Notify the pharmacy about expired medication.
 - Follow facility policies and protocols.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.
- VI. Provide for patient privacy.
It is important to maintain patient dignity.
- VII. Identify the patient by using two identifiers.
Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.
- VIII. Explain the procedure to the patient.
The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Inhaled Medication: Metered-Dose Inhaler

Follow preprocedure steps I through VIII.

1. Provide a glass of warm water and a basin for the patient to rinse the mouth after inhalation.

Preparing supplies in advance avoids interruption during the procedure, thereby avoiding possible medication errors.

2. Prepare medications in a No Interruption Zone according to facility policy. Obtain the medication. Verify that the label of the medication matches the medication administration record (MAR), perform any dosage calculation, and check the expiration date of the medication.

- a. If using an automated dispensing system, enter the appropriate information, and remove the medication from the dispenser. Verify that the correct medication and dosage has been dispensed. Store unused medication doses according to facility policy.

- b. If using barcoding, scan the MAR and the medication. Verify that the correct dose has been dispensed.

- c. If using a medication cart, unlock the cart, and find the patient's drawer. Remove the patient's medication from the drawer, and verify that they are the correct dose.

Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication label against the MAR three times.

3. Ensure that a canister of medication is in the holder, and check the expiration date. Check the medication label against the MAR a second time.

Medication must be in the container so that the patient receives the ordered dose. Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.

4. Prime the MDI by shaking the container and then spraying it in the air away from you and the patient. If there is a priming button on the bottom, push the button.

Proper preparation of the MDI ensures that the medication is delivered.

5. Perform patient identification, assess the patient's knowledge, and educate the patient as needed. Ask the patient about any allergies.

The correct individual must receive the correct treatment.

Communication with the patient facilitates patient cooperation. Avoid possible medication errors by adhering to the Six Rights of Medication Administration.

6. Perform premedication respiratory assessments including respiratory rate and pulse oximetry.

Promote safe, quality patient care by providing baseline assessment data to evaluate the patient's response to medication.

7. If using a barcoding device, scan the medication and the patient identification. Enter any pertinent information. Recheck the label on the medication with the MAR a third time before returning the medication to its storage place *or* before opening the package at the bedside.

Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.

8. Discuss the purpose of an MDI and how it works.
9. Administer the medication. Assist the patient as needed, or the patient may self-administer the medication.
 - a. The patient may sit, stand, or lie in bed with the head of the bed elevated at least 30 degrees.
 - b. The patient shakes the MDI.
 - c. The patient must take a deep breath in and then blow out completely.
 - d. The patient places the mouthpiece of the inhaler into the mouth holding it in one hand.

STEP 9D (Copyright Mosby's Clinical Skills: Essentials Collection.)

- e. The patient should inhale slowly while the medication is dispensed. With a traditional MDI, pushing the canister releases the medication; with an inhalation-activated MDI, inhaling releases the medication.
- f. The patient should continue the deep inhale over a period of 3 to 5 seconds and then should hold that breath for approximately 10 seconds. The patient removes the inhaler from the mouth.
- g. The patient exhales through the nose or through pursed lips.

STEP 9G (Copyright Mosby's Clinical Skills: Essentials Collection.)

Patient position promotes optimal lung expansion. Shaking the MDI ensures the medication is mixed and improves dose accuracy through the delivery of fine particles. The breathing procedure promotes medication effectiveness and keeps the small airways patent.

10. If more than one inhalation of the same medication is ordered, wait at least 20 to 30 seconds (check recommendation for specific medications) between doses. If a different medication is ordered, allow 2 to 5 minutes between the inhalation.

Pausing between doses allows the earlier medication dose to become effective before the next dose is administered.

11. After 2 minutes, have the patient rinse the mouth with warm water and spit it into the emesis basin.

Take steps to prevent infection (such as yeast infections) or soreness in the patient's mouth to reduce the adverse effect of some inhaled medication.

12. Clean the inhaler holder and cap with warm running water after each use. Allow to dry completely.

Cleaning of equipment should be performed to prevent the spread of microorganisms and ensure proper functioning

of equipment.

13. Perform a medication follow-up assessment: Return to obtain information within an appropriate time frame. Assess the respiratory status and compare to the pre-administration assessment. Encourage the patient to demonstrate self-administration of medication. Educate the patient on the expected effect of the medication.

Prevent adverse effects by performing the appropriate follow-up. Communication with the patient eases anxiety, facilitates cooperation, and gives the patient control.

14. If the canister is new, mark the date on the canister and calculate the number of doses of medication.

Follow postprocedure steps I through VI.

Inhaled Medication: Dry Powder Inhalation

Follow preprocedure steps I through VIII.

1. Follow procedure steps 1 through 7 in the “[Inhaled Medications: Metered-Dose Inhaler](#)” section. *Exceptions:* Priming, shaking, and using a spacer are not indicated with a dry powder inhaler (DPI).
2. If the patient is receiving a DPI for the first time, explain that a training device will be used prior to the administration of the medication. Administer the medication. Assist the patient as needed, or the patient may self-administer the medication.
 - a. Have the patient sit, stand, or lie in bed with the head of the bed elevated.
 - b. Assess the patient's ability to hold, manipulate, and activate the DPI.
 - c. Point out the dose indicator on the DPI.
 - d. Follow the manufacturer's instructions to prepare for administration.
 - e. Follow the manufacturer's instructions for correct positioning of the DPI during administration.
 - f. Have the patient take a deep breath in and then blow out completely.
 - g. Place the mouthpiece of the inhaler into the patient's mouth.
 - h. For dosing, a capsule is punctured or a spring-loaded mechanism is triggered before or while the

patient begins inhaling slowly. Check the manufacturer's instructions.

- i. Ask the patient to hold that breath for approximately 10 seconds. Remove the inhaler from the patient's mouth.

STEP 2I (Copyright Mosby's Clinical Skills: Essentials Collection.)

- j. Have the patient exhale through pursed lips.

STEP 2J (Copyright Mosby's Clinical Skills: Essentials Collection.)

- k. Instruct the patient to clean the device after each use.

Positioning promotes optimal lung expansion.

Manufacturer's instructions delineate priming and appropriate medication delivery for accurate dosing.

3. If more than one inhalation of the same medication is ordered, wait at least 1 minute between doses.

Pausing between doses allows the earlier medication dose to become effective before the next dose is administered.

4. After 2 minutes, have the patient rinse the mouth with warm water and spit the solution into an emesis basin.

Take steps to prevent infection (specifically thrush) or soreness in the patient's mouth to reduce the adverse effect of some inhaled medications.

5. Perform a medication follow-up assessment: Return to obtain information within an appropriate time frame. Assess the respiratory status and compare to the pre-administration assessment. Encourage the patient to demonstrate self-administration of medication. Educate the patient on the expected effects of the medication.

Prevent adverse effects by performing the appropriate follow-up. Communication with the patient eases anxiety, facilitates cooperation, and gives the patient control.

Follow postprocedure steps I through VI.

Inhaled Medication: Nebulizer

Follow preprocedure steps I through VIII.

1. Follow procedure steps 1 through 7 in the “[Inhaled Medications: Metered-Dose Inhaler](#)” section. *Exceptions:* Priming, shaking, and using a spacer are not indicated with nebulizers.
2. If other inhaled medication has been ordered, administer those delivered through the nebulizers first, unless contraindicated; then wait 5 minutes before administering the other medication.

The sequence and timing of administration of inhaled medications allows the first medication to become effective before the next one is administered.

3. In addition to respiratory assessment, monitor the pulse during the procedure, especially if beta-adrenergic bronchodilators are used.

Promote safe, quality patient care by providing baseline assessment data to evaluate the patient’s response to medication.

4. Assemble the nebulizer (model with mouthpiece) (see [Fig. 35.6](#)):
 - a. Connect the tubing to the air compressor source (i.e., nebulizer machine, compressed air source, or compressed oxygen source) following the manufacturer's instructions.
 - b. Connect the other end of the tubing to the bottom of the nebulizer chamber.

- c. Place the medication in the nebulizer chamber in accordance with the PCP order; ensure that saline for inhalation has been added if it is needed.
 - d. Close the nebulizer chamber (the top screws onto the bottom).
 - e. Connect the T-piece connector to the top of the chamber.
 - f. Place the mouthpiece in one end of the T-piece.
Proper assembly ensures correct and accurate medication administration. Avoid wasting medication by using reservoir tubing.
5. Assemble the nebulizer (face mask model):
- a. Follow procedure step 4, a through d.
 - b. Place the nebulizer face mask on top of the chamber.
Patients may be unable to hold the delivery device for the entire treatment; the face mask allows medication delivery with minimal patient effort.
6. Administer treatment:

STEP 6 (Copyright Thinkstock.com.)

- a. Have the patient sit or lie in bed with the head of the bed elevated at least 30 degrees.
- b. Turn on the nebulizer machine, or turn on the compressed air or oxygen to 6 to 8 L/min.
- c. Check that the mode for administration of medication is set to *misting*.

- d. If a mouthpiece will be used, hand the patient the setup or secure the face mask on the patient.
- e. Encourage the patient to take slow, deep breaths throughout the treatment.

Proper patient positioning promotes optimal lung expansion. Placing the face mask or delivery device with the patient as the last step ensures equipment functioning and prevents oxygen deprivation.

- 7. When the nebulizing is complete, discontinue the treatment:
 - a. If medication drops are adhering to the side of the chamber, tap the chamber until the misting is complete.
 - b. Remove the mask or mouthpiece setup from the patient.
 - c. Turn off the compressed air source.
 - d. Disconnect the tubing from the nebulizer chamber and air source.

Nebulizing occurs by airflow from the bottom of the chamber. Ensuring that all droplets are at the bottom of the chamber promotes full-dose administration.

- 8. Have the patient rinse the mouth with warm water and spit the solution into an emesis basin.

Take steps to prevent infection or soreness in the patient's mouth to reduce the adverse effect of some inhaled medications.

- 9. Clean the nebulizer administration setup.
 - a. After each use with warm running water.
 - b. Once each week with mild soap and warm water.
 - c. Once each month, soaking it for 30 minutes in a solution of three parts water to one part vinegar. Allow it to air-dry while covered by a paper towel.
 - d. Certain medications cannot share nebulizers; follow the policy and procedure of the facility. Change nebulizers according to facility policy and procedure.

Store the setup in a clean plastic bag. Proper cleaning should be done to prevent the spread of microorganisms. Air-drying and bag storage prevents lint and other particles from getting into the delivery device and possibly entering the respiratory system in a future administration.

10. Perform a medication follow-up assessment. Return to obtain information within an appropriate time frame. Educate the patient on the expected effect and the time of your return. Assess the respiratory status and pulse, and compare to the pre-administration assessment. Encourage the patient to demonstrate self-administration of medication. Educate the patient on the expected effect of the medication.

Assess the patient to evaluate the effectiveness of the medication and treatment and prevent adverse effects. Communication with the patient eases anxiety, promotes adherence, and gives the patient control.

Follow postprocedure steps I through VI.

Postprocedure

- I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

- II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

- III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

- IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document immediately after medication administration. Include the medication, dose, route, date, time, assessment, and the patient's response to the medication in the documentation.

Accurate documentation is essential to communicate medications administered and to provide legal evidence of care. Avoid possible medication errors by adhering to the Six Rights of Medication Administration.

Skill 35.3 Preparing Injections: Ampules, Multidose Vials, and Reconstituting Medications

Purpose

- Preparing medications from ampules and multidose vials and reconstituting medications must be done appropriately and safely and should follow the Six Rights of Medication Administration:
 - The right medication
 - The right dose
 - The right time
 - The right route
 - The right patient
 - The right documentation
- Medications from ampules and multidose vials and reconstituted medications are administered to improve or maintain the patient's underlying pathophysiology.
- When compatible, medications given by the same route should be prepared in one syringe for one injection to minimize discomfort and inconvenience to the patient.

Resources

- Filter needle or filtered straw for withdrawing medication from ampules
- Needle or blunt-tip cannula for withdrawing medication from vials

- Appropriate syringe and needle (see [Skill 35.5](#) and [Skill 35.6](#))
- Alcohol swabs
- 2 × 2 gauze pad
- Reconstitution solution for powdered medication vials according to the medication manufacturer's instructions

Interprofessional Collaboration and Delegation

- Refer to [Box 35.4](#).
- Medication administration may not be delegated.
- Unlicensed assistive personnel should report any of the following to the nurse:
 - Changes in vital signs and any patient complaints or discomforts
 - Medication found in the patient's room
 - Patient questions regarding medication
- Collaborate with the pharmacist on any medication questions before or during preparation.

Evidence-Based Practice

- Many of the techniques in this skill apply to medications produced by mixing two or more substances together (i.e., admixtures) rather than the traditional procedure of drawing up medications for administration in an injection.
- Many medication errors and adverse events occur during these processes. [George, Henneman, and Tasota \(2010\)](#) explain the concerns: “IV

admixture is known to be an error-prone procedure. Limiting the number of people who mix medications can minimize this, and assigning this responsibility to pharmacists is a common safety measure. However, because of the timing of pharmacy delivery of premixed agents and the need to start medications emergently, nurses may need to mix infusions. Nurses mixing medications must be knowledgeable about standard concentrations and procedures. They must alert the pharmacy if they have deviated from the standard concentration so that subsequent bags are mixed appropriately to avoid alteration in subsequent dose concentrations” (p. S141).

- Single-dose vials are preferred for any medication preparation; whenever possible, multidose vials and ampules should be avoided to prevent contamination, spread of microorganisms, and infections ([WHO, 2010](#)).

If possible, multidose vials should be used only for a single patient. Assign the medication to that patient for reuse, rather than using the vial for multiple patients ([CDC, 2017](#); [WHO, 2010](#)).

Special Circumstances

1. **Assess:** How should an ampule be broken?

Intervention:

- Hold the ampule in the nondominant hand.
- Use the dominant hand to grasp the top of the ampule with 2 × 2 gauze pad or an ampule sleeve.
- Push the middle of the ampule (neck) away from the hands.
- Dispose of the ampule tip in a sharps container.

2. **Assess:** Did the ampule break in a jagged manner so that it obviously does not have an even break around the neck?
Intervention: Discard the ampule and its solution, and restart the procedure.
3. **Assess:** How should a needle be covered to safely transport the injection to the bedside?
Intervention:
- Place the syringe cap on a counter surface.
 - Hold the syringe with one hand; do *not* stabilize the cap with your hand.
 - Use a scooping motion to pick up the cap with the needle. Do *not* let the needle touch any other surface.
 - After the cap is on the needle, hold the syringe vertically.
 - Snap the cap tightly onto the syringe by holding the sides of the cap. Do *not* push the cap on while holding the top of the cap.
4. **Assess:** What additional steps should be taken when opening a new multidose vial?
Intervention: Appropriately open and label the vial:
- Check the expiration date, and examine the solution.
 - Add the date, time of day, and your initials to the label (in ink).
 - Remove the plastic top of the vial.
5. **Assess:** Is there a reconstitution solution attached to the powdered medication vial?
Intervention: Follow the manufacturer's instructions to reconstitute the solution:
- Typically, the vial with the reconstitution solution is on top of the vial with the powder.
 - Usually, the two vials are pushed into each other to mix the solution and powder.
 - Roll the vial between your palms to ensure that the solution and powder are mixed evenly.

Procedure

Ampules

1. Prepare medications in a No Interruption Zone according to facility policy. Obtain the medication. Verify that the label of the medication matches the medication administration record (MAR), perform any dosage calculation, and check the expiration date of the medication and make sure the solution has no sediment. Check the expiration date of the syringe and filter needle or filtered straw packaging.
 - a. If an automated dispensing system is used, enter the appropriate information, and remove the medication. Verify the correct medication, dose, and form.
 - b. If barcoding is used, scan the MAR and medication. Verify the correct medication, dose, and form.
 - c. If using a medication cart, unlock the cart, and locate the correct patient drawer. Remove the medication from the drawer, and verify the correct medication, dose, and form.
 - d. If the medication is in a refrigerator: Unlock the refrigerator, find the vial or ampule, and verify that it is the correct medication, dose, and form.

Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.
2. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.
3. Tap the top of the ampule, and verify that the solution is entirely below the neck of the ampule.

The entire dose should be below the ampule neck to ensure that the entire dose can be withdrawn.
4. Unwrap the syringe, and place the filter needle or straw on the syringe.

The filter needle or straw prevents fragments of glass from entering the medication solution as it is drawn up into the syringe.
5. Open the ampule.
 - a. Clean the ampule head with an alcohol swab.
 - b. Hold the ampule in the nondominant hand.

STEP 5B

- c. Use the dominant hand to grasp the top of the ampule with 2 × 2-inch gauze.
- d. Snap off the top of the ampule. Use a quick and smooth motion toward you.

STEP 5D

- e. Dispose of the ampule top in a sharps container.
Using the proper technique to open an ampule prevents the spread of microorganisms and prevents cross-contamination. The top should be snapped towards the nurse to avoid fragments of glass from hitting the nurse. Proper disposal of waste protects caregivers from injury and reduces the spread of microorganisms.
6. Remove the cap of the filter needle or filtered straw. Place the cap on the medication cart.
Protects the caregiver from injury and prevents the spread of microorganisms.
7. Draw the solution into the syringe:
 - a. Place the ampule on the counter, and hold it with the nondominant hand.

- b. Fully insert a filter needle or straw into the center of the ampule.
- c. Withdraw the entire solution from the ampule into the syringe with the ampule upright or inverted while keeping the needle in the solution.

STEP 7C

- d. Remove the syringe from the ampule.
By avoiding exposure of the solution to open air, contamination of the solution and the spread of microorganisms diminish.
8. Engage the safety device or re-cover the filter needle or filtered straw by scooping the cap from the medication cart.
Proper procedure protects the caregiver from injury.
9. If there is excess air in the syringe, invert the syringe and expel the air.
Air rises to the top of the syringe, making it easier to expel.
10. Verify that the appropriate dose has been drawn into the syringe; work over a sink, and adjust to the ordered dose while holding the syringe at eye level with the needle pointing upward.

STEP 10

Holding the syringe at eye level ensures accuracy of the measurement.

11. Remove the filter needle or filtered straw from the syringe, and dispose of it in a sharps container.
Proper disposal protects the caregiver from injury.
12. Attach the appropriate needle for medication administration using aseptic technique.
Aseptic technique is used for preparation and administration of all parenteral medications.
13. Double-check the dose and check the medication label against the MAR a second time before disposing of the ampule in the sharps container.
Verification of the dose promotes ultimate safe, quality care and avoids possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times. Proper disposal of the ampule prevents possible injury.
14. Administer the medication immediately after completing its preparation. If unable to administer immediately, label the syringe with name of medication and the amount in the syringe.

Multidose Vials

1. Prepare medications in a No Interruption Zone according to facility policy. Obtain the medication. Verify that the label of the medication matches the MAR. Perform any dosage calculation including concentration of drug, volume of drug to be drawn, and which medication require verification by a second RN. Check the expiration date of the medication vial, and make sure the solution has no sediment. Check the

expiration date of the syringe and blunt cannula or needle packaging:

- a. If an automated dispensing system is used, enter the appropriate information, and remove the medication. Verify the correct medication, dose, and form.
- b. If barcoding is used, scan the MAR and medication. Verify the correct medication, dose, and form.
- c. If using a medication cart, unlock the cart, and locate the correct patient drawer. Remove the medication from the drawer, and verify the correct medication, dose, and form.
- d. If the medication is in a refrigerator: Unlock the refrigerator, find the vial or ampule, and verify that it is the correct medication, dose, and form.

Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.

2. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

3. Clean the top of the vial with an alcohol swab.

Proper antiseptic procedures should be used to prevent the spread of microorganisms.

4. Unwrap the syringe, and place the needle or blunt cannula on the syringe. Check medication administration instructions to see if a filter needle is required.

Some medications may require the use of a filter needle

5. Remove the cap of the needle or blunt cannula, and place it on the medication cart.

Protects the caregiver from injury and prevents the spread of microorganisms.

6. Draw sufficient air into the syringe to equal the ordered dose.

Air injection creates pressure in the vial to facilitate withdrawal of the solution in a later procedural step.

7. Keep the multidose vial on the counter.

- a. Insert the needle or blunt cannula straight into the vial.
- b. Inject the air from the syringe into the vial; keep the plunger depressed.
- c. Invert the bottle with the syringe, keeping the tip of the needle in the liquid.

STEP 7C

- d. Withdraw the ordered dose keeping the end of the needle in the fluid.
- e. Remove the syringe from the vial.
- f. Check the dose and remove any air or excess medication from the syringe. Work over a sink, and adjust to the ordered dose while holding the syringe at eye level with the needle pointing upward.

Keeping the vial on the counter while inserting the needle establishes stability and promotes safety. Air injection creates pressure in the vial to facilitate withdrawal of solution. Holding the syringe at eye level ensures accuracy of the measurement.

8. Re-cover the sterile needle or cannula by scooping the cap from the medication cart.
Proper procedure protects the caregiver from injury.
9. Remove the needle or cannula from the syringe, and dispose of it in a sharps container.
Proper procedure protects the caregiver from injury.
10. Attach the appropriate needle for medication administration using sterile technique.
11. Double-check the dose against the MAR one more time.
Verification of the dose promotes ultimate safe, quality care and avoids possible medication errors by adhering to the Six Rights of Medication Administration.
12. Administer the medication immediately after completing its preparation. If unable to administer immediately, label the syringe with name of medication and the amount in the syringe.
13. If using a multidose vial, mark it with the date and your initials.

Once opened medications have to be used within a certain time frame according to manufacturer's recommendations.

Reconstituting Medications

1. Prepare medications in a No Interruption Zone according to facility policy. Obtain the medication. Verify that the label of the medication matches the MAR, perform any dosage calculation, and check the expiration date of the medication.
 - a. If an automated dispensing system is used, enter the appropriate information, and remove the medication. Verify the correct medication, dose, and form.
 - b. If barcoding is used, scan the MAR and medication. Verify the correct medication, dose, and form.
 - c. If a medication cart is used, unlock the cart, and locate the correct patient drawer. Remove the medication, and verify the correct medication, dose, and form.

Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.

2. Obtain the correct reconstitution or diluent solution according to the manufacturer's instructions.

The correct reconstitution solution or diluent must be used to ensure compatibility and the correct concentration after reconstitution. Avoid possible medication errors by adhering to the Six Rights of Medication Administration.

3. Perform hand hygiene.

Hand hygiene prevents the spread of microorganisms.

4. Clean the top of the vial with an alcohol swab.

Proper antiseptic procedures should be used to prevent the spread of microorganisms.

5. Unwrap the syringe, and place the needle or blunt cannula on the syringe. Check medication administration instructions to see if a filter needle is required.

Some medications may require the use of a filter needle.

6. Remove the cap of the needle or blunt cannula, and place it on the medication cart.

Protects the caregiver from injury and prevents the spread of microorganisms.

7. Draw sufficient air into the syringe to equal the ordered dose of the reconstitution or diluent solution.

Air injection creates pressure in the vial to facilitate withdrawal of the solution in a later procedural step.

8. Keep the multidose vial on the counter:
 - a. Insert the needle or blunt cannula straight into the vial.
 - b. Inject the air from the syringe into the vial; keep the plunger depressed.
 - c. Invert the bottle with the syringe.
 - d. Withdraw the ordered dose of solution keeping the end of the needle in the fluid.
 - e. Remove the syringe from the vial.
 - f. Check the dose and remove any air or excess solution from the syringe. Work over a sink, and adjust to the ordered dose while holding the syringe at eye level with the needle pointing upward.

Keeping the vial on the counter when inserting the needle establishes stability and promotes safety. Air injection creates pressure in the vial to facilitate withdrawal of solution. Holding the syringe at eye level ensures accuracy of the measurement.

9. Re-cover the sterile needle or blunt cannula by scooping the cap from the medication cart.

Proper procedure protects the caregiver from injury.

10. Remove the cap from the powdered medication vial.

11. Clean the top of the vial with an alcohol swab.

Proper antiseptic procedures should be used to prevent the spread of microorganisms.

12. Remove the cap of the needle or blunt cannula, and place the cap on the medication cart.

Proper procedure protects the caregiver from injury and prevents the spread of microorganisms.

13. Keep the powdered medication vial on the counter:

- a. Insert the needle straight into the vial.
- b. Inject the reconstitution or diluent solution.
- c. Remove the syringe from the vial.

Keeping the vial on the counter establishes stability and safety.

14. Re-cover the sterile needle or cannula by scooping the cap from the medication cart.

Proper procedure protects the caregiver from injury.

15. Roll the vial between your palms. Make sure that all the powder dissolves and the solution contains no sediment.
Proper procedure ensures that the medication is evenly mixed.
16. Draw sufficient air into the syringe to equal the ordered dose.
Air injection creates pressure in the vial to facilitate withdrawal of the solution in a later procedural step.
17. Place the medication vial on the counter.
 - a. Insert the needle straight into the vial.
 - b. Inject the air from the syringe into the vial; keep the plunger depressed.
 - c. Invert the vial with the syringe.
 - d. Make sure the needle stays within the fluid.
 - e. Withdraw the ordered dose.
 - f. Remove the syringe from the vial.
Keeping the vial on the counter establishes stability while inserting the needle and promotes safety. Air injection creates pressure in the vial to facilitate withdrawal of the solution. Inverting the vial ensure that the needle is in the fluid for withdrawal into the syringe.
18. Re-cover the sterile needle or blunt cannula by scooping the cap from the medication cart.
Proper procedure protects the caregiver from injury.
19. Remove the blunt cannula if used, and dispose of it in a sharps container.
Proper procedure protects the caregiver from injury.
20. Attach the appropriate needle for medication administration using sterile technique, or use the needle that was used to draw up the medication if appropriate.
Proper procedure protects the patient from microorganisms.
21. Double-check the dose against the MAR. Check the medication label against the MAR a second time. Check the medication label against the MAR a third time before administration.
Verification of the dose promotes ultimate safe, quality care and avoids possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.
22. Administer the medication immediately after completing its preparation.

Skill 35.4 Medication Administration: Mixing Insulin

Purpose

- The mixing and administration of insulin must be done appropriately and safely and should follow the Six Rights of Medication

Administration:

- The right medication
- The right dose
- The right time
- The right route
- The right patient
- The right documentation
- Insulin is administered to improve or maintain the patient's underlying pathophysiology and prevent complications by regulating blood glucose levels.
- The ordered insulin should be prepared in one syringe for one injection, if not contraindicated, to minimize discomfort and inconvenience to the patient.

Resources

- Insulin syringe (50 or 100 units)
- Multidose insulin vials
- Alcohol swabs

Interprofessional Collaboration and Delegation

- Refer to [Box 35.4](#).

- Medication administration (including the mixing of insulin) may not be delegated.
- Unlicensed assistive personnel should report any of the following to the nurse:
 - Changes in vital signs and any patient complaints or discomforts
 - Medication found in the patient's room
 - Patient questions regarding medication
- The timing of insulin administration is important.
- Ensure proper administration and collaboration with dietary administration in the facility; insulin must be administered with regard to meals.
- Administer insulin immediately after its preparation.
- Immediate administration ensures that the medication remains mixed appropriately within the syringe.
- Rapid-acting insulin can reduce the effectiveness of long-acting insulin after the two are mixed.
- Collaborate with the pharmacist about medication questions before or during preparation.

Special Circumstances

- Intermediate-acting insulin is cloudy. Rapid-acting and short-acting insulin are clear.
 - Key mnemonic: *clear before cloudy*.
1. **Assess:** While injecting air into intermediate-acting (cloudy) insulin, did you let the needle

touch the solution?

Intervention: Obtain a new syringe for the next step.

2. **Assess:** While withdrawing intermediate-acting (cloudy) insulin, did you accidentally inject clear insulin?

Intervention: Start the procedure over.

- Dispose of the intermediate-acting (cloudy) vial according to facility policies and procedures.

- Obtain a new intermediate-acting (cloudy) vial.

3. **Assess:** While withdrawing intermediate-acting (cloudy) insulin, did you overdraw the total amount calculated?

Intervention: Discard the syringe, and start the procedure over.

Procedure

1. Prepare medications in a No Interruption Zone according to facility policy. Obtain the medication. Verify that the label of the medication matches the medication administration record (MAR). **Perform any dosage calculation, and determine the total number of units of insulin to be administered.** Check the expiration date of the medication:
 - a. If an automated dispensing system is used, enter the appropriate information, and remove the medication. Verify that the device contains the correct type of insulin.
 - b. If barcoding is used, scan the MAR and medication. Verify the correct insulin type.
 - c. If a medication cart is used, unlock the cart, locate the correct patient drawer, remove the medication, and verify the correct insulin type.
 - d. If the medication is in a refrigerator, unlock the refrigerator, find the multidose vials, and verify that you have the correct insulin type. Allow the

insulin to come to room temperature before administration.

Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.

2. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

3. If the insulin is cloudy, roll the vial between your hands. Do not shake it.

STEP 3 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Rolling the vial mixes the insulin to ensure an even suspension of the dose.

4. Place both vials on the counter, and clean their tops with alcohol swabs.

Proper cleaning should be used to prevent the spread of microorganisms.

5. Use an insulin syringe of the appropriate size (50 or 100 units) based on the calculation of total insulin units ordered.

6. Check the expiration date on the syringe packaging.

Avoid possible medication errors by adhering to the Six Rights of Medication Administration; they apply to the equipment and the medication.

7. Unwrap the syringe; remove the cap, and place it on the medication cart.

Careful handling of the syringe protects caregivers from injury and reduces the spread of microorganisms.

8. Draw sufficient air into the syringe to equal the number of ordered units of cloudy, intermediate-acting insulin.
Air injection creates pressure in the vial to facilitate withdrawal of the solution in a later procedural step.
9. Keep the vial of cloudy, intermediate insulin on the counter:
 - a. Insert the needle straight into the vial; do *not* let the needle touch the solution.

STEP 9A (Copyright Mosby's Clinical Skills: Essentials Collection.)

- b. Inject the air from the syringe into the vial; keep the plunger depressed.
 - c. Remove the syringe from the vial.
Keeping the vial on the counter establishes stability and promotes safety. Not letting the needle touch the solution avoids contamination of the next insulin solution. Air injection creates pressure in the vial, which facilitates withdrawal of the solution in a later procedural step. Keeping the plunger depressed while removing the needle from the vial prevents the accidental withdrawal of insulin.
10. Draw sufficient air into the syringe to equal the number of ordered units of clear, rapid- or short-acting insulin.
Air injection creates pressure in the vial to facilitate withdrawal of the solution.
11. Keep the vial of clear, rapid- or short-acting insulin on the counter:
 - a. Insert the needle straight into the vial.

- b. Inject the air from the syringe into the vial; keep the plunger depressed.
- c. Invert the vial with the syringe.
- d. Withdraw the ordered number of units of rapid- or short-acting insulin.

STEP 11D (Copyright Mosby's Clinical Skills: Essentials Collection.)

- e. Remove the syringe from the vial.
Keeping the vial on the counter while inserting the needle establishes stability and promotes safety. Air injection creates pressure in the vial to facilitate withdrawal of the solution. Inverting the vial ensures that the needle reaches the solution in order to withdraw the ordered amount of medication.
12. Check the medication label against the MAR a second time.
Avoids possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.
13. Keep the vial of cloudy, intermediate insulin on the counter:
 - a. Insert the needle straight into the vial, but do *not* push on the plunger.
 - b. Invert the vial with the syringe.
 - c. Withdraw insulin to obtain the total number of units calculated.
 - d. Remove the syringe from the vial.
Keeping the vial on the counter while inserting the needle establishes stability and promotes safety. Not pushing on the plunger keeps the correct dose of the first insulin in the syringe.

14. Re-cover the sterile needle or cannula of the syringe by scooping the cap from the medication cart.
Careful handling of the syringe protects caregivers from injury and reduces the spread of microorganisms.
15. Check the dose against the MAR one more time, and verify that the volume of the combined units of insulin is accurate.
Rechecking the dosage promotes ultimate safe, quality care and avoids possible medication errors by adhering to the Six Rights of Medication Administration.
16. Verify the dose with a second licensed nurse according to facility policy.
This provides a final check of accuracy of your calculations and total dosage for what is considered a high-risk medication.
17. Administer the medication within 5 minutes of completing procedure step 17; use the subcutaneous injection technique.
Prompt administration of the medication ensures that it remains mixed appropriately within the syringe.
18. Dispose of the needle and syringe in a sharps container according to facility policies or procedures.
Proper disposal of waste reduces the spread of microorganisms and protects caregivers from injury.

Skill 35.5 Subcutaneous, Intramuscular, and Intradermal Injections

Purpose

- The administration of injected medication must be done appropriately and safely and should follow the Six Rights of Medication

Administration:

- The right medication
- The right dose
- The right time
- The right route
- The right patient
- The right documentation
- Injected medication is administered to improve or maintain the patient's underlying pathophysiology.

Resources

- Alcohol swab (or approved cleansing agent in accordance with facility policies and procedures)
- 2 × 2 gauze pad
- Adhesive bandage
- Nonsterile gloves
- For subcutaneous injections:
 - Syringe: ½- to 3-mL or U-100 insulin syringe
 - Needle: 25 to 31 gauge, ⅜ to ⅝ inch (up to 1 inch for an obese patient)

- For intramuscular (IM) injections:
 - Syringe: 2 to 5 mL (adult); 0.5 to 1 mL (pediatric)
 - Needle: 19 to 25 gauge, 1 to 3 inches (adult); 22 to 25 gauge, $\frac{5}{8}$ to 1 inch (pediatric)
- For intradermal injections:
 - Syringe: Up to 1-mL tuberculin syringe
 - Needle: 25 to 27 gauge, $\frac{1}{4}$ to $\frac{3}{8}$ inch

Interprofessional Collaboration and Delegation

- Refer to [Box 35.4](#).
- Medication administration may not be delegated.
- Unlicensed assistive personnel (UAP) should report the following to the nurse:
 - Changes in vital signs or any patient complaints or discomforts
 - Medications found in the patient's room
 - Patient questions regarding medications
- Collaborate with the pharmacist about medication questions before administration.

Evidence-Based Practice

- Research indicates that administering subcutaneous heparin injections slowly over 30 seconds, may reduce pain associated with the injection ([Mohammady, Janani, & Akbari, 2017](#)).
- Aspiration (pulling back on the plunger after injecting the needle but before administering the medication) for possible blood during IM injection

of immunizations is not recommended. The rationale for aspiration is to ensure that the injection is not entering a large blood vessel. No large blood vessels are present in recommended immunization IM injection sites and aspiration causes more pain for infants (CDC, 2018b; Shepherd, 2018a).

- Because the dorsogluteal site has the highest risk of incorrect placement, potential nerve damage, and entry into a large blood vessel, its use is no longer recommended for IM injection. In an emergency situation in which an IM injection must be given in the dorsogluteal site, aspiration for 5–10 seconds is indicated to avoid accidental injection into the venous or arterial system rather than muscle (Mraz, Thomas, & Rajcan, 2018).
- Injection of medication during IM administration should always be slow (Mraz, Thomas, & Rajcan, 2018).
- In regard to “eliminating unnecessary injections,” the WHO (2010) states that “when effective treatment can be given by other routes (oral or rectal), this is preferred, because it reduces potential exposure to blood and infectious agents and reduces infection risks” (p. 4).

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.

Preparing for the patient encounter saves time and promotes patient trust.

III. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

IV. Maintain standard precautions.

Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient by using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Injections: Subcutaneous

Follow preprocedure steps I through VIII.

1. Prepare medications in a No Interruption Zone according to facility policy. Obtain the medication. Verify that the label of the medication matches the medication administration record

(MAR), perform any dosage calculation, and check the expiration date of the medication:

- a. If using an automated dispensing system, enter the appropriate information, and remove the medication. Verify the correct dose.
- b. If using barcoding, scan the MAR and medication. Verify the correct dose.
- c. If using a medication cart, unlock the cart, locate the correct patient drawer, remove the medication, and verify the correct dose.

Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.

2. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

3. Check the medication label against the MAR a second time. Verify that the correct medication and dosage have been obtained, and draw up the medication in an appropriate syringe with an appropriate needle (see [Skill 35.3](#)).

- a. An appropriate fluid amount is 0.5 to 1 mL.
- b. Some syringes are prefilled (multidose-unit pens) (see [Box 35.13](#)).

Avoids possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.

4. Assess the patient's knowledge, and educate the patient about the procedure as needed.

Communication with the patient eases anxiety and facilitates cooperation.

5. Perform premedication assessments as indicated.

Evaluation of the patient before administering medication promotes safe, quality patient care and provides baseline assessment data to evaluate the effectiveness of the medication and interventions.

6. If using barcoding, scan the medication and the patient identification. Enter pertinent information. Recheck the label on the medication with the MAR a third time before returning the medication to its storage place *or* before opening the package at the bedside.

Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the

medication with the MAR three times.

7. Determine an appropriate injection site:
 - a. Does the medication require that a specific injection site be used?
 - b. Should the injection site be rotated on a schedule?
 - c. Assess the skin and tissue of the selected site to be sure the site is acceptable.
 - d. Allow patient choice or input if possible.

Some medications absorb better in certain sites. The injection sites for routine medications are rotated to prevent tissue damage. Obvious skin or tissue integrity issues (such as, scars, moles, or rashes) require avoidance of the site. Permitting patient input promotes adherence and gives the patient control.
8. Site locations, beginning with the most common (see [Fig. 35.13](#)).
 - a. Lateral aspect of the upper arm
 - b. Abdomen, below the costal margin to the iliac crests (avoid injections within 2 inches of the umbilicus)
 - c. Lateral anterior thigh
 - d. Upper ventrodorsal gluteal area
 - e. Upper back or scapular areas

Subcutaneous injection areas are not bony, muscular, or dense with nerves or blood vessels. Correct anatomic placement of the injection prevents injury.
9. Position the patient for optimal access to the chosen site.

Proper patient position promotes optimal administration and technique for ultimate safe, quality care and promotes patient comfort during administration.
10. Perform hand hygiene, and apply clean gloves.

Frequent hand hygiene and proper glove use prevent the spread of microorganisms.
11. Clean the site with an alcohol swab, using a circular motion that moves from the center outward 2 inches, or follow facility policies and procedures. Allow the site to air-dry.

STEP 11 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Proper antiseptic procedures should be used to prevent the spread of microorganisms.

12. Administer the injection:

- a. Have the patient relax.
- b. Hold a piece of gauze in the third and fourth fingers of the nondominant hand.
- c. Pull the needle cap straight off, and set the cap aside.
- d. Hold the syringe as you would a pen or dart, with the thumb and tips of one or two (forefinger and middle) fingers of the dominant hand and with the palm of the hand directed downward.

STEP 12D (Copyright Mosby's Clinical Skills: Essentials Collection.)

- e. Pinch or stretch the tissue at the site with the nondominant hand.
- f. Insert the needle quickly, with the bevel up at a 45- to 90-degree angle. The nondominant hand releases the pinched tissue and stabilizes the syringe.
- g. Use the dominant hand to slowly depress the plunger and inject the medication.

STEP 12G (Copyright Mosby's Clinical Skills: Essentials Collection.)

Relaxing the muscles facilitates injection into the subcutaneous tissue rather than inadvertent injection into muscle. Proper technique promotes minimal discomfort and easy manipulation of supplies. Taking proper precaution to remove the needle cap prevents the spread of microorganisms. Pinching the skin allows smooth injection. Keeping the bevel up and using the appropriate needle angle promote proper medication administration into subcutaneous tissue rather than into muscle (avoiding possible errors) and promote safe, quality patient care.

13. Perform the following steps in quick succession:
 - a. With the dominant hand, withdraw the syringe.
 - b. Using only the dominant hand, activate the needle safety protection device.
 - c. With the nondominant hand, apply the gauze and slight pressure to the site; do *not* massage the site.
 - d. Apply an adhesive bandage as needed.

Following this procedure minimizes discomfort and tissue damage. Massage can damage tissue by pushing the medication into surrounding tissues and may cause the medication to be absorbed faster than intended. The needle safety device protects caregivers from injury.

14. Dispose of the needle and syringe in a sharps container according to facility policy.

Proper disposal of waste reduces the spread of microorganisms and protects caregivers from injury.

15. If the medication requires follow-up assessment, return to obtain information within an appropriate time frame. Educate the patient on the expected effect of the medication.

Performing a follow-up assessment can prevent adverse effects and provides information regarding the effectiveness of the medication administered.

Communication with the patient eases anxiety and facilitates cooperation.

Follow postprocedure steps I through VI.

Injections: Intramuscular

Follow preprocedure steps I through VIII.

1. Prepare medications in a No Interruption Zone according to facility policy. Obtain the medication. Verify that the label of the medication matches the MAR, perform any dosage calculation, and check the expiration date of the medication.
 - a. If using an automated dispensing system, enter the appropriate information, and remove the medication. Verify the correct dose.
 - b. If using barcoding, scan the MAR and medication. Verify the correct dose.
 - c. If using a medication cart, unlock the cart, locate the correct patient drawer, remove the medication, and verify the correct dose.

Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.
2. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.
3. Check the medication label against the MAR a second time. Verify that the correct medication and dosage have been obtained, and draw up the medication in an appropriate syringe with an appropriate needle (see [Skill 35.3](#)).
 - a. The fluid amount for IM injections is 1 to 5 mL, depending on the site and muscle mass.
 - b. Some syringes are prefilled (e.g., multidose-unit pens) (see [Box 35.14](#)).

This approach avoids possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.
4. Follow procedure steps 4 through 7 in the “[Injections: Subcutaneous](#)” section.
5. Locate the intramuscular (IM) injection site (see [Fig. 35.14](#)).

- a. For ventrogluteal injection, place the heel of the hand over the greater trochanter of the patient's femur; the thumb should point toward the pelvic area. If the patient's right ventrogluteal area is the injection site, the left hand is used; if the patient's left ventrogluteal area is the injection site, the right hand is used. The index finger should be over the anterior superior iliac spine, and the index and middle fingers spread to form a V shape as far apart over the iliac crest as possible. The point of injection is between the index and middle fingers in the middle of the V shape.

STEP 5A(1) (From Lilley, et al, 2017.)

STEP 5A(2) (From Lilley, et al, 2017.)

- b. For deltoid muscle injection, place the ring finger of the nondominant hand along the lower edge of the acromial process (placing it so that the 5th finger is closest to the ear), with the middle finger (and possibly index finger) joined with the ring finger. The point of injection is just posterior to midline immediately below the middle or index finger, in line with the axilla.

STEP 5B

- c. For vastus lateralis injection, place one hand below the greater trochanter of the femur, with the thumb pointing toward the knee to form an L or backward-L shape. Place the other hand above the knee, with the thumb pointing toward the hip to form an L or backward-L shape. The point of injection is in the center third of the lateral thigh between the hands and at the center of the side of the leg.

STEP 5C

A ventrogluteal site is preferred due to muscle size. Intramuscular (IM) injection areas are not bony, are highly muscular, and have low density of pertinent nerve areas or major blood vessels. The correct anatomic placement of an injection prevents injury to the patient.

6. Follow procedure steps 9 through 11 in the “[Injections: Subcutaneous](#)” section.
7. Use the Z-track method to insert the needle.

STEP 7

- a. Remember the injection site.
- b. Use the third and fourth fingers of the nondominant hand to hold the gauze.
- c. Pull the needle cap straight off.
- d. Use the thumb and tips of the one or two (forefinger and middle) fingers to hold the syringe, palm down, as you would a pen or dart.
- e. Use the side of the nondominant hand to pull the skin tight below the injection site or to the side (Z-track).
- f. Insert the needle quickly at a 90-degree angle.
- g. Continue to pull on the skin with the side of the nondominant hand; use the thumb and index finger to stabilize the barrel of the syringe.
- h. Move the dominant hand up on the barrel to the end of the plunger.

The Z-track technique ensures that medication is “locked” into the muscle. The procedure promotes injection into the muscle, provides minimal patient discomfort, and allows accessibility of supplies. Uncapping the needle by pulling the cap straight off prevents the spread of microorganisms. The angle of needle entry promotes medication administration into the muscle rather than inadvertent administration into other tissue, and it avoids possible medication errors and promotes patient safety and quality care.

8. Administer the medication by slowly depressing the plunger, delivering 1 mL of medication over 10 seconds. Hold the needle in place for 10 seconds after the medication is administered.

Injecting the medication slowly minimizes patient discomfort and tissue damage. Holding the needle in place allows the medication to disperse into the tissue.

9. Perform the following steps in quick succession:

- a. Withdraw the needle and syringe with the dominant hand.
- b. Activate the needle safety protection device with the dominant hand.
- c. Release the Z-tracked tissue from the nondominant hand.
- d. Apply gentle pressure with the gauze with the nondominant hand. Do *not* massage the site.
- e. Apply an adhesive bandage if needed.

Following this procedure minimizes discomfort and tissue damage. Massage can damage tissue by pushing the medication into surrounding tissues and may cause the medication to be absorbed faster than intended. The needle safety device protects caregivers from injury.

10. Follow procedure steps 14 and 15 in the “[Injections: Subcutaneous](#)” section.

Follow postprocedure steps I through VI.

Injections: Intradermal

Follow preprocedure steps I through VIII.

1. Prepare medications in a No Interruption Zone according to facility policy. Obtain the medication. Verify that the label of the medication matches the MAR, perform any dosage calculation, and check the expiration date of the medication.
 - a. If using an automated dispensing system, enter the appropriate information, and remove the medication. Verify the correct dose.
 - b. If using barcoding, scan the MAR and medication. Verify the correct dose.
 - c. If using a medication cart, unlock the cart, locate the correct patient drawer, remove the medication, and verify the correct dose.

Proper procedure to avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.

2. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

3. Verify the correct medication and dosage. Check the medication label against the MAR a second time.
 - a. Draw up the medication in an appropriate syringe with an appropriate needle (see [Skill 35.3](#)).
 - b. The usual amount for an intradermal injection is 0.1 mL.

Proper procedure avoids possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.

4. Follow procedure steps 4 through 7 in the “[Injections: Subcutaneous](#)” section.
5. Locate the injection site.
 - a. For the anterior forearm, locate a site that is three to four finger widths below the antecubital area and one hand width above the wrist. If the skin at the injection point is intact, proceed with the injection.
 - b. For the upper back, use the scapular area.
 - c. If the upper back is not acceptable, choose a site typically used for subcutaneous injection (see [Fig. 35.13](#)).

The anterior forearm is the preferred site for intradermal injections. The skin must be intact and without blemishes, marks, or scars for proper interpretation of results.

6. Follow procedure steps 9 through 11 in the “[Injections: Subcutaneous](#)” section.
7. Administer the injection.
 - a. Use the third and fourth fingers of the nondominant hand to hold the gauze.
 - b. Pull the needle cap straight off.
 - c. Use the thumb and tip of the forefingers of the dominant hand to hold the syringe.
 - d. Use the thumb and forefinger of the nondominant hand to apply outward traction to the skin around the injection site.
 - e. Insert the needle against the skin, with the bevel up and at a 5- to 15-degree angle; the needle should be visible under the skin.

STEP 7E (Copyright Mosby's Clinical Skills: Essentials Collection.)

- f. Release the skin, and use the thumb and forefinger of the nondominant hand to stabilize the barrel of the syringe.
- g. Move the dominant hand up on the barrel to the plunger.

Stretching the skin facilitates the needle entering the dermis rather than underlying tissue. Following this procedure promotes accessibility of supplies, prevents the spread of microorganisms, and promotes patient safety and quality care. The needle and syringe angle promotes medication administration into the dermis rather than inadvertent administration into other tissue and avoids possible medication errors. Stabilization of the syringe minimizes patient discomfort.

- 8. Administer the medication by slowly depressing the plunger. Observe the resulting bubble formation; a wheal or bleb should appear at the injection site when the medication has been properly injected into the dermis.

STEP 8 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Using this technique ensures intradermal placement; resistance indicates dermal administration. Injecting the medication slowly minimizes patient discomfort and

tissue damage. A bubble or wheal indicates dermal administration has occurred.

9. Perform the following steps in quick succession:
 - a. Withdraw the needle and syringe at the same angle as that of insertion, using the dominant hand.
 - b. Activate the needle safety protection device with the dominant hand.
 - c. Use the nondominant hand, apply gauze gently to the site. Do *not* massage it.

Following this procedure minimizes discomfort and tissue damage. Massage can damage tissue by pushing the medication into surrounding tissues and may cause the medication to be absorbed faster than intended. The needle safety device protects caregivers from injury.

10. Follow procedure steps 14 and 15 in the “[Injections: Subcutaneous](#)” section.

Follow postprocedure steps I through VI.

Postprocedure

- I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

- II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

- III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document immediately after medication administration. Include the medication, dose, route, date, time, assessment, and the patient's response to the medication in the documentation.

Accurate documentation is essential to communicate medications administered and to provide legal evidence of care. Avoid possible medication errors by adhering to the Six Rights of Medication Administration.

Steps 5a (1) and 5a (2) under Injections: Intramuscular are from Lilley LL, Collins SR, Snyder JS: *Pharmacology and the nursing process*, ed 8, St. Louis, 2017, Elsevier.

Skill 35.6 Administering Intravenous Medications and Intermittent Solutions

Purpose

- The administration of intravenous (IV) medications and solutions must be done appropriately and safely and should follow the Six Rights of Medication Administration:
 - The right medication
 - The right dose
 - The right time
 - The right route
 - The right patient
 - The right documentation
- Peripheral IV lines are used to:
 - Prevent infections.
 - Provide fluids.
 - Administer medications.
 - Replace electrolytes.
 - Promote comfort.
 - Provide nutrition.
 - Maintain emergency access for medications.

Resources

- 3- to 10-mL prefilled saline flush
- Antiseptic or alcohol swabs
- IV solution in accordance with the primary care provider (PCP) order
- Infusion-set tubing, primary or secondary, appropriate for the pump; needle or blunt cannula

if applicable

- Clean gloves
- IV pole and pump
- Personal protective equipment (PPE), as required

Interprofessional Collaboration and Delegation

- Maintaining a peripheral IV line, including changing tubing or solutions, may not be delegated to unlicensed assistive personnel (UAP).
- UAP may observe a peripheral IV site and running infusions during other procedures and should report the following to the nurse:
 - Burning, redness, pain, coolness, leaking, or swelling at the peripheral IV site
 - Patient concerns or complaints
 - Low volume in any IV bag
 - Alarms being produced by IV equipment
 - Changes in vital signs
- Many facilities have an IV therapy team that maintains IV sites. For the comfort and safety of the patient, nurses should coordinate with this team in accordance with facility policy and procedure and their own skill level.

Special Circumstances

1. **Assess:** Is the IV solution discolored, leaking, or expired?
Intervention: Discard the IV solution, and obtain a new solution; document according to facility policy and procedure.
2. **Assess:** Is the IV solution in a bottle instead of a bag?

- Intervention:** Clean the port on the bottle with an antiseptic swab, and insert a spike into the port on the bottle. Open the vent on the IV tubing.
3. **Assess:** Was the tubing spike touched by anything other than the clean port of an IV bottle?
Intervention: Discard the spike, and restart with a new one.
4. **Assess:** What should be done if an IV solution will not infuse?
Intervention: Check the tubing, ensure all clamps are opened, and assess the IV site.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.
- VI. Provide for patient privacy.
It is important to maintain patient dignity.
- VII. Identify the patient by using two identifiers.
Identifying a patient involves scanning barcodes or comparing the patient's stated name and

birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Intravenous Piggyback Medication, or Intermittent Infusion

Follow preprocedure steps I through VIII.

1. Follow instructions in [Box 35.4](#). Prepare medications in a No Interruption Zone according to facility policy.
Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.
2. Obtain all medication for the assigned time before entering the patient's room.
Promote patient rest through minimal interruptions.
3. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
4. Verify medication, dosage, and solution compatibility with any IVs already infusing.
Verification of compatibility is critical to reduce medication errors and promote patient safety.
5. Obtain the prescribed IV medication or solution bag.
Medication should be prepared by the pharmacy.
The Joint Commission's Standard MM.4.20, EP 1, states: "When an on-site, licensed pharmacy is available, only the pharmacy compounds or admixes all sterile medications, IV admixtures, or other drugs except in emergencies or when not feasible."
6. Check the IV medication or solution bag against the MAR a second time. Verify that the correct medication and dosage have been obtained.

STEP 6 (Copyright Mosby's Clinical Skills: Essentials Collection.)

This approach avoids possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.

7. Connect the tubing to the IV solution.

STEP 7 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Open the tubing package, slide a roller clamp 2 inches below the drip chamber, and roll the clamp closed.
- b. Remove the sterile protections. Pull or snap off the cover from the port on the bag, and slide off the cover from the spike on the tubing.
- c. Use sterile technique to insert the spike into the port with a twisting motion. Ensure that it is fully inserted.

Using a roller clamp ensures the accuracy of drip regulation and prevents wasting of solution during preparation. Maintain sterility while preparing the port and spike to prevent the spread of microorganisms.

8. Squeeze the drip chamber, and then fill it approximately half-full with the IV solution.

STEP 8 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Squeezing removes air from the tubing and creates suction.

9. Prime or fill the tubing with solution.
 - a. Remove the cap on the end of the tubing if necessary; do *not* discard the cap, and keep it sterile. Place the end of the tubing over the sink; do *not* let the end of the tubing touch the sink.
 - b. Slowly open the clamp.
 - c. Allow the solution to run through the tubing. Hold the tubing upside down, and tap the ports to release the air and fill the ports.
 - d. Close the clamp when the tubing is full.
 - e. Replace the cap on the tubing.

Maintain sterility and prevent contamination. Proper preparation of the tubing and ports prevents air from entering the tubing and prevents loss of solution.

10. Inspect the tubing for air. If air is present, tap the tubing to move the air up.

Remove air from the tubing to prevent adverse events and complications.

11. If a saline lock is being used, clean the injection port with an alcohol swab and connect the tubing to the port by screwing the tubing into the port or using a needleless cannula, depending on the type of equipment.

STEP 11 (Copyright Mosby's Clinical Skills: Essentials Collection.)

12. Program the IV pump with the correct mL/hr for the infusion, following the manufacturer's instructions.

STEP 12 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Use the correct infusion volume and time to prevent adverse events and medical errors.

13. Ensure that the tubing and solution is labeled in accordance with facility policies and procedures.

Proper labeling of solutions prevents adverse events and medical errors.

14. If using barcoding, scan the IV medication or solution bag and the patient identification. Enter pertinent information. Recheck the label on the IV medication or solution bag with the MAR a third time.

Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.

15. If a continuous infusion is already in place, connect the tubing to a port above the pump. Ensure that the secondary medication and its IV solution are compatible with the primary IV solution.

- a. Scrub the port with an alcohol swab.

- b. Connect the tubing by screwing it into the port or using a needleless cannula, depending on the equipment type.
- c. Program the pump following the manufacturer's instructions.
- d. Verify that the tubing and solution are labeled according to facility policy and procedure.

Knowledge of medication interactions is critical for safe patient care. Proper antiseptic procedures should be used to prevent the spread of microorganisms and prevent infection. Proper labeling of samples prevents adverse events and medical errors.

16. When the infusion is complete, disconnect the tubing in accordance with the type of infusion.

- a. If using a saline lock, see [Box 39.11](#).
- b. If using a continuous infusion, ensure that the solution containing medication is empty, stop the pump (follow the manufacturer's instructions), and clamp the tubing. The tubing may be left in place. Reset the pump for the maintenance IV infusion solution. Some pumps will automatically revert to the primary IV solutions when the piggybacked solution is completed.

Discontinuing the infusion at the appropriate time prevents adverse events and medication errors. Leaving the tubing in place reduces the spread of microorganisms by keeping the system closed.

Follow postprocedure steps I through VI.

Intravenous Push or Intravenous Bolus

Follow preprocedure steps I through VIII.

1. Follow procedure steps 1 through 6 in the “Intravenous Piggyback Medication” or “Intermittent Intravenous” section.
2. If using barcoding, scan the medication and the patient identification. Enter pertinent information. Recheck the label on the medication with the MAR a third time before returning the medication to its storage place *or* before opening the package at the bedside.

Avoid possible medication errors by adhering to the Six Rights of Medication Administration and by checking the medication with the MAR three times.

3. If using a saline lock:
 - a. Use an alcohol swab to clean the injection port of the saline lock.
 - b. Flush the IV line (see [Box 39.11](#)).
 - c. Attach the syringe by screwing it into the port or using a needleless cannula depending on the equipment available.
 - d. Inject the medication, adhering to safe medication guidelines (see [Box 35.4](#)).
 - e. Flush the IV line (see [Box 39.11](#)).

Injection rates for IV medication given via IV push vary; knowledge of safe guidelines is essential for patient safety.

4. If using a continuous infusion:
 - a. Place the pump on hold.
 - b. Use an alcohol wipe to clean the injection port that is closest to the saline lock.
 - c. Flush the IV line (see [Box 39.11](#)).
 - d. Attach the medication syringe by screwing it into the port or using a needleless cannula depending on the equipment available.
 - e. Inject the medication, adhering to safe medication guidelines (see [Box 35.4](#)).

STEP 4E (Copyright © Mosby's Clinical Skills: Essentials Collection.)

- f. Flush the IV line (see [Box 39.11](#)).
 - g. Restart the infusion pump.

Stopping the pump and flushing with saline prevents adverse events and medication errors. Because saline is

compatible with all medications, it is used to flush the line to prevent incompatible medications from mixing. Keeping the system closed reduces the risk of spreading microorganisms. Injection rates for IV medication given by IV push vary; knowledge of safe guidelines is essential for patient safety.

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document immediately after medication administration. Include the medication, dose, route, date, time, assessment, and the patient's response to the medication in the documentation.

Accurate documentation is essential to communicate medications administered and to provide legal evidence of care. Avoid possible medication errors by adhering to the Six Rights of Medication Administration.

Summary of Learning Outcomes

LO 35.1 *Verbalize how government, facility, and professional regulations affect medication administration by nurses:* Medication production, distribution, prescription, and administration are regulated by law. Controlled substances have additional regulations governing their use.

LO 35.2 *Explain the physiologic outcomes of medication actions:* A medication's action results from chemical interactions between the medication and the cells of the body, producing a physiologic response. Medication response can be altered by absorption, distribution, metabolism, or excretion of the drug.

LO 35.3 *Identify differences between prescription and nonprescription medications:* Medications that are obtained with a prescription are used to treat many illnesses and symptoms. Many patients use alternative and over-the-counter therapies to self-treat health conditions. To prevent potential interactions with prescribed medications, nurses need to assess for and identify all therapies used by the patient.

LO 35.4 *Summarize common medication forms and routes:* Medications come in many forms, including tablets, capsules, powders, solutions, inhalants, ointments, lotions, and suppositories. Routes of medication administration include oral, topical, transdermal, inhalation, and parenteral, which includes intradermal, subcutaneous, intramuscular, and intravenous routes.

LO 35.5 *Describe measures for administering medications safely:* To ensure patient safety, the nurse must follow the Six Rights (i.e., the right drug in the right dose at the right time by the right route to the right patient with the right documentation). To follow the Six Rights, the nurse needs to be able to interpret medication orders and calculate safe medication dosages.

LO 35.6 *Discuss assessments necessary for safe medication administration:* The nurse is responsible for assessing subjective and objective data and following established administration guidelines before administering medications.

LO 35.7 *Choose nursing diagnoses related to safe medication administration:* The nurse bases nursing diagnoses for each patient on individual data collected during assessment. Examples of nursing diagnoses applicable to patients with needs surrounding medication administration include *Lack of Knowledge, Constipation, and Impaired Health Maintenance*.

LO 35.8 *Determine individual patient goals:* Patient goals are based on the problem or need as stated in the nursing diagnoses. Goals should be patient-centered, realistic, and measurable.

LO 35.9 *Implement guidelines and essential nursing actions for safely administering medications and evaluate patient outcomes:* Nursing knowledge of safe medication administration includes applying the Six Rights of Medication Administration using proper administration techniques and conducting

ongoing evaluation of patient outcomes and the nursing care plan.

Review Questions

1. The nurse is teaching a patient about how to take a sublingual nitroglycerin tablet. Which statement by the patient best demonstrates understanding of the teaching?
 - a. "I will take the tablet with plenty of water."
 - b. "I will place the tablet inside my cheek."
 - c. "I will put the tablet under my tongue."
 - d. "I will take the tablet while I am eating."
2. The nurse is caring for a critically ill patient. What are the contraindications for administering medications by the oral route for this type of patient? (*Select all that apply.*)
 - a. Vomiting
 - b. Unconsciousness
 - c. Diarrhea
 - d. Penicillin allergy
 - e. Intubation
3. The nurse is in a patient room ready to administer a new medication to the patient. Which action best demonstrates awareness of safe, proficient nursing practice?
 - a. Identify the patient by comparing her name and birth date to the medication administration record (MAR).
 - b. Determine whether the medication and dose are appropriate for the patient.

- c. Make sure the medication is in the medication cart.
 - d. Check the accuracy of the dose with another nurse.
4. A patient has been using herbal medication as part of her daily routine. Which actions should the nurse take? (*Select all that apply.*)
- a. Document the herbs as part of the medication history.
 - b. Recommend a reputable company from which to buy herbs.
 - c. Allow the patient to self-administer the herbs with her morning medications.
 - d. Inform the primary care provider of the findings.
 - e. Identify possible adverse effects of the herbal medications.
5. A nurse must give 1 g of Keflex, PO, q 6 hr × 3 days. The supply on hand is 500 mg/capsule. How many capsules should the nurse administer at each dose?
6. The health care provider prescribes a transdermal medication. The nurse understands what feature of the transdermal route?
- a. It is inhaled into the respiratory tract.
 - b. It is dissolved inside the cheek.
 - c. It is absorbed through the skin.
 - d. It is inserted into the vaginal cavity.
7. The nurse is caring for a patient who is unable to hold a cup or spoon. How should the nurse

- administer oral medications to the patient?
- a. Crush the pills and mix them in pudding before administering.
 - b. Ask the pharmacist to change all of the medications to a liquid form.
 - c. Use a small paper cup to place the pills into the patient's mouth.
 - d. Place the pills on the table and have the patient take the pills by hand.
8. What should the nurse do first when preparing to administer medications to a patient?
- a. Check the medication expiration date.
 - b. Check the medication administration record (MAR).
 - c. Call the pharmacy for administration instructions.
 - d. Check the patient's name band.
9. The nurse is preparing a plan of care for a patient. What is the most appropriate goal for a patient related to medications?
- a. The patient will administer all medications correctly by discharge.
 - b. The patient will be taught common side effects of prescribed medications.
 - c. The patient will have a good understanding of prescribed medications.
 - d. The patient will have all medications administered by staff as prescribed.

10. The nurse reviews a primary care provider's order and finds that the medication amount is greater than the standard dose. What should the nurse do?
- a. Give the standard dose rather than the one that is ordered.
 - b. Consult with the nursing supervisor to get a second opinion.
 - c. Call the primary care provider to discuss the order in question.
 - d. Administer the medication as ordered by the primary care provider.

CHAPTER 36

Pain Management

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 36.1 Define pain.
- LO 36.2 Describe the role of the nurse in pain management.
- LO 36.3 Explain the physiology of pain and its perception.
- LO 36.4 Articulate factors that influence pain perception and response.
- LO 36.5 Determine individual physiologic, behavioral, and psychosocial responses to pain during patient assessment.
- LO 36.6 Identify nursing diagnoses for patients experiencing pain.
- LO 36.7 Generate nursing care goals and outcome criteria for patients experiencing pain.
- LO 36.8 Plan pain management care that includes implementation and evaluation of pharmacologic and nonpharmacologic interventions for pain.

KEY TERMS

- A-delta fibers, p. 853**
- acute pain, p. 855**
- addiction, p. 866**

visceral pain, p. 855

Case Study

Martin Charles (M. C.) is a 45-year-old man who was admitted to the emergency department with a fracture of his left femur. He was riding a four-wheeler downhill when it overturned and pinned his left leg, causing edema and pain with movement.

On admission, M. C.'s vital signs are T 37.5° C (99.6° F), P 100 and regular, R 24 and unlabored, BP 150/88, with a pulse oximetry reading of 94% on 4 L of oxygen via nasal cannula. His left leg is pale, cool to touch, with decreased sensation in the left foot. There is a large ecchymotic area on the midthigh. Pulses distal to the fracture are weak. Capillary refill is 4 seconds in the left foot. M. C. complains of sharp, stabbing pain on movement of the left leg, with a pain rating of 10 of 10. He is grimacing and visibly restless. He states, "My leg is killing me. Please give me something for pain." His code status is full. He is allergic to aspirin (reaction: hives) and has a medical history of hypertension. Left leg x-ray results show a closed, displaced fracture of the mid-femur. M. C. is taken to surgery for internal fixation to reduce and immobilize the fracture.

Postoperative treatments are as follows:

- Vital signs with neurovascular checks of the left leg q 15 minutes for the first hour, then hourly for 4 hours, and then q 4 hr
- Keep left leg elevated
- Ice packs to left leg; PRN for relief of pain or swelling
- Up in chair and bathroom privileges with assistance

Medication orders are as follows:

- Morphine sulfate patient-controlled analgesia (PCA) per anesthesia dose for 24 hours
- Lactated Ringer's solution IV at 125 mL/hr

- Oxycodone/acetaminophen 10/325 mg PO, one or two tablets q 4 hr PRN for pain
- Atenolol 50 mg PO q AM
- Diphenhydramine 10 mg IV q 4 hr PRN
- Senna two tablets PO q AM

Refer back to this case study to answer the critical-thinking questions throughout the chapter.

Pain is the most common reason people seek health care. Acute or chronic pain from any cause affects more individuals than do diabetes mellitus, cancer, and cardiac disease combined, and it remains undertreated. It is estimated that 100 million adults in the United States suffer from chronic pain ([Rivich, McCauliff, & Schroeder, 2018](#)). Approximately 5.5 billion people worldwide suffer from pain due to insufficient treatment or no treatment ([Kunnumpurath, Julien, Kodumudi, et al., 2018](#)).

LO 36.1 The Concept of Pain

Pain has physical and emotional aspects. It is what the person feels and how the person perceives how it feels. Margo McCaffery, a pain management nurse expert, developed a definition of pain in 1968 that has served as a practical guide for health care providers for many years. McCaffery maintains that pain is whatever the person with the pain says it is and that it exists whenever the person says it does, leaving pain *open to interpretation* (Pasero & McCaffery, 2011).

The [International Association for the Study of Pain \(2018\)](#) defines pain as an “unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.” This is the most widely used definition today. Pain prevents injury in some cases (e.g., when a person instantly withdraws a hand after touching a hot surface) and results from injury in other cases (e.g., the pain of a fractured hip from a fall). Long-term disability is most commonly the result of chronic pain ([National Institutes of Health \[NIH\], 2018](#)). As the population ages, the number of people who need pain management for back disorders, degenerative joint diseases, rheumatologic conditions, visceral diseases, and cancer is expected to rise.

Pain is the most subjective of all symptoms that patients experience, and it is felt differently by each individual. Cognitive, affective, behavioral, and sensory factors can influence pain. An alert, oriented patient knows what pain is, can verbalize what it is, knows what it feels like, and can perform behaviors to prevent or alleviate it. Unrelieved pain can result from the health care professional's failure to assess pain, failure to accept a patient's reported pain, and failure to initiate pain relief (Pasero & McCaffery, 2011). Nurses must be aware of their own attitudes and expectations regarding pain. Awareness allows the nurse to focus on the patient's experience of reported pain. All patients have a right to effective management of pain.

LO 36.2 Nursing and Pain Management

Pain should be assessed and documented to provide comfort at a level acceptable to each patient. In 2018, the American Nurses Association (ANA) published a position statement on pain management to guide nursing practice. The ANA believes:

- Nurses have an ethical responsibility to relieve pain and the suffering it causes.
- Nurses should provide individualized nursing interventions.
- The nursing process should guide the nurse's actions to improve pain management.
- Multimodal and interprofessional approaches are necessary to achieve pain relief.
- Pain management modalities should be informed by evidence.
- Nurses must advocate for policies to assure access to all effective modalities.
- Nurse leadership is necessary for society to appropriately address the opioid epidemic. ([ANA, 2018](#)).

In 2001 The Joint Commission (TJC) developed a standard of pain management for the care of hospitalized patients. This standard resulted from the undertreatment of pain. Since that time, TJC has required that pain be assessed on a regular basis. Nurses assess pain using various pain assessment tools or strategies, perform a comprehensive pain assessment, and document the patient's response after assessment, before and after pain control interventions, or if, **analgesic** (pain-reducing) medication is administered. TJC introduced new and revised standards for pain assessment and management in 2018 to improve the management of pain relief while addressing the opioid epidemic in the United States ([Box 36.1](#)).

Box 36.1

The Joint Commission's New and Revised Standards Related to Pain Assessment and Management

The Joint Commission requires all organizations to meet the following pain assessment standards:

- Assess and manage patient pain and minimize the risks associated with treatment.
- Screen patients for pain during emergency department visits and at the time of admission.
- Treat patient's pain or refer the patient for treatment.
- Develop a pain treatment plan based on evidence-based practices and the patient's clinical condition, past medical history, and pain management goals.
- Develop realistic expectations and measurable goals that are understood by the patient for the degree, duration, and reduction of pain.
- Discuss the objectives used to evaluate treatment progress with the patient.
- Provide patient education on pain management, treatment options, and safe use of opioid and nonopioid medications.
- Monitor patients at high risk for adverse outcomes related to opioid treatment.
- Provide information to staff on available services for consultation and referral of patients with complex pain management needs.
- Educate patients and families on discharge plans related to pain management, including side effects of pain treatment and safe use, storage, and disposal of opioids, when prescribed.
- Collect data on pain assessment and management, including types of interventions prescribed and effectiveness.
- Monitor the use of opioids to determine their safe use, including tracking of adverse effects, naloxone use, and the duration and dose of opioid prescriptions.

Pain management and pain relief are essential elements of nursing practice. In addition to assessing pain, the nurse monitors pain management, evaluates the level of pain relief, advocates for the patient, and educates the patient about treatment options for pain management. In most health care settings, only advanced practice nurses and physicians can prescribe medications for pain relief. To understand how a patient perceives pain, the nurse must understand the physiology of pain.

LO 36.3 Normal Structure and Function

The nature of pain is complex and poorly understood. It may be a protective mechanism, a warning signal, an unmet need, or a malfunction of the nervous system secondary to a disease process. It is a motor, sensory, and emotional response to a subjective feeling. It may be a symptom of a problem or disease, but it is also a disease entity that can be treated. Pain may arise from many factors: thermal or heat injury, mechanical injury (such as, a fracture), chemical injury (as the result of inhalation), or ischemic pain from lack of oxygen in tissues.

The peripheral and central nervous systems are involved in processing painful stimuli. Various structures and mechanisms in the nervous system are part of pain transmission, including nociceptors. **Nociceptors** are the free endings of afferent nerve fibers, which are sensory neurons sensitive to noxious thermal, mechanical, or chemical stimuli. These pain receptors are distributed throughout the body, with the highest density found in the skin, making the skin extremely sensitive to pain. The joints, tissues, and organs have nociceptors, although the internal organs have the lowest density of receptors that respond only to painful stimuli.

Nociception

Nociception is the process by which the sensation of tissue injury is conducted from the peripheral to the central nervous system (Fig. 36.1). The four steps in this process are transduction, transmission, modulation, and perception.

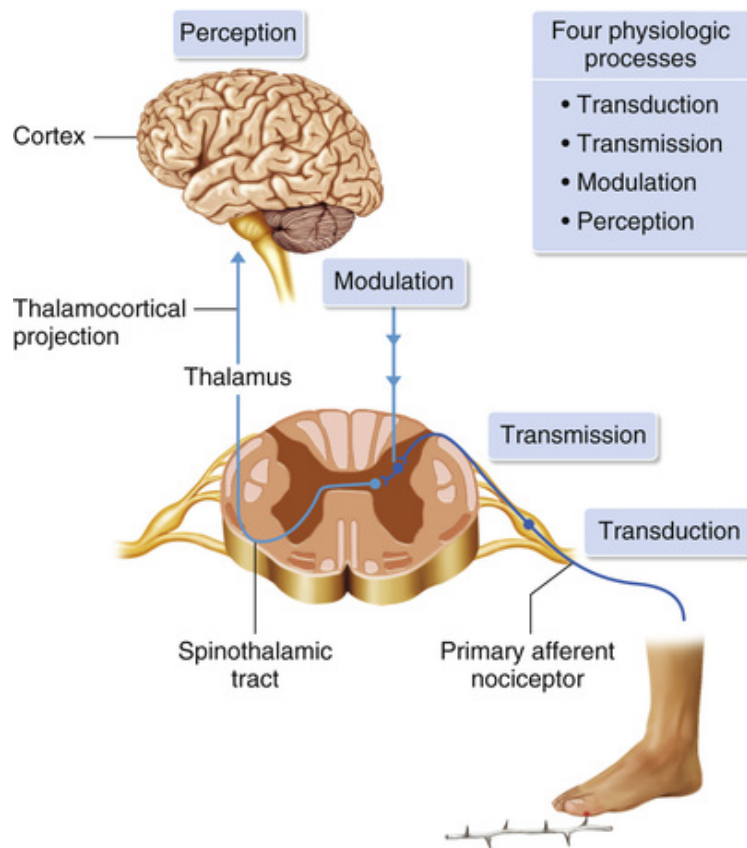

FIGURE 36.1 Four physiologic processes conduct pain from injured tissue to the peripheral and central nervous systems.

Transduction

At the site of tissue injury, nociceptors detect pain stimuli and convert (transduce) this electrochemical response into an electrical impulse (signal). This process is called *transduction*. Tissue injury initiates the release of **neurotransmitters**, chemicals that transmit signals across synapses from one neuron to another. This release of neurotransmitters is part of the inflammatory response. Release of bradykinin, substance P, histamine, serotonin, cytokines, calcium ions, potassium ions, sodium ions, and prostaglandins further activates pain receptors and amplifies the inflammatory response ([Table 36.1](#)). The inflammatory process may be the most significant cause of generalized pain.

TABLE 36.1**Neurotransmitters Involved in the Inflammatory Response**

NEUROTRANSMITTER	DEFINITION AND FUNCTION
Bradykinin	A peptide produced in the blood that mediates the inflammatory response and stimulates pain receptors
Substance P	Neuropeptide that transports pain impulses from the periphery to the central nervous system
Histamine	An amine released by immune cells in response to inflammation
Serotonin	A neurotransmitter released from the brainstem and dorsal horn that inhibits pain transmission
Cytokines	Proteins secreted by immune system cells that control inflammation
Calcium, sodium, and potassium ions	Molecules that activate nerve endings (synapses), which respond to painful stimuli by changing ionic movement into and out of nerve cells
Prostaglandins	Hormone-like compounds derived from fatty acids that are thought to increase sensitivity to pain by stimulating pain receptors on neurons

Transmission

After transduction takes place, the action potential, or electrical signal, is transmitted through an afferent nerve to the spinal cord and brain. This process is called *transmission*. Substance P, which transmits the pain impulses in nerve fibers, is one of the most important neurotransmitters in the transmission process.

Signals from the nociceptors travel along two types of afferent (sensory) nerve fibers: **A-delta fibers**, which are large-diameter, myelinated fibers with rapid conduction of signals that are translated as sharp, acute pain; and **C fibers**, which are smaller, unmyelinated fibers with slow conduction of signals that are translated as diffuse, dull, and longer lasting pain. The signals are transmitted by the spinothalamic pain transmission route (Fig. 36.2). A-delta and C fibers in the peripheral tissues carry impulses to the dorsal root ganglia and then on to the spinal dorsal horn, the spinothalamic tract, the brainstem, the thalamus, and the cerebral cortex.

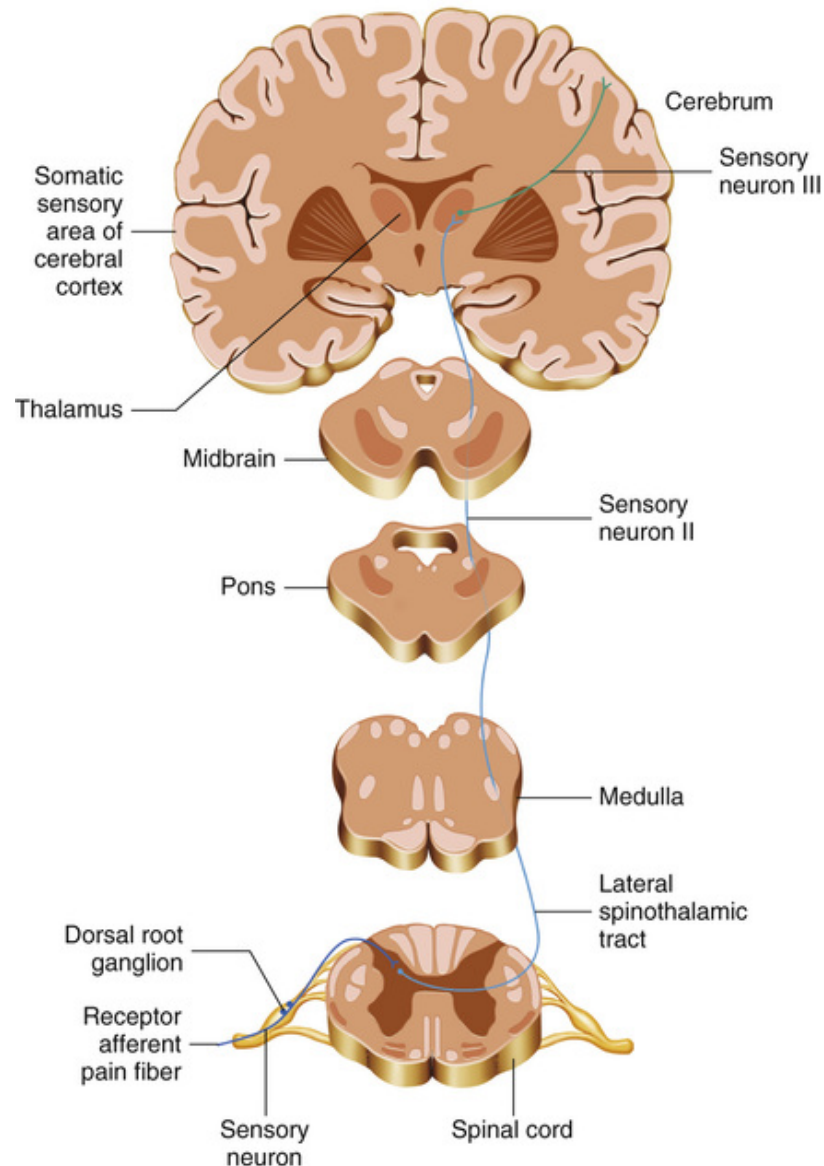

FIGURE 36.2 Spinothalamic tract through which pain sensation is conducted to the brain.

In addition to the signals traveling along the sensory transmission pathways, motor reflexes, when intact, are initiated as a protective mechanism that causes withdrawal from a pain source, as occurs when a person touches a hot item. The action potential, or electrical impulse, is propagated along nerve fibers, causing contraction of the muscle and withdrawal from the heat source.

Perception

Perception (recognition) of pain occurs when the brain translates the afferent nerve signals as pain. The thalamus sends the impulse to the somatosensory cortex, which perceives physical sensations about the location, intensity, and quality of pain; to the limbic system, which

controls emotional reactions to stimuli; and to the frontal cortex of the brain, which is involved in thought and reason. The stimulation of these areas allows a person to perceive pain.

The **pain threshold** is the lowest intensity at which the brain recognizes the stimulus as pain. This threshold varies from person to person. For instance, one person may report pain from a fracture injury as being severe, whereas another person may report pain from the same type of fracture injury as being moderate. **Pain tolerance** is the intensity or duration of pain that a patient is able or willing to endure. Tolerance varies from person to person and from one injury to another. For example, one patient in early labor may request pain medication as soon as possible because she has a low tolerance for pain. Another patient may not request pain medication until she is in active labor because she has a high tolerance for pain. People who have a decreased sense of pain or lack the ability to sense pain, such as elderly or diabetic patients with neuropathy, are at risk for tissue injury because tissue damage may occur before the individual is aware of any problems.

Modulation

Once pain is recognized, the brain can change the perception of it by sending inhibitory input to the spinal cord to impede the transmission through a process called *modulation*. The brainstem activates descending nerve fibers to send the signal back to the spinal cord. This triggers the release of natural analgesic neurotransmitters called *endogenous opioids* (i.e., enkephalins, beta-endorphins, dynorphins). Enkephalins influence the perception of pain and the associated emotional aspects. Beta-endorphins act on the central and peripheral nervous systems to reduce pain. Dynorphins are modulators of pain that may stimulate pain or reduce it, depending on which receptors are activated. These three types of neurotransmitters inhibit the transmission of pain impulses and the release of substance P by binding to opiate receptor sites in the central and peripheral nervous systems.

Pain Theories

Although the physiology of pain is not totally understood, many researchers have worked to gain a clearer idea of how pain affects the human body. Four key theories have significantly influenced current nonpharmacologic and pharmacologic interventions in pain management.

Specificity Theory

In the last decade of the 19th century, von Frey conducted research to enhance earlier primitive theories of pain. von Frey identified four somatosensory modalities—touch, cold, heat, and pain—that he believed were the origin of all skin sensations. He identified pressure points on the skin's surface associated with specific nerve endings. von Frey's work provided a foundation for later research that identified the existence of pain receptors and peripheral pathways (Moayedi & Davis, 2013).

Sensory Interaction Theory

As early as 1953, Willem Noordenbos proposed that when an injury occurs, a signal is carried along large-diameter nerve fibers (touch fibers) that may inhibit a signal carried by thin fibers (pain fibers). He thought the difference between a large-diameter signal and a small-diameter signal determined whether a person felt pain. Noordenbos's theory hinted at the physiology of pain that is now accepted science and provided a foundation for the gate control theory.

Gate Control Theory

Melzack and Wall (1965) proposed the gate control theory of pain to explain why thoughts and emotions influence pain perception. Tissue injury causes the release of bradykinin, histamine, potassium ions, sodium ions, calcium ions, prostaglandins, and serotonin. Movement of these substances in and out of the cell creates an action potential (electrical impulse). This action potential can travel along sensory nerve A-delta fibers and be translated by the brain as sharp pain, or it can travel along sensory nerve C fibers and be interpreted as chronic or persistent pain.

According to the theory, a gating mechanism exists in the dorsal horn of the spinal cord. The interplay of signals from different nerve fibers at this *gate* determines whether painful stimuli are stopped or go on to the brain. If unimpeded, impulses transmitted by activated A-delta fibers or C fibers enter the spinal cord through the gate and travel to the brain, where they are perceived as pain. If the impulses are stopped at the spinal cord gate by competing signals, they are not transmitted to the brain and there is no perception of pain.

Endorphins and enkephalins produced in the body fight pain by binding to opioid receptors at synaptic nerve terminals. Receptor binding closes the gate, inhibiting signal transmission to the brain and decreasing or eliminating pain. Opioid medications, massage, nonpainful stimuli, and topical analgesics stimulate various nerve

fibers, which close the gate, inhibit impulse transmission to the brain, and reduce the recognition of C fiber signals, resulting in analgesia.

Neuromatrix Theory

More recently, [Melzack \(2001\)](#) introduced a pain theory suggesting that pain is a multidimensional experience controlled by a body-self neuromatrix. This contemporary pain theory seeks to address the distinctive experience of pain as it is perceived and regulated by each person. The neuromatrix theory proposes that each person has a genetically controlled network of neurons that is unique and affected by that person's physical, psychological, cognitive, and life experiences. This theory seeks to take into consideration additional factors in the pain experience other than the direct relationship between tissue injury and pain ([McAllister, 2016](#)).

Types of Pain

Pain can be classified in many different ways. It can be classified by its cause: cancer pain or noncancer pain. It can be categorized by the underlying pathophysiology: nociceptive or physiologic pain and neuropathic or nervous system pain ([Pasero & McCaffery, 2011](#)). Pain also can be classified by its duration. The parameters for pain based on duration depend on the researcher defining the terms. **Acute pain** most frequently is defined as pain lasting less than 3 to 6 months. **Chronic pain** is identified as persisting longer than 3 months postoperatively ([Gilron, Vandenkerhof, Katz, et al., 2017](#)), longer than 6 months, or beyond a normal healing period ([Jamison & Edwards, 2012](#)). Treatment for each type of pain is different, as is each patient's response to the various types of pain.

Nociceptive Pain

Nociceptive pain is the most common type of pain. This type of physiologic (physical) pain occurs when nociceptors are stimulated in response to trauma, inflammation, or tissue damage from surgery. Characteristically, nociceptive pain may be sharp, burning, aching, cramping, or stabbing. Nociceptive pain originates in visceral and somatic locations. **Visceral pain** arises from the organs of the body and occurs in conditions such as appendicitis, pancreatitis, inflammatory bowel disease, bladder distention, and cancer. **Somatic pain** results from injury to skin, muscles, bones, and joints. Somatic pain occurs in conditions such as sunburn, lacerations, fractures, sprains, arthritis, and bone cancer.

Two types of symptoms are related to pain: referred pain and radiating pain. **Referred pain** originates in one area but hurts in another area, such as pain from a myocardial infarction (i.e., heart attack) (Fig. 36.3). The pain is caused by lack of oxygen to the heart muscle, but the pain may be felt in the jaw or down the left arm. **Radiating pain** extends from the source to an adjacent area of the body. For example, in gastroesophageal reflux, pain in the stomach radiates up the esophagus.

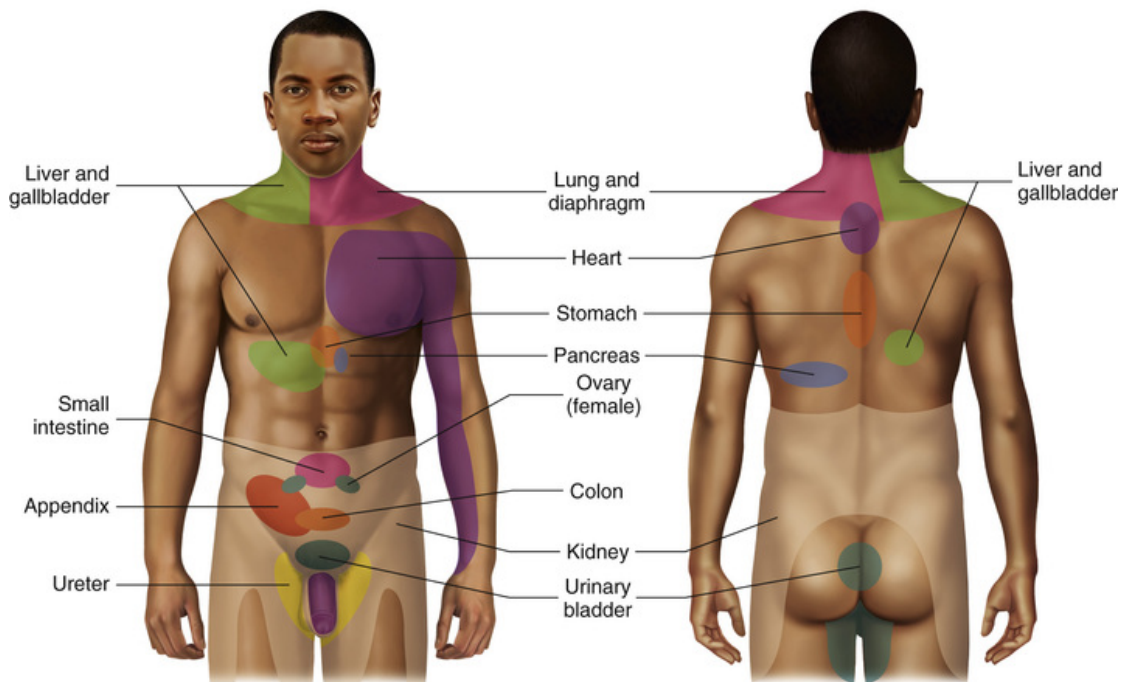

FIGURE 36.3 Pain may be referred from its site of origin to different areas of the body.

Neuropathic Pain

Neuropathic pain results from nerve injury, and the pain continues even after the painful stimuli are gone. Sometimes referred to as *pathologic pain*, neuropathic pain may stem from injury to nerves in the central or peripheral nervous system (Baron, Binder B, & Wasner, 2017). It is usually chronic pain that may be continuous or episodic. Characteristically, neuropathic pain may be burning, aching, crushing, stabbing, shooting, tingling, or numbing.

Patients may have dysesthesia (unpleasant, abnormal sensation), allodynia (pain from noninjury stimuli), hyperalgesia (excessive sensitivity), or hyperpathia (greatly exaggerated pain reaction to stimuli). Sources of neuropathic pain include neuropathies, tumors, infection, and chemotherapy. Examples of disease processes that may

invoke or involve secondary neuropathic pain are diabetes mellitus, cerebrovascular accident (such as brain attack or stroke), viral infections, carpal tunnel syndrome, and phantom limb pain. **Phantom pain** occurs when the brain continues to receive messages from the area of an amputation. Over time, the brain adapts to the loss of the limb, and the pain stops. This adaptation is called *plasticity* (Yanagisawa, Fukuma, Seymour, et al., 2016).

Psychogenic Pain

Pain that is perceived by an individual but has no physical cause is called **psychogenic pain**. It may be caused, increased, or prolonged by mental, emotional, or behavioral factors. Some patients may report headaches, back pain, or stomach pain that is psychogenic pain. Even though there is not a physical cause, the pain is treated through a variety of interventions to alleviate the patient's distress. [Table 36.2](#) outlines the various types of pain.

TABLE 36.2**Types of Pain**

PAIN TYPE	DEFINITION	SOURCES OF PAIN
Acute	Pain that results from an acute injury, has a rapid onset and short duration, and subsides when the injury is healed	Trauma, surgery, labor, acute disease
Cancer (malignant)	Pain that stems from cancer or cancer treatment	Tumor pressing on a bone or nerve, organ obstruction, toxicity from chemotherapy
Noncancer	Acute pain that becomes chronic pain and may be prolonged and potentially life-threatening	Whiplash injury, low back pain, osteoarthritis, sickle cell disease, neuralgia
Chronic	Persistent pain that lasts longer than 6 months, may be episodic or continuous, and may lead to disability	Arthritis, fibromyalgia, neuropathy
Neuropathic	Episodic or continuous pain that results from a nerve injury and persists even without painful stimuli	Tumor, infection, toxicity from chemotherapy, neuropathy
Nociceptive	Physiologic pain that results from nociceptor stimulation in response to an injury or tissue damage	Surgery, inflammation, trauma
Visceral	Nociceptive or physiologic pain	Organs, such as heart, lungs, kidneys, gallbladder
Labor	Pain during birthing of a baby	Uterine contractions, cervical dilation, pelvic pressure
Referred	Pain in an area other than the area causing the pain	Jaw and left arm pain with a myocardial infarction
Radiating	Pain that extends to other areas	Gastroesophageal reflux, extending to the thorax
Somatic	Nociceptive or physiologic pain	Bone, skin, joint, muscle
Phantom	Neuropathic or pathologic pain from loss of a body part	Amputated extremity
Psychogenic	Perceived pain without a physical cause	Headache, backache, stomach ache
Breakthrough	Spike in pain when chronic pain already exists	Surgery, injury, fluctuation in pain associated with existing condition such as cancer

LO 36.4 Altered Structure and Function

Pain is a complex collection of physical sensations and emotional responses that can be altered by many variables. Physiologic changes, age, gender, emotions, cognitive function, sociocultural factors, and the ability to communicate may influence the sensation of pain.

Alterations in Pain Pathways

Damage and hypersensitivity anywhere along the pain pathway—in pain receptors, the spinal cord, or cerebral cortex—can alter a patient's perception of pain. Neurologic injuries that result in permanent damage to the spinal cord, such as paraplegia or quadriplegia, prevent a person from feeling pain in areas below the level at which the spinal cord was injured or severed. Neurologic damage resulting from disease processes such as peripheral neuropathy due to diabetes mellitus alters pain perception. Psychological dysfunction may result from or lead to altered pain perception.

Physiologic Alterations Caused by Pain

Acute injury or tissue damage triggers physiologic stress responses, which are attempts by the body to protect itself. These responses may have adverse effects for the patient if pain is left untreated. The sympathetic nervous system is stimulated first, and if the pain is not relieved, the parasympathetic nervous system is stimulated. Each body system has its specific response to pain, as follows (Pasero & McCaffery, 2011):

- *Endocrine system:* Pain triggers the release of excessive amounts of hormones, including cortisol, adrenocorticotrophic hormone (ACTH), antidiuretic hormone (ADH), growth hormone, catecholamines, glucagon, insulin, and testosterone. The release of these hormones results in carbohydrate, protein, and fat catabolism (breakdown), and poor use of glucose, leading to hyperglycemia (high blood glucose levels).

- *Cardiovascular system:* Pain increases cardiac workload and oxygen demand. Decreased oxygen delivery to the cells leads to increases in the heart rate and force of contraction. Blood pressure increases, and increased workload may cause plaque formation, narrowing of the arteries, possible blood clot formation, and increased risk for myocardial infarction (heart attack). In situations of prolonged or unrelieved pain, blood pressure and pulse may decrease due to parasympathetic stimulation.
- *Respiratory system:* Pain reduces tidal volume (air exchange) and increases inspiratory and expiratory pressures. The respiratory rate increases and becomes irregular in an attempt to distribute more oxygen to the cells. Prolonged pain may cause a reluctance to breathe deeply, which limits thoracic expansion. If this continues, pneumonia and atelectasis may occur.
- *Musculoskeletal system:* Pain impairs muscle function and the capacity to perform activities of daily living (ADLs). The patient experiences muscle spasms, muscle tension, and fatigue. A withdrawal response is initiated by the patient's prolonged pain.
- *Genitourinary system:* Pain causes the release of ACTH, catecholamines, aldosterone, angiotensin II, cortisol, and prostaglandins. Blood pressure increases through activation of the renin-angiotensin system. Urine output decreases, and urinary retention increases. Fluid overload and hypokalemia may result.
- *Gastrointestinal system:* Pain decreases gastric emptying and motility, increases gastrointestinal

secretions, and increases smooth muscle tone. Metabolism is slowed, resulting in indigestion from the slow movement of food in the gastrointestinal tract. Constipation may develop from decreased intestinal motility.

- *Immune system:* The inflammatory response is initiated by painful stimuli. Inflammatory mediators are released in an attempt to prevent further tissue injury, fight infection, and reduce pain. Some of the inflammatory mediators that are released may contribute to persistent pain.

Factors Influencing Pain

Differences in individual characteristics—age, gender, morphology, disabilities, culture, ethnicity, and religion—play a role in the behavioral reaction to pain and in the perception of pain. Reactions to pain and perceptions of pain vary among individuals, even within the same culture. The nurse must understand differences in cultures and attend to the particular needs of each patient. When providing culturally sensitive nursing care, the nurse adjusts the plan of care to incorporate the patient's needs.

The meaning of pain varies among individuals. Pain is physical, part of a disease entity or a symptom of an injury, but it also can result from emotional or psychological distress. For example, unresolved psychological pain may result in posttraumatic stress disorder, anxiety, or depression. In cases of acute pain, anxiety increases the severity of the pain experienced, reduces the individual's tolerance to pain, and decreases the ability to cope with pain. Individuals with chronic pain are more likely to suffer from depression and fatigue and are more likely to attempt suicide (Triñanes et al., 2015). Current pain is influenced by an individual's previous experiences with pain. Having had an injury or surgery previously, a patient has a preconceived idea about what the pain will feel like and what methods are effective for pain relief.

Just as the meaning of pain and the perception of pain are individualized responses, the response to analgesics is influenced by each person's genetic makeup (Box 36.2). Differences in pain perception and management are described in Box 36.3.

Box 36.2

Genetics and Analgesic Metabolism

Research is being conducted to determine the degree to which genetic makeup influences how individuals respond to medications:

- Pharmacogenetics looks at a person's genotype to determine how the individual metabolizes medications. Pharmacogenomics is the study of how genes influence an individual's response to medications ([US National Library of Medicine, 2018](#)).
- Genetic testing can predict how individuals are likely to respond to certain drugs.
- Studies indicate that genetic variations in several genes may predispose patients to increased postoperative pain. These genetic variations regulate the severity of postoperative pain, and influence the metabolism, effectiveness, and adverse side effects of analgesics ([Palada, Kaunisto, & Kalso, 2018](#)).
- Pain management can be improved through pharmacogenetics by predicting the patient response to analgesics before they are administered ([Palada, Kaunisto, & Kalso, 2018](#)).

Box 36.3

Diversity Considerations

Life Span

Infants and Children

- Preterm infants may exhibit an exaggerated response to pain and more severe behavior and sensory outcomes than full term infants ([Witt, Coynor, Edwards, et al., 2016](#)).
- Newborns have measurable behavioral, metabolic, hormonal, and physiologic reactions to pain ([Witt, Coynor, Edwards, et al., 2016](#)).
- Signs and symptoms of pain in infants and young children include pallor, diaphoresis, decreased oxygen saturation, and increased heart rate, blood pressure, and respiratory rate. Preverbal children should be observed for excessive crying, irritability, poor feeding, and sleep disturbance as indications of pain ([Krauss, Calligaris, Green, et al., 2016](#)).

- Parents or caregivers may hold infants or children during painful procedures to promote comfort.
- Toys, video games, or other forms of entertainment may be used to distract children undergoing painful procedures.
- Age-appropriate language should be used with children to prevent unnecessarily frightening them before a potentially painful treatment.
- Undertreatment of pain is frequently reported in young children, children with cognitive challenges, and children in developing countries (Krauss, Calligaris, Green, et al., 2016).
- There is a lack of research evidence on the effectiveness of available analgesics to treat postoperative pain in children (Ferland, Vega, & Ingelmo, 2018).

Older Adults

- Pain is not a consequence of natural aging but is common in the elderly (Booker, Bartoszczyk, & Herr, 2016). All pain needs to be investigated by the health care provider.
- The sensation of pain is just as acute in elderly patients as it is in young-adult patients, but among elderly patients the transmission of pain impulses may be altered by chronic diseases or disorders causing a decreased or increased sensation of pain with diabetes mellitus and peripheral neuropathies, or an increased sensation of pain with arthritis (Booker, Bartoszczyk, & Herr, 2016).
- The ability of elderly individuals to recognize pain may be blunted or masked by illness and medications.
- Older adults are at an increased risk of experiencing negative side effects from analgesics taken to treat chronic pain. Analgesics that may cause difficulty include acetaminophen, nonsteroidal antiinflammatory medications, and opioids (McDonald, Coughlin, and Jin, 2018).
- Elderly people who are depressed or cognitively impaired may be unable to tell others that they are in pain. Elderly patients, like all adults, may be reluctant to take pain medications for fear of addiction (Booker & Haedtke, 2016; Nolan, 2017).
- Decreased metabolism and clearance of drugs may lead to toxic levels in older adults; therefore many medications need to be administered in lower doses (Booker, Bartoszczyk, & Herr, 2016).
- Polypharmacy is a common concern with elderly or chronically ill patients who take multiple medications simultaneously, including

prescription drugs, over-the-counter medications, and herbal supplements (Cantlay, Glyn, & Barton, 2016).

- Patients should be encouraged to keep all medications in their original containers to prevent confusion and facilitate medication reconciliation by health care personnel in the event of an individual's hospitalization.

Gender

- The effect of prescribed opioids on men and women can differ depending on the type of opioid, dose, and hormonal interaction (Mazure & Fiellin, 2018).
- Women seek help for pain more often than men do, but women are less likely to receive treatment (Musey, Linnstaedt, Platts-Mills, et al., 2014).
- Women are more likely to be given sedatives for pain, and men are more likely to be given analgesics for pain (Musey, Linnstaedt, Platts-Mills, et al., 2014).
- Pregnant women who abuse prescription pain relievers put their infants at risk for neonatal abstinence syndrome after delivery (CDC, 2018).

Culture, Ethnicity, and Religion

- Not all individuals of the same culture or ethnicity express pain in the same manner.
- Acceptable treatment for pain may vary depending on an individual's religious beliefs or cultural background.
- Education regarding pain management strategies and medication administration information should be provided in the patient's native language to enhance comprehension and effectiveness.

Disability

- A patient with impaired cognition may not be able to communicate pain. Facial expressions, vocalization of noises, or changes in physical activity or routines may be signs of pain.
- Noncognitive pain assessment tools such as the Wong-Baker FACES Pain Rating Scale may be used to assess pain levels.

- Patients who are intubated may be able to write or point to a pain assessment tool to indicate their level of pain.
- Restlessness, elevated blood pressure, and/or pulse rate may signal increased pain levels in patients who are intubated and sedated and unable to communicate verbally or in writing.

Morphology

- Pain medication dosages need to be adjusted based on the height and weight of patients of all ages due to body surface area and metabolic differences.
- Individuals who are morbidly obese are at greater risk of respiratory depression and upper airway obstruction when given opioids (Kramer, Gazelka, Thompson, et al., 2018).
- Research indicates that obese people tend to experience more pain in more locations than individuals of average weight (Okifuji & Hare, 2015).

Safe Practice Alert

When treating an elderly patient for pain, start with a low dose within the prescribed range and slowly increase the dosage to relieve pain. Opioid doses should start 50% to 75% lower than the normal adult dose to avoid oversedation (Booker, Bartoszczyk, & Herr, 2016).

LO 36.5 ♦ Assessment

Completing a thorough pain assessment helps the nurse develop a profile of the patient, facilitating the identification of patient needs or problems in relation to pain. [Box 36.4](#) contains sample questions to ask patients about their pain. Except in emergent situations, the nurse begins a thorough, focused assessment by obtaining a health history specifically related to the patient's complaint of pain.

Box 36.4

Health Assessment Questions

- What is the intensity of your pain? Would you describe your pain as mild, moderate, or severe? On a pain scale with 0 being no pain and 10 being excruciating pain, how do you rate your pain?
- How long have you been experiencing this pain? Has the pain begun recently, or have you been in pain longer than 6 months?
- Where is the pain you are experiencing? Does it radiate anywhere? Point to exactly where the pain is and where it radiates to, if it does.
- Have you noticed any pattern with the pain you are experiencing? Does the pain occur in the morning, occur when you are ambulating, or awaken you during the night?
- Is the pain sharp or dull, aching or throbbing, or burning? Is the pain constant or intermittent (comes and goes)?
- Are there precipitating factors that occur before the pain is felt? What have you tried for pain relief? Have you tried applying heat or ice packs, or massaging or rubbing the area? Has what you have tried helped?
- What medications are you currently using, or have you taken in the past to relieve pain?

If a patient is in excruciating pain due to trauma or an ischemic attack, a rapid, narrowly focused assessment to determine the location, onset, quality, and severity of the pain must be completed before appropriate emergency treatment can be initiated. In these emergent situations, the more complete pain assessment may be deferred until some degree of pain relief is achieved. Patients who are in severe pain

are unable to focus on answering open-ended questions designed to gather extensive information. When patients are exhibiting signs of severe pain, nurses must use short, closed-ended questions to gather specific information in the most expedient manner possible.

Pain History and Assessment

Because pain is a very individual, subjective experience, nurses cannot objectively assess pain in patients. Completing a thorough pain assessment requires nurses to ask patients about several critical areas of concern: pain location, onset, quality, intensity, and pattern; precipitating and alleviating factors; and associated symptoms. The mnemonics SOCRATES, PQRST, and OLDCARTS are used by many health care personnel to help them remember each area of pain assessment. The letters in SOCRATES have the following meanings:

- S:** Site (Where is the pain located?)
- O:** Onset (When did the pain start? Was it gradual or sudden?)
- C:** Character (What is the quality of the pain? Is it stabbing, burning, or aching?)
- R:** Radiation (Does the pain radiate anywhere?)
- A:** Associations (What signs and symptoms are associated with the pain?)
- T:** Time course (Is there a pattern to when the pain occurs?)
- E:** Exacerbating or relieving factors (Does anything make the pain worse or lessen it?)
- S:** Severity (On a scale of 0 to 10, what is the intensity of the pain?)

PQRST stands for provocation (initiating factor), quality, region (location), severity, and temporality (onset, duration, fluctuation), and OLDCARTS represents the pain assessment aspects of onset, location/radiation, duration, character, aggravating factors, relieving factors, timing, and severity.

In addition to asking about the previous factors, nurses should ask patients who are experiencing pain about past pain experiences, the effect their pain is having on ADLs, the meaning patients associate with their pain, and coping strategies that they are using to deal with the discomfort. Nurses should observe carefully the emotional response of patients who are in pain. When patients are unable to communicate verbally, nurses must observe for signs or symptoms of pain and evaluate precipitating factors that could result in pain. Although there are no laboratory or diagnostic studies that assess for pain level, many

types of pain assessment tools have been developed to assist patients of all ages.

Pain Assessment Tools

Pain can be assessed with the use of tools specifically designed to help patients evaluate the intensity and location of their pain and to aid health care team members in evaluating the effectiveness of pain management. Many types of pain assessment tools are available, including cognitive and noncognitive scales. The most reliable indicator of the existence and intensity of pain is the patient's self-report. The most often used pain assessment tool is the 0-10 Numeric Rating Scale (NRS), which allows patients to verbally report and quantify their pain level. Nurses can introduce the 0–10 pain scale to patients by saying, “On a scale of 0 to 10, with 0 being no pain and 10 being the worst pain possible, how would you describe your pain?” Generally, a reported pain level of 1 to 3 is considered mild pain. Pain reported in the range of 4 to 7 is moderate pain. Pain of 8 to 10 is interpreted as severe pain. These categories may change depending on pain-related interference with functioning (Boonstra, Stewart, Köke, et al., 2016).

Descriptors of pain are denoted verbally in the Verbal Descriptor Scale and the Wong-Baker FACES Pain Rating Scale. Use the FACES scale or behavioral observations to interpret expressed pain when patients have difficulty communicating their pain intensity. These tools can be used worldwide for assessing pain (Fig. 36.4).

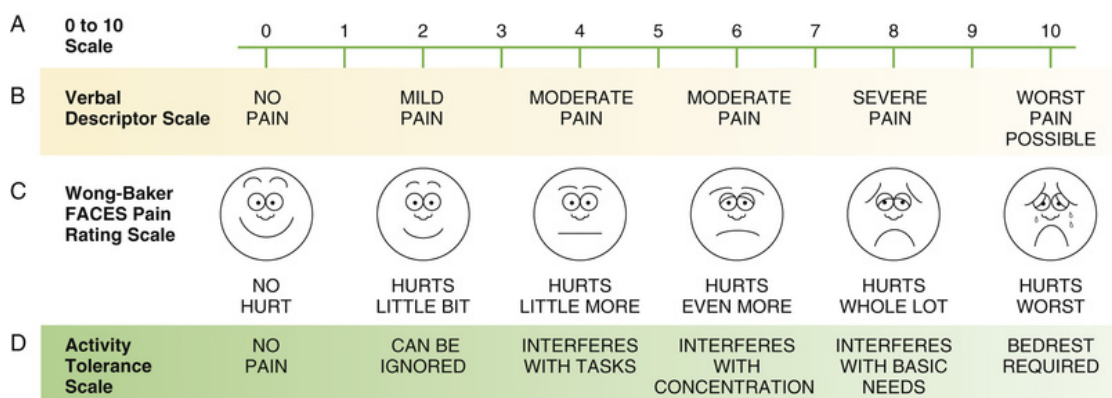

FIGURE 36.4 Visual cues, descriptive terms, and activity levels can be useful in helping patients identify their level of pain if they are unable to relate to the numeric scale. A, Numeric Scale. B, Verbal Descriptor Scale. C, Wong-Baker Faces Pain Rating Scale. D, Activity Tolerance Scale. (C, From Wong-Baker FACES Foundation (2018). Wong-Baker FACES Pain Rating Scale. Retrieved with permission from <http://www.WongBakerFACES.org>.)

Many pain assessment tools are used, but there is a lack of tools for chronic pain in neonates, newborns, and young children (Hall & Kanwaljeet, 2014). Table 36.3 shows the Neonatal Infant Pain Scale (NIPS) that is recommended for use with children younger than 1 year of age. A score higher than 3 indicates that the child is in pain. It is used as a noncognitive pain assessment scale in the neonatal intensive care unit (NICU), newborn nursery, and pediatrics department to determine pain levels of newborns and infants. On the basis of the score, the nurse can determine the need for pain medication.

TABLE 36.3
Neonatal Infant Pain Scale

PAIN ASSESSMENT	EXAMPLE	SCORE
Facial expression	Restful face, neutral expression	0 (relaxed muscles)
	Tight facial muscles; furrowed brow, chin, and jaw (negative facial expression, including nose, mouth, and brow)	1 (grimace)
Cry	Quiet, not crying	0 (no cry)
	Mild moaning, intermittent	1 (whimper)
	Loud scream; rising, shrill, continuous (If baby is intubated, silent cry with obvious mouth and facial movement may be scored.)	2 (vigorous cry)
Breathing patterns	Usual pattern for this infant	0 (relaxed)
	Indrawing, irregular, faster than usual; gagging; breath-holding	1 (change in breathing)
Arms	No muscular rigidity; occasional random movements of the arms	0 (relaxed/restrained)
	Tense, straight legs; rigid and/or rapid extension, flexion	1 (flexed/extended)
Legs	No muscular rigidity; occasional random leg movement	0 (relaxed/restrained)
	Tense, straight legs; rigid and/or rapid extension, flexion	1 (flexed/extended)
State of arousal	Quiet, peaceful sleeping or alert random leg movement	0 (sleeping/awake)
	Alert, restless, and thrashing	1 (fussy)

From Hockenberry, M., Wilson, D., & Rodgers, C. (2017). *Wong's essentials of pediatric nursing* (10th ed.). St. Louis: Elsevier.

Vital Signs

Physical assessment of the patient with pain begins with vital sign assessment. Vital signs may vary according to how the patient perceives pain. Elevated pulse and blood pressure values may indicate acute pain and a need for pain medication. A decrease in blood pressure and pulse

rate may indicate chronic pain. While taking vital signs, the nurse may ask the patient what his or her pain level is or, for the nonverbal patient, determines the pain level on a noncognitive pain scale. The nurse can perform measures such as repositioning the patient or therapeutically touching the patient in an effort to decrease the pain level before administering pain medication.

Physiologic Responses to Pain

Multiple systems of the body may be affected by pain, depending on its severity and duration. For instance, if a patient is in acute pain, the patient's heart rate, respiratory rate, and blood pressure increase above the patient's normal baseline due to a response by the sympathetic nervous system. With chronic or prolonged pain, the parasympathetic nervous system responds with a decrease in the systolic blood pressure and a decrease in the pulse rate below the patient's normal baseline. [Table 36.4](#) contains a list of the clinical manifestations commonly associated with each body system.

TABLE 36.4**Clinical Manifestations of Pain**

BODY SYSTEM	CLINICAL MANIFESTATIONS
Cardiovascular	Increased heart rate and force of contraction in acute pain Increased systolic blood pressure in acute pain Decreased systolic blood pressure in prolonged pain or chronic pain Decreased pulse in prolonged pain or chronic pain Increased myocardial oxygen demand Increased vascular resistance Hypercoagulation Chest pain
Respiratory	Increased respiratory rate Increased bronchospasms Pneumonia Atelectasis
Gastrointestinal	Delayed gastric emptying Decreased intestinal motility Constipation Anorexia Weight loss
Musculoskeletal	Muscle spasms Increased muscle tension Impaired mobility Weakness Fatigue
Endocrine	Fever Shock
Genitourinary	Decreased urine output Urinary retention Fluid overload Hypokalemia
Sensory	Pallor Diaphoresis Dilated pupils in acute pain Constricted pupils in deep or prolonged pain Rapid speech in acute pain Slow speech in deep or prolonged pain
Immune	Impaired immune function Infection

Behavioral and Psychological Responses to Pain

While assessing the patient, the nurse may notice behaviors that the patient is exhibiting in response to pain, including facial grimaces, clenched teeth, rubbing or guarding of the painful area, agitation, restlessness, and withdrawal from painful stimuli. A patient in labor may use effleurage (rhythmic massaging of the abdomen with her hands) and immobilization to help deal with uterine contraction pain.

Vocalizations of pain may be expressed as crying, moaning, or screaming.

Patients may exhibit psychological responses to pain, including anxiety, fear, depression, anger, irritability, helplessness, and hopelessness. When a patient is anxious, fearful, or angry, the nurse addresses the patient's physical needs first. The nurse provides a comfortable environment and privacy for the patient. Then the nurse communicates with clear, simple validating statements to relieve the stress of the situation and develop a trusting relationship with the patient. The nurse needs to allow time for the patient to verbalize feelings and concerns regarding pain relief to assess the patient's coping abilities. The nurse acknowledges the patient's pain experience and expresses acceptance of the patient's response to pain. After pain has been assessed, the nurse uses nursing diagnoses to develop a plan of care for the patient.

LO 36.6 ♦ Nursing Diagnosis

Nurses should carefully document all physiologic, behavioral, and psychological responses observed during assessment so that appropriate nursing diagnoses and goals can be formulated, making holistic pain management possible. After a thorough pain assessment, the type and meaning of a patient's pain are established, allowing appropriate nursing diagnoses to be identified, goals and outcomes to be set, and adequate pain management to take place.

Nursing diagnoses for pain are developed based on objective and subjective patient data collected by the nurse during the patient's assessment. Common International Classification for Nursing Practice (ICNP) nursing diagnoses directly associated with pain include:

Acute Pain

- Supporting Data: Long-bone fracture, reported pain of 10 of 10, pain with movement, request for pain medication

Chronic Pain

- Supporting Data: Deformity of joints, limited mobility, inability to manage activities of daily living, feelings of helplessness

Difficulty Coping

- Supporting Data: Severe pain, inability to ask for help, lack of appetite, poor concentration

After nursing diagnoses are identified from the assessment information, the nursing care plan is developed, starting with goal development.

LO 36.7 ♦ Planning

Reviewing data collected during the assessment phase of the nursing process helps the nurse identify and prioritize nursing diagnoses and set realistic outcome criteria based on a patient's condition and capabilities. Goals and expected outcomes must take into consideration the economic, psychosocial, physical, and other resources available in individual situations.

Goals and Outcome Statements

The following are examples of goals or outcome statements:

- Patient will report a steady decrease in pain level to 4 or 5/10 within 5 postoperative days.
- Patient will perform activities of daily living each day, reporting chronic pain at a level of 3 or less within 1 week of starting on newly prescribed pain medication.
- Patient will report increased ability to concentrate on routine activities within 2 hours of receiving the prescribed dose of analgesic medication.

Because various members of the health care team specialize in different ways of accomplishing pain relief, a multidisciplinary approach is often needed to achieve pain relief goals. The multidisciplinary team collaborates to develop a plan of care for the patient's pain management. While maintaining ultimate responsibility for overseeing the implementation and proper completion of duties, the nurse may delegate appropriate duties to unlicensed assistive personnel (UAP) (Box 36.5).

Box 36.5

Interprofessional Collaboration and Delegation

Complementary Pain Therapy

- The patient with pain needs a multidisciplinary treatment plan to ensure pain management and relief.
- Music therapy, massage therapy, physical therapy, and the services of health care providers specializing in pain management provide exercise, muscle manipulation, and other complementary therapies to manage pain in addition to medication.
- The nurse can delegate unlicensed assistive personnel to perform nonpharmacologic pain management techniques, such as administering back rubs, repositioning the patient, performing oral hygiene, changing the linens, talking to the patient, and darkening the room, to help make the patient more comfortable and assist in decreasing pain.

1. Write a short-term and long-term goal or outcome for M. C.'s postoperative nursing diagnosis: *Acute Pain* with supporting data of internal fixation of left femur, increased heart rate, reluctance to move, and reported pain level of 8 of 10 (8/10).

While planning care, the nurse must consider ethical and legal aspects of managing pain to comply with the American Nurses Association (ANA) standards of practice and Code of Ethics for Nurses and with the regulatory standards of TJC. The most commonly encountered ethical dilemmas are undertreatment of pain, especially among children and elderly patients, and thorough management of pain. The nurse has a legal obligation to act on behalf of patients to ensure pain relief (ANA, 2016) (Box 36.6).

Box 36.6

Ethical, Legal, and Professional Practice

Meeting Pain Management Standards

When patients are satisfied with nursing care and obtain pain relief and no adverse effects from medication or errors in administration occur,

patients are more likely to report satisfaction with their care. Nurses can implement several strategies to ensure ethical compliance with pain management standards and to reduce legal risks of medication administration:

- Check patient allergies and sensitivities before administering any medication.
- Use the Six Rights of Medication Administration when administering medications.
- Follow the steps of the nursing process.
- Monitor for side effects or adverse effects of medication.
- Report uncommon patient responses to analgesia to the patient's primary care provider.
- Communicate effectively with the patient.
- Teach the patient about the use of medications and potential adverse side effects.
- Evaluate the effect of medication on the patient, and document the patient's response. Use equipment such as patient-controlled anesthesia pumps properly.
- Document accurately and in a timely manner.
- Follow the facility's policies and procedures.
- Arrange for appropriate referrals to meet the needs of the patient.

When the pain assessment has been completed and the plan of care has been formulated with nursing diagnoses and goals appropriate for the patient, implementation of the plan of care begins (Table 36.5).

TABLE 36.5
Care Planning

ICNP NURSING DIAGNOSIS WITH SUPPORTING DATA	NURSING OUTCOME CLASSIFICATION (NOC)	NURSING INTERVENTION CLASSIFICATION (NIC)
<i>Acute Pain</i> Long-bone fracture Reported pain of 10 of 10 Pain with movement Request for pain medication	<i>Pain control</i> Reports pain controlled	<i>Pain management</i> Select and implement a variety of measures (e.g., pharmacologic, nonpharmacologic, interpersonal) to facilitate pain relief as appropriate.

From Butcher, H. K., Bulechek, G. M., Dochterman, J., & Wagner, C. (2018). *Nursing interventions classification (NIC)* (7th ed.). St. Louis, MO: Mosby; Moorhead, S., Swanson, E., Johnson, M., & Maas, M. (Eds.) (2018). *Nursing outcomes classification (NOC)* (6th ed.). St. Louis: Mosby. The conceptual care map for M. C. can be found at <http://evolve.elsevier.com/YoostCrawford/fundamentals/>. It is partially completed to indicate how to use the map as a learning tool. Complete the nursing diagnoses using the example conceptual care maps shown in **Chapters 8 and 25 to 33**.

LO 36.8 ♦ Implementation and Evaluation

Implementation of the plan of care is performed in response to the patient's needs. The plan of care is modified as the patient's status changes. The goal of implementation is to progress toward the desired outcomes of care. Multimodal pain management combines a variety of treatments to provide holistic pain management, including nonpharmacologic interventions, nonopioid analgesics, opioid analgesics, and adjuvant analgesics (coanalgesics) to optimize patient outcomes (ANA, 2016).

Nonpharmacologic Pain Management and Complementary and Alternative Therapies

Nonpharmacologic pain management and complementary and alternative therapies are recommended for patients with mild pain who do not want to use medication to control pain. These therapies are often used concurrently with medication administration and counseling to support patients with intractable or chronic pain. Complementary therapies are implemented to enhance the effect of pharmacologic treatment, and alternative therapies take the place of pharmacologic interventions. During the assessment process, nurses should inquire about the patient's use of herbal remedies to avoid potential medication interactions if analgesics are included in the plan of care.

Many types of social interaction and therapies target the mind, body, and spirit and help alleviate pain. Many are independent nursing interventions that do not require a practitioner order. They may include the positioning of patients for comfort and for proper body alignment (see Chapter 28); postoperative splinting (see Chapter 37); massage to promote relaxation and decrease muscle tension and pain perception (see Chapter 27); and progressive relaxation techniques, guided imagery, and meditation (see Chapter 32).

Distracting patients by encouraging them to watch television or listen to music may lessen their focus on and awareness of pain. Engaging patients in conversation and singing are other forms of distraction. Spiritual support, such as prayer or meditation, can be encouraged in individual circumstances to draw on the patient's beliefs and faith as a means of diminishing pain. Additional complementary and alternative pain therapies are listed in Box 36.7.

Box 36.7

Complementary and Alternative Pain Therapies

- *Herbal remedies:* The use of certain herbal mixes relieves pain; examples are ginger, rosehips, feverfew, and black cohosh.
- *Yoga:* Slow stretches and deep breathing build strength, release muscle tension, and improve flexibility to bring the body into balance and the mind into a focus on something other than pain.
- *Biofeedback:* Taking control of body responses to pain is achieved through voluntary control over physiologic body activities, such as relieving muscle tension.
- *Meditation:* Meditating (sometimes referred to as mindfulness) restores the body to a calm state through controlled breathing and relaxation to decrease stress and pain.
- *Aroma therapy:* Breathing the fragrance of essential oils that contain oxygenating molecules can help transport nutrients to the cells in the body.
- *Hypnosis:* Used for all types of pain, hypnosis alters the state of consciousness to modify memory and perception of pain and reduces cortical activation associated with painful stimuli.
- *Reiki and therapeutic touch:* Hand placement to correct or balance energy fields restores health by restoring communication between cells, thereby diminishing pain.
- *Traditional Chinese medicine:*
 - *Acupuncture:* The insertion of fine needles into the skin at various depths causes secretion of endorphins and interferes with transmission of pain impulses.
 - *Acupressure:* The application of pressure at acupuncture sites interferes with transmission of pain impulses.
 - *Cupping:* The application of plastic or glass cups with suction over muscle areas increases local circulation and promotes muscle relaxation and pain reduction.

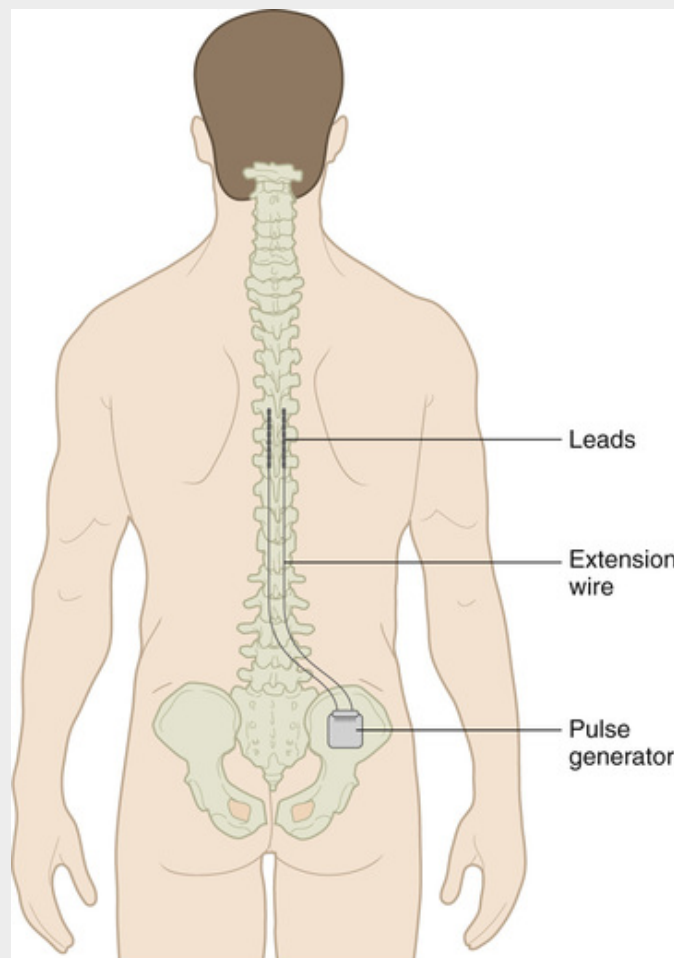

2. Identify a minimum of five nursing interventions to decrease M. C.'s pain using nonpharmacologic methods.

Neurologic and neurosurgical pain therapies using electrical stimulation of the area of pain and brain stimulation are options for dealing with chronic pain, as are types of neurosurgery (Box 36.8). Although many of these therapies are not independent nursing actions, the nurse should understand these interventions to better support patients in need of such treatment. When patients experiencing chronic pain have decided to try complementary or alternative therapies for pain relief, it is important that nurses listen and support their requests. Increasing numbers of patients are embracing nonpharmacologic pain interventions on the basis of research and fear of addiction or side effects from narcotic analgesics.

Box 36.8

Neurologic and Neurosurgical Pain Therapies

- *Spinal cord stimulation* (SCS): Implantation of a device into the epidural space treats chronic neurologic pain by producing a tingling sensation that alters pain perception. Leads are connected to a generator in the abdomen or buttocks. (see illustration)

- *Transcutaneous electrical nerve stimulation (TENS)*: Stimulation of selective receptors by applying low-intensity current through skin electrodes interferes with transmission of pain impulses in nerve fibers, reducing pain and analgesia use and improving mobility. A TENS unit is a portable, battery-operated stimulator with a lead wire and electrode pads that are applied to the skin in the area of pain. It is contraindicated for patients with pacemakers or cardiac arrhythmias.
- *Application of heat and cold*:
 - *Cryotherapy*: Application of cold decreases swelling and pain, produces local analgesia, and slows nerve conduction, which improves functioning. Examples of cold therapy are ice bags and cold compresses.
 - *Thermotherapy*: Application of heat decreases pain by producing local analgesia, dilating blood vessels, and improving functioning. Examples of heat therapy are hot compresses, heating pads, and sitz baths.
 - Apply heat or cold for 15 minutes to avoid tissue injury.

- *Cordotomy*: Surgical procedure in which pain-conducting tracts in the spinal cord are disabled to diminish severe pain and cancer pain.
- *Neurectomy*: Surgical removal of a nerve or a section of nerves to treat chronic pain when other treatments fail.
- *Rhizotomy*: Surgery to sever nerve roots in the spinal cord for neuromuscular conditions such as spastic cerebral palsy and back pain.
- *Sympathectomy*: Surgical dissection of nerve tissue of the sympathetic nervous system in the cervical, thoracic, or lumbar spine to disrupt signals to the brain.

Pharmacologic Pain Management

The nurse's role in pharmacologic pain management is to assess for pain, administer pain medication accurately and safely, and teach the patient about medication self-administration (Box 36.9). To safely administer medications, the nurse needs to understand many routes of administration. Administration is achieved by oral, transmucosal, sublingual, rectal, intradermal, subcutaneous, intramuscular, transdermal, and intravenous routes, as well as by gastric tube and inhaler.

Box 36.9

Patient Education and Health Literacy

Empowering Patients Experiencing Pain

- Teach patients to keep a journal of the type of pain, onset of pain, activity related to the pain, intensity of the pain, and nonpharmacologic and pharmacologic measures used to relieve pain.
- Teach patients methods of nonpharmacologic treatment to relieve pain, such as massage, guided imagery, muscle relaxation, and distraction.
- Instruct patients to consult with their primary care provider (PCP) before using herbal remedies because this helps avoid interactions with pharmacologic agents.
- Teach patients to take pain medication before the pain becomes severe or occurs around the clock. This helps maintain a consistent

blood level of medication, producing sustained analgesia.

- Instruct patients about when to contact their PCP or pain specialist, and stress the importance of doing so in the event that the pain control measures used are ineffective.
- Offer information on community agencies or resources and support groups that provide information and educational materials.

QSEN Focus!

Nurses must read current research to be familiar with pain relief options and provide evidence-based care that is acceptable to each patient.

Two therapeutic strategies used to manage pain are multimodal analgesia and preemptive analgesia. **Multimodal analgesia** is the use of more than one means for controlling pain. When more than one type of agent is used, analgesia is more effective, requires lower doses of each agent, and produces fewer side effects. Multimodal analgesia may be two medications (e.g., acetaminophen with codeine, morphine sulfate with gabapentin) or a medication used in combination with a complementary therapy (e.g., topical ointment with massage therapy, essential oils). **Preemptive analgesia** is the administration of medications before a painful event to minimize pain. Medications administered before surgery or before dressing changes are examples of preemptive analgesia.

Safe Practice Alert

Check for allergies before administering medications. Watch the patient for at least 30 minutes after administering a medication to assess for an anaphylactic reaction. Allergic responses may occur with initiation of an agent or after sensitization to the medication on the first, second, or later exposure to the drug. Spending a short time on monitoring the patient may save the patient's life.

Nonopioid Analgesics

Nonopioid analgesics include acetaminophen and **nonsteroidal antiinflammatory drugs (NSAIDs)** such as ibuprofen and aspirin. These drugs are used in the treatment of many types of mild to moderate pain. Mild pain is rated as 1 to 3 on a numeric pain scale; it may be an achy feeling to the patient. Moderate pain is classified as 4 to

7 on a numeric pain scale; it may be the type of pain a patient experiences on day 3 after surgery. Nonopioids are not addictive and are safer for the patient to use than opioid analgesics, although patients may become dependent on nonopioids for pain relief.

Acetaminophen has analgesic and antipyretic capabilities and is a safe pain relief agent for most patients, including those with liver disease, if monitored closely and administered within the safe dosage range. Special caution should be taken when giving acetaminophen to infants, children, and the elderly. Long-term use may result in hepatotoxicity, renal damage, or leukopenia. The total daily dose should not exceed 3,000 mg. The nurse should review the entire list of medications a patient is taking, including over-the-counter (OTC) medications that may contain acetaminophen, to determine the total dose being received. An overdose may cause liver damage and can be fatal. Acetaminophen is used for fever reduction and for mild to moderate pain from conditions such as a mild headache or general achiness.

NSAIDs are more useful than acetaminophen in treating inflammatory pain and bone pain. NSAIDs have antiinflammatory effects in addition to analgesic and antipyretic qualities. Aspirin is also an effective agent for decreasing platelet aggregation in patients who are prone to blood clots or at risk for myocardial infarction.

Unfortunately, NSAIDs have significant side effects, including possible gastrointestinal upset and bleeding and cardiac and renal complications. These side effects may be avoided by taking the drugs with food and taking the prescribed dose. Proton pump inhibitors (PPIs) or histamine H₂-receptor blockers are often prescribed for patients who are on long-term NSAID therapy to help reduce the incidence of stomach ulcers.

Opioid Analgesics

Opioid analgesics are the most effective agents for relief of moderate to severe pain. These narcotic medications work by binding to the opioid receptors in the nervous system, which are sites of endorphin action. There are many types of opioid analgesics, including agonist analgesics and agonist-antagonist analgesics.

Agonist analgesics, such as morphine, hydromorphone, oxycodone, fentanyl, and meperidine, are the most effective agents for relief of severe pain, which is rated 7 to 10 on a numeric pain scale. They may change the patient's perception of pain while relieving the pain. Routes of administration include oral, transdermal, intramuscular, or intravenous. Research continues to identify the best methods for pain relief in various situations ([Box 36.10](#)). When administered

intramuscularly or intravenously, these medications may be given every 1 to 3 hours, depending on the dose administered. The nurse needs to be aware of adverse effects such as respiratory depression, seizures, nausea, vomiting, constipation, itching, and urinary retention. The nurse may administer an antagonist analgesic for the respiratory depression, antiemetics for the nausea and vomiting, and an antihistamine for itching. Dizziness, blurred vision, confusion, and orthostatic hypotension may occur.

Box 36.10

Evidence-Based Practice and Informatics

Postoperative Pain Management

Research on pain management is ongoing. Development of devices that promote patient mobility should improve postoperative recovery and reduce the resources required by nurses to help patients complete tasks such as ambulation and personal care. A meta-analysis was conducted on ease of care from the perspective of nurses comparing morphine sulfate intravenous patient-controlled analgesia (PCA) with fentanyl iontophoretic transdermal system (ITS) in postoperative pain management. The fentanyl ITS is a preprogrammed, needleless, on-demand device applied directly to the patient's skin that does not require intravenous access. Over 800 nurses participated in the study. Research findings indicated a significant preference for the fentanyl ITS over the morphine sulfate intravenous PCA. Reasons provided for the fentanyl ITS preference included the following:

(In Lindley, P., Ding, L., Hassan, M. A., et al. (2017). Meta-analysis of the ease of care from a patients' perspective comparing fentanyl iontophoretic transdermal system versus morphine intravenous patient-controlled analgesia in postoperative pain management. *Journal of PeriAnesthesia Nursing*, 32(4), 320–328. Reprinted with permission from The Medicines Company, Parsippany, NJ.)

- Greater efficiency and convenience allowing more time for direct patient care
- Increased patient mobility potentially reducing the incidence of postoperative pneumonia, pulmonary embolus, deep vein thrombosis, and urinary tract infections
- Lower analgesia gaps per 100 patients
- Overall greater satisfaction with the fentanyl ITS by nurses

From Pestano, C., Lindley, P., Ding, L., Danesi, H., & Jones, J. (2017). Meta-analysis of the ease of care from the nurses' perspective comparing fentanyl iontophoretic transdermal system (ITS) vs morphine intravenous patient-controlled analgesia (IV PCA) in postoperative pain management. *Journal of PeriAnesthesia Nursing*, 32(4), 329-340.

Agonist-antagonist analgesics include pentazocine, butorphanol, dezocine, and nalbuphine. These medications are used for moderate to severe pain. They depress the pain-impulse transmission at the spinal cord by acting with opioid receptors. They are normally administered by the intramuscular or intravenous route. Dosing is every 1 to 4 hours, depending on the drug. The nurse needs to be aware of patient drowsiness, dizziness, nausea, vomiting, itching, and respiratory depression. Treatment for these adverse effects is the same as that for the adverse effects associated with agonist analgesics.

Antagonist analgesics such as naloxone are used for the treatment of opioid analgesic overdose. They compete with opioids at the opioid receptor sites, decreasing the side effects of opioids. They are administered intravenously, intramuscularly, subcutaneously, or into an endotracheal tube every 2 to 3 minutes until symptoms of opioid overdose subside. Signs of opioid withdrawal, such as vomiting, hypertension, and anxiety, may occur up to 2 hours after administration.

Safe Practice Alert

Check vital signs before administering opioid analgesics. Overdose of opioids may cause respiratory depression. Respiratory depression is defined as fewer than 10 respirations per minute. Administer 0.4 to 2 mg of naloxone every 2 to 3 minutes to a maximum dose of 10 mg to increase the respiratory rate to more than 10 respirations per minute. Administering opioids when a patient is hypotensive (systolic blood pressure of 90 or less) also may cause hypoperfusion.

Patient-controlled analgesia (PCA) is a system in which an electronically controlled infusion pump immediately delivers a prescribed amount of analgesic to the patient when he or she activates a button, without the need for a nurse to administer it (**Box 36.11**). The purpose of PCA is improved pain control. PCA uses more frequent but smaller doses of medication, usually opioids (i.e., morphine sulfate, fentanyl, or hydromorphone), and provides more even levels of medication in the patient's body. The PCA pump can deliver medicine into a vein (intravenously, the most common method), under the skin (subcutaneously), or between the dura mater and the spinal cord (epidurally). When the medication is delivered intravenously, the site must be monitored for infiltration and phlebitis.

Box 36.11

Nursing Care Guideline

Patient-Controlled Analgesia

Background

- Patient-controlled analgesia (PCA) involves the intravenous administration of a controlled substance as a pain medication.
- Patient control of the infusion pump is restricted to certain parameters, as prescribed by the primary care provider (PCP):
 - The PCP may prescribe continuous doses of pain medication with additional boluses administered by the patient as needed.
 - The PCP orders a specific lockout time between patient doses to avoid overdosing.
- PCA by proxy is unauthorized activation of the PCA pump by someone other than the patient. The PCP may order authorized nurse-controlled or caregiver-controlled anesthesia by PCA pump when a patient is unable to activate the dosing button. This type of order is indicated for young children and unconscious or incompetent adults.
- Nurses should refer to the manufacturer's instructions for pump operation.
- Nurses should follow facility policies and procedures for frequency of assessment and documentation of PCA use.

Procedural Concerns

- Perform assessments:
 - Assess the patient at the beginning of PCA use and again 30 minutes later.
 - Check the patient every hour for the first 8 hours of PCA use after the initial assessments.
 - After the first 8 hours, assess the patient as specified in the PCP order or every 4 hours at a minimum. Assessment may be done more frequently in accordance with nursing judgment, depending on patient status.
- Take precautions:
 - Ensure that only the patient operates the PCA pump. Family members should never activate the pump for the patient.
 - Keep naloxone or another specifically indicated antagonist analgesic immediately accessible in case of an overdose or emergency.
 - Follow the PCP order for medications, dosage, and pump settings.
- Two nurses must verify or witness medication changes and check orders against pump settings at the change of shift and with any

changes in pump settings. Conscientiously monitor the following:

- Proper PCA pump function
- Fluid levels
- Intravenous line patency
- Respiratory rate, level of consciousness, and blood pressure
- Pain level and itching, nausea, and vomiting (common side effects of opiates)

Documentation Concerns

- Note the patient and family education that was provided.
- Education may initially occur preoperatively.
- Education must be reinforced postoperatively.
- Record assessment and monitoring results.
- Document the medications administered, medications remaining, and pump settings on each shift.

Evidence-Based Practice

- Research indicates that PCA provides more effective analgesia and fewer episodes of breakthrough pain.
- Some studies indicate that PCA reduces patient length of hospitalization and increases patient satisfaction and feelings of control in their treatment (Katz, Takyar, Palmer, et al., 2016)

Safe Practice Alert

Administer the prescribed medication dose that best manages pain and has the fewest side effects.

The following are additional methods by which opioids are delivered:

- On-Q infusion pump provides continuous infusion of local anesthesia through an antimicrobial catheter, which destroys or inhibits microorganism growth on the catheter. It is most often used for postoperative pain control after abdominal surgery.

- Transdermal administration consists of a medicated adhesive patch (e.g., fentanyl ITS) that is placed on the skin to deliver a specific dose of medication through the skin, allowing absorption into the bloodstream.
- Intrathecal injection or infusion of a narcotic or local anesthetic into the subarachnoid space through a needle or catheter provides pain relief to a large area of the body. It may be used as spinal anesthesia for surgery, cancer pain, or relief from spasms that occur with spastic cerebral palsy.
- Epidural analgesia is continuous infusion of a narcotic or local anesthetic into the epidural space by insertion of a needle or catheter for relief of acute or chronic pain. It is used for labor pain, surgery, and cancer pain because it numbs the nerve endings in a local area of the body.
- **Nerve block** is an injection of a local anesthetic into or near spinal nerves for temporary pain control. The anesthetic can be injected into the cervical, thoracic, lumbar, and sacral areas of the spinal column. Nerve blocks can be used for migraine headaches, dental work, back pain, herniated disks, and cancer pain.

Opioid analgesics are essential in adequate pain management, although risks for tolerance, physical dependence, addiction, and accidental ingestion are associated with their use. The nurse needs to understand these risks and be able to differentiate them. **Drug tolerance** is an adaptation to the medication, which eventually leads to less effective pain relief. It is better to change to another medication than continue increasing the dose of the same medication. **Physical dependence** builds as the body becomes unable to function normally without the medication, reaching the point of withdrawal symptoms on abrupt cessation of the medication.

Addiction

Addiction is a psychological or emotional dependence on a prescribed medication or illicit drug. The addicted individual craves the drug and engages in compulsive use, or abuse, regardless of the consequences.

Substance use disorder occurs when a person's repeated use of alcohol and/or drugs causes significant impairment such as disability; inability to fulfill work, home, or school responsibilities; or health problems (Substance Abuse and Mental Health Services Administration [SAMHSA], 2018). In 2017 it was estimated that 1.7 million Americans aged 12 or older had a substance use disorder involving prescription pain relievers, and an estimated 7.5 million Americans aged 12 or older had an illicit drug use disorder (SAMHSA, 2018). Drug overdose is the leading cause of accidental death in the United States, with estimates of over 63,000 overdose deaths in 2016 (Seth, Scholl, Rudd, & Bacon, 2018). Many special facility treatment centers are available to treat individuals with substance use disorder, although they are underutilized. First responders and, in some cases, family members of persons who are addicted, are being trained to recognize opioid overdose and administer supplied naloxone.

Nurses with substance use disorder pose a threat to both patient and colleague safety. Some studies suggest that the prevalence of substance use disorder among nurses may be similar to that of the general population (Kunyk, 2015). Nurses who suspect substance abuse by a co-worker need to address their concerns with a supervisor so treatment can be initiated. The National Council of State Boards of Nursing (NCSBN, 2018) stresses the importance of early recognition, reporting, and intervention to patient safety and nurse recovery. Substance use disorder resources including the video, *Substance Use Disorder in Nursing*, are available at <https://www.ncsbn.org/substance-use-in-nursing.htm>.

Accidental Ingestion

In addition to individuals dying from accidental overdose and substance use disorder, children are in danger of accidental ingestion when narcotics are not kept secure and out of reach. Approximately 60,000 young children are taken to the emergency department because of taking medications left unsecured (Up & Away.org, 2018). Nurses can be instrumental in reducing accidental overdose by minors by educating patients, family members, and care providers of prevention strategies (Box 36.12). Research findings indicate that when a primary care provider (PCP) failed to discuss safe disposal of analgesics, twice as many parents kept leftover pain medication at home, vulnerable to child access (C.S. Mott Children's Hospital, 2016).

Box 36.12

Home Care Considerations

Protecting Children From Accidental Ingestion of Medication

Up & Away (<http://www.upandaway.org/>) is an initiative of PROTECT in partnership with the Centers for Disease Control and Prevention. To prevent accidental ingestion of medication by children, the following six recommendations should be undertaken by adults and care providers:

- Store medication out of reach and out of sight of children.
- Put medication up and away after each use.
- Always lock and relock safety caps on prescription and over-the-counter medications, vitamins, and herbs.
- Teach children about medication safety at an appropriate age level. Never tell them that medication is candy.
- Tell house guests about medication safety, including keeping purses, bags, or coats that contain medications up, away, and out of sight of children.
- Keep the Poison Help number (800-222-1222) easily accessible in case of an emergency.

Medical Marijuana

A newer form of pain management is the use of medical marijuana. Medical marijuana is the use of the marijuana plant (*Cannabis sativa*) or its extracts to treat symptoms of disease processes, such as neuropathic pain and spasms of multiple sclerosis, pain and/or nausea from cancer and its treatment, and pain from HIV and AIDS. Delivery can be through an inhaler spray or vaped to produce a response within minutes. It can be eaten or taken in liquid form, which works within 1 hour. It is a Schedule 1 drug of the Controlled Substance Act.

Medical marijuana is approved for use more than 30 states and in Washington, DC ([ProCon, 2018](#)). Its legislative use varies by state. It has not been approved by the US Food and Drug Administration (FDA) due to lack of large-scale clinical trials to determine if benefits outweigh the risks for use.

Research studies have demonstrated that smoking medical marijuana leads to the development of lung disease ([National Institute on Drug](#)

Abuse [NIDA], 2018). Some short-term effects of marijuana use include a negative impact on memory, learning, the ability to think and problem solve, coordination, and aggravation of depression and psychoses (SAMHSA, 2018; Fitzcharles, Clauw, Ste-Marie, & Shir, 2014). Research into its efficacy is ongoing.

Adjuvant or Coanalgesic Medications

Adjuvant medications, or **coanalgesic medications**, work synergistically with standard pain medications to enhance pain relief and to treat side effects of the medication. For example, tricyclic antidepressants and anticonvulsants may be used together to treat neuropathic pain. Antiemetics are often administered with opioid analgesics to counteract the nausea and vomiting. Laxatives or stool softeners (e.g., senna, docusate) are prescribed to prevent constipation, and antihistamines (e.g., diphenhydramine) are given to decrease the itching side effect of morphine. Ketorolac (Toradol) is an NSAID used along with opioid analgesics to enhance pain relief. Caffeine is used with analgesics to treat migraine headaches.

3. Explain why M. C.'s medication orders include the stool softener senna and the antihistamine diphenhydramine.

Palliative Care

Another option for pain relief is palliative nursing care. The goal of palliative care is to help relieve pain caused by serious illness, regardless of the patient's prognosis. Palliative care is appropriate for patients of any age and for any stage of serious illness. Typically, a group of physicians, nurses, and social workers work as a team to provide the appropriate treatment for the patient. Palliative care improves the quality of life of patients and families who face a life-threatening illness by providing pain and symptom relief and supplying spiritual and psychosocial support from diagnosis to the end of life and bereavement.

Therapeutic Decision Making

The nurse evaluating and administering care to the patient makes the therapeutic decision about best treatment based on knowledge of pain relief techniques and the PCP orders. After vital sign and pain scale assessments are completed, the nurse determines the level of intervention the patient needs. When the PCP has ordered a range of pain medication for a patient, the nurse can titrate the dose on the basis of the patient's pain assessment. If the pain is severe, the nurse may begin with a higher dose or stronger opioid to obtain pain relief. If the patient complains of moderate pain, the nurse may try giving a nonopioid pain medication, such as acetaminophen or ibuprofen. For mild pain, the nurse may try nonpharmacologic interventions before administering a nonopioid pain medication if ordered. Helpful information from the American Society of Pain Management Nurses and the American Pain Society on range dosing of opioid analgesics for pain management is available at <http://americanpainsociety.org/uploads/about/position-statements/ps-opioid-dosage.pdf>.

The timing of pain medication administration can be critical in providing adequate pain relief. There is strong support for providing around-the-clock dosing of analgesia to prevent pain levels from getting too high. Consistent analgesia helps maintain medication blood levels and prevent pain recurrence. If a patient delays asking for pain medication until the pain is severe, the nurse may need to administer higher doses of analgesia or stronger medications to initially get the patient's pain under control. Relief from pain may take longer. In light of this, nurses should administer or encourage patients to take (or request) pain medicine on a scheduled basis, especially when patients are recovering from surgical or diagnostic procedures known to cause moderate to severe pain or when they are experiencing chronic pain.

4. Provide the rationale for administering postoperative pain medications intravenously to M. C. instead of orally or intramuscularly.

To determine whether pain relief methods are effective, the nurse evaluates the patient's level of pain relief and documents the results in the patient's chart. The WHO's (2018) pain relief ladder to treat cancer pain is a tool that helps health care providers determine which pain medication and adjuvant therapy may be most effective on the basis of the intensity of the reported pain (Fig. 36.5). Although criticism of the pain ladder has emerged in recent years, it remains a framework on which to determine analgesic dosing in a variety of situations (ACOG, 2018).

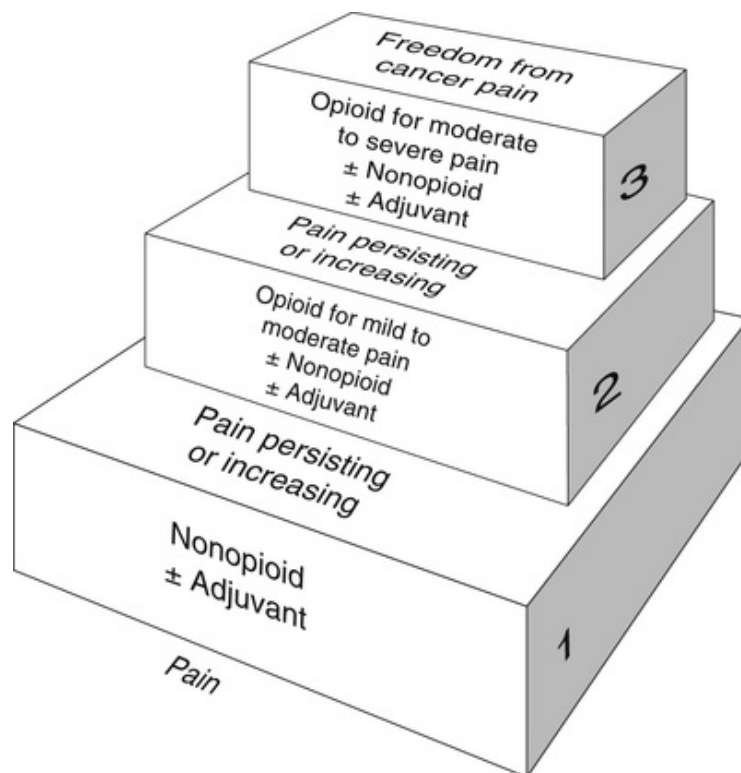

FIGURE 36.5 World Health Organization's Pain Relief Ladder. (Retrieved from <http://www.who.int/cancer/palliative/painladder/en/>.)

Barriers to Adequate Management

There are many barriers to adequate pain management, including a patient's personal barriers (Nolan, 2017). Fear of addiction or tolerance to the drug may cause an individual to refuse medication for pain. The cost of medication and no access to health care may be factors. Some people think that pain is inevitable and should be tolerated, believing that “good” patients do not complain about pain.

Health care providers may have barriers as well. Adequate pain relief for patients may be compromised by poor pain assessment skills,

inaccurate beliefs, or prejudicial attitudes on the part of health care team members about the experience of pain. Forgetting to consider the culture and personal experiences of patients related to pain may thwart nurses from providing patients with acceptable pain relief. A lack of education regarding physical dependence and addiction also may be a hindrance. The PCP may be overly concerned about the side effects associated with the drugs or about tolerance developing. Sometimes pain relief medication cannot be prescribed until after the patient has been diagnosed, which can cause pain levels to increase so significantly that they become very difficult to get under control.

Pain Management for Addicted Patients

Although addicted patients are entitled to receive pain relief, many PCPs and nurses are reluctant to address their needs or are unsure about how best to do so. The American Society for Pain Management Nursing (ASPMN) and the American Society of Addiction Medicine (ASAM) provide guidelines for pain management in patients with substance use disorders ([Drew, Gordon, Morgan, et al., 2018](#); [Kampman & Jarvis, 2015](#)). Addicted patients are different from opioid-dependent patients who rely on analgesia for treatment of chronic conditions. Whereas addicted patients exhibit a lack of control and a compulsive need for medication, dependent patients experience an improved quality of life and increased level of function with treatment. Nurses who work with addicted individuals collaborate with PCPs to closely monitor prescription control, document the patient's complaints of pain, and report the effectiveness of prescribed medication ([Rosier, 2017](#)).

Barriers Within the Health Care System

The barriers to adequate pain management are especially high within the health care system. Pain is often not a high priority for treatment. Systematic pain management approaches and pain management teams may not be in place. There may be inadequate reimbursement for pain medications, and regulations may restrict access to medications.

Patients have a right to pain relief. Inadequate pain management may lead to detrimental outcomes such as the following:

- Impaired recovery and progression to chronic pain
- Compromised ability to carry out ADLs

- Inability to get adequate rest and sleep, leading to a diminished quality of life
- Significant suffering, with increasing anxiety, depression, fear, and anger
- Work absenteeism and potential underemployment or loss of employment
- Increased health care costs
- Difficulty accessing disability compensation

Patients are not the only ones affected. Relationships with family and friends may be stressed and strained. It is the nurse's responsibility to provide every patient with adequate pain management to ensure maximum relief with the fewest side effects that leads to the highest quality of life possible.

Evaluation

Evaluation of treatment interventions for patients with pain is based on the attainment of goals and is an ongoing process. If medication intervention is required for pain management, the pain is reassessed and documented. Initial time intervals for reassessment are patient specific and depend on the route of administration:

Nonpharmacologic techniques	30 to 60 minutes after intervention
Intramuscular, subcutaneous, or oral administration	30 to 60 minutes after intervention
Transdermal administration	12 to 16 hours after intervention
Intravenous or sublingual administration	15 to 30 minutes after intervention

The nurse documents the time the medication is given, the time of postintervention reassessment, and the duration of acceptable pain relief after intervention. The nurse is required to document the pain scale on every shift, whether the patient is having pain or is pain free.

When discharging a patient, the nurse is responsible for educating the patient, family, and support persons about the proper administration of medications. Patient education must be documented in the nurse's notes and on the patient education sheet. The patient is given a copy of the education sheet, which explains the medication, its intended purpose, how to take it, and side effects ([Box 36.13](#)).

Box 36.13

Patient Education and Health Literacy

Providing Medication Education

- When educating the patient about medication administration, turn off the television and handheld devices to minimize interruptions.
- Make sure the patient has assistive devices in place, such as glasses and hearing aids.
- Teach the patient about the medication currently prescribed, including the name of the medication, the dose, why it is prescribed, when to take it, side effects or adverse effects, and special considerations for taking the medication.
- Provide written instructions for reference after discharge. Include family members and significant others in the teaching, as appropriate.
- Instruct the patient on when to call the health care provider with questions or concerns about the medication.

To provide appropriate nursing care for a patient in pain, the nurse must have an understanding of the pathophysiology of pain, types of pain, physiologic alterations caused by pain, and factors influencing pain. With this knowledge, the nurse can apply the nursing process to develop a patient-centered plan of care, incorporating nonpharmacologic and pharmacologic treatments and educating the patient and caregivers about the treatment methods. If pain relief goals are unmet, the nurse needs to collaborate with other health care team members and the patient to determine other options for treatment. Nurses must advocate for the most effective pain management regimen possible for every patient.

Summary of Learning Outcomes

LO 36.1 *Define pain*: Pain is a subjective sensation that involves the total person, including psychological and physiologic responses. Any definition of pain must include the perceptions of pain and its associated sensations.

LO 36.2 *Describe the role of the nurse in pain management*: The nurse assesses pain using a pain assessment tool and documents the patient's response after assessment and before and after pain control interventions are performed or analgesics are administered. Pain management and pain relief are essential elements of nursing practice.

LO 36.3 *Explain the physiology of pain and its perception*: Acute injury or tissue damage to the body leads to physiologic stress responses, which are an attempt by the body to protect itself. First, the sympathetic nervous system is stimulated; if pain is not relieved, the parasympathetic nervous system is stimulated. Each body system has its specific response to pain.

LO 36.4 *Articulate factors that influence pain perception and response*: Individual characteristics, such as age, gender, morphology, disabilities, culture, ethnicity, and religion, affect each person's behavioral reaction to pain and its perception. Past experiences with pain and emotional issues also may have an impact on patient response.

LO 36.5 *Determine individual physiologic, behavioral, and psychosocial responses to pain during patient assessment*: The nurse uses cognitive and

noncognitive tools to assess physical changes in the patient that are caused by pain, such as increased blood pressure and pulse rate, and behavioral and psychological changes, such as anxiety, fear, and impatience.

LO 36.6 *Identify nursing diagnoses for patients experiencing pain:* Typically, the highest-priority nursing diagnoses for pain are *Acute Pain* and *Chronic Pain*. Other concerns that may need to be addressed when pharmacologic pain interventions are implemented are gastric distress and respiratory depression. Other relevant nursing diagnoses related to emotional distress caused by pain include *Anxiety* and *Fear*.

LO 36.7 *Generate nursing care goals and outcome criteria for patients experiencing pain:* The pain level is the primary outcome criterion used in developing pain management goals. The patient's vital signs and changes in behavior may be incorporated into pain-related goals.

LO 36.8 *Plan pain management care that includes implementation and evaluation of pharmacologic and nonpharmacologic interventions for pain:* The nurse talks with the patient, reviews the latest research, and consults other members of the health care team to determine the best course of pain management. Medication and alternative and complementary therapies may be implemented to provide holistic pain relief.

Review Questions

1. When assessing the patient for pain, which factors should the nurse consider? (*Select all that apply.*)
 - a. Previous medical history
 - b. Physical appearance
 - c. Age, gender, and culture
 - d. Lifestyle and loss of appetite
 - e. Hair color and style
2. Which statement best describes the dosage of prescribed pain medication that a nurse should administer given pharmacologic treatment considerations?
 - a. The smallest dose possible to avoid opioid addiction
 - b. The smallest dose possible to decrease adverse effects
 - c. A dose that best manages pain with fewest side effects
 - d. A large dose initially to decrease the initial level of pain
3. Which method is the most accurate way to determine the pain level of a patient who is alert and oriented?
 - a. Evaluate whether the patient is crying or grimacing.
 - b. Assess the patient's heart rate and blood pressure.
 - c. Consider the seriousness of the patient's condition.
 - d. Ask the patient to describe the pain and rate its level.

4. A patient who has a serious back injury received intravenous medication for pain approximately 1 hour earlier. The patient practices relaxation techniques but still is reporting pain at a level of 9 of 10. What intervention should the nurse implement next?
 - a. Report the lack of pain relief to the primary care provider.
 - b. Tell the patient to give the medication more time.
 - c. Reposition the patient, and try diversion activities.
 - d. Document in the nurse's notes that the patient has a low pain tolerance.
5. Which symptom does the nurse recognize as a physiologic response to acute pain?
 - a. Increased blood pressure
 - b. Decreased pulse
 - c. Increased temperature
 - d. Restlessness
6. When administering analgesics to elderly patients, what information does the nurse need to understand?
 - a. Start with a low dosage, and increase the dosage as needed for pain relief.
 - b. Start with a high dosage, and decrease the dosage as pain is relieved.
 - c. Start with a midrange dosage, and increase or decrease the dosage as needed for pain.
 - d. Start with a low dosage, and decrease the dosage every other day.

7. The nurse administered intravenous morphine at 0830. At what time will the nurse ask the patient if pain relief was obtained?
 - a. 1000
 - b. 1030
 - c. 0900
 - d. 0930
8. The patient who had a below-the-knee amputation 3 days ago complains of pain from the amputated extremity. Which response by the nurse best explains what the patient is experiencing?
 - a. "Your phantom pain will subside when the brain realizes the lower extremity is no longer there."
 - b. "Your radiating pain will continue for months because the lower extremity is no longer there."
 - c. "You are suffering from referred pain, which you will always have, but it will lessen with time."
 - d. "You are experiencing psychogenic pain because loss of an extremity is an emotional loss."
9. The endocrine system releases excessive hormones during episodes of acute pain. The nurse should monitor patients experiencing acute pain for which potential problem?
 - a. Hyperglycemia
 - b. Migraine headache
 - c. Hyperkalemia
 - d. Diarrhea
10. A patient with a fractured femur thinks about vacationing on the beach to help relieve pain. What

nonpharmacologic pain relief technique should the nurse document the patient is using?

- a. Distraction
- b. Imagery
- c. Relaxation
- d. Biofeedback

CHAPTER 37

Perioperative Nursing Care

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 37.1 Differentiate between the phases of the perioperative period.
- LO 37.2 Classify different types of surgery.
- LO 37.3 Discuss safety during the perioperative period.
- LO 37.4 Describe alterations that can occur during the perioperative period.
- LO 37.5 Identify vital perioperative assessment data.
- LO 37.6 Select nursing diagnoses for each perioperative stage.
- LO 37.7 Establish nursing care goals and outcome criteria for surgical patients.
- LO 37.8 Evaluate the effectiveness of the perioperative nursing interventions.

Case Study

Patricia Logan (P. L.) is a 72-year-old female admitted to the hospital with a diagnosis of abdominal pain and cholecystitis that required surgery. She has a history of hypertension and no known drug allergies. Her do-not-resuscitate (DNR) document specifies a full code. Prior to surgery, P. L. stated she was “afraid of surgery and nervous about being under anesthesia.” She has never had surgery before. Her preoperative vital signs were T 37° C (98.6° F), P 104 and regular, R 24 and shallow, BP 150/88, with a pulse oximetry reading of 94% on room air. She stated her pain level was 4 of 10 preoperatively

A laparoscopic cholecystectomy was performed under general anesthesia, and P. L. was just transferred from the postanesthesia care unit (PACU) to a surgical unit. Her vital signs on admission to the surgical floor are T 36.8° C (98.2° F), P 74 and regular, R 18 and unlabored, BP 138/82, with a pulse oximetry reading of 98% on 2 L of O₂ via face mask. The abdomen is soft and tender with three adhesive bandages over the small incisions where the laparoscopic instruments were inserted during surgery, and one 2 × 2 gauze pad applied over the small incisions near the umbilicus where the laparoscope was inserted. All dressings are dry and intact. Her pain level is 6 of 10. The pain is located in her abdomen and described as throbbing and sharp.

Treatment orders are as follows:

- Vital signs with oxygen saturation every 4 hours
 - Discontinue supplemental oxygen if oxygen saturation on room air is more than 92%
- Incentive spirometry every hour while awake
- Bed rest with bathroom privileges (BRPs) with assistance
- Sequential compression devices (SCDs) while in bed
- Intake & Output (I&O) every shift
- Assess voiding, bladder scan if unable to void in 6 hours

- Abdominal dressing change every shift
- Advance to clear liquid diet when bowel sounds return

Medication orders are as follows:

- Intravenous (IV) 5% dextrose and 0.9% sodium chloride at 100 mL/hr
- Cefazolin 2 g intravenous piggyback (IVPB) every 8 hours
- Hydrochlorothiazide 25 mg PO daily
- Potassium 20 mEq PO daily
- Enoxaparin 40 mg subcutaneously daily
- Acetaminophen and codeine 300 mg/30 mg, 2 tablets PO every 4 hours as needed (PRN) for moderate pain
- Morphine 4 mg IV every 4 hours PRN for severe pain
- Ondansetron 4 mg IV every 8 hours PRN for nausea

Refer back to this case study to answer the critical-thinking exercises throughout the chapter.

Surgery is a significant event in an individual's life. It is a major decision involving the patient's body and health. Surgery may be performed to diagnose a medical disease, reconstruct or remove diseased tissue or organs, improve appearance, or relieve symptoms or pain.

The patient undergoing planned or unplanned surgery experiences unique physical adaptations. The operation becomes the central focus for these patients, and the thought of having surgery can cause stress and anxiety. The patient and family may have to adapt physically, socially, and psychologically before and after the surgical procedure.

Perioperative nursing is the care nurses provide for patients before, during, and after surgery. Perioperative nurses plan, direct, and coordinate the care of every patient undergoing operative and other invasive procedures. They are responsible for patient outcomes resulting from the nursing care provided during the perioperative experience.

LO 37.1 Phases of Surgery

The patient having a procedure goes through three phases: preoperative, intraoperative, and postoperative. Each patient receives individualized care with safety as a priority to minimize risks and complications. The three phases together are known as the **perioperative period**.

Preoperative Phase

The first phase of surgery is known as the **preoperative phase**. Depending on the patient's health status, this phase may last for several months. In an emergency situation, the preoperative period may be a few hours or less. It begins when the patient decides to have surgery. Typically, patients, or their families when the patient is not cognitively or emotionally competent, make this decision in collaboration with a surgeon. The agreement to have surgery validates the patient's want or need for surgery and confirms that the procedure will take place.

After the agreement, the patient undergoes diagnostic testing and other procedures. Nursing activities focus on preparing the patient for surgery. The ultimate goal of nursing care is to promote positive surgical outcomes. The nurse assesses the patient and identifies actual or potential health problems. All preoperative forms are completed. Physician's orders are implemented. Preoperative teaching begins, and supportive care is provided. This includes explaining the necessity for preoperative tests. Risk assessment by a member of the anesthesia team is performed during this period.

In an emergency situation, there is not always time for all of the preoperative activities to occur. The surgeon decides how soon surgery needs to be performed and which diagnostic tests and assessments are required. The preoperative phase ends when the patient is transferred to the operating room.

Intraoperative Phase

The second phase is known as the **intraoperative phase**. It begins when the patient enters the operating room. During this phase, the patient is anesthetized, monitored, prepped, and draped, and the surgical procedure is performed. The [Joint Commission \(2019\)](#) recommends implementing a time out and preprocedure verification before the procedure begins to help eliminate risk. During the time out, all personnel in the operating room stop what they are doing and use

active communication. This allows a final assessment to verify the correct patient, procedure, and surgical site. The time out is documented. Throughout the intraoperative phase, nursing activities focus on safety, infection prevention, and physiologic response to **anesthesia**, which is provided by an agent (anesthetic) that makes the patient insensitive to pain and sensation.

Most surgical patients are given an antibiotic to prevent surgical site infections. Strict adherence to the measures in the Joint Commission's Surgical Care Improvement Project (SCIP) is essential for reimbursement. One measure outlines guidelines for administration of antibiotics, most commonly cefazolin, clindamycin, or vancomycin. These antibiotics are often administered by the anesthesia provider within an hour of the initial incision. The dosage may need to be repeated depending on the medication and its half-life ([Heuer, Kossick, Riley, et al., 2017](#)).

Positioning

An important task of the surgical team is properly positioning the patient. Intraoperative injuries can occur and have devastating effects on the patient. Injuries resulting from improper positioning can be short term (such as, minor discomfort) or long term (such as, pressure injuries or nerve damage). The patient is commonly positioned for the surgical procedure after having been anesthetized. Proper positioning allows safety to be maintained. The patient is placed in a functional position with good body alignment. Pressure points are padded, and an electrical grounding pad is placed under the patient. Special precautions are taken when a patient is very thin, obese, or elderly or has a physical deformity.

The entire surgical team is responsible for properly positioning the patient. Attachments to the operating table, straps, pillows, and wedges are used to ensure proper positioning. Proper positioning allows access to the patient's airway and the surgical site, and it permits the nurse to monitor vital signs, intravenous (IV) lines, and comfort level. Common positions used in the operating room include supine or dorsal recumbent, prone, lithotomy, sitting, lateral, Trendelenburg, and jackknife ([Rothrock & McEwen, 2019](#)) [Fig. 37.1](#) shows these surgical positions, and [Table 37.1](#) describes their use.

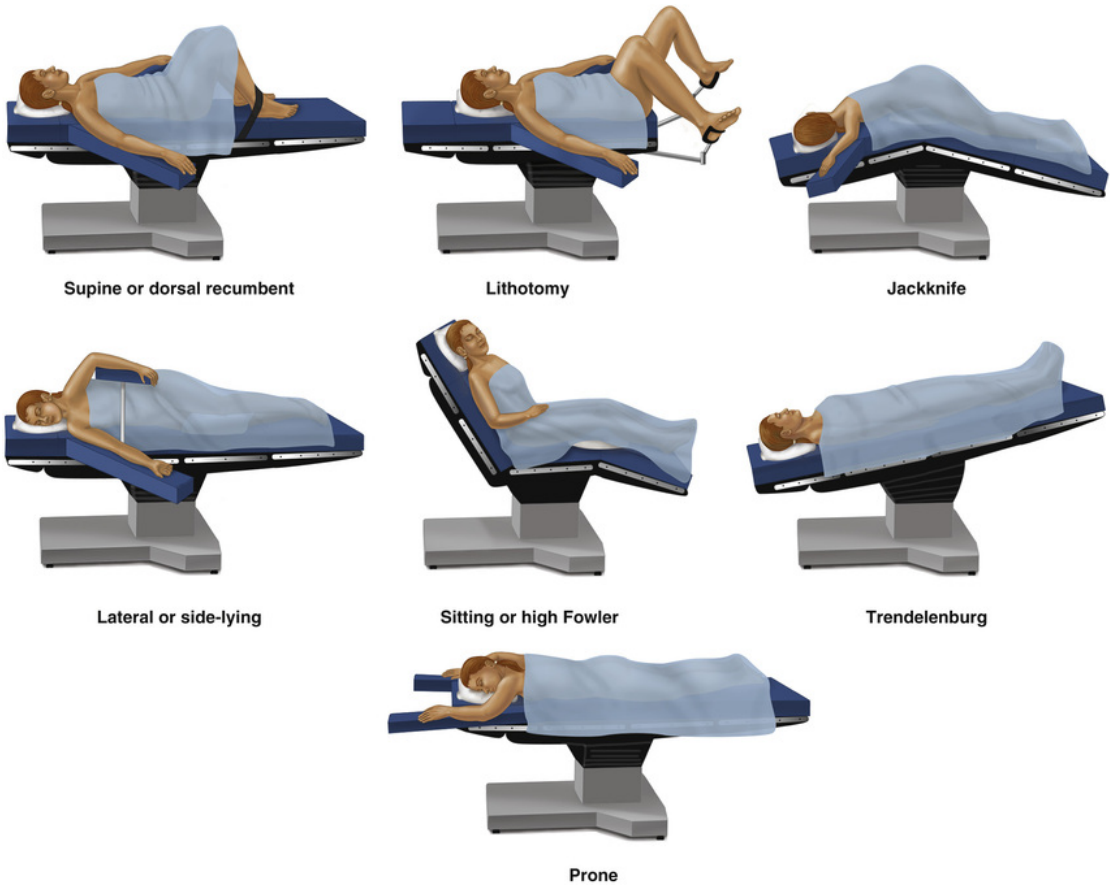

FIGURE 37.1 Surgical positions.

TABLE 37.1**Positions for Surgical Procedures**

POSITION	DESCRIPTION AND TYPE OF SURGERY	POTENTIAL POSITIONING INJURIES
Supine (horizontal recumbent)	Flat on back (thoracic, heart, abdominal)	Backache Nerve injury Postural hypotension Pressure alopecia Pressure point compression
Dorsal recumbent	Flat on back with knees flexed and hips externally rotated (thoracic, heart, vaginal)	Backache Nerve injury Postural hypotension Pressure alopecia Pressure point compression Hip and leg discomfort
Prone	Flat on abdomen (posterior thorax, spine, back of legs)	Neck pain Nerve injury Joint damage Eye abrasion Ear abrasion Reduced respiratory circulation Injury to breasts and male genitalia
Lithotomy	Flat on back and legs up in stirrups (gynecologic, perineal, rectal, genitourinary)	Lower back pain Perineal nerve injury related to stirrups Hypotension
Sitting	Upright or semi-reclining with legs elevated to the level of the heart (breast, thoracic, head, neck)	Airway edema Cerebral air embolism Facial edema Hypotension Tachycardia
Lateral	Side-lying (thoracic, kidney, hip)	Neck pain Nerve injury Ventilation-perfusion mismatch Eye abrasion Ear abrasion Venous pooling in dependent extremities
Trendelenburg	Flat on back, head down, feet elevated	Airway problems Difficulty breathing Backache Nerve injury

POSITION	DESCRIPTION AND TYPE OF SURGERY	POTENTIAL POSITIONING INJURIES
Jackknife	Placed on abdomen, head lowered, feet lowered, buttocks up (rectal)	Neck pain Nerve injury Joint damage Eye abrasion Ear abrasion Reduced respiratory circulation

Safe Practice Alert

The supine position ensures a significant degree of patient immobility and access to many surgical sites.

Safe Practice Alert

Obese patients with respiratory and cardiovascular disease may have difficulty lying supine, which may result in hypotension and occlusion of the inferior vena cava. A towel can be positioned under the right lower back and hip to correct the inferior vena cava occlusion by causing the patient to shift to the left side.

Preparing the Surgical Site

After positioning, the skin is prepared for the surgical procedure to minimize the risk of postoperative infection. Skin preparation consists of cleansing the skin and using an antimicrobial agent (Box 37.1). Hair is left in place on the surgical site when possible. Some procedures may require the hair to be removed preoperatively. Hair removal depends on the location of the surgical incision, the type of surgery, and the amount of hair at the incision site. If hair is removed, precautions must be taken to prevent injury to the skin. Clippers can be used for hair removal. If hair is removed from the head, the patient is asked preoperatively how he or she would like the hair to be cared for. Some patients may want to save the hair for cultural or religious reasons.

Box 37.1

Evidence-Based Practice and Informatics

Preoperative Preparations

- **Shower:** The patient is instructed to shower or bathe with an antimicrobial soap the day of surgery or the day before the surgical procedure if outpatient surgery is planned. A shower or bath is given preoperatively if the patient is hospitalized. Assistance is provided if the patient is unable to bathe independently.
- **Hair removal:** To decrease the risk of infection, hair is not routinely removed from the surgical site. The surgeon decides whether hair removal is indicated. Electric clippers are used. The clippers should have a head that can be sterilized before it is used again or a disposable head. Razors are not recommended because they can increase the risk of infection.
- **Documentation:** Skin preparation is documented on the intraoperative record.

More information can be found at Anderson, D. J., Podgorny, K., Berrios-Torres, S. I., et al. (2014). Strategies to prevent surgical site infections in acute care hospitals, *Infect Control Hosp Epidemiol*,35(6), 605–627.

The skin is cleansed and dried with a sterile towel. After the skin has been prepped, surgical draping begins. Drapes are applied to create a sterile field, maintain the patient's privacy, and only expose the surgical site.

Safety is a priority of all surgical team members during the intraoperative period, because the patient is totally dependent on the team while under anesthesia. The intraoperative period ends when the patient is transferred to the postanesthesia care unit (PACU), also called the *recovery room*.

Postoperative Phase

The **postoperative phase** is the third phase of surgery. It begins when the patient is admitted to the PACU and ends when the patient has completely recovered from the surgical procedure, which may be several months. To ensure a smooth transition to the PACU, the anesthesia provider and **circulating nurse**, who is the patient's advocate and a liaison between scrubbed personnel and the surgical team, often accompany the patient to the PACU. The [Joint Commission \(2019\)](#) recommends using hand-off communication, which takes place between the intraoperative nurse and the postoperative nurse. The anesthesia provider also may provide hand-off communication to the

postoperative nurse. The communication should include an update on the status of the patient and medications given during the procedure.

During the postoperative phase, the patient begins to recover from surgery and anesthesia. The postoperative nurse assesses the patient's response to the surgical procedure, carries out nursing interventions to prevent complications, and promotes healing (Card, Sawyer, Degnan, et al., 2014). Priority nursing assessments include assessing the respiratory, circulatory, and neurologic status of the patient. The pain level is monitored. Blood pressure, pulse oximetry, and cardiac monitoring are initiated.

LO 37.2 Types of Surgery

Surgical procedures can be classified according to the purpose, degree of urgency, and degree of risk. The classifications assist the nurse in recognizing the level of care that is required for a patient. Keep in mind that these classifications can overlap.

Classification by Purpose

Surgical procedures can be grouped based on their purpose. Terms used to classify surgical procedures are diagnostic, ablative, constructive, reconstructive or restorative, transplantation, palliative, and cosmetic (Box 37.2).

Box 37.2

Purposes of Surgical Procedures

- *Diagnostic*: Establishes or confirms a diagnosis (e.g., laparoscopy of the abdomen)
- *Ablative*: Removes a part of the body that is diseased (e.g., removal of a gangrenous toe)
- *Constructive*: Restores functioning that has been lost or reduced (e.g., cleft lip or palate)
- *Reconstructive or restorative*: Restores function or appearance of traumatized or malnourished tissues (e.g., skin graft for a burn victim, reconstruction after cancer surgery)
- *Transplantation*: Replaces dysfunctional body part (e.g., heart, kidney)
- *Palliative*: Improves comfort and decreases pain or symptoms but does not cure (e.g., back surgery to decrease pressure).
- *Cosmetic*: Improves personal appearance (e.g., liposuction)

Classification by Degree of Urgency

The degree of urgency is determined by the surgeon. All presurgical screening examinations and diagnostic testing results are reviewed. After the degree of urgency has been determined, the operating room can be scheduled for the appropriate time.

Elective Surgery

Elective surgery is a procedure that is performed to improve the patient's quality of life. The patient's health may improve physically and psychologically. Elective procedures are planned in advance, and the patient chooses when to undergo surgery. The date selected to perform the procedure is based on the convenience of the patient and surgeon. Other factors to be considered are adequate time for preparation, planning, and evaluation of the patient.

Elective surgery is not considered an urgent procedure. Examples of elective surgery include hysterectomy for uterine fibroids and cholecystectomy for chronic gallbladder disease.

Urgent Surgery

Some patients have a medical problem that has the potential for complications to develop if a surgical procedure is not performed.

Urgent surgery is performed when the patient's health condition is not immediately life-threatening. Failure to have the surgical procedure performed may result in complications or death. Surgery is required within 24 hours of the diagnosis to avoid preventable complications.

Because urgent surgery does not need to be performed immediately, the patient can continue to be evaluated over the next 24 hours. Examples of urgent surgery include hip pinning for a hip fracture and bowel resection to remedy a bowel obstruction.

Emergency Surgery

When a patient has a critical medical problem, emergency surgery may be needed. **Emergency surgery** is a procedure that is unanticipated and is performed immediately to preserve the life of the patient, a body part, or body function. Delay of this surgery can have a detrimental effect on the patient. Morbidity and mortality rates increase with emergency surgery because of risks associated with the underlying medical problem, surgical procedure, and medications administered during and after surgery. Examples of emergency surgery include control of internal bleeding caused by a gunshot wound and appendectomy to treat a ruptured appendix.

Classification by Degree of Risk

The degree of risk depends on the surgical procedure, health status, coexisting illnesses, and physical fitness. A healthy person with no preexisting health conditions has a better chance of surviving surgery without complications. Some health conditions increase risk and may

cause surgery to be cancelled until the patient's health has improved. Based on the degree of risk, surgery can be classified as major or minor.

Minor Surgery

When surgical alteration of the body is minimal and there is low risk to the life of the patient, the operation is classified as **minor surgery**. Many minor surgical procedures require little or no anesthesia and respiratory assistance. Most minor procedures are associated with few postoperative complications. Cataract surgery and a breast biopsy are examples of minor surgical procedures.

Major Surgery

When there is a higher risk to the life of the patient and surgery involves reconstruction or alteration of a body part, it is classified as **major surgery**. Anesthesia and respiratory assistance are usually required. Major surgery may be a complicated or prolonged procedure with a large amount of blood loss involving vital organs, and it may have a higher risk of postoperative complications. Mastectomy and bowel resection are examples of major surgery.

Factors Affecting the Degree of Risk

All surgical procedures have some degree of risk. People in good health have lower risks. Certain health conditions increase the surgical risk for complications, such as infection, delayed wound healing, and anesthesia reactions ([Box 37.3](#)).

Box 37.3

Diversity Considerations

Life Span

- Older adults and children have greater risks associated with surgery.
- Infants have an immature sympathetic nervous system, which can increase the risk of bradycardia during surgery.
- Infants have lower blood volumes, and blood loss can contribute to dehydration and the inability to respond to an increased oxygen demand.

- The infant's renal system metabolizes drugs slower, and the immature liver can lead to lengthened effects of narcotic medications.
- Shivering reflexes are not well developed in infants, and they have a relatively large body surface area that contributes to difficulty maintaining a stable body temperature, resulting in hyperthermia or hypothermia.
- The immune system is immature in infants, which compromises the ability to resist infection.
- A pregnancy test is often performed on women of child bearing age before surgery. There are risks to the fetus during surgery so the benefits of a procedure are considered against the risks to the mother and fetus.
- Older adults may have unique physical, physiologic, and pharmacologic changes that can influence how the body responds to anesthesia, which affects preoperative and postoperative care.
- Many older adults have a decreased physiologic reserve that can reduce the ability to compensate for changes that take place during the surgical procedure.
- Certain disorders combined with anesthesia and surgery amplify the surgical risk for older adults. Complications may include infection, anemia, and hemorrhage.
- There is the potential for a fluid and electrolyte imbalance, because older adults have a smaller percentage of body water, a decreased thirst response, and decreased kidney function.

Culture, Ethnicity, and Religion

- Cultural influences, beliefs, and practices can influence how a patient responds to surgery and pain, which can have a positive or negative impact on the patient. Cultural beliefs may contribute to stress, anxiety, and fear related to surgery.
- Certain cultural or ethnic groups do not believe in blood transfusions, which can present a risk in surgeries in which a large volume of blood is lost. Some of these patients may be able to donate and store their own blood before surgery.

Disability

- Any disorder that causes extreme anxiety, hinders the ability to understand, interferes with coping with the stress of surgery, or

impedes the patient's ability to respond appropriately can increase the risks of surgery and postoperative complications.

Morphology

- Malnutrition can lead to a delay in wound healing, infection, fluid and electrolyte imbalances, and fatigue.
- Obesity can cause significant mechanical difficulty for the surgeon. It can lead to excessive blood loss and problems exposing, accessing, and retracting tissue of the surgical site.
- During the postoperative phase, the obese patient may have difficulty with lung expansion, which can contribute to the development of pneumonia and wound infections. The increased depth and size of the surgical wound may cause wound infections and poor wound healing.
- People who are obese have higher risks of hypertension, and cardiovascular, respiratory, and gastrointestinal complications, as well as delays in metabolizing medications.
- Hypoxemia is often associated with obesity due to increased respiratory effort, ventilation-perfusion mismatch, closure of small airways, and reduced total lung capacity.

General Health

All patients who are scheduled to have surgery have a careful review of their current health status. When a person is in a poor state of health, surgery may be delayed or cancelled. When a patient's risk for infection is high, antibiotics are given prophylactically to allow the medication to reach therapeutic levels in tissues before surgery.

Medications

Over-the-counter, prescribed, or herbal medications can increase surgical risk and affect how the patient responds to the stress of undergoing surgery or anesthesia. During assessment, the nurse questions the patient about all medications taken at home. The following adverse interactions occur when medications are combined with surgery or anesthetic agents:

- Diuretics contribute to fluid and electrolyte imbalances.

- Anticoagulants increase the risk for bleeding and are discontinued before surgery.
- Tranquilizers increase the risk of respiratory depression.
- Corticosteroids increase the risk of bleeding, increase the risk of infection, and delay wound healing and immune response.
- Medications that affect the central nervous system can interfere with anesthesia.
- Herbal medications can affect the patient's reaction to the stress of surgery. Some herbal medications may potentiate the action of some anesthetic agents, and others may increase the risk of bleeding.

Safe Practice Alert

When conducting a health assessment, ask about herbal and over-the-counter medications.

Mental and Cognitive Status

Disorders that affect cognitive functioning, such as schizophrenia, dementia, developmental delay, and mental retardation, compromise a person's ability to interpret and understand medical information. These disorders can increase the surgical risk and interfere with the patient's ability to follow instructions and care for the surgical wound. Some individuals may be prescribed antipsychotic or anticonvulsant medications, which can interact with anesthetic agents.

Surgery is a major psychological stressor. Extreme anxiety and fear increase the surgical risk and cause the patient to have difficulty understanding information. Anxiety may be expressed as frustration, anger, withdrawal, crying, or questioning. Patients commonly fear that they will experience severe pain after surgery, the anesthesia will not put them to sleep, they will not be able to tell anyone that they feel intense pain, or they will not wake up from the anesthesia. Patients fear the unknown, and education about what to expect in each phase of the perioperative period helps allay some fears and to decrease stress and anxiety. Nurses encourage patients to verbalize concerns and fears. In

some cases, patients may need counseling before the surgical procedure. Nurses determine the support systems and coping skills of the patient before the surgical procedure.

Nutrition

Malnutrition and obesity increase surgical risks. Nutrients are necessary to promote wound healing and resist infection. Protein and vitamin K deficiencies contribute to poor wound healing, respiratory depression, sedation, and clotting disorders. A protein deficiency interferes with a drug's ability to bind with proteins. As a result, plasma concentrations of drugs can remain elevated, increasing the risk for side effects and adverse effects of medications given. Vitamin K deficiency can lead to increased bleeding.

Cardiac Disorders

Cardiovascular diseases increase the risk of surgery. Disorders such as myocardial infarction (MI), dysrhythmias, chest pain, hypertension, and heart failure (HF) need to be managed or controlled before surgery. Recent MI, chest pain, and dysrhythmias increase the risk of a second MI and life-threatening dysrhythmias. When a patient has hypertension, the scheduled dose of antihypertensive medication may be given before surgery. If hypertension is not controlled, the risk of anesthesia and surgical complications significantly increases. In some cases, diuretics are withheld if the patient does not have a Foley catheter inserted or fluid loss is expected during surgery. HF may cause surgery to be delayed due to the risk of additional fluid and electrolyte imbalances.

Blood Coagulation Disorders

Bleeding, hemorrhage, blood clots, and shock can be caused by coagulation disorders, which can significantly increase surgical risk. Laboratory results for prothrombin, thrombin, platelets, red blood cells, hemoglobin, and hematocrit are monitored to help identify potential risks.

Respiratory Disorders

A thorough assessment of the respiratory system is completed before surgery. Some anesthetics cause respiratory depression, predisposing the patient to greater surgical risk. Respiratory disorders, such as chronic obstructive pulmonary disease (COPD) and pneumonia, can increase the risk of respiratory depression during surgery.

Renal Disorders

Renal disorders contribute to fluid and electrolyte imbalances, which can increase the risk of surgery. People with acute or chronic renal failure may not be good surgical candidates. They have the additional risks of blood pressure abnormalities, acid-base imbalances, fluid instability, and a metabolism that is not able to excrete drugs properly.

Liver Disease

Liver disease interferes with metabolism, protein synthesis, coagulation, and glucose homeostasis. These manifestations of liver disease can contribute to fluid and electrolyte imbalances, acid-base imbalances, and altered excretion and metabolism of drugs, each of which can increase surgical risk.

Diabetes Mellitus

Diabetes can increase the risk of delayed wound healing. On the day of surgery, patients may not be able to have anything by mouth (non per os [nothing by mouth; NPO]). Glucose levels are monitored closely, and insulin doses are adjusted accordingly. Oral hypoglycemic agents may be withheld. Glucose levels may fluctuate in people with diabetes because of the stress of surgery resulting in hypoglycemia or hyperglycemia. The stress of surgery often causes elevated glucose levels. This may result in patients temporarily receiving insulin even when this is not part of their preoperative medication regimen. IV insulin is often used during surgical procedures.

Safe Practice Alert

It is important to monitor glucose levels closely, because they may elevate due to the stress of surgery.

Use of Illicit Drugs and Nicotine

People who use illicit drugs and nicotine have a higher risk of adverse drug interactions. Certain drugs change the way anesthetics work during surgery. Drugs that are commonly abused include cocaine, marijuana, alcohol, and opiates. When these drugs are taken, a potentially dangerous situation can develop for the patient.

Wound healing is compromised if a patient smokes, because smoking causes vasoconstriction, resulting in decreased blood flow. Smoking contributes to decreased ciliary action in the tracheobronchial tree, and mucous secretions may increase. The tracheobronchial tree may become chronically irritated, and anesthesia can increase this irritation.

Before surgery is an excellent time to teach a smoker about the effects and risks of smoking. Smoking puts a person at risk for reactive airway disease, which can contribute to complications, such as laryngospasm. A **laryngospasm** causes the laryngeal muscle to suddenly contract (spasm), blocking air inflow. A laryngospasm typically lasts for less than 1 minute, during which the patient has trouble speaking and breathing. If intubation is required, it may be very difficult. When possible, patients are encouraged to stop smoking 6 weeks before having surgery. If patients are unable to cease smoking weeks ahead of surgery, abstaining for 24 to 48 hours before surgery can have a positive impact.

Family History

Understanding family history is important. It should be determined whether family members had surgery in the past and whether there were complications associated with surgery or anesthesia. Obtaining a thorough history of anesthesia problems of family members or the patient can help determine the likelihood of complications developing in the current situation. If a patient reveals there were complications related to anesthesia in the past, their causes are discussed.

Malignant hyperthermia (MH) is a rare, hereditary, and life-threatening condition that usually occurs when inhaled general anesthetics or a neuromuscular blocking agent is administered. Susceptibility to MH is inherited as an autosomal dominant disorder, which occurs when one parent carries the trait (mutated gene) for the disease. It usually occurs during the intraoperative or early postoperative phases, but it has occurred during exercise and on exposure to hot environments.

MH causes severe muscle contractions and a rapid elevation of the body temperature. During an acute episode, the patient can develop a very high fever, cyanosis, muscle rigidity, hypertension, tachycardia, tachypnea, hyperkalemia, dysrhythmias, and acidosis. This change in body chemistry can be life-threatening and result in death without proper treatment. Even with treatment, the patient may die of MH. The signs of this disorder must be recognized early so that treatment can begin promptly. When MH occurs, surgery is stopped, and anesthesia is discontinued. Treatment consists of oxygen, IV fluids, and cooling the patient. Dantrolene sodium is used to alleviate muscle spasms.

Previous Surgery

Previous operations and the patient's response to anesthesia are assessed. If there were complications from surgery or anesthesia, the surgical risk is increased because of the potential for these problems to

occur again. It is possible for previous operations to influence a patient's psychological and physiologic response to subsequent surgery. A past negative surgical experience may contribute to the patient experiencing stress, anxiety, and fear.

Surgical Settings

Surgical procedures traditionally occur in the hospital setting (Fig. 37.2). Most hospitals are able to accommodate a wide variety of surgical procedures, including complex procedures with a high degree of risk. Patients may be hospitalized and transferred to the operating room or admitted the day of surgery to decrease costs. For patients admitted the day of surgery, all laboratory and diagnostic tests are performed before the day of surgery. The patient's response to surgery and anesthesia is evaluated. The physician determines whether the patient is admitted to the hospital after surgery or discharged to home.

FIGURE 37.2 Surgical suite. (Copyright Thinkstock.com)

Many operations that used to require a hospital stay are now much less invasive and commonly performed on an outpatient basis. This decreases costs associated with hospitalization. Operations can be performed in ambulatory care centers, same-day surgery centers, and outpatient centers. These facilities are designed for the patient to be admitted the morning of surgery and go home the same day. The

centers can be freestanding or affiliated with a hospital. Some centers perform a variety of procedures, and some specialize in a particular area. Examples of specialized ambulatory centers are eye surgery centers and plastic surgery centers.

LO 37.3 Safety Concerns During Surgery

The Association of periOperative Registered Nurses (AORN) has identified patient safety as a major goal. Perioperative nurses should be knowledgeable about AORN's Perioperative Standards and Recommended Practices ([AORN, 2015a](#)). These standards should be integrated into clinical practice, such as during surgery.

Nurses participate in patient safety programs and hold peers accountable for all safety standards ([Serino, 2015](#)). Communication is important in the operating room to ensure patient safety. If the sterile field or technique is broken, the behavior that does not follow patient safety guidelines is addressed immediately, such as with the following examples: "You contaminated your glove," and "The patient's arm is not straight; it needs to be repositioned." The communication style of the nurse can have a positive impact on patient outcomes ([Serino, 2015](#)). Being assertive rather than aggressive is viewed more positively.

Successful surgery occurs as a result of a common goal and the surgical team understanding and respecting the importance of each person's role. To achieve positive patient outcomes, mutual accountability of all health care team members is needed ([Serino, 2015](#)). Accountability is achieved by preventing errors from occurring and taking responsibility when they do happen. Patient safety is always at the forefront of the health care team's actions in the surgical suite. Health care organizations create a culture of safety that encourages an environment in which the perioperative team can freely discuss concerns, such as errors and suggestions for improvements without fear of reprimand. A patient safety culture in combination with good teamwork, communication, and accountability improves patient care ([Serino, 2015](#)).

Safe Practice Alert

Patient safety is always at the forefront of the health care team's actions. The nurse uses at least two patient identifiers before administering nursing care, treatments, or procedures.

LO 37.4 Altered Structure and Function During Phases of Surgery

Physiologic and psychological alterations may occur in each phase of surgery. The extent of the alteration depends on the individual patient's physical and emotional state, the type of surgery and anesthesia used, and the patient's individual risk factors.

Preoperative Phase

The thought of having surgery can cause emotional responses by the patient and their family members. The patient scheduled for surgery often experiences stress, anxiety, and fear. The patient is encouraged to ask questions before the surgical procedure ([American College of Surgeons, 2018](#)). The nurse can use therapeutic communication to establish a positive and trusting nurse–patient relationship. When attempting to decrease stress, anxiety, and fear, it is important for the nurse to avoid providing the patient false reassurance. Providing information and preoperative teaching on the surgery, pain management, and how to perform activities to reduce the risk for postoperative complications can help patients and allay some of their concerns ([Card, Sawyer, Degnan, et al., 2014](#)).

Intraoperative Phase

Many patients experience increased anxiety after they are transferred to the operating room. When the patient enters the operating room, they are told what to expect and introduced to all people in the operating room. Explanations are given in simple terms about what is happening before anesthesia induction. The patient is told when they are being moved from a stretcher to the operating table, when an IV line is started, and when anesthesia is begun.

Types of Anesthesia

Anesthetic agents are chosen by the anesthesia team. This decision is based on the type, location, and length of surgery and on the patient's condition.

Sedation

Moderate sedation, also known as *conscious sedation*, induces an altered state of consciousness providing a moderate to deep level of **sedation** (a

state of calm or reduced anxiety), amnesia, and analgesia that minimizes pain and discomfort. This is achieved by using pain medications and sedatives. Patients receiving conscious sedation may be asked to speak or respond to verbal cues during the surgical procedure. They are able to communicate discomfort experienced and are able to maintain an open airway. For some patients, a short period of amnesia obliterates their memory of the procedure.

When the patient is not being monitored by the anesthesia team, the registered nurse monitors the patient. Nurses who provide sedation conduct an airway and pre-sedation assessment (Card, Sawyer, Degnan, et al., 2014). The nurse monitoring the patient who is receiving sedation does not leave the patient unattended and must be able to identify adverse reactions. The nurse is prepared to respond appropriately if the patient becomes heavily sedated or other complications develop.

General Anesthesia

Major operations are performed under **general anesthesia**, which causes central nervous system depression and puts the patient in a drug-induced coma. This type of anesthesia causes a loss of consciousness, loss of sensation, amnesia, analgesia, and skeletal muscle relaxation. It is considered very safe and has few side effects. The term *balanced anesthesia* is often used to describe general anesthesia, because the goal is to attain a balance among analgesia, hypnosis, and immobility.

Risks associated with general anesthesia are circulatory and respiratory depression. General anesthesia is commonly administered by gases, volatile liquids that are vaporized and inhaled with oxygen, or IV drugs. A blend of inhaled gases and IV drugs is commonly used. Patients who receive general anesthesia cannot be aroused, even in response to painful stimulation. Individuals undergoing general anesthesia may not be able to maintain their airway or breathe on their own. Most inhaled anesthetic agents can be rapidly modified if necessary. Anesthetics given intravenously are more difficult to change or modify after they have been administered.

The four stages of general anesthesia were developed to help health care providers evaluate induction of and emergence from anesthesia. When general anesthesia is given, the patient moves through stages I and II to stage III. Surgery is performed during stage III. After anesthetic agents have been discontinued, patients can emerge from anesthesia into consciousness backward through all three stages. During induction, a patient can move to stage IV (anesthetic overdose); this stage represents a great danger and can result in death. [Table 37.2](#) describes the stages of general anesthesia.

TABLE 37.2**Stages of General Anesthesia**

STAGE	DESCRIPTION
I. Analgesia	Patient is awake, becomes drowsy, and loses consciousness Experiences analgesia or a loss of pain sensation
II. Excitement	Begins with loss of consciousness Excitement of muscles Involuntary movement Muscles become tense Breathing may be irregular Ends with regular breathing and loss of eyelid reflexes
III. Surgical anesthesia	Vital signs and reflexes are depressed Skeletal muscles relax Breathing is regular Operation begins
IV. Medullary paralysis	Respiratory centers in the medulla oblongata of the brain, which control breathing and other vital functions, cease to function Complete respiratory depression Cardiopulmonary resuscitation (CPR) needed Death can occur

The nurse should have an understanding of the anesthetic agents used, including the actions, indications for use, and potential side effects. Monitoring for MH (discussed earlier) is a concern for the entire surgical team. A combination of medications can be administered when a patient receives general anesthesia. Some medications decrease anxiety, promote sedation, and cause rapid induction, maintenance of anesthesia, loss of consciousness, skeletal muscle relaxation, and temporary paralysis.

Safe Practice Alert

Some medications administered during surgery and postoperatively to decrease pain can cause respiratory depression. All patients receiving medications that can cause respiratory depression need close monitoring of vital signs, including pulse oximetry, and oxygen therapy as indicated.

Safe Practice Alert

When reversal agents are used, they reverse the effects of anesthesia, pain medication, and sedation. The nurse conducts an assessment, including a pain assessment, when these agents are used.

Regional Anesthesia

Regional anesthesia disrupts the transmission of nerve impulses to a specific area of the body. It is achieved by performing spinal, epidural, or peripheral nerve blocks. The application of regional anesthetics blocks pain impulses. With this type of anesthesia, there is no loss of consciousness, the patient is not intubated, and the need for additional pain medication may decrease. The patient remains awake. The area of the body that is anesthetized becomes numb and loses sensation. Some medications may cause reflexes in the area to be temporarily lost. Regional anesthesia is preferred for patients who are hemodynamically compromised.

Regional anesthetic that is injected into a particular nerve, group of nerves, or surrounding tissue is called a **nerve block**. When a nerve block is used, intraoperative anesthesia and postoperative analgesia are provided. Injections are given in the head, neck, extremities, or trunk.

A **bier block** involves injection of anesthetic agents into the venous circulation of an extremity. This type of regional anesthesia is commonly used when the surgical procedure involves an extremity, or it can be used to help manage chronic pain. A tourniquet is used to entrap the anesthetic in the extremity. Major concerns for this type of anesthesia consist of failure of the tourniquet and premature releasing of the tourniquet. It is important to document the time the tourniquet is inflated. Surgery is completed within the specified time to prevent complications developing in the extremity.

When an anesthetic agent is injected into the epidural space in the lumbar or thoracic region, **epidural anesthesia** is achieved. Narcotics may be combined with the local anesthesia to produce a better analgesic effect. Low concentrations of local anesthetics allow sensory pathways to be blocked. Higher concentrations of local anesthetics also cause motor pathways to be blocked. The epidural catheter may remain in place to assist with postoperative pain control. It is possible for the epidural catheter to be advanced too far. When this happens, the catheter punctures the dural membrane, causing cerebrospinal fluid to leak into the epidural space.

With **spinal anesthesia**, an anesthetic agent is injected into the subarachnoid space. This blocks sensations in the lower body. Sensory and motor sensations are inhibited by the anesthetic. [Fig. 37.3](#) illustrates placement of the needle for epidural and spinal anesthesia.

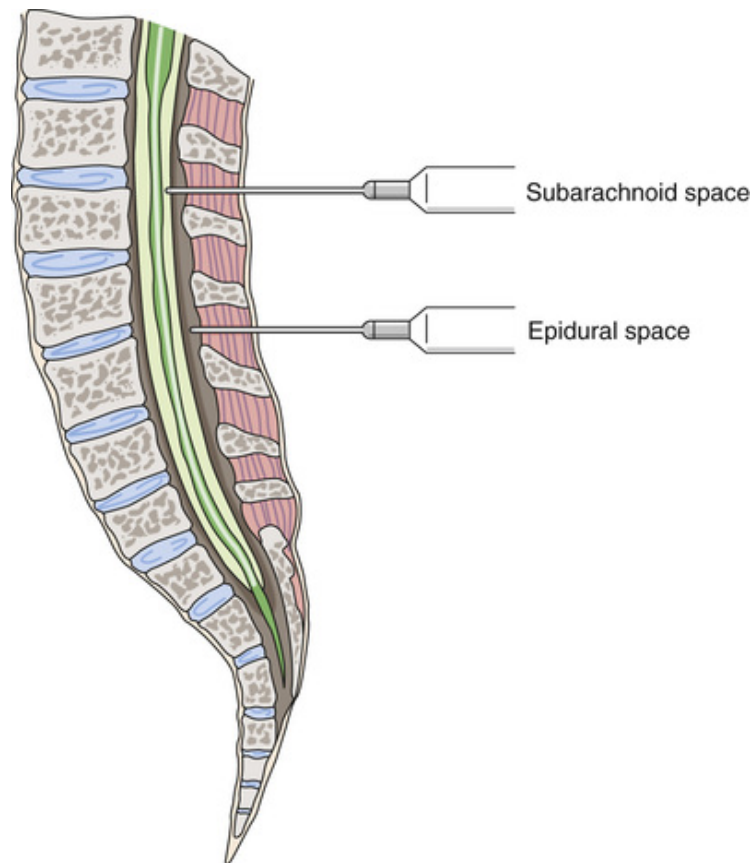

FIGURE 37.3 Placement of the needle for epidural and spinal anesthesia. (From Monahan, F. D., Sands, J. K., Neighbors, M., et al. [2007]. *Phipps' medical-surgical nursing: Health and illness perspectives* [8th ed.]. St Louis: Mosby.)

Many people experience severe headaches known as *spinal* or *postspinal headaches*. If the headache does not resolve, a blood patch may be placed over the dura hole. Blood is removed from the patient's arm and injected into the epidural space at the level of the dura hole. Many patients experience immediate relief. The patient must remain flat for approximately 2 hours after this procedure.

When minor surgical procedures require anesthesia to numb a certain area of the body requiring surgery, this type of anesthesia is administered by injecting an anesthetic into that specific site to block pain and other sensation in either a small or large region of the body. The application or injection of anesthetic drugs subcutaneously to a specific area of the body is called **local anesthesia**. The medication is often injected into the tissue surrounding the affected area and is designed to block nerve stimuli at their origin. It can be applied as drops to numb the eye or topically to relieve pain and itching. Consciousness is not altered. **Topical anesthesia** is a type of local anesthesia often used to decrease discomfort. It can be used to numb the surface of a specific area of the body, such as the mucous membranes, ear, or skin.

Postoperative Phase

Many patients are not alert and oriented when they are transported to the PACU. The gag reflex may be suppressed, and the patient may still be intubated. Depending on the operation and anesthetic agent, the patient may have decreased or absent peristalsis, decreased urine production, and a decreased level of consciousness. Patients may have surgical dressings, which are monitored for drainage. Vital sign changes can signify hemorrhage or shock. As the effects of anesthesia wear off, the patient may experience pain.

LO 37.5 ♦ Assessment

The nurse assesses the patient during each phase of the perioperative period: preoperative, intraoperative, and postoperative. Assessment data assist the nurse in planning care of the patient. The nurse gathers patient health data by collaborating with the patient and family if appropriate. Information is obtained from the medical record and the patient (Box 37.4). It is important for the nurse to validate all information obtained. The data are evaluated, interpreted correctly, and prioritized.

Box 37.4

Health Assessment Questions

Preoperative Phase

- Do you have medication, food, or contact allergies?
- What operations have you had in the past, and when were they performed?
- Have you or family members had problems with anesthesia?
- What prescription medications are you currently taking?
- Do you take over-the-counter medications?
- Do you take herbal medications or vitamin supplements?
- Is there a possibility you may be pregnant?
- Do you smoke?
- How often you do smoke, and how long have you smoked?
- How much alcohol do you drink in a typical day or week?
- Do you use recreational marijuana or drugs?

Intraoperative Phase

- Are you comfortable? What is your pain rating?
- Do you have questions or concerns?

Postoperative Phase

- How is your breathing?

- Can you take several slow, deep breaths?
- What is your name?
- Do you know where you are?
- How do you feel?
- Are you having pain?
- Are you cold? Would you like a warm blanket?

Preoperative Health History and Physical Assessment

During the preoperative phase, the nurse conducts a health history and physical assessment to identify physical and psychosocial risk factors and strengths. Additional information gathered consists of sociocultural needs, coping patterns, support systems, and the patient's knowledge, understanding, and perception of the surgical procedure. Obtaining this information assists the nurse in individualizing the preoperative assessment and developing interventions to decrease surgical risk and complications, such as infections, atelectasis, deep vein thrombosis, and constipation. The [Joint Commission \(2019\)](#) recommends the use of proven guidelines to prevent infection after surgery.

The preoperative assessment serves as a screening process to determine whether patients are in the best possible state of health before surgery and to establish baseline data to be compared with postoperative assessments. Preoperative assessments and interventions have an influence on quality improvement and patient outcomes, because potential problems are identified ([Nicholls, Gaskin, Ward, et al., 2016](#)). During the preoperative phase, the patient communicates their concerns and fears about the procedure. This allows discussions to occur and helps alleviate some of the stress, anxiety, and fear related to the surgical procedure. The nurse provides information that improves the outcome of surgery, such as facts about smoking cessation and weight loss.

Discharge planning begins in the preoperative phase. A successful discharge plan is achieved by identifying potential problems preoperatively. During the preoperative assessment, the nurse evaluates the home environment and familial support. This can assist the nurse in identifying special needs or arrangements required to prepare the patient for discharge and the need for assistance from other health care team members, such as a case worker or social worker.

In addition to a complete head-to-toe assessment by the nurse, the surgeon and anesthesia team evaluate the patient. Careful assessment of the cardiovascular and respiratory systems, including the airway, is completed before surgery. Preexisting conditions are evaluated to

determine their relevance to the procedure and consider the problems or complications that could occur. A member of the anesthesia team assesses the patient's physical and emotional health preoperatively. The patient's past experiences and adverse effects from anesthesia are reviewed to determine anesthesia risks. The surgeon or anesthesia provider orders preoperative testing.

After performing the history and physical assessment, the nurse prepares the patient for surgery, reviews preoperative testing results, and verifies that consent has been obtained. Abnormal preoperative testing results are reported to the physician. Based on the results of testing, additional tests may be ordered to provide more detailed information regarding the health status of the patient.

Safe Practice Alert

Preoperative assessments can improve patient safety and patient outcomes by identifying potential risk factors that can increase the patient's surgical risk.

Activity Level and Level of Consciousness

A baseline assessment of the patient's level of consciousness, orientation, the ability to maintain thought patterns, follow commands, and respond to questions and tactile stimulation is obtained. During the postoperative phase, a comparison with the preoperative neurologic assessment can be used to determine changes. This information assists the nurse in planning and implementing safe care.

Vital Signs

Preoperative vital signs are taken to establish baseline data. The patient's blood pressure, pulse, respiratory rate, temperature, and pain level can alert the nurse and health care team to current problems. During the intraoperative and postoperative phases of surgery, vital signs are compared with the preoperative vital signs to detect changes that may herald complications.

Laboratory and Diagnostic Examinations

When a patient is scheduled for surgery, diagnostic preoperative tests may be ordered to provide baseline data and identify problems that may contribute to postoperative complications. The type of testing is based on the patient's current medical problem, preexisting illness,

overall health status, age, and the surgical procedure to be performed. [Table 37.3](#) lists common preoperative diagnostic tests and detailed nursing assessment information.

TABLE 37.3**Common Preoperative Diagnostic Tests**

Before all blood tests and procedures, explain the procedure and purpose to the patient. After blood tests, apply pressure to the venipuncture site.		
TEST	RATIONALE	NURSING ASSESSMENT
CBC	To detect hemorrhage, dietary deficiencies, anemia, hydration status, coagulation ability, and infection	Assess overall appearance for nutritional and hydration status. Assess vital signs to detect anemia, infection. Assess for signs of blood loss to detect hemorrhage or anemia.
Electrolytes	To monitor fluid and electrolyte balance and therapy	Assess preoperative medications for diuretics, potassium supplements, or other medications that affect electrolyte levels. Assess cardiac and neurologic function.
Blood type and crossmatch	To determine blood type before donating or receiving blood	Assess the patient's views on blood transfusions.
BUN and creatinine	To measure renal function	Assess intake and output.
Pulmonary function test	To assess lungs and pulmonary reserve before anesthesia, to assess response to bronchodilator therapy, and to detect pulmonary deficiencies.	Assess patient medications and respiratory status.
Chest x-ray	To obtain information about the heart, lungs, bone structure, and large blood vessels in the chest.	Ask female patient if she is pregnant or suspects being pregnant. Have the patient remove clothing and metal objects (e.g., necklaces, pins) from the neck to the waist.
Blood glucose	To directly measure blood glucose used to evaluate diabetic patients	Assess for preoperative diabetic medications, hyperglycemia and hypoglycemia.
ALT (formerly SGPT), AST	To identify disease of the liver	Assess for signs of jaundice.
Coagulation studies	To evaluate clotting mechanisms	Assess preoperative anticoagulant medications. Check skin color and monitor for bleeding.
ECG	To evaluate arrhythmias, conduction defects, myocardial injury and damage, and pericardial disease	Assess preoperative cardiac and antihypertensive medications. Assess cardiac status.
Urinalysis	To detect urinary tract disease, and to gain basic information about kidneys and other metabolic processes	Assist with collection as needed. Assess the patient's intake and output.
Human chorionic	To diagnose pregnancy	Assess the patient's pregnancy history, last menstrual period, and

gonadotropin	prenatal care if results are positive.
--------------	--

ALT, Alanine aminotransferase; *AST*, aspartate Aminotransferase; *BUN*, blood urea nitrogen; *CBC*, complete blood count; *ECG*, electrocardiogram; *SGPT*, serum glutamic pyruvic transaminase.

Adapted from Pagana, K. D., & Pagana, T. J. (2018). *Mosby's manual of diagnostic and laboratory tests* (6th ed.). St Louis: Elsevier.

Intraoperative Phase

During the intraoperative phase, the nurse assesses the patient's response to surgery. An important role for the circulating nurse is to be the patient advocate, because anesthetized patients cannot speak for themselves. Safety is evaluated in the operating room throughout the intraoperative phase.

Continuous Monitoring of Vital Signs

During the intraoperative phase, the nurse and the anesthetist continuously monitor the patient's vital signs, including temperature, heart rate, blood pressure, respiration, oxygen saturation, intake and output, and the electrocardiogram (ECG). The amount of blood loss is always assessed. Continuous monitoring is essential to quickly distinguish adverse effects from anesthesia or the surgical procedure. Prompt interventions can help control the adverse effects and prevent further complications from developing.

Assessment of Positioning and Other Safety Concerns

An important task for the circulating nurse is assessment of safe and proper positioning. The surgical team places the patient in a position that allows access to the patient's airway and surgical site. Safety, comfort, and monitoring vital signs are considered when the patient is being positioned.

The circulating nurse assists in managing other safety concerns. The **scrub nurse** prepares and maintains the sterile field. The circulating nurse can provide assistance to the scrub nurse by transferring equipment and supplies to the sterile field. Sharps, sponges, and instruments are counted as they are added to the sterile field. Additional counts are performed before the surgery is completed to ensure that supplies are not left inside the patient. Specimens obtained during surgery are labeled and handled appropriately to ensure proper evaluation. All specimens, sharps, sponges, and instrument counts are

documented on the intraoperative record ([Card, Sawyer, Degnan, et al., 2014](#)).

Postoperative Phase

After surgery has been completed, the patient is transferred to the PACU. Often, two or more individuals from the surgical team, including the anesthesia provider, accompany the patient to the PACU. The patient may be awake, alert, drowsy, sedated, or intubated. This is a critical time for the patient. Sudden or rough handling can cause injury, hypotension, or cardiac arrest.

The PACU nurse receives a report on the patient that includes the following:

- Patient identification
- Type of anesthesia received
- Name and length of the procedure performed
- Location and number of drains and dressings
- Estimated blood loss
- Name and amount of fluid received
- Vital signs
- Oxygenation saturation
- Urinary output

In the postoperative phase, the nurse assesses the patient's physical response to surgery and monitors for postoperative complications. The PACU nurse immediately assesses the patient, including airway, breathing quality, vital signs, level of consciousness, orientation, speech pattern, motor and sensory ability, and dressings. Ongoing detailed assessments include the following data:

- General health and appearance
- Level of consciousness and neurologic status
- Vital signs and pain level
- Respiratory system—breath sounds, rate, rhythm, depth, use of accessory muscles, gag reflex
- Oxygenation saturation and capillary refill
- Skin color and temperature

- Patency of IV lines, IV fluids, and infusion rate
- Patency of drains
- Urinary output
- Surgical site
- Dressing drainage (type, amount, and color)
- Drainage under the patient
- Ability to move all extremities
- Nausea
- Emesis
- Laboratory results

Based on the patient's health status and the surgical procedure, additional assessments may be needed. The frequency of postoperative assessments is based on the physician's orders, the patient's condition, identified risk factors, and hospital policies. Commonly, assessments are made every 15 minutes during the first hour and then every 30 minutes for the next 2 hours. If the patient is unstable, assessments are performed more frequently.

Vital Signs

The nurse assesses patient vital signs throughout the postoperative period. The temperature, heart rate, blood pressure, respiration, and oxygen saturation are monitored every 15 minutes until the patient stabilizes. Some facilities may have different protocols. It is important for the nurse to follow the facility's protocol and policy. The postoperative vital signs are compared with the preoperative vital signs. The nurse assesses postoperative problems (such as, pain, hypovolemia, hemorrhage, and shock) that can affect vital signs.

Monitoring Dressings, Drains, and Tubes

Dressings are monitored for drainage. The amount and type of drainage is documented by measuring the diameter of the drainage on each dressing. The surgeon often prefers to be the first person to change the surgical dressing. As a result, the nurse may need to reinforce the dressing. The amount of reinforcement dressing applied is documented.

Drainage that accumulates on a dressing, on clothing, and underneath the patient is monitored for odor, amount, color, and consistency. Drains and tubes are positioned to facilitate proper

functioning and patency. Excessive drainage from dressings, drains, and tubes may indicate hemorrhage and the need to notify the surgeon.

Neurologic Assessment

A neurologic assessment is conducted as soon as the patient enters the postoperative phase. This allows the nurse to establish the current functioning of the patient's neurologic system and to determine changes from assessments that were previously conducted. The neurologic assessment includes level of consciousness, orientation, pupillary responses, muscle strength, and movement of the extremities. The patient's response to verbal or tactile stimulation and the ability to sense touch and pain are assessed.

Elimination

Urinary and bowel elimination are monitored during the postoperative phase. Anesthesia and anticholinergic medication can decrease muscle tone, contributing to an accumulation of urine in the bladder and resulting in urinary retention. The nurse monitors the patient for restlessness, diminished urinary output, bladder distention, difficulty or inability to void, and hypertension.

Opioid medications, anesthesia, and immobility can decrease peristalsis. Decreased peristalsis can contribute to the development of hard stool and constipation. Some patients may develop ileus due to a decreased peristalsis from anesthesia or manipulation of the intestines during the surgical procedure. The nurse assesses the patient for abdominal distention, flatus, and a change in bowel habits.

1. List focused assessments and rationales for each assessment to be completed on P. L. during the first postoperative day.

LO 37.6 ♦ Nursing Diagnosis

The perioperative nurse analyzes the assessment data and makes judgments regarding the information collected. Actual or potential nursing diagnoses are developed based on the interpretation of data about the patient's health problems, needs, or health status. International Classification for Nursing Practice (ICNP) nursing diagnoses are developed for each perioperative period. Some examples are:

Preoperative phase:

Anxiety

- Supporting Data: Change in health status, fear of the unknown, increased blood pressure, heart rate, respiratory rate, verbal reports of feeling nervous

Lack of Knowledge

- Supporting Data: Preoperative procedures, asking questions, repeated need for explanations

Intraoperative phase:

Impaired Breathing

- Supporting Data: Effects of anesthesia, narcotic medications, shallow breathing, tachypnea, abnormal blood gas results

Risk for Perioperative Positioning Injury

- Supporting Data: Improper positioning during the surgical procedure

Postoperative phase:

Acute Pain

- Supporting Data: Tissue injury at the surgical site, verbal reports of pain, rubbing and guarding the surgical site, increase in blood pressure, heart rate, and respiratory rate, loss of the ability to sleep, ambulate, and perform activities of daily living (ADLs)

Risk for Infection

- Supporting Data: Invasive surgical procedure

2. Write two nursing diagnoses for P. L. in the postoperative period.

LO 37.7 ♦ Planning

During the preoperative phase, the nurse plans for the entire perioperative period (Table 37.4). This includes the expected outcomes and the nursing interventions to achieve the identified outcomes. The nurse reviews these expected outcomes with the patient and family before surgery. Collaboration with other members of the health care team is necessary during the perioperative period (Box 37.5).

TABLE 37.4
Care Planning

ICNP NURSING DIAGNOSIS WITH SUPPORTING DATA	NURSING OUTCOME CLASSIFICATION (NOC)	NURSING INTERVENTION CLASSIFICATION (NIC)
<i>Anxiety</i> Change in health status Fear of the unknown Increased blood pressure, heart rate, and respiratory rate Verbal reports of feeling nervous	<i>Coping</i> Reports decrease in physical symptoms of stress	<i>Anxiety reduction</i> Explain all procedures, including sensations likely to be experienced during the procedure

From Butcher, H. K., Bulechek, G. M., Dochterman, J. M., et al. (Eds.). (2018). *Nursing interventions classification (NIC)* (7th ed.). St Louis, MO: Mosby; Moorhead, S., Swanson, E., Johnson, M., et al. (Eds.). (2018). *Nursing outcomes classification (NOC)* (6th ed.). Box 37.5

Interprofessional Collaboration and Delegation

Multidisciplinary Care of the Perioperative Patient

- Physical therapy and occupational therapy provide assistance with ambulatory support and the use of assistive devices.
- Unlicensed assistive personnel (UAP) assist with turning immobilized patients at least every 2 hours.

- UAP encourage and assist the patient to move in bed, ambulate, eat, and increase fluid intake.
- Dietitians provide support for nutritional problems and concerns.
- The application of sequential compression devices can be delegated to UAP who have had training in this task.
- Leg exercises are taught initially by a registered nurse. Reinforcement of performing leg exercises can be delegated to UAP.

The perioperative nurse determines goals for patients having surgery. In the perioperative period, goals are developed following nursing diagnoses. It is important to individualize the goals based on the priority needs of the patient. All goals must be realistic, specific, and measurable. This helps guide the nurse when providing nursing care. The following are examples of goals for the nursing diagnoses listed earlier:

- Patient will exhibit vital signs within normal limits in the preoperative period.
- Patient will verbalize understanding of the surgical procedure before the operation.
- Patient's airway will remain patent during surgery.
- Patient will be positioned appropriately during surgery.
- Patient will report a pain level of 3 or less in the postoperative period.
- Patient will remain free from infection in the postoperative period.

The conceptual care map for P. L. can be found at <http://evolve.elsevier.com/YoostCrawford/fundamentals/>. It is partially completed to indicate how to use the map as a learning tool.

Complete the nursing diagnoses using the example conceptual care maps shown in [Chapters 8](#) and [25 to 33](#).

LO 37.8 ♦ Implementation and Evaluation

Nursing interventions provide the patient with an understanding of the surgical procedure and expectation after surgery and with care during all phases of the perioperative period. The patient is prepared psychologically and physically. The nurse is alert for potential problems and complications as the patient moves through each phase.

Interventions

The perioperative nurse implements nursing interventions to help the patient achieve goals that have been identified. This includes physiologic and psychological preparation for surgery, the immediate postoperative phase, and the patient's discharge to home. Many nursing interventions are carried out in the perioperative period, and they all are focused on achieving positive outcomes.

Preoperative Phase

During the preoperative phase, nurses are focused on assessment and teaching in preparation of the patient for surgery. Patient teaching before surgery enhances postoperative care, because the patient knows what to expect and how to respond ahead of time.

Preoperative Teaching

Many surgical patients experience stress, anxiety, and fear, which may result from the recognition of a lack of control. Preoperative teaching can help decrease fear, anxiety, and stress and reduce postoperative complications by preparing the patient for the surgical procedure and the postoperative period.

Some people fear the unknown, including surgery, anesthesia, and death. It is important for nurses to acknowledge these concerns and fears and address them with the preoperative patient. Educating the patient and family can help alleviate some of their concerns. When a patient is scheduled for surgery, teaching starts as early as possible to allow the patient to seek clarity and make appropriate decisions. Teaching may begin in the physician's office and includes the family when appropriate. The purpose is to prepare the patient for surgery and discharge. Information can be given when the patient comes for diagnostic testing and when they have been admitted for surgery. Nurses should give information in several sessions so that the patient has time to assimilate the information provided.

Preoperative teaching helps the patient and family understand what is required before, during, and after the procedure (Card, Sawyer, Degnan, et al., 2014). For teaching to be effective, the nurse provides information at a level that the patient and family understand. The patient's cultural background is considered. If there is a language barrier between a patient and a nurse, it may be necessary to arrange for a hospital-provided translator to explain information to the patient.

If the patient needs to perform certain activities in the initial postoperative phase, explaining these activities preoperatively gives the patient the opportunity to learn and practice. Teaching includes information about postoperative bandages, tubes, drains, medications, exercises, pain control, turning, antiembolism measures, assistive devices, and dietary guidelines. Box 37.6 details areas to include in preoperative teaching. The nurse develops an understanding of what the preoperative patient knows and what they need to know.

Box 37.6

Patient Education and Health Literacy

Preoperative Teaching

Before admission to the hospital, the patient receives information that explains perioperative care and routines. Preadmission education can increase adherence to postoperative care, decrease anxiety, and contribute to better performance of exercises.

- Explain preoperative testing (e.g., laboratory tests, x-rays, electrocardiogram [ECG]). This helps the patient understand how to prepare for surgery.
- Teach the patient about preoperative washing and antibacterial products that may be used to prepare the skin before surgery. Education can decrease perioperative anxiety.
- Exercises and activities that need to be performed are reviewed with the patient. This includes leg exercises, coughing, deep breathing, and incentive spirometry. Preoperative instruction can help the patient successfully perform postoperative exercises.
- Explain the importance of deep breathing, coughing, use of the incentive spirometer, splinting, and leg exercises. Coughing and deep breathing (Box 37.7) and incentive spirometry (Box 37.11) help expand the lungs and improve ventilation. Splinting helps support the incision and promote comfort (Box 37.8). Leg exercises

help stimulate circulation and minimize the risk of thrombus formation.

Box 37.7

Nursing Care Guideline

Cough and Deep-Breathing Techniques

Background

- The following breathing techniques are used by postoperative patients:
 - Controlled cough
 - Deep breaths in through the nose and exhaled through the mouth
 - Diaphragmatic breathing
 - Pursed-lip exhalation
- The techniques have the following benefits:
 - Maintenance of lung expansion
 - Prevention of atelectasis and pneumonia
- If surgery is planned, the patient can benefit from being taught one or more of these techniques *before* surgery to allow time to practice them before they are needed.

Procedural Concerns

- The patient should be in an upright position (semi-Fowler or Fowler if possible).
- Instruct the patient in deep breathing:
 - Rest the palms of the hands below the rib cage, with the middle fingers touching.
- Take slow, deep breaths:
 - Inhale through the nose.
 - Feel the abdomen push against the hands.
 - Keep the chest and shoulders still.
 - Inhale as deeply as possible.
 - Hold that breath for 3 to 5 seconds.
 - Exhale slowly through pursed lips (see the pursed-lip breathing instruction), and stop exhaling when the middle fingers touch again.
- Perform each inhalation and exhalation three to five times before resting.
- Perform all of these steps 10 times every hour if possible.
- Controlled coughs:
 - If the patient has an abdominal or thoracic incision, provide a splint (see [Box 37.8](#)).
 - Have the patient take two deep breaths in and out.
 - The patient then inhales as deeply as possible and holds it for 3 to 5 seconds.
 - Release the breath as a full cough; cough two or three times, but do not inhale between coughs if possible.
- Perform these steps two or three times every 2 hours if possible.
- Pursed-lip breathing:

- Have the patient purse the lips as if to make a whistling sound (into an O shape) and then release a slow, controlled exhalation.

Documentation Concerns

- Document the patient education concerning correct procedure and performance times.
- Note patient concerns or discomfort, and document any issues.
- Include the respiratory assessment before and after the procedure.
- Document the number of times the patient performed each step and the patient's tolerance of the procedure.

Evidence-Based Practice

- Deep-breathing exercises are included as part of the routine guidelines and taught preoperatively to maximize understanding on the part of the patient when not impaired by the effects of medications.
- There is a definitive fall in lung volume postoperatively, and these exercises are as effective as continuous positive airway pressure in increasing lung volume (LaBrin, Markley, & Rice, 2012).

Box 37.8

Nursing Care Guideline

Postoperative Splinting

Background

- Postoperative splinting is used to support an incision and to promote comfort by decreasing pressure, discomfort, and pain related to an incision.
- It is used during coughing, deep breathing, or movement that may cause sutures to tear.

(From Lewis, S. L., Bucher, L., Heitkemper, M. M., et al. [2017]. *Medical-surgical nursing: Assessment and management of clinical problems* [10th ed.]. St Louis: Elsevier.)

- Postoperative splinting is used primarily for incision sites on the abdomen and the thorax.

Procedural Concerns

- One of the patient's hands is placed on top of the incision; the other hand is placed on top of the first.
- For comfort, the patient may use a pillow, holding it under the hands and over the incision.

- After placement, the patient may continue with controlled coughing or deep-breathing procedures (see [Box 37.7](#)) or with repositioning and getting out of bed.

Documentation Concerns

- Document that the patient has been educated about how to correctly perform the procedure.
 - Document any patient's concerns or discomfort.
 - Include assessments of the incision.
- The patient performs a return demonstration of exercises before surgery. Return demonstration is an effective method to evaluate learning and reinforce instruction.
 - Teach the patient how to move in bed and out of bed after surgery. This enables the patient to assist with turning and changing positions in bed.
 - Explain that pain medication will be given to help manage pain. Providing information can promote comfort, help the patient

understand what to expect after surgery, and decrease fear and anxiety.

- Describe the type of assessments that will be conducted. This enables the patient to become knowledgeable about dressings, drains, and equipment.
- Explain that the patient will be cared for in the postanesthesia care unit (PACU) immediately after surgery. After a period of observation, the patient will be discharged home or sent to a surgical unit.
- If the patient is going to be discharged after surgery, provide instructions on what to wear the day of surgery, and inform the patient that another adult will need to drive home. This will help familiarize the patient with expectation.

Pain Management Plan

The patient having surgery often has anxiety and fear related to pain. The surgical patient can expect to experience some type of pain from surgery. The patient is informed of the treatment plan to help manage pain. It is important for the patient to understand that the pain must be controlled to allow maximized participation in postoperative therapy (Card, Sawyer, Degnan, et al., 2014).

Pain levels should be monitored frequently by using a pain scale. An assessment is conducted to determine aggravating and alleviating factors related to pain. If patient-controlled analgesia (PCA) is ordered for pain control, the patient is taught how to push the button for pain moderation. Cultural beliefs and expectations regarding pain management are considered. Effective pain management strategies and therapies used in the past are explored. Complimentary and alternative therapy used for pain management (such as, massage, distraction, guided imagery, and relaxation) can be utilized in the postoperative period. Chapter 36 provides more information on pharmacologic and nonpharmacologic complimentary and alternative methods used to control of pain.

Informed Consent

When surgery is recommended for treatment, patients must be given information that allows them to make informed decisions. Having a good understanding of proposed procedures allows a patient to select or reject treatment options.

The physician is responsible for obtaining the informed consent for surgery (Card, Sawyer, Degnan, et al., 2014). The signed **informed consent** document gives legal authorization for the surgical procedure,

and it helps protect the patient from having unauthorized procedures performed. It can protect the health care team and hospital from claims by the patient that an unauthorized procedure was performed.

Qsen Focus!

Patient-centered care is facilitated through informed consent and by informing the patient of care that will be provided throughout the perioperative period. The preoperative nurse witnesses the informed consent for surgery and explains the care that will be provided.

The written signature enables the consent form to become a legal document. After the patient signs the document, the consent form becomes a permanent part of the medical record. The consent form is signed before the patient is given analgesics or sedative medications.

Before consent is obtained, the patient is given a description of the surgical procedure, benefits, risk factors, potential complications, expected outcome, and postoperative recovery by the surgeon. Additional information regarding the procedure or the health status of the patient is provided. The consent form ([Fig. 37.4](#)) discloses enough information to allow the person to make an informed decision. The informed consent includes documentation of the patient's mutual understanding of, and agreement to, treatment and care. A patient needs to voluntarily give consent without persuasion or threats to influence the patient to agree to the procedure.

Date of procedure: ____/____/____

CONSENT FOR PROCEDURE

I, _____, request and give consent to _____
(Type or print patient name) (Type or print doctor or practitioner name(s))
to perform the following procedure(s) _____
(Please list site and side if appropriate)

The benefits, risks, complications, and alternatives to the above procedure(s) have been explained to me. I understand that the procedure(s) will be performed at the facility by and under supervision of my doctor or practitioner. My doctor or practitioner may use the services of other doctors or practitioners, or members of the resident staff as he or she deems necessary or advisable. I authorize my doctor or practitioner and his or her associates and assistants to perform such additional procedures, which in their judgment are necessary and appropriate to carry out my diagnosis or treatment. I authorize the hospital to retain, photograph, preserve and use for scientific, teaching purposes, or to make other dispositions of, at their convenience, any specimens, tissues, or parts taken from my body during the course of this operation. I consent to observers in the procedure area in accordance with hospital policy. I consent to a healthcare industry representative being present during the procedure, if necessary, to provide technical assistance or to perform calibration of equipment. I consent to photography or video taping of my surgical procedure for educational purposes, provided my identity remains anonymous and confidential. I consent to the administration of sedation or analgesia during my procedure. The risks, benefits, and alternatives to receiving sedation or analgesia have been explained to me. If anesthesia is required, I consent to the administration of anesthesia by members of the Department of Anesthesiology. I also consent to the use of non-invasive and invasive monitoring techniques as deemed necessary. I understand that anesthesia involves risks that are in addition to those resulting from the operation itself including, but not limited to, dental injury, hoarseness, vocal cord injury, infection, nerve injury, corneal abrasion, seizures, heart attack, stroke and even death. If applicable, I consent to the use of fluoroscopy. I understand that prolonged exposure to fluoroscopy may result in skin reactions, such as redness, irritation or a burn. Please initial one of the following statements (females 55 years and under): _____I believe I am pregnant. _____To the best of my knowledge I am not pregnant. I certify that I have read and understand the above consent statements. In addition, I have been offered the opportunity to ask my doctor or practitioner any questions I have regarding the procedure(s) to be performed and they have been answered to my satisfaction. I acknowledge that I have been given no guarantee or assurance as to the results that may be obtained from the procedure(s).

Signature of Patient or Decision Maker _____	Date ____/____/____	Time _____	Doctor or Practitioner Signature/Title _____	Date ____/____/____	Time _____
Relationship to Patient _____			Doctor or Practitioner Print Name or ID# _____		
Witness Signature _____	Date ____/____/____	Time _____			
Witness Print Name _____					

Telephone Consent:

Name of person providing consent _____	Relationship to Patient if Decision Maker _____				
Witness Signature _____	Date ____/____/____	Time _____	Witness Signature _____	Date ____/____/____	Time _____
Witness Print Name _____	Witness Print Name _____				

Interpretation: The information presented orally to the patient representative decision maker was interpreted into (language): _____ . The person for whom the information was interpreted stated s/he understood the interpretation.

Interpreter Name _____	Agency and ID# (if applicable) _____		
Staff Signature/Title _____	Print Name or ID# _____	Date ____/____/____	Time _____

FIGURE 37.4 Sample informed consent document. (Courtesy Christiana Care Health Services, Newark, DE.)

Failure to obtain an informed consent can have legal consequences. If a surgical procedure is performed without consent, it can be viewed as assault, battery, or malpractice. [Box 37.9](#) provides information that is included in a consent form. Barriers to understanding the informed consent are cultural issues, font size, forms that are too long, and a patient's lack of medical knowledge and education ([Perrenoud, Velonaki, Bodenmann, et al., 2015](#)).

Box 37.9

Ethical, Legal, and Professional Practice

Informed Consent

Informed Consent Discloses the Following

- Medical diagnosis and reason for treatment
- Procedure to be performed
- The name of the person performing the procedure
- Qualifications of the person performing the procedure
- Names of individuals assisting with the procedure
- Risks and benefits of the procedure
- Alternative treatments
- The right to refuse or withdraw consent at a later date

Ethical and Legal Concerns

- Every person has the right to agree to or refuse health care treatment.
- When informed consent is given, the person understands the treatment options.
- Consent is given voluntarily.
- The law requires the medical provider to obtain consent for medical treatment.
- The nurse may sign a consent form as a witness to the patient's signature.
- A legal guardian may give consent for a minor child, an unconscious patient, or someone with dementia (Rothrock & McEwen, 2019).
- If there is a question about an individual's competency, a court will make a determination. A legal guardian is appointed by the court if a person is determined incompetent.

Safe Practice Alert

The physician or surgeon is responsible for obtaining informed consent. The preoperative nurse is responsible for making sure the consent is signed by the patient and placed in the patient's chart.

Informed consent is not needed in emergency circumstances. When the patient is not able to give consent, the physician attempts to obtain the consent from the next of kin or legal guardian. The consent may be obtained by telephone or court order. If time does not allow for this, the physician has the responsibility of documenting the need for treatment to save the patient's life in the medical record. The physician also considers the organizational policy and state laws when emergency surgery is needed and the consent has not been obtained.

During the consent process, the nurse provides information about nursing care, facilitates preoperative teaching, and reinforces information about the procedure. The nurse is a witness to the patient's signature and to the patient being competent and signing voluntarily. If the nurse finds that the patient does not understand the procedure or that the patient is unsure about signing the consent form, the nurse informs the physician of the situation and asks the physician to talk to the patient (Box 37.10).

Box 37.10

Nursing Care Guideline

Obtaining and Completing Informed Consent

Background

- Obtaining and completing the informed consent document is the responsibility of the surgeon.
- Witnessing a consent form means:
 - The nurse has watched the correct patient signing the form.
 - The nurse has verified the correct identity of the patient who is signing the form.
 - The nurse signs the form as a witness to the preceding two events.
- Be aware of individual facility policy and procedures.

Procedural Concerns

- Never witness a blank or incomplete informed consent form. Ensure all the information is complete.

- Do *not* administer analgesic or sedative medications before the informed consent form is signed by the patient.
- If the patient does not understand any aspect of informed consent, contact the surgeon to speak with the patient again and to answer questions before sedation.
- To sign the informed consent, the patient must:
 - Be mentally sound
 - Have all information in the patient's primary language
 - Be of legal age
 - Not be under sedation
- The patient has the right to withdraw consent at any time and refuse treatment.

Documentation Concerns

- Document that consent was obtained.
- Indicate that all information is complete.
- Include the preoperative checklist.

Evidence-Based Practice

- Health literacy is often overlooked on an informed consent form, but it should be considered to ensure that the consent is valid.
- Incorporating language that is in terms an average person can read, shortening the form, increasing the font size, bulleting information, and using a teach-back technique (i.e., the patient restates information) can enhance the intended meaning and value of informed consent ([Perrenoud, Velonaki, Bodenmann, et al., 2015](#)).

After consent has been obtained, the signed and witnessed form is a legal document that becomes a part of the patient's chart. Consent forms are not legal if the patient is sedated, confused, or incompetent. When a patient refuses to sign the consent form, the nurse documents in the patient's medical record that the patient refused to consent to surgery. Some organizations request that the patient sign a release form that identifies the refusal to consent.

Safe Practice Alert

A nurse acts as a patient advocate before the consent form is signed, ensuring that the patient has been informed about the surgical procedure and has no further questions for the physician. If the patient does not have additional questions, the nurse has the responsibility to act as a witness to the patient signing the consent form.

Patient Preparation

The type of surgery dictates the preparation necessary to get a patient ready for the procedure. When scheduled for an elective or urgent procedure, some patients are required to fast before surgery. Some anesthetics delay normal reflexes so that the body's usual defenses may not be working properly. An empty stomach helps decrease the chances of regurgitating undigested food or liquids. Aspiration of gastric contents during the intraoperative or postoperative period may lead to aspiration pneumonia. If a patient is ordered to be NPO but has scheduled oral medications, the nurse needs to clarify with the surgeon which medications are to be given. The surgeon may order some medications to be given with sips of water the day of surgery. Surgery may be cancelled or delayed if a person does not remain NPO when necessary. Each organization may have policies that provide guidelines for fasting.

Patients who are admitted because of medical emergencies (such as, trauma) and those whose health deteriorates rapidly may need to have surgery performed quickly. This means they will have a shortened preoperative phase. Patients having emergency surgery may not have time to fast and therefore may have a nasogastric (NG) tube inserted to assist with gastric emptying.

Usually a preoperative checklist ([Fig. 37.5](#)) needs to be completed on paper or in the electronic health record before the surgical procedure. The nurse has the responsibility of completing the information on the checklist. If some areas of the checklist have not been completed, the nurse communicates this information to the health care team.

FIGURE 37.5 Sample preoperative checklist. (From Lewis, S. L., Bucher, L., Heitkemper, M. M., et al. [2017]. *Medical-surgical nursing: Assessment and management of clinical problems* [10th ed.]. St Louis: Elsevier.)

Intraoperative Phase

The operating room has a specialized team to assist with the surgical procedure. Each member of the surgical team has a specific job and function. All members work together to achieve positive outcomes for the patient. The team is created with the primary goal of maintaining patient safety.

Nursing Roles During Surgery

Table 37.5 lists the surgical team members and their functions. The members of the team vary slightly based on the procedure being performed, the type of anesthesia being administered, and the hospital policy. Each sterile (scrubbed) member of the team performs surgical scrub, gowning, and gloving before the operation or procedure (Skill 37.1).

TABLE 37.5**Intraoperative Surgical Team**

TEAM MEMBER	FUNCTION
Surgeon (physician)	Treats malformations, injuries, and diseases by manipulation or operation
Scrub nurse/assistant (registered nurse or surgical technologist)	Prepares the surgical setup, handling instruments Maintains surgical asepsis while draping Assists the surgeon by passing instruments, sutures, and supplies
Circulating nurse (registered nurse)	Acts as the patient's advocate and a liaison between scrubbed personnel and the surgical team Coordinates the needs of the surgical team by obtaining supplies and carrying out the nursing care plan Assesses patient safety and aseptic practice Documents in the electronic medical record (EMR)
Anesthesiologist (physician)	Administers anesthesia Monitors the patient during surgery
Certified registered nurse anesthetist (CRNA)	Administers anesthesia and collaborates with the anesthesiologist Monitors the patient during surgery
Registered nurse first assistant (RNFA)	Collaborates with the surgeon and health care team members during the procedure

Anesthesia

Shortly before the intraoperative phase begins, some patients may be given medications to help them relax and to dry secretions. The patient's transfer by cart, bed, or wheelchair to the operating room begins the intraoperative phase. Assistance is provided to transfer the patient to the operating room table. For safety, the patient is strapped to the table. Members of the surgical team are introduced to the patient. At this time, the administration of anesthesia begins. Until anesthesia induction, the patient is kept informed about what is happening to help decrease anxiety.

Safe Practice Alert

Patient safety is the nurse's first priority. The circulating nurse maintains patient safety during the surgical procedure by monitoring the patient's condition and surgical asepsis.

Surgical procedures can be very uncomfortable. Anesthesia allows surgery to be performed, making the patient insensitive to pain and sensation. The type of anesthetic agent to be administered is largely determined by the anesthesia provider, the type of surgery, and the

patient's health. When there are preexisting illnesses, certain types of anesthesia may be used to help manage the underlying health condition of the patient. The surgeon collaborates with the anesthesia provider to determine the type of anesthesia used, but the anesthesia provider makes the final decision. The anesthesia provider is in charge of the medical management and anesthetic care of the patient during surgery.

Support is given to the patient on induction of anesthesia, during the procedure, and as he or she emerges from anesthesia to help allay fear and anxiety. The patient's responses to anesthesia are monitored during surgery. Continuous medical assessment of the patient includes monitoring and controlling the heart rate, heart rhythm, blood pressure, temperature, fluid balance, pain, breathing, and level of consciousness. Care is taken to match the anesthetic needs and the medical condition of the patient.

General anesthesia causes a drug-induced coma, not a sleeplike state. When the medications begin to be metabolized and excreted, the patient gradually begins to recover consciousness. It takes time for this to happen. Patients are at risk for a variety of medical problems as they emerge from the anesthesia. Complications that can occur include injury to the throat or vocal cords, laryngeal edema, and laryngospasms. The nurse monitors the patient closely and must be prepared to provide assistance to support the respiratory system.

Safe Practice Alert

Airway and ventilation status is assessed for all patients receiving anesthesia.

During the intraoperative phase, perioperative nurses document appropriately. This includes documenting how the patient is positioned, the start of surgery, medications, drains, specimens, instrumentation, sponges, needles, dressings, and the end of surgery.

Postoperative Phase

The postoperative period begins with transfer to the PACU. The postanesthesia nurse provides care to the patient after the surgical procedure in the PACU. Postoperative care consists of caring for the patient and providing intensive support in the immediate postoperative phase. The nurse focuses on quickly recognizing the best way to reestablish a normal homeostatic balance for the patient. The nurse orients the patient and informs the patient that surgery is over. To promote comfort and decrease anxiety, the nurse pays special attention

to the patient's pain level, position, and need to urinate. Bright overhead lights and a noisy environment are avoided, and room temperature is kept at a level comfortable for the patient (Rothrock & McEwen, 2019).

Airway Management

Maintaining the patient's airway is the nurse's first priority. The patient is positioned in a manner that facilitates breathing. The surgical procedure and preexisting health problems are considered when positioning the patient. The patient is positioned to prevent aspiration, facilitate respiration, promote comfort, and accommodate tubes, casts, and incisions.

Monitoring Vital Signs

Vital signs are monitored during the postoperative phase. Nursing assessments and interventions focus on temperature, blood pressure, pulse, respiration, and oxygen saturation. All vital signs are compared with the baseline data, and deviations from the preoperative vital signs are documented and reported. Changes in vital signs can be symptomatic of many complications. Diligent assessment of the patient is conducted to quickly identify problems or complications.

Monitoring Neurologic Status

Assessing the patient's neurologic system provides data for nursing interventions to reduce surgical risk factors and postoperative complications. The nurse compares the postoperative data with preoperative baseline data to plan interventions. The PACU nurse orients the patient to the environment, monitors mental status, and provides a calm environment in the immediate postoperative setting.

Pain Management

Surgery is an invasive procedure, and pain is an expected outcome. It is difficult to eliminate pain completely after a major surgical procedure. Pain stimulates the sympathetic nervous system, resulting in tachycardia, immobility, shallow breathing, and impaired gas exchange. Each of these effects is potentially harmful. The nurse thoroughly assesses a patient and the response to pain in the postoperative period at least every 2 hours and treats accordingly. If the patient's pain is poorly controlled, assessment is performed more frequently. If a patient does not experience a significant decrease in pain from ordered pain medications and alternative therapies, the nurse should consider revising the plan of care and notify the surgeon. Education is necessary if a patient is being sent home on pain medications.

Safe Practice Alert

The patient's report of pain, the type of pain medication, the medication order, and vital signs determine pain management strategies. The only exception to this is when the patient is not able to communicate.

It is difficult to manage acute pain in patients who use opioids for chronic pain. These patients use opioids to achieve pain control on a daily basis. Surgery causes acute pain, and additional pain management techniques may be necessary. A pain management plan can determine how to better manage a patient's pain.

After the immediate postoperative period, a patient whose pain is controlled is more likely to perform leg exercises, ambulate, cough and deep-breathe, turn, and use the incentive spirometer, decreasing the likelihood of postoperative complications. Administering pain medications and using nonpharmacologic complimentary and alternative pain management techniques enable the patient to feel more comfortable. Pain is managed by a variety of medications, including narcotics, nonopioid medications, and analgesics. Activities (such as, distraction, relaxation, music, and guided imagery techniques) create comfort and decrease anxiety (see [Chapter 36](#)). Heat and cold applications are used as complimentary therapies in pain management (see [Chapter 29](#)). It is important for the nurse to follow the primary care provider's orders and understand hospital policy to determine which applications are appropriate for the patient.

Postoperative Safety

Safety measures are carefully implemented for postoperative patients. In the postoperative phase, the top side rails are kept up and the call light in reach so that the patient can call for assistance. Pillows are not used with unconscious patients to decrease the risk of airway complications, such as accidental suffocation. When unconscious patients begin to wake up, the nurse orients them to where they are, informs them that the surgical procedure has been completed, and gives additional instructions or information they may need.

Nursing Care of Common Postoperative Complications

Postoperative complications are a major concern. Many postoperative complications and problems rapidly become critical situations. A

patient can be at risk for postoperative complications for numerous reasons.

Many postoperative complications can be prevented by preoperative assessments, vigilance during the immediate postoperative period, and nursing interventions. Understanding how adverse events and errors occurred can prevent future errors and improve morbidity and mortality rates (Boehm, Baumgarten, & Hoeft, 2016). If a postoperative complication does occur, the nurse performs an assessment, provides nursing care, and carries out the interventions designed to minimize the effects of the complication. During this time, the nurse may need to provide the patient and family emotional support.

Airway Obstruction

An **airway obstruction** is a life-threatening emergency that produces reduced airflow. It is a common postoperative complication. Airway obstruction can occur when the tongue falls back into the pharynx, or it can result from laryngospasm, bronchospasm, or aspiration of gastric contents. It often occurs when the patient is lying in a supine position and is very relaxed.

Airway obstruction is a high priority because it interferes with the delivery of oxygen to vital organs. Nursing care of a patient with an airway obstruction includes manual opening of the airway with a jaw-thrust or chin-lift maneuver. Close assessment determines whether there is an obvious obstruction, such as the tongue, vomit, blood, secretions, loose teeth, or a foreign body that needs to be removed. Suctioning can be performed to remove vomit, blood, and secretions. Interventions performed are evaluated to determine their effectiveness. The patient with an advanced airway problem sometimes needs the assistance of an anesthesia provider. Manual resuscitation with an Ambu bag or bag-valve-mask device or re-intubation may be necessary to force oxygen into the lungs and facilitate obtaining a patent airway.

Hemorrhage

A large amount of bleeding, or **hemorrhage**, can occur in the immediate postoperative period from internal or external blood loss. During the postoperative phase, hemorrhage can occur from a weak suture, stress on the surgical site, medications, or a clot that has become dislodged.

Nursing care focuses on controlling the bleeding and replacing blood volume if needed. Careful assessment is performed to look for clinical indications of hemorrhage, such as anxiety; restlessness; cold, clammy skin; a weak, thready, rapid pulse; hypotension; respirations that are rapid and deep; increased thirst; and decreased urine output. The nurse pays close attention to the surgical dressing.

When assessing for bleeding, the nurse observes the color of the blood. Bright red blood suggests recent bleeding; dark, brownish blood indicates that the bleeding is not fresh. The perimeter of the blood stain on the original dressing is outlined. Reinforcement of the original dressing may be needed. The date and time the outline was made is noted on the dressing. When external bleeding occurs, pressure is applied to the site manually with gloved hands or with a pressure dressing to stop or slow the bleeding. Manual pressure is performed with caution to prevent further injury to the affected area. If bleeding is severe, the patient may need to return to the operating room.

Safe Practice Alert

Always wear gloves when changing or reinforcing dressings or when applying manual pressure over a wound that is bleeding.

Shock

When the circulatory system fails to maintain adequate perfusion to the vital organs, **shock** occurs. As a result, the heart is unable to pump enough blood to the body. This is a life-threatening postoperative complication, and cell and organ death will occur if it is untreated. Hypovolemic shock is the most common type of shock seen in postoperative patients. It occurs when there is a decrease in circulating blood volume due to hemorrhage or dehydration.

Common assessment findings are similar to those identified for hemorrhage. Hypovolemic shock is considered a medical emergency. The symptoms and prognosis can vary according to the amount of blood volume lost, the rate of blood loss, and the underlying cause of shock.

The goals of treatment for shock consist of improving and maintaining tissue perfusion by correcting the cause of shock. Nursing care is focused on establishing a patent airway, monitoring vital signs, administering oxygen as ordered, maintaining a flat position with the legs elevated to increase venous return, and monitoring laboratory test results (e.g., arterial blood gases, complete blood count). Additional interventions aimed at regaining homeostasis and increasing circulating fluid volume include maintaining body temperature and administering blood, IV fluids, and prescribed medications.

Thrombophlebitis

Thrombophlebitis is inflammation of a vein with the formation of a thrombus (i.e., blood clot). For postoperative patients, a blood clot

commonly originates in the deep veins of the legs, known as *deep vein thrombosis* (DVT) or *venous thromboembolism* (VTE). It can result from trauma during surgery, decreased blood flow, immobility, and varicose veins. Patients have cramping, pain, redness, and swelling in the extremity with the thrombus. A venous Doppler ultrasound can be used as a diagnostic test and to guide treatment.

Nursing care focuses on preventing clots from developing and preventing a thrombus from becoming detached if they have formed. Antiembolism stockings (see [Chapter 28](#), Skill 28.4), sequential compression devices (see [Chapter 28](#), Skill 28.5), leg exercises, and ambulation can be used to promote circulation and help prevent a thrombus from forming. If thrombophlebitis occurs, treatment consists of the administration of anticoagulants and analgesics, bed rest, elevation of the affected extremity, and measuring the circumference of the affected extremity every shift. Laboratory values for clotting times are monitored, and the patient is instructed not to rub or massage the affected extremity.

3. Identify at least three nursing interventions with rationales to prevent the postoperative complication of deep vein thrombosis for P. L.

Pulmonary Embolism

A blood clot that detaches and lodges in the pulmonary artery is called a **pulmonary embolism (PE)**. Fat droplets, air bubbles, venous stasis, amniotic fluid, tumor cells, and clotting disorders contribute to the development of a PE. Venous stasis, which is commonly seen in postoperative patients, is a risk factor for development and dislodgment of a thrombus, a portion of which may break away from the wall of the vein and travel to the heart, lungs, or brain. PE is a life-threatening complication, and immediate intervention is needed to sustain life. Patients have the following signs and symptoms at clinical presentation:

- Anxiety
- Restlessness

- Chest pain
- Dyspnea
- Cough
- Cyanosis
- Leg pain and swelling (in one or both legs)
- Dysrhythmias
- Tachypnea
- Tachycardia
- Hypotension

Nursing care includes stabilizing the respiratory and cardiovascular systems. A concern for these patients is the potential development of other emboli. Treatment consists of administering anticoagulants to dissolve the clot, analgesics for pain, and sedatives for anxiety. The patient is administered oxygen and placed on bed rest. The head of the bed is elevated to facilitate breathing. The nurse provides instructions to the patient to avoid activities that increase intrathoracic pressure (Valsalva maneuver), which can increase the risk of more emboli traveling to the pulmonary artery. The nurse monitors vital signs, pulse oximetry, laboratory tests for clotting times, and the cardiovascular and respiratory systems.

Pneumonia

Pneumonia is inflammation of the lungs. It is usually caused by an infection or foreign material. In postoperative patients, pneumonia may occur (usually 48 to 72 hours postoperatively) as a result of aspiration, excessive pulmonary secretions, immobility, failure to cough deeply, and a depressed cough reflex. Assessment of the patient reveals dyspnea, adventitious breath sounds, chest pain, chills, fever, and cough. The cough may be productive with purulent or rust-colored secretions.

Treatment includes promotion of lung expansion and preventing the spread of infection. Nursing care includes interventions to improve lung function, such as encouraging the use of the incentive spirometer ([Box 37.11](#)), nebulizer treatments, and intermittent positive-pressure breathing (IPPB). Antibiotics are given to treat the infection. Other treatments are expectorants, antipyretics, and analgesics. The patient is positioned in a semi-Fowler or Fowler position to facilitate expansion of the lungs. Hydration orally and with IV fluids helps liquefy secretions.

Oxygen is administered as ordered to maintain adequate oxygen saturation levels for the patient.

Box 37.11

Nursing Care Guideline

Incentive Spirometry

Background

- An incentive spirometer is used by the patient to encourage deep inhalation.
- The patient attempts to reach a set inhalation volume.
- The volume may be set by the primary care provider (PCP) or respiratory therapy specialist or calculated from standardized charts.
- The technique encourages deep breathing, maintains lung expansion, and helps prevent atelectasis and pneumonia.
- If surgery is planned, the technique is taught to the patient before surgery to allow time for practice.

Procedural Concerns

- The patient should be in an upright position (semi-Fowler or Fowler) if possible.
- The patient's goal is to have a steady rise of a marker in the device to achieve a specific inhalation volume, which is marked on the device.

(From Sorrentino, S. A., & Remmert, L. [2012]. *Mosby's textbook for nursing assistants* [8th ed.]. St Louis: Mosby.)

- Instruct the patient to inhale slowly with the mouth on the mouthpiece.
- Inhale as much as possible, and hold that breath for 3 to 5 seconds.
- Remove mouthpiece and exhale slowly.
- Repeat each inhalation and exhalation 5 to 12 times.
- End with two controlled coughs (see [Box 37.7](#)).
- Perform this exercise every 1 to 2 hours per orders.

Documentation Concerns

- Document the patient education concerning correct procedure and performance times.
- Note the patient's concerns and discomfort, and document any issues.
- Include a respiratory assessment before and after the procedure.
- Document the patient's use of the incentive spirometer and tolerance of the procedure.

Evidence-Based Practice

- Incentive spirometry benefits patients after abdominal surgery by promoting deep breathing which can decrease the incidence of pulmonary complications, such as atelectasis and pneumonia. Preoperatively it is the nurse's role to teach the patient how to use incentive spirometry correctly, and postoperatively to encourage and monitor its use (Davis, 2012).

Atelectasis

Atelectasis (Fig. 37.6) is the collapse of all or part of the lung. It is caused by pressure on the outside of the lung or a blockage of the air passages (bronchus or bronchioles). As a result, pulmonary secretions are retained, and the patient has poor gas exchange. Common assessment findings are cough, dyspnea, anxiety, chest pain, cyanosis, diminished breath sounds over the affected area, and crackles.

FIGURE 37.6 Postoperative atelectasis. A, Normal bronchiole and alveoli. B, Mucous plug in bronchiole. C, Collapse of alveoli due to atelectasis following absorption of air. (From Lewis, S. L., Bucher, L., Heitkemper, M. M., et al. [2017]. *Medical-surgical nursing: Assessment and management of clinical problems* [10th ed.]. St Louis: Elsevier.)

Treatment focuses on promoting expansion of the lung and improving oxygenation. Nursing care includes administering oxygen and analgesics as ordered, positioning in a Fowler or semi-Fowler

position, ambulation, hydration, coughing, deep breathing, incentive spirometry, and turning every 2 hours.

Wound Complications

Surgery may cause a disruption in skin integrity. This endangers the skin's ability to protect against infection. A wound infection is a common postoperative complication (Anderson, Podgorny, Berrios-Torres, et al., 2014), and it usually occurs 48 to 72 hours postoperatively.

The edges of a healing surgical wound should be pink with healthy granulation tissue. They should be well approximated. This means the edges precisely meet together. Incisions may be held together by staples, sutures, surgical super glue, or Steri-Strips. A delay in wound healing can be caused by infection, blood clots, tissue hypoxia, trauma, advanced age, abnormal laboratory values, obesity, undernourishment, immunosuppression, and systemic diseases (such as, diabetes). Chapter 29 provides more information on wound healing.

When wound dehiscence occurs, the surgical incision fails to remain closed. The edges of the incision separate without organs protruding (Fig. 37.7). This can occur in any wound but is commonly seen after abdominal surgery. With dehiscence, the surgical dressing reveals a large amount of serosanguineous fluid. If dehiscence occurs or is suspected, the nurse assists the patient into a position that allows minimal strain to be placed on the incision. The wound is covered with a sterile saline dressing, and the surgeon is notified immediately. Dehiscence usually is a later postoperative wound complication, occurring 48 to 72 hours after surgery.

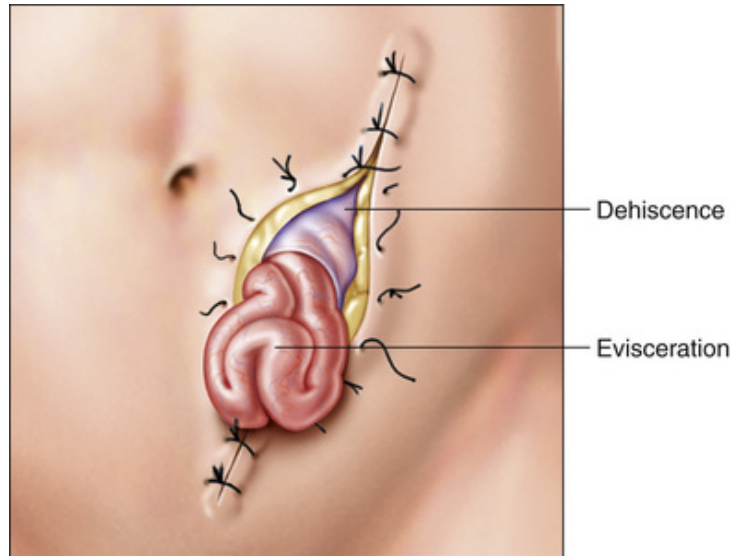

FIGURE 37.7 Dehiscence and evisceration. (From Harkreader, H., Hogan, M. A., & Thobaben, M. [2007]. *Fundamentals of nursing: Caring and clinical judgment* [3rd ed.]. St Louis: Saunders.)

Evisceration (see [Fig. 37.7](#)) occurs when the surgical incision fails to remain closed and organs protrude. The patient may report feeling the wound “coming loose.” When this occurs, the patient is placed in a position that puts the least amount of strain on the incision. The semi-Fowler position is often used. Sterile gauze soaked in sterile saline is placed on the incision, and the surgeon is notified immediately. The patient is encouraged to remain calm.

Dehiscence and evisceration are medical emergencies. Surgical repair is often needed. Both wound complications can be caused by delayed wound healing or sutures that have been removed too soon. When the sutures have been removed too early, deep muscle support to maintain the closure of the wound may be decreased. The length of time sutures remain in the patient depends on the type of sutures used, the procedure, the length of the incision, and the size of the patient. Sutures are commonly removed when the edges of a healing wound appear pink and slightly raised.

Smoking, medications, and preexisting medical problems contribute to poor wound healing. Additional causes for dehiscence and evisceration are wound infection, defective sutures, allergic reaction to sutures, obesity, sneezing, coughing, and vomiting.

Safe Practice Alert

When dehiscence or evisceration occurs, the patient is placed in a position that produces minimal strain on the surgical wound. Apply a

sterile saline dressing, and call the surgeon. Both are medical emergencies and require immediate intervention.

Care of the Surgical Site

In the PACU, there may be limited assessment of the surgical site. Some hospitals may have policies stating that the surgeon removes the first surgical dressing, which is the preference of many surgeons. Every attempt is made to reinforce a postoperative dressing, but the dressing sometimes must be removed because of excessive bleeding. The surgeon is notified if this occurs.

When a wound assessment is performed and the dressing is not removed, the nurse notes the location and size of the dressing and the characteristics of the drainage, such as color, amount, consistency, and odor. [Box 37.12](#) shows a wound assessment checklist for use when the dressing is removed.

Box 37.12

Wound Assessment Checklist

When dressings are being removed, the nurse assesses the following wound characteristics:

- Size (current size; size may decrease with healing)
- Type of closure (transverse, midline, horizontal)
- Edges (well approximated with staples, sutures, Steri-Strips, or surgical glue)
- Drains (type of drain; amount and type of fluid in drains)
- Drainage (type, consistency, color, amount, and odor for the type)
- Signs of infection (redness in the surrounding skin, yellow wound bed, purulent drainage, and foul-smelling drainage)

Safe Practice Alert

Until orders have been given to remove the dressing, the initial surgical dressing is not removed.

When a patient has a wound with excess drainage, dressings may need to be changed frequently. Tape can be very irritating to the skin. In some cases, Montgomery straps (ties) are used when surgical dressings are in place for extended periods, and the dressing is changed

frequently (Fig. 37.8). The straps are designed to decrease the skin irritation and discomfort that are caused by repeated removal of tape.

FIGURE 37.8 Montgomery straps.

Postoperative Care After the Postanesthesia Care Unit

Specific discharge criteria must be met for the patient to be discharged from the PACU. Criteria include the patient's vital signs, respiratory status, level of consciousness, and activity level. The Aldrete score was developed in 1970 to determine if a patient is ready to be transferred to a less-intensive area of the hospital after recovery from anesthesia (Aldrete & Kroulik, 1970). This score has since been modified for use with ambulatory and outpatient surgery patients. The main criteria used to determine the level of a patient's recovery include activity, respirations, consciousness, circulation, and oxygen saturations (Fig. 37.9).

		Score
Activity (moving voluntarily on command)	4 extremities	2
	2 extremities	1
	0 extremities	0
Respiration	Able to breathe deeply and cough freely	2
	Dyspnea, shallow or limited breathing	1
	Apneic	0
Circulation	BP \pm 20mmHg of premedation level	2
	BP \pm 20–50mmHg of premedation level	1
	BP \pm 50mmHg of premedation level	0
Consciousness	Fully awake	2
	Arousable on having name called	1
	Not responding	0
Color	Normal	2
	Pale, dusky, blotchy, jaundiced, or other change	1
	Cyanotic	0

BP, Blood pressure.

FIGURE 37.9 Aldrete scoring system. (From Aldrete, J. A. [1995].

The post-anesthesia recovery score revisited, *J Clin Anesth* 7:89;

Aldrete, J. A. [2007]. Post-anesthetic recover score, *J Am Coll Surg* 205[5]:3.)

For patients being admitted to a nursing unit, the PACU nurse gives a thorough hand-off report on the patient's postoperative status to the unit nurse when the patient is transferred. After arrival in the nursing unit, the patient is moved to a bed. The unit nurse assesses the patient's vital signs and respiratory status, dressings and drains, and level of consciousness and provides care according to the patient's needs. Before the nurse leaves the patient, the top side rails on the bed are raised to aid in positioning and turning, the bed is returned to the lowest position to prevent injury if the patient attempts to get out of bed, and the call light is placed within reach so that the patient can call for assistance.

Early Ambulation

The nurse instructs the patient to call for assistance when he or she wants to get out of bed. Many patients feel weak and dizzy the first time they ambulate after surgery. Dangling before attempting to stand up for ambulation helps prevent injury to patients who have been immobile for some time. Having one or two caregivers assist the first time the patient gets out of bed is recommended. Early ambulation helps prevent many complications postoperatively, including constipation, deep vein

thrombosis, atelectasis, pneumonia, and urinary stasis. Many patients who experience abdominal distention and gas pain obtain some relief from ambulating.

Fluids and Hydration

To maintain fluid volume, IV fluids are infused at the ordered rate. The intake and output values are monitored to determine fluid imbalances. The IV site, IV solution, infusion rate, and patency are assessed. Adequate fluid intake helps keep stools soft, ease the passage of stool, keep lung secretions thin, and prevent urinary complications.

4. Identify at least three nursing interventions with rationales to prevent postoperative respiratory complications for P. L.

Diet Advancement

Patients remain NPO until the gag reflex returns. Ice chips and oral fluids can be administered as prescribed. Oral feedings may be delayed until peristalsis returns. The abdomen is assessed for bowel sounds, flatus, and distention. Many patients move from a clear diet to a regular diet very quickly.

Discharge

During the postoperative phase, the nurse, patient, and family collaborate to prepare the patient for discharge. Discharge instructions are given to the patient. Additional information is provided to the patient about medications, wound care, activity level, and diet ([Box 37.13](#)). Specific information related to the disease process and the surgical procedure is given. Some patients may be required to urinate before they can be discharged. The physician determines the readiness for discharge and writes an order for the patient to be discharged from the hospital. When anesthesia has been administered, patients are not allowed to drive themselves home because of the effects of anesthetic medications.

Box 37.13

Home Care Considerations

Postoperative Care in the Home

The patient and family are evaluated to determine their ability to manage required care after the patient is discharged. Some patients may require medications, dressing changes, activity limitations, and physical therapy. Patients may be at risk for complications.

- Do the patient and family understand the signs and symptoms that may require follow-up with a physician?
- Do the patient and family have a plan to meet the needs of the patient?
- How often will caregivers or support people be able to provide assistance?
- Is a referral for home care needed to assist with self-care activities?
- Can the home be modified to allow necessary medical equipment to be moved into the home?

If a patient is admitted to a nursing unit after surgery, the length of stay depends on the disease process and the surgical procedure. Inpatients must meet clinical discharge criteria that are determined by the physician and receive discharge instructions before leaving the hospital.

Many patients want to be discharged from the hospital as soon as possible. After the physician has indicated that the patient can leave the hospital, the discharged process is completed as quickly as possible. Often, nurses make follow-up calls to patients within 24 hours after discharge to determine whether the patient has questions or concerns. This promotes comfort and reassures the patient as he or she heals and returns to a preoperative state of health.

Evaluation

In each phase of the perioperative period, the nurse evaluates the effectiveness of all nursing interventions. The nurse determines whether expected outcomes were met. If not, they are reevaluated. If outcomes are met, the nurse evaluates whether continuing the interventions is appropriate. Throughout the perioperative period, ongoing assessments are consistently made.

The nurse documents during each phase of the perioperative period. Documentation reflects the plan of care, nursing assessments, diagnosis, outcome identification, planning, interventions, and evaluations. The perioperative record reflects continuous evaluation of nursing care and the patient's response to all treatments and nursing interventions.

Skill 37.1 Surgical Scrub, Gowning, and Gloving

Purpose

- Surgical handwashing prevents the spread of microorganisms.
- Wearing a surgical gown prevents the spread of microorganisms and allows the wearer to perform activities in the operating room in comfort while maintaining sterility.
- Surgical gloving is used to prevent the spread of microorganisms, protect the provider and patient from infection, and perform activities in the operating room in comfort while maintaining sterility.

Resources

- Sink with knee or foot controls
- Antimicrobial soap per facility policy and procedures
- Disposable surgical scrub sponge
- Disposable plastic nail pick
- Sterile towels
- Sterile disposable or cloth surgical gown
- Adjunct surgical clothing—face mask with eye shield or face mask and protective eyewear, cap, shoe covers
- Work area above waist height, located near the procedure
- Sterile surgical gloves of the correct size

Interprofessional Collaboration and Delegation

- Surgical handwashing is required for all health care workers who will be sterile or scrubbed in the surgical environment.
- Surgical handwashing is essential to prevent infections. Team members should speak up when they see anyone breaking surgical technique. Handwashing should start over if sterile technique is broken.
- The scrub nurse/assistant may assist with certain aspects of the procedure.
- Surgical gowning is performed by any health care provider who may be participating in a procedure that requires sterile surgical technique.
- Unlicensed assistive personnel (UAP) who are assisting in a procedure and have been trained in the proper application may perform surgical gowning and gloving. Check with the state board of nursing for specific policies.
- Surgical gloving is completed by all health care providers who participate in a procedure that requires sterile surgical technique.

Evidence-Based Practice

- Natural fingernails should be kept no longer than fingertip length. Clear nail polish that has been applied within the past 4 days and is not chipped is acceptable. Rings and other jewelry are removed, because the evidence has associated even a plain band with a higher bacterial count. Artificial nails may not be worn because they can harbor bacteria and fungus that could cause surgical site infection ([AORN, 2015b](#)).

- [Ward, et al. \(2014\)](#) found that disposable paper gowns showed a lower rate of bacterial contamination than cloth surgical gowns. They recommended disposable paper gowns for all surgery personnel.
- Due to the risk of tearing a hole in the gloves and therefore increasing the risk of contamination, many organizations, such as the Association of periOperative Registered Nurses (AORN), the Operating Room Nurses Association of Canada (ORNAC), the Association for Perioperative Practice (AfPP), and the Australian College of Operating Room Nurses (ACORN), recommend double-gloving in certain situations to protect the provider ([Pirie, 2010](#)). Exchanging the outer glove for a new sterile glove an hour into the procedure, or before handling implants or prosthetic joints, reduces contamination ([Ward, Cooper, Lippert, et al., 2014](#)).

Special Circumstances: Surgical Scrub

1. *Assess:* Are there cuts, open sores, hangnails, or breaks in the skin or around cuticles?
Intervention: Cover them with an appropriate dressing after cleaning.
2. *Assess:* Are there long nails, artificial nails, or nail polish?
Intervention: File long nails, remove artificial nails, and remove nail polish. Check facility policy; usually only clear nail polish is allowed, and if it has been on the fingernails longer than 4 days, it should be removed because it is a place for microorganisms to grow.
3. *Assess:* Is the surgical team member wearing jewelry, a watch, or long sleeves?
Intervention: Remove the jewelry, watch, and long sleeves.
4. *Assess:* Are there visible marks, spots, or dirt to be removed?
Intervention: Use the soap and water method to remove them.

5. *Assess:* Have hands (skin) directly touched the sink, body, or another surface?
Intervention: Start handwashing again.
6. *Assess:* Did hands (skin) touch another surface when retrieving the sterile towels?
Intervention: Start handwashing again.

Special Circumstances: Gowning

1. *Assess:* Has there been inadvertent contamination of the gown against the wearer's body or an object?
Intervention: Obtain a new gown and start the procedure over.
2. *Assess:* Has the skin touched a sterile part of the gown or sterile field, or has the gown touched the skin or anything outside of the sterile field?
Intervention: Obtain a new gown and start the procedure over.
3. *Assess:* Have the surgical team members turned their backs on the opened sterile gown or sterile area?
Intervention: Obtain new gowns and start the procedure over.
4. *Assess:* Did the gown tear during the procedure?
Intervention: Obtain a new gown and start the procedure over.

Special Circumstances: Gloving

1. *Assess:* Is the surgical team member wearing jewelry?
Intervention: Remove *all* jewelry before surgical gloving to avoid the possibility of tearing the gloves.
2. *Assess:* Is the glove package damaged, or has it expired?
Intervention: Obtain a new pair of gloves.
3. *Assess:* Is any part of the work area below waist level?
Intervention: Raise the work area, or find a new area to place surgical gloves.
4. *Assess:* Has skin directly touched a sterile part of the glove or sterile field, or has the glove touched skin or anything outside of the sterile field?
Intervention: Obtain a new pair of gloves and start over.
5. *Assess:* Have scrubbed members of the surgical team turned their backs on the opened package of gloves or sterile area?

Intervention: Obtain a new pair of gloves and start over.

6. *Assess:* Did the gloves tear during the procedure?

Intervention: Obtain a new pair of gloves and start over.

Procedures

Surgical Scrub

1. Apply the adjunct surgical clothing (i.e., surgical cap, face mask, and shoe covering) before entering the surgical area. Use the knee or foot controls to turn on warm water at a medium flow.

Adjunct surgical clothing is applied before entering the surgical area and before the surgical scrub and the donning of sterile gown and gloves. Warm water helps remove dirt and microorganisms but not protective skin oils. Use medium flow to avoid splashing.

2. Wet the skin from 2 inches above the elbows to the hands; hands remain above the elbows.

Hands should be the least contaminated when finished washing if this procedure has been followed.

STEP 2 (From Ignatavicius, et al, 2018.)

3. Apply soap.

Using soap reduces microorganisms.

4. Prescrub: Lather, rub using a circular movement, and wash for 20 seconds in the following order:
 - a. Fingertips (clean under the nails with a pick)
 - b. Fingers
 - c. Between fingers (interlaced, including the thumbs)
 - d. Palm of hands with fingertips
 - e. Back of hands
 - f. Wrists
 - g. Forearms

h. Elbows

Friction helps remove microorganisms; the presence of lather indicates friction has occurred.

STEP 4 (From Ignatavicius, et al, 2018.)

5. Rinse from fingertips to elbows. Keep the hands above the elbows.
Proper technique and hand position prevent the spread of microorganisms.
6. Scrub with a disposable surgical brush in the order specified:
 - a. Fingers, hands, arms (four strokes each)
 - b. Nails (15 strokes each with the brush)
 - c. Palm, back of hand, thumb, fingers (all sides receive 10 strokes each with the brush)
 - d. Arm (divide the arm into thirds; scrub each third with 10 strokes with the brush)
 - e. Rinse the brush; repeat on the other arm.
 - f. Throw away the brush.*Scrubbing removes microorganisms.*
7. Rinse from fingertips to elbows. Keep the hands above the elbows.
Proper technique and hand position prevents the spread of microorganisms.
8. Turn off the water using the knee or foot controls; hold arms in the air in front with hands raised if indicated.
This maintains sterility of the hands by using the knee or foot controls to turn off the water. Keeping the hands raised and avoiding touching anything with them prevents contamination.
9. Obtain one sterile towel. Dry one arm from the fingertips to the elbows, using a patting motion.
Use a dry, sterile towel to prevent the spread of microorganisms; microorganisms like dampness. Avoid injury to the skin from rubbing.

10. Drop the towel into the linen hamper, or the circulating nurse collects it in outstretched hands.

Proper disposal of the towel maintains sterility and prevents contamination.

11. Repeat procedure steps 9 and 10 for the other arm.

Applying a Gown

1. Perform the surgical scrub procedure as described earlier.
2. Obtain a sterile gown:
 - a. Reach for the gown from the circulating nurse by grasping the gown inside just below the neckband.
 - b. Alternatively, lift the gown from the sterile table by grasping the inside of the gown and stepping away from the table.

The circulating nurse assists with sterile technique and proceeds in such a way as to avoid inadvertent contamination of the gown.

3. Open the gown by grabbing the inside of the gown below the neckline and allowing it to unfold in front and away from the body.

Maintain sterility by avoiding inadvertent contamination of the gown.

STEP 3 (From Ehrlich and Coakes, 2017.)

4. Put the gown on:
 - a. Place both arms inside the sleeves. Do *not* touch the outside of the gown.
 - b. Have the circulating nurse pull the gown on and tie it in the back.
 - c. Do *not* put hands through the sleeve openings.
Avoid inadvertent contamination of the gown by allowing the circulating nurse to assist with sterile technique and by keeping the hands inside the gown for a closed gloving procedure. The back of the gown is not considered sterile.

STEP 4 (From Ehrlich and Coakes, 2017.)

5. Apply sterile gloves (see the [Applying Surgical Gloves](#) section).
6. If needed, complete the remainder of the gown preparation and securing according to the manufacturer's instructions.

Applying Surgical Gloves

1. Perform the surgical scrub procedure (see the [Surgical Scrub](#) section).
2. Perform the surgical gowning procedure, if needed (see the [Applying a Gown](#) section).
3. Keep hands inside the surgical gown sleeves. The circulating nurse opens the outer sterile glove package and places the inner sterile glove package on a sterile field.

The circulating nurse assists with sterile technique; the provider who will wear the gloves keeps hands inside the gown for the closed gloving procedure.

4. Open the inner sterile glove package while keeping the hands inside the gown.

This maintains sterility and prevents the spread of microorganisms.

5. If right handed, use the right hand as the working hand to grab the cuff of the glove for the left hand; if left handed, use the left hand to grab the cuff of the glove for the right hand.

STEP 5 (From Ehrlich and Coakes, 2017.)

Grabbing the cuffs of the gloves prevents contamination.

6. Prepare to put on the glove. Extend the forearm straight out from the body, with the elbow held at a 90-degree angle and the palm

facing upward.

Arm and hand positions are intended to maintain sterility.

7. Put the glove over the gowned hand:
 - a. The working hand is used to pull the glove cuff over the gowned (sleeve-covered) hand.
 - b. Unfold the glove while pulling it over the gowned hand.
 - c. The fingers of the glove need to fall or point toward the elbow, *not* toward the floor.

This creates a glove-gown seal and prevents the spread of microorganisms.

8. Insert fingers into the glove:
 - a. With the ungloved, gown-covered hand, hold the glove with the glove fingers up.
 - b. Push the partially gloved hand out of the gown and into the glove, extending the fingers into the fingers of the glove.

STEP 8 (From Ehrlich and Coakes, 2017.)

9. Repeat procedure steps 5 through 8 for applying the opposite glove.
10. Ensure both gloves are fitted properly. Avoid snapping the cuffs and ensure the cuffs are completely unrolled and covering the cuff of the gown.

This creates a sealed sterile gown and glove combination.

STEP 10 (From Ehrlich and Coakes, 2017.)

11. Maintain sterility:
 - a. Hold both hands together, and interlock the fingers.

- b. Keep the hands above the waist and away from the body at all times.

Interlocking the fingers helps ensure the gloves are correctly fitted. Keeping the hands up and away from the body reduces the risk of contamination until ready to begin the procedure.

Removing Surgical Gloves

1. Use the dominant hand to pull off one glove by grasping the outside of the cuff; do *not* touch the skin (see the illustrations in the Applying Sterile Gloves and Removing Sterile Gloves sections in [Chapter 26](#), Skill 26.2).

Grasping the cuff prevents the spread of microorganisms from the contaminated surfaces of the gloves.

2. Hold the glove that was just removed crumpled in the hand that is still wearing a glove.

Keeping the contaminated gloves together prevents the spread of microorganisms.

3. Using the gloveless hand, slide the thumb under the cuff of the remaining glove (skin-to-skin) while keeping the ungloved fingers curled.

Keeping the skin surfaces together and avoiding touching the outer glove surface with bare fingers prevents the spread of microorganisms.

4. Peel off the glove, turning it inside out so that the first glove that was removed is contained inside the last glove that was removed.

The most contaminated glove surfaces are inside the crumpled gloves to prevent the spread of microorganisms.

5. Throw away the gloves.

Proper disposal of waste reduces the spread of microorganisms.

Removing the Gown and Other Personal Protective Equipment

1. Remove the gloves first as described in the previous section.

Gloves are contaminated. Removing them first allows the hands to touch the least contaminated portions of other personal protective equipment for removal and prevents the spread of microorganisms.

2. If separate from the mask, remove eyewear, handling it by the ear pieces.
Eyewear is removed so that the mask can be removed without contamination; holding eyewear by the ear pieces lessens the chance of contaminating the hands.
3. Throw the eyewear into the trash, or place it in an appropriate container for cleaning.
Proper disposal of the used equipment reduces the spread of microorganisms.
4. Remove the gown:
 - a. Untie the waist.
 - b. Untie the neck.
 - c. Pull the gown off from the back of a shoulder, touching *only* the inside of the gown.
 - d. While pulling off the gown, turn it inside out and roll it into a ball.
The front of the gown and sleeves are contaminated; touching only the inside of the gown prevents the spread of microorganisms.
5. Throw the gown into the trash if it is disposable, or place it in the laundry bin for cleaning if it is cloth.
Proper disposal of the contaminated gown reduces the spread of microorganisms.
6. Remove the mask:
 - a. Untie the bottom of the mask.
 - b. Untie the top of the mask and hold onto the ties.
 - c. Pull the mask away from the face using the ties. Do *not* touch the outside of the mask.
*Holding the mask by the ties prevents contamination.
Removing the mask last prevents the spread of microorganisms.*
7. Throw the mask into the trash.
Proper disposal of waste reduces the spread of microorganisms.
8. Remove the cap and shoe covers, and throw them into the trash.
Proper disposal of waste reduces the spread of microorganisms.
9. Perform hand hygiene (see [Chapter 26](#), Skill 26.1).
Frequent hand hygiene prevents the spread of microorganisms.

radiography (9th ed.). St. Louis: Elsevier.

Summary of Learning Outcomes

LO 37.1 *Differentiate between the phases of the perioperative period:* Perioperative nursing includes the care of the patient during three phases: preoperative, intraoperative, and postoperative.

LO 37.2 *Classify different types of surgery:* Surgical procedures are classified by the purpose (e.g., diagnostic, ablative, constructive, reconstructive, transplant, palliative, cosmetic); degree of urgency (e.g., elective, urgent, emergent); and degree of risk (e.g., major, minor). Factors affecting the degree of risk are type of procedure, general health, age, medications, mental status, and nutrition. Disorders of the cardiac, blood coagulation, respiratory, renal, liver, and endocrine systems can increase surgical risks.

LO 37.3 *Discuss safety during the perioperative period:* Safety is the major goal of perioperative care. The nurse is responsible for upholding all operating room safety standards and acting as a patient advocate in the preoperative, intraoperative, and postoperative phases.

LO 37.4 *Describe alterations that can occur during the perioperative period:* Alterations depend on patient factors and the type of surgery. Preoperatively, anxiety can occur. Intraoperative alterations depend on the type of surgery, positioning, and anesthesia. Postoperative alterations may include changes in consciousness, abnormal vital signs, and pain.

LO 37.5 *Identify vital perioperative assessment data:* Preoperative vital signs and physical assessment provide baseline data for comparing with

postoperative assessment findings. Intraoperative assessment includes vital signs and safety concerns. The postoperative nurse assesses vital signs, respiratory status, level of consciousness, dressings and drains, intake and output, and elimination.

LO 37.6 Select nursing diagnoses for each perioperative stage: Nursing diagnoses are developed based on interpretation of the data regarding the patient's particular surgery and stage within the perioperative period.

LO 37.7 Establish nursing care goals and outcome criteria for surgical patients: Nursing care goals and outcome criteria are based on the specific nursing diagnoses in each phase of the perioperative period.

LO 37.8 Evaluate the effectiveness of the perioperative nursing interventions: During the preoperative phase interventions are focused on patient education.

Safety interventions are a priority in the operating room. Interventions during the postoperative phase are aimed at promoting healing and comfort, restoring the highest level of wellness, and decreasing the risk for potential complications. All nursing care and patient responses are evaluated during the perioperative period.

Review Questions

1. The nurse is caring for a patient scheduled for a breast reduction to decrease pain in her back. How is this operation classified according to the degree of urgency?
 - a. Urgent
 - b. Emergency
 - c. Emergent
 - d. Elective
2. The postanesthesia care recovery unit (PACU) nurse is concerned about postoperative hemorrhage. Which clinical manifestation alerts the nurse to this problem?
 - a. Incisional pain
 - b. Elevated blood pressure
 - c. Increased heart rate
 - d. Bradypnea
3. What is the role of the nurse in securing an informed consent for a surgical procedure?
 - a. Ensuring that the patient signs the informed consent document
 - b. Signing the consent form as a witness
 - c. Ensuring that the patient does not refuse treatment
 - d. Refusing to participate based on legal guidelines
4. The nurse provided preoperative teaching about pain management to a patient scheduled for surgery. Which postoperative activity by the patient indicates the effectiveness of teaching?

- a. Doing something enjoyable, such as relaxing and reading a book
 - b. Requesting pain medication when no longer able to tolerate the pain
 - c. Removing the postoperative dressing to see the surgical incision
 - d. Refusing to wear antiembolism stockings while still on bed rest
5. A 55-year-old male is scheduled to have a bowel resection for a diagnosis of colon cancer. He is very nervous about the surgery. How can the nurse help decrease his anxiety?
- a. Ask him if he is concerned the cancer has spread to other areas of his body.
 - b. Talk to him to find out what is causing his anxiety.
 - c. Question him to find out what the surgeon has told him about the surgery.
 - d. Give him a preoperative medication to help him relax.
6. How does malnutrition compromise wound healing?
- a. There is increased stress on the wound.
 - b. Blood supply to the wound is increased.
 - c. It causes patients to be energized and overexert.
 - d. It can increase the risk of infection.
7. Which set of patient data assists the nurse in determining whether the nursing actions taken to prevent airway obstruction have been effective?
- a. Temperature 97.8° F, breathing regular and unlabored, no cough

- b. Intake equals output, denies pain or chest discomfort
 - c. Oxygen saturation 91%, shortness of breath, R 26
 - d. Oxygen saturation 89%, breathing shallow and regular, R 24
8. While conducting a preoperative health assessment, the nurse is informed about a patient's preexisting heart problem. What postoperative interventions should be included in the plan of care for this patient?
- a. Perform a systematic head-to-toe assessment every 4 hours.
 - b. Monitor breath sounds and oxygen saturation.
 - c. Administer pain medications as needed.
 - d. Monitor the electrocardiogram (ECG), apical pulse, and capillary refill.
9. A patient who recently had abdominal surgery complains of feeling as though their "wound is coming loose." Upon assessment, the nurse notes the presence of bowel loop protruding through the surgical incision. Which nursing intervention(s) should the nurse take? Select all that apply.
- a. Place the patient in semi-Fowler position.
 - b. Contact the surgeon.
 - c. Document findings and actions taken.
 - d. Place dry sterile gauze over the bowel loop.
 - e. Push the bowel loop back into the patient.
10. When caring for a postoperative patient on a surgical unit, which nursing intervention(s) are included in the patient's plan of care to help reduce

the risk of both pulmonary embolism (PE) and deep vein thrombosis? (Select all that apply.)

- a. Encourage oral hydration.
- b. Apply antiembolism stockings.
- c. Monitor laboratory values for clotting times.
- d. Encourage frequent ambulation.
- e. Instruct the patient to perform the Valsalva maneuver frequently.

CHAPTER 38

Oxygenation and Tissue Perfusion

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 38.1 Describe the basic anatomy and physiology of the cardiovascular and respiratory systems in relation to ventilation and perfusion.
- LO 38.2 Summarize alterations in structure and function of the cardiovascular and respiratory systems.
- LO 38.3 Demonstrate assessment of the cardiovascular and respiratory systems.
- LO 38.4 Choose nursing diagnoses for patients with decreased oxygenation.
- LO 38.5 Identify goals for patients with complications from decreased oxygenation.
- LO 38.6 Evaluate interventions to enhance patient oxygenation, promote safety, and reverse the negative effects of decreased oxygenation.

KEY TERMS

- afterload, p. 913
- antiembolism hose, p. 930
- arrhythmias, p. 919
- asthma, p. 914
- atelectasis, p. 915
- bronchodilators, p. 928
- cardiac output, p. 913
- chronic bronchitis, p. 914
- chronic obstructive pulmonary disease (COPD), p. 914

coronary artery disease, p. 914
cyanosis, p. 922
electrocardiogram (ECG), p. 918
emphysema, p. 914
endotracheal tubes, p. 927
forced expiratory flow (FEF), p. 917
forced expiratory volume in 1 second (FEV), p. 917
forced vital capacity (FRC), p. 917
fraction of inspired oxygen (FIO₂), p. 922
functional residual capacity, p. 917
hemoptysis, p. 917
hypercapnia, p. 922
hypoxemia, p. 921
myocardial infarction (MI), p. 914
nasopharyngeal airway, p. 926
necrosis, p. 918
pleural effusion, p. 918
pneumonia, p. 914
postural drainage, p. 928
preload, p. 913

residual volume (RV), p. 917
sequential compression devices, p. 930
tracheostomy tube, p. 927
vibration, p. 929

Case Study

Michael Ross (M. R.) is a 72-year-old male admitted to the hospital with severe chronic obstructive pulmonary disease (COPD). He has a 40-year history of smoking 2 packs per day and quit 10 years ago, and he has a history of hyperlipidemia.

M. R.'s vital signs are: T 36.7° C (98° F), P 98 and regular, R 26 and labored, BP 144/73, with a pulse oximetry reading of 90% at rest on 2 liters of oxygen per nasal cannula. The patient has a productive cough with thick secretions but has no hemoptysis. Heart sounds are distant. Breath sounds are diminished with inspiratory and expiratory wheezes and a prolonged expiratory phase. He denies pain but complains of difficulty breathing. The chest is barrel-shaped and the abdomen is protruding without acute changes. M. R. is on an adult regular diet but only ate 25% of his breakfast.

Laboratory and diagnostic test results are as follows:

- Lipids: Total cholesterol 212 mg/dL, high-density lipoprotein (HDL) cholesterol 89 mg/dL, low-density lipoprotein (LDL) cholesterol 123 mg/dL, triglycerides 107 mg/dL
- Complete blood count (CBC): White blood cells (WBC) 10.7 cell/mm³
- Glucose 122 mg/dL, electrolytes and kidney function values within normal limits
- Arterial blood gases: pH 7.37, PaCO₂ 57 mm/Hg, PaO₂ 65 mm Hg, HCO₃⁻ 32 mEq/L
- Chest x-ray film indicated increased density in the right lower lobe.

Treatment orders are as follows:

- Physical therapy to help with conservation of energy with activity
- Respiratory therapy for breathing treatments

- Blood glucose level before meals and at bedtime
- Titrate oxygen up to 3 L/min to keep SpO₂ at 92% or greater

Medications are as follows:

- Albuterol nebulizer six times daily
- Simvastatin 5 mg PO daily
- Methylprednisolone sodium succinate 125 mg IV q 6 hr

Refer back to this case study to answer the critical-thinking questions throughout the chapter.

Human tissues require oxygen to meet metabolic requirements. The purpose of respiration is to deliver oxygen to the cells and remove carbon dioxide. The cardiovascular system moves oxygen from the lungs to the tissues and carbon dioxide from the tissues back to the lungs, where it can be expired (Patton & Thibodeau, 2016). Respiration is controlled by neural and chemical changes that direct the depth and rate of respirations.

Respiratory disorders range from upper respiratory tract illnesses caused by viruses to life-threatening disorders of the lower respiratory system. Cardiovascular disorders include coronary artery disease, heart failure, arrhythmias, and peripheral vascular disease. This chapter discusses the anatomy and physiology of the cardiovascular and pulmonary systems and provides an overview of disorders that can interfere with respiratory function and tissue perfusion.

LO 38.1 Normal Structure and Function of Oxygenation

Adequate oxygenation of tissues depends on the cardiovascular and respiratory systems working together to oxygenate tissues. Taking in oxygen and delivering it to the bloodstream requires a healthy respiratory system. The ability to circulate oxygen in the body depends on an intact cardiovascular system.

Cardiovascular System

The heart is a hollow, cone-shaped organ. It is normally in the center area of the chest known as the mediastinum and rests on the diaphragm. The size of the heart varies but usually is about 9 cm wide, 12 cm long, and 6 cm deep (Patton & Thibodeau, 2016).

The heart is composed of four chambers divided into the right and left sides (Fig. 38.1). The chambers on the top are atria. The lower chambers are ventricles. The wall of the heart is composed of three layers. The epicardium also is known as the serous pericardium. This outer layer protects the heart and secretes serous fluid. The second layer is the myocardium, a thick layer of contractile muscle that contracts to push the blood out of the heart chambers. The third layer is the endocardium, which is the innermost layer that provides a protective lining in the chambers and valves of the heart, as well as the blood vessels (Patton & Thibodeau, 2016).

FIGURE 38.1 Cardiac anatomy. (From Ball, J. W., Dains, J. E., Flynn, J. A., et al. [2019]. *Seidel's guide to physical examination* [9th ed.]. St. Louis: Elsevier.)

Blood returns from the body in the venous system to the heart, where it enters the right atrium (Fig. 38.2). It passes through the tricuspid valve to enter the right ventricle during diastole. During systole, the pressure in the right ventricle exceeds the pressure in the pulmonary artery, and the blood passes through the pulmonic valve into the pulmonary artery. From there it flows into the capillary system, where oxygen is picked up by the red blood cells (RBCs) and carbon dioxide is released to the alveoli of the lungs. The oxygenated blood then flows into the pulmonary vein and enters the left atrium. The blood flows from the left atrium through the mitral valve into the left ventricle during diastole. During systole, the blood is pumped from the left ventricle past the aortic valve into the aorta and then distributed to the rest of the body (Patton & Thibodeau, 2016).

FIGURE 38.2 Circulation of blood in the body. (From Ball, J. W., Dains, J. E., Flynn, J. A., et al. [2019]. *Seidel's guide to physical examination* [9th ed.]. St. Louis: Elsevier.)

The initiation of cardiac stimulation begins in the sinoatrial (SA) node, followed by the electrical stimulation going through the atrium, followed by conduction through the atrioventricular (AV) node for the impulse. It is slightly delayed before traveling through the ventricles. **Cardiac output** is calculated by multiplying the heart rate in beats per minute (beats/min or bpm) times stroke volume in liters per beat (Huether & McCance, 2017). Preload and afterload are contributing factors to cardiac output. **Preload** is the amount of blood and pressure in the ventricle at the end of diastole. **Afterload** is the resistance that has to be exceeded for the ventricle to eject the blood during systole.

Respiratory System

The respiratory system is divided into the upper respiratory tract and the lower respiratory tract (Fig. 38.3). The upper respiratory tract

includes the nose, nasal cavity, sinuses, and pharynx. The nasal cavity is the space behind the nose that is divided by the nasal septum. The sinuses, located in the skull, are air filled. The pharynx, or throat, is the passageway through which food travels from the mouth to the esophagus and air flows from the nose to the larynx.

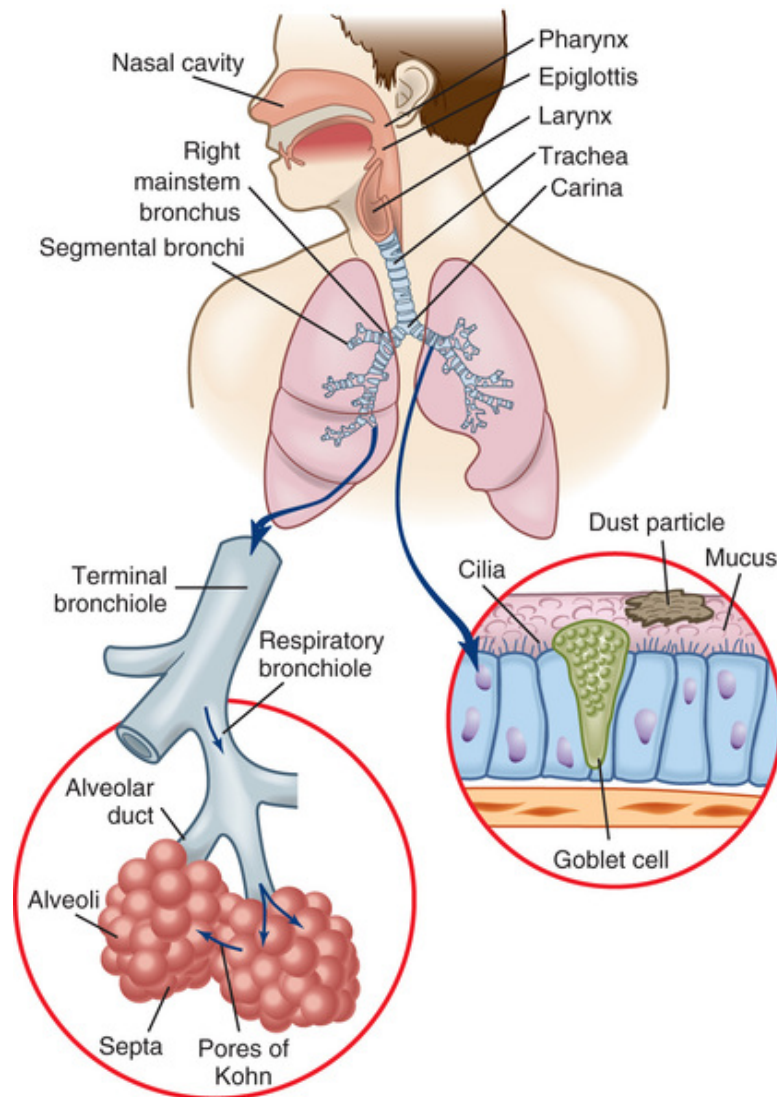

FIGURE 38.3 The respiratory system. (In Lewis, S. L., Bucher, L., Heitkemper, M. M., et al. [2017]. *Medical-surgical nursing: Assessment and management of clinical problems* [10th ed.]. St. Louis: Elsevier. Redrawn from Price, S. A., & Wilson, L. M. [2003]. *Pathophysiology* [6th ed.]. St. Louis: Mosby.)

The lower respiratory tract contains the larynx, where the vocal cords are located. The lower tract also includes the trachea, which is a flexible tube about 2.5 cm in diameter and 11 cm long that transports air from the pharynx and larynx to the lungs, where it branches into right and

left bronchi. These mainstem bronchi and their further subdivisions form the bronchial tree. Each bronchus divides repeatedly into increasingly smaller tubes, forming a network of bronchioles and alveolar ducts that terminate in alveoli (Fig. 38.4) (Patton & Thibodeau, 2016).

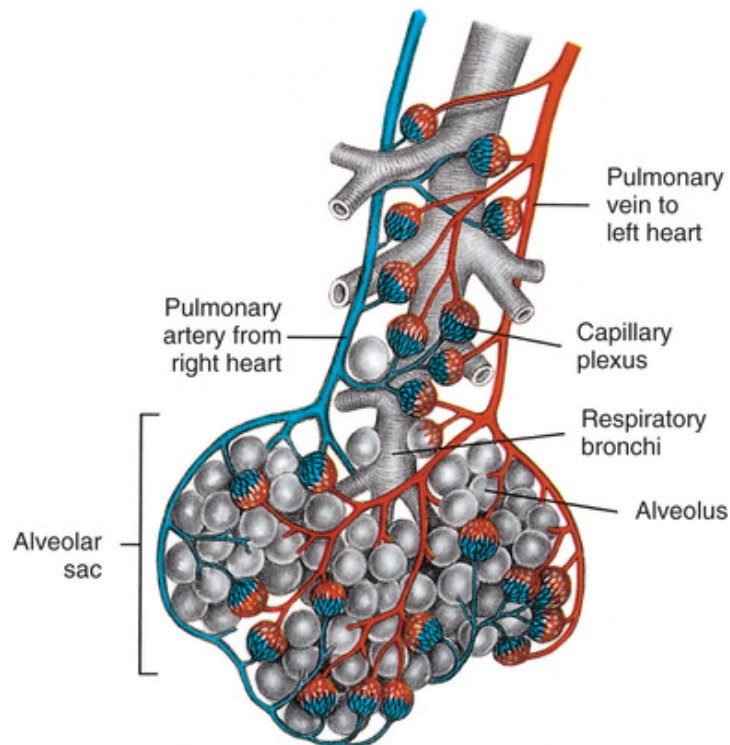

FIGURE 38.4 Alveolar ducts and alveoli. (From Wilson, S. F., & Giddens, J. F. [2013]. *Health assessment for nursing practice* [4th ed.]. St. Louis: Mosby.)

The physiology of oxygenation includes the movement of air into and out of the lungs. Movement of air into the lungs is known as *inspiration*. Inspiration (inhalation), or moving air into the lungs, begins with impulses from the respiratory center in the brain that travel through the phrenic and intercostal nerves and stimulate the diaphragm to move downward and the chest cavity to expand. The resulting expanded lung volume decreases the intraalveolar pressure. Atmospheric pressure is then higher than the intraalveolar pressure, causing air to move into the respiratory tract and the lungs to fill with air.

The reversal of air movement is called *expiration*, or moving air out of the lungs. During expiration (exhalation), the diaphragm relaxes, the elastic tissues of the chest and lungs recoil, and intraalveolar pressures increase, causing air to be forced out of the lungs (Patton & Thibodeau, 2016).

LO 38.2 Altered Structure and Function of Oxygenation

The ability to inspire oxygen from the atmosphere depends on intact lung structure. Alteration of lung tissue may decrease delivery of oxygen to the alveoli, impede transfer of oxygen from alveoli to the bloodstream, and hinder expulsion of carbon dioxide.

Cardiovascular Alterations

The heart functions as a pump. The heart pumps the oxygenated blood from the lungs to tissues throughout the body, where oxygen is used by the cells. A weakened or diseased heart cannot pump correctly, decreasing the supply of oxygen to tissues and compromising their function.

The coordinated beating of the heart begins with organized impulse generation. The pacemaker of the heart is located in the right atrium and normally generates an impulse that produces a pulse that is 60 to 100 beats/min and regular. When the heart beats too slowly, too fast, or irregularly, the ability to pump oxygen to cells can be interrupted. The pathway of the electrical impulses in the heart can be seen in the animation “Electrical Conduction System of Heart.”⁶

The heart requires blood flow to the myocardium to continue to beat adequately. Blood is supplied to the heart through the coronary arteries: the right coronary artery, left main, left anterior descending, and circumflex arteries (Fig. 38.5). Interruption of blood flow to the myocardium (heart muscle) can result from narrowing of the arteries by atherosclerosis, spasms, or congenital malformations resulting in **coronary artery disease**. Decreased blood flow to the myocardium decreases the ability of the heart to pump adequately.

FIGURE 38.5 Coronary arteries. (From Ignatavicius, D. D., Workman, M. L., Rebar, C. R., et al. [2018]. *Medical-surgical nursing: Concepts for interprofessional collaborative care* [9th ed.]. St. Louis: Elsevier.)

Blood clot formation or build up of plaque in the coronary arteries may totally block blood flow to a portion of the myocardium and cause a **myocardial infarction (MI)**, or heart attack. The clinical manifestations of an MI include pain or discomfort between the neck and navel. The patient may have associated dyspnea, diaphoresis, nausea, and vomiting.

Other cardiac irregularities may be associated with decreased blood flow, interrupted electrical impulses, or electrolyte disturbances. Assessment findings may include an irregular heartbeat, difficulty breathing, or dizziness with possible loss of consciousness.

The heart may develop cardiac failure, which decreases contractility, impairs systolic function, leads to ventricular dilation, and reduces the ability of the heart to meet the needs of the body tissues. The ejection fraction is reduced in heart failure (Huether & McCance, 2017). Causes of heart failure include damage to a heart valve, pressure around the heart, vitamin B deficiency, and damage to blood vessels.

Respiratory Alterations

Chronic obstructive pulmonary disease (COPD) is a general term used for a group of disorders characterized by impaired airflow in the lungs. **Emphysema** is one of the disorders and is characterized by enlargement of gas-exchange airways and damage to the alveolar walls in the lungs. Due to the loss of elasticity, expiration is difficult and air becomes

trapped in the lungs causing hyperinflation of the chest (Huether & McCance, 2017) (Fig. 38.6). The major contributing factor for emphysema is cigarette smoking. Exposure to pollution, a family history of the disease, or childhood respiratory tract infections are other risk factors (Huether & McCance, 2017).

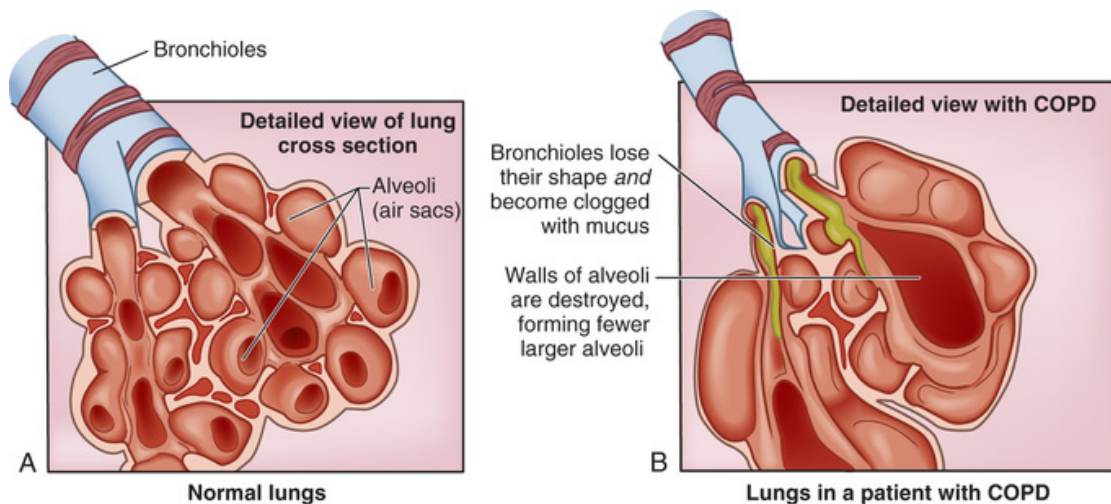

FIGURE 38.6 (A) Normal lungs showing bronchioles and alveoli. (B) Changes in the bronchioles and alveoli in the lungs of a patient with chronic obstructive pulmonary disease (COPD). (From Lewis, S. L., Bucher, L., Heitkemper, M. M., et al. [2017]. *Medical-surgical nursing: Assessment and management of clinical problems* (10th ed.). St. Louis: Elsevier.)

Chronic bronchitis is another disorder associated with COPD. It is characterized by inflammation of the larger airways, increased production of mucus, and chronic cough. Eventually, the lining of the airways is damaged, increasing the difficulty of clearing mucus. Environmental exposures, including smoking, pollutants in many settings, and second hand smoke, increase the risk for chronic bronchitis.

Smoking and frequent bronchopulmonary infections may contribute to COPD (American College of Physicians, 2016). Pulmonary insufficiency, chronic pulmonary emphysema, pneumonia, atelectasis, asthma, and tuberculosis are other disorders that cause respiratory disease.

Asthma produces symptoms of dyspnea, intermittent cough, chest tightness, exertional wheezing heard on auscultation, and prolonged expiration. The disorder may be inherited, may begin in childhood and continue into adulthood, and may be linked to allergies. The symptoms of asthma are caused by airway spasms, bronchial narrowing or obstruction, mucous accumulation, and airway inflammation (American

College of Physicians, 2016; Huether & McCance, 2017) The main feature of asthma is constriction and spasms of airways in response to irritants, allergens, pollutants, or cold air.

Pneumonia is an infection in the lungs. The clinical manifestations of pneumonia include fever, cough, increased secretions, and difficulty breathing. Key points for nursing management of pneumonia are monitoring gas exchange and maintaining a patent airway. If aspiration is determined to be a contributing cause, swallow precautions are implemented, including thickened liquids and having the patient in an upright position for feeding and drinking.

Atelectasis results from blockage or collapse of air passages in at least one lobe of the lungs. Anesthesia, prolonged bed rest, and shallow breathing can decrease movement of the diaphragm and chest wall, which results in hypoventilation. The process may lead to small airway obstructions from retained secretions. Patients who have had abdominal or chest surgery are at risk for hypoventilation and atelectasis, because incisional pain may result in shallow breathing. Nursing interventions and patient teaching that help reduce these risks include encouraging incentive spirometry use, coughing and deep breathing exercises, pain control measures, and abdominal/chest splinting when the patient needs to cough.

Untreated chronic lung disease may result in respiratory failure. Respiratory failure occurs when the body is unable to maintain sufficient oxygenation to tissues because of disease or injury to the lungs. Early intervention for disease or injury helps prevent respiratory failure. [Box 38.1](#) addresses concerns about the cardiopulmonary system.

Box 38.1

Diversity Considerations

Life Span

- Changes in cardiopulmonary function occur throughout the life span. The maximum oxygen uptake declines for adults after the age of 25.
- Cardiovascular performance declines in the 40s and 50s, even in well-trained athletes.
- Emphysema, when present, usually begins in the 30s and 40s, but it becomes severe in the 50s and later ([Sommers & Fannin, 2015](#)).
- In pregnancy, cardiac output and blood volume increase and the growing uterus exerts pressure on the diaphragm, making

breathing more difficult.

- Prevalence of coronary heart disease (CHD) steadily increases with age through the age of 85 and beyond ([American Heart Association, 2015](#)).

Gender

- Children's hearts show no significant gender differences. The heart mass of males increases by about 15% to 30% more than that of females after puberty.
- Emphysema occurs more often in men than women.
- Incidence of CHD is higher in men than women through the age of 84, after 85 the incidence of CHD is higher in women than men ([American Heart Association, 2015](#)).

Culture, Ethnicity, and Religion

- Emphysema does not occur more often in any racial or ethnic groups ([Sommers & Fannin, 2015](#)).
- Black men have a higher incidence of heart attack or fatal heart disease than white men, white women, or black women from age 35 through age 84 ([American Heart Association, 2015](#)).

Disability

- Scoliosis, a disorder that may begin in childhood, causes the spine to develop a lateral curvature. Kyphosis is an outward deformity of the upper spine. Over time, kyphoscoliosis (combined kyphosis and scoliosis) compromises the respiratory system, resulting in hypoventilation, retention of carbon dioxide, and shortness of breath for the patient.
- Other conditions that limit the ability of the lungs to fully expand, such as being confined to a wheelchair, may contribute to respiratory compromise.

Morphology

- Obesity contributes to diabetes and high cholesterol levels, which are risk factors for coronary artery disease.
- Obesity also contributes to hypertension and heart failure.

LO 38.3 ♦ Assessment

A detailed account of the patient's chief complaint and history of current illness can be obtained by asking focused questions (Box 38.2). Some questions seek specific information, whereas others are open-ended to allow the patient more freedom to respond.

Box 38.2

Health Assessment Questions

Cardiovascular Focus

- Are you having chest pain? If so, rate it on a scale of 0 to 10.
- How long have you had the pain?
- Is the pain located in one area, or does it radiate to other areas?
- Do activities or medications make it worse or better?
- Are symptoms such as shortness of breath or sweating associated with the pain?
- Do you have increased fatigue?
- Have you had recent weight gain?
- Have you had changes in skin texture, color, or temperature?
- Do you take medications that prevent blood clots?
- Have you had sores on your lower extremities that have not healed?
- Have you had episodes of dizziness or loss of consciousness?
- Do you have other chronic diseases?

Pulmonary Focus

- Have you had breathing difficulties when you are exercising or at rest?
- Have you had a loss of appetite, weight loss, or weakness?
- Have you ever smoked?
 - If so, are you still smoking, or did you quit smoking?
 - How many packs per day (ppd)?
- Do you sleep on one or more pillows?
- How much do you exercise?

- Do you have wheezing, pain with breathing, or difficulty clearing your secretions?
- Have you had asthma, bronchitis, or other lung diseases in the past?
- Do you use oxygen at home?
- What type of work have you done, and were you exposed to hazardous materials?
- Do you have anxiety related to your breathing condition?
- Do you have a cough? For how long?
- Are you coughing anything up? Color of sputum?
- Is it worse when you lie down?

Health History

Assessment of the cardiovascular and pulmonary systems involves gathering subjective and objective data. The subjective information is gathered from the health history and includes information the patient verbalizes throughout the examination, such as when asked about smoking history, including if the patient does or has smoked and how many packs per day. Objective data are gathered from an examination of the patient.

Alterations of the Cardiopulmonary System

A focused cardiopulmonary assessment is performed for any patient with symptoms of decreased oxygenation, shortness of breath, activity intolerance, or a history of cardiac or respiratory problems. The nurse begins this physical assessment by obtaining a set of vital signs and then performs a cardiac, respiratory, and peripheral vascular assessment, looking for alterations.

Vital Signs

Obtaining objective data begins with taking vital signs that include the blood pressure taken in three positions (lying, sitting, and standing), the respiratory rate, and an apical and peripheral pulse. The apical and peripheral pulses are compared to determine whether a pulse deficit exists. A pulse deficit occurs when the apical pulse rate is higher than the peripheral pulse rate due to some cardiac contractions not resulting in peripheral perfusion. [Chapter 19](#) provides more information about pulse and respiration assessment.

Inspection, Palpation, and Auscultation of the Heart and Lungs

The precordium of the chest is visually inspected, noting any musculoskeletal abnormalities. Use of muscles for breathing is evaluated. The use of accessory muscles may indicate respiratory distress. The nurse looks at the precordium to detect movement of the chest wall when the heart contracts. Left ventricular hypertrophy may cause the chest wall to move with each heartbeat. Evaluate the shape of the chest; a barrel-shaped chest may indicate air trapping, which accompanies COPD.

Palpation over the precordium for cardiac function assesses for cardiac enlargement or abnormal vibrations from turbulent blood flow due to hyperactivity or valve disease. Abnormal vibration over the heart is documented as a *thrill*. During auscultation, the vibration may be heard and is referred to as a *murmur*. Auscultation of the heart includes listening for the heart sounds that correlate with closure of the valves of the heart. [Chapter 20](#) provides detailed information about cardiac assessment.

Auscultation of the lungs is completed on the anterior, lateral, and posterior of the chest. Auscultation of the lungs begins at the top of the chest and moves down to below the rib cage. The nurse compares lung sounds side to side. The nurse listens for normal breath sounds and abnormal or adventitious breath sounds that are made when air enters and leaves the lungs through the constricted or diseased airways. A complete discussion of lung assessment can be found in [Chapter 20](#).

Cough Assessment

A patient with a cough needs to be evaluated. Cough may be caused by inflammation or by mechanical or chemical stimulation of the cough receptors in the lung. When taking the history, the nurse determines how long the patient has had the cough and whether the patient has a fever or wheezing. The amount and characteristics of sputum are documented. **Hemoptysis** is the presence of blood in the sputum. The characteristics of the blood—whether it occurs as flecks, streaks, or frank bleeding—are noted. The duration and timing of the cough are important data for the nurse to collect.

Peripheral Vascular Assessment

An important part of the vascular system assessment is the finding of edema in the extremities. Edema may result from excessive fluid in the vascular system that increases pressure in the capillaries and forces

fluid out of the vessels and into the surrounding tissues. Poor venous return may contribute to peripheral edema, particularly in the lower extremities. Another contributing factor is damage to the lymphatic system, which decreases the system's ability to remove excessive fluid from the interstitial spaces. [Chapter 20](#) provides more information on assessment of edema.

Peripheral vascular assessment includes evaluation of peripheral pulses, skin color and texture, and capillary refill in the fingers and toes. Patients with cardiopulmonary problems may have thready or absent peripheral pulses, changes in skin color and texture, and slow capillary refill.

1. List focused assessments that need to be completed for M. R.

Laboratory and Diagnostic Tests

Laboratory assessments determine whether the patient has chemical imbalances or abnormal substances in the blood. For example, when cardiac cells die, cardiac enzymes (e.g., troponins) are released into the bloodstream. Measured levels of these enzymes correlate with heart muscle injury. These and other diagnostic tests are performed to determine the function and structure of heart and lung tissues. Evaluation of the cardiovascular and pulmonary system includes assessment of blood components, including blood counts, lipids, and cardiac enzymes. Noninvasive assessment includes a 12-lead electrocardiogram (ECG), chest x-ray, echocardiogram, pulmonary function tests, and physical assessment. Invasive assessment may include a cardiac catheterization to evaluate coronary arteries and cardiac structures.

Pulmonary Function Tests

Forced vital capacity (FVC) is the amount of air that can be forcefully expelled or exhaled after the lungs are maximally inflated. The normal amount varies by age and size of the patient but is approximately 4 L in an adult. The amount of air expelled is lower in patients with

obstructive pulmonary disease because airways are narrowed (Pagana & Pagana, 2018).

Forced expiratory volume in 1 second (FEV₁) is the volume of air expelled in 1 second from the beginning of the FVC. The expected finding is 75% to 85% of FVC. Patients with obstructive lung disease will have less air expelled than the predicted value (Pagana & Pagana, 2018).

Forced expiratory flow (FEF) is the maximal flow rate attained during the middle of the FVC maneuver. The expected findings vary by body size. In cases of emphysema, the result is 25% of the predicted normal value for the patient's size. A low value predicts airway trapping in the patient's small bronchioles (Sommers & Fannin, 2015).

Residual volume (RV) is the amount of air remaining in the lungs after forced expiration. The expected finding is approximately 1 L. In emphysema, the result may be up to four times the expected normal value (Pagana & Pagana, 2018).

Functional residual capacity (FRC) is the volume of air that is left in the patient's lung after normal expiration. The predicted normal volume is 2.3 L. In emphysema, it may be increased up to 200% over the expected amount due to air trapping (Pagana & Pagana, 2018).

Complete Blood Count

The complete blood count (CBC) and differential provide information regarding oxygen and carbon dioxide transport capabilities and the status of the immune response. RBC, hemoglobin, and hematocrit levels indicate oxygen carrying capacity. The hemoglobin level may be decreased in patients with heart failure due to excess fluid in the system that causes hemodilution. It may be increased in patients with COPD due to overproduction of RBCs stimulated by low oxygen levels and a resultant increase in the hematocrit. Elevation of the white blood cell (WBC) level indicates an infection, and the WBC differential count shifts to the left, with levels of neutrophils increasing and basophils decreasing. [Chapter 34](#) provides detailed information on the CBC.

Basic Metabolic Panel

The basic metabolic panel is a series of blood tests used to assess a patient's renal function, glucose level, and electrolyte status. A patient with heart failure or hypertension may be on diuretics, some of which can cause hypokalemia and hypomagnesemia. Many electrolyte imbalances can cause cardiac arrhythmias. [Chapter 39](#) provides a detailed discussion of the functions of intracellular and extracellular electrolytes, normal values, and the common causes of abnormal values.

Arterial Blood Gases

Blood samples for arterial blood gas determinations are drawn from patients with decreased oxygenation and a suspected acid-base imbalance. COPD causes impaired gas exchange, leading to decreased oxygen levels and higher circulating levels of carbon dioxide (i.e., respiratory acidosis). [Chapter 39](#) discusses acid-base balance.

Lipids

A lipoprotein profile is used to diagnose hyperlipidemia, which is a risk factor for coronary heart disease. The profile usually measures four levels: total cholesterol, low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, and triglycerides. Cholesterol is the primary lipid associated with the development of atherosclerosis if the levels are too high. Cholesterol is evaluated further by measuring HDL and LDL components. A total cholesterol level higher than 200 mg/dL is considered a risk factor for atherosclerosis. The target value for HDL is greater than 45 mg/dL for males and greater than 55 mg/dL for females. The desired value for LDL is less than 130 mg/dL. The desired value for triglycerides is less than 160 mg/dL for males and less than 135 mg/dL for females ([Pagana & Pagana, 2018](#)).

Cardiac Enzymes

Cardiac enzymes and other proteins are released when myocardial **necrosis** (death of heart muscle cells) occurs. When a patient has chest pain or related signs and symptoms, enzyme levels are evaluated to determine whether damage to the heart has occurred. The cardiac troponin T and I proteins are the most helpful biomarkers for determining whether an MI has occurred. Their levels increase 4 to 6 hours after an MI, peak 10 to 24 hours after an MI, and return to baseline several days after an MI ([Lewis, Bucher, Heitkemper, et al., 2017](#)). See [Table 34.7](#) for cardiac marker information.

Chest X-Ray

A chest x-ray is performed to examine the lungs, heart, and bones of the chest ([Fig. 38.7](#)). A chest x-ray shows areas of increased density in the lungs, the proximity of organs to each other, and the size of the heart. Abnormal findings include rib fractures, tumors, pneumothorax (air in the pleural cavity), pneumonia (inflammation of the lungs due to infection), **pleural effusion** (excess fluid accumulation in the pleural cavity), pericardial effusion (fluid around the heart), an enlarged heart,

and atelectasis. Location and position of the diaphragm may be visualized.

FIGURE 38.7 Chest x-ray. (In Urden, L. D., Stacy, K. M., & Lough, M. E. [2014]. *Critical care nursing* [7th ed.]. St. Louis: Elsevier. From Dettenmeier, P. [1995.]. *Radiographic assessment for nurses*. St. Louis: Mosby.)

Electrocardiogram

An **electrocardiogram** (ECG; also called EKG) is a graphic representation of the electrical activity that occurs in the heart. The heart's electrical system is an organized series of impulses that transmit a signal from the SA node in the right atrium, which travels through the atria and AV node to the bundle branches in the ventricles, from which it travels to all parts of the ventricle. The electrical impulses precede the mechanical contraction of the heart. For normal contraction to occur, the impulses travel through the heart in an organized way. The ECG is performed using a 12-lead approach that gathers impulses from 12 areas. The ECG is recorded on special standardized paper (Fig. 38.8). Test results are interpreted for rate and rhythm of the heart, lack of blood supply, abnormalities of the conduction system, and **arrhythmias**, which are abnormal rhythms of the heart. The animation[©]

“Normal Sinus Rhythm” depicts an ECG in conjunction with the heart's contractions.

- P wave: Represents atrial depolarization.
- PR segment: Represents the time required for the impulse to travel through the AV node, where it is delayed, and through the bundle of His, bundle branches, and Purkinje fiber network, just before ventricular depolarization.
- PR interval: Represents the time required for atrial depolarization as well as impulse travel through the conduction system and Purkinje fiber network, inclusive of the P wave and PR segment. It is measured from the beginning of the P wave to the end of the PR segment.
- QRS complex: Represents ventricular depolarization and is measured from the beginning of the Q (or R) wave to the end of the S wave.
- J point: Represents the junction where the QRS complex ends and the ST segment begins.
- ST segment: Represents early ventricular repolarization.
- T wave: Represents ventricular repolarization.
- U wave: Represents late ventricular repolarization.
- QT interval: Represents the total time required for ventricular depolarization and repolarization and is measured from the beginning of the QRS complex to the end of the T wave.

FIGURE 38.8 Normal electrocardiogram (From Ignatavicius, D. D., Workman, M. L., Rebar, C. R., et al. [2018]. *Medical-surgical nursing: Concepts for interprofessional collaborative care* [9th ed.]. St. Louis: Elsevier.)

Echocardiogram

An echocardiogram is a noninvasive ultrasound of the heart (Fig. 38.9). The examination uses sound waves to visualize the heart structure and

evaluate the function of the heart. An echocardiogram shows movement of blood through the heart, and it is used to measure cardiac output. This test can be used to evaluate congenital heart defects, pericardial effusion, disorders of the heart valves, heart size, and effectiveness of cardiac output. Echocardiograms may be obtained alone or in conjunction with a stress test to evaluate the heart when the blood flow to the heart is decreased.

FIGURE 38.9 Echocardiogram. (From Lewis, S. L., Dirksen, S. R., Heitkemper, M. M., et al. [2011]. *Medical-surgical nursing: Assessment and management of clinical problems* [8th ed.]. St. Louis: Mosby.)

Cardiac Catheterization

Cardiac catheterization uses contrast and a long, flexible catheter to visualize the heart chambers, coronary arteries, and great vessels. It is used to evaluate chest pain, locate the region of coronary artery occlusion, and determine the effects of valvular heart disease. In this invasive procedure, a catheter is inserted into the right femoral or brachial artery to view the left side of the heart and inserted into the antecubital or femoral vein to view structures on the right side of the heart. Cardiac valves, chamber pressures, cardiac output, and the ejection fraction may be assessed using cardiac catheterization. Congenital or acquired structural cardiac abnormalities can be visualized. If a coronary artery is narrowed, a balloon can be used to widen its lumen or a stent can be placed to permanently keep the vessel open (Pagana & Pagana, 2018).

Cardiac catheterization is performed in a specialized setting by cardiologists using sterile procedures. The patient is given medication to help with relaxation but may be able to follow commands. This is an invasive procedure, and there can be complications such as allergy to the contrast medium, arrhythmias, blood clots, and bleeding at the catheter insertion site. After the procedure, the nurse monitors the patient for signs of an allergic reaction and obtains frequent vital signs according to facility policy. The insertion site is assessed for bleeding and the affected extremity for peripheral pulses, temperature, color, and pain.

LO 38.4 ♦ Nursing Diagnosis

Selection of the correct nursing diagnosis is important to plan care based on patient needs. Recognition of the potential for decreased oxygen to the tissues directs a focused assessment and the plan for care. The following are common [International Classification for Nursing Practice \(ICNP\)](#) diagnoses related to decreased oxygenation:

Impaired Gas Exchange

- Supporting Data: SpO₂ of 90% on 2 L of oxygen via nasal cannula, patient complaints of difficulty breathing.

Impaired Breathing

- Supporting Data: Ineffective movement of air into and out of the lungs, difficulty breathing with activity and at rest, use of pursed-lip breathing.

Impaired Cardiac Output

- Supporting Data: Decreased pumping ability of the heart, decreased activity tolerance.

2. List at least two nursing diagnoses that are appropriate for M. R.

LO 38.5 ♦ Planning

During the planning phase, the assessment data and nursing diagnoses are used to develop individualized goals (Table 38.1). The following examples of goal statements reflect the desired outcomes for patients with decreased oxygenation:

TABLE 38.1
Care Planning

ICNP NURSING DIAGNOSIS WITH SUPPORTING DATA	NURSING OUTCOME CLASSIFICATION (NOC)	NURSING INTERVENTION CLASSIFICATION (NIC)
<i>Impaired Gas Exchange</i> SpO ₂ of 90% on 2 L of oxygen via nasal cannula, Patient complaints of difficulty breathing	<i>Respiratory status</i> Oxygen saturation	<i>Oxygen therapy</i> Administer supplemental oxygen as ordered

Butcher, H. K., Bulechek, G. M., Dochterman, J., M., et al. (Eds.) (2018). *Nursing interventions classification (NIC)* (7th ed.). St. Louis, MO: Mosby; Moorhead, S., Swanson, E., Johnson, M., et al. (Eds.) (2018). *Nursing outcomes classification (NOC)* (6th ed.). St. Louis, MO: Mosby. ICNP is owned and copyrighted by the International Council of Nurses (ICN). Reproduced with permission of the copyright holder.

- Patient will maintain SpO₂ at 92% or greater by the end of the shift.
- Patient will demonstrate a breathing cycle that returns to a normal pattern after aerosol treatments.
- Patient will be able to walk to the bathroom without shortness of breath within 48 hours.

The conceptual care map for M. R. can be found at <http://evolve.elsevier.com/YoostCrawford/fundamentals/>. It is partially completed to indicate how to use the map as a learning tool.

Complete the nursing diagnoses using the example conceptual care maps shown in [Chapters 8](#) and [25 to 33](#).

LO 38.6 ♦ Implementation and Evaluation

The care plan is implemented using safe practices. To determine whether nursing care has been effective, the nurse carefully evaluates the steps that have been taken. Based on the evaluation, the plan of care is revised to provide effective care to the patient.

Promoting Optimal Cardiopulmonary Function

Many nursing interventions promote optimal cardiopulmonary function. Placing a dyspneic patient in the semi-Fowler position; aiding airway clearance by teaching the patient to cough, deep-breathe, and use an incentive spirometer; and providing adequate hydration to help thin secretions are examples of nursing measures to promote optimal oxygenation. Nurses are responsible for administering ordered oxygen and medication therapies and for monitoring the effectiveness of treatments. Lifesaving procedures are sometimes performed by the nurse ([Box 38.3](#)).

Box 38.3

Ethical, Legal, and Professional Practice

Life and Death Decisions

- When a patient is hospitalized, protocols are in place to begin the lifesaving procedure of cardiopulmonary resuscitation when breathing and heart contractions stop.
- These protocols are not begun if a patient has a do-not-resuscitate (DNR) order.
- The advance directives of a person may determine whether artificial airways and ventilations are given to the patient. An ethical dilemma may occur when a patient is no longer able to make this decision. The family or health care power of attorney decides about advanced procedures for oxygenation.
- [Quinn, et al. \(2012\)](#) studied roles portrayed in families when making end-of-life decisions in intensive care units. The authors concluded that end-of-life decisions are burdensome and are complicated by differing family members wishes. The study determined an early decision-making process with input from

family members and health care providers is important during the difficult time.

Oxygen Therapy

Supplemental oxygen can be used on a temporary or permanent basis, depending on the patient's diagnosis and oxygenation status. Oxygen therapy for more than 15 hours per day for patients with COPD improves survival, functioning level, exercise capacity, and mental status (Box 38.4). The goal of long-term therapy is usually to have a baseline PaO₂ of 60 mm Hg at rest and an oxygen saturation level of more than 90%, which represents adequate delivery of oxygen to the tissues (American College of Physicians, 2016). Oxygen saturation may decrease during exercise, sleep, or deterioration of the respiratory status.

Box 38.4

Home Care Considerations

Oxygen Therapy in the Home

- The order to place oxygen in a home is obtained from a primary care provider and is based on the diagnosis of a medical condition that confirms the need for home oxygen.
- A patient who is using oxygen at home is educated on the proper use and storage of oxygen.
- Signs stating “No Smoking” need to be in place in the home.
- The size and configuration of the home is used to determine the placement of oxygen and length of tubing to allow the patient to go from one room to another.

Oxygen Administration

Oxygen concentration of room air is 21%. When a patient has documented or suspected low oxygen levels, oxygen therapy may be indicated. The goal of oxygen therapy is to decrease the symptoms related to low oxygen levels and decrease the workload on the cardiovascular system. Collaboration with other members of the health care team is essential for patients receiving oxygen therapy so that comprehensive care is provided (Box 38.5).

Box 38.5

Interprofessional Collaboration and Delegation

Multidisciplinary Care of Patients With Oxygenation Problems

- Coordination of care for a patient with oxygenation problems involves interprofessional collaboration among nurses, physicians, respiratory therapists, speech therapists, and physical therapists.
- The plan of care is based on the physical examination by the primary care provider and is modified based on nursing assessments, including vital signs and ongoing cardiac and pulmonary assessments.
- The medication orders by the primary care provider follow the national hospital inpatient quality measures and the individual needs of the patient. These orders include oxygen therapy, respiratory medications and treatments, and other medications.
- Respiratory therapists initiate the administration of inhaled respiratory medications and assess the patient's status.
- Speech therapists become involved if aspiration is suspected as a contributing factor in the development of the abnormal respiratory status. The speech therapist evaluates swallowing and provides a plan of care using thickened liquids if appropriate.
- Physical therapists evaluate the patient who has the nursing diagnosis of *Activity Intolerance* to assist with a plan of care for mobilization of the patient.
- Social workers address patient and family coping skills and direct them to possible financial resources, in-home care, or appropriate care facility options.

Clinical practice guidelines for safe and effective patient care include evaluating the indications for oxygen therapy, taking necessary safety precautions, determining the need for oxygen, assessing the outcome of therapy, and monitoring the patient on supplemental oxygen. Assessing the need for oxygen is an important nursing function. Assessment includes using laboratory results to document **hypoxemia**, which is a low level of oxygen in the blood. The low levels can be determined by use of arterial blood gas analysis or measurement of hemoglobin

oxygen saturation. Monitoring the patient's condition is another way to evaluate the need for continued oxygen therapy. Hypoxemia may manifest as a high respiratory or heart rate. Other indications may be **cyanosis**, a bluish discoloration of the skin related to deoxygenation of hemoglobin, a decreasing oxygen saturation level, and a feeling of distress.

QSEN Focus!

Safety requires the nurse to demonstrate effective use of strategies, such as monitoring oxygen therapy and keeping oxygen away from open flames. These measures reduce the risk for harm to patients and health care workers.

Safe Practice Alert

Safe administration of oxygen includes careful assessment and monitoring of the patient. Oxygen is a medication and is used with the same precautions and safety checks as all other medication administration.

It is important to use precautions and monitor for complications when administering oxygen. Historically it was thought that a patient with chronic **hypercapnia**, an abnormally high level of carbon dioxide in the blood (>45 mm Hg in arterial blood), may have respiratory depression when supplemental oxygen levels are too high. A concern with this theory is that patients may not be given adequate supplemental oxygen when needed. [Abdo and Heunks \(2012\)](#) recommend that oxygen therapy be titrated to maintain a patient with an acute exacerbation of COPD to an oxygen saturation of 88% to 92%. Another concern about oxygen administration is that when the **fraction of inspired oxygen (FIO₂)** or percentage of oxygen in inspired air) exceeds 50%, atelectasis or oxygen toxicity may occur. High levels of oxygen pose a fire hazard. Nebulizers and humidifiers may have bacterial contamination, promoting infections.

Oxygen Delivery Systems

Devices used to deliver oxygen are categorized as low-flow systems, reservoir systems, and high-flow systems. A commonly used low-flow system is the nasal cannula. Cannulas are contraindicated for newborns and infants with obstructed nasal passages.

Mask delivery systems gather and store oxygen between patient breaths. The mask has holes in the side that allow carbon dioxide to be exhaled. If the unit becomes disconnected from oxygen, the patient can breathe in room air through the holes when inhaling.

Safe Practice Alert

The mask may be uncomfortable for the patient, and the patient may try to remove the mask when unattended. An alternative oxygen delivery system is required when the patient is eating.

Two types of masks have similar designs. The partial rebreather mask and nonrebreather mask have a 1-L reservoir bag that is flexible and has an oxygen inlet. The reservoir allows higher inspired oxygen levels, and these masks can deliver higher levels of oxygen to a patient. The main difference in the types of **reservoir masks** is the valve system. With use of the partial rebreather mask, some exhaled air enters the reservoir bag. As long as the bag remains full, the amount of carbon dioxide that the patient breathes back in is small. The amount of oxygen delivered to the bag typically needs to be more than 10 L to prevent the bag from collapsing (White, 2013).

[Box 38.6](#) and [Box 38.7](#) provide information about the use of supplemental oxygen and assisted breathing techniques.

Box 38.6

Nursing Care Guideline

Oxygen Administration Techniques

Background

- Oxygen administration provides supplemental oxygen when lungs are not functioning optimally.
- It can provide humidity to increase expectoration and improve lung function.
- Room air is 21% oxygen. Administering higher concentrations of oxygen is considered medication administration.
- All rights of medication administration should be followed (see [Box 35.4](#)).

- High oxygen levels can be toxic and damage the lungs. High concentrations can damage the retinas of neonates. Careful monitoring and adherence to orders is imperative.
- Respiratory therapists and nurses may set up and administer ordered oxygen therapy. UAP with special training may set up oxygen administration equipment and monitor the flow rate.

Procedural Concerns

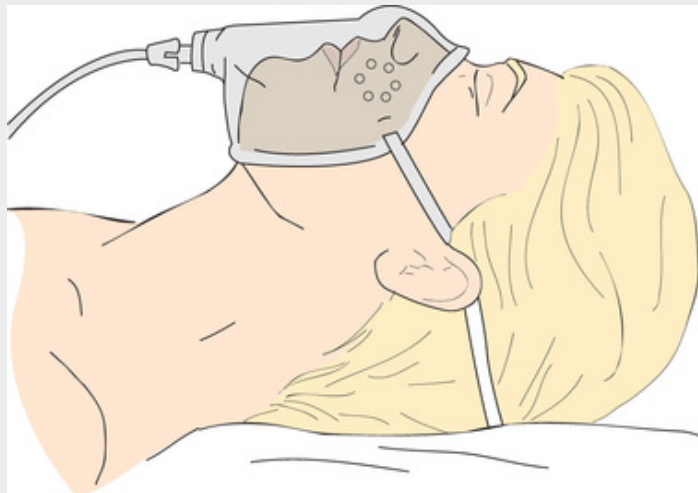

- Thoroughly assess respiratory status:
 - Vital signs
 - Indications of anxiousness, confusion, and restlessness
 - Color, cyanosis
 - Respiratory rate and quality
 - Lung sounds
 - Chest movement and retractions
 - Finger clubbing
- Ensure that orders are obtained for the following:
 - The device
 - Correct flow rate and percent oxygenation
 - Optimal pulse oximetry
- Always ensure oxygen is flowing before placing the oxygen apparatus on the patient.
- If the patient has COPD, use low-flow oxygen delivery *only* (≤ 2 L/min) unless a higher level of oxygen administration is indicated by low oxygen saturation levels (Sole, Klein, & Moseley, 2017).
- Monitor the patient for 15 to 30 minutes after starting the oxygen, and repeat assessments as needed, depending on the patient's status.
- Oxygen signage indicates that oxygen is in use.
- Oxygen delivery devices fall into two broad categories:
 - Low-flow systems
 - Simple nasal cannula
 - Simple face mask
 - Partial-rebreather mask
 - Nonrebreather mask
 - High-flow systems (Sole, Klein, & Moseley, 2017)
 - Air-entrainment or Venturi mask
 - High-flow nasal cannula
- Oxygen delivery by simple nasal cannula

(Copyright © Mosby's Clinical Skills: Essentials Collection)

- Correct application:
 - Place the prongs in the patient's nares with the curved side at the top and the prongs pointing toward the back of the head.
 - Loop the tubing around the patient's ears. Gauze or special tubing covers may be used as a cushion where the tubing rests on the ears to prevent sores and protect the skin.
 - Tuck the tubing under the patient's chin and secure it with the sliding adjustment piece.
- Encourage the patient to breathe through the nose.
- Flow rates and percent oxygenation values are as follows:
 - 1 L/min = 24%
 - 2 L/min = 28%
 - 3 L/min = 32%
 - 4 L/min = 36%
 - 5 L/min = 40%
 - 6 L/min = 44%
- Do not administer oxygen through a simple nasal cannula at greater than 6 L/min.
- Consider humidification at all levels, especially at flow rates of 4 L/min and higher.
- Oxygen delivery by high-flow nasal cannula
 - Air is properly heated and humidified

- Delivered with a high-flow system
- Oxygen delivery rate 15 to 40 L/min
- Oxygen delivered from 60% to 90% (Sole, Klein, & Moseley, 2017)
- Oxygen delivery by mask
 - If there is a bag reservoir, ensure it is filled before placing the mask on the patient.
 - Always humidify oxygen delivered by mask.
 - If the patient is able to eat, obtain an order for a nasal cannula during meals.
 - Correct application:
 - Place the mask over the patient's nose and mouth.
 - Secure the mask around the back of the head with the adjustable strap, pulling evenly from both ends of the strap to secure it in place. If the straps are around the ears where they may chafe, cushion the ears with gauze.
 - Adjust the nosepiece by pinching it to provide comfort and ensure fit.
- Oxygen masks include simple face masks, partial rebreather masks, nonrebreather masks, Venturi masks, tracheostomy masks, and face tents.
 - Simple face mask.

(From Sorrentino, S. A., & Remmert, L. [2017]. *Mosby's textbook for nursing assistants* [9th ed.]. St. Louis: Elsevier.)

- There is no reservoir bag.
- Flow rates and percent oxygenation values are as follows:
 - 5 L/min = 40%

- 6 L/min = 45%
- 7 L/min = 50%
- 8 L/min = 55%
- >8 L/min = 60%
- Partial rebreather mask
 - Flow rates and percent oxygenation values are 6 to 15 L/min and 70% to 90%, respectively.
 - The partial rebreather mask looks very similar to the nonrebreather mask. The partial rebreather mask allows some of the exhaled air to enter the reservoir. The patient rebreathes part of the exhaled air, which contains carbon dioxide and acts as a stimulus to breathe for some patients.
- Nonrebreather mask.

(Copyright © Mosby's Clinical Skills: Essentials Collection.)

- Flow rates and percent oxygenation values are 10 to 15 L/min and 60% to 100%, respectively.
- Special valves on the mask prevent room air from entering the mask but allow exhaled air to leave the mask.
- The nonrebreather mask looks very similar to the partial rebreather mask. The difference is that the reservoir bag on the non-rebreather mask has a one-way valve that prevents exhaled air from entering

the reservoir. This provides a larger concentration of oxygen in the bag for the patient to inhale.

- Ensure a snug fit around the face.
- Venturi mask.

(Copyright © Mosby's Clinical Skills: Essentials Collection.)

- A Venturi mask is used to ensure accuracy of the oxygen concentration delivered; it is considered for use with carbon dioxide–retaining patients.
- Flow rates and percent oxygenation values vary by manufacturer but are in the range of 4 to 12 L/min and 24% to 60%, respectively.
- Although the manufacturer's instructions need to be consulted for specific details, the Venturi apparatus includes a set of color-coded adaptors (i.e., jets) or a dial.
- Each color-coded adaptor has a corresponding liters-per-minute setting listed on it for the allowed percent oxygenation. To change the percentage of oxygen being delivered, the adaptor must be changed inside the tubing.
- If the apparatus has a dial, turn it to set the correct percent oxygenation.
- Tracheostomy mask and collar.

(Copyright © Mosby's Clinical Skills: Essentials Collection.)

- Patients with tracheostomies require a special adaptation for oxygen administration.
- Oxygen is always humidified for tracheostomies.
- Correct application:
 - Center the mask and collar over the tracheostomy.
 - Secure the mask and collar around the back of the patient's neck with the strap, pulling evenly on both ends of the strap to secure it in place.
- Flow rates and percent oxygenation values are similar to those for simple face masks.
- Face tent.

(Copyright © Mosby's Clinical Skills: Essentials Collection.)

- When a face tent is used, the oxygen is always humidified.
- Correct application:
 - Center the face tent over the face, covering from the jaw upward.
 - Secure it around the top of the patient's head with the strap, pulling evenly on both ends of the strap to secure it in place.
 - Flow rates and percent oxygenation values vary.

Documentation Concerns

- Record patient tolerance of the oxygen delivery device.
- Document the respiratory assessment, including information obtained.
 - Before initiation of oxygen therapy
 - At initiation of oxygen therapy and 15 to 30 minutes after initiation
 - At subsequent times determined by patient status and nursing judgment
- Include the flow rates and percent oxygenation values.

Evidence-Based Practice

- Patients receiving oxygen therapy have up to one-third higher mortality rates than other patients in the hospital. [Eastwood and](#)

colleagues (2011) found that these patients were missing up to 10% of routine documentations, such as respiratory rates and pulse oximetry readings. Decalmer and O'Driscoll (2013) noted that oxygen is a frequently used medication and monitoring of the administration may be haphazard, resulting in potential harm to patients from either too much or too little oxygen administration.

- The lack of documentation indicates a lack of vigilance in monitoring, which can increase the mortality rate.
- Patients on oxygen are high-risk patients, and nurses need to be vigilant in monitoring and documentation to prevent further complications.
- According to Siemieniuk, et al. (2018) 90% to 94% is the desired range for SpO₂ in hospitalized patients; or 88% to 92% for those patients who are hypercapnic. Recommendations include using the minimal amount of supplemental oxygen to reach the desired SpO₂.

Box 38.7

Nursing Care Guideline

Continuous Positive Airway Pressure and Bilevel Positive Airway Pressure Applications

Background

- Positive airway pressure is primarily used in patients with obstructive sleep apnea (see Chapter 33), pneumonia, and chronic obstructive pulmonary disease (COPD), and to prevent atelectasis.
- Forced air is administered through a mask over the nose or through nasal pillows at the nares, which keeps the airway open at all times (see Fig. 33.4).
- There are two types of positive airway pressure applications:
 - Continuous positive airway pressure (CPAP) provides continuous positive airway pressure; that is, it provides the same pressure during both inhalation and exhalation.
 - Bilevel positive airway pressure (BPAP) provides continuous bilevel positive pressure. It uses two pressures: a higher pressure during inhalation and a lower pressure during exhalation.

- Both types of applications usually deliver room air but can deliver supplemental oxygen if ordered.

Procedural Concerns

- Interprofessional collaboration is required when either device is used for long periods.
 - A respiratory therapist usually sets up the device and administers therapy to the patient in acute care.
 - The respiratory therapist or nurse may set up the device in long-term care.
 - The patient sets up the apparatus in the home.
 - Follow the primary care provider (PCP) orders for the settings.
- Assessments
 - The patient's tolerance and frequency of use are evaluated.
 - Necessary assessments are made of the potential barriers to use of CPAP and BPAP:
 - Dry nares
 - Skin irritation
 - Claustrophobia
 - Perceived inability to breathe against air
 - Noise of the apparatus
- Refer to the manufacturer's instructions for operation of the device.
- Do not initiate the use of or operate the device without proper education.

Documentation Concerns

- Document the patient's tolerance of the device.
- Include the respiratory assessment.
- Note patient issues or complaints.
- Include the patient and family education provided.

Evidence-Based Practice

- Nurses must teach patients and families about the effectiveness of CPAP in treating and reducing the negative consequences of obstructive sleep apnea. Education can increase the patient's use of CPAP and ultimately improve quality of life.

- Baker, et al. (2016) noted that in patients using CPAP, at least 50% used it less than 4 hours per night. They conducted a randomized controlled study using motivational enhancement during short appointments and phone calls during the study. The authors of the controlled trial concluded that the intervention significantly increased the adherence to the use of CPAP.

Bag-Valve-Mask Device

The bag-valve-mask (BVM) device uses a one-way valve to support, ventilate, and oxygenate a patient who needs ventilatory support (Fig. 38.10). All emergency crash carts are supplied with a BVM unit for emergency use. Only personnel who have been properly trained and certified in the use of the devices should administer ventilation using the BVM units.

FIGURE 38.10 Bag-valve-mask device. (From Sorrentino, S. A., & Remmert, L. [2017]. *Mosby's textbook for nursing assistants* [9th ed.]. St. Louis: Elsevier.)

When it is necessary to use the BVM device, health care personnel should be positioned at the head of the bed. An oral airway is inserted when possible, and the BVM unit is connected to high-flow oxygen. An adequate amount of oxygen and appropriate tidal volume is delivered based on the patient's size. Bags are available in sizes ranging from infant to adult. An adequate seal between the mask and the patient's face, if the patient is not intubated, is necessary to maximize the amount of air that is moved in each ventilation cycle.

Artificial Airways

Pharyngeal Airways

Pharyngeal airways keep obstruction from occurring by pulling the tongue forward and away from the back of the throat (Fig. 38.11).

Pharyngeal airways are needed most often when a patient has a decreased level of consciousness and loss of muscle tone.

Oropharyngeal airways are inserted through the mouth. The airway goes over the tongue and is used in unconscious patients. The **nasopharyngeal airway** is placed nasally. It is used most often for patients who require frequent nasotracheal suctioning. **Box 38.8** provides information about applying these airways.

FIGURE 38.11 Pharyngeal airways. (From Monahan, F. D., Sands, J. K., Neighbors, M., et al. [2007]. *Phipps' medical-surgical nursing: Health and illness perspectives* [8th ed.]. St. Louis: Mosby.)

Box 38.8

Nursing Care Guideline

Oropharyngeal and Nasopharyngeal Airway Insertion

Background

- An artificial airway can be used in an emergency situation to maintain a patent airway in a patient who is otherwise breathing on his or her own.
- Oropharyngeal airway:
 - Keeps the patient's tongue from blocking his or her airway
 - Keeps excessive secretions out of the airway in an unconscious patient
 - Is used primarily for unconscious patients
- Nasopharyngeal airway (i.e., nasal trumpet):
 - Primarily used with patients who require frequent suctioning
 - Acts as a guide for the suction catheter

Procedural Concerns

- Refer to agency policies and procedures and primary care provider (PCP) orders.
- Secure the airway in place with a holder or tape.
- Oropharyngeal airway:
 - The average adult size is 90 mm; it is measured from the mouth opening to the back of the jaw.
 - Insert the airway while directing the curve of the airway at the roof of the mouth, and then rotate the airway 180 degrees after it reaches the back of the throat.
 - Remove the airway every 4 to 8 hours.
- Nasopharyngeal airway:
 - The size of the airway is based on the patient's height.
 - Lubricate the airway before attempting insertion.
 - The airway is inserted gently; if resistance is encountered, try the other nostril.
 - Maintain oral care at least every 2 to 4 hours and as needed.
 - Remove the airway, and alternate nares as directed in institutional guidelines.

Documentation Concerns

- Document the reason for insertion of the airway.
- Airway size.

- Patient and family education.
- Note patient tolerance of the airway.
- Include mucous membrane assessments and respiratory assessments.
- Document the oral care given.

Safe Practice Alert

Visually check placement of the airway. Improper placement may result in inadequate ventilation.

Tracheal Airways

Airways that go beyond the pharynx and into the trachea are called *tracheal airways*. **Endotracheal tubes** are semirigid, curved tubes with a cuff at the distal end that seals to prevent aspiration of gastric contents into the lung, allow positive pressure for ventilation, and keep air from leaking out of the airway. Further information is available by watching the animation “Endotracheal Intubation.”[ⓔ]

The **tracheostomy tube** is placed directly in the trachea to control the airway. It is usually made of plastic polymers, but some are made of metal (Fig. 38.12). Most plastic tracheostomy tubes have an outer cannula that has a flange and a cuff attached. A removable inner cannula has a standard 15-mm adapter. The inner cannula is removed for cleaning. The tracheostomy tube fits through a stoma in the neck. Tracheostomy insertion can be viewed in the animation [ⓔ] “Tracheotomy.” Suctioning procedures for airways and tracheostomy care are outlined in Skills 38.1 and 38.2.

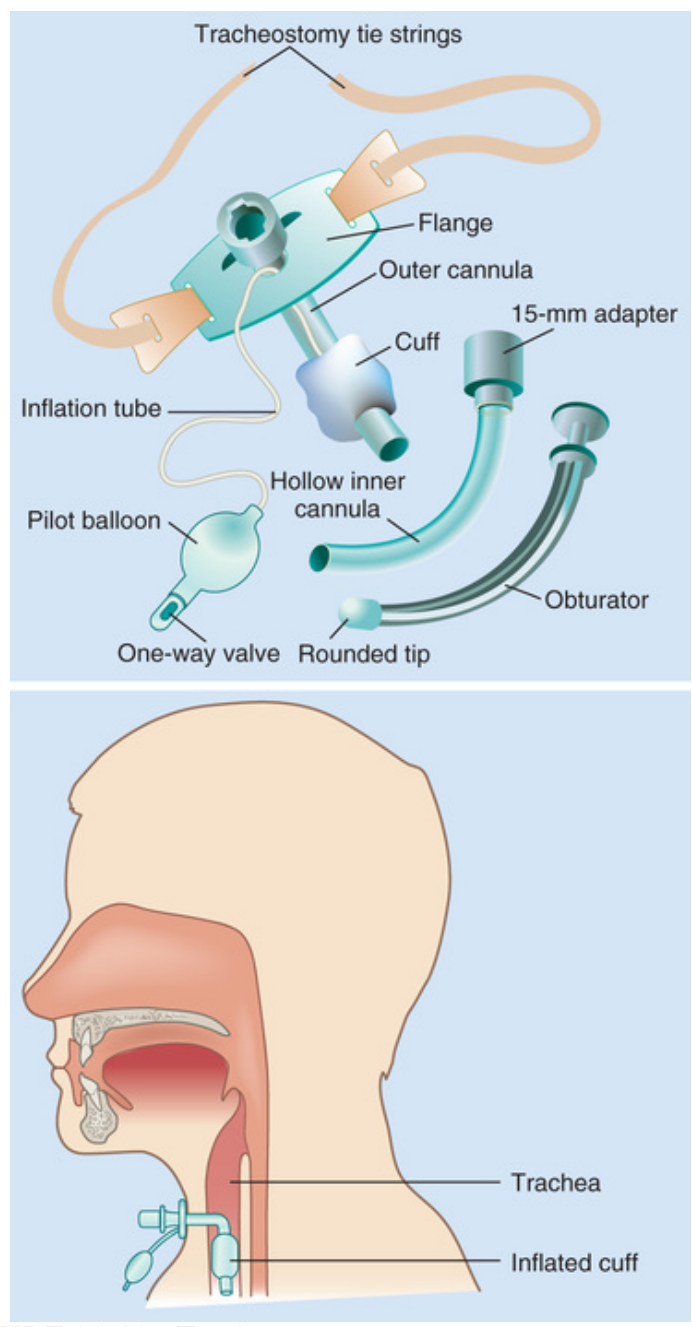

FIGURE 38.12 Tracheostomy components. (In Lewis, S. L., Bucher, L., Heitkemper, M. M., et al. [2017]. *Medical-surgical nursing: Assessment and management of clinical problems* [10th ed.]. St. Louis: Elsevier.)

Diet Therapy

A high-fiber and low-fat diet is recommended for patients at risk for cardiopulmonary disease. The patient is advised to avoid meats that are high in fat and eat lean cuts of meat, such as chicken or turkey breasts. Eating fruits and vegetables is encouraged. Weight management and a high-fiber diet may help lower LDL cholesterol levels (Box 38.9).

Box 38.9

Evidence-Based Practice and Informatics

Women and Cardiovascular Risk

- Middle-aged and older women who were sedentary and overweight or obese were studied to determine the effect of an intervention program.
- An additional daily serving of fruit and vegetable decreased risk for ischemic heart disease and stroke.
- For each kilogram lost, there was an associated reduction of blood pressure and decreased risk for high blood pressure and diabetes (Folta, Sequin, Chui, et al., 2015).

Exercise Programs

Regular exercise is recommended for cardiac and pulmonary patients to optimize functioning. Cardiac and pulmonary rehabilitation is an individualized exercise program for patients with a cardiopulmonary condition. Patients in the outpatient setting are followed with a cardiac monitor during prescribed exercises. Pulmonary rehabilitation patients are assessed for changing breath sounds and oxygen saturation levels at rest and with exercise. Oxygen therapy is used for patients whose oxygen saturation levels fall below a designated value, typically less than 90%. The benefits of rehabilitation include educational material, improved oxygen use, and social interactions.

Safe Practice Alert

Stop exercise for a patient if chest pain occurs. Place the patient in resting position, and evaluate the pain.

Medications for Pulmonary Diseases

The use of medications for lung disease can help decrease symptoms, improve the ability to exercise, decrease the number of exacerbations, and improve the patient's health status. The preferred route of pulmonary medications for antiasthma drugs is inhalation; medications can be administered orally and intravenously for serious conditions.

Several medications are used for treating pulmonary diseases ([Burcham & Rosenthal, 2016](#)):

- Oral **bronchodilators** increase the diameter of the bronchi and bronchioles, which decreases wheezing and improves oxygenation.
- Inhalation therapy bronchodilators increase the diameter of the bronchi, which decreases wheezing and improves oxygenation.
- Anticholinergic agents decrease secretions, which improves airway clearance and decreases bronchospasms.
- Corticosteroids decrease inflammation, which improves respiratory function.
- Vaccines provide protection against communicable diseases, including influenza and pneumonia.
- Antibiotics treat infections when they occur.
- Mucolytic therapy decreases the thickness of secretions, which improves airway clearance.
- Leukotriene modifiers decrease inflammation in the airways.

3. Which of M. R.'s medications may elevate blood glucose levels?

Medications for Cardiovascular Diseases

Many medications are available to treat cardiovascular diseases. Hypertension is treated with diuretics, such as thiazides, angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor antagonists, beta-blockers, calcium channel blockers, alpha-1

antagonists, alpha-2 agonists, and vasodilators. It is important for the nurse to monitor the patient's blood pressure and be alert for adverse reactions to these medications such as dizziness and hypotension. Diuretics may be given to patients with heart failure or edema. Monitoring daily weights and intake and output are appropriate nursing measures for these patients. Antiarrhythmics may be given to patients with arrhythmias or heart failure to slow the heart rate and increase cardiac output.

4. Provide at least four nursing interventions with rationales that can help relieve some of M. R.'s respiratory distress.

Chest Physiotherapy

Chest physiotherapy includes postural drainage, coughing, deep breathing, and incentive spirometry. **Postural drainage** is a therapeutic way to position a patient to use gravity to help mobilize respiratory tract secretions. Positioning of the patient improves ventilation and perfusion and normalizes the functional residual capacity of the lungs. Postural drainage therapy includes turning, postural drainage, and external manipulation of the thorax using percussion and **vibration** (gently shaking a flat hand against the chest).

Patients who benefit from postural drainage therapy include those who are unable or reluctant to change body positions and patients with unilateral lung diseases that are related to poor oxygenation due to position. Patients who have diseases such as cystic fibrosis or bronchiectasis, COPD, abscesses, or difficulty removing secretions may benefit from postural drainage therapy (Huether & McCance, 2017).

The risks of postural drainage therapy should be considered for some patients. Empyema, pulmonary edema, and pulmonary embolism are a few of the conditions for which the therapy is contraindicated. External manipulation of the thorax is contraindicated for patients with a new pacemaker.

Complications of postural drainage therapy include hypoxemia, increased intracranial pressure (ICP), a drop in blood pressure during the procedure, vomiting, and bronchospasm. Cardiac dysrhythmias,

pain, and injury to the musculoskeletal system may occur. It is important to monitor the patient carefully during the procedure. The cardiac rhythm, breathing patterns, and skin color are assessed to determine oxygenation. Breath sounds, blood pressure, and oxygen saturation levels indicate the movement of air.

Chest Tubes

The physician determines the size of the catheter used for chest drainage tubes; larger chest tubes are more likely to stay patent than smaller tubes. Chest tubes help drain fluid or blood (hemothorax) and excessive air (pneumothorax) from the pleural space. The chest tube is attached to a water-sealed chamber system that helps regulate the pleural pressure (Fig. 38.13). Most chest drainage systems are based on older three bottle systems but are self-contained plastic units. The three chambers are a collection chamber, a water-seal chamber, and a suction control chamber. There are also waterless suction chest drainage systems. Skill 38.3 details the care of chest tubes and disposable drainage systems.

FIGURE 38.13 (Left) The Pleur-Evac drainage system, a commercial three-bottle chest drainage device. (Right) Schematic of the drainage device. (From Ignatavicius, D. D., Workman, M. L., Rebar, C. R., et al. [2018]. *Medical-surgical nursing: Concepts for interprofessional collaborative care* (9th ed.). St. Louis: Elsevier.)

Anticoagulant Therapy

Anticoagulation may be used in patients with cardiac arrhythmias such as atrial fibrillation to prevent the formation of blood clots in the atrium. If a clot forms in the left atrium, the patient is at risk for the clot dislodging, entering the cerebral circulation, and causing a cerebrovascular accident.

Anticoagulation is used to prevent venous thromboembolism (VTE) in acutely ill patients. Risk factors for development of VTE include trauma, major surgery, and age older than 40 years. Other risk factors include venous stasis and peripherally inserted central venous catheter use. A history of smoking during pregnancy, hormone use, hypercoagulability conditions, and previous deep vein thrombosis (DVT) increase the risk of VTE. Malignancy may contribute to increased coagulation in patients. Additionally, stroke, severe respiratory disease, inflammatory bowel disease, sepsis, and nephrotic syndrome may increase the risk for VTE ([American Association of Critical Care Nurses \[AACN\], 2016](#)).

National health policy organizations have described evidence-based practice to prevent DVT. The danger of DVT is the possibility of the blood clot traveling from the deep vein to the pulmonary artery and causing a pulmonary embolus (PE). The development of pulmonary embolism is the most frequent cause of preventable hospital deaths (The Joint Commission, 2019).

To prevent development of VTE, anticoagulation medications are administered. Anticoagulants are medications that reduce formation of fibrin. Two basic mechanisms are involved in clot formation. First is the formation of a platelet plug, followed by reinforcement of the platelet plug with fibrin to form the clot. Both processes are set in motion by blood vessel injury (Burcham & Rosenthal, 2016) (Box 38.10).

Box 38.10

Anticoagulants Prototype Drugs

- Classification of drugs used for prevention or treatment of blood clots:
 - Anticoagulants
 - Drugs that activate antithrombin
 - Heparin (unfractionated)
 - Enoxaparin (low-molecular-weight heparin)
 - Vitamin K antagonist
 - Warfarin
 - Direct thrombin inhibitor
 - Dabigatran
 - Direct factor Xa inhibitors
 - Rivaroxaban
 - Apixaban
 - Antiplatelets
 - Aspirin (cyclooxygenase [COX] inhibitor)
 - Clopidogrel (P2Y₁₂ ADP receptor antagonist)
 - Abciximab (glycoprotein IIb/IIIa receptor antagonist)
 - Thrombolytics
 - Streptokinase
 - Alteplase (tissue-type plasminogen activator)

Warfarin interferes with the synthesis of clotting factors, including factor X and thrombin. All other anticoagulants inhibit the activity of clotting factors: factor Xa, thrombin, or both. Unfractionated heparin and low-molecular-weight heparins may be given parentally for patients who have confirmed acute VTE; parenteral drugs for anticoagulation are administered first. Oral anticoagulation with warfarin has a slower onset. Warfarin can be administered after the parenteral anticoagulation has been started (The [Joint Commission, 2019](#)). It takes days to get the anticoagulation levels in the therapeutic range when warfarin therapy is initiated. The adequacy of anticoagulation is monitored using the international normalized ratio (INR, see [Chapter 34](#)) (The [Joint Commission, 2019](#)). Discharge teaching for a patient on anticoagulation therapy is crucial. The topics include the importance of following the prescribed regimen, dietary advice regarding controlling foods high in vitamin K, signs of adverse reactions to anticoagulants such as bleeding, and interactions with other medications (The [Joint Commission, 2019](#)). Other anticoagulants may be used and are encouraged but not required (The [Joint Commission, 2019](#)).

Anticoagulants in two other pharmacologic classes—direct factor Xa inhibitors and direct thrombin inhibitors—also can be administered by mouth.

Safe Practice Alert

Patients on anticoagulation therapy need to be monitored carefully for signs and symptoms of bleeding, including heart rate, blood pressure, mental status changes, increased bruising, or bleeding of the mucous membrane.

Antiembolism Hose

Antiembolism hose are tightly fitting, elastic stockings that are used to promote venous blood return and prevent edema in the lower extremities, DVT, venous stasis, and PE. Refer to [Chapter 28](#), Skill 28.4 for detailed information about antiembolism hose.

Sequential Compression Devices

Sequential compression devices (SCDs) are inflatable sleeves that wrap around the legs of patients. SCDs are used for immobile patients who are at risk for lower extremity venous stasis. Refer to [Chapter 28](#), Skill 28.5 for information about SCDs.

Safe Practice Alert

Remove sequential compression devices if a patient complains of calf pain until DVT is ruled out.

Patient Education

Patient education helps patients manage disease and control risk factors. Educational topics include diet, exercise, smoking cessation, and the importance of influenza and pneumonia immunizations to prevent these communicable diseases.

Heart Failure Patient Education

Key components for education in patients with heart failure includes the recognition of symptoms if the disease progresses and guidelines for response to a change in condition. Other elements include exercise and activity recommendations individualized to the patient. The importance of monitoring daily weight, ideally at the same time each day with the same garments and on the same scale, is stressed. Teach the patient about what his or her ideal weight should be and when to notify the health care provider. Discuss smoking cessation and dietary restriction, including restricting alcohol consumption ([American Heart Association, 2018](#)). Emphasize the importance of taking medications as prescribed and having an accurate, up-to-date list to take to medical appointments. Report to the primary care providers (PCP) all medications that are being taken, including prescription and over-the-counter medications and supplements.

Smoking Cessation

Smoking cessation is important for all patients, but especially for those with heart or lung disease. The first step is the patient's desire to stop using tobacco products. An intellectual understanding of the need to stop smoking does not translate into cessation due to the addictive nature of nicotine. Helpful recommendations from the American Lung Association include eliminating triggers to smoking, allowing time for the smoking cessation program to make a difference, joining support groups, having a plan for dealing with the desire to smoke, using nicotine replacement therapy, using behavioral therapies, and benefitting from community education programs. Medications covered by Medicare include bupropion and varenicline. Additionally, nicotine nasal spray and nicotine inhalers are covered smoking cessation medications ([American Lung Association, 2018](#)).

The Joint Commission's *Specifications Manual for National Hospital Inpatient Quality Measures* (2018) states that hospital patients who are given smoking cessation information and treatment are more likely to quit. Interventions include brief advice by the health care provider, counseling, and medications (Box 38.11).

Box 38.11

Patient Education and Health Literacy

Components of a Smoking Cessation Program

- Education about the dangers of smoking and health benefits of smoking cessation
- Self-help materials
- Being aware of smoking triggers and planning ways to cope with them
- Counseling and support in person or by telephone
- Use of problem-solving approach such as planning a day without smoking
- Nicotine replacements
- Nonnicotine medications (e.g., bupropion works on parts of the brain that are involved with nicotine addiction)
- Alternative therapy approaches

From National Cancer Institute. (2017). Tobacco, 2017. Retrieved from <https://www.cancer.gov/about-cancer/causes-prevention/risk/tobacco>

Immunizations

Recommended immunizations for adults are yearly influenza vaccines and pneumococcal vaccinations for all persons who are 65 years old or older and those younger than 65 who have chronic lung disease or chronic cardiovascular disease (Centers for Disease Control and Prevention [CDC], 2018). The rationale for the recommendation is based on the research that the pneumococcal vaccination is up to 75% effective in preventing pneumococcal bacteremia.

Pneumonia National Hospital Inpatient Quality Measures

The quality measures for caring for pneumonia patients include giving patients the pneumococcal vaccination and drawing blood cultures within 24 hours of hospitalization when indicated. If appropriate, the patient should be given advice and counseling for smoking cessation. Antibiotic therapy should begin within 6 hours of arrival at the hospital, and influenza vaccination should be administered before the patient is discharged if the immunization was not administered within the recommended time frame ([The Joint Commission, 2019](#)).

Evaluation

The evaluation of the patient's treatment regimen is an ongoing part of the nursing process. Evaluation of goal statements and desired outcomes helps the nurse modify the plan of care according to goal attainment. Not achieving the desired outcomes prompts the nurse to modify the care plan according to current assessment data. Patients with cardiopulmonary disorders often need frequent reevaluation and modification of interventions to meet basic oxygen needs.

SKILL 38.1 Tracheostomy, Nasotracheal, Nasopharyngeal, Oropharyngeal, and Oral Suctioning

Purpose

- To remove mucus from the respiratory tract
- To assist the patient in clearing the airway
- To obtain specimens for ordered tests
- To prevent infections

Resources

- Suction kit
- Sterile normal saline solution (NSS)
- Wall suction or portable suction unit
- Suction canister
- Suction tubing
- Yankauer suction catheter (for oral suctioning)
- Oral suction catheter (for oropharyngeal suctioning)
- Bag-valve-mask (BVM) device with 100% oxygenation capability
- Face mask or shield
- Sterile gloves
- Clean gloves
- Personal protective equipment (PPE) as needed

Interprofessional Collaboration and Delegation

- Oral and oropharyngeal suctioning may be delegated to unlicensed assistive personnel (UAP) after assessment by a registered nurse according to

facility policy and procedures and after completing the appropriate training.

- Tracheostomy and nasotracheal or nasopharyngeal suctioning of a patient may not be delegated to UAP.
- UAP should report any of the following to the nurse:
 - Changes in vital signs, respiratory status, or level of consciousness
 - Pain or discomfort noticed by the patient
 - Skin breakdown or open areas on the oral mucosa
 - Excessive secretions
 - Difficulties encountered during the procedure or other concerns verbalized by the patient
- UAP should be instructed in the following:
 - Appropriate emergency procedures
 - Appropriate equipment use
 - Appropriate documentation
- The respiratory therapist may administer medications that assist with expectoration of secretions. The nurse should time these interventions and coordinate procedures appropriately.
- Depending on the status of the patient, the respiratory therapist may wish to perform the respiratory assessment and suctioning. It is important for the nurse to coordinate procedures with interprofessional personnel.

Evidence-Based Practice

- Historically nurses and respiratory therapists used sterile normal saline instilled into the trachea to facilitate removal of secretions, believing that it would thin secretions and aid in mobilization. However, current evidence shows that this technique has no benefit, because saline does not mix with secretion.
- Introducing a liquid into the respiratory tract can be an emotionally disturbing experience and produce harmful physiologic effects, such as decreasing oxygenation and inducing lower respiratory tract infections. To aid in thinning and mobilization of secretions, airway humidification and adequate hydration should be initiated ([Halm & Krisko-Hagel, 2008](#)). A systematic review of literature concluded that instilling saline in airway before suctioning was not supported ([Caparros, 2014](#)).

Special Circumstances

1. **Assess:** Has the patient experienced pain during or after the suctioning procedure?
 - Intervention:** Consider administering pain medication before suctioning.
 - Ensure there is an appropriate primary care provider (PCP) order. If not, advise the PCP of the patient's pain.
 - Document appropriately.
2. **Assess:** Does the tracheostomy patient have copious amounts of secretions before suctioning?
 - Intervention:** Ventilate with an appropriate system to avoid worsening the condition.
 - Do *not* use a BVM device to apply ventilation to the patient before suctioning; using the bag pushes the secretions deeper into the lungs.

- Use a tracheostomy oxygenation mask set for 100% FiO₂ for several respiratory cycles.
3. **Assess:** Are you unable to maintain a sterile hand while applying ventilation to the patient during tracheostomy suctioning?

Intervention: Obtain a second person to administer ventilation to the patient with a BVM device during the procedure.
 4. **Assess:** If nasotracheal or nasopharyngeal suctioning is ordered, have you checked the patient for epistaxis, injuries from the base of the neck up, reactive airway disease, and coagulation problems?

Intervention: Do *not* suction through the nares (i.e., procedure is contraindicated for all listed conditions). Notify the PCP, and document.
 5. **Assess:** Is there difficulty inserting a catheter in a naris during nasotracheal or nasopharyngeal suctioning?

Intervention: Withdraw the catheter, and attempt the procedure with the other naris.

 - If there is a possible nasal obstruction, do *not* force the catheter into the naris.
 - Ensure the catheter is lubricated using a water-soluble lubricant.
 - Try inserting a nasal trumpet.
 - Ensure the catheter enters along the floor of the nasal passage.
 6. **Assess:** Is there difficulty inserting the catheter past the pharyngeal area during nasotracheal suctioning?

Intervention: Turn the patient's head to one side or the other to elevate the bronchial passages:

 - Turning the patient's head to the left allows right mainstem bronchus entry.
 - Turning the patient's head to the right allows left mainstem bronchus entry.
 7. **Assess:** Is the tongue in the way during oral or oropharyngeal suctioning?

Intervention: Use gauze to physically move the tongue if necessary. Using gauze reduces the risk for trauma.
 8. **Assess:** Is the patient unconscious or unable to assist in positioning when nasotracheal, nasopharyngeal, oral, or oropharyngeal suctioning is required?

Intervention: Position the patient to the side.

- The tongue falls out of the way of the catheter insertion.
 - The side position prevents aspiration and provides comfort by facilitating procedural technique.
9. **Assess:** Is the patient going to be using Yankauer suction catheters at home?
- Intervention:* Teach the patient how to clean the catheter between uses:
- a. Wash the catheters in warm soapy water and soak them in a soap solution for 10 to 15 minutes. Rinse well with clean water.
 - b. Soak the catheters in a container of disinfectant solution for 30 minutes.
 - c. Using a clean disposable glove, remove the catheters from the solution and rinse with warm water.
 - d. Place on a clean towel to air-dry.
 - e. Place dry catheters in a clean, dry container with a lid

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.
- VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient, using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record.

The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Tracheostomy Suctioning

Follow preprocedure steps I through VIII.

1. Put on specific PPE (e.g., face mask or shield, clean gloves).

Using gloves and masks controls the spread of microorganisms among patients and providers and protects providers from infection.

2. Ensure the patient is in the Fowler or semi-Fowler position by elevating the head of the bed.

Elevation of the patient's head and upper body facilitates comfortable respiration, prevents aspiration, and provides comfort to the patient by facilitating procedural technique.

3. Assess the patient's respiratory status.

Establish baseline and assess the need for an appropriate procedure.

4. Place the BVM device at the head of the bed, and ensure it is operational and has 100% oxygen airflow.

Proper placement of the BVM device prevents disruption of the sterile procedure and ensures quick access during the procedure.

5. Determine the best placement to set up the suction device and tubing:

a. If right handed, work on the patient's right side; the nurse's right hand is the sterile hand, and left hand is the clean hand.

b. If left handed, work on the patient's left side; the nurse's left hand is the sterile hand, and right hand is the clean hand.

Optimal placement promotes sterile technique, prevents contamination by microorganisms in the sterile field,

prevents infection, and provides organization to facilitate performing the procedure.

6. Set the pressure of the suction device to 80 to 120 mm Hg continuous, and place the end of the tubing close to the working field.

This is the optimal pressure setting for the procedure. The tubing needs to be connected quickly to the catheter within the sterile field.

7. Prepare items from the suction kit on the sterile field (see the Sterile Fields section in [Chapter 26](#), Skill 26.4). Use a sterile drape. If doing tracheostomy care, the kit may have a drape.
 - a. Open the kit. Create the sterile field.
 - b. Before gloving, pour 100 mL sterile NSS into the sterile solution container. To pour liquids into a container within the sterile field, hold the lid of the container in the nondominant hand with the inside facing up. Pour slowly, holding the bottle 2 to 4 inches above the container. (Some kits have rigid plastic containers and some have collapsible cardboard containers lined in plastic.)
 - c. Put on sterile gloves (see the Sterile Gloving section in [Chapter 26](#), Skill 26.2).
 - d. Place the sterile suction catheter on the sterile field.

Maintain sterile procedure. Preparation of the work field in this manner reduces microorganisms on the equipment, prevents microorganisms from entering the respiratory system and causing infection, and provides organization to facilitate the procedure.

8. Prepare the remainder of the needed items:
 - a. Grasp suction catheter with your sterile hand and wrap the tubing around your fingers.
 - b. Grasp the connection tubing with your clean hand.
 - c. Connect the catheter to the connection tubing. Be careful not to touch your hands together or to touch the connection tubing with the sterile hand.
 - d. Test the functioning of the suction by using your thumb to occlude the suction control port on the catheter and dipping the catheter tip into the center of the NSS, avoiding the edges of the container. The solution collects in the suction canister. Release the suction control port on the catheter.

Maintain sterile procedure to reduce the number of microorganisms on the equipment and prevent microorganisms from entering the respiratory system,

where they may cause infection. Avoiding the edges of the solution container prevents microorganisms from entering the respiratory system. Using NSS decreases risk for trauma to respiratory tissues. Testing ensures equipment functioning and prevents adverse events.

9. Use your clean hand to remove the tracheostomy oxygen mask from the patient (if it was needed.)

Provide access to the tracheostomy to perform the procedure.

10. If the BVM device is not contraindicated (e.g., patient with a tracheostomy who has copious secretions), use your clean hand to give 3 to 5 slow, deep breaths with the BVM device; time the breaths with the patient's inhalations.

STEP 10 (From Sorrentino and Remmert, 2017.)

Provide for extra oxygen during the procedure to promote coughing and deep breathing and facilitate secretion removal.

11. Suction the patient:
 - a. Ensure the suction control port is open.
 - b. With the patient inhaling, gently and quickly insert the catheter approximately 12 to 13 cm into the tracheostomy. If resistance is encountered, pull the catheter back 1 cm.
 - c. Withdraw the catheter slowly while rotating it and moving your thumb on and off the suction control port to promote intermittent suctioning.

STEP 11C (Copyright Mosby's Clinical Skills: Essentials Collection.)

- d. The maximum time for each suctioning is 10 to 15 seconds.

Resistance indicates that the catheter is at the bottom of the trachea, where the bronchi divide. Rotating the catheter allows all areas to be suctioned. Follow the insertion technique to reduce the risk for trauma. Use intermittent suctioning to reduce the risk for trauma to tissues. Restricting the time allotted for each suctioning procedure ensures adequate oxygen levels are maintained for the patient.

12. Replace the tracheostomy oxygen mask with your clean hand if it was removed in procedure step 10. Wait 1 to 3 minutes between suctioning.

Replacing the oxygen source allows oxygen levels to return to normal, promotes comfort, and increases respiratory functioning.

13. Repeat procedure step 8d to clear the suction catheter.
14. Repeat procedure steps 9 through 12 as needed and tolerated.
15. Assess the patient's cardiac and respiratory status after the procedure.

Observing the patient's cardiac and respiratory status allows the nurse to evaluate the effectiveness of the procedure.

Follow postprocedure steps I through VI.

Nasotracheal or Nasopharyngeal Suctioning

Follow preprocedure steps I through VIII.

1. Follow procedure steps 1 through 8 in the Tracheostomy Suctioning section. Assess the nasal cavity.

Ensuring that the nasal passages are intact prevents further damage to any areas that are not intact.

2. Hyperextend the patient's head if able and tolerated.

Hyperextension provides the optimal positioning for the procedure, reduces strain on the caregiver, promotes patient comfort, prevents aspiration, and reduces gagging.

3. Apply water-soluble lubricant to the first 15 cm of the suction catheter tip using sterile technique.

Water-soluble lubricant may be used in addition to sterile NSS. Lubricant facilitates catheter entry into the naris and reduces the risk for trauma to the nasal tissues.

4. Remove the nasal cannula or oxygen mask from the patient with the clean hand, if applicable.

Provide access to the nares to perform the procedure.

5. Suction the patient:

- a. Ensure the suction control port is open.
- b. With the patient inhaling, gently and quickly insert the catheter into a naris, slanting it downward and inserting it to the appropriate depth (15 to 20 cm for nasotracheal; 15 to 18 cm for nasopharyngeal). If resistance is encountered, pull the catheter back 1 cm.

STEP 5B (Copyright Mosby's Clinical Skills: Essentials Collection.)

- c. Withdraw the catheter slowly while rotating the catheter and moving the thumb on and off the suction control port to promote intermittent suctioning. If the patient experiences gagging or nausea, pull the catheter out.
- d. The maximum time for each suctioning pass is 10 to 15 seconds.

Using a downward slanted entry ensures avoidance of and possible injury to the scroll-shaped bones (i.e., turbinates) in the nose. Resistance indicates that the catheter is at the bottom of the trachea, where the bronchi divide. Gagging or nausea indicates placement is in the esophagus. Rotating the catheter allows all areas to be suctioned and reduces the risk for trauma. Intermittent suctioning reduces the risk for trauma to tissues. Restricting the time allotted for each suctioning procedure ensures adequate oxygen levels are maintained for the patient.

6. Using your clean hand, replace the nasal cannula or oxygen mask if it was removed in procedure step 4.
Replacing the oxygen source allows oxygen levels to return to normal, promotes comfort, and increases respiratory functioning.
7. Follow procedure step 8d in the Tracheostomy Suctioning section to clear the suction catheter if needed.
8. Repeat procedure steps 4 through 7 as needed and tolerated.
9. Assess the patient's cardiac and respiratory status after the procedure.

Noting the patient's cardiac and respiratory status allows the nurse to evaluate the effectiveness of the procedure.

Follow postprocedure steps I through VI.

Oral or Oropharyngeal Suctioning

Follow preprocedure steps I through VIII.

1. Put on specific PPE (e.g., face mask or shield, clean gloves).
Assess the oral cavity.
Using gloves and masks prevents and controls the spread of microorganisms among patients and providers and protects providers from infection. Assessing the oral cavity prevents further damage to areas that are not intact.
2. Place the BVM device at the head of the bed, and ensure it is operational and has 100% oxygen airflow.
Proper placement of the BVM device ensures quick access during the procedure.
3. Set the pressure of the suction device to 120 mm Hg continuous, and place the end of the tubing close to the working field.
This is the optimal pressure setting for the procedure. Correct placement of the tubing facilitates timely performance of the procedure.
4. Prepare and test the following items:
 - a. Open the suction catheter kit or disposable suction catheter packaging. A Yankauer catheter may be attached in the room.
 - b. Obtain the sterile solution container, and place it on the clean work field. Do *not* touch the inside of the container.
 - c. Before gloving, pour 100 mL sterile NSS into the sterile solution container.
Proper preparation of supplies reduces the number of microorganisms, provides organization to facilitate performance of the procedure, and reduces the risk for microorganisms entering the respiratory system. The sterile NSS provides a mechanism to clear the tubing of excessive secretions.
5. Prepare the remainder of the items.
 - a. Connect a catheter to the tubing (Yankauer catheter is preferred).
 - b. Test the functioning of the suction for the Yankauer catheter by dipping the catheter in NSS; the solution

collects in the suction canister.

- c. Alternatively, test the functioning of the disposable suction catheter by using your thumb to occlude the suction control port on the catheter and then dipping the catheter tip into the center of the NSS, avoiding the edges of the container; the solution collects in the suction canister.

The Yankauer catheter is larger, is safe for patient use, and has less risk for inducing gagging than the disposable suction catheter. Dipping the catheter tip into the center of the solution prevents microorganisms from being transferred from the edges of the container into the patient's respiratory system. Testing ensures proper functioning of the equipment and prevents adverse events. Using the NSS decreases the risk for trauma to the oral mucosa.

6. Place the patient in a semi-Fowler position. Hyperextend the patient's neck if able and tolerated.

Use the optimal positioning for the procedure; it reduces strain on the caregiver, promotes comfort, prevents aspiration, and reduces gagging.

7. If used by the patient, remove the oxygen mask; a nasal cannula may remain in place.

Remove the oxygen mask in use to provide access to the oropharyngeal area for performing the procedure. A nasal cannula may remain in place to allow oxygen levels to remain normal, promote patient comfort, and increase respiratory functioning.

8. Using a disposable suction catheter or Yankauer catheter to suction the patient:

STEP 8 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Place the catheter in the patient's mouth.
- b. Slide the catheter down the inner surface of the cheek toward the back of the throat; do *not* apply suction until the catheter reaches the back of the throat. If the patient has gagging or nausea, pull the catheter out without suction. If able, the patient may assist with suctioning.

- c. Apply continuous suction by keeping your thumb on the suction control port if using a disposable suction catheter.
- d. Encourage the patient to cough, deep breathe, and expectorate.
- e. Or if using a Yankauer catheter, suction only the oral area and use continuous suction.

Sliding the catheter down the side of the cheek without suction prevents trauma to the oral mucosa, allows suctioning of secretions deeper in the pharyngeal area, and prevents gagging.

9. Replace the oxygen mask if it was removed in procedure step 7.
Replacing the oxygen source allows oxygen levels to return to normal, promotes comfort, and increases respiratory functioning.

10. Repeat procedure steps 7 through 9 as needed and tolerated.

11. Clean the equipment.

- a. If using a disposable suction catheter, use a new catheter for each procedure.
- b. If using a Yankauer catheter, rinse it thoroughly with NSS through the suction equipment. Suction air through the catheter to dry the inside, and clean the outside with alcohol wipes or a hydrogen peroxide (H₂O₂) solution.

Proper cleaning is used to reduce the number of microorganisms on the equipment and prevent the spread of microorganisms to the respiratory tract.

12. Assess the patient's cardiac and respiratory status after the procedure.

Observing the patient's cardiac and respiratory status allows the nurse to evaluate the effectiveness of the procedure.

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach of the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Step 10 photo under "Tracheostomy Suctioning" is from Sorrentino, S. A., & Remmert, L. (2017). *Mosby's textbook for nursing assistants* (9th ed.). St. Louis, Elsevier.

SKILL 38.2 Tracheostomy Care

Purpose

- To prevent skin breakdown at the tracheostomy site
- To prevent infection
- To maintain a patent airway

Resources

- Tracheostomy care kit
- Three sterile solution containers
- Sterile brush
- Sterile field
- Sterile gloves
- Clean gloves
- Velcro tracheostomy tube holder or tracheostomy ties
- Foam tracheostomy dressing or sterile 2 × 2 gauze pad
- Sterile cotton swabs
- Bifurcated 2 × 2 sterile gauze pad tracheostomy dressing
- Sterile normal saline solution (NSS)
- Sterile cotton swabs
- Bag-valve-mask (BVM) device
- Suction canister
- Suction tubing
- Wall suction or portable suction unit
- Oxygenation source with 100% oxygen availability
- Two extra inner cannulas (one the same size as worn by the patient and one a size smaller)

- Two extra outer cannulas (one the same size as worn by the patient and one a size smaller)
- Scissors
- Stethoscope
- Face mask or shield
- Personal protective equipment (PPE) as needed

Interprofessional Collaboration and Delegation

- Care of an established tracheostomy may be delegated to UAP after assessment by a registered nurse according to facility policy and procedures and after appropriate training.
- Care of a new tracheostomy may not be delegated to UAP.
- UAP should report the following to the nurse:
 - Changes in vital signs, respiratory status, or levels of consciousness
 - Problems or tube positioning difficulties
 - Pain or discomfort noted by the patient
 - Skin breakdown or open areas noted at the site of the tracheostomy
 - Excessive secretions
 - Difficulties in performing the procedure or other concerns verbalized by the patient
- UAP should be instructed in the following:
 - Emergency procedures
 - Appropriate equipment usage
 - Appropriate documentation
- The respiratory therapist may wish to care for or assist with care of a new tracheostomy, and the nurse should coordinate these procedures appropriately.

- The PCP determines the need for a long-term tracheostomy.

Evidence-Based Practice

- Tracheostomy twill ties cut into a patient's skin, causing trauma and providing a site for infection. A Velcro tracheostomy tube holder is recommended because it is easier to use by the patient and provider; it provides soft, cushioned support that prevents injury; and it is preferred by patients. Only a commercially prepared bifurcated tracheostomy dressing should be used, to prevent foreign objects from entering the airway.
- If possible, a dressing should be avoided altogether. If it is not possible due to secretions, the current recommendation is to use a 2 × 2 gauze dressing, rather than a 4 × 4 gauze dressing, for minimal to moderate secretions. Do not cut 4 × 4 gauze pad, because the frayed edges may increase the risk for infection ([AACN, 2017](#)). The larger dressing has a higher rate of inadvertent tracheostomy dislodgment while attempting to fit the dressing under the face plate. For excessive secretions, a special foam dressing is recommended to prevent the most adverse events ([Dennis-Rouse & Davidson, 2008](#)).
- An endotracheal tube may be replaced with a tracheostomy tube when the health professionals determine that long-term airway management is required. [Sofi and Wani \(2010\)](#) studied the effect on pulmonary mechanics with tracheostomies. The researchers determined that tracheostomy tubes

were frequently placed when failure of weaning a patient from mechanical ventilation occurred. They determined that the work of breathing was less with the tracheostomy tube than with the endotracheal tube. Some patients therefore benefit from the placement of a tracheostomy tube. [Cheung and Napolitano \(2014\)](#) noted that use of a tracheostomy is a feasible alternative to lengthy endotracheal intubation.

Special Circumstances

1. **Assess:** Is appropriate equipment within reach to ensure emergency preparedness?

Intervention: The following items are always kept at the bedside of a tracheostomy patient:

- BVM device
- Endotracheal and oropharyngeal suction equipment
- Waterproof adhesive tape
- An extra tracheostomy care kit
- Two extra inner cannulas (one the same size as worn by the patient and one a size smaller)
- Two extra outer cannulas (one the same size as worn by the patient and one a size smaller) with obturators
- Scissors
- Extra Velcro tracheostomy tube holder
- Oxygenation equipment

2. **Assess:** Has the tracheostomy been dislodged?

Intervention: Replace the tracheostomy from the emergency supplies at the bedside:

- Place the obturator in the outer cannula.
- Insert the outer cannula into the stoma.
- Remove the obturator.
- Secure with a tracheostomy tube holder.
- Assess the tracheostomy for placement and the patient for respiratory status.
- Insert the inner cannula.

- Notify the primary care provider (PCP).
3. **Assess:** Is subcutaneous emphysema observed around the stoma?
- Intervention:** Assess placement of the tracheostomy and the patient's respiratory status. Notify the PCP.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct PPE is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.
- VI. Provide for patient privacy.
It is important to maintain patient dignity.
- VII. Identify the patient, using two identifiers.
Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.
- VIII. Explain the procedure to the patient.
The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Tracheostomy Cleaning and Changing the Inner Cannula

Follow preprocedure steps I through VIII.

1. Follow procedure steps 1 through 4 in the Tracheostomy Suctioning section of Skill 38.1.
2. Remove the tracheostomy dressing and discard according to facility policy and procedures.
Proper disposal of waste reduces the spread of microorganisms.
3. Assess the tracheostomy site.
Obtaining an assessment before performing a procedure provides a baseline measurement for subsequent comparisons and determines the need for further intervention.
4. Remove and dispose of gloves, perform hand hygiene.
Handwashing reduces the spread of microorganisms.
5. Prepare items for the procedure:
 - a. Open the sterile tracheostomy kit.
 - b. Remove the sterile solution containers (some contain dividers), and place them on the clean work field.
 - c. Before sterile gloving, fill each sterile solution container half full with sterile NSS. To pour liquids into a container within the sterile field, hold the lid of the container in the nondominant hand with the inside facing up.
 - d. Apply clean gloves.
Follow proper procedure to reduce the number of microorganisms and reduce the risk for infection. Preparing items in advance provides organization to facilitate the performance of the procedure.
6. Remove the inner cannula, if needed.

STEP 6 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Stabilize the face plate with one hand.
- b. With the nondominant or clean hand, twist the inner cannula to unlock it.
- c. Pull the inner cannula up and out.
- d. If the inner cannula is disposable, replace it with a new cannula (see procedure step 8). If it is not disposable or is to be reused, place the inner cannula in sterile NSS.
- e. Remove clean gloves and apply sterile gloves (see the Sterile Gloving section in [Chapter 26](#), Skill 26.2.)

Follow proper procedure to reduce the number of microorganisms and reduce the risk for infection. Preparing items in advance provides organization to facilitate the performance of the procedure.

7. If using a nondisposable inner cannula, clean it:
 - a. Use your clean hand to retrieve the inner cannula from the NSS container; hold the cannula by its edges.
 - b. Use your dominant or sterile hand to pick up the sterile brush.
 - c. Working above the NSS container, clean the inner cannula with the brush.
 - d. Do *not* allow your clean and sterile hands to touch each other.
 - e. Rinse the inner cannula in the NSS solution container.
 - f. Remove excess NSS from the inner cannula by tapping it on the inside of the NSS container.
 - g. Repeat procedure steps c through f as needed.
 - h. Allow the inner cannula to air-dry.

Using a new or cleansed inner cannula prevents microorganisms from entering the respiratory system and prevents infection. Using the appropriately designated hand and not allowing the two hands to touch maintains sterile procedure, reduces the number of microorganisms, and reduces the risk for infection. Air-drying prevents unintentional contamination.

Not all tracheostomies have inner cannulas. Stabilize the face plate to reduce the risk for inadvertent dislodgment. The NSS loosens secretions.

8. Insert a new or cleansed inner cannula:
 - a. Use your clean hand to position the inner cannula over the tracheostomy, with the cannula pointing down and inward.
 - b. Twist the inner cannula to lock it into place.

Using the appropriately designated hand reduces the spread of microorganisms and prevents infection. Proper positioning of the cannula prevents microorganisms from entering the respiratory system, where they may cause infection. Locking the cannula secures it in place.

9. Clean the tracheostomy site, including the face plate, outer cannula, and surrounding areas, one to three times per day:

STEP 9 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Use your sterile hand to cleanse the site with sterile cotton swabs; use your clean hand to manipulate the tracheostomy.
- b. Dip a sterile cotton swab into the center of the NSS solution.
- c. Gently cleanse the outer area of the tracheostomy, moving from the stoma outward.
- d. Pat the outer area of the tracheostomy dry with sterile gauze.
- e. Repeat procedure steps b and c as needed.

Using the appropriately designated hand maintains sterile procedure and reduces the number of microorganisms. Avoiding the more contaminated edges of the NSS solution container reduces the risk for transferring microorganisms to the patient's respiratory system, reducing the risk for infection. Cleaning the skin around the tracheostomy prevents skin breakdown and unintentional contamination. Cleaning from the least-contaminated to the most-contaminated areas prevents infection.

10. Change the Velcro tracheostomy tube holder:

STEP 10 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Secure the new holder; do *not* remove the old holder.
 - b. Place the holder around the back of the patient's neck.
 - c. Insert the ends of the holder in the face plate, wrap the ends around the back of the neck, and secure them to the Velcro.
 - d. Secure the new holder *before* removing the old holder.
Precautions are taken to maintain patient safety, prevent dislodging the tracheostomy, and prevent necrosis.
11. If a dressing is required due to secretions, ensure the tube holder is secure:
- a. Use a commercially prepared 2 × 2 bifurcated gauze pad for minimal to moderate secretions.
 - b. Use a commercially prepared foam tracheostomy dressing for excessive secretions. Carefully lift one side of the face plate slightly, and insert the dressing under it; repeat on the other side.
Smaller dressings prevent accidental dislodgement. Foam dressings absorb excessive secretions and keep moisture away from the skin, preventing skin breakdown.
12. Assess the patient's cardiac and respiratory status following the procedure.
Observing the patient's cardiac and respiratory status allows the nurse to evaluate the effectiveness of the procedure.

Follow postprocedure steps I through VI.

Postprocedure

- I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach of the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

SKILL 38.3 Care of Chest Tubes and Disposable Drainage Systems

Purpose

- To promote optimal respiratory functioning
- To monitor drainage to ensure ultimate lung expansion
- To monitor and prevent complications

Resources

- Emergency equipment at the bedside (see the Special Circumstances section)
- Clean gloves
- Stethoscope
- Hemostats
- Pulse oximeter
- Pen

Interprofessional Collaboration and Delegation

- Care of a chest tube may not be delegated to UAP.
- UAP should report the following to the nurse:
 - Changes in vital signs, respiratory status, or levels of consciousness
 - Pain or discomfort expressed by the patient
 - Skin breakdown or open areas observed at the site of the chest tube
 - Other concerns verbalized by the patient
- UAP should be instructed in the following:
 - Appropriate emergency procedures
 - Appropriate equipment use with ambulation or positioning

- Appropriate documentation
- A respiratory therapist may care for or assist with care of a patient with a chest tube according to facility policy and procedures, and the nurse coordinates procedures appropriately.
- The surgeon assesses chest tube drainage and the insertion site, and the nurse coordinates and documents monitoring and care appropriately.

Evidence-Based Practice

- Many nurses were taught to “strip” or “milk” the tubing of a chest tube when there was a lack of drainage or an occlusion. However, this practice is outdated and can be dangerous. Evidence shows that it can result in negative pressure in the cavity and result in damage to the lung, (Durai, Hoque, & Davies, 2010)

Special Circumstances

1. **Assess:** Is appropriate equipment within reach to ensure emergency preparedness?
Intervention: The following items are always kept at the bedside of a chest tube patient:
 - Two hemostats with tips covered in soft material (e.g., gauze dressings)
 - Waterproof adhesive tape
 - Occlusive dressing
 - BVM device
 - Oxygenation equipment
2. **Assess:** Has the chest tube become disconnected from the drainage collection device?
Intervention: Immediately clamp the tube at two places with the covered hemostats.
3. **Assess:** Has the chest tube pulled out from the pleural space?
Intervention: Immediately cover the insertion site with occlusive dressing. Notify the primary care provider (PCP) immediately.

4. **Assess:** Does the patient require another procedure (e.g., transport) that requires the drainage collection device be lifted above the level of the chest?

Intervention: Temporarily clamp the tubing at two places with hemostats; release the clamps as soon as possible after the drainage collection device has been restored to the correct position. Tubing is clamped only when the collection device is lifted above the level of the chest, the drainage collection device needs to be changed, or the device breaks.

5. **Assess:** Does the inspiration/expiration water chamber level rise and fall?

Intervention: Ensure proper functioning of the drainage system and collection device.

- For a patient who is not being ventilated mechanically, inspiration causes the level to rise and expiration causes it to fall.
- For a patient being mechanically ventilated, the opposite occurs. Inspiration causes the level to fall, and expiration causes it to rise.

6. **Assess:** Has the drainage suddenly ceased?

Intervention: Notify the PCP. Do *not* milk the tubing; trauma or pleural damage may result.

7. **Assess:** Has a large amount of drainage suddenly appeared?

Intervention: The drainage usually results from positional changes or coughing; assess the patient for a recent position change or coughing. If none is noted, follow the appropriate protocol.

8. **Assess:** Is the tubing free of dependent loops and kinks?

Intervention: While ensuring that the insertion point of the chest tube into the patient is not moved, straighten the loops or kinks so that drainage is unobstructed.

9. **Assess:** Is the drainage system set to the ordered amount of suction?

Intervention: Adjust the level of suction as needed to maintain the ordered suction pressure; there should be gentle bubbling in the suction chamber.

10. **Assess:** Is the water level in the water-seal chamber at the marked level?

Intervention: Fill the water-seal chamber to the mark as needed.

11. **Assess:** Is there bubbling in the water-seal chamber?

Intervention: Bubbling indicates an air leak, which may be a sign of a new or persistent pneumothorax. Notify the PCP immediately.

Preprocedure

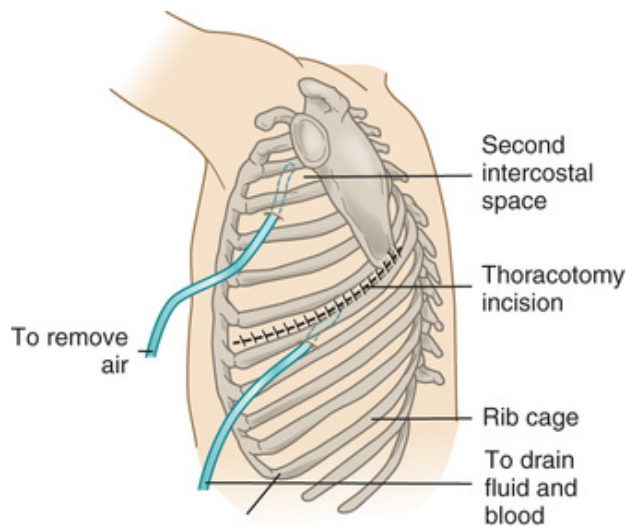

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct PPE is required whenever contact with body fluids is possible, to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.
- VI. Provide for patient privacy.
It is important to maintain patient dignity.
- VII. Identify the patient, using two identifiers.
Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.
- VIII. Explain the procedure to the patient.
The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Chest Tube Monitoring and Care

Follow preprocedure steps I through VIII.

1. Adjust patient and bed position to accommodate the patient's diagnosis and the placement of the chest tube:

STEP 1 (From Lewis, et al, 2017.)

- a. Use the high-Fowler position for a hemothorax.
 - b. Use the semi-Fowler position for a pneumothorax.
- Use the position that promotes optimal drainage of fluid or air.*
2. Ensure the tubes are secure and patent:
 - a. Check the water-seal vent and the suction control vent (if suction is used).
 - b. Verify that the tubing is resting as close to horizontal as possible on the bed (across a chair if needed) and is directly vertical to the drainage collection device. If coils are made in the tube (not ideal), drain the tube every 15 minutes by moving it. Do *not* lift it above the level of the chest.

The tubes must be patent for optimal functioning and lung expansion. Coiling may cause resistance and inability to drain.
 3. Ensure the drainage collection device placement is upright and *below* the level of the chest tube. *Never* raise the drainage collection device above chest level unless it has been appropriately clamped and then only for as short a period as possible.
- Raising the drainage collection device above the level of the chest causes fluid to reenter the lungs.*
4. Check the water-seal chamber; the water level should always rise and fall with the patient's breathing.
 - a. For a water-seal system, bubbling is normal for a newly placed chest tube.
 - b. For a suction control chamber, bubbles are normal. Ensure the water is at the prescribed level.

- c. For a waterless system, ensure that the ball in the suction control chamber is at the prescribed level.

Following guidelines ensures the system is functioning properly to promote optimal respiratory support. Suction pressure is controlled by the suction control chamber, not by its connection to wall suction.

5. Drainage assessment:

- a. Assess the type, amount, color, and consistency of the drainage. Notify the PCP of changes.
- b. Mark the quantity, time the assessment was made, and your initials on the drainage collection device at least every 4 hours (more frequently per PCP or facility policy and procedures).
- c. Document assessment findings.

Increased drainage or a change in the type of drainage can indicate a physiologic change that requires immediate intervention.

6. Dressing assessment:

STEP 6 (Copyright 2018 Centurion Medical Products Corporation.)

- a. Verify that the dressing is secure, and reinforce it as needed.
 - b. Drainage on the dressing should be minimal (or none).
 - c. Document dressing assessment findings.
 - d. Reinforce the dressing, but do not change it.
- The dressing must remain secured with occlusive dressing to prevent air from entering the lungs and decreasing respiratory status.*

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach of the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Step 1 photo is from Lewis, S. L., Bucher, L., Heitkemper, M. M., et al. (2017). *Medical-surgical nursing: Assessment and management of clinical problems* (10th ed.). St. Louis: Elsevier.

Summary of Learning Outcomes

LO 38.1 *Describe the basic anatomy and physiology of the cardiovascular and respiratory systems in relation to ventilation and perfusion:* The heart is a hollow, cone-shaped organ composed of four chambers divided into right and left sides. The chambers on the top are atria; the lower chambers are ventricles. The respiratory system is divided into the upper (nose, nasal cavity, sinuses, and pharynx) and lower (larynx, trachea, right and left bronchi, bronchioles, alveoli) respiratory tract. The cardiac and pulmonary systems work together to deliver oxygen to tissues. An intact respiratory system is necessary to inspire oxygen and deliver it to the circulatory system. A healthy heart pumps oxygenated blood to tissues through the vascular system.

LO 38.2 *Summarize alterations in structure and function of the cardiovascular and respiratory systems:* Alterations in the cardiovascular and respiratory system may decrease the ability to deliver oxygen to alveoli, absorb oxygen, expel carbon dioxide, and deliver oxygen to tissue throughout the body.

LO 38.3 *Demonstrate assessment of the cardiovascular and respiratory systems:* Cardiovascular and respiratory assessments begin with an assessment of subjective data. Objective data are obtained through vital signs and through inspection, palpation, and auscultation of the heart, lungs, and peripheral vascular system, noting any alterations. Diagnostic tests, including blood work, pulmonary function tests, x-rays, echocardiogram, electrocardiogram, and cardiac catheterization, may be ordered.

LO 38.4 *Choose nursing diagnoses for patients with decreased oxygenation:* Nursing diagnoses for the patient with decreased oxygenation are based on the patient's specific problem. Some diagnoses include *Impaired Gas Exchange, Impaired Breathing, and Impaired Cardiac Output.*

LO 38.5 *Identify goals for patients with complications from decreased oxygenation:* Nursing care goals are specific to each patient and reflect the desired measurable outcome for each nursing diagnosis. Goals for patients with decreased oxygenation are designed to meet basic oxygen needs.

LO 38.6 *Evaluate interventions to enhance patient oxygenation, promote safety, and reverse the negative effects of decreased oxygenation:* Interventions for patients with decreased oxygenation include oxygen therapy; artificial airways, including pharyngeal airways, endotracheal airways, and tracheostomies; postural drainage; and pharmacologic therapy. Evaluation of goal attainment and updating the plan of care is ongoing.

Review Questions

1. The nurse assesses a patient with chronic obstructive pulmonary disease (COPD). Which finding does the nurse anticipate when inspecting the chest?
 - a. A ratio of 1 : 2 when comparing the side and front views of the chest
 - b. A barrel chest
 - c. A concave shape to the sternum
 - d. A severe lateral curvature of the spine
2. Which is a goal for a patient with the nursing diagnosis of *Impaired Airway Clearance*?
 - a. Patient's respiratory secretions will become thicker so they are not moved when coughing.
 - b. Patient's respiratory secretions will have a thinner consistency after being given a mucolytic agent.
 - c. Patient will have improved range of motion while in bed.
 - d. Patient's respiratory rate will increase to 28 breaths/min during hospitalization.
3. Which position is the priority for a patient experiencing acute shortness of breath?
 - a. Supine position
 - b. Reverse Trendelenburg position
 - c. Face-down position
 - d. Upright position
4. Which oxygen delivery setting places a patient in danger of receiving inadequate oxygen?
 - a. Nasal cannula at a flow rate of 2 L/min

- b. Nasal cannula at a rate of 5 L/min
 - c. Simple mask at a flow rate of 5 L/min
 - d. Nonrebreather mask at a flow rate of 5 L/min
5. Which action does a nurse anticipate when suctioning a patient with excessive secretions?
- a. Decrease the patient's oxygen flow rate before beginning the deep suctioning.
 - b. Avoid lubricating the catheter tip to prevent getting the substance in the lung tissues.
 - c. Limit the time that the catheter is suctioning to prevent excessive loss of oxygen during the process.
 - d. Flush the artificial airway with 3 mL of tap water to loosen secretions before suctioning.
6. Which of the chambers of the heart becomes enlarged when mitral valve stenosis occurs?
- a. Right atrium
 - b. Right ventricle
 - c. Left atrium
 - d. Left ventricle
7. Which situation contributes to cyanosis in the pulmonary patient?
- a. Increased PaCO₂ levels
 - b. Hemoglobin that is not saturated with oxygen
 - c. Elevated white blood cell count
 - d. Decreased PaCO₂ levels
8. A patient with chronic pneumonia may be evaluated by a speech therapist for which cause?

- a. Persistent aspiration of liquids
 - b. Hypoventilation due to smoking
 - c. Hyperventilation due to anxiety
 - d. Decreased respiratory effort due to scoliosis
9. A patient with chronic obstructive pulmonary disease (COPD) uses which drive to breathe?
- a. Increased PaCO₂
 - b. Decreased hemoglobin
 - c. Decreased PaO₂ levels
 - d. Increased PaO₂ levels
10. Which questions are included in a focused history for a cardiac patient? (*Select all that apply.*)
- a. Are you having pain?
 - b. Where is the pain located?
 - c. Do you attend religious services regularly?
 - d. Do you have increased fatigue?
 - e. Do you have any episodes of dizziness?

CHAPTER 39

Fluid, Electrolyte, and Acid-Base Balance

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 39.1 Discuss the normal structure and function of fluids, electrolytes, acids, and bases in the body.
- LO 39.2 Differentiate among common fluid, electrolyte, and acid-base imbalances and their underlying causes.
- LO 39.3 Outline assessment priorities for patients with fluid, electrolyte, and acid-base imbalances.
- LO 39.4 Identify the most common nursing diagnoses related to fluid, electrolyte, and acid-base imbalances.
- LO 39.5 Integrate nursing goals and outcomes into the plan of care for patients with fluid, electrolyte, and acid-base imbalances.
- LO 39.6 Carry out and evaluate nursing interventions to maintain normal fluid, electrolyte, and acid-base balance or to correct imbalances.

Case Study

Rashad Abdul (R. A.) is a 76-year-old male who has been admitted to the hospital with a diagnosis of heart failure. He complains of being tired all the time and barely having enough energy to sit up sometimes. "I think I've put on some weight. My waistband and shoes seem to be tighter and more uncomfortable to wear." He has a history of coronary artery disease. He has smoked one pack of cigarettes per day for 56 years. He has no known drug allergies and has full code status.

R. A.'s vital signs on admission are T 36.5° C (97.7° F), P 118 regular and bounding, R 32 and labored, BP 160/100, with a pulse oximetry reading of 90% on room air. He denies pain and is alert and oriented to person, place, time, and event. He can move all extremities easily but requires assistance with activities of daily living such as bathing and dressing. He becomes short of breath on exertion. He has fine crackles throughout all lung fields and has a moist, nonproductive cough. Bowel sounds are active in all four quadrants. The last bowel movement, a formed brown stool, was yesterday. His skin is warm, dry, and slightly pale. He has 3+ pitting edema in the lower extremities. Bilateral dorsalis pedis and posterior tibial pulses are diminished.

Admission laboratory test results are as follows:

- Electrolytes: Sodium 142 mEq/L, potassium 3.3 mEq/L, chloride 100 mEq/L, bicarbonate 29 mEq/L, blood urea nitrogen 18 mg/dL, creatinine 0.8 mg/dL, glucose 140 mg/dL
- Complete blood count: Hemoglobin 15 g/dL, hematocrit 45%, white blood cells 8000 mm³, platelets 300,000 mm³
- Arterial blood gases: pH 7.34, PCO₂ 56 mm Hg, bicarbonate 32 mEq/L, PO₂ 80 mm Hg, O₂ saturation 90%

Medications are as follows:

- Lisinopril 50 mg PO q a.m.

- Digoxin 0.125 mg PO q a.m.
- Furosemide 80 mg IV now, then Lasix 40 mg PO q a.m. beginning tomorrow

Treatment orders are as follows:

- O₂ 2 L/min per nasal cannula
- Vital signs q 4 h with pulse oximetry
- Daily weight
- Strict intake and output
- Diet: No added salt
- Activity: Bed rest
- Saline lock

Refer back to this case study to answer the critical-thinking exercises throughout the chapter.

The human body is composed primarily of water and chemicals that keep it functioning at optimal levels. Through a series of complex processes, the body is able to maintain normal fluid and chemical balances under various circumstances. However, trauma, disease, and aging can alter the ability to maintain homeostasis and impair normal functioning. The nurse must have an understanding of the homeostatic processes to identify patients at risk for imbalances, recognize when an imbalance has occurred, and intervene appropriately to reestablish equilibrium.

LO 39.1 Normal Structure and Function of Fluids, Electrolytes, Acids, and Bases

Balanced levels of fluids and various chemicals in the body are essential to maintain health and high-level functioning. Fluctuations in fluid intake and output and alterations brought about by illness can destabilize the balance between fluids and electrolytes. The equilibrium between the acidity and alkalinity of body fluids is acid-base balance, which is regulated by the pulmonary and renal compensatory systems and by chemical (buffering) systems.

Composition of Body Fluids

The human body requires sufficient water to survive. Water regulates body temperature, lubricates joints, serves as a shock absorber for internal organs, and transports nutrients and waste products throughout the body. Water is the medium for metabolic reactions within cells.

Total body water (TBW) is the percentage of body weight that consists of water. Almost 60% of a healthy adult's weight is water. However, TBW varies according to age and gender. For example, an infant has a much higher percentage (75%) of TBW than an elderly or obese person (45%). Men tend to have a higher percentage than women (~60% and 50%, respectively).

Body fluid is intracellular or extracellular. Most body fluid is **intracellular fluid** (within the cell). **Extracellular fluid** (fluid outside the cell) is interstitial, intravascular, or **transcellular**, which includes cerebrospinal, synovial, peritoneal, pleural, and pericardial fluids. Vitreous and aqueous fluid in the eye and bile and other digestive fluids are included in this category. **Interstitial fluid** is fluid between the cells of an organ or tissue; it accounts for approximately 25% of total body fluid. **Intravascular fluid**, which is blood plasma, accounts for approximately 8% of body fluid.

Body fluids are composed of water and solutes. Water moves in and out of the cell, transporting these molecules throughout the body. **Solutes** are chemical substances that dissolve in a liquid (the **solvent**). Solutes that dissolve easily are called **crystalloids**. Substances such as proteins that do not dissolve easily are called **colloids**. Solutes consist of electrolytes and nonelectrolytes, such as oxygen, carbon dioxide, and glucose.

Electrolytes are charged atoms or molecules (ions) that conduct electrical impulses across cells. They carry a positive charge (cation) or a negative charge (anion). The number of electrolytes that carry a positive charge (cations) and the number that carry a negative charge (anions) should be equivalent. The term **milliequivalent** denotes the ability of cations to bond with anions to form molecules. Electrolytes are measured in milliequivalents per liter of water (mEq/L).

The concentrations of particular electrolytes are measurably different in intracellular fluid and extracellular fluid. The extracellular fluid has essentially the same components in the intravascular and interstitial compartments, with the exception of protein. The intravascular fluid, which is blood plasma, is unique in that it also contains a large amount of proteins, predominantly albumin.

Movement of Body Fluids

Water is always moving in and out of cells and throughout the interstitial and intravascular spaces. Movement occurs primarily by two processes: osmosis and filtration.

Osmosis

Osmosis is the movement of water across cell membranes. **Osmotic pressure** is the force created when two solutions of different concentrations are separated by a **selectively permeable membrane**. The cell membrane allows water to move across but not the solutes. Water moves by osmosis from an area of lower concentration of solutes to an area of higher concentration of solutes in an attempt to equalize the concentration across the membrane. The higher the difference in concentration of solutes, the greater is the osmotic pressure.

Two terms, *osmolality* and *osmolarity*, are often used interchangeably. **Osmolality** refers to the number of osmols (unit of osmotic pressure) per kilogram of solvent, which in this case is water. **Osmolarity** is the number of osmols per liter of solvent. In discussions of body fluids, the differences between the two values are very small. For the purposes of this chapter, osmolarity is used to denote solute concentration.

Another term used to describe osmolarity is **tonicity** of the fluid (Fig. 39.1). Tonicity refers to the level of osmotic pressure of a solution. An administered solution that has the same osmolarity as blood plasma is an **isotonic solution**. Normal saline, which is 0.9% sodium chloride, is isotonic. Fluids with a higher osmolarity than body fluids are considered hypertonic. A **hypertonic solution** pulls water from the cell to the extracellular fluid compartment, causing cellular shrinkage. Solutions with a lower osmolarity than body fluids are considered

hypotonic solutions. Excess water moves into the cells, producing cellular swelling.

FIGURE 39.1 Effect of tonicity on cells. (From Van Meter, K. C., Hubert, R. J., & VanMeter, W. G. [2010]. *Microbiology for the healthcare professional*. Philadelphia: Elsevier.)

Osmotic pressure in the intravascular space is controlled by the concentration of plasma proteins, specifically **albumin**. This is known as colloid osmotic pressure, or **oncotic pressure**. Because these plasma proteins are too large to pass through the capillary membrane, they hold the fluid in the intravascular space.

Filtration

Filtration is the process by which fluid and solutes move together from an area of higher pressure to one of lower pressure. **Hydrostatic pressure** is the force of the fluid pressing against the blood vessel; it is controlled by the force of myocardial contraction, rate of contraction, and blood flow. The force, or pressure, is different on the arterial and venous sides of the capillary bed (Fig. 39.2). Fluid balance is influenced by the opposing forces of hydrostatic and oncotic pressure. Filtration across a selectively permeable membrane occurs when the hydrostatic pressure is greater than the oncotic pressure. This allows oxygen and

nutrients to move from the arterial capillary bed into the cells. As oncotic pressure rises on the venous side, fluid and waste products are pulled back into the intravascular space.

FIGURE 39.2 Filtration pressure changes in a capillary bed.
 (From Copstead, L. E., & Banasik, J. [2013]. *Pathophysiology* (5th ed.).
 St. Louis: Elsevier.)

Regulation of Body Fluids

Maintaining adequate fluid volume requires a balance between fluid intake and output. Most of the water is brought into the body through intake of fluids or food. A small amount of water is generated through various metabolic processes, including the breakdown of carbohydrates. Fluid volume and composition are regulated by several body systems, hormones, and other homeostatic mechanisms.

Water is lost from the body primarily through the kidneys and excreted as urine. Water loss also occurs through insensible loss, which is moisture lost through respiration and perspiration; a very small amount is lost through feces (Table 39.1).

TABLE 39.1

Average Daily Fluid Intake and Output

INTAKE (mL)		OUTPUT (mL)	
Fluids	1600	Urine	1500
Food	700	Feces	200
Metabolism	200	Skin, including perspiration	500
		Lungs	300
Total intake	2500	Total output	2500

Homeostasis, the maintenance of fluid balance, is controlled by several physiologic mechanisms, including the renin-angiotensin system (Fig. 39.3), the secretion of antidiuretic hormone (Fig. 39.4), and the thirst mechanism (Fig. 39.5). The **renin-angiotensin system** regulates blood pressure and fluid balance through vasoconstriction and excretion or reabsorption of sodium. **Antidiuretic hormone (ADH)**, which is secreted by the pituitary gland, maintains serum osmolality by controlling the amount of water excreted in the urine. Homeostasis is monitored by the kidneys through changes in blood pressure.

FIGURE 39.3 The renin-angiotensin-aldosterone mechanism. (Modified from Herlihy, B. [2018]. *The human body in health and illness* [6th ed.]. St. Louis: Elsevier.)

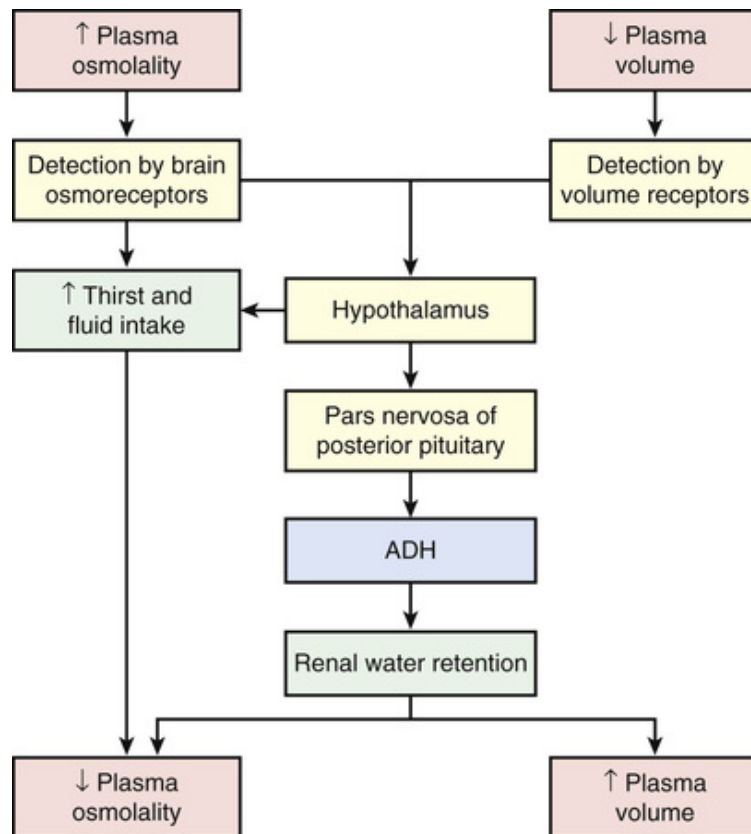

FIGURE 39.4 Action of antidiuretic hormone (ADH). (From McCance, K. L., & Huether, S. E. [2019]. *Pathophysiology* [8th ed.]. St. Louis: Elsevier.)

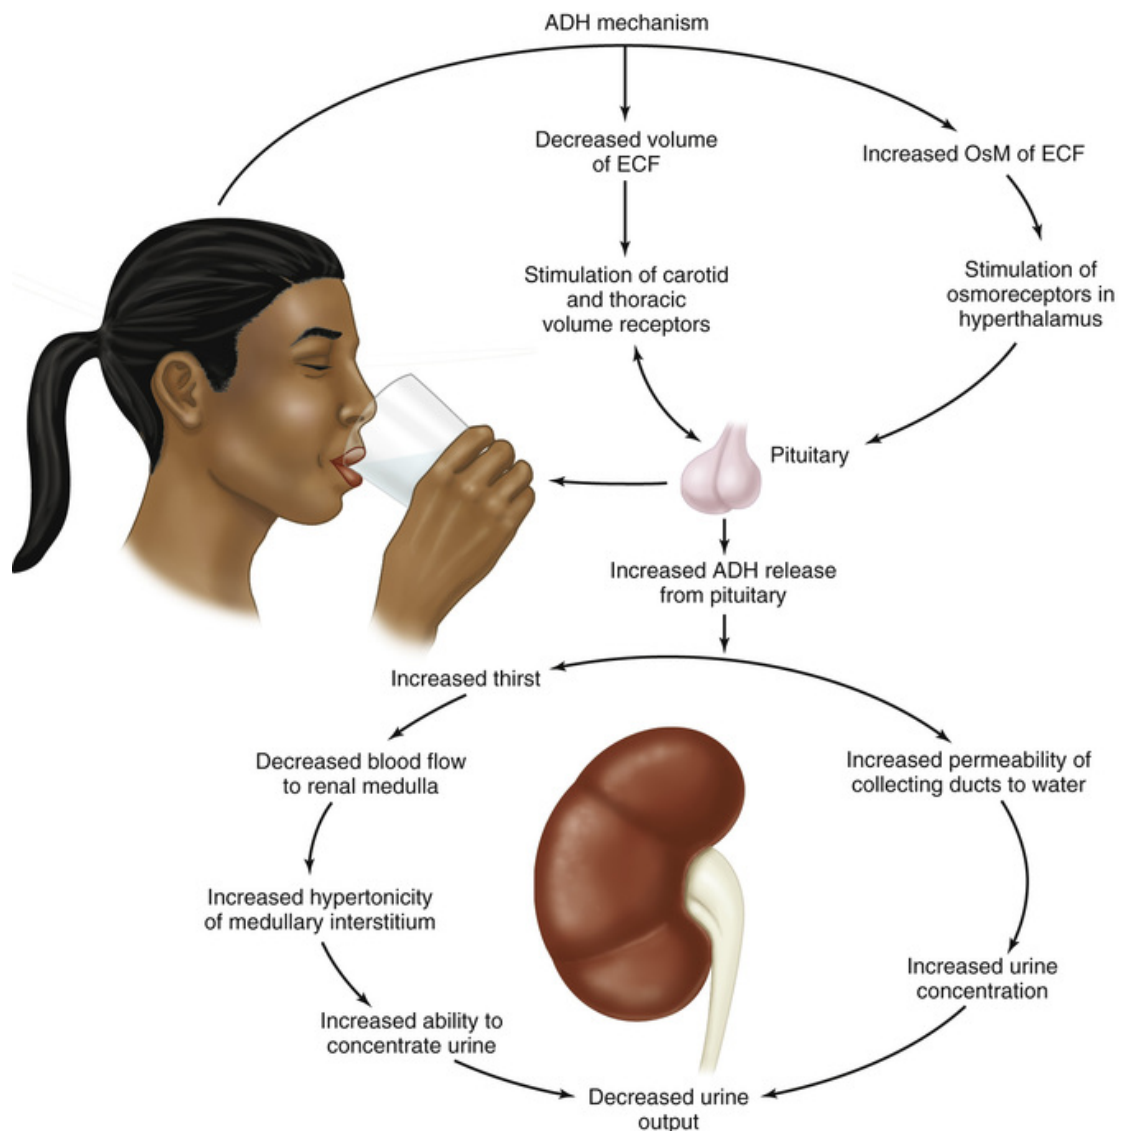

FIGURE 39.5 Dehydration, thirst, and rehydration.

A decrease in fluid volume (**hypovolemia**) and a corresponding decrease in blood pressure stimulate the release of the enzyme renin by the kidneys. Renin converts angiotensinogen into angiotensin I. Angiotensin-converting enzyme (ACE), found in the lungs and kidneys, then changes angiotensin I to angiotensin II. Angiotensin II is a hormone that causes several things to occur:

- **Vasoconstriction** (narrowing of blood vessels) throughout the body increases arterial blood pressure.
- Water from the nephron is reabsorbed back into the intravascular space due to changes in hydrostatic pressure in the nephron.

- Stimulation of the adrenal cortex releases the hormone **aldosterone**. Aldosterone acts on the distal convoluted tubule of the kidney to increase the amount of water and sodium reabsorbed back into the bloodstream.
- ADH is secreted.
- The thirst mechanism is stimulated.

Osmoreceptors, located in the hypothalamus, monitor the osmolarity of blood plasma. When osmolarity increases (becomes more concentrated, as in dehydration), the osmoreceptors stimulate the posterior pituitary to secrete ADH. ADH works on the collecting ducts of the kidneys to reabsorb more water, and less urine is produced as a result (see [Fig. 39.4](#)). As more water moves back into the bloodstream, the plasma osmolarity decreases and returns to normal, and the pituitary stops releasing ADH through a negative feedback loop.

There is an important distinction between aldosterone and ADH. In response to a decrease in circulating blood volume, aldosterone stimulates the reabsorption of water and sodium, thereby increasing volume but not affecting osmolarity. The release of ADH leads to reabsorption of water only. ADH secretion increases fluid volume and decreases plasma osmolarity.

The osmoreceptors, in response to increased osmolarity, stimulate the cerebral cortex to produce a conscious awareness of thirst. As osmolarity returns to normal levels, the thirst sensation subsides (see [Fig. 39.5](#)).

Atrial natriuretic peptide (ANP) is secreted by cells in the atrium of the heart in response to an increase in blood pressure. When released, ANP causes an increase in the glomerular filtration rate (GFR), which leads to increased excretion of water in urine. It inhibits secretion of renin by blocking the renin-angiotensin system, inhibits secretion of ADH, and inhibits reabsorption of sodium chloride and water into the bloodstream ([Reddi, 2014](#)).

Movement of Electrolytes

Electrolytes move in and out of the intracellular and extracellular spaces through three mechanisms: diffusion, filtration, and active transport.

Diffusion is the movement of solutes across a selectively permeable membrane from areas of higher concentration to areas of lower

concentration until equilibrium is reached. The rate of diffusion is influenced by the following factors:

- *Temperature*: The higher the temperature, the faster the particles diffuse.
- *Molecular weight*: Lighter weight molecules (i.e., gases and electrolytes) diffuse more quickly than heavier molecules.
- *Steepness of the concentration gradient*: The more uneven the concentrations on either side of the membrane, the faster solutes move across.
- *Membrane permeability*: There are conditions that cause the membrane to become more permeable to larger molecules, which otherwise would not be able cross.

Many small molecules, such as oxygen and carbon dioxide, can move across cell membranes by diffusion. Facilitated diffusion occurs when a solute is unable to pass through a membrane and requires a carrier. Because the solute is moving down the concentration gradient (i.e., from a higher to a lower concentration), it does not require the use of energy; this is considered a passive process. For example, glucose is unable to move into the cell without insulin as its carrier.

The filtration process described earlier for solvents also applies to the movement of solutes. When water moves as a result of increased pressure, the solutes dissolved in the water also move across the membrane.

④ The processes of osmosis and diffusion strive to maintain equilibrium of fluids and electrolytes across a membrane. However, for the body to function properly, higher concentrations of specific substances must be inside or outside the cell. **Active transport** is the transport of a solute from areas of lower to higher concentration; it is the opposite of diffusion. The process is considered active because it requires energy. For example, the exchange of sodium and potassium across the cell membrane is facilitated by the sodium-potassium pump. The animation “[Active Transport](#)” illustrates this process.

Regulation of Electrolytes

The major cations are sodium (Na^+), magnesium (Mg^+), potassium (K^+), calcium (Ca^{2+}), and hydrogen (H^+). The major anions are chloride (Cl^-), bicarbonate (HCO_3^-), and phosphate (PO_4^{3-}). Hydrogen and bicarbonate are covered more in depth in the discussion of acid-base balance.

The cellular concentration of these electrolytes is different from their concentration in the extracellular fluid. Potassium and phosphate are found primarily inside the cell, and sodium and chloride are found in highest concentrations in intravascular fluid (i.e., blood plasma). [Table 39.2](#) summarizes the normal serum values, functions, sources, and regulation of these electrolytes.

TABLE 39.2**Electrolyte Function and Homeostasis**

ELECTROLYTE	NORMAL LEVELS	FUNCTION	HOMEOSTASIS	SOURCES
Sodium (Na ⁺)	136-145 mEq/L	Principal ion responsible for resting membrane potential of cells Essential in depolarization needed for nerve and muscle function Principal cation of the ECF; accounts for 90% to 95% of osmolarity Na-K pump important mechanism for producing body heat; essential element for acid-base buffering	Moves out of cell by Na-K pump Regulated by secretion of aldosterone and ANP	Breads, cereals, chips, cheese, processed meats such as lunch meats, hot dogs, bacon, ham Commercially canned foods Table salt
Potassium (K ⁺)	3.5-5 mEq/L	Along with sodium, produces resting membrane potentials and action potentials of nerve and muscle cells Principal cation of the ICF and responsible for intracellular osmolarity Essential component of Na-K pump and involved in protein synthesis	Moves into the cell by Na-K pump Serum levels regulated by the kidneys through reabsorption or excretion	Fish, excluding shellfish; whole grains, nuts, broccoli, cabbage, carrots celery, cucumbers, potatoes with skins, spinach, tomatoes, apricots, bananas, cantaloupe, nectarines, oranges, tangerines

ELECTROLYTE	NORMAL LEVELS	FUNCTION	HOMEOSTASIS	SOURCES
Calcium (Ca^{2+})	9-10.5 mg/dL	Along with phosphate, the primary component of bones and teeth; up to 99% of calcium is found in teeth and bones Role in blood clotting, nerve impulse transmission, cardiac conduction, and muscle contraction	As serum calcium levels drop, parathyroid hormone and calcitriol pull calcium from the bone to maintain normal levels Calcitonin moves excess calcium into the bone	Cheese, ice cream, milk, yogurt, rhubarb, spinach, tofu
Magnesium (Mg^{2+})	1.3-2.1 mEq/L	Found primarily inside cells Key role in production and use of ATP, helps regulate intracellular metabolism by activation of enzymes, part of Na-K pump Required for synthesis of nucleic acids and proteins Helps maintain normal serum calcium levels	Normal levels maintained by increased reabsorption or excretion by the kidneys Additional amount is absorbed through the intestine in the presence of vitamin D and parathyroid hormone	Cashews, halibut, Swiss chard and other green leafy vegetables, tofu, wheat germ, dried fruit
Chloride (Cl^-)	98-106 mEq/L	Most abundant anion in the ECF Key role in maintaining serum osmolarity Required for formation of stomach (hydrochloric) acid Buffering role in acid-base balance	Homeostasis maintained in similar way as sodium; where sodium goes, chloride also goes	Seaweed, rye, tomatoes, lettuce, celery, and olives Table salt, salt substitutes

ELECTROLYTE	NORMAL LEVELS	FUNCTION	HOMEOSTASIS	SOURCES
Phosphate (PO_4^{3-})	3-4.5 mg/dL	Most abundant anion in the ICF Along with calcium, helps maintain bone and teeth structure Role in cellular metabolism and ATP production Essential for carbohydrate metabolism	Phosphate has inverse relationship with calcium; as serum calcium levels increase, phosphate levels fall Parathyroid hormone increases excretion by the kidneys	Milk, meat, nuts, legumes, and grains

ANP, Atrial natriuretic peptide; *ATP*, adenosine triphosphate; *ECF*, extracellular fluid; *ICF*, intracellular fluid; *Na-K pump*, Na^+/K^+ -ATPase enzyme that pumps sodium out of and potassium into cells.

Acid-Base Balance

For normal cellular functioning to occur, the pH of body fluids must remain balanced. Any disruption of normal acid-base balance can adversely affect cellular functions and metabolic processes. The pH is a measure of the level of acids and bases in a solution and is determined by the concentration of hydrogen ions in the solution. On the pH scale of 0 to 14, 7 is neutral. A pH less than 7 is acidic, and a pH greater than 7 is basic.

An **acid** is a chemical that can release hydrogen ions in solution. Sources of hydrogen include the by-products of the metabolic process, such as ketone bodies, phosphoric acid, carbonic acid, and lactic acid. There is an inverse relationship between pH and the hydrogen ion. The greater the number of hydrogen ions, the lower is the pH value. The lower the pH number, the stronger is the acid.

Bases are substances that can accept hydrogen ions. Most bases are chemicals that break down into hydroxide ions (OH^-). Hydroxide ions can combine with hydrogen ions to form water, thereby neutralizing the acidic solution. Bicarbonate is a weak base found primarily in the plasma; it plays a crucial role in acid-base balance.

Optimal metabolic function can occur only in a constant balance between acids and bases. Blood and body tissues require a pH between 7.35 and 7.45, which is slightly alkaline. There is a complex system in place to maintain normal acid-base balance consisting of three components: chemical buffering systems, which are the primary

mechanisms for maintaining acid-base balance; respiratory control of carbon dioxide; and renal control of bicarbonate.

Buffering Systems

A buffering system consists of a weak acid and weak base. It is designed to adjust to small changes in pH. The carbonic acid–bicarbonate system is the primary buffering system in extracellular fluid and is based on the following chemical reaction:

This is a reversible chemical reaction. When the reaction moves to the right, carbonic acid breaks down into bicarbonate and hydrogen ions, lowering the pH. When the reaction moves to the left, bicarbonate binds with hydrogen ions and ultimately forms carbon dioxide and water. This buffering system works well because the lungs control the level of hydrogen ions by removing carbon dioxide while the kidneys excrete or reabsorb bicarbonate ions. The normal ratio of bicarbonate to carbonic acid is 20 : 1 (Fig. 39.6). As long as this ratio remains stable, the pH is within a normal range. Any change to this ratio leads to increases or decreases in plasma pH.

FIGURE 39.6 The bicarbonate–carbonic acid ratio. (From Ignatavicius, D. D., & Workman, M. L. [2013]. *Medical-surgical nursing: Patient-centered collaborative care* [7th ed.]. St. Louis: Elsevier.)

The phosphate buffering system is the primary buffering system in the cell. This buffering system is used to a greater degree in the renal tubules than in the cells. It converts alkaline sodium phosphate (NaHPO_4) to the acid solution phosphate ($\text{Na}_2\text{H}_2\text{PO}_4$) with the addition of a hydrogen ion.

Potassium and hydrogen ions can be interchanged inside the cell as needed. When there are excess hydrogen ions in the extravascular space, potassium moves out of the cell as the hydrogen ions move into the cell. As a result, acid-base imbalances can affect serum potassium levels and potassium imbalances can influence acid-base balance.

Several plasma proteins and the hemoglobin in red blood cells have the ability to bind or release hydrogen ions. This helps maintain balance in the intracellular fluid and blood plasma.

Respiratory Regulation

The lungs control the amount of carbonic acid available by retaining or exhaling carbon dioxide. When the pH falls below normal, the lungs exhale more carbon dioxide by increasing the rate and depth of respirations. When the pH is too alkaline (>7.45), respirations slow and become shallower in an effort to conserve carbon dioxide. This compensation occurs very quickly, allowing the return to normal levels.

Renal Regulation

The kidneys neutralize more acid or base than the chemical buffers or the lungs. They do so by excreting or retaining hydrogen ions and excreting or forming bicarbonate ions. It is the only system that removes excess hydrogen ions from the body. When the body is in an acidotic state (<7.35), the kidneys excrete more hydrogen ions and retain bicarbonate. When the pH is abnormally high (i.e., alkalotic, >7.45), the kidneys retain hydrogen ions and excrete bicarbonate ions. Although effective, this mechanism is rather slow. It can take up to 3 days for normal pH levels to be achieved by the renal mechanism.

Blood Groups

Human blood contains antigens, which are proteins located on the surfaces of red blood cells. Compatibility between the blood donor and recipient antigens is essential in blood transfusion. Many antigens have been identified on human blood cells, but the two types most likely to cause a transfusion reaction are the ABO and Rh groups of antigens.

The ABO system was discovered in 1901 and is still considered the most important antigen group for transfusions. There are four

combinations of antigens or blood types, which are based on genes. If a person produces the A antigen, the blood type is classified as A; if a person produces the B antigen, the blood type is classified as B. If the person produces both A and B, the blood type is AB. Type O blood means no antigens are present. [Table 39.3](#) lists the frequency of occurrence of each type.

TABLE 39.3

Blood Types

BLOOD TYPE: ABO, RH	ANTIGENS PRESENT	% OF POPULATION
O+	Rh	35
O-	None	7
A+	A, Rh	35
A-	A	7
B+	B, Rh	8
B-	B	2
AB+	A, B, Rh	4
AB-	A, B	2

From [Pagana, K. D., & Pagana, T. J. \(2018\). *Mosby's manual of diagnostic and laboratory tests* \(6th ed.\). St. Louis: Elsevier.](#)

Individuals with type O blood are classified as universal donors because their blood cells contain no antigens. People with AB blood type are considered universal recipients because their blood cells contain both A and B antigens, and they can receive type A, B, or O blood.

The Rhesus (Rh) factor was discovered in 1940 and is the second most important antigen to test for before blood transfusions. The Rh antigens are responsible for many of the transfusion reactions that occur, especially in newborns. Approximately 85% of white and 95% of African Americans are Rh positive (Rh⁺), which means they have the Rh factor on the surface of their red blood cells. Those who do not have the Rh factor are considered Rh negative (Rh⁻). When an Rh⁻ person is exposed to Rh⁺ blood for the first time, Rh antibodies develop. This can occur when a pregnant woman who is Rh⁻ is carrying a fetus who is Rh⁺ or an Rh⁻ person receives Rh⁺ blood. After the person has been exposed, subsequent contact with Rh⁺ blood can lead to life-threatening destruction of red blood cells, known as **hemolytic reactions**.

Blood Testing

There is a continuing need for donated blood. To be eligible to donate blood, a person must be at least 17 years of age, weigh at least 110 pounds, and have not donated blood within the past 56 days. Donors

(Fig. 39.7) must also be symptom free and answer an extensive questionnaire of screening questions (American Red Cross, 2018). The donated blood is then tested for ABO and Rh type, screened for antibodies, and tested for infectious disease markers such as hepatitis and HIV.

FIGURE 39.7 Blood donation. (Copyright [istock.com](https://www.istock.com).)

Before administration, a “type and screen” is done on the patient's blood. The blood is typed for ABO antigens and Rh factor and screened for antibodies. A crossmatch or mixing of the patient's and donor's blood is performed to detect any incompatibilities. This is carried out in the laboratory before the unit of blood or blood product is released to the nurse. Autologous blood donation uses the patient's own blood donated 2 to 3 weeks before elective surgery.

Blood Components

Whole blood is composed of red blood cells, white blood cells, platelets, and plasma, which contains plasma proteins, antibodies, and electrolytes. Packed red blood cells are prepared from whole blood by removing the plasma and are commonly administered for patients with hemoglobin levels less than 7 g/dL. Because of the ability to separate the various components, whole blood is used only in situations when the blood components and blood volume are needed, such as massive hemorrhage. Table 39.4 describes the various blood components and their uses.

TABLE 39.4**Blood Components for Infusion**

BLOOD COMPONENT	NURSING CONSIDERATIONS
Whole blood	<i>Use:</i> Used only in situations with a major loss of blood (>25% of circulating volume). Available in bags of 500 mL. Must be infused within 4 hours after leaving the laboratory.
	<i>Concerns:</i> Should not be used in patients with a history of heart failure or renal impairment. Cautious use in the elderly, because it can lead to fluid overload. Requires ABO and Rh matching before administering. Patient is monitored for transfusion reactions.
Packed red blood cells (PRBCs)	<i>Use:</i> Plasma removal leaves only the red blood cells. Replaces the oxygen-carrying blood cells in patients with anemia or hemorrhage. Can correct blood losses during and after surgery. Must be initiated within 30 minutes after leaving the laboratory and completely infused within 4 hours.
	<i>Concerns:</i> Requires ABO and Rh matching before administering. Patient is monitored for transfusion reactions.
Fresh frozen plasma (FFP)	<i>Use:</i> FFP contains plasma proteins, fibrinogen, clotting factors, sugar, vitamins, minerals, hormones, and antibodies. Used to treat hemorrhage, as a volume expander, and to correct clotting disorders. Must be infused within 6 hours after leaving the laboratory.
	<i>Concerns:</i> Rh matching before administration. Need to monitor for allergic reactions.
Cryoprecipitate	<i>Use:</i> Also known as factor VIII. Used to treat various bleeding disorders
	<i>Concerns:</i> Need to monitor for allergic reactions.
Albumin	<i>Use:</i> Available in 5% and 25% concentrations. Contains globulins and other plasma proteins. Used to treat acute renal failure, burns, or trauma. Increases plasma oncotic pressure, causing excess fluid to move from the interstitial space and into the vascular system.
	<i>Concerns:</i> Fluid shifts can lead to fluid overload and heart failure or pulmonary edema. Use cautiously in the elderly and patients with impaired cardiac and/or renal function.
Platelets	<i>Use:</i> Indicated for patients with thrombocytopenia or platelet dysfunction and in patients who have had multiple transfusions of PRBCs. Should be infused as quickly as possible, usually within 10 minutes after leaving the laboratory.
	<i>Concerns:</i> Should be Rh compatible. Monitor patients for allergic reactions.
Autologous blood	<i>Use:</i> Also known as autotransfusion, refers to using the patient's own blood or blood components. Blood can be donated before surgery or collected in special containers and infused during and after surgery.
	<i>Concerns:</i> Patients with history of cancer or current infections are not candidates for autotransfusion.

Modified from [Weinstein, S. M., & Hagle, M. E. \(2014\). *Plumer's principles & practice of infusion therapy* \(9th ed.\). Philadelphia: Lippincott Williams & Wilkins.](#)

LO 39.2 Altered Structure and Function of Fluids and Electrolytes

Adequate fluid balance is essential for maintenance of homeostasis. Physical and environmental alterations can affect the stability of fluids, electrolytes, and acid-base balance and disrupt essential physiologic processes.

Fluid Imbalances

Excessive fluid loss or retention can interfere with metabolism and transport of oxygen, nutrients, and waste products. Causes, clinical manifestations, laboratory findings, and nursing interventions for fluid imbalances are presented in [Table 39.5](#). Excessive fluid loss can lead to decreased circulating volume, which directly affects cardiac output. Fluid volume excess leads to an increase in circulating fluid, thereby increasing the workload of the heart.

TABLE 39.5**Fluid Imbalances**

DISORDER	UNDERLYING CAUSES	CLINICAL MANIFESTATIONS	LABORATORY FINDINGS	INTERVENTIONS
Isotonic fluid volume deficit (hypovolemia)	Hemorrhage, burns, vomiting, diarrhea, Addison disease, fever, excessive perspiration	Confusion, thirst, dry mucous membranes, orthostatic hypotension, tachycardia, weak and thready pulse, decreased skin turgor, prolonged capillary refill, and decreased urinary output	Urine specific gravity >1.030 Increased hematocrit Adult males >52 Adult females >48 BUN >20	Administer fluids Monitor vital signs Monitor intake and output Monitor laboratory results, especially hematocrit, BUN, and urine specific gravity
Hypertonic fluid volume deficit (dehydration)	Diabetes insipidus, diabetic ketoacidosis; administration of osmotic diuretics, hypertonic enteral tube feedings, or hypertonic intravenous fluids; prolonged vomiting and diarrhea	Similar to hypovolemia, dry sticky mucous membranes, flushed dry skin, increased body temperature, irritability, seizures, and coma	Urine specific gravity >1.030 Increased hematocrit Adult males >52 Adult females >48 BUN >20 Serum sodium >145	Administer fluids Monitor vital signs Monitor intake and output Assess for neurologic changes Monitor laboratory results, especially hematocrit, BUN, and urine specific gravity
Isotonic fluid volume excess	Heart failure, renal failure, and cirrhosis	Weight gain, edema in dependent areas, bounding peripheral pulses, hypertension, JVD, dyspnea, cough, abnormal lung sounds	Urine specific gravity <1.005 Decreased hematocrit Adult males <42 Adult females <37 BUN <7	Monitor vital signs Monitor intake and output Assess for edema and JVD Auscultate lung fields Monitor laboratory results, especially hematocrit, BUN, and urine specific gravity

DISORDER	UNDERLYING CAUSES	CLINICAL MANIFESTATIONS	LABORATORY FINDINGS	INTERVENTIONS
Hypotonic fluid volume excess	Excessive water intake, prolonged use of hypotonic IV solutions, SIADH	Symptoms similar to isotonic fluid volume excess plus neurologic changes that indicate cerebral edema, including decreased level of consciousness, coma, and seizures	Urine specific gravity <1.005 Decreased hematocrit Adult males <42 Adult females <37 BUN <7 Serum sodium <135	Monitor vital signs Monitor intake and output Assess for neurologic changes Monitor laboratory results, especially hematocrit, BUN, and urine specific gravity

BUN, Blood urea nitrogen; *JVD*, jugular vein distention; *SIADH*, syndrome of inappropriate antidiuretic hormone secretion.

Fluid Volume Deficit

Fluid volume deficit occurs with excessive loss or inadequate intake of fluid. Two types of fluid deficits can occur: isotonic and hypertonic.

Isotonic fluid deficit, or hypovolemia, occurs when water and sodium are lost at the same rate. In this situation, circulating volume decreases, but serum osmolarity remains unchanged. The other type of fluid volume deficit occurs when water is lost in excess of sodium. Hypertonic fluid volume deficit, or **dehydration**, can be serious if not recognized and treated. As fluid loss continues, the circulating fluid volume decreases and serum osmolarity increases. When monitoring fluid loss, it is important to remember that even small losses can lead to undesirable consequences. Age-related changes predispose older adults to fluid volume deficit. Some of these include decreased thirst mechanism, kidneys that are less able to concentrate urine to conserve water, polypharmacy/medication side effects, diuretic use, swallowing problems, frailty, dementia, and inability to independently drink or hold a cup. [Box 39.1](#) discusses dehydration in older adults. Severity of dehydration is classified by percentage of total body weight:

Box 39.1

Evidence-Based Practice and Informatics

Alterations in Fluids and Electrolytes in Older Adults

- Hyperosmolar dehydration (HD), a state of water depletion (serum osmolality >300 mOsm/kg) is common in older adults and has been linked with increased morbidity and mortality. HD may be present

in over a third of older adults admitted to hospital as medical emergencies.

- Nurses should be astute in assessing, recognizing, and treating dehydration in older adults to improve patient outcomes (El-Sharkawy, Watson, Neal, et al., 2015; Miller, 2015).
- Traditional markers of dehydration are not always accurate in elderly (Campbell, 2016; Miller, 2015). These include tachycardia (>100 bpm), low systolic blood pressure (<100 mm Hg), dry mucous membranes, long capillary refill time (>3 seconds), dark urine color, elevated urine specific gravity, elevated plasma osmolality, and elevated blood urea nitrogen.
- Skin turgor is not an accurate indicator in older adults due to the normal changes of aging, which cause a decrease in skin elasticity.
- Low systolic blood pressure (<100 mm Hg) has been shown in a study by Fortes et al. (2015) to be the most sensitive indicator for aiding in the diagnosis water-and-solute-loss dehydration.
- Innovative drinking aids and personal hydration systems, such as “the Hydrant,” use a clipped straw that can be attached to beds or wheelchairs so the user has drinks available at all times without needing to call for help (Johnstone, Alexander, & Hickey, 2015).

- A 2% loss is mild dehydration.
- A 5% loss is moderate dehydration.
- An 8% loss is severe dehydration.
- A 15% loss is life-threatening, usually fatal.

Fluid Volume Excess

Fluid volume excess occurs when fluid intake exceeds output. Fluid volume excess is isotonic or hypotonic, depending on corresponding changes in serum osmolarity. Severity of the fluid volume excess is assessed by the corresponding increase in total body weight:

- A 2% gain is mild excess.
- A 5% gain is moderate excess.
- An 8% gain is severe excess.

Edema is the abnormal accumulation of fluid in the interstitial spaces, typically in the extremities such as fingers, ankles, and feet, and also may be present in the face and/or abdomen. Edema, also known as third spacing, develops when fluid moves into a tissue at a faster rate than it

can be reabsorbed into the intravascular space (see Fig. 20.6). There are four primary causes of edema formation: increase in hydrostatic pressure due to fluid overload, decreased production of circulating plasma proteins, obstruction of lymphatic drainage, and increased capillary permeability due to tissue damage (Fig. 39.8). When fluid is trapped in the interstitial spaces, it is not available for use inside the cell or in the intravascular space.

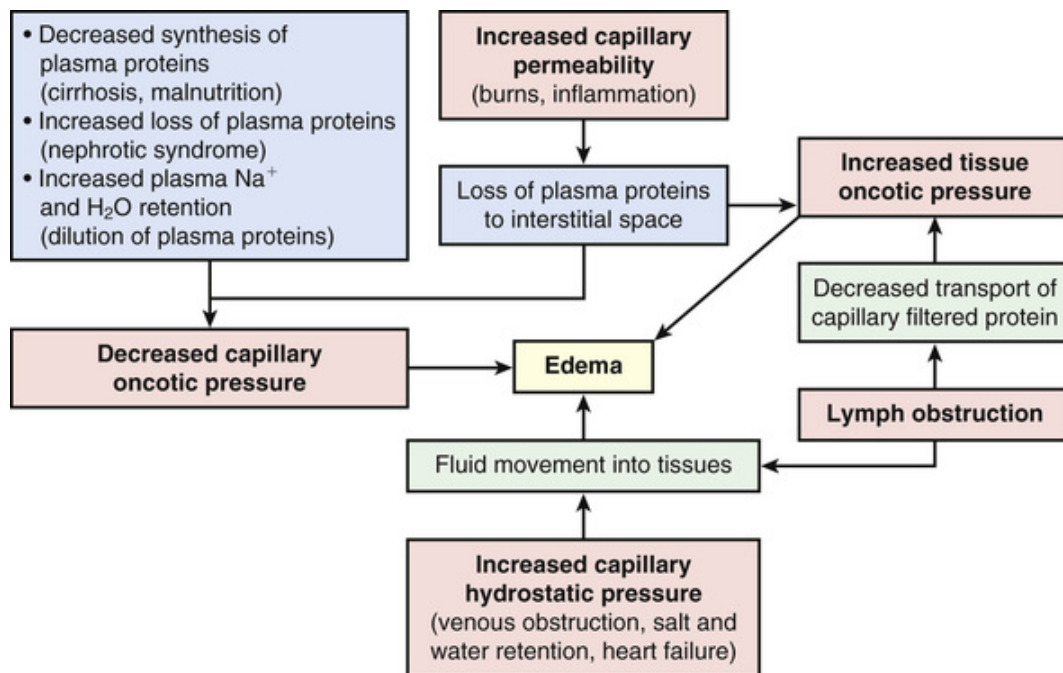

FIGURE 39.8 Mechanisms of edema formation. (From McCance, K. L., & Huether, S. E. [2019]. *Pathophysiology* [8th ed.]. St. Louis: Elsevier.)

In isotonic fluid volume excess, there is an equal increase in fluid and sodium retention. The result is an increase in circulating blood volume while serum osmolarity remains unchanged. Hypotonic fluid volume excess occurs when water is ingested at a rate greater than sodium. Although there is an increase in circulating blood volume, the serum osmolarity decreases as a result of hemodilution. This decrease in serum osmolarity leads to fluid moving into the cells, causing cellular swelling. Swelling leads to pulmonary congestion and cerebral edema. There are situations in which inappropriate secretion of ADH (i.e., syndrome of inappropriate antidiuretic hormone secretion [SIADH]) occurs. Remember that ADH leads to increased retention of fluid and not necessarily sodium. As a result, serum osmolarity decreases. There are several causes of SIADH, including head injury, brain tumors, and postoperative effects of surgery and anesthesia.

Simultaneous Fluid Volume Excess and Deficit

There are some situations (e.g., cirrhosis) in which fluid volume excess and fluid volume deficit can occur simultaneously. When the serum albumin level is very low, the hydrostatic pressure is greater than the oncotic pressure, and fluid seeps into the interstitial spaces. As a result, many of the signs of fluid volume excess are present, such as weight gain, pulmonary congestion, and edema. Because this fluid has been lost from the intravascular space, signs of fluid volume deficit are also present, such as hypotension, weak and thready pulse, and tachycardia. In this situation, treatment focuses on replacing the plasma proteins and allowing the fluids to shift back to the intravascular space. Fluid replacement, whether administered orally or intravenously, should begin after this fluid shift has occurred.

Electrolyte Imbalances

Although the body has many complex mechanisms to maintain homeostasis, in the presence of disease or trauma, it is not uncommon to have electrolyte imbalances. Understanding the cause and common symptoms of these imbalances helps the nurse identify the patients at risk and recognize electrolyte imbalance in the early stage. [Table 39.6](#) describes the common electrolyte imbalances, causes, symptoms, and interventions.

TABLE 39.6**Electrolyte Imbalances**

DISORDER	UNDERLYING CAUSES	CLINICAL MANIFESTATIONS	INTERVENTIONS
Sodium			
Hyponatremia Na ⁺ <136 mEq/L	Hypovolemic hyponatremia Diuretics GI fluid loss (vomiting, diarrhea) Profuse diaphoresis Water intoxication Prolonged use of hypotonic IV solutions SIADH	Lethargy, confusion, weakness Muscle cramping Seizures Anorexia, nausea, vomiting Serum osmolarity <280 mOsm/kg	Monitor vital signs. Monitor intake and output. Monitor laboratory results, especially serum sodium and serum osmolality. Encourage foods high in sodium. Restrict water intake. Administer hypertonic IV saline solutions as ordered.
Hypertatremia Na ⁺ >145 mEq/L	Excess sodium due to: Excessive sodium intake Hypertonic IV solutions Hypertonic enteral feedings without adequate water Excessive loss of water due to: Diarrhea Inadequate intake of water Insensible loss due to fever	Thirst, dry and sticky mucous membranes, weakness, elevated temperature Severe hypertatremia causing confusion and irritability, decreased levels of consciousness, hallucinations, and seizures Serum osmolarity >300 mOsm/kg	Monitor vital signs. Monitor level of consciousness. Monitor intake and output. Monitor laboratory results, especially serum sodium and serum osmolarity. Limit salt intake and foods high in sodium. Increase water intake. Administer hypotonic IV solutions as ordered.
Potassium			

DISORDER	UNDERLYING CAUSES	CLINICAL MANIFESTATIONS	INTERVENTIONS
Hypokalemia K ⁺ <3.5 mEq/L	Loss of potassium due to: Vomiting, gastric suction, diarrhea Laxative abuse, frequent enemas Use of potassium-wasting diuretics Inadequate intake seen in anorexia, alcoholism, debilitated patients Hyperaldosteronism	Weak, irregular pulse Fatigue, lethargy Anorexia, nausea, vomiting Muscle weakness and cramping Decreased peristalsis, hypoactive bowel sounds Paresthesia Cardiac dysrhythmias Increased risk for digitalis toxicity	Monitor vital signs, especially heart rate and rhythm. Monitor cardiac rhythm with ECG. Monitor laboratory results for serum potassium levels. Assess for signs of digitalis toxicity. Encourage foods high in potassium. Administer potassium supplements as ordered; IV potassium is diluted properly and administered slowly, usually by infusion. <i>Never administer potassium as an IV bolus or IV push.</i>
Hyperkalemia K ⁺ >5.0 mEq/L	Renal failure Massive trauma, crushing injuries, burns Hemolysis IV potassium Potassium-sparing diuretics Acidosis, especially diabetic ketoacidosis	Anxiety, irritability, confusion Dysrhythmias, including bradycardia and heart block Muscle weakness, flaccid paralysis Paresthesia Abdominal cramping	Monitor vital signs, especially heart rate and rhythm. Monitor cardiac rhythm with ECG. Monitor laboratory results for serum potassium levels. Limit potassium-rich foods. Administer cation-exchange resins (Kayexalate) as ordered Administer glucose and insulin as ordered (potassium moves back into cell)
Calcium			
Hypocalcemia Ca ²⁺ <9 mg/dL	Hypoparathyroidism Pancreatitis Vitamin D deficiency Inadequate intake of calcium-rich foods Hyperphosphatemia Chronic alcoholism	Confusion, anxiety Numbness and tingling of extremities Muscle cramps that progress to tetany and seizures Hyperactive reflexes Cardiac dysrhythmias Positive Chvostek and Trousseau signs	Monitor heart rate and rhythm. Monitor cardiac rhythm with ECG. Institute fall and seizure precautions. Administer oral and/or IV calcium supplements as ordered. Encourage calcium-rich foods.

DISORDER	UNDERLYING CAUSES	CLINICAL MANIFESTATIONS	INTERVENTIONS
Hypercalcemia Ca ²⁺ >10.5 mg/dL	Prolonged bed rest Hyperparathyroidism Bone malignancy Paget disease Osteoporosis	Lethargy, stupor, coma Decreased muscle strength and tone Anorexia, nausea, and vomiting Constipation Pathologic fractures Dysrhythmias Renal calculi	Monitor heart rate and rhythm. Monitor cardiac rhythm with ECG. Encourage increased fluid intake. Increase patient activity, including active ROM.
Chloride			
Hypochloremia Cl ⁻ <98 mEq/L	Overhydration Heart failure SIADH Vomiting or gastric suction Addison's disease Burns Metabolic alkalosis Certain medications such as aldosterone, bicarbonates, steroids, loop and thiazide diuretics	Irritable nerves and muscles, tetany, hypotension, shallow breathing	Monitor vital signs. Monitor intake and output. Monitor laboratory results. Restrict water intake. Administer hypertonic IV saline solutions as ordered.
Hyperchloremia Cl ⁻ >106 mEq/L	Dehydration Anemia Excessive normal saline infusion Cushing syndrome Kidney disease Metabolic acidosis Respiratory alkalosis or hyperventilation	Weakness, lethargy, deep breathing	Monitor vital signs. Monitor level of consciousness. Monitor intake and output. Monitor laboratory results. Limit salt intake. Increase water intake. Administer hypotonic IV solutions as ordered.
Magnesium			

DISORDER	UNDERLYING CAUSES	CLINICAL MANIFESTATIONS	INTERVENTIONS
Hypomagnesemia Mg ²⁺ <1.3 mEq/L	Decreased intake TPN without magnesium Decreased absorption Nasogastric suction Draining fistulas Prolonged diarrhea Laxative abuse Malabsorption syndrome Ulcerative colitis Crohn disease Increased renal excretion Diuresis Loop and thiazide diuretics	Irritable nerves and muscles Hyperactive deep tendon reflexes Seizures Dysrhythmias, especially tachyarrhythmias ECG changes Altered level of consciousness Mood swings Delusions, hallucinations Dysphagia, nausea, and vomiting	Assess vital signs, especially heart rate and rhythm. Monitor cardiac rhythm with ECG. Assess mental status, changes in level of consciousness. Monitor laboratory results, including potassium and calcium levels. Assess swallowing before administering medications, food, or fluid. Institute seizure precautions. Administer oral or IV supplements as ordered.
Hypermagnesemia Mg ²⁺ >2.1 mEq/L	Excessive intake of magnesium-containing antacids or cathartics TPN with too much magnesium Prolonged use of intravenous magnesium sulfate Renal failure Severe dehydration Adrenal insufficiency Leukemia	Warm, flushed appearance Nausea, vomiting Drowsiness, lethargy Decreased muscle strength Generalized weakness Decreased deep tendon reflexes Hypotension Dysrhythmias, especially bradycardia and heart block Slow, shallow respirations; respiratory arrest	Assess vital signs, especially heart rate and rhythm. Monitor cardiac rhythm with ECG. Assess mental status, changes in level of consciousness. Assess neuromuscular strength and activity. Encourage increased oral intake, increased IV fluids. Administer loop diuretics as ordered. Provide respiratory support (supplemental oxygen or mechanical ventilation) as needed.
Phosphate			

DISORDER	UNDERLYING CAUSES	CLINICAL MANIFESTATIONS	INTERVENTIONS
Hypophosphatemia PO ₄ ³⁻ <3 mg/dL	Abnormal shift into the cell Hyperventilation Respiratory alkalosis Hyperglycemia Absorption from the GI tract Phosphorus-binding antacids Starvation Malabsorption syndrome Inadequate vitamin D Chronic diarrhea, laxative abuse Increased excretion by kidneys Thiazides and loop diuretics Diabetic ketoacidosis Hyperparathyroidism Hypocalcemia	Weak pulse Shallow respirations Hypotension Decreased cardiac output Hemolytic anemia Bleeding, increased bruising Muscle weakness Decreased deep tendon reflexes Tremors Bone pain Anorexia Increased risk for infection	Assess vital signs, especially respirations, pulse oximetry, and blood pressure. Assess muscle strength and neuromuscular function. Assess for signs of heart failure. Encourage phosphate-rich foods. Instruct patient to avoid phosphorus-binding antacids. Administer oral and IV phosphorus as ordered. Administer pain medications as ordered. Monitor for signs of infection.
Hyperphosphatemia PO ₄ ³⁻ >4.5 mg/dL	Impaired renal function Hypoparathyroidism Acid-base imbalances Cellular injury	Signs of hypocalcemia Tetany Hyperreflexia Muscle spasms, weakness Tachycardia Nausea Diarrhea, cramping	Monitor vital signs. Monitor serum phosphorus and calcium levels. Monitor BUN, creatinine. Assess signs of hypocalcemia. Monitor intake and output. Teach patient to avoid phosphorus-rich foods.

BUN, Blood urea nitrogen; *ECG*, electrocardiogram; *GI*, gastrointestinal; *IV*, intravenous; *ROM*, range of motion; *SIADH*, syndrome of inappropriate antidiuretic hormone secretion; *TPN*, total parenteral nutrition.

Hyponatremia and Hypernatremia

Hyponatremia occurs when the sodium level is decreased in relation to body water. It is defined as a serum level less than 136 mEq/L. As a result of the decreased concentration in the extracellular fluid, water moves into the cell, causing cellular swelling.

There are two types of hyponatremia: hypovolemic hyponatremia and hypervolemic hyponatremia. Hypovolemic hyponatremia occurs when there is loss of water and sodium, but the sodium loss is greater. Hypervolemic hyponatremia is also known as dilutional hyponatremia. In this situation, water intake exceeds sodium intake, which leads to an overall decrease in serum sodium levels.

Hypernatremia occurs when the serum sodium level is greater than 145 mEq/L. This imbalance results from a greater loss of water compared with sodium or a greater intake of sodium. As sodium levels increase, water moves from the cells into the intravascular space, which can lead to cellular dehydration. Movement of the fluid into the vascular space can lead to fluid overload, or hypervolemia. Hypernatremia can occur rather quickly or have a slower onset (Box 39.2).

Box 39.2

Onset of Hypernatremia

Rapid Onset

- Severe vomiting
- Hypertonic intravenous fluids
- Excessive sweating

Slow Onset

- Heart failure
- Renal failure
- Increased sodium intake

Hypokalemia and Hyperkalemia

Because of the critical role that potassium plays in cellular metabolism, even slight imbalances can affect cardiac and neuromuscular functions. Because the body is unable to conserve potassium, serum levels are easily influenced by potassium intake and excretion. These imbalances need to be prevented when possible and identified and treated quickly.

Hypokalemia occurs when the serum potassium level falls below 3.5 mEq/L. Inadequate intake occurs as a result of decreased oral intake or insufficient potassium in intravenous (IV) fluids. Box 39.3 outlines some concerns regarding fluids and electrolytes.

Box 39.3

Diversity Considerations

Life Span

- Infants are more susceptible to fluid volume deficits or dehydration because of their high percentage of total body water.
- The elderly are more prone to hypokalemia because of increased use of potassium-wasting diuretics.
- Hypokalemia can enhance the effect of digitalis and lead to digitalis toxicity and subsequent cardiac arrest. The elderly are often prescribed both digitalis and potassium-wasting diuretics. They are encouraged to eat foods high in potassium, take prescribed potassium supplements, and learn the signs of hypokalemia.

Gender

- Hormonal fluctuations in females can cause fluid retention.
- Men have a higher total body water percentage than women.

1. On day 2 of his hospital stay, R. A. begins to complain of increased muscle weakness and cramping. Assessment findings include an irregular apical pulse and hypoactive bowel sounds. Provide a possible explanation for these findings, and identify appropriate nursing action.

There are primarily four sources of **hyperkalemia** (serum potassium >5.0 mEq/L): excessive intake of potassium, transfusions and medications, impaired renal excretion, and cellular movement. Because potassium levels are lowered by renal excretion, homeostasis requires normal renal functioning. In acute and chronic renal failure, the kidneys lose the ability to maintain this homeostatic function. Cells that are damaged due to trauma release intracellular potassium into the extracellular space, raising serum levels.

Hypocalcemia and Hypercalcemia

Hypocalcemia occurs when serum calcium levels fall below 9 mg/dL. It occurs as a result of inadequate intake of calcium, lack of absorption, or excessive losses. Decreased serum calcium levels occur when calcium cannot be absorbed from the small intestine. A large portion (40%) of

serum calcium is bound to plasma proteins. When the protein stores are decreased, as in malnutrition and cirrhosis, the level of unbound calcium increases, making it available to be excreted by the kidneys.

Administration of loop diuretics can lead to increased calcium excretion.

Hypercalcemia occurs when serum calcium levels exceed 10.5 mg/dL. High intake of calcium and increased release of calcium from the bone are the most common reasons for increased serum calcium. An increase in secretion of the parathyroid hormone, as occurs in hyperparathyroidism, leads to increased calcium released from the bones.

Hypomagnesemia and Hypermagnesemia

A decreased serum magnesium level, or **hypomagnesemia**, is a serum level of less than 1.3 mEq/L. However, most people are not symptomatic until levels fall below 1 mEq/L. Decreased serum levels result from decreased intake, decreased absorption, or increased loss through the kidneys. Hypomagnesemia often occurs in conjunction with hypokalemia and hypocalcemia.

Hypermagnesemia, defined by serum levels greater than 2.1 mEq/L, does not commonly occur. When it does, it is usually due to an excessive intake of magnesium-containing antacids or cathartics. It occurs in patients on total parenteral nutrition (TPN) containing too much magnesium or with the prolonged use of IV magnesium such as magnesium sulfate. Renal failure can lead to decreased excretion of magnesium. Severe dehydration can lead to hemoconcentration of magnesium. Adrenal insufficiency and leukemia also have caused increased serum levels of magnesium.

Hypochloremia and Hyperchloremia

Hypochloremia occurs when serum chloride levels fall below 98 mEq/L and usually occurs with simultaneous shifts in water balance, sodium levels, or bicarbonate levels. Fluid volume excess and certain medications such as corticosteroids and/or diuretics may cause hypochloremia.

Hyperchloremia occurs when serum chloride levels go above 106 mEq/L and can be affected by dehydration or certain medications. Excessive infusion of normal saline intravenously also may cause hyperchloremia.

Hypophosphatemia and Hyperphosphatemia

Hypophosphatemia occurs when serum phosphorus levels fall below 3 mg/dL. It normally results from an abnormal shift of phosphate into the cell, decreased absorption of phosphorus from the gastrointestinal tract, or increased excretion of phosphorus by the kidneys. Hyperventilation, which leads to respiratory alkalosis (discussed later), facilitates

movement of phosphorus into the cell. **Hyperglycemia** (increased blood glucose levels) stimulates the pancreas to release insulin, which transports phosphate along with glucose into the cell. Absorption of phosphorus from the gastrointestinal tract can be decreased as a result of phosphorus-binding antacids, starvation, and malabsorption syndrome. Inadequate intake of vitamin D, chronic diarrhea, and laxative abuse can limit absorption. The use of thiazides and loop diuretics increases phosphate loss in the urine. Osmotic diuresis from diabetic ketoacidosis or an increase of parathyroid hormone secretion (as occurs in hyperparathyroidism or hypocalcemia) can lead to increased excretion of phosphate.

Hyperphosphatemia, or serum phosphorus levels greater than 4.5 mg/dL, most often occurs as a result of impaired renal function. As the GFR decreases, the ability of the kidneys to excrete excess phosphate ions diminishes. Increased levels of phosphate ions occur as a result of decreased parathyroid hormone secretion seen in hypoparathyroidism. Acid-base imbalances and cellular injury can cause phosphate ions to shift into the extracellular fluid, increasing serum levels.

Acid-Base Imbalances

For normal cellular functioning to occur, the pH of body fluids must remain in the narrow range between 7.35 and 7.45. Death can occur if the pH falls below 6.9 or rises higher than 7.80. Various chemical buffering systems are designed to maintain normal pH balance. Two compensatory mechanisms, respiratory (carbon dioxide) and renal (metabolic), are designed to help maintain homeostasis.

Four acid-base imbalances can occur: respiratory acidosis and alkalosis and metabolic acidosis and alkalosis ([Table 39.7](#)).

TABLE 39.7**Acid-Base Imbalances**

ACID-BASE IMBALANCE	UNDERLYING CAUSES	CLINICAL MANIFESTATIONS	INTERVENTIONS
Respiratory acidosis	Hypoventilation due to: Chest injury Asthma attack Pulmonary edema Brainstem injury Medications: Anesthetics, opioids, sedatives	Headache Altered level of consciousness, irritability, confusion Dyspnea Tachycardia Muscle twitching Uncompensated ABG results: pH <7.35 PaCO ₂ >45 mm Hg HCO ₃ ⁻ normal Partially compensated ABG results: pH <7.35 PaCO ₂ >45 mm Hg HCO ₃ ⁻ >28 mEq/L As compensation continues, the pH increases.	Assess vital signs, especially rate and depth of respirations, pulse oximetry. Assess breath sounds. Assess cardiac rhythm. Administer oxygen as ordered. Monitor ABG results. Have mechanical ventilation available. Encourage deep breathing and coughing. Encourage fluid intake.
Respiratory alkalosis	Pain Hyperventilation Salicylate overdose Nicotine overdose Increased metabolic states	Tachypnea (rapid, shallow breathing) Numbness, tingling of fingers Muscle cramping Palpitations Anxiety, restlessness ECG changes ABG results: pH >7.45 PaCO ₂ <35 mm Hg HCO ₃ ⁻ normal Partially compensated ABG results: pH >7.45 PaCO ₂ <35 mm Hg HCO ₃ ⁻ <21 mEq/L As compensation continues, the pH decreases.	Assess vital signs. Encourage patient who is tachypneic to take slow, deep breaths. Have patient breathe into a paper bag. Monitor ABGs. Provide reassurance and emotional support to anxious patient.

ACID-BASE IMBALANCE	UNDERLYING CAUSES	CLINICAL MANIFESTATIONS	INTERVENTIONS
Metabolic acidosis	Shock Trauma Cardiac arrest Diabetic ketoacidosis Chronic renal failure Salicylate overdose Sepsis Chronic diarrhea	Kussmaul respirations Hypotension Headache Decreased level of consciousness Weakness Nausea, vomiting, anorexia ABG results: pH <7.35 PaCO ₂ normal HCO ₃ ⁻ <21 mEq/L Partially compensated ABG results: pH <7.35 PaCO ₂ <35 mm Hg HCO ₃ ⁻ <21 mEq/L As compensation continues, the pH increases.	Assess vital signs, especially respiratory rate and rhythm, blood pressure, and pulse oximetry. Monitor cardiac rhythm. Monitor ABGs and serum electrolytes, glucose, and BUN or creatinine. Monitor level of consciousness. Have mechanical ventilation available as needed. Administer sodium bicarbonate as ordered.
Metabolic alkalosis	Vomiting Nasogastric suctioning Overuse of bicarbonate antacids Hypokalemia Loop and thiazide diuretics	Hypotension Mental confusion Muscle twitching, tetany Increased deep tendon reflexes Numbness, tingling of fingers and toes Seizures Anorexia, nausea, vomiting Polyuria ABG results: pH >7.45 PaCO ₂ normal HCO ₃ ⁻ >28 mEq/L Partially compensated ABG results: pH >7.45 PaCO ₂ >45 mm Hg HCO ₃ ⁻ >28 mEq/L As compensation continues, the pH decreases.	Assess vital signs, especially cardiac rate and rhythm, respiration rate and depth, pulse oximetry, blood pressure. Monitor ABGs and serum electrolytes, especially potassium. Assess level of consciousness. Administer oxygen as ordered. Initiate seizure precautions. Treat hypokalemia if appropriate.

ABG, Arterial blood gases; BUN, blood urea nitrogen; ECG, electrocardiogram.

Respiratory Acidosis

Respiratory acidosis occurs when gas exchange is decreased due to abnormal ventilation, perfusion, or diffusion. This leads to hypercapnia—increased carbon dioxide levels—in the blood. Respiratory acidosis can be acute or chronic. In acute situations, the hydrogen ion concentration is increased, with a pH less than 7.35, and the partial arterial pressure of carbon dioxide (PaCO_2) is increased to greater than 45 mm Hg. There is an inverse relationship between the pH and PaCO_2 . As one increases, the other decreases. Acute respiratory imbalances are not quickly adjusted due to the delay in the renal (metabolic) compensatory mechanism. In chronic respiratory imbalances, such as chronic obstructive pulmonary disease (COPD), the PaCO_2 is increased, but the pH is within a normal range. The renal compensation mechanism has time to adjust to the chronic hypercapnia. The animation “[Respiratory Acidosis](#)” further explains how the body compensates.📺

Renal compensation of respiratory acidosis focuses on excreting excess metabolic acids and conserving bicarbonate. However, renal compensation is fairly slow, taking 12 to 24 hours to adjust to the abnormal pH levels. As a result of compensation, pH levels move toward the normal range, and bicarbonate levels are abnormally high.

Respiratory Alkalosis

Respiratory alkalosis is a result of hyperventilation and excess exhalation of carbon dioxide. The pH is increased to greater than 7.45, and the PaCO_2 is decreased to less than 35 mm Hg. Acute hypoxia leads to an increased respiratory rate by overstimulating the respiratory center of the brain, which leads to hypocapnia (i.e., decreased carbon dioxide levels in the blood). Renal compensation of this imbalance focuses on preserving metabolic acids, thereby decreasing the amount of available bicarbonate. Renal compensation is slow. As compensation occurs, the pH decreases to normal and the bicarbonate level is below normal levels.

Metabolic Acidosis

Metabolic acidosis is defined as high acid content in the blood, with a pH less than 7.35 and a bicarbonate level less than 21 mEq/L. It occurs when there is a loss of bicarbonate ions or an increase in acids produced as by-products of a metabolic process (i.e., ketones). Lactic acidosis, a result of anaerobic respiration, can quickly lead to a metabolic acidotic state. This occurs in shock, sepsis, or cardiac arrest. Decreased renal function can lead to metabolic acidosis as kidneys lose the ability to secrete hydrogen ions or conserve bicarbonate ions. Loss of intestinal fluids from diarrhea, draining intestinal fistulas, and malabsorption syndrome leads to decreased levels of bicarbonate ions. In metabolic acidosis, the lungs

compensate by increasing the rate and depth of respirations in an attempt to remove excess carbon dioxide, thereby lowering the amount of carbonic acid in the blood. This type of deep, rapid breathing is known as *Kussmaul respirations*. The “[Metabolic Acidosis](#)” animation further explains this problem. ©

Metabolic Alkalosis

In **metabolic alkalosis**, there is an excess of bicarbonate ions, which raises the pH above 7.45 and produces bicarbonate levels greater than 28 mEq/L. This occurs as a result of excessive intake of bicarbonate-containing medications (i.e., antacids), loss of gastric acids through vomiting or nasogastric suctioning, and frequent blood transfusions (due to the citrate preservative used in the storage of the red blood cells). Loop and thiazide diuretics facilitate increased excretion of hydrogen ions. Hypokalemia can lead to hydrogen ions shifting into the cell in exchange for potassium ions, decreasing circulating blood levels of hydrogen ions. The lungs attempt to compensate by decreasing the rate and depth of respirations. This hypoventilation leads to carbon dioxide retention, increasing carbonic acid levels. Although respiratory compensation can be very effective, it cannot continue indefinitely and may be limited due to hypoxemia. It is essential to identify and treat the underlying metabolic disorder.

◆ LO 39.3 Assessment

To provide appropriate nursing care, it is essential for the nurse to understand how trauma, disease, and other disorders lead to fluid, electrolyte, and acid-base imbalances. By conducting a thorough assessment, the nurse identifies patients at risk for these imbalances, recognizes specific imbalances, and develops an individualized plan of care. The nursing assessment includes a thorough health history, a focused assessment, and review of diagnostic testing.

Health History

The health history includes questions designed to highlight recent changes in fluid intake, diet, and other lifestyle habits (Box 39.4). It is important to ascertain recent changes in weight (i.e., loss or gain). A complete list of over-the-counter and prescription medications helps the nurse identify drug-related influences on homeostasis. Questions regarding the recent medical history, including chronic diseases, surgery or trauma, draining wounds, and changes in elimination patterns, assist the nurse in recognizing patients who are at high risk for or have imbalances.

Box 39.4

Health Assessment Questions

Fluid and Electrolyte Focus

- What is your typical intake of fluids each day? What type of fluids do you normally drink? Has that changed?
- What do you normally eat in a 24-hour period? (Look for use of processed meats, canned foods, and other high-sodium sources.)
- Do you use salt or salt substitutes?
- How much protein do you typically have in a 24-hour period? What types of protein?
- Do you often feel thirsty?
- Are you on a special diet or do you have dietary restrictions? Do you have food allergies?
- Have you lost or gained weight recently? If so, how much, and was it intentional?

- What prescription and over-the-counter medications do you take on a routine basis? (Look for diuretics, steroids, nonsteroidal antiinflammatory drugs [NSAIDs], aminoglycosides, sodium-based antacids, lithium, or narcotics.)
- What herbals, vitamins, or mineral supplements do you take on a routine basis and for what reason?
- Do you use laxatives?
- Do you have a history of renal disease, diabetes mellitus, diabetes insipidus, heart failure, thyroid or parathyroid disorders, or pulmonary disease?
- Do you have a recent history of surgery, trauma (including burns), gastroenteritis, head injury, infection, vomiting, diarrhea, or fever?
- Have you noticed swelling of your hands and feet?

The health history includes questions about the use of herbal medicines. Certain herbals affect the patient's risk for fluid and electrolyte imbalances (Box 39.5).

Box 39.5

Patient Education and Health Literacy

Fluid and Electrolyte Imbalances and Herbals

Patients often do not understand how herbs and supplements can affect fluid and electrolyte balance. It is important for the nurse to do a complete medication reconciliation including documentation of herbs and supplements used and educate patients about the effects of the following herbals:

- *Aloe*: Acts as a cathartic/laxative and can lead to hypokalemia. Aloe also can cause hypoglycemia when taken with oral diabetic medications.
- *Celery and Dandelion*: Each acts as a diuretic in the body
- *Ginseng*: Contraindicated in renal failure
- *Licorice*: Pseudoaldosteronism leading to sodium retention and hypokalemia

Vital Signs

A prolonged fever can lead to an increased loss of body fluids. In severe dehydration (i.e., hyperosmolar fluid volume deficit), the body temperature increases, whereas in isotonic fluid volume deficit, the body temperature decreases.

Tachycardia, or increased heart rate, may be the first indication of a fluid volume deficit. When there is a decrease in circulating blood volume, the stroke volume decreases. To ensure adequate oxygenation of the tissues, the heart rate accelerates to maintain normal cardiac output. Alterations in potassium, calcium, and magnesium levels can lead to dysrhythmias, or abnormal heart rhythms. The strength or quality of the pulse is assessed. Fluid volume deficit leads to a weak pulse on palpation, and fluid volume excess causes a strong, bounding pulse.

Changes in respirations are closely linked to acid-base balance. Alterations in respiratory rate, depth, and rhythm can lead to respiratory acid-base imbalance or be a compensatory mechanism for metabolic imbalances. The nurse should be able to differentiate between the underlying disorder and the compensatory mechanism.

Changes in blood pressure can indicate fluid and electrolyte imbalances. With a fluid volume excess, the circulating volume and blood pressure increase. With fluid volume deficit, the blood pressure decreases. It is important to assess for **orthostatic hypotension**, a decrease of more than 20 mm Hg in systolic pressure or 10 mm Hg in diastolic pressure when moving from one position to another, such as sitting to standing. The pulse pressure, which is the difference between the systolic and diastolic blood pressures, is approximately 40 mm Hg. A pulse pressure less than 24 mm Hg can indicate severe fluid volume deficit.

Electrolyte imbalances can affect blood pressure values. Hypernatremia can increase circulating fluid volume, leading to hypertension. Hyperkalemia can cause the blood pressure to decrease.

Intake and Output

Measurement of intake and output is routinely ordered for patients who are at risk for or who have fluid and electrolyte imbalances. It is important that patients, family members, and health care workers are aware of this intervention.

Oral intake comprises all fluids and foods that become liquid at room temperature, including gelatin, Popsicles, ice cream, and ice chips. Ice chips, when melted, are approximately half of the frozen amount. For example, one cup of ice chips (240 mL) is equal to 120 mL of water. All IV fluids, including medications and blood products, are recorded as

intake. Other sources of fluid intake include enteral tube feedings, nasogastric or bladder irrigations, and large-volume enemas.

Output consists of body fluids and drainage that can be measured. This includes urine, emesis, liquid stool, wound drainage, and drainage from suction devices. Containers with calibrations, such as urinals and urine hats, can be used to collect and measure the fluids.

To measure output in infants and incontinent adults, the diapers or disposable briefs are weighed to determine the amount of fluid. Normally, output is totaled for an 8-hour shift and a 24-hour period. For critically ill patients, insertion of a Foley catheter allows hourly intake and output measurements.

When assessing intake and output, the nurse documents intake and output each shift, making sure there are no omissions. Daily the shift totals are added to obtain the 24-hour balances. The fluid balance is positive when intake exceeds output, and it is negative when output surpasses intake. Trends over subsequent days should be noted. For example, a 200-mL positive fluid balance for 1 day is not a substantial amount. However, when there is a positive fluid balance for each of the next few days, the excess fluid has a cumulative effect (Fig. 39.9).

Intake/Output					
Table		3-Day		7-Day

FIGURE 39.9 The 24-hour intake and output record. (Courtesy Epic Systems Corporation, Verona, WI, 2012.)

Weight

Despite best intentions, the intake and output record is not always an accurate reflection of changes in fluid balance for various reasons. Patients may forget to save their urine or lose track of the amount of fluids ingested. Daily weights are a more precise method of monitoring changes in fluid balance. A change of 1 kg (2.2 lb) is equivalent to 1 L (1000 mL) of fluid. Patients are weighed at the same time each day with the same scale and in the same clothes. Daily weights can be initiated by the nurse for any patient considered at high risk for fluid imbalances.

Edema

Edema is a significant and visible indication of fluid volume excess. Edema is usually found in the dependent areas of the body. For ambulatory patients or those who spend time sitting in a chair, edema is most prominent in the ankles and feet. For patients who are bedridden, the edema is usually localized in the sacral area.

Pitting edema is characterized by a lasting indentation in the skin when pressure is applied. To assess edema in the lower extremities, press a finger to the lower tibia and behind the medial malleolus. The edema is graded on a 4+ scale and is based on the depth of the indentation:

1+	Slight indentation (2 mm); mild indentation returns to normal fairly quickly
2+	Deeper indentation (4 mm); indentation lasts longer
3+	Deep indentation (6 mm); indentation lasts several seconds
4+	Very deep indentation (8 mm); indentation remains several minutes

Brawny edema occurs when there is obvious swelling, but the tissue is too firm and hard to be indented. Although edema is a definitive indicator of fluid volume excess, it is also considered a fairly late indicator. The circulating volume increases as much as 30% before even 1+ edema is apparent.

2. List key assessment findings for R. A. and explain the underlying pathophysiology.

Skin Turgor and Mucous Membranes

Skin turgor can provide an indicator of fluid volume imbalance. With normal fluid balance, pinched skin quickly returns to normal on release. In fluid volume deficit, the skin remains pinched, or tented, after release. Skin turgor is usually assessed at the forehead, anterior chest, and medial forearm. It may not be accurate in older adults who have decreased skin elasticity from aging.

Visual inspection of the tongue and mucous membranes may reveal hydration. The tongue and mucous membranes are normally moist and pink. In severe fluid volume deficit, they are dry and sticky, with furrows in the tongue. It is common to see dry, cracked lips. [Table 39.8](#) lists assessments of hydration in other body systems.

TABLE 39.8**Assessment of Hydration**

BODY SYSTEM	ASSESSMENT
Neurologic	Chvostek sign (spasm of the facial muscle after tapping on the facial nerve) Trousseau sign (spasm of the muscles in the hand and wrist from pressure on the nerves of the upper arm) Deep tendon reflexes Tremors Confusion, agitation, coma
Cardiovascular	Jugular vein distention Electrocardiographic (ECG) waveforms Pulses Blood pressure
Respiratory	Abnormal lung sounds (crackles) Diminished lung sounds Respiratory rate
Musculoskeletal	Muscle strength
Elimination	Frequency and characteristics of stool (constipation or diarrhea) Nausea and vomiting Amount of urine output

Diagnostic Tests

Several laboratory tests are useful in identifying fluid, electrolyte, and acid-base imbalances. It is the nurse's responsibility to be knowledgeable about these tests and communicate the results to the primary care provider. Tests include serum electrolyte levels, renal function tests, and measurement of oxygen-carrying capacity. Urinalysis provides diagnostic information regarding fluid balance. [Chapter 34](#) discusses the specific tests and their diagnostic function.

Diagnostic Testing for Fluid and Electrolyte Imbalance

Several laboratory tests are available to determine fluid and electrolyte imbalances. [Table 39.9](#) lists the diagnostic tests used for evaluating fluid and electrolyte balance.

TABLE 39.9**Diagnostic Tests for Fluid and Electrolyte Balance**

LABORATORY TEST	INFORMATION PROVIDED
Levels of serum electrolytes, including sodium, potassium, magnesium, calcium, chloride, and phosphate	Direct information on extracellular levels and indirect information on intracellular levels of the electrolytes.
Blood urea nitrogen (BUN), creatinine	Indicates renal function.
Serum osmolarity	Information on hydration status; useful in managing fluid requirements.
Red blood cells, hemoglobin, hematocrit	Indicates oxygen-carrying capacity. Hematocrit levels can be influenced by fluid volume, can be diagnostic of fluid volume deficit or fluid volume excess.
Levels of serum albumin	Indicates colloid oncotic pressure capability.
Urinalysis	
pH	Information about the hydrogen ion concentration in the urine. The pH increases or decreases based on the body's acid-base balance.
Specific gravity	Increases when fluid volume is concentrated and is low with fluid volume excess.
Urine osmolarity	Reflects solute concentration of the urine. Urine osmolarity is increased in fluid volume deficit and decreased in fluid volume excess.

Arterial Blood Gases

Measurement of **arterial blood gases (ABGs)** provides essential information on a patient's acid-base balance and oxygenation status (Table 39.10). These test results help evaluate respiratory function and determine acid-base balance. Interpretation of ABGs requires a systematic approach, keeping in mind the following normal values:

TABLE 39.10**Arterial Blood Gas Results for Acid-Base Imbalances**

ACID-BASE IMBALANCE	pH	PaCO ₂	HCO ₃ ⁻
Respiratory acidosis	↓	↑	Normal
Respiratory alkalosis	↑	↓	Normal
Metabolic acidosis	↓	Normal	↓
Metabolic alkalosis	↑	Normal	↑

↓, Decreased value; ↑, increased value.

pH	7.35 to 7.45
PaCO ₂	35 to 45 mm Hg
HCO ₃ ⁻	21 to 28 mEq/L
PaO ₂	80 to 100 mm Hg
O ₂ saturation	95% to 100%

The first step in interpreting ABGs is to examine the oxygenation status by examining the PaO₂ and O₂ saturation values. Oxygen saturation is the amount of O₂ bound to hemoglobin. It accounts for 97% of the oxygen molecules. As oxygen enters the bloodstream from the alveoli in the lungs, it is bound until all the hemoglobin is fully saturated. The PaO₂ represents the free-floating oxygen molecules. In situations of **hypoxemia** (decreased oxygen concentration in arterial blood), the PaO₂ decreases:

- PaO₂ of 60 to 80 mm Hg: Mild hypoxemia
- PaO₂ of 40 to 60 mm Hg: Moderate hypoxemia
- PaO₂ less than 40 mm Hg: Severe hypoxemia

The second step is to examine the pH and determine whether the value falls within the normal range. If the pH is less than 7.35, there is an underlying acidosis. If the pH is greater than 7.45, the imbalance is alkalotic. The imbalances are caused by a respiratory or metabolic disorder. An underlying compensatory mechanism may be the reason that the pH is normal.

The third step is to examine the PaCO₂ and HCO₃⁻ values to determine whether the underlying disorder is metabolic or respiratory. If the PaCO₂ is abnormal and the HCO₃⁻ is normal, the imbalance results from a respiratory problem. If the PaCO₂ is normal and the HCO₃⁻ is abnormal, there is a metabolic disorder. In respiratory disorders, there is an inverse relationship between the pH and the PaCO₂ values.

The fourth step in interpreting ABGs is to determine whether compensation is occurring. When acid-base imbalances occur, the body attempts to compensate to keep the pH within the normal range ([Table 39.11](#)). Compensation can make it more difficult to interpret the ABG results. The PaCO₂ and HCO₃⁻ may be abnormal, and the pH may be normal. If the pH value is in the normal range, it tends to be near the upper or lower end of the range and provides a clue to the underlying problem. For example, a pH of 7.36 is considered normal but is on the

acidotic end. Examine the PaCO_2 and HCO_3^- values for an explanation of the imbalance.

TABLE 39.11
Compensated Acid-Base Imbalances

ACID-BASE IMBALANCE	pH	PaCO_2	HCO_3^-
Compensated respiratory acidosis	On the ↓ side of normal	↑	↑
Compensated respiratory alkalosis	On the ↑ side of normal	↓	↓
Compensated metabolic acidosis	On the ↓ side of normal	↓	↓
Compensated metabolic alkalosis	On the ↑ side of normal	↑	↑

↓, Decreased value; ↑, increased value.

- Analyze the R. A.'s arterial blood gas results, and identify factors contributing to the results.

Factors Affecting Fluid, Electrolyte, and Acid-Base Balances

In assessing an individual for potential fluid, electrolyte, and acid-base imbalances, several factors should be considered, including age, stress, surgery, weight, and medical disorders. Infants are more susceptible to fluid imbalances because their higher metabolic rate creates more toxins, which require additional water to excrete. Their kidneys are not mature, and the ability to concentrate urine is not fully developed. Infants have a greater ratio of body surface area to volume, and more water is lost through evaporation. As a person ages, the thirst sensation tends to decrease. Older adults often drink less fluid than desirable.

Aldosterone production with associated extracellular fluid retention is increased in stress. It leads to increased ADH secretion, which decreases renal excretion of water. Total body fluid is disproportionate to body weight in people who are obese.

Surgery can alter fluid balance in several ways. Preoperatively, patients usually are ordered to have nothing by mouth (NPO). It is common to use cathartics or enemas in preparation for surgery.

Intraoperatively, there is an increase in blood loss due to surgery and an increase in insensible fluid loss because the internal structures are exposed to air. Postoperatively, the stress of surgery increases ADH production; there is drainage of body fluids from nasogastric tubes or wounds and postoperative vomiting.

Medical conditions that can affect homeostasis include cardiac, hepatic, renal, and respiratory disorders. When cardiac output decreases (i.e., heart failure), blood pressure decreases. This leads to an increased secretion of aldosterone and ADH, causing retention of excess fluid. Patients with liver failure have decreased plasma levels of albumin, which leads to fluid moving out of the intravascular space and into the interstitial space. **Ascites** is an abnormal collection of fluid in the peritoneal cavity. People with impaired renal function are at a higher risk for fluid and electrolyte imbalances because of the decreased ability to regulate excretion and reabsorption. They are more likely to retain metabolic waste products, which are normally acidic, making these patients more prone to metabolic acidosis. In COPD, the damage to the alveoli limits gas exchange, which leads to decreased oxygen levels and higher circulating levels of carbon dioxide. Chronic respiratory acidosis results.

◆ LO 39.4 Nursing Diagnosis

The information that the nurse gathers from the assessment determines the appropriate nursing diagnoses for the patient. Selection of nursing diagnoses related to fluid, electrolyte, and acid-base balance is based on the following considerations:

- Actual fluid imbalances
- Possible complications of fluid and electrolyte imbalances
- Conditions that lead to fluid, electrolyte, and acid-base imbalances

The goal for nursing is to prevent imbalances whenever possible. This includes ongoing assessment and instruction to patients, families, and other health care providers on adequate fluid intake and dietary requirements of electrolytes. The following are examples of International Classification for Nursing Practice (ICNP) nursing diagnoses:

Fluid Retention

- Supporting Data: Pulse 116 and bounding, respirations 32 and labored, 3+ pitting edema in the feet, crackles in lungs, weight gain

Fluid Imbalance

- Supporting Data: Nausea and vomiting, output greater than intake, dry mucous membranes, weight loss, excessive thirst

Dehydration

- Supporting Data: Fluid volume loss, weak pulse, tachycardia, thirst

The nurse should remember that fluid and electrolyte imbalances affect function in other areas. Some nursing diagnoses pertaining to a few of the complications that can occur with fluid and electrolyte imbalances are *Impaired Cardiac Output*, *Acute Confusion*, *Risk for Injury*, and *Impaired Skin Integrity*.

4. Identify two nursing diagnoses appropriate for R. A. Include supporting data.

◆ LO 39.5 Planning

Patient goals are the measures a nurse uses to determine effectiveness of the plan of care (Table 39.12). The goals provide a description of desired outcomes based on the identified nursing diagnoses. For patients who are at risk for or have imbalances, the goals are based on returning to or maintaining normal balance:

TABLE 39.12
Care Planning

ICNP NURSING DIAGNOSIS WITH SUPPORTING DATA	NURSING OUTCOME CLASSIFICATION (NOC)	NURSING INTERVENTION CLASSIFICATION (NIC)
<i>Fluid Retention</i> Pulse 116 and bounding Respirations 32 and labored, 3+ Pitting edema in the feet Crackles in lungs Weight gain	<i>Fluid balance</i> Stable body weight	<i>Fluid monitoring</i> Monitor weight

From Butcher, H. K., Bulechek, G. M., Dochterman, J.M., et al. (Eds.) (2018). *Nursing interventions classification (NIC)* (7th ed.). St. Louis, MO: Mosby; Moorhead, S., Swanson, E., Johnson, M., et al (Eds.) (2018). *Nursing outcomes classification (NOC)* (6th ed.). St. Louis, MO: Mosby. ICNP is owned and copyrighted by the International Council of Nurses (ICN). Reproduced with permission of the copyright holder.

- Patient will exhibit no pitting edema within 48 hours.
- Patient's mucous membranes will be moist by the end of the shift.
- Patient will have normal pulse rate before discharge.

The conceptual care map for R. A. can be found at <http://evolve.elsevier.com/YoostCrawford/fundamentals/>. It is partially

completed to indicate how to use the map as a learning tool.
Complete the nursing diagnoses using the example conceptual care maps shown in [Chapters 8](#) and [25 to 33](#).

◆ LO 39.6 Implementation and Evaluation

Caring for patients with fluid, electrolyte, and acid-base imbalances involves monitoring fluid balance and implementing interventions designed to maintain fluid and electrolyte balance. Replacement of fluids and electrolytes through the use of IV solutions is commonly used to improve fluid and electrolyte balance.

Monitoring Fluid Balance

The nurse's role in monitoring fluid balance is to evaluate the impact of disease or effect of treatment on an ongoing basis. Vital signs, intake and output measurement, and daily weights provide valuable information about fluid and electrolyte status. Vital signs are assessed on a regular basis, which is at least every 4 hours for patients with fluid and electrolyte imbalances. When the imbalances are severe and aggressive treatment is required, vital signs are monitored on a more frequent basis.

Daily weights are compared with previous findings to determine changes in fluid status. Depending on the situation, a change in weight is a desired outcome or a significant concern.

Intake and output measurements are usually reviewed at the end of 8 hours and 24 hours. For patients with normal fluid balance, the intake should equal the output at the 24-hour mark. Positive fluid balance (i.e., intake greater than output) can be a desired outcome in patients with fluid volume deficits or can indicate fluid volume excess. It is the nurse's responsibility to evaluate the significance of the daily measurement of intake and output.

It is common for measurement of vital signs, intake and output, and daily weights to be delegated to unlicensed assistive personnel. However, it is important for the nurse to be aware of these assessment findings to evaluate effectiveness of prescribed interventions and nursing care.

Blood tests are often ordered to monitor fluid, electrolyte, and acid-base balance and to assess the effectiveness of prescribed treatments. These tests are commonly ordered to be drawn on a daily or more frequent basis. The nurse is responsible for confirming that the ordered tests have been completed and the results are communicated to the appropriate health care providers.

Maintaining Fluid and Electrolyte Balance

Depending on the situation, maintaining fluid and electrolyte balance may require increased intake or restriction of fluids and certain electrolytes. The nurse is essential in determining the appropriate interventions on the basis of the underlying disorder and assessment findings.

Restricting Fluid Intake

When a patient is experiencing severe fluid volume excess, the primary care provider may decide to restrict the amount of fluid the patient takes in. This situation is commonly seen in patients with heart failure and chronic renal failure. Normally, the order indicates the amount of fluid to be consumed in a 24-hour period (e.g., 1000 mL). It is up to the nurse to divide that total into smaller amounts throughout the day. The normal recommendation is to use 50% of the amount during the day, when the patient is most active and consumes two meals. The amount is then further divided into fluid with meals and fluid available between meals and with medication administration. For example, a 1000-mL fluid restriction may be divided as follows:

Breakfast	200 mL
Lunch	200 mL
Dinner	200 mL
Between meals and medications	300 mL
Night shift medications	100 mL

If the patient has IV fluids running, the fluids need to be subtracted from the ordered fluid restriction; the remaining oral fluid is then divided throughout the 24-hour period. When developing the fluid breakdown, it is essential to involve the patient and incorporate fluid preferences when possible to facilitate patient cooperation. Several strategies can assist in patient cooperation with the restriction:

- Explain the purpose of the restriction. Make sure the patient understands that ice chips, Jell-O, and ice cream are considered fluids and are included.
- Offer fluids frequently in small amounts to prevent dry mouth. Using a smaller 4- or 6-oz glass offers the impression of more fluid. Give the patient a choice in fluid preferences.

- Instruct the patient to avoid overly sweet or salty foods. Both stimulate the thirst sensation.
- Offer small amounts of ice chips. Remember that 100 mL of ice chips is approximately 50 mL of water.
- Encourage the patient to assist in maintaining the intake and output record. This helps the patient feel more in control of the situation.

Restricting Electrolyte Intake

Patients with fluid volume excess may need to restrict sodium intake to prevent worsening of the fluid excess. Sodium restrictions are classified as mild, moderate, or severe:

- Mild restriction is 3000 to 4000 mg/day; it is indicated as “no added salt.”
- Moderate restriction is 2000 mg/day; it is indicated as the need to consume foods with a low-sodium content.
- Severe restriction is 500 mg/day.

It is important to instruct the patient to avoid using the salt shaker. Salt substitutes or herbal seasonings are used to enhance the flavor of food. Canned foods and processed or cured meats are avoided because of their high sodium content. Encourage the patient to buy fresh or frozen foods whenever possible. Make sure the patient knows how to read and interpret nutrition labels for the amount of sodium per serving. Several over-the-counter medications contain high amounts of sodium. It is important to read the label to determine the amount of sodium contained in the medicine.

Other electrolytes may need to be restricted based on the patient's medical condition. As part of the plan of care, the nurse instructs the patient about the dietary restrictions and common foods to avoid.

Oral Replacement of Fluids and Electrolytes

In situations of fluid volume deficit, the patient may need to increase the amount of fluids taken orally. It is the nurse's responsibility to

encourage fluid intake and monitor the patient's response to the increased fluids.

Fluid Replacement

A patient may need to increase fluid intake to offset losses (e.g., mild to moderate diarrhea). This is especially important when the goal is to decrease or eliminate the need for IV fluids.

The same process is used to encourage fluids as when restricting intake. At least 50% of the fluid is taken during the day. The patient avoids drinking large amounts in the evening; it may interrupt sleep with frequent urination. Offer a variety of fluids, and ask the patient's preference. Beverages with caffeine have a diuretic effect and are avoided. Keeping a pitcher of water on hand and within easy reach encourages the patient to drink. For patients who are unable to pour the water, a glass of water is offered every time the nurse enters the room. Encouraging the patient to participate in the planning and involving the patient and family in keeping track of fluid intake helps meet the desired outcome.

Electrolyte Replacement

In normal situations, the body is able to extract the needed electrolytes from the food consumed. Under certain conditions, it is necessary to supplement dietary intake. The two most commonly prescribed supplements are potassium and calcium.

When a patient is prescribed a potassium-wasting diuretic, such as loop diuretics, it is common for the primary care provider to prescribe a potassium supplement to replace what is excreted. Several points should be included in the teaching plan, as follows:

- Explain the importance of taking the supplement daily as prescribed.
- Taking a supplement with juice can mask an unpleasant taste of the medication.
- A change in diuretic therapy may require a change in the potassium dose.
- Many patients use salt substitutes as part of a sodium-restricted diet. It is important to teach that these salt substitutes often use potassium instead of sodium and must be used with caution.

Calcium is essential for bone strength, neuromuscular functioning, and blood clotting. Inadequate intake of milk, milk products, and vitamin D prompts the need for calcium supplements. According to the [National Institutes of Health \(2018\)](#), the recommended dietary allowance for adults between the ages of 19 and 70 is 1000 mg/day. For adults older than 70, the recommended amount increases to 1200 mg/day. Those taking calcium supplements should increase fluid intake to at least 2500 mL/day to prevent constipation and reduce the risk for kidney stones.

Excessive loss of fluids and electrolytes, especially sodium and potassium, can occur with strenuous exercise or severe diarrhea. It is recommended that athletes consume fluid before, during, and after strenuous exercise ([Thomas, Erdman, & Burke, 2016](#)). Sports drinks such as Gatorade contain fluid and electrolytes and are used during and after strenuous exercise to replace what is lost in perspiration. Pedialyte is an electrolyte solution designed specifically for children and is used to replace losses from diarrhea and prevent dehydration.

Intravenous Therapy

Patients are often unable to maintain normal fluid balance because of disease, surgery, or trauma. As a result, it is common to replace needed fluids directly into the bloodstream through IV administration. IV fluids are considered medications and are given with the same caution and rights used for medication administration ([Box 39.6](#)). There are several advantages to using the IV route. It provides immediate access for fluid and electrolyte maintenance or replacement; medications given intravenously have a much faster onset and more predictable effect. The IV route provides access for supplemental or total nutrition replacement and allows transfusion of blood and blood products to increase oxygen-carrying capacity and reestablish normal oncotic pressure. Concerns related to IV therapy administration are outlined in [Box 39.7](#).

Box 39.6

Ethical, Legal, and Professional Practice

Administration of Intravenous Fluids

Intravenous (IV) fluids are considered medications. Before and during IV therapy, check the Rights of medication administration:

- *Right patient:* Use two unique identifiers, such as patient barcode, patient hospital identification number, patient name, date of birth, picture, or verification from family member. Room and bed number should not be used.
- *Right solution (medication):* Several IV solutions have similar names (e.g., 0.33% NS and 0.9% NS). Make sure the correct solution is infusing.
- *Right rate (dose):* Verify that the IV is infusing at the ordered rate.
- *Right route:* Certain IV fluids, such as total parenteral nutrition (TPN), are too hypertonic to be administered through a peripheral site without causing necrosis.
- *Right time:* If infusing correctly, the IV infusion should finish at a designated time.
- *Right documentation:* IV therapy documentation is ongoing as long as the IV solution is infusing, and it includes the assessment of the IV site, solution, rate, and patient tolerance.

The nurse should also assess the:

- *Right reason:* The nurse should understand and be able to educate the patient on the rationale for the use of the particular IV solution.
- *Right response:* The nurse should monitor the patient for the desired response and any unwanted complications of IV therapy such as fluid overload.

Box 39.7

Interprofessional Collaboration and Delegation

Nursing Responsibilities for Intravenous Therapy

- In many states, licensed practical/vocational nurses (LPN/LVNs) with intravenous (IV) training have the authority to perform many of the functions in IV therapy, including adjusting flow rates, changing IV solutions, administering IV medications, and changing IV tubing and dressings. These functions vary across states. Specifics can be found in the state nurse practice act.
- The registered nurse (RN) is responsible for ensuring that these functions are performed only by LPN/LVNs who have received this

specialized training.

- The RN is ultimately responsible for assessing the patient and evaluating the effects of IV therapy.

Intravenous Solutions

The type of fluid used and the rate at which it is infused depend on the purpose and desired outcomes. IV fluids are classified broadly as crystalloids or colloids. Crystalloids are solutions with small molecules, usually electrolytes that are able to pass through cell membranes. These fluids are used primarily for fluid and electrolyte maintenance and replacement.

Crystalloids are further categorized based on the tonicity of the fluid compared with normal blood plasma: hypotonic, isotonic, or hypertonic. Tonicity of blood plasma is 290 mOsm/L. IV solutions with a tonicity significantly less than 290 mOsm/L are hypotonic. Hypotonic fluids lower the osmolarity of blood plasma and cause fluid to shift into the cell. These fluids are used to treat hypernatremia or severe dehydration. Continued use of hypotonic fluids can lead to intracellular swelling or water intoxication. Swelling of brain cells causes increased intracranial pressure.

Isotonic solutions have a tonicity essentially the same as that of blood plasma. These types of fluids increase intravascular volume but do not cause fluid shifts in or out of the cell. When not monitored closely, isotonic fluids can lead to circulatory overload.

Hypertonic fluids have a tonicity that is markedly higher than 290 mOsm/L. These solutions increase the osmotic pressure of plasma and force fluids to move out of the cell and into the bloodstream. This can lead to cellular dehydration and fluid volume overload. Hypertonic solutions can be especially irritating to peripheral veins and the sites must be closely monitored.

The choice of IV fluid is based on the purpose of the therapy. It can contain any or all of the following substances: glucose (in the form of dextrose), sodium, bicarbonate, and chloride. Dextrose is a common element of IV solutions and can provide additional calories for energy. It is usually ordered in 5% or 10% concentrations. An IV solution of 5% dextrose in water (D₅W) is an isotonic solution before it enters the body. The dextrose is quickly broken down, leaving a hypotonic solution circulating. Because dextrose is a monosaccharide, patients should be monitored for hyperglycemia.

Safe Practice Alert

Continued use of 5% dextrose in water (D₅W) as a primary infusion can lead to water intoxication or intracellular fluid excess. After the dextrose enters the bloodstream, it is quickly metabolized, leaving only free water, a hypotonic solution.

Saline solutions contain sodium and chloride in various amounts. Normal saline consists of 0.9% NaCl and is considered isotonic. Normal saline is used for replacement of fluid, sodium, and chloride. It is the only fluid used to begin or finish blood transfusions.

Safe Practice Alert

Prolonged use of normal saline can lead to hypernatremia and circulatory overload.

Normal saline solutions have various amounts of NaCl, ranging from 0.33% to 3%. Saline solutions that have more than 0.9% NaCl are hypertonic, and those that have less than 0.9% are hypotonic. Saline is often combined with dextrose to provide calories along with fluid and electrolyte replacement. This combination solution is considered hypertonic.

Lactated Ringer solution contains sodium, potassium, calcium chloride, and lactate (which metabolizes to bicarbonate) and most closely resembles blood plasma. It is considered a balanced electrolyte solution and is often used as a replacement solution after surgery or trauma. [Table 39.13](#) lists common IV solutions, tonicity, and nursing considerations.

TABLE 39.13**Common Intravenous Solutions**

INTRVENOUS SOLUTION	NURSING CONSIDERATIONS
Hypotonic	
0.33% NS	Provides sodium, chloride, and free water. Allows kidneys to select amount of electrolyte to retain or excrete.
0.45% NS	Fluid replacement for clients who do not need extra glucose (diabetics). Useful for establishing renal function. Not used as NaCl replacement therapy. Use cautiously because may cause cardiovascular collapse or increased intracranial pressure.
Isotonic	
D ₅ W	Considered isotonic but becomes free water after dextrose is metabolized; then acts as a hypotonic solution. Because it does not contain sodium, continued use can lead to hyponatremia. Useful in IV medication administration. Can cause hyperglycemia.
0.9% NS	Replaces losses without altering fluid concentrations. Commonly used to reestablish normal extracellular fluid levels in patients with hypovolemia. Helps with NaCl replacement but continued use can lead to hypernatremia/hyperchloremia. Do not use in patients with heart failure, edema, or hypernatremia.
D ₅ 0.2% NS	Useful for maintenance of fluids when less sodium is required. The dextrose provides approximately 170 calories/L.
Lactated Ringer solution	Most closely resembles blood plasma. Contains sodium, potassium, calcium, chloride, and lactate. Used when there is loss of fluid and electrolytes, as in burns, severe diarrhea, or during surgery. Do not use in patients with renal or liver disease.
Hypertonic	
D ₅ 0.45% NS	Commonly used to treat hypovolemia and maintain normal fluid balance, especially in the postoperative period.
D ₅ 0.9% NS	Used as replacement fluid. Provides calories, sodium, and chloride. Prolonged use can lead to hypernatremia. Do not use in patients with cardiac or renal failure. Monitor for fluid volume overload.
D ₅ LR	Same content as lactated Ringer solution but adds calories with the dextrose. Useful when patient's caloric intake is reduced. Monitor for fluid volume overload.
3% NS	Used to treat severe hyponatremia. Administered in an intensive care setting where the patient can be closely monitored.

D₅, 5% dextrose; NS, normal saline; W, water.

Safe Practice Alert

To avoid or treat hypokalemia, IV potassium is often ordered to be added to a continuous IV infusion. IV potassium is always diluted; usually it is added to an IV bag in the pharmacy. The nurse must *never* administer IV potassium as a push or bolus medication because it can cause severe cardiac arrhythmias and death.

Colloids, also known as plasma expanders, are solutions that contain protein or starch. The particles remain intact in the solution and are unable to pass through the capillary membrane. They are used to reestablish circulating volume and oncotic pressure. Examples of colloids include albumin, dextran, Plasmanate, and hetastarch. Blood and blood components are also considered colloids and are discussed later.

Intravenous Sites

When a patient requires IV therapy, there are several aspects to consider. What are the purpose (i.e., replacement or maintenance) and expected duration of therapy? Key considerations include the patient's age, diagnosis, health history, and condition of the veins. All of these factors determine whether IV therapy is administered through a peripheral vein or a larger, central vein. Peripheral sites are used when IV therapy will be short term or intermittent or to maintain vascular access with the use of an intermittent infusion device. An **intermittent infusion device** is a saline lock or PRN adapter that allows periodic or emergency venous access. This provides IV access for intermittent infusions or emergency medications. These devices are sometimes capped or have a port that is cleansed before use.

When selecting an appropriate vein for venipuncture, the nurse considers the location and condition of the vein and the purpose and duration of the therapy. The sites most commonly used with peripheral IV therapy are located in the hands and arms and include the cephalic, basilic, accessory, upper cephalic, median basilic, median cubital, and the metacarpal veins of the hands (Fig. 39.10). Foot veins are not used in adults because of the risk for thrombophlebitis. In older adults, venous return from the feet and legs may be compromised, causing inconsistent administration of fluids and medications. However, the veins of the feet are often used for infants and children. Scalp veins are a common site for newborns and infants.

FIGURE 39.10 Veins of the hand and arm. (From Ignatavicius, D. D., & Workman, M. L. [2016]. *Medical-surgical nursing: Patient-centered collaborative care* [8th ed.]. St. Louis: Elsevier.)

It is important to select a site with a vein that is easily seen and palpable for venipuncture that can support the duration of therapy (Infusion Nurses Society [INS], 2016). Selecting a more distal site, if possible, may help preserve more proximal sites for future insertions. Avoid areas at the wrist and elbow. Flexion of these joints may obstruct IV flow. Venipuncture is contraindicated on an extremity that has been compromised due to surgery (e.g., mastectomy) or injury or if there is a dialysis graft in place.

The condition of the vein should be carefully considered. Avoid areas of prior bruising or **phlebitis** (inflammation of the vein). The vein of choice should feel soft and full, be splinted by bone, and be easily palpated when a tourniquet is applied. If no veins can be found or palpated, use a vein visualization device or consider ultrasound-guided insertion to improve chances for success. The recommendation is that no more than two attempts be made per clinician and four total attempts per patient before consulting with the provider for possible alternatives (INS, 2016).

The purpose of IV therapy also influences vein selection. Large veins are preferred when large amounts of fluid need to be infused rapidly or if the fluids are highly viscous. When administered through a larger

vein, hypertonic fluids and caustic/irritating medications are less likely to cause phlebitis. Documentation of IV therapy in the electronic health record follows a standardized format ([Box 39.8](#)).

Box 39.8

Evidence-Based Practice and Informatics

Standardized Documentation of Intravenous Therapy in the Electronic Health Record

- It is important for all documentation of intravenous therapy to follow a standardized format in the electronic health record (EHR).
- All start and stop times for continuous intravenous (IV), IV bolus, or IV antibiotics should be documented. This is often done using barcode scanning technology.
- Smart infusion pumps with preprogrammed safety alerts have features such as error reduction software, which can assist with calculating dose and delivery rates to prevent medication errors. However, clinicians must still use professional judgment and adhere to established standards of care and standard operating procedures when using this technology ([Canadian Agency for Drugs and Technologies in Health, 2014](#)).
- A second nurse should independently witness the dose/rate/pump settings for high-risk medications such as heparin and insulin ([Institute for Safe Medication Practices, 2018](#)).

Intravenous Catheters

When venous access is necessary to administer fluids or medications, the IV catheter provides that access. The type of catheter chosen depends on the length of time the access is needed, the type of medication or fluid to be administered, and the age and overall health of the patient. The nurse selects the site and catheter that can provide the least risk for complications.

Peripheral Catheters

IV catheters come in several types and sizes. IV catheters are sized by the diameter of the needles, which is known as gauge. The smaller the diameter, the larger is the gauge. For example, a 16-gauge needle has a

larger diameter than a 24-gauge needle. Selection of the appropriate gauge is important for effective therapy (Table 39.14).

TABLE 39.14
Peripheral Intravenous Catheters

NEEDLE GAUGE	COMMON USES
16-18 gauge	Trauma Surgery Rapid infusion of fluids or blood
20-22 gauge	General and intermittent infusions Blood transfusions
24 gauge	General and intermittent infusions Children and the elderly May be used for blood transfusions in adults with very small veins (INS, 2016; Stupnycky, Smolarek, Reeves et al., 2014)

The nurse selects the smallest size needed for IV therapy. The three basic types of peripheral access catheters are as follows:

- Over-the-needle catheter (ONC), also known as an Angiocath, is a polyurethane or Teflon catheter with a needle stylet inside. After needle insertion, the catheter is threaded into the vein, and the stylet is removed
- Winged infusion needle, also known as a butterfly needle, is a smaller needle commonly used with children and elderly patients for short-term use. The short, steel needle has two flexible wings instead of a catheter hub. The needle is attached to short, flexible extension tubing. The wings are pinched together during insertion and then taped flat to secure the needle.
- Midline catheters are used for longer-term IV therapy and are inserted by specially trained nurses through a peripheral vein using ultrasound guidance. These catheters are 3 to 8 inches long and are usually inserted in the antecubital area, with the tip resting in the cephalic or basilic vein, right below

the axilla. They are considered inside-the-needle catheters because the catheter remains inside the needle or introducer during insertion. After the catheter is threaded through the vein, the needle is removed. Midlines are used when IV therapy is expected for less than 2 weeks; if longer therapy is anticipated, a peripherally inserted central catheter (PICC) may be a more appropriate choice. Midlines last longer and have lower rates of phlebitis than short peripheral catheters, but have higher rates of non-life-threatening complications compared to PICC lines, and so careful consideration should be made based on individual patient needs (O'Grady, Alexander, Burns, et al., 2011; Xu, Kingsley, DiNucci, et al., 2016).

5. Identify five priority interventions for R. A. and provide the rationales.

Central Venous Catheters

Another type of IV access frequently used is the **central venous catheter (CVC)** or central venous access device (CVAD). The CVC (Fig. 39.11) is inserted into a major vein in the arm or chest, and the tip lies in the superior vena cava, outside the right atrium. The CVC has several advantages. It allows rapid infusion of large amounts of fluid; irritating medications and hypertonic solutions (e.g., TPN) are rapidly diluted, reducing the risk for phlebitis; it can be used for blood draws for patients needing frequent laboratory monitoring; and it allows monitoring of central venous pressure. There are several types of CVCs:

FIGURE 39.11 Tunneled central venous catheter. (From Lewis, S.L., Bucher, L., Heitkemper, M. M., et al. [2017]. *Medical-surgical nursing: Assessment and management of clinical problems* [10th ed.]. St. Louis: Elsevier.)

- Peripherally inserted central catheter (PICC)
- Nontunneled CVC
- Tunneled CVC
- Implanted port

The **peripherally inserted central catheter (PICC)** has become very common in patients requiring long-term IV therapy because it can be inserted in a vein in the arm and has lower rates of complications compared to other types of CVCs. It can be inserted by a specially trained nurse and can be left in indefinitely as long as there are no complications (Association for Professionals in Infection Control and Epidemiology [APIC], 2015). The catheter is inserted in the cephalic or basilic vein or antecubital space and threaded up until it rests in the superior vena cava outside the right atrium. Strict sterile technique is used during insertion and maintenance care of PICC lines to prevent central-line associated bloodstream infection (CLABSI). The PICC device often has multiple lumens and can simultaneously infuse incompatible medications, fluid, blood, or total parenteral nutrition (TPN). They require regular assessment, flushing, and sterile dressing changes per facility policy (see [Skill 39.3](#)). PICC lines are ideal devices for patients who require long-term antibiotics, or other medications, especially patients who have a history of failed or difficult IV access with short peripheral catheters. It is often the nurse who must advocate

to the provider if he or she thinks the patient might benefit from a PICC line.

The nontunneled CVC is commonly used in patients who require short-term but extensive IV therapy (e.g., multiple IV medications), TPN, or recurring blood transfusions. The CVC is inserted by the physician, usually at the bedside, using the subclavian vein. The Centers for Disease Control and Prevention advises to avoid using the jugular and femoral veins because of the higher incidence of catheter-related infections (CDC, 2011). These catheters often have double or triple lumens, allowing for simultaneous administration of incompatible medications, fluids, and TPN. They are designed for short-term therapy (days to weeks) and are associated with a high risk for complications, including catheter-related infections, pneumothorax, and pulmonary embolism.

Tunneled CVCs (see Fig. 39.11) are used for lifelong or long-term IV therapy such as TPN, chemotherapy, and dialysis use. These catheters are inserted into the subclavian or jugular vein and then pulled through (i.e., tunneled) the subcutaneous tissue in the chest wall before exiting the skin. They are initially sutured into place, but they also have a cuff that the subcutaneous tissue eventually adheres to, holding the catheter in proper position.

Another device is an implanted port, or MediPort, which is surgically placed in the chest wall and can be used for long-term IV therapy that is continuous or intermittent (e.g., chemotherapy, hemophilia, sickle cell disease). A tunneled CVC is attached to a port or access device that has been implanted into the subcutaneous tissue in the chest wall, leaving no visible signs of the device. To access the site for IV infusions, the nurse inserts an angled or Huber needle through the skin and into the port. After the infusion is complete, the needle is removed, leaving a closed system (Box 39.9). According to the CDC (2011), implanted ports have the lowest incidence of catheter-related infections. An implanted port should be accessed at least monthly to ensure patency with either a heparin or saline flush.

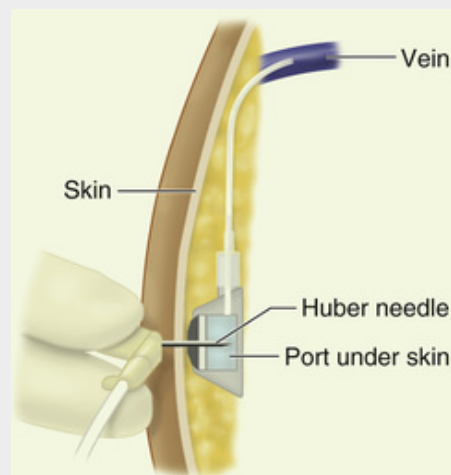

Box 39.9

Nursing Care Guideline

MediPort: Access, Dressing Changes, and Care

Background

- A MediPort (sometimes called a portacath) is a central venous access device with a subcutaneous injection port that is surgically implanted in the upper chest.
- It is used for long-term intravenous access, usually for oncology or hematology clients.
- Mediports have a lower risk for complications, including catheter-related bloodstream infections (CRBSIs) among vascular access devices (VADs), because the tip of the catheter ends in a large vein and the port is not always accessed (i.e., not open to air).
- The animation “[Accessing an Implantable Port](#)” shows the procedure for using this type of VAD.

Procedural Concerns

- Follow strict sterile technique to prevent CRBSIs.
- If a dressing change is needed, follow [Skill 39.3](#).
- Accessing a MediPort involves the following steps:
 - Cleanse the site from the center to 2 inches around the port with a chlorhexidine preparation.
 - Prime the tubing connected to the Huber needle with sterile saline and keep the syringe connected.
 - Hold the Huber (non-coring) needle at a 90-degree angle (perpendicular) to the port.
- For insertion:
 - Hold the port between the thumb and index finger.
 - Fully insert the needle until it meets with resistance and is at the back of the port before inserting fluids.

- Cover the Huber needle with sterile dressing per facility protocol, and reinforce it with tape at its edges. Date, time, and initial the dressing.
- Flush to assess the port's patency (see [Box 39.11](#)):
 - Use a 10-mL sterile syringe to flush it with 10 mL of the prescribed sterile fluid per facility policy. If port is not being used regularly, it should be flushed every 4 weeks to maintain it.

Documentation Concerns

- Document the site and catheter assessments.
- Include the type and size of needle used to access the port.
- Report the patency of the port and the type and quantity of solution used.
- Note any problems or patient discomfort with the procedure.

Evidence-Based Practice

- The [Infusion Nurses Society \(2016\)](#) recommends that the noncoring Huber needle be replaced every 7 days if continual access is needed.

Safe Practice Alert

After any central venous catheter is inserted, the nurse must ensure correct placement has been confirmed by radiographic (x-ray) examination before the first use.

Equipment

Before beginning an IV infusion, the nurse gathers and assembles the appropriate equipment. Because of the risk for catheter-related infections, the nurse uses sterile technique when assembling and initiating IV therapy. The equipment needed includes the IV solution bag or container, IV tubing, peripheral access needle or catheter, and flow-monitoring device. All packages are examined for expiration dates and for damage to or breaks in sterile packaging.

IV solutions come in sterile, prefilled plastic bags or, less commonly, glass containers with 50 to 1000 mL of solution. The smaller bags (50 to 250 mL) are used to administer medications, whereas the larger bags are

used for continuous infusions of fluids (Fig. 39.12). The solution container is checked for the following:

FIGURE 39.12 Intravenous solution bags. (Copyright Mosby's Clinical Skills: Essentials Collection.)

- The correct fluid as ordered by the primary care provider
- Fluid that is clear without evidence of contamination or leaks in the container
- An expiration date that has not passed (questionable IV solution is returned to the pharmacy)

The IV tubing, or administration set, connects the IV solution to the catheter. The tubing consists of an insertion spike, a drip chamber, tubing with at least one secondary port, a roller clamp and slide clamp, and a connection port or hub. The insertion spike and hub are covered with protective caps to maintain sterility. The caps remain in place until the equipment is ready to insert and use.

The drip chamber provides a prespecified amount of fluid per drop (i.e., drop factor). Common drop factors are 10, 15, and 20, known as *macrodrop*, or 60, known as *microdrop* (Fig. 39.13). For IV tubing with a drop factor of 10, 10 drops equals 1 mL of fluid. The drop factor is found on the outside of the package and is used to regulate IV flow rate. Macrodrop tubing is used for most IV infusions. Microdrop tubing is used for very slow infusions and in children and the elderly for whom

potential fluid overload is a concern. The roller clamp compresses the tubing to various degrees, allowing regulation of the IV flow rate. The slide clamp is used to completely occlude the IV tubing; it is not used to regulate IV infusion rates. Secondary ports are used to administer medications mixed in IV solutions, IV piggybacks, or IV push medications (see [Chapter 35](#)). When a glass container is used, vented IV tubing is needed for the infusion to flow smoothly. This type of tubing allows air to replace the fluid moving out of the container. Plastic bags collapse as the fluid moves through the IV tubing and do not require vented tubing.

FIGURE 39.13 (A and B) Different types of intravenous administration sets that make use of a macrodrip chamber. (C) An administration set that includes a microdrip chamber. (From Clayton, B. D., & Willihnganz, M. J. [2013]. *Basic pharmacology for nurses* [16th ed.]. St. Louis: Elsevier.)

After the supplies have been gathered, the IV tubing is flushed with solution before attaching it to the IV catheter, removing all air from the line to prevent an air embolus. At this point, the IV catheter is inserted

and the tubing is attached. The tubing is placed in the infusion pump, the roller clamp is opened, and the IV begins to flow. [Skill 39.1](#) reviews the procedure for starting a peripheral IV infusion.

When a continuous infusion is no longer needed but IV access is, an intermittent infusion device is attached ([Box 39.10](#)). These devices are known as saline locks or PRN adapters. When converting a continuous IV to a saline lock, the IV tubing is removed, and the adapter is attached. Some adapters come with extension tubing. It is important to flush the adapter with normal saline before attaching it to prevent an air embolism. The lock is flushed before and after each use, normally with sterile saline ([Box 39.11](#)).

Box 39.10

Nursing Care Guideline

Converting an Intravenous Line: Intermittent to Continuous, and Continuous to Intermittent Infusions

Background

- Conversion between continuous and intermittent intravenous (IV) infusions permits administration of intermittent medications and intermittent rehydration.
- This flexibility allows therapeutic interventions to be performed without limiting the patient's mobility, as with a continuous IV infusion.

Procedural Concerns

- Follow strict sterile technique to prevent catheter-related bloodstream infections (CRBSIs).
- Place sterile gauze under the connection hub:
 - This avoids contamination (i.e., maintains sterile technique).
 - The gauze keeps excess fluid away from the skin.
- Ensure all connection hubs and ports are sterile before any connections are made by wiping the port and ridges in a twisting motion with chlorohexidine or alcohol for at least 30 seconds.

- If there is any question about sterility of the IV tubing, discard the tubing and obtain a sterile replacement.
- To convert from an intermittent to a continuous infusion:
 - Flush the saline lock (see [Box 39.11](#)).
 - Connect the prepared IV tubing to the port while maintaining sterile technique.
 - Unclamp the IV tubing and extension tubing.
 - Start the infusion.
- To convert from a continuous to an intermittent:
 - Clamp the IV tubing and extension tubing.
 - Disconnect the IV tubing from the extension tubing.
 - Flush the saline lock (see [Box 39.11](#)).
 - Cap the IV tubing and saline lock with a sterile cap.

Documentation Concerns

- Document the patency of the line, date, and the type and amount of flush.
- Include the site assessment.
- Indicate whether fluids are being started or discontinued.
- Note any problems or patient discomfort with the procedure.

Evidence-Based Practice

- To prevent CRBSIs, many hospitals have begun using alcohol-impregnated caps on unused IV ports. Several recent studies have shown that this greatly reduces the number of CLABSIs in comparison with scrubbing the hub with alcohol alone ([Flynn, Rickard, Keogh, et al., 2017](#); [Sweet, Cumpston, Briggs, et al., 2012](#))
- A study by [Flynn et al. \(2017\)](#), concluded that a 5-second alcohol scrub was inadequate and that the ideal method of decontamination for needleless ports was scrubbing ports with chlorhexidine for 30 seconds.

Box 39.11

Nursing Care Guideline

Flushing an Intravenous Line

Background

- Flushing an intravenous (IV) line maintains the saline lock patency.
- Flushing keeps incompatible solutions separate and allows assessment of the IV line.

Procedural Concerns

- Use a prefilled, sterile saline syringe, or fill a syringe with the appropriate quantity of sterile saline solution for injection.
- Wipe the port with chlorohexidine or an alcohol wipe for at least 30 seconds.
- Wear clean gloves.
- Insert the blunt cannula of the saline syringe into the port on the extension tubing, or screw it into the port, depending on the equipment.
- Unclamp the extension tubing (a saline lock is clamped when not in use).
- Slowly inject the solution over 1 minute into the IV access port.
- Leave 0.5 mL of solution in the syringe so that air is not injected.
- Observe for leaking and swelling at the IV site and for resistance when pushing saline. If they are observed, stop the procedure, and discontinue the IV infusion.
- Reclamp the extension tubing.
- Remove the syringe, and discard per institutional policy and procedures.

(Copyright © Mosby's Clinical Skills: Essentials Collection.)

Documentation Concerns

- Document the patency of the line, the date, and the type and quantity of flush used.
- Include all site assessment information.
- Note problems or patient discomfort with the procedure.

Evidence-Based Practice

- Some nurses have been taught to push the saline flush, pause, and then repeat when flushing a vascular access device, whether it is a central or peripheral line. The [Infusion Nurses Society \(2016\)](#) states that the pulsating technique “may be effective at removing solid deposits” (p. 114).

Safe Practice Alert

Never use force when flushing a vascular access device (central or peripheral line) with normal saline. Attempting to force the flush may dislodge a clot that can become an embolism.

Flow Rate

Several factors can influence the flow rate: distance, patient position, catheter size, and tubing obstruction. The shorter the distance between the IV bag and IV catheter, the slower the IV infusion flows. To increase the flow, raise the bag to a higher level. Smaller-gauge catheters (e.g., 24 gauge) cannot infuse fluids quickly. For example, if the IV rate needs to be increased to 150 mL/hr, the nurse may need to insert a large-gauge catheter to accommodate the new rate. Make sure the tubing is not kinked or obstructed in any way. It is the nurse's responsibility to ensure that the IV solution infuses at the ordered rate.

A volume control device (i.e., Buretrol, Soluset) is often used for infants or children (Fig. 39.14). These devices prevent accidental fluid overload due to an improperly regulated IV infusion. The devices usually have a microdrip, or a drop factor of 60 gtt/mL. Another way of manually regulating flow rates is through the use of an in-line controller such as a Dial-A-Flo (Fig. 39.15). This is a more precisely calibrated roller clamp and is used when possible fluid overload is a concern or if an electronic infusion device is not available.

FIGURE 39.14 Volume control device. (From Perry, A. G., Potter, P. A. Ostendorf, W. R., et al: *Clinical nursing skills and techniques* [9th ed.]. St. Louis: Elsevier.)

FIGURE 39.15 Dial-a-flow. (From Hospira, Inc., Lake Forest, IL.)

In most hospitals, an **electronic infusion device** or IV infusion pump (Fig. 39.16) is used for even more precise delivery. These devices allow the nurse to program the rate and volume of the fluid to be infused. There are two general types: controllers and pumps. An alarm sounds when the infusion is complete and when there are complications with the flow, such as air in the tubing or obstruction. Controllers operate by gravitational force and regulate the flow using an electronic dispenser. When the rate falls below the programmed rate, an alarm sounds. An infusion pump uses positive pressure to overcome vascular pressure at the insertion site. When the pressure required to infuse the fluid reaches a preset level, an alarm sounds, signaling the nurse to assess for IV patency and tubing obstruction. With controllers and pumps, rates are programmed in milliliters per hour. The nurse programs the ordered rate during the set-up process. Electronic infusion devices are used for patients who have additives such as potassium in their IV solutions, those receiving IV medications, children, the elderly, and any person for whom fluid overload is a concern. Electronic infusion devices are used when administering IV fluids and medications with all CVCs.

FIGURE 39.16 Electronic infusion pump. (Copyright Mosby's Clinical Skills: Essentials Collection.)

The IV flow rate is the amount of milliliters infused over 1 hour (mL/hr). When the primary care provider orders an IV infusion, the rate usually is written in mL/hr. Sometimes, the order specifies the amount of fluid to be infused in a 24-hour period, and the nurse needs to determine the hourly flow rate.

Complications of Intravenous Therapy

IV therapy is considered an invasive procedure; a needle is entering and resting in a blood vessel. As with any invasive procedure, the risk for infection is increased. Careful sterile technique is essential in preventing catheter-related infections. Other complications associated with IV therapy include occlusion, phlebitis, infiltration, and extravasation. Systemic complications include fluid overload, speed shock, and embolism. It is vital for nurses to recognize that they are responsible for a patient's IV line. Unrecognized complications can result in long-term damage and lawsuits. [Table 39.15](#) summarizes complications, symptoms, and nursing considerations.

TABLE 39.15**Complications of Intravenous Therapy**

COMPLICATIONS	SYMPTOMS	NURSING CONSIDERATIONS
Local Complications		
<i>Catheter occlusion:</i> Partial or complete obstruction of a vascular access device, caused by clot formation within the catheter or a mechanical obstruction	IV flow is sluggish or stopped. Attempts to flush catheter are met with resistance.	Assess tubing and site for obstructions such as kinked tubing or arm position. Attempt to flush catheter with normal saline. <i>Do not force.</i> Forcing the flush can dislodge the clot, which becomes an embolism. If peripheral IV, discontinue the site and restart a new site. If a CVC, notify PCP or IV team.
<i>Catheter-related infection:</i> Local infection that occurs at insertion site, if not recognized, can become systemic (septicemia) and possibly life-threatening; usually caused by poor aseptic technique during inserting or dressing or tubing changes; can occur when peripheral site has been in use for longer than 4 days.	<i>Local symptoms:</i> Pain at site, tenderness, erythema (redness), swelling, increased temperature, purulent drainage <i>Systemic symptoms:</i> Fever, chills, tachycardia, hypotension, complaints of headache, backache	Prevention is key. Use aseptic technique during insertion and site care. Rotate sites per agency protocol or when clinically indicated. Assess site frequently for signs of infection. If symptoms evident, discontinue peripheral IV, and restart in another location. Place used catheter in sterile container and send to laboratory for culture and sensitivity testing. Notify PCP of findings. Replace old IV tubing and solution with new. Do not discontinue a CVC without a physician's order.

COMPLICATIONS	SYMPTOMS	NURSING CONSIDERATIONS
<p><i>Phlebitis</i>: Inflammation of the vein caused by poor insertion and care technique, frequent manipulation of IV catheter, size and length of the catheter, use of irritating medications or fluids, and infection</p>	<p>Tenderness, redness, swelling at site Pain, burning, heat along the vein, especially during infusion Palpable venous cord Scale to grade severity: 0: No symptoms 1: Redness at site with or without pain 2: Pain with erythema 3: All the above plus red streak along vein and palpable venous cord 4: All the above plus purulent drainage</p>	<p>Discontinue catheter immediately if infection suspected; send catheter tip for culture and sensitivity testing. Clean insertion site with disinfectant. Apply warm moist compresses for 20 min three or four times per day. When inserting new IV catheter, use opposite extremity if possible. To avoid phlebitis, use smallest gauge possible (22 or 24 gauge), stabilize catheter securely to minimize movement, and rotate sites according to agency policy or when clinically indicated.</p>

COMPLICATIONS	SYMPTOMS	NURSING CONSIDERATIONS
<p><i>Infiltration:</i> Infusion of IV solution and/or nonvesicant medications into surrounding tissues, caused by puncturing of the blood vessel through improper insertion or frequent manipulation of IV catheter</p>	<p>Swelling, tenderness, coolness, and firmness of extremity; blanching of skin.</p> <p>Scale to grade severity:</p> <p>0: No symptoms</p> <p>1: Skin blanched, edema <1 inch, cool to touch, may have pain</p> <p>2: All the above plus edema of 1 to 6 inches</p> <p>3: All the above plus extremity translucent, edema >6 inches, mild to moderate pain, possible numbness</p> <p>4: All the above plus tight, leaking skin, deep pitting edema, circulatory impairment, moderate to severe pain (typically considered extravasation)</p>	<p>Assess for signs of infiltration at least q 2 h.</p> <p>Discontinue infusion, and remove catheter.</p> <p>Apply pressure at site to stop bleeding.</p> <p>Apply warm compresses to increase circulation for isotonic or hypotonic fluids.</p> <p>Apply cold for infiltration of hyperosmolar fluids.</p> <p>Outline the area of visible damage with a marker to assess changes.</p> <p>If leaking of tissues occurs, cover area with sterile dressing until leaking subsides.</p> <p>Report grade 3 or 4 infiltrations to PCP.</p> <p>Use opposite extremity when inserting new IV catheter.</p>

COMPLICATIONS	SYMPTOMS	NURSING CONSIDERATIONS
<p><i>Extravasation:</i> Inadvertent infusion of vesicant (causing blisters, ulceration, sloughing) or irritating solution or medication into surrounding tissues. This can lead to permanent tissue damage and/or nerve damage.</p>	<p>Similar to infiltration Burning and discomfort Blistering is a late sign</p>	<p>Know which medications are considered vesicants, including dopamine, norepinephrine, high concentrations of electrolytes, and several antibiotics. Vesicant and irritating solutions or medications should be infused slowly and through a larger vein or CVC. If extravasation is suspected, infusion is discontinued immediately. Notify PCP and obtain orders for extravasation treatment and/or antidote. Use a skin marker to outline area of visible damage to assess changes. Cautious use of cold or warm compresses and elevate the extremity. Never apply pressure to the area. Use opposite extremity when inserting new IV.</p>
<p>Systemic Complications</p>		

COMPLICATIONS	SYMPTOMS	NURSING CONSIDERATIONS
<p><i>Fluid overload and pulmonary edema:</i> Occurs when the volume infused is greater than the cardiovascular system can tolerate; can lead to heart failure, shock, and cardiac arrest</p>	<p><i>Early signs:</i> Restlessness, gradual increase in heart rate, headache, dyspnea, nonproductive cough</p> <p><i>Late signs:</i> Hypertension, severe dyspnea, gurgling respirations, productive cough of frothy sputum, crackles in lung bases, increased jugular vein distention</p>	<p>Prevention is key (slower infusions for patients with underlying heart or renal disease). Monitor for early signs and symptoms of fluid excess. Use an electronic infusion device for patients at risk, such as those with cardiac disease history or the elderly. Measure daily weights, intake, and output. Frequently assess IV infusion and ensure it is not infusing too rapidly. If fluid overload suspected, provide bed rest in high Fowler position, slow infusion rate to keep vein open, notify PCP immediately, provide oxygen as needed, and administer diuretics and pain medications as ordered.</p>

COMPLICATIONS	SYMPTOMS	NURSING CONSIDERATIONS
<p><i>Speed shock:</i> Systemic reaction when medication is administered too quickly</p>	<p>Sudden onset of dizziness, facial flushing, headache, and irregular heart rate during medication administration</p>	<p>Prevention is key. Follow recommended infusion rate for medication. Monitor gravity-flow sets closely during medication administration. Use electronic infusion devices whenever possible for medication administration. If suspected, stop infusion immediately, maintain IV access with IV solution that does not contain medication, notify PCP immediately, and monitor vital signs.</p>
<p><i>Air embolism:</i> Accidental entry of air into bloodstream due to improper preparation of IV tubing or loose connections</p>	<p>Chest pain, shoulder or low back pain, dyspnea, cyanosis, hypotension, tachycardia, syncope, or decreased level of consciousness</p>	<p>Prevention is key. Ensure that catheter and tubing are clamped closed when changing tubing. Use Luer-Lok connections on all tubing. Prime all tubing with IV solution before attaching to catheter. Follow agency protocol when removing a CVC. If IV bag has run dry, inspect tubing closely for air. If air embolism suspected, place patient in Trendelenburg position on left side. Locate the source of air and close off. Notify PCP immediately. Administer oxygen as needed. Have emergency resuscitation equipment available.</p>

COMPLICATIONS	SYMPTOMS	NURSING CONSIDERATIONS
<i>Catheter embolism:</i> Occurs when a catheter piece breaks off and enters bloodstream, leading to blockage of blood vessel; can occur during insertion when an over-the-needle catheter stylet is partially removed and then reinserted or when a through-the-needle catheter is pulled back and then reinserted through the needle; can occur when the catheter rests over a joint such as wrist or elbow, and the continued flexion weakens the catheter	Depends on where embolism is lodged General signs include cyanosis, hypotension, tachycardia, syncope, and decreased level of consciousness	Prevention is key. Use correct technique when inserting IV catheter. Avoid joints as insertion sites. Apply pressure when removing an IV. If suspected, place tourniquet above insertion site, ensure arterial flow is still intact. Initiate strict bed rest. Notify PCP immediately. Monitor patient for signs of distress. Have emergency equipment available.

CVC, Central venous catheter; IV, intravenous; PCP, primary care provider.

Modified from Infusion Nurses Society. (2016). *Policies and procedures for infusion nursing* (5th ed.). Norwood, MA: Author.

Safe Practice Alert

Notify the primary care provider when problems exist with a central venous catheter. Never discontinue a central venous catheter without an order.

Care of the Patient With a Peripheral Intravenous Catheter

When caring for a patient receiving IV fluids or medications or both, several key nursing assessments and interventions can ensure effective care. When initially assessing patient information, the nurse reviews the IV therapy currently ordered, including the type of catheter, date of insertion, and solution type and rate. The time that the current solution bag was started indicates when the next IV solution should be ready. A good rule of thumb is to have the new bag ready to hang when there is an hour's worth of fluid left in the bag currently infusing.

On entering a patient's room, there are key areas to assess. Begin at the bag and verify that the correct solution is infusing at the correct rate and the appropriate amount of fluid is in the bag. Examine the drip chamber, make sure it is half full and the IV is dripping. Examine the

tubing for kinks or loose connections. Check the date on the tubing. Tubing is changed every 24 to 72 hours, depending on the type of IV therapy (Table 39.16).

TABLE 39.16
Intravenous Tubing Change

TYPE OF INFUSION	FREQUENCY OF TUBING CHANGE
Primary intravenous solution	<i>Continuous:</i> Change primary and secondary (piggyback) tubing q 72-96 h; check agency policy.
	<i>Intermittent:</i> Change primary and secondary tubing q 24 h.
Blood and blood components	<i>Continuous:</i> If multiple units are to be administered continuously, tubing is changed q 4 h.
	<i>Intermittent:</i> If only one unit is to be administered, dispose of tubing after infusion is completed and tubing is flushed with saline.
Intravenous fat emulsion (IVFE)	<i>Continuous:</i> If the fat emulsion is to be infused on a continuous basis, the tubing is changed q 12 h.
	<i>Intermittent:</i> Dispose of the tubing after the fat emulsion has completely infused; use new tubing with the next dose.
Total parenteral nutrition	<i>Continuous with IVFE:</i> Tubing is changed q 24 h.
	<i>Continuous without IVFE:</i> Tubing is changed q 72 h.
	<i>Intermittent:</i> Tubing is changed q 24 h.

From Infusion Nurses Society. (2016). *Policies and procedures for infusion nursing* (5th ed.). Norwood, MA: Author.

Move down to the insertion site, checking for signs of complications. Observe the dressing; it should be clean, dry, and intact. If the dressing is soiled, wet, or loose, it is changed immediately (Skill 39.2). Notice the date of insertion. For peripheral IV lines, the site may need to be rotated routinely every 72 to 96 hours based on facility protocol.

The IV solution, rate, tubing, and insertion site should be assessed every hour. Certain catheter-related complications require the IV infusion to be discontinued immediately (Box 39.12). Assess the patient for systemic complications.

Box 39.12

Nursing Care Guideline

Discontinuing a Peripheral Intravenous Line

Background

- To avoid catheter-related bloodstream infections (CRBSIs), remove vascular access devices (VADs) if the following occur:
 - The device is no longer needed.
 - It is no longer patent (will not flush or is leaking).
 - It shows signs or complications such as infiltration or phlebitis (redness, pain, swelling).
 - Break in the integrity of the device occurs (notify the primary care provider of the need for removal).
- Remove all intravenous (IV) lines before discharge, unless the VAD is a central line and the patient will be receiving home intravenous therapy.

Procedural Concerns

- Clamp all tubing.
- Wear clean gloves.
- Loosen all dressings and tape.
- Apply opposing pressure to skin while removing adhesives.
- Secure the catheter with slight pressure to avoid dislodgement while removing the dressing.
- Holding the gauze over the site with one hand, use the other hand to slide the catheter out.

(Copyright Mosby's Clinical Skills: Essentials Collection.)

- Apply pressure over the site using the gauze.
- Dispose of the catheter and dressing per facility policy and procedures.
- Apply a slight pressure dressing to the site.

Documentation Concerns

- Document removal and discontinuation information, including the following:
 - Fluids infused
 - Date
 - Time of day
 - Site
- Record the site and catheter assessment. For example, if the catheter removed is fully intact.
- Note any problems or patient discomfort with the procedure.

Evidence-Based Practice

- A literature review of research that compared routine IV catheter changes with changing the catheter only if there were signs of inflammation or infection concluded that there was no evidence to support changing catheters routinely every 72 to 96 hours ([Webster, Osborne, Rickard, et al., 2015](#)).
- Many health care organizations are changing policies whereby catheters are changed only if clinically indicated, which saves significant costs and spares patients unnecessary pain of routine IV restarts. To minimize IV catheter–related complications, nurses should inspect the IV site often and discontinue the catheter if signs of inflammation, infiltration, or phlebitis are present.

Care of the Patient With Central Venous Access

The assessment and care of a patient with a CVC, including PICCs, is similar to that of a patient with a peripheral IV line, but there are some key differences ([Boxes 39.13](#) and [39.14](#)). The tubing is changed more frequently, usually every 24 hours. Check the agency policy for specifics. According to the [INS \(2016\)](#), gauze dressings for a CVC should be changed every 48 hours. With transparent dressings, the interval increases to every 5 to 7 days, depending on agency policy. Dressings are changed immediately if wet, soiled, or loose. CVC dressings are changed using strict aseptic, or sterile, technique ([Box 39.15](#) and [Skill 39.3](#)). CVCs also must be routinely checked for blood return and flushed and locked with either 0.9 normal saline or heparin lock solution (10 units/mL) based on facility policy.

Box 39.13

Ethical, Legal, and Professional Practice

Informed Consent

- Insertion of a central venous catheter is considered an invasive procedure and requires a signed consent form.
- It is the responsibility of the primary care provider to obtain written consent from the patient.
- It is the nurse's responsibility to ensure the consent form has been signed and that the patient has no questions or concerns.

Box 39.14

Evidence-Based Practice and Informatics

Guidelines for Central Venous Catheter Use in Adults

A systematic review of medical and nursing research led to recommendations when caring for a patient with a central venous catheter (CVC):

- Patients should receive clear verbal and written information about CVCs, including the risks and benefits, before providing consent for CVC insertion. Signed informed consent is obtained by the primary care provider before insertion.
- Ultrasound-guided insertion is recommended to improve success rates and decrease complications (INS, 2016).
- Vigorous cleansing of the skin with chlorhexidine is recommended before insertion. If chlorhexidine is contraindicated, povidone-iodine or alcohol may be used.
- Dressings are changed using sterile technique (usually within first 24 hours and then weekly) and immediately if the dressing is loose, soiled, or for further assessment if site infection is suspected.
- Engineered stabilization devices (ESD) should be used in place of sutures. ESDs are devices placed subcutaneously or topically to control movement at the catheter hub and prevent unintentional dislodgment. Adhesive ESDs should be changed with dressing changes.

- Reduction in central line–associated bloodstream infection (CLABSI) has been associated with the use of chlorhexidine-impregnated sponges, which should be changed at the same time as the dressing following facility protocol (APIC, 2015; INS, 2016).
- Needle-free connectors are used to reduce risk for infection to patients and needlestick injury to nurses. Disinfecting alcohol-impregnated caps have shown to reduce CLABSIs (APIC, 2013).

Disinfecting alcohol-impregnated caps.

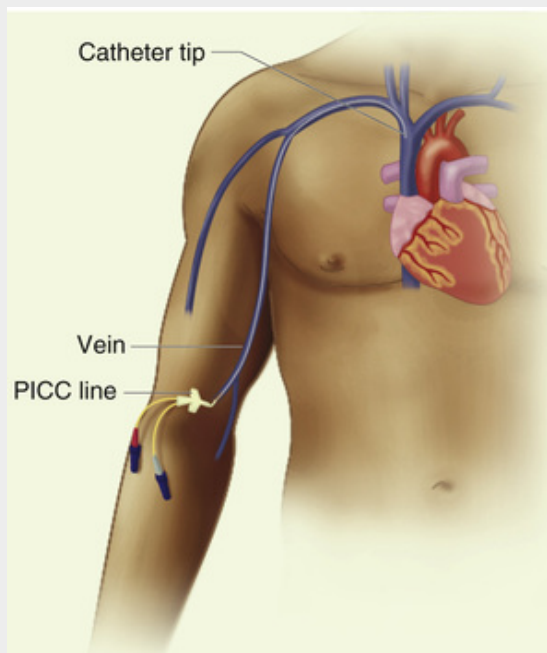

Box 39.15

Nursing Care Guideline

Peripherally Inserted Central Catheter: Dressing Change and Care

Background

- Primary use of a peripherally inserted central catheter (PICC) is to permit intermediate to long-term intravenous (IV) access.
- Fewer complications occur with a PICC than with other IV forms because the tip of the line ends in a large vein.
- PICC use is beneficial in that it allows therapeutic interventions without hospitalization.

Procedural Concerns

- Follow strict sterile technique to prevent catheter-related bloodstream infections (CRBSIs).
- Be familiar with individual facility policy and procedures for use of PICCs.
- Never take a blood pressure on an arm with a PICC.
- Avoid strenuous exercise of an arm with a PICC.
- Do not get the site wet.
- Assess the site often.
- Flush all lumens with 10 mL of preservative-free saline (see [Box 39.11](#)).
- Follow [Skill 39.3](#).
- Some PICCs have an extra catheter from the site to the hub.
- Ensure the catheter is not moved or pushed into the arm during the dressing change. Measure the length of the catheter from the site to the hub outside the body to be sure that it has not changed from the previous assessment.
- Maintain the sterility of the catheter: Clean it and coil it under the dressing.
- Per facility policy and procedures, nurses may be responsible for removing PICCs:
 - Ensure proper education and competency of the nurse removing the PICC.

- Remove any securement devices or sutures.
- Have the patient bear down (i.e., perform the Valsalva maneuver) when removing the PICC.
- Gently pull the catheter parallel to the skin to remove it; it should slide out without resistance or discomfort.
- Apply pressure to the site with a sterile 2 × 2 gauze pad for at least 5 minutes.
- Apply an occlusive dressing for 24 hours.

Documentation Concerns

- Document the site and catheter assessments.
- Include the measured length of the catheter from the site to the hub outside the body.
- Record the patient and family education that was provided regarding the procedures for home therapy.
- Note any problems or patient discomfort with the procedure.
- Document the removal or discontinuation information, including the fluids infused, the date and time of day, and the assessment of the site.

Evidence-Based Practice

- When assessing patency of a PICC, if unable to flush, try repositioning the patient or have the patient cough. The tip of the catheter may lie against a structure, which this technique may help resolve. Never force the flush or apply more pressure because it could dislodge a clot or cause catheter breakage. Notify the primary care provider for a PICC that will not flush ([INS, 2016](#)).
- Chlorohexidine-impregnated sponges used at the insertion site should be changed at the same time as the transparent dressing ([APIC, 2015](#)).

Routine site rotation is not needed for CVCs or PICCs. CVCs are discontinued only with a written order from the primary care provider (PCP). A specially trained nurse can remove a nontunneled CVC. To do so, place the patient in a supine position, clamp the infusion, and remove the dressing. Apply clean gloves. Remove any securement device or sutures. Instruct the patient to take a deep breath and hold it. Grasp the catheter, and remove it in a continuous motion with the dominant hand. Have a sterile dressing ready in the nondominant

hand, and place it over the site after the catheter is removed. Instruct the patient to breathe normally while providing direct pressure to the site until bleeding has stopped (at least 1 minute). Cover the site with an occlusive dressing. Inspect the catheter to ensure that it is intact.

Dispose of the catheter, tubing, and dressing in the hazardous waste container. Document the process, significant findings, and patient response. Removal of a PICC is performed by nurses trained in insertion and maintenance of these catheters.

Blood Administration

For patients with fluid volume deficit, IV therapy is effective in restoring fluids and electrolytes to normal levels. However, crystalloids cannot replace the other essential components of blood loss resulting from trauma, anemia, hemorrhage, or surgery. Blood components are often necessary to maintain the patient's oxygen and carbon dioxide transport capacity, for clotting, to maintain oncotic pressure, and to protect from infection. When replacing the lost blood components becomes necessary, a blood transfusion is ordered ([Box 39.16](#)).

Box 39.16

Nursing Care Guideline

Administering Blood Products

Background

- Blood products are administered to replace lost blood or blood components.
- Ensure the blood that will be administered is the appropriate type for the recipient and that crossmatching was done.
- Informed consent (see [Box 37.10](#)) must be obtained before administration.
- Rapid transfusions may occur through a central line, but blood is warmed before being administered.

Procedural Concerns

- Assessments of the following are performed:
 - Verify patient allergy information.

- Verify whether the patient has had a previous transfusion reaction.
- If a patient does not already have a patent 18- to 24-gauge intravenous (IV) line in place, start one (see [Skill 39.1](#)).
- The U.S. [Food and Drug Administration \(2018\)](#) requires blood products to have barcodes to enable scanning to reduce the incidence of administration errors.
- Check the blood product that is to be administered to verify that it is not clotted. If it is clotted, do not use it; obtain a replacement bag.
- Obtain the patient's vital signs.
- Working with another nurse, identify the following:
 - The patient
 - Blood group and type (of the patient and the blood product to be administered)
 - Identification number of the blood product
 - Expiration date of the blood product
- Maintain sterile technique.
- Disconnect running infusions, leaving a saline lock (see [Box 39.10](#)).
- Prime a Y-type blood infusion set.
- It must have an in-line filter.
- Hang it with sterile 0.9% normal saline solution (NSS) on a Y line. Never infuse any other solution or medications with blood products except 0.9% NSS.
- Use the NSS to prime the infusion set.

(Copyright Mosby's Clinical Skills: Essentials Collection.)

- Infuse the blood product slowly over the first 15 minutes. The Infusion Nursing Society (2016) recommends a rate of 2 mL/min for the first 15 minutes.
- Do not leave the patient during the first 15 minutes.
- Monitor the patient for adverse reactions:
 - Flushing
 - Fever
 - Dyspnea
 - Hypotension
 - Itching
 - Pain
 - Chills
 - Shortness of breath
 - Nausea
 - Unexplained emotions
- Increase the infusion rate if the patient does not demonstrate adverse reactions.
- Blood products must be infused within 4 hours (maximum) after leaving the laboratory.
- Minimum infusion rate is determined per facility policy and procedures or per primary care provider (PCP) order.
- Continue to monitor the patient frequently. The minimum frequency is per facility policy and procedures or PCP order.

- Monitoring may be performed more frequently according to nursing judgment and depending on the patient's status. If the patient shows any signs or symptoms of transfusion reaction, take the following actions:
 - Stop the transfusion immediately.
 - Change all tubing and the infusion set.
 - Hang a new IV solution of 0.9% NSS.
 - Notify the PCP.
 - Send the blood product and tubing to the laboratory or blood bank per facility policy and procedures.
- After the transfusion is complete, take the following steps:
 - Disconnect the tubing from the saline lock (see [Box 39.10](#)).
 - Tubing is discarded per facility policy and procedures.
 - New tubing is used for each transfusion.
 - Restart the primary infusion if ordered.

Documentation Concerns

- Document the reason for the transfusion.
- Document vital signs before, during, and after the transfusion.
- Record follow-up specifics regarding the transfusion's effectiveness as a treatment for the patient's condition.
- Include the date, starting and ending times for the transfusion, blood type, and the component and amount infused.
- Record the blood product and patient identification information and the blood product expiration date.
- Note any observations made during the required monitoring period during and after the transfusion.
- Document patient intake and output.
- Evaluate pertinent laboratory results before and after the procedure.
- If the patient has an adverse event, document the event in detail, and follow facility policy and procedures.

Evidence-Based Practice

- It is imperative to follow facility policy and procedures for the identification of the patient and the blood product before beginning the transfusion, including use of two nurses during the verification process. The most common reason for a transfusion

reaction is inappropriate identification of the patient and matching the blood product to the patient.

- Most reactions to a transfusion occur within the first 15 minutes of initiation. This is why the nurse should remain with the patient at the bedside during this time to observe for signs of a reaction.
- In the past it was believed that blood products had to be infused through an 18- to 20-gauge IV or larger, but new research confirms blood can be safely infused in as small as a 24-gauge IV (INS, 2016).

Qsen Focus!

The [Joint Commission's National Patient Safety Goals for 2019](#) include eliminating transfusion reactions by preventing transfusion mismatch. The value of standardization for safety is exhibited through the use of bar code scanning before blood product administration.

Complications

The three main types of adverse reactions to blood products are hemolytic, allergic, and febrile. Hemolytic reactions (i.e., destruction of red blood cells) occur because of ABO or Rh incompatibilities between the patient and donor blood. This life-threatening reaction can occur with administration of only 10 mL of incompatible blood. Multiple checks of the patient and donor information are essential.

Allergic reactions are much more common and can range from mild to severe. Allergic reactions occur when a patient has a hypersensitivity response to plasma proteins in the donor's blood.

Febrile nonhemolytic reactions occur when the patient reacts to the white blood cells, platelets, or plasma proteins. It causes a rise of 2° F in the patient's temperature and can occur during or after the transfusion. If patient is febrile at initiation of blood product, verify administration of the infusion with health care provider.

For any signs of adverse reaction, the nurse's first action is to stop the transfusion. The nurse then begins an IV infusion of 0.9% normal saline with new tubing at a keep-vein-open rate, notifies the ordering physician, and closely monitors the patient.

Other complications include fluid overload and bacterial contamination. [Table 39.17](#) lists complications of blood transfusions, symptoms, and nursing care.

TABLE 39.17**Complications of Blood Transfusion**

OCCURRENCE	SYMPTOMS	NURSING IMPLICATIONS
Allergic Response		
Fairly common, based on a hypersensitivity response to the foreign plasma proteins	<i>Mild:</i> Local erythema, hives, itching, asthmatic wheezing <i>Severe:</i> Laryngeal swelling, dyspnea, tachypnea, chest pain, cardiac arrest	Stop transfusion. Notify ordering physician immediately. Administer antihistamines; in mild cases, may be able to continue transfusion after antihistamine has taken effect. Continue to assess patient and monitor vital signs. Document the reaction, subsequent treatment, and patient response.
Acute Hemolytic Reaction		
Occurs when with antigen-antibody reaction due to ABO or Rh incompatibilities Can result from errors in mislabeling crossmatch sample sent to laboratory, improper crossmatching, or errors in patient and blood verification at bedside	Chills, fever, facial flushing, burning along the vein, lumbar or flank pain, chest pain, shock	Stop transfusion immediately. Remove tubing and replace with new intravenous tubing and normal saline solution at keep-vein-open (KVO) rate. Notify ordering physician immediately. Notify the blood bank. Monitor vital signs. Have emergency equipment available. Send remaining blood, blood tubing and filter, and a sample of patient's blood and urine to the laboratory. Document the reaction, subsequent treatment, and patient response.
Febrile Nonhemolytic Reaction		
Occurs the patient reacts to the white blood cells in donor blood Occurs in up to 6% of all transfusions	Defined as a 2° F rise in body temperature compared with pretransfusion reading Chills and malaise common	Stop the infusion. Notify ordering physician immediately. Notify the blood bank. Administer antipyretics and/or antihistamines as ordered. Document the reaction, subsequent treatment, and patient response. Can be avoided by using leukocyte-reduced components or washed red blood cells.
Bacterial Contamination		

OCCURRENCE	SYMPTOMS	NURSING IMPLICATIONS
Occurs during the donation or preparation of blood, usually by organisms capable of surviving cold temperatures, such as <i>Pseudomonas</i> or <i>Staphylococcus</i>	Abdominal cramping, chills, diarrhea, fever, shock, onset of renal failure, vomiting	<p>Infuse blood in less than 4 h; stop infusion after 4 h.</p> <p>Change administration sets q 4 h or after each unit.</p> <p>Stop the infusion immediately if symptoms occur.</p> <p>Notify the ordering physician.</p> <p>Administer antibiotics, corticosteroids, and epinephrine as ordered.</p> <p>Have emergency equipment available.</p> <p>If the patient is discharged shortly after transfusion, explain the symptoms of infection, such as fever, chills, diarrhea, and abdominal cramping.</p> <p>Instruct the patient to contact the ordering physician immediately if symptoms occur.</p>
Circulatory Overload		
Usually occurs when whole blood is transfused too quickly or packed red blood cells (PRBCs) lead to a fluid shift from the interstitial to vascular space	Signs of fluid volume excess, including dyspnea, headache, tachycardia, hypertension, and distended jugular veins	<p>Slow or stop infusion.</p> <p>Use PRBCs instead of whole blood.</p> <p>Notify the ordering physician immediately.</p> <p>Administer oxygen as needed.</p> <p>Administer diuretics as ordered.</p> <p>If the patient is discharged shortly after transfusion, explain the symptoms of fluid overload, such as difficulty breathing, edema, headache, or increased heart rate.</p> <p>Instruct the patient to contact the physician immediately if symptoms occur.</p>

From Weinstein, S. M., & Hagle, M. E. (2014). *Plumer's principles & practice of infusion therapy* (9th ed.). Philadelphia: Lippincott Williams & Wilkins.

Total Parenteral Nutrition

Total parenteral nutrition (TPN) is a hypertonic IV solution designed to meet a patient's total nutritional needs. It contains amino acids, glucose, lipids, vitamins, minerals, electrolytes, and trace elements. TPN provides the calories, protein building blocks, and fluid needed to promote wound healing and meet metabolic requirements. It is used when the patient is unable to meet nutritional and metabolic demands through oral intake or when disease (e.g., pancreatitis, ulcerative colitis,

bowel obstruction) or surgery requires complete bowel rest. Indications for TPN include debilitating illnesses lasting longer than 2 weeks, loss of more than 10% of pre-illness weight, serum albumin levels less than 3.5 g/dL, or nitrogen loss due to extensive burns or draining wounds.

Infusion

Because of the increased tonicity of TPN, it is infused through central venous access with a PICC, CVC, or implanted port. Often, a multilumen CVC is used, with one lumen dedicated to TPN only. If a patient requires other IV medications or therapy, the other lumens can be used or a peripheral IV site can be used.

Safe Practice Alert

Never piggyback or administer other medications or blood products into the same line as total parenteral nutrition.

When beginning TPN, the infusion should begin slowly, allowing the pancreas to adjust to the increased glucose levels. The normal amount of TPN is 2.5 to 3 L infused over 24 hours. A continuous infusion allows for more stable blood glucose control ([Box 39.17](#)).

Box 39.17

Nursing Care Guideline

Administering Total Parenteral Nutrition and Lipids

Background

- Nutritional fluids are administered intravenously when the patient's digestive system is not functioning.
- Total parenteral nutrition (TPN) is ordered specifically for a patient's needs and is based on laboratory results for the patient. TPN must be given in a central line (not peripheral line).

(Copyright © Mosby's Clinical Skills: Essentials Collection.)

- The primary ingredients are proteins, carbohydrates, and fats (i.e., lipids).
- TPN also includes electrolytes and vitamins.
- If needed, TPN may include medications, such as insulin.
- Lipids are fatty substances that provide calories and are given as emulsions or in conjunction with TPN.
- TPN is a hypertonic solution (highly concentrated) that easily flows into body fluids.
- Collaboration with the dietician and pharmacist is necessary when caring for a patient receiving TPN.

Procedural Concerns

- Ensure sufficient training, education, and competency before performing this skill.
- A central line must be used to administer TPN.
- Designate a separate lumen for TPN.
- Do not infuse any other substances into this line.

- Keeping TPN separate prevents incompatibility issues with other solutions. Clearly mark the TPN line.
- TPN is infused using a pump.
- Assess and monitor the patient for the following:
 - Allergies
 - Laboratory results:
 - Electrolytes
 - Blood urea nitrogen (BUN)
 - Clotting factors
 - Glucose (tested every 6 to 24 hours, as ordered)
 - Serum protein
 - Central line patency and insertion site
- Perform the following working with another nurse:
 - Identify the patient.
 - Verify the TPN components against the primary care provider order.
 - Check the expiration date.
- Ensure vitamin K has been ordered, because vitamin K is produced largely by intestinal bacteria that currently may be absent, but it is needed to produce clotting factors in the gut.
- Because TPN is considered a medication, ensure compliance with the Six Rights of Medication Administration (see [Box 35.4](#)).
- Maintain sterile technique.
- Prime the infusion set:
 - Use a new infusion set with each infusion.
 - Use an in-line filter with TPN.
 - Do not use a filter with lipids.

- Do not use TPN after it has been hanging for 24 hours; discard any unused solution and tubing.
- Assess the following:
 - Patient vital signs at least every 4 hours
 - Daily weight
 - Intake and output
- The administration rate of TPN is increased slowly at the beginning of the infusion and weaned off gradually at the end.
- Do not suddenly stop a TPN transfusion. Hang D₁₀ solution if line runs dry and new bag of TPN is delayed or unavailable, because TPN must be weaned off.
- The gradual increase and decrease in infusion rate prevents hypoglycemic shock.
- Nurses should never mix medications into TPN.

Documentation Concerns

- Document the reason for administering TPN and lipids.
- Include assessments and monitoring as described in the Procedural Concerns section.
- Note the date, starting and ending times for the infusion, and the second nurse's verification.
- Document the TPN and lipid product information and the patient identification information.
- Describe the observations made during the required monitoring period throughout the infusion.
- Record intake and output.
- If the patient has an adverse event, document the event in detail, and follow facility policy and procedures.

Evidence-Based Practice

- TPN has been determined to be a high risk factor for catheter-related bloodstream infections (CRBSIs) due to the invasive line and the hyperosmolar solution. Handwashing and disinfection of the central line port before flushing is essential. Many facility protocols require monitoring of blood glucose and temperature routinely for any patient receiving TPN.
- TPN is usually run over 12 to 14 hours daily, and because the intravenous (IV) tubing must be changed every 24 hours, a new IV

tubing set should be hung with each bag of TPN (APIC, 2015).

Complications

The complications associated with TPN are similar to those for any CVC use: infection, air embolism, or fluid overload. Because of the contents in TPN, the patient is at a higher risk for infection. Strict sterile technique is used during IV care, especially during dressing, bag, and tubing changes. With the high levels of dextrose in TPN, patients, especially those with a history of diabetes, can develop hyperglycemia. Blood sugar levels are checked on a routine basis. Insulin is often ordered by the PCP and added by the pharmacy to the TPN solution to help offset this effect. Rebound hypoglycemia can occur when the TPN solution is abruptly discontinued. TPN infusion rates should be decreased incrementally before completely discontinuing the solution. The nurse must continually monitor the rate to ensure the TPN is infusing at the ordered rate and that new bags are hung promptly to prevent interruptions in the infusion.

With the increased use of long-term CVCs and decreased length of hospital stays, many patients find it necessary to continue IV therapy at home (Box 39.18). This can take the form of continuous IV infusions, such as TPN, or intermittent medication administration, such as long-term antibiotics. The nurse works closely with the patient and family members to ensure correct administration of the therapy and diligent monitoring for signs of complications.

Box 39.18

Home Care Considerations

Intravenous Therapy at Home

- Key aspects of teaching include the purpose of the intravenous (IV) therapy, initiating the infusion, monitoring the infusion, and assessing for complications. Also how to properly store the solutions and whether refrigeration is needed (e.g., total parenteral nutrition [TPN]).
- Inform patients and caregivers about the Oley Foundation (<http://oley.org>), which provides support and education for those requiring home IV TPN.
- Maintaining sterile technique is critical during preparation of the IV, while accessing the site, and for tubing and dressing changes.

- The patient should understand the signs and symptoms of complications and know when to notify the home health nurse or the primary care provider.
- The home health nurse plans frequent visits during the IV infusion, especially when the caregiver is accessing the site and during tubing and dressing changes to assess the family's understanding of the process and their ability to safely administer IV therapy.
- The home health nurse assesses the patient frequently to evaluate the effectiveness of the therapy and signs of complications, especially catheter-related infections.

When oral intake is limited, peripheral parenteral nutrition (PPN) can be used to supplement a patient's nutritional status. PPN contains the same ingredients as TPN but at much lower concentrations. It can be infused through a peripheral line, eliminating the need for and avoiding the risks for a CVC.

Evaluation

To determine the effectiveness of the interventions, the nurse evaluates achievement of the patient goals and outcomes designed to establish and maintain normal fluid, electrolyte, and acid-base balance.

Continuous evaluation of goals and revision of the care plan are necessary for patients with fluid, electrolyte, and acid-base imbalances. Laboratory tests such as albumin, prealbumin, transferrin, total protein, glucose, and electrolyte levels indicate the patient's response to therapy and determine whether changes are needed.

Assessing measures of fluid balance such as weight and urine output allows the nurse to identify problems and intervene early to avoid severe or life-threatening complications. Significant deviations from normal patient responses are reported to the primary care provider.

SKILL 39.1 Starting a Peripheral Intravenous Infusion

Purpose

- To provide fluids
- To administer medications
- To replace electrolytes
- To promote comfort
- To provide nutrition
- To maintain emergency access for medications

Resources

- IV Angiocath (16 to 24 gauge, depending on the size of the vein and type of infusion)
- Chlorhexidine swab
- 2 × 2 gauze pads
- Tourniquet
- Saline lock extension tubing
- 3- to 10-mL prefilled saline flush
- Dressing supplies and tape (per facility policy and procedures)
- Clean gloves
- Personal protective equipment (PPE) as required

Interprofessional Collaboration and Delegation

- Starting a peripheral IV line may not be delegated to unlicensed assistive personnel (UAP).
- UAP may observe a peripheral IV line during care and should report the following to the nurse.
 - Burning, redness, pain, coolness, leaking, bleeding, or swelling at the peripheral IV

insertion site

- Patient concerns or complaints
- Low volume in an IV bag
- Alarms sounding on the IV pump
- Many facilities have an IV therapy team that maintains the IV sites. For the comfort and safety of the patient, nurses coordinate with these teams per facility policy and procedures and their own skill level.

Evidence-Based Practice

Chlorhexidine antiseptic is the recommended antiseptic to clean the peripheral IV insertion site for 30 seconds to best reduce infections (Flynn, Rickard, Keogh, Zhang, 2017; INS, 2016).

- Select a vein that can be easily seen and palpated and will support the duration of therapy. If veins cannot be easily seen or palpated, consider using a vein visualization device or ultrasound guidance to improve chances for success (INS, 2016).

Special Circumstances

1. **Assess:** Is the nurse unable to obtain IV placement after two attempts?

Intervention: Seek assistance; do *not* continue attempts.

Preprocedure

I. Check patient care provider (PCP) orders and the patient care plan.

Knowledge of patient-specific orders is critical for safe patient care.

II. Gather supplies and equipment.

Preparing for the patient encounter saves time and

promotes patient trust.

III. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

IV. Maintain standard precautions.

Use of the correct PPE is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient, using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Starting a Peripheral Intravenous Line

Follow preprocedure steps I through VIII.

1. Preparing the infusion site: Prepare the necessary supplies on the bedside table.
 - a. Obtain an appropriate-size catheter, and have an extra one available.
 - b. Connect a 3- to 10-mL, sterile syringe prefilled with normal saline solution (NSS) to the saline lock extension tubing. Inject the saline to prime the tubing, and keep the syringe connected.

- c. Set out gauze, dressing supplies, and tape.

Preparing items in advance provides organization to facilitate the performance of the procedure by avoiding interruptions. Using a prefilled syringe promotes accuracy. Priming reduces the risk of an air embolus.

2. Raise the bed to working height, and lower a side rail as needed.
Setting the bed at the correct working height for the provider prevents provider discomfort and possible injury.
3. Identify an appropriate site preferably on the patient's nondominant arm.
 - a. Apply a tourniquet 4 to 6 inches above the site using a quick-release knot.

STEP 3A (Copyright Mosby's Clinical Skills: Essentials Collection.)

- b. Ensure there is a distal pulse.
- c. Move the extremity to a dependent position.

Using the patient's nondominant arm if possible promotes patient comfort and allows the patient to perform activities of daily living (ADLs). The tourniquet restricts blood flow and makes the veins more visible and palpable. The quick-release knot allows one-handed release.

4. Select an appropriate vein:

STEP 4 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Preferred veins are the cephalic, basilic, median, radial, and the dorsal veins of the hand.

- b. Use the index finger to trace and palpate the selected vein; it should be bouncy and well dilated.

The listed veins are preferred due to strength, resilience, and size. Using larger veins reduces the risk for hematoma. Palpation determines the size, depth, and direction of the vein and facilitates accuracy during the procedure.

5. Leave the tourniquet in place for a maximum of 2 minutes and then release.
Releasing the tourniquet restores blood flow, prevents tissue damage, and promotes patient comfort.
6. After 2 minutes, repeat procedure steps 3 through 5 until an appropriate vein is located. Release the tourniquet.
Releasing the tourniquet restores blood flow, prevents tissue damage, and promotes patient comfort.
7. Apply clean gloves.
Using gloves reduces the spread of microorganisms.
8. Repalpate the selected vein.
Ensure accuracy of the original assessment.
9. Reapply the tourniquet, using a quick-release knot.
The tourniquet restricts blood flow and makes the veins more visible and palpable. The quick-release knot allows one-handed release.
10. Cleanse the site using a 2% chlorhexidine swab and using a brisk motion until all of the solution is used. Allow the site to air-dry.
Proper antiseptic procedure is used to prevent the spread of microorganisms. There is no specific direction or technique to be used when preparing a site with 2% chlorhexidine. Air-drying prevents contamination.
11. Insert the IV Angiocath.
 - a. Uncap the needle.
 - b. Place the thumb of the nondominant hand below the site.
 - c. Use the thumb to apply slight pressure, and pull down toward the wrist.
 - d. Hold the bevel at a 10- to 30-degree angle below the insertion site.
 - e. Insert the needle stylet. The initial resistance indicates entry into the vein; advance $\frac{1}{4}$ inch. If blood returns, stop inserting the needle.

STEP 11E (Copyright Mosby's Clinical Skills: Essentials Collection.)

f. Remove the tourniquet with one hand.

STEP 11F (Copyright Mosby's Clinical Skills: Essentials Collection.)

- g. Advance the catheter off of the needle stylet.
- h. Slide the needle out of the catheter, stabilize the vein and device using gentle pressure 1 to 2 inches above (proximal to) the site to hold the catheter in place, and activate the safety device on the needle stylet.

STEP 11H (Copyright Mosby's Clinical Skills: Essentials Collection.)

Proper caregiver hand position stabilizes the patient's arm and vein, which prevents vein rolling or movement, reduces the risk for puncturing a vein, and promotes accuracy and stability during insertion. Using the proper bevel angle prevents accidental needlestick and provider injury. Applying pressure decreases bleeding. Releasing

the tourniquet restores blood flow, prevents tissue damage, and promotes patient comfort. Use gentle pressure to ensure the catheter is still secure. Activating the safety device prevents needlestick injuries.

12. Connect the catheter hub to the saline lock extension tubing.
 - a. Secure the catheter using gentle pressure above the site.
 - b. Carefully twist the tubing onto the hub.
 - c. Flush the IV line with NSS (see [Box 39.11](#)).
 - d. Connect to the IV solution if ordered.

Adding the hub completes the device and closes it from the external environment. Applying pressure assists in securing the device and reduces bleeding. Flushing blood from the line with NSS reduces risk for infection and ensures patency.

STEP 12 (Copyright Mosby's Clinical Skills: Essentials Collection.)

13. Secure the device with an engineered securement device or sterile tape and transparent dressing per facility policy and procedures.

Dressings decrease bleeding and risk for infection.
14. Label the dressing with initials, date and time of day when it was applied, and the gauge of the catheter.

Proper labeling prevents adverse events and medical errors.
15. Discard the needle that has the safety device engaged into a sharps container.

Proper disposal of the needle reduces the spread of microorganisms and prevents accidental needlestick.

Follow postprocedure steps I through VI.

Postprocedure

- I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within

reach of the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

SKILL 39.2 Maintaining a Peripheral Intravenous Infusion

Purpose

- To prevent infections
- To provide fluids
- To administer medications
- To replace electrolytes
- To promote comfort
- To provide nutrition
- To maintain emergency access for medications

Resources

- A 3- to 10-mL prefilled saline flush
- Antiseptic or alcohol wipes
- IV solution per primary care provider (PCP) order
- Appropriate infusion set tubing (primary or secondary, appropriate for pump)
- Clean gloves
- IV pole and pump
- Personal protective equipment (PPE) as required

Interprofessional Collaboration and Delegation

- Maintaining a peripheral IV line, including changing tubing or solutions, may not be delegated to unlicensed assistive personnel (UAP).
- UAP may observe a peripheral IV line and running infusions during care and should report the following to the nurse:
 - Burning, redness, pain, coolness, leaking, bleeding, or swelling at the site of a

- peripheral IV line
- Patient concerns or complaints
- Low volume in an IV bag
- Alarms sounding on the IV pump
- Many facilities have an IV therapy team that maintains the IV sites. For the comfort and safety of the patient, nurses coordinate with these teams per facility policy and procedures and their own skill level.

Evidence-Based Practice

Research has shown that there is no known benefit from the routine changing of IV sites in the absence of clinical indicators, and this can cause unnecessary pain for patients and expense for the facility ([Webster, Osborne, Rickard, et al., 2015](#)).

Special Circumstances

1. **Assess:** Is the IV solution discolored, leaking, or expired?
Intervention: Discard the IV solution and obtain a new solution; document per facility policy and procedures.
2. **Assess:** Is the IV solution in a bottle instead of a bag?
Intervention: Clean the port on the bottle with an antiseptic wipe, and insert a spike into the port on the bottle.
3. **Assess:** Was the tubing spike touched by anything other than the sterile port of an IV bottle?
Intervention: Discard the spike, and restart with a new one.
4. **Assess:** What should be done if an IV solution does not infuse?
Intervention: Check the tubing, and assess the IV site.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and

promotes patient trust.

III. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

IV. Maintain standard precautions.

Use of the correct PPE is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient, using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record.

The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Maintaining a Peripheral Intravenous Line

Follow preprocedure steps I through VIII.

1. Adhere to the Rights of Medication Administration (see [Box 35.4](#)).
Avoid possible medication errors by adhering to the Rights of Medication Administration.
2. Be familiar with and use techniques to reduce medication errors.
It is critical to reduce medication errors and promote patient safety.
3. Obtain all medications for the assigned time before entering the patient's room.

- Promote patient comfort through minimal interruptions.*
4. Ensure medication and solution compatibility.
Verification of compatibility is critical to reduce medication errors and promote patient safety.
 5. Administering IV fluid therapy: Connect the tubing to the IV solution.

STEP 5 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Open the tubing package, slide a roller clamp 2 inches below the drip chamber, and roll the clamp closed.
- b. To remove sterile protections, pull or snap off the cover from the port on the bag and slide off the cover from the spike on the tubing.
- c. Use aseptic technique to insert the spike into the port using a twisting motion. Ensure that it is fully inserted.

Using a roller clamp ensures the accuracy of drip regulation and prevents wasting of solution during preparation. Maintain sterility while preparing the port and spike to prevent the spread of microorganisms.

6. Squeeze the drip chamber, and then fill it half to one-third full with the IV solution.

STEP 6 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Squeezing removes air from the tubing and creates suction.

7. Fill the tubing with solution:
 - a. Remove the cap on the end of the tubing; do *not* discard it, and keep the cap sterile. Place the end of the tubing over the sink; do *not* touch the sink.
 - b. Slowly open the clamp.
 - c. Allow the solution to run through the tubing. Hold tubing upside-down, and tap the ports to release the air and fill the ports.
 - d. Close the clamp when the tubing is full.
 - e. Replace the cap on the tubing.

Maintain sterility and prevent contamination. Proper preparation of the tubing and ports prevents air from entering the tubing and prevents loss of solution.

8. Inspect the tubing for air; if air is present, tap the tubing to move the air up.
Remove air from the tubing to prevent adverse events and complications.
9. Connect the tubing to the peripheral IV catheter (see [Box 39.10](#)).
10. Program the IV pump for infusion; see manufacturer instructions.
Use the correct infusion rate to prevent adverse events and medical errors.
11. Ensure the tubing and solution are labeled per facility policy and procedures.
Proper labeling of solutions prevents adverse events and medical errors.

12. Disconnect the tubing after the infusion is complete (see [Box 39.10](#)).

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach of the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

SKILL 39.3 Central Line Dressing Change and Care

Purpose

- To prevent infection
- To provide long-term intravenous (IV) fluids
- To administer long-term IV medications
- To administer rapid infusions
- To administer irritating medications such as hypertonic solutions or total parenteral nutrition (TPN)
- To maintain emergency access for medications

Resources

- Central line dressing kit including two pairs of sterile gloves, two masks, antiseptic scrub, and transparent dressing
- Sterile gloves, if not included in the central venous line dressing kit
- Clean gloves
- Two face masks or shields if not included in kit
- Chlorhexidine swab (if required by facility and different from that included in the kit)
- Chlorhexidine gluconate patch and/or engineered stabilization device (if required by facility)

Interprofessional Collaboration and Delegation

- Dressing change and care of the central line may not be delegated to unlicensed assistive personnel (UAP).

- UAP may observe a central line during care and should report the following to a nurse:
 - Burning, redness, pain, coolness, leaking, bleeding, or swelling at the site of the central line
 - Patient concerns or complaints regarding the central line
 - Low solution volume in an IV bag
 - Alarms sounding on the IV pump
 - Changes in vital signs

Evidence-Based Practice

- Using chlorhexidine as the antiseptic agent for cleaning the central venous catheter (CVC) site and applying a chlorhexidine gluconate patch is recommended for cleaning and dressing a CVC site.
- Ensuring dressing changes occur every 5 to 7 days has been shown to significantly reduce catheter-related infections ([INS, 2016](#)).

Special Circumstances

1. **Assess:** Has the central venous pressure kit been opened, torn, or contaminated during opening, or has it expired?
Intervention: Stop the procedure and obtain a new kit.
2. **Assess:** Has the site or caregiver's dominant hand been contaminated during the procedure?
Intervention: Stop the procedure and start over.
3. **Assess:** Is the insertion site red or swollen, or have other signs or symptoms of infection been observed?
Intervention: Document the observations appropriately, and notify the primary care provider.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.
- IV. Maintain standard precautions.
Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.
- V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.
- VI. Provide for patient privacy.
It is important to maintain patient dignity.
- VII. Identify the patient, using two identifiers.
Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.
- VIII. Explain the procedure to the patient.
The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Central Line Dressing Change and Care

Follow preprocedure steps I through VIII.

1. Prepare the supplies on a bedside table:
 - a. Place the CVC dressing kit on a bedside table.

- b. Place a small bag (to be used for waste disposal) on the bed, making sure that it is lower than the sterile field (ideally, place it at the foot of the bed).
Alternatively, use a trash can at the side of the bed.

Preparing supplies in advance avoids interruption during the procedure and provides organization that facilitates performance of the procedure. Provide a waste receptacle at a location that will not contaminate the sterile field.

2. Raise the bed to working height, and lower the head of the bed.
Setting the bed at the correct working height for the provider prevents provider discomfort and possible injury. A flat bed provides the optimal position for the procedure.
3. Open the CVC line dressing kit and place a mask on the patient if indicated by facility or manufacturer policy. Have the patient turn his or her face away from the catheter site.
Having the patient avoid breathing on the site while it is unprotected prevents spread of microorganisms and infection.
4. Put on a face mask or shield and the first pair of gloves from the kit.
Use of the correct PPE is required whenever contact with bodily fluids is possible to reduce the spread of microorganisms and prevent infection among patients and providers.
5. Remove the dressing and any engineered stabilization device:

STEP 5 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Remove the dressing in the direction of catheter insertion to prevent accidental catheter removal. Hold the skin taut and gently pull the dressing away from the taut skin.
- b. Dispose of the dressing into the waste receptacle.
- c. Inspect the insertion site.
- d. Remove the gloves, and dispose them in the waste receptacle.
- e. Perform hand hygiene.

The dressing is removed to allow assessment of the site and to facilitate

the remainder of the procedure. Proper disposal of waste prevents contamination of the sterile field with microorganisms. Hand hygiene reduces the spread of microorganisms and reduces infections.

6. Add the engineered stabilization device to the sterile field if required by facility policy. Put on sterile gloves (see [Chapter 26, Skill 26.2](#)), and prepare items from the kit on the sterile field (see [Chapter 26, Skill 26.4](#)).

Maintain sterile procedure to reduce the spread of microorganisms and prevent infection. Preparing supplies in advance maintains organization and avoids interruption during the procedure.

7. Cleanse the central line site:

STEP 7 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Use the nondominant hand to hold the catheter vertically in the air (i.e., off the skin).
- b. With the dominant hand, use a chlorhexidine swab with a vertical and horizontal motion around the site for at least 30 seconds. Cleanse the tubing with the swab. Discard the swab in the waste receptacle. If a chlorhexidine swab is not available, refer to facility policy and procedures for an appropriate antiseptic solution or swab.

Proper cleansing technique is used to prevent the spread of microorganisms and avoid infection.

8. Allow the site to air-dry for 30 seconds. Apply skin protectant to the site and allow it to dry.

Air-drying prevents contamination and reduces infection and the spread of microorganisms. Skin protectant helps the adhesive stick to the skin and protects skin from tearing.

9. Apply a chlorhexidine gluconate patch around the catheter and over the site, with the slit positioned over the central line. If a chlorhexidine gluconate patch is not available, refer to facility policy and procedures for an appropriate dressing.

STEPS 9 AND 11 (Copyright Thankstock.com.)

Proper antiseptic equipment and procedures are used to prevent the spread of microorganisms and infection.

10. Apply a stabilization device to secure the catheter if required by facility policy.

STEP 10

Secures the catheter to the skin.

11. Apply a transparent dressing over the site.
Transparency allows for site assessment without removing the dressing.
12. Write initials, date, and time of day on the dressing label; apply the label over the dressing, but do *not* occlude the site.
Proper labeling of the dressing prevents adverse events and medical errors by communicating essential information. Avoid placing labels over the site to allow for visualization of the insertion point of the line.
13. Remove gloves, and discard used supplies in a waste receptacle.
Proper disposal of waste prevents the spread of microorganisms.

Follow postprocedure steps I through VI.

Postprocedure

- I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach of the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Summary of Learning Outcomes

LO 39.1 *Discuss the normal structure and function of fluids, electrolytes, acids, and bases in the body:* Fluids can be found in two areas in the body: intracellular and extracellular; extracellular sites include the interstitial, intravascular, and transcellular spaces. Fluid moves by osmosis from areas of lower concentration of solutes to areas of higher concentration. The major electrolytes in the body are sodium, potassium, calcium, magnesium, chloride, and phosphate ions. Movement of electrolytes occurs through diffusion, filtration, and active transport. The body must maintain a normal pH (7.35 to 7.45) to function efficiently. Three mechanisms maintain normal pH levels: buffering systems, respiratory control of carbon dioxide (CO_2), and renal control of bicarbonate (HCO_3^-).

LO 39.2 *Differentiate among common fluid, electrolyte, and acid-base imbalances and their underlying causes:* Common fluid and electrolyte imbalances include fluid volume deficit, fluid volume excess, hyponatremia, hypernatremia, hypokalemia, hyperkalemia, hypocalcemia, hypercalcemia, hypomagnesemia, hypermagnesemia, hypochloremia, hyperchloremia, hypophosphatemia, and hyperphosphatemia. The numerous causes of fluid and electrolyte imbalances include inadequate or excessive intake and output, medications and IV therapy, and a variety of illnesses. Four acid-base imbalances can occur: respiratory acidosis, respiratory alkalosis, metabolic acidosis, and metabolic alkalosis.

LO 39.3 *Outline assessment priorities for patients with fluid, electrolyte, and acid-base imbalances:* Assessment parameters for fluid, electrolyte, and acid-base imbalances include the health history, especially recent changes in fluid intake, diet, and weight; edema and altered skin turgor; and diagnostic test results.

LO 39.4 *Identify the most common nursing diagnoses related to fluid, electrolyte, and acid-base imbalances:* Nursing diagnoses related to fluid and electrolyte imbalances include *Fluid Imbalance, Fluid Retention, Dehydration, Impaired Cardiac Output, Acute Confusion, Risk for Injury, and Impaired Skin Integrity.*

LO 39.5 *Integrate nursing goals and outcomes into the plan of care for patients with fluid, electrolyte, and acid-base imbalances:* Nursing goals reflect attainment of balanced intake and output, a stable daily weight, normal urine specific gravity, vital signs within the patient's normal limits, and normal serum levels of electrolytes and arterial blood gases.

LO 39.6 *Carry out and evaluate nursing interventions to maintain normal fluid, electrolyte, and acid-base balance or to correct imbalances:* Interventions for fluid imbalances include ongoing focused assessment and evaluation, such as when to restrict or encourage fluids, when to restrict or provide supplemental electrolytes, and management of IV therapy. Blood infusions and total parenteral nutrition may be needed by select patients.

Review Questions

1. A patient has reported a 2-kg (4.4-lb) weight gain over the past 3 days. Which dietary factor should the nurse assess?
 - a. Protein intake
 - b. Potassium intake
 - c. Calorie intake
 - d. Sodium intake
2. A nurse caring for a hospitalized patient with diarrhea and dehydration is told in the shift report that the patient's laboratory results have just come in. Which abnormal laboratory values should be reported to the primary care provider? (*Select all that apply*).
 - a. Sodium (Na) level 150 mEq/L
 - b. Potassium (K) level 3.3 mEq/L
 - c. Calcium (Ca) level 9.5 mg/dL
 - d. Magnesium (Mg) level 1.0 mEq/L
 - e. Chloride (Cl) level 101 mEq/L
3. For a patient with a nursing diagnosis of *Dehydration*, the nurse is alert to which signs and symptoms? (*Select all that apply*).
 - a. Hypertension
 - b. Flushed skin
 - c. Dry mucous membranes
 - d. Weak, thready pulse
 - e. Pale yellow urine

4. The nurse is caring for a patient with hypocalcemia who does not like milk. Which food should the nurse encourage the patient to consume?
 - a. Cod
 - b. Eggs
 - c. Spinach
 - d. Tomatoes

5. A nurse in the emergency department is caring for an adult patient with numerous draining wounds from gunshots. The patient's pulse rate has increased from 100 to 130 beats/min over the past hour, and the patient is experiencing orthostatic hypotension. For which imbalance should the nurse assess?
 - a. Respiratory acidosis
 - b. Extracellular fluid volume deficit
 - c. Metabolic alkalosis
 - d. Intracellular fluid volume excess

6. A 65-year-old female patient is a two-pack-a-day cigarette smoker with a history of chronic obstructive pulmonary disease (COPD). What is the interpretation of her arterial blood gas values (pH 7.34, PCO_2 55, PO_2 82, HCO_3^- 32)?
 - a. Partially compensated respiratory alkalosis
 - b. Uncompensated metabolic acidosis
 - c. Uncompensated respiratory alkalosis
 - d. Partially compensated respiratory acidosis

7. A patient with a continuous IV of D_5 0.9% NS running at 150 mL/hr begins to exhibit hallucinations

and confusion. Which laboratory value should the nurse expect to check?

- a. Calcium
 - b. Carbon dioxide
 - c. Magnesium
 - d. Sodium
8. The nurse is assessing the intravenous (IV) site in the right forearm and notices the area about 1 inch around it is cool, swollen, firm, and tender to touch. Which action should the nurse take first?
- a. Take patient's temperature
 - b. Apply an ice pack to site
 - c. Stop infusion and remove IV catheter
 - d. Call the primary care provider immediately
9. Which activity is important to include in the plan of care for a client with a peripherally inserted central catheter (PICC)?
- a. Use sterile technique when changing the PICC dressing.
 - b. Change the IV tubing every 72 hours.
 - c. Take blood pressure in the arm with the PICC line.
 - d. Use only macrodrip tubing with IV infusions through the PICC line.
10. The nurse has just begun an infusion of packed red blood cells (PRBC). Which of the following changes would indicate a transfusion reaction and warrants stopping the infusion?
- a. Respirations increased from 16/min to 20/min.

- b. Urine output in Foley catheter bag has 50 mL/h output of dark yellow urine.
- c. Heart rate decreased from 77 beats/min to 62 beats/min.
- d. Temperature increased from 100° degrees to 102.2°

CHAPTER 40

Bowel Elimination

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 40.1 Describe the anatomy and physiology of the gastrointestinal tract and the processes involved in formation, storage, and elimination of waste products.
- LO 40.2 Identify common alterations in bowel elimination.
- LO 40.3 Integrate components of a comprehensive assessment of the patient to identify issues with bowel elimination.
- LO 40.4 Identify nursing diagnoses related to bowel elimination.
- LO 40.5 Outline goals for patients experiencing alterations in bowel elimination.
- LO 40.6 Implement and evaluate interventions to maintain normal bowel elimination.

KEY TERMS

cathartic, p. 1012

chyme, p. 1005

***Clostridium difficile*, p. 1007**

colonoscopy, p. 1015

colostomy, p. 1008

constipation, p. 1007

defecation, p. 1007

diarrhea, p. 1007

enema, p. 1019

fecal occult blood test, p. 1014

flatulence, p. 1008
hemorrhoids, p. 1006
ileostomy, p. 1010
impaction, p. 1008
incontinence, p. 1007
lavage, p. 1019
laxatives, p. 1012
ostomy, p. 1008
paralytic ileus, p. 1012
peristalsis, p. 1006
polyps, p. 1014
stoma, p. 1008
suppository, p. 1019
Valsalva maneuver, p. 1008

Case Study

Theresa Schaffer (T. S.) is an 82-year-old woman admitted to the rehabilitation center after undergoing surgery for repair of a right hip fracture from a fall at home. At 72 hours post-surgery, she is receiving morphine patient-controlled anesthesia (PCA) for moderate postoperative pain, with results of reduction in reported pain. She has no significant medical history and no known drug allergies (NKDA). Her do-not-resuscitate (DNR) document specifies a full code.

T. S.'s vital signs are T 37.1° C (98.9° F), P 70 and regular, R 12 and unlabored, and BP 110/76, with a pulse oximetry reading of 97% on room air. Weight 101.4 kg (223 lb), Height 170.2 cm (67 in). T. S. is reluctant to move around, stating that the pain is worse when she moves. She rates her pain as 5 of 10 and refuses additional medication. She needs the assistance of one person to move from bed to chair. She has been ordering her own meals from the cafeteria but has not eaten more than half of the meal that was sent. Her morning tray included eggs with sausage and a slice of toast. Her fluid intake over the past shift was 200 mL in 8 hours, and her output was 180 mL. On auscultation, she has hypoactive bowel sounds, and her abdomen is slightly firm and tender to deep palpation. During the evening assessment, the patient informs the nurse that she “feels constipated” and that she has not moved her bowels in a few days.

Treatment orders are as follows:

- Physical therapy for ambulation
- Vital signs q shift
- Regular diet as tolerated
- Intake and output q shift
- Incentive spirometer q 1 h while awake
- Complete blood count and serum chemistry panel daily

Medication orders are as follows:

- Morphine PCA 1 mg/h basal with 0.4 mg q 10 min, with 4 mg/h lockout
- Enoxaparin 60 mg subcutaneously daily
- Docusate 1 capsule daily

Refer back to this case study to answer the critical-thinking questions throughout the chapter.

In most American households, bowel elimination is considered a private matter, one that generally is not talked about with others. Within the health care environment, however, the patient's bowel elimination function, or dysfunction, is evaluated, analyzed, and discussed frankly and openly. The nurse must be aware of the patient's discomfort and embarrassment that can potentially accompany discussion of bowel elimination, understand the associated issue of self-esteem, and be sensitive to what the patient may regard as a personal matter.

Elimination of solid waste products is a normal function of the body and critical to maintaining nutritional status, hydration, and fluid and electrolyte balance. Regular bowel elimination may be disrupted by various factors, including food and fluid intake, various illnesses and diseases, trauma and surgery, medications, immobility, and psychological issues. Alteration in bowel elimination can become a life-threatening medical emergency. Consistent monitoring of bowel patterns is an essential nursing assessment. The nurse must understand the physiology of elimination, factors that alter elimination, and measures that assist the patient in maintaining bowel function.

LO 40.1 Normal Structure and Function of the Gastrointestinal Tract

The gastrointestinal (GI) tract is the body system responsible for the digestion of food and absorption of nutrients and fluids. Because this chapter addresses bowel elimination, the focus is on the essential role of the GI system in the formation, storage, and elimination of waste products. The GI system is a series of muscular organs extending from the mouth to the anus (Fig. 40.1).

FIGURE 40.1 The gastrointestinal system: Mouth through anus. (From Monahan, F. D., Sands, J. K., Neighbors, M., et al. [2007]. *Phipps' medical-surgical nursing: Health and illness perspectives* [8th ed.]. St. Louis: Mosby.)

Esophagus

The esophagus is a collapsible tube, connecting the pharynx to the stomach. From the pharynx, the esophagus passes through the mediastinum and diaphragm and meets the stomach at the location of the lower esophageal sphincter. The primary function of the esophagus

is to transport solids and liquids from the mouth, where digestion begins, into the stomach (Heuther & McCance, 2017).

Stomach

The stomach begins at the cardiac sphincter of the esophagus and extends into the duodenum through the pyloric sphincter. Anatomically it is located in the left upper quadrant of the abdomen, slightly inferior to the diaphragm. The function of the stomach is to mix food with digestive juices, causing the chemical and mechanical breakdown of food into **chyme** before entering the small intestine. Chyme is a thick fluid mass of partially digested food and gastric secretions that is passed from the stomach to the small intestine.

The stomach produces and secretes hydrochloric acid, pepsin, intrinsic factor, and mucus. The hydrochloric acid combines with the digestive enzymes to cause a breakdown of the food structures and helps kill harmful bacteria ingested with the foods. Pepsin is an enzyme produced in the mucosal lining of the stomach that acts to degrade protein. Intrinsic factor is a protein produced by cells in the stomach lining. It is needed for the intestines to efficiently absorb vitamin B₁₂, which is needed to produce red blood cells. Mucus protects the stomach lining from damage by the gastric acid and enzyme activity (Heuther & McCance, 2017)

Small Intestine

The small intestine has digestive and absorptive functions. Intestinal juices and bile from the liver, gallbladder, and pancreas mix with the chyme for digestion and absorption of nutrients. The small intestine is a hollow cylindrical organ, approximately 6 meters (18 to 21 feet) in length; it contains three segments.

The first section of the small intestine, the *duodenum*, begins at the pyloric sphincter. The duodenum has two secretory functions. First, hormones are secreted that trigger the pancreas to release pancreatic juice and bile. Second, the duodenum protects the intestine by secreting chemicals that neutralize the acidity of the chyme from the stomach before it reaches the jejunum.

The midregion of the small intestine, the *jejunum*, controls carbohydrate and protein absorption. The third section, the *ileum*, extends from the jejunum to the ileocecal valve at the cecum of the large intestine. The ileum is responsible for the absorption of fats, bile salts, and water. Contents that remain undigested after passing through the small intestine, such as fiber, the indigestible portion of plant foods,

empty into the cecum in the lower right quadrant of the abdomen (Heuther & McCance, 2017).

Large Intestine

The large intestine is the primary organ of bowel elimination. It is shorter in length, 1.5 m (5.5 ft), but wider in diameter than the small intestine; it extends from the ileocecal valve to the anus. The large intestine is composed of the cecum, ascending colon, transverse colon, descending colon, sigmoid colon, rectum, and anus. Anatomically, the large intestine is located on the periphery of the abdominal compartment and surrounds the small intestine and other structures.

Peristalsis, the mechanism of progressive contraction and relaxation of the walls of the intestine, forces chyme into the large intestine through the ileocecal valve, which prevents regurgitation (backflow) of chyme (Heuther & McCance, 2017) (Fig. 40.2).

FIGURE 40.2 Peristalsis. (From Hall, J. E. [2016]. *Guyton and Hall textbook of medical physiology* [13th ed.]. St. Louis: Elsevier.)

The colon is made up of muscular tissue that is able to expand and contract to accommodate and eliminate varying amounts of waste and gas (flatus). The functions of the colon are absorption, secretion, and elimination. Serious electrolyte imbalances may occur with alterations in colonic function. Water is absorbed from indigestible food residue. Nutrients and electrolytes, especially sodium and chloride, are absorbed from digested food that has passed from the small intestine. Bicarbonate is secreted in exchange for chloride. The colon excretes 4 to 9 mEq of potassium daily. A mucous layer is in place to help protect the intestinal wall. Waste from the body is eliminated through the formation of feces and expelled from the body by way of the rectum and anus (Heuther & McCance, 2017).

Rectum and Anus

The rectum is the final portion of the large intestine; it is approximately 10 to 15 cm (4 to 6 inches) in length. At the distal portion lies the anus, which is 2.5 to 5 cm, or 1 to 2 inches. The rectum has folds of tissue that temporarily hold fecal contents. Each fold contains an artery and a vein that can become distended from pressure during straining. This distention may result in the formation of hemorrhoids. **Hemorrhoids** are swollen and inflamed veins in the anus or lower rectum.

The anal canal contains an internal and an external sphincter, each controlled by the sympathetic and parasympathetic nervous system. The sensory nerves in the anal canal help control bowel continence (Heuther & McCance, 2017).

Defecation

The final act of digestion by which the solid, semisolid, or liquid waste is expelled by the body is the process of **defecation**, or bowel movement. Feces and flatus are expelled from the GI tract through the anal canal and anus. Frequency and amount of defecation will vary and differs from person to person, ranging from two or three times per week to several times per day. When peristaltic waves move the waste into the rectum, the nerves in the rectum are stimulated so that the person becomes aware of the need (urge) to defecate (Heuther & McCance, 2017).

Feces can be hard and dry, formed, soft, or liquid and dark to light brown. The characteristics of feces vary, depending on diet, illness, medications, and age.

LO 40.2 Altered Structure and Function of the Gastrointestinal Tract

Many hospitalized patients either are at risk for or have some type of alteration in bowel elimination. The changes may be due to physiologic issues, such as surgical alterations or disease processes, changes in diet, medication effects, or mobility issues. Changes may be psychological and related to stress, anxiety, depression, or eating disorders. The role of the nurse is to recognize the disorders as well as the associated risks and prevent further impairment of the patient's health status.

Abnormal Defecation Patterns

Because the organs of the GI system process food and fluids for use within the body systems, any alteration may lead to serious issues for the patient. Impaired elimination has serious implications for patient well-being and treatment outcomes.

Diarrhea

Diarrhea is an intestinal disorder that is characterized by an abnormal frequency and fluidity of bowel movements. Hyperactive bowel sounds, urgency, abdominal pain, and cramping are characteristics. Diarrhea is associated with disorders that affect digestion, absorption, and secretion in the GI tract. Ingested materials pass too quickly through the intestine, resulting in a decrease in the amount of time for absorption of fluids and nutrients. Many pathologic conditions and other factors may cause diarrhea, including allergies or intolerance to food, fluids, or drugs; antibiotic use; cathartic or laxative use; communicable foodborne pathogens; diseases of the colon; diagnostic testing of the lower GI tract; enteral nutrition usage; medications; psychological stress; surgery of the GI tract; and **Clostridium difficile**.

C. difficile is a bacterium that causes diarrhea. It can lead to life-threatening inflammation of the colon. *C. difficile* infection with associated diarrhea, often called simply "C-diff," most commonly affects older adults in hospitals and long-term care facilities and typically occurs after use of antibiotic medications (Napolitano & Edmiston, 2017). C-diff is easily transmitted by contact, and in recent years these infections have become more difficult to treat. The most common clinical symptoms in mild to moderate C-diff consist of occurrence of foul-smelling, watery diarrhea three or more times a day

for 2 or more days, accompanied by mild abdominal cramping and tenderness (Napolitano & Edmiston, 2017).

The patient with diarrhea produces an increased number of stools, with passage of liquid or unformed feces, and finds it difficult to control the urge to defecate. In addition to frequent liquid stools, the patient often experiences spasmodic cramps and hyperactive bowel sounds. Prolonged diarrhea may lead to nutritional and metabolic disturbances, with resultant fatigue, weakness, malaise, and loss of a substantial amount of fat and muscle tissue, making the patient look extremely thin or emaciated. Serious fluid and electrolyte losses can develop within a short time, particularly in infants, small children, and elderly people, causing symptoms of nausea, vomiting, headache, confusion, fatigue, restlessness, and muscle weakness and spasms. With persistent diarrhea, the patient may experience irritation of the anal region, increasing the risk for skin breakdown.

Incontinence

Incontinence refers to the loss of voluntary control of fecal and gaseous discharges through the anus. Incontinence can have a profound impact on the affected person's body image. In many cases, the patient is alert but unable to control defecation. The patient is at risk for skin breakdown and may suffer from social isolation related to embarrassment from the soiling of clothing or use of incontinence products.

Constipation

Constipation is a common problem, affecting the quality of life for many. It is estimated that more than 4 million Americans complain of frequent constipation. Women report constipation more often than men, and adults older than 65 years of age are more likely to have constipation. Constipation is a complication of pregnancy and after surgery (National Institutes of Health [NIH], 2018).

Constipation is defined as having infrequent or difficult bowel movements, as well as having fewer than three bowel movements per week. Slowed intestinal peristalsis and infrequent bowel movements result in increased water absorption in the colon, leading to difficulty passing stool, excessive straining at defecation, the inability to defecate at will, hard feces, and rectal pain. In addition, the patient may experience abdominal cramping, pain, pressure, distention, anorexia, and headache.

Causes of constipation extend across the clinical spectrum. Irregular bowel habits, ignoring the urge to defecate, a diet low in fiber or high in

animal fats, hemorrhoids, and low fluid intake are causative factors. Patients with conditions that block nerve impulses to the colon, including spinal cord injury and tumor, may have changes in bowel patterns. Metabolic conditions such as hypothyroidism, hypercalcemia, or hypokalemia slow GI motility or increase water absorption. Psychiatric issues, including anxiety, depression, and cognitive impairment, may lead to changes in bowel habits or decreased recognition of defecation urge. Prolonged periods of bed rest or lack of regular exercise will slow GI motility. Medications, including anticholinergics, antispasmodics, anticonvulsants, antidepressants, antihistamines, antihypertensives, antiparkinsonian agents, bile acid sequestrants, diuretics, antacids, iron supplements, calcium supplements, and opioids, have been shown to slow colonic action. Laxative misuse is associated with rebound constipation. Older adults may experience slowed peristalsis related to the loss of muscle elasticity, reduced intestinal mucous secretion, or a low-fiber diet. The patient with hemorrhoids may experience pain and have difficulty passing stool, which can lead to retention of fecal material and contribute to constipation.

Constipation presents a significant health risk to the patient. Straining during defecation can induce elevations in intraocular pressure, increased intracranial pressure, changes in cardiac rhythms, and hemorrhoids. The **Valsalva maneuver** consists of “bearing down” while holding the breath. The person thus is exerting force against a closed windpipe, creating increased intrathoracic pressure. This maneuver causes an extremely rapid rise in blood pressure, which is followed by a fall in arterial blood pressure. Dizziness, blurred vision, and fainting can result.

Impaction

Impaction refers to the presence of a hard fecal mass in the rectum or colon that the patient is incapable of expelling. Impaction is the result of unresolved constipation. Over time, a mass of stool becomes wedged in the bowel and cannot be passed with a bowel movement. Impaction is seen most often in debilitated, confused, or unconscious patients.

The patient may report the inability to pass a stool for several days or longer, despite repeated urges to defecate. The cardinal sign of impaction is continuous oozing of liquid stool, with no normal stool. Oozing occurs as the liquid portion of feces higher in the intestines seeps around the mass. Loss of appetite, nausea, vomiting, distention, cramping, and rectal pain accompany the condition. Barium used in radiologic examinations contributes to the risk for impaction. The at-risk patient receiving barium for diagnosis or treatment is encouraged

to increase fluids or is given laxatives or enemas to ensure removal of the barium.

Diagnosis of impaction is by digital examination and palpation of the fecal mass. Digital examination, manipulation, and removal of a fecal impaction are within the scope of practice for nurses, although some agencies require an order from a primary care provider (PCP).

Flatulence

Flatulence is the production of a mixture of gases in the intestine, by-products of the digestive process. The mixture, known as *flatus*, is expelled from the mouth (belching) or the anus (passing of flatus). The noises commonly associated with flatulence are caused by air escaping. Discomfort may develop from the buildup of gas pressure. Severe flatulence often is associated with abdominal distention and severe sharp pain.

Flatulence is a normal body function and an important signal of normal activity. It is documented by nursing staff after surgical procedures or other treatments to indicate the return of normal bowel function.

Flatulence results from a variety of sources. Action of bacteria in chyme passing through the large intestine, swallowed air and gases that diffuse between the bloodstream and the intestine, foods such as cabbage and onions, abdominal surgery, and narcotics can lead to changes in the motility of the bowel and may increase flatulence. Movement such as walking and rocking may help relieve pain and promote movement of the gases through the intestines. It may be necessary to insert a rectal tube if excessive gas cannot be expelled through the anus.

Bowel Diversions

The terms *ostomy* and *stoma* often are used interchangeably, although they have different meanings. An **ostomy** is a surgically created opening in a GI, urinary, or respiratory organ that is exited onto the skin. A **stoma** ("mouth" in Greek) is any body opening but usually refers to the actual exit point for a GI surgical ostomy, which forms a slight protuberance of mucosa (gut lining tissue) through the skin.

Bowel diversions or ostomies are created to divert and drain fecal material. Bowel ostomies are classified as either temporary or permanent and by their anatomic location and technique of stoma construction. Bowel diversions are created for patients with conditions that prevent normal passage of feces from the rectum. The location of the ostomy determines the consistency of the stool. Water reabsorption

varies for specific areas of the bowel, leading to differences in the consistency of the stool (e.g., very liquid stool with an ileostomy and very formed stool with a descending colostomy).

Colostomy

A **colostomy** is surgically created when a portion of the colon (large intestine) or the rectum is removed and the remaining colon is brought through the abdominal wall. A temporary colostomy is used to allow the lower portion of the colon to rest or heal. Usually created in emergency situations, temporary colostomies are designed to be closed at a later time. The colostomy may have one or two openings (with two, one of them will discharge only mucus).

Permanent colostomies are placed when surgical resection of diseased tissue leads to loss of part of the colon. They are created as a treatment for colorectal cancer or after the lower digestive tract is removed due to illness or disease. Single stomas are created when one end of the bowel is brought out through an opening onto the anterior abdominal wall. The distal portion of the GI tract usually is removed or sewn closed. This type is referred to as an end, or terminal, colostomy and is permanent.

Sigmoid and descending colostomies are the most common type of ostomy surgeries. The end of the descending or sigmoid colon is brought to the surface of the abdomen, usually on the lower left quadrant (Fig. 40.3). The descending colostomy is located higher than the sigmoid colostomy. Both produce solid fecal material. The frequency of discharge with both types can be regulated. Patients with descending or sigmoid colostomies may not need to wear an appliance at all times, and odors usually can be controlled (Schreiber, 2016).

The **ascending colostomy** is used for right-sided tumors.

The **transverse (double-barrel) colostomy** is often used in such emergencies as intestinal obstruction or perforation because it can be created quickly. There are two stomas. The proximal one, closest to the small intestine, drains feces. The distal stoma drains mucus.

The **descending colostomy** is used for left-sided tumors.

The **sigmoid colostomy** is used for rectal tumors.

FIGURE 40.3 Location of colostomies. (From Ignatavicius, D. D., Workman, M. L., Rebar, C. R., et al. [2018]. *Medical-surgical nursing: Concepts for interprofessional collaborative care* [9th ed.]. St. Louis: Elsevier.)

A transverse colostomy is created in the transverse colon, resulting in one or two openings. It is located in the upper abdomen, in the middle or on the right side (see Fig. 40.3). Transverse colostomies produce semiformed liquid, malodorous drainage because some liquid has been reabsorbed. The patient usually has no control over the frequency of discharge of stool, so appliances are in place at all times (Schreiber, 2016).

Ascending colostomies are similar to ileostomies. Drainage is liquid and cannot be regulated. Digestive enzymes are present and cause an odor. Ascending colostomies are relatively rare. The opening is in the ascending portion of the colon and is located on the right side of the abdomen (see Fig. 40.3) (Schreiber, 2016).

The loop colostomy is a temporary colostomy created in a surgical emergency; it is on the right abdomen. The loop colostomy consists of

one stoma with two openings (Fig. 40.4). The proximal end of the stoma is active and discharges stool. The distal end is inactive and may discharge mucus. The loop colostomy is created when a loop of bowel is brought out onto the abdominal wall and supported by a bridge. The loop colostomy procedure results in a large stoma that may be difficult to manage because of its size and inability to be covered with available ostomy products (Schreiber, 2016).

FIGURE 40.4 Loop colostomy. (From Phillips, N. [2017]. *Berry & Kohn's operating room technique* [13th ed]. St. Louis: Elsevier.)

With the double-barrel colostomy, two ends of bowel are brought out onto the abdominal wall, resulting in two distinct stomas (see Fig. 40.3). The proximal end is the functional stoma, and the distal end is the nonfunctional stoma. The bowel between the double-barrel colostomy stomas is surgically severed.

Ileostomy

An **ileostomy** is a surgically created opening in the small intestine, usually at the end of the ileum (Fig. 40.5). The intestine is brought through the abdominal wall to form a stoma. Ileostomies may be temporary or permanent and may involve removal of all or part of the colon. An ileostomy bypasses the large intestine. Stools from an ileostomy are frequent and liquid and cannot be regulated. Drainage contains digestive enzymes, which can be damaging to the skin; therefore patients with ileostomies wear an appliance continuously and take special precautions to prevent skin breakdown. Because few

bacteria are present, odor is minimal. Fluid and electrolyte balance is monitored closely for the patient who has an ileostomy in place.

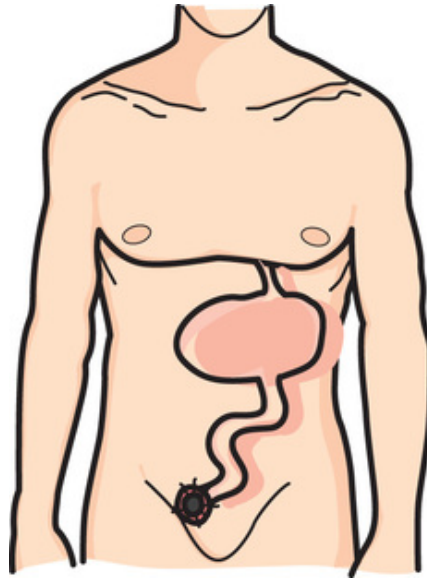

FIGURE 40.5 Ileostomy. (From Phillips, N. [2017]. *Berry & Kohn's operating room technique* [13th ed.]. St. Louis: Elsevier.)

The ileoanal pouch is now the most common ileostomy. Technically, it is not an ostomy because there is no stoma. In this procedure, the colon and most of the rectum are surgically removed, and an internal pouch is formed out of the terminal portion of the ileum. An opening at the bottom of this pouch is attached to the anus so that the existing anal sphincter can be used for continence (Fig. 40.6). This procedure is performed on patients with ulcerative colitis or familial polypos in whom the anal sphincter is still intact (not removed in previous surgery). Other terms to describe this procedure are a pull-through, endorectal pull-through, pelvic pouch, and J-pouch procedure. After the initial pouch creation, the patient has a temporary ileostomy to allow the anastomosis to heal.

FIGURE 40.6 Ileoanal reservoir. (From Lewis, S. L., Bucher, L., Heitkemper, M. M., et al. [2017]. *Medical-surgical nursing: Assessment and management of clinical problems* [10th ed.]. St. Louis: Elsevier.)

The Kock pouch is a surgical variation of the ileostomy. A reservoir pouch is created inside the abdomen with a portion of the terminal ileum. A valve is constructed in the pouch, and a stoma is brought through the abdominal wall. A catheter or tube is inserted into the pouch several times a day to drain feces from the reservoir.

Factors Affecting Bowel Elimination

Elimination patterns can be altered in health as well as illness. A regular elimination pattern is specific to each patient, and influenced by age, environment, and culture (Box 40.1). Diet, physical activity, emotional health, and surroundings may affect elimination in either a positive or a negative way.

Box 40.1

Diversity Considerations

Life Span

- Meconium is the first fecal material passed by the newborn. It is black, tarry in consistency, odorless, and sticky.
- Infants have a small stomach, less secretion of enzymes, and a fast transit of food through the gastrointestinal tract. As a result, they

pass stool frequently, often after each feeding. Because the intestine is immature and water is not well absorbed, infants who are breast-fed have light yellow to golden feces that are soft and liquid.

Infants who are fed formula have stool that is dark yellow in color and well formed.

- Control of defecation typically is achieved at the age of approximately 2 years.
- School-age children and adolescents have bowel habits similar to those of adults.
- Constipation may be an issue with school-age children related to lack of privacy, risk for bullying, limited access, and dirty bathrooms. These factors can cause a child to delay defecation during school ([Xinias and Mavroudi, 2015](#)).
- Older adults may have poor fluid intake, be unable to eat fiber, have limited access to consistent meals, or have swallowing and chewing difficulties, which may lead to constipation.
- Constipation is the most common bowel management problem in the elderly population.
- Bowel elimination problems are especially prevalent in long-term care facilities.

Culture, Ethnicity, and Religion

- In the United States, African Americans have the highest incidence of colorectal cancer ([American Cancer Society; 2018b](#)).
- In the world's ethnic populations, people of Eastern European Jewish descent have a high risk for colorectal cancer ([American Cancer Society; 2018b](#)).
- Cultural factors, such as the gender of the caregiver, may affect bowel elimination and nursing care.

Disability

- Patients with physical limitations and mobility problems may have difficulty with constipation and incontinence.
- A reduction in activity levels and muscle weakness decreases peristalsis and slows esophageal emptying.
- Patients with impaired mobility may have difficulty getting to the bathroom and may need assistive devices such as bars or raised toilet seats or elevated commodes.

- Cognitive impairment such as Alzheimer disease may decrease the ability to respond to urge, contributing to constipation or incontinence.
- Patients with mental limitations may have difficulty recognizing or responding to urge.
- A slowing of nerve impulses to the anal region in some neurologic diseases may make the patient become less aware of the need to defecate, leading to development of irregular bowel movements.

Morphology

- Up to 66% of obese people suffer from osteoarthritis, which causes functional impairment and interferes with activities of daily living.
- Obesity can lead to gastroesophageal reflux disease (GERD), stress incontinence, hemorrhoid formation, and abdominal hernias.
- Morbidly obese patients have an increased risk for incontinence related to several factors, among which is the difficulty sitting on a standard size bedpan, bedside commode, or toilet.
- The additional time it takes for the obese patient to get to the toilet, or to move the patient to the toilet, may be responsible for incontinence episodes.
- Pressure of an enlarged abdomen on the bowel places pressure on the sphincter, resulting in stool leakage ([Schreiber, 2016](#)).

Diet

Daily food intake maintains peristalsis. Ingestion of a high-fiber diet improves the likelihood of a normal elimination pattern. Fiber in whole grains, fresh fruits, and vegetables flushes fats and waste products more efficiently and helps keep stool soft. It is recommended that adults include 20 to 35 g of fiber in the diet each day to promote bowel health.

With consumption of gas-producing foods such as onions, cauliflower, and beans, intestinal walls can become distended, increasing colon motility. Food intolerance (e.g., lactose intolerance) results in digestive upset and, in some instances, the passage of watery stools, diarrhea, cramps, or flatulence. Fluid intake or loss affects characteristics of feces. Increased water intake eases the passage of stools. Poor fluid intake increases the risk for constipation because passage of stool is slower, promoting additional water reabsorption that results in harder stools. Spicy foods produce diarrhea and flatus in some people. Cheese, pasta, eggs, and lean meats can be constipation-producing foods. Bran, prunes, figs, chocolate, and alcohol have a

laxative effect. Many people whose lifestyle includes the same mealtimes daily exhibit a regularly timed response to food and a regular pattern of peristaltic activity in the colon.

Physical Activity

Regular physical activity promotes peristalsis and facilitates movement of chyme through the colon. Regular activity maintains the tone of pelvic and abdominal floor muscles. Weakened abdominal and pelvic floor muscles resulting from lack of exercise, immobility, or altered neurologic function are often ineffective in increasing the intraabdominal pressure during defecation, leading to constipation.

Psychological Factors

Emotional stress accelerates the digestive process, and peristalsis is increased. Diarrhea, nausea, and gaseous distention often occur. Diseases associated with stress include colitis, Crohn disease, ulcers, and irritable bowel syndrome. Patients with depression may have slowed peristalsis, resulting in constipation.

Personal Habits

Sharing a bathroom with another person, privacy concerns, convenience of toileting facilities, and busy schedules all influence bowel habits in hospitalized patients. These patients need support to establish or maintain regular personal elimination habits.

Hospitalized patients may have activity intolerance and limited balance because of disease states. The sounds, sights, and odors associated with use of bedpans and bedside commodes, or of shared toilet facilities, are embarrassing to the patient, contributing to development of constipation. Patients may ignore the urge to defecate, allowing for increased water absorption in the colon, in turn making feces hard and difficult to expel. When habitually suppressed, the urge to defecate may be lost and constipation and impaction occur.

Posture

The normal posture during defecation is squatting, which most modern toilets facilitate. The immobilized patient is not able to effectively contract abdominal muscles, making defecation difficult. If permitted, the head of the patient's bed is elevated to allow for a position more likely to facilitate defecation.

Pain

Hemorrhoids, rectal surgery, fistulas, and abdominal surgery will cause patients to suppress the urge to defecate, to avoid pain. With repeated failure to defecate, constipation may result or become worse. Narcotic pain medications also contribute to development of constipation. Stool softeners may be prescribed.

Pregnancy

As the fetus grows, pressure is exerted on the rectum, impairing passage of feces. Straining during defecation or the delivery process can result in hemorrhoid formation. Prenatal vitamins high in iron increase the risk for constipation.

Surgery and Anesthesia

Anesthesia blocks parasympathetic stimulation to the muscles of the colon and causes peristalsis to slow or cease. Surgery that requires manipulation of the intestines causes temporary cessation of intestinal movement. The stoppage of peristalsis is called **paralytic ileus**, which lasts 24 to 48 hours. For patients who remain inactive or are unable to eat after surgery, return of bowel function may be further delayed. Patients whose surgery was conducted with use of spinal or local anesthesia are less likely to experience this problem. Early activity and frequent assessment of bowel sounds are important during this period.

Medications

Some medications interfere directly or indirectly with bowel elimination. **Laxatives** ease defecation, often by stimulating bowel activity. Types of laxatives include bulk-forming agents, osmotics, salines, stimulants, and stool softeners. **Cathartics** are strong laxatives that stimulate evacuation of the bowel by causing a change in GI transit time. Other medications soften stool, promoting defecation. Some suppress peristaltic activity and are used to control diarrhea and decrease gastric emptying.

Certain medications cause diarrhea or constipation as a side effect. Antibiotics contribute to diarrhea by interfering with the normal bacterial flora in the GI tract. Anticholinergic drugs inhibit gastric acid secretion and depress GI motility. Opioid analgesics also depress GI motility. Histamine antagonists suppress secretion of hydrochloric acid and interfere with digestion of some foods. Calcium supplements and opioids slow colonic action.

Some medications affect the appearance of the feces. Drugs that can cause GI bleeding when taken for extended periods, such as nonsteroidal antiinflammatory drugs (NSAIDs), may cause red or black stools, depending on where the bleeding is occurring. Iron salts, which cause constipation, can cause stool to be black. Antacids cause whitish discoloration or white specks.

1. List and explain the factors related to T. S.'s elimination problem.

Diagnostic Tests

Before diagnostic procedures of the bowel, the patient may be placed on a restricted diet or given cleansing enemas. Prescribed bowel preparations to ensure emptying of the bowel are given to facilitate visualization at endoscopic, radiographic, or other examinations. After the procedure, changes in elimination, such as increased gas and loose stools, may persist until the patient returns to a normal eating pattern.

LO 40.3 ♦ Assessment

Gathering subjective and objective data for assessment of bowel elimination allows the nurse to identify patterns and abnormalities. The assessment of the GI system includes a focused interview, including health history (Box 40.2); physical assessment of the abdomen; inspection of the feces; and a focused diet history including chewing difficulties, medications, illnesses, and food intolerance.

Box 40.2

Health Assessment Questions

History

- Have you been diagnosed with an abdominal disease such as cholecystitis, ulcers, diverticulitis, cholelithiasis, or cirrhosis?
- Do you have a family history of gastrointestinal disturbances?
- Have you had abdominal surgery or trauma?
- Have you ever been diagnosed with an infection in the abdomen?
- Do you have abdominal changes, or physical problems that affect appetite or bowel function? If so, for how long?
- Do you have any physical limitations such as difficulty walking to the bathroom?
- Do you have any stairs to go up or down to get to a bathroom in your home?

General Questions

- Have you experienced changes in diet or appetite recently?
- Describe your daily diet and fluid intake.
- What is your current weight? Have you had recent weight changes (planned or unplanned)?
- What is your height?
- Describe your bowel habits.
- Describe the color and consistency of your stool.
- Are you experiencing changes in your bowel habits, including diarrhea or constipation?

- When did the changes start?
- Describe the type of change you have been experiencing?
- Have you been taking any medication that would cause changes in the consistency of the stool, such as laxatives or cathartics or antibiotics?
- What do you think may be the cause of the changes?
- What have you done to correct the situation? Have these measures helped?
- Do you experience rectal pain or itching?
- Have you experienced feelings of bloating or gas? What do you do to relieve feelings or symptoms of bloating or gas?
- Are the symptoms related to specific meals, types or quantity of food, or time of day or night?
- Do you have other symptoms that accompany the bloating or gas such as vomiting, headaches, belching, flatulence, heartburn, or pain?
- If pain is experienced, does it radiate to the shoulders or arms? How would you describe the pain? What number would you rate your pain, on a scale of 0 to 10, with 0 being no pain?
- Do you use antacid medications? If so how often? Do you notice a positive response to the medication?
- Do you have nausea or vomiting? If so, what is the onset of the nausea or vomiting? Is it related to particular stimuli?
- Describe the emesis. Are there any associated symptoms?
- Are you using any types of home remedy?
- Are you experiencing any abdominal pain? If so, rate the pain on a 0 to 10 pain scale.
- Describe the onset, location, duration, and characteristics of the pain.
- Does the pain radiate?
- What makes the pain better? What makes it worse?
- Are you taking any medication for the pain?
- Describe your current stress level.
- How do you think you cope with stress? Describe some of your coping skills.
- Do you work with any chemical irritants?
- Have you traveled recently? Where have you traveled?

Pregnant Patient

- Do you suffer from constipation, heartburn, or flatulence?
- Are you experiencing nausea and vomiting? If so, does it occur at certain times of the day or with specific foods?

Older Adult

- Do you experience constipation? If so how often?
- Are you ever incontinent of feces?
- Do you take laxatives? Which one? How often?
- What type of fiber-containing food do you eat during a typical day?
- What types of fluids do you drink? How much fluid do you drink in a day?
- Are you able to get to the store for your groceries?
- Do you eat alone or with someone?
- Do you wear dentures?

While performing the bowel elimination assessment, the nurse considers the patient's physical, mental, and functional abilities, as well as the home environment and family and social support. Attention focuses on identification and prioritization of immediate problems and relief of symptoms, before a full assessment is undertaken.

Health History

A comprehensive history identifying normal and abnormal patterns of bowel elimination and comparing them to the patient's perception of normal is a crucial step in identifying elimination issues. Include any history of surgeries or illness affecting the GI tract. Family history is evaluated for GI cancer, Crohn disease, and other GI disturbances with familial links.

Gastrointestinal Tract and Abdominal Assessment

To begin, inspect the patient's mouth, teeth, tongue, and gums for sores, dentition, and moisture. Poor dentition, mucosal dryness, and mouth sores can cause pain or make swallowing difficult. An abdominal assessment should always begin with inspection and auscultation, because palpation and percussion alter peristaltic activity. Percussion is an advanced skill and usually is performed by nurses with special training.

Inspection

The abdominal assessment is performed while the patient is in the supine position with a pillow behind the head and knees. Determine the contour of the abdomen by viewing at eye level. Abdominal contour may appear flat, round, scaphoid, or protuberant in pregnancy, obesity, or ascites. Abdominal distention may appear as a protuberant abdomen with taut skin. Observe the symmetry of the abdomen, noting bulging, masses, or pulsations. Observe the position of umbilicus; if it is protruding or displaced, a mass or hernia may be present. Observe the abdominal wall for movement. Increased peristaltic activity could indicate an obstructive process. The nurse notes scars, stomas, and lesions during inspection.

Auscultation

With the patient in the supine position, auscultation begins in the right lower quadrant and proceeds through each of the remaining quadrants. Ensure that the stethoscope is in contact with the patient's skin. Normal bowel sounds are irregular, high-pitched, and gurgling and occur every 5 to 15 seconds. Hyperactive bowel sounds tend to be loud, high-pitched, and rushing; they are commonly heard with diarrhea or inflammatory disorders. Hypoactive bowel sounds are slow and sluggish, with occurrence of less than five sounds per minute. Decreased bowel sounds are common after surgery. Absence of sounds may be a sign of obstruction or paralytic ileus. Patients with ileus or intestinal obstruction require immediate medical attention. The nurse listens for 5 full minutes before documenting the absence of sounds.

Palpation

Palpation determines organ size, organ placement, masses, pain, and presence of fluid. Painful areas are palpated last. Light touch is used over all four quadrants. The abdomen should be soft, smooth in contour, and pain-free. The patient should be relaxed during palpation, because tense muscles will interfere with palpating underlying organs or masses. In obese patients, bimanual or deep palpation is required to detect underlying organs. If a pulsation is noted on visual examination, do not palpate the area.

2. Identify the focused assessments that must be completed for T. S. related to her current elimination problem.

Laboratory Tests

Laboratory tests are necessary to obtain information on elimination problems. Laboratory testing can help determine the presence of bleeding, inflammation, or infection. Some tests that are performed are stool cultures, stools for occult blood, and a blood draw to test serum electrolytes.

Stool Cultures and Occult Blood

A stool culture is used along with other tests to detect parasites in the stool and help determine the cause of diarrhea. Stool cultures are ordered if the patient complains of diarrhea for several days or when blood or mucus is noted in loose stools. Cultures may be ordered if the history suggests that the patient may have consumed food contaminated with bacteria associated with undercooked meat or raw eggs, or the same food that has made others ill. Recent travel outside the United States may suggest possible food contamination. If the patient has had a previous pathogenic bacterial infection of the GI tract that has been treated or resolved, additional stool cultures may be performed to verify that the pathogenic bacteria are no longer detectable.

If the culture is negative for the major pathogens, it is likely that the diarrhea is due to another cause. If the stool culture is positive for pathogenic bacteria, infection is the most likely cause of prolonged diarrhea. The stool sensitivity testing report may identify the causative agent, with appropriate treatment suggestions.

Testing for the presence of blood in the feces is performed using a **fecal occult blood test** (see Skill 34.3). Fecal occult blood tests measure for microscopic amounts of blood in the feces. Blood may be present in the stool in association with benign (noncancerous) or malignant (cancerous) growths or **polyps** in the colon, hemorrhoids, anal fissures, intestinal infections, ulcerative colitis, Crohn disease, diverticular disease, and abnormalities of the blood vessels in the large intestine. GI bleeding may be microscopic (occult blood) or may be easily seen as red blood or black, tar-like stools called *melena*. A positive fecal occult blood test indicates that blood has been found in the stool. A negative test result indicates that no blood was found in the stool sample. The fecal occult blood test requires the collection of three small stool samples taken 1 day apart. The consecutive specimens are collected separately because colon cancers may bleed intermittently. Fecal occult blood test results are affected by ingestion of certain foods. A special diet is

prescribed 48 to 72 hours before the test. Foods that affect the test results and therefore should be avoided are beets, broccoli, cantaloupe, carrots, cauliflower, cucumbers, fish, grapefruit, horseradish, mushrooms, poultry, radishes, red meat, turnips, and vitamin C-enriched foods and beverages.

Diagnostic Examinations

Diagnostic tests provide information about alterations in clinical status that may not be evident from laboratory test results. Many of the diagnostic tests used for patients with alterations in GI function allow for visualization of the organ systems and function. Tissue samples can be obtained during some of the tests. The nurse must be familiar with diagnostic tests and implications of the results, both to prepare the patient for a specific test and to provide care that may be required at completion of the procedure.

Upper Gastrointestinal Series

An upper GI series (barium swallow) is a radiologic study that defines the anatomy of the upper digestive tract to visualize the esophagus, stomach, and duodenum. This series of images assists in the diagnosis of upper GI tract diseases and conditions such as ulcers, tumors, hiatal hernias, scarring, blockages, and abnormalities of the GI tissues. An upper GI study involves some risk from radiation exposure. Patients who are or may become pregnant should notify the radiology department staff, because such studies carry some risk for harm to the fetus from radiation exposure.

Before the procedure, the patient should not eat or drink anything for 4 to 8 hours. The procedure involves swallowing a liquid that contains barium, which fills and coats the intestinal lining, making the anatomic structures visible. X-ray images are taken at different angles through the chest and abdomen.

A major side effect of the upper GI series is constipation. Patients who undergo an upper GI study are encouraged to drink extra fluids after the test. A laxative may be recommended to promote evacuation of the bowels if the barium is not eliminated completely within 1 or 2 days. Barium has a whitish appearance that may be apparent in the stool for several days after the test.

Lower Gastrointestinal Series

The lower GI series, also known as a barium enema, consists of x-ray imaging of the rectum, colon, and lower portion of the small intestine to

assist in diagnosis of abnormal growths, ulcers, polyps, diverticula, and colon cancer. Barium is inserted into the colon, and then x-ray pictures of the colon and rectum are taken. The barium aids in visualizing the size and shape of the colon and rectum.

The patient undergoing a lower GI series is informed that the barium will cause fullness and pressure in the abdomen and there will likely be the urge to have a bowel movement. The patient is asked to change positions while x-ray pictures are taken, to obtain different views of the colon.

To prepare for the procedure, the patient will have a restricted diet for a few days beforehand, generally a liquid diet for the 2 prior days, clear liquids only for 24 hours, and then a laxative or enema just before the procedure. As in the upper GI series, the barium may cause constipation and cause the stool to turn gray or white for a few days after the procedure.

Endoscopy

An esophagoscopy is an endoscopic procedure to view the inside of the esophagus. A gastroscopy is a procedure to view the inside of the stomach. A duodenoscopy is a procedure to view the inside of the duodenum, the first part of the small intestine. These examinations are performed as a single procedure and are collectively referred to as an upper endoscopy, or esophagogastroduodenoscopy (EGD).

In this procedure, a fiberoptic endoscope, a flexible instrument with a small camera on the end, is passed through the mouth, down the throat, and into the stomach. This examination assists in the diagnosis or clarification of any abnormalities that may have been seen on an x-ray image. Upper endoscopies are prescribed for patients with swallowing difficulties, vomiting, bleeding, gastric reflux, abdominal pain, or chest pain.

Because direct visualization of the structures is necessary, the stomach must be empty; therefore the patient should not have anything to eat or drink for at least 8 hours before the examination. The patient receives medication that causes drowsiness, relaxation, amnesia, and possibly light-headedness. The throat is sprayed with a numbing medicine that helps prevent discomfort and gagging. The numbness lasts about 30 to 45 minutes. The patient is asked to swallow once or twice during the initial period of insertion to facilitate movement of the endoscope. The tube does not interfere with the patient's ability to breathe and is only mildly uncomfortable after the initial insertion. The examination takes approximately 10 to 20 minutes. During the procedure and afterward, the patient may have a feeling of fullness,

because it requires injection of a moderate amount of air to expand the abdomen, allowing for better visualization.

A biopsy specimen may be obtained for examination, or electro-surgical instruments may be used to treat some medical conditions. Photographs or videos may be taken to document abnormalities. Driving is not permitted for 12 hours after the procedure to allow the sedative time to wear off. The nurse is responsible for checking for return of the gag reflex before allowing the client to eat or drink after the procedure. 📺 The animation “Endoscopy” further explains this procedure.

Colonoscopy

Colonoscopy is a procedure performed to visualize inflamed tissue, ulcers, and abnormal growths in the anus, rectum, and colon. The procedure is used to identify early signs of colorectal cancer and diagnose unexplained changes in bowel habits, abdominal pain, bleeding from the anus, and weight loss.

Before the procedure, the patient performs bowel preparation to empty solids from the GI tract by following a clear liquid diet for 1 to 3 days. The patient should not drink beverages containing red or purple dye. A laxative or an enema may be required the night before the colonoscopy. Patients should inform the PCP of all medical conditions and any medications, vitamins, or supplements taken regularly, including aspirin, arthritis medications, anticoagulants, diabetes medications, and vitamins that contain iron. Patients usually are on NPO (nothing by mouth) status for several hours before the procedure.

For colonoscopy, the patient lies on the left side on an examination table. A light sedative, and possibly pain medication, are given intravenously to promote relaxation. A long, flexible, lighted tube called a colonoscope, or scope, is inserted into the anus and slowly guided through the rectum and into the colon. A small camera transmits a video image to a computer screen, allowing careful examination of the intestinal lining. Bleeding and puncture of the large intestine are possible but uncommon complications of colonoscopy. During the procedure, growths (polyps) or abnormal tissues may be removed (biopsy) and tested for cancer. Tissue removal and the treatments to stop any bleeding usually are painless. Cramping or bloating may occur during the first hour after the procedure. Driving is not permitted for 12 hours after colonoscopy, to allow time for the sedative effects to wear off. 📺 See the animation “Colonoscopy,” in which the procedure can be visualized.

LO 40.4 ♦ Nursing Diagnosis

On completion of the nursing assessment of the patient's bowel function, data obtained may reveal the risk for or an actual elimination problem. To determine the appropriate International Classification for Nursing Practice (ICNP) nursing diagnoses for the patient with impaired elimination, the nurse clusters the supporting data:

Constipation

- Supporting Data: Narcotic pain medication use, poor fluid intake, no stools for a few days, hypoactive bowel sounds, firm and tender abdomen

Diarrhea

- Supporting Data: Malabsorption, bloating, cramping, loose liquid stools

Bowel Incontinence

- Supporting Data: Sphincter dysfunction, constant dribbling of soft and liquid feces, inability to recognize the urge to defecate, fecal staining of underclothing

In addition to the nursing diagnoses for issues related to bowel elimination that are listed, the patient may be *at risk* for developing these elimination diagnoses. The patient with bowel elimination issues also may have associated nursing diagnoses not directly related to elimination, such as *Disturbed Body Image*, *Risk for Impaired Skin Integrity*, *Fluid Imbalance*, *Impaired Self Toileting* and *Acute or Chronic Pain*.

3. Based on the information in the case study, identify three nursing diagnoses with supporting data for T. S., along with patient teaching interventions that may be necessary for each.

LO 40.5 ♦ Planning

The goals for patients with elimination problems are structured around maintaining normal elimination patterns, returning to previous levels of function, and preventing associated risks (Table 40.1). Goals related to reestablishing normal bowel function and prevention of further complications include the following:

TABLE 40.1
Care Planning

ICNP NURSING DIAGNOSIS WITH SUPPORTING DATA	NURSING OUTCOME CLASSIFICATION (NOC)	NURSING INTERVENTION CLASSIFICATION (NIC)
<i>Constipation</i> Narcotic pain medication use Poor fluid intake No stools for a few days Hypoactive bowel sounds Firm, tender abdomen	<i>Bowel elimination</i> Stool soft and formed	<i>Constipation/impaction management</i> Encourage increased fluid intake unless contraindicated

From Butcher, H. K., Bulechek, G. M., Dochterman, J., et al. (Eds.). (2018). *Nursing interventions classification (NIC)* (7th ed.). St. Louis: Mosby; Moorhead, S., Swanson, E., Johnson, M., et al. (Eds.). (2018). *Nursing outcomes classification (NOC)* (6th ed.). St. Louis: Mosby. ICNP is owned and copyrighted by the International Council of Nurses (ICN). Reproduced with permission of the copyright holder.

- Patient will pass soft stools daily during rehabilitation.
- Patient will defecate formed stools within 24 hours.
- Patient's episodes of bowel incontinence will decrease within 48 hours after starting a bowel training program.

The conceptual care map for T. S. can be found at <http://evolve.elsevier.com/YoostCrawford/fundamentals/>. It is partially completed to indicate how to use the map as a learning tool. Complete the nursing diagnoses using the example conceptual care maps shown in **Chapters 8 and 25 to 33**.

LO 40.6 ♦ Implementation and Evaluation

The nurse can help patients achieve regular bowel elimination by performing or assisting the client with techniques and habits that promote regular elimination. Nursing measures to aid in bowel elimination include interventions for diarrhea, constipation, impaction, and incontinence, as well as those for patients with bowel diversions.

Interventions

After assessing the pattern of the patient's elimination and determining the patient's perception of normal bowel elimination, encourage the establishment of a regular elimination pattern. Variations in diet and personal habits lead to misconceptions regarding the frequency of bowel movements and can lead to overuse of laxatives. In such cases, the patient is warned that ongoing use of laxatives is associated with harmful side effects such as an increase in constipation and impaction, predisposition to colorectal cancer, dependency, and electrolyte imbalance.

Suggest warm liquids, which stimulate peristalsis and aid in defecation. Emphasize the necessary ingredients for a normal bowel regimen (fluid, fiber, activity, and a regular schedule for defecation). Laxatives may be needed to establish a regular pattern; however, provide laxatives, suppositories, and enemas as needed and as ordered only. Laxative use varies the patient's regular pattern, so the nurse and the patient together establish a goal of eliminating their use. Instruct the patient to avoid straining to defecate. Straining is a form of the Valsalva maneuver and can cause bradycardia and possibly death, especially in patients with cardiac disease.

Every patient with elimination problems is weighed daily, because weight is an important indicator of fluid balance in the body. Dementia, acute confusion, and intellectual disability are risk factors for fecal incontinence; therefore mental status is monitored closely. Patients are monitored for impaction, which is more common in elderly than in younger people. The patient is checked for impaction before administration of antidiarrheal medications. Teach appropriate methods of taking these medications and instruct the patient on their side effects. Immobile patients who are incontinent with liquid stool may have a fecal management system inserted to drain the stool. This device is similar to a urinary drainage system and is used to protect the surrounding skin.

The nurse helps control or prevent diarrhea in patients by following some simple guidelines. Handwashing between caring for patients, after using the bathroom, and before and after preparation of foods will greatly reduce the risk for diarrhea from a foodborne or communicable illness.

Meticulous skin care and containment of fecal drainage are necessary to prevent skin breakdown; a fecal collector can be used if necessary. Barrier creams containing zinc oxide, lanolin, or a petroleum-based product are used to protect the skin in patients who are incontinent. The barrier cream is wiped off if soiling occurs and a new layer of cream is applied after cleansing (Schreiber, 2016).

Elderly patients are evaluated for fecal incontinence on admission to the acute or long-term care facility. The rate of incontinence in the acute care setting is 3%; in long-term care facilities, incontinence rates can be as high as 50%.

Preventive Screening

Patients are encouraged to follow recommended colorectal screening guidelines. The fecal occult blood test is recommended yearly for everyone 50 years of age and older. Sigmoidoscopy and colonoscopy, which are screening tests for colorectal polyps and early signs of cancer, should begin at age 45 for most people and earlier in those with a family history of colorectal cancer, a personal history of inflammatory bowel disease, or other risk factors. The tests are performed every 5 to 10 years, depending on the individual's history and the type of test performed (American Cancer Society, 2018a).

Diet

Patients with elimination problems may need to make changes in their diet to promote regular elimination patterns. In general, a diet of high-fiber foods, with adequate fluid intake, is encouraged, although this diet may not be sufficient for the patient with alterations to normal elimination patterns. For more information on a high-fiber diet, see Chapter 30. Daily intake of fiber helps prevent constipation by giving stool bulk (Box 40.3). Food such as fresh fruits, beans, vegetables, and bran cereals are incorporated into the patient's diet. Fluid intake up to 6 to 8 glasses of liquids per day should be consumed to help prevent hard, dry stools.

Box 40.3

Fiber and Bowel Health

Fiber in the diet has many benefits, including:

- Normalization of bowel movements
- Maintenance of bowel integrity and health
- Lowering blood cholesterol levels
- Helping control blood sugar levels
- Aiding weight loss
- Potentially helping prevent colorectal cancer

The Mayo Clinic website, <http://www.mayoclinic.com/health/fiber/NU00033>, among others, can guide patients in increasing the amount of fiber in their diet.

The patient with diarrhea benefits from bland, small meals, which may be more easily tolerated. Milk products, spices, food that irritates or stimulates the GI tract, gas-producing foods, and caffeine are avoided. Hot and cold liquids also are avoided because they stimulate peristalsis; liquids of tepid temperatures are preferred. Oral or intravenous intake of fluids to prevent dehydration is necessary for the patient with diarrhea.

The healthy patient should drink at least 6 to 8 glasses of fluid daily. Hot liquids and fruit juices, such as prune juice and apple juice, are encouraged because they stimulate peristalsis, although they are to be avoided by the patient with diarrhea. For the patient with flatulence, gas-forming foods such as cabbage, beans, onions, and cauliflower are avoided.

The patient receiving tube feedings is taught principles of safe food handling, including rinsing feeding containers every 8 hours and replacing the containers every 24 hours to prevent bacterial growth. Rapid administration of tube feeding has been associated with diarrhea; therefore the rate of infusion may need to be adjusted. Bulking agents, including soluble fiber such as psyllium, may be used in tube feedings to prevent diarrhea. The nurse should consult a dietitian when diarrhea occurs, to identify food allergies and intolerance but still maintain the patient's dietary requirements. Close monitoring of the patient's fluid and electrolyte balance will help prevent life-threatening fluid deficiency and electrolyte or acid-base imbalance.

Exercise

Encourage the patient to be out of bed as soon as possible after surgery or illnesses. Exercises such as turning and changing positions in bed and passive or active range-of-motion exercises increase peristalsis and help prevent constipation. Aerobic exercise raises respiratory and heart rates, which stimulates contraction of intestinal muscles.

After eating, blood flow is increased to the stomach and intestines to promote digestion. However, strenuous exercise causes blood to be diverted to the heart and brain. Waiting approximately an hour after a meal to exercise is advised. Walking 10 to 15 minutes per day has been shown to increase digestive function.

Promoting Normal Bowel Patterns in Health Care Facilities

The nurse assists patients in health care facilities achieve regular defecation by providing privacy and assisting in establishing a regular pattern of elimination. The patient is offered toileting opportunities often, because soiling may occur if the patient is forced to wait. The nurse encourages independence with toileting activities when possible, although the need to toilet increases the risk for falls or accidents. Assisting the patient to a commode or to a sitting position facilitates bowel elimination, and the nurse or unlicensed assistive personnel (UAP) may need to stay with a patient who is too weak to be left alone.

Bedpan

Patients who are unable to walk to the bathroom or who are restricted to bed secondary to procedures, illness, injury, or surgery require the use of the bedpan for elimination (Box 40.4). The caregiver must be quick to respond to the toileting needs of the patient restricted to bed, because frequently there is little time between urge and elimination.

Box 40.4

Nursing Care Guideline

Assisting the Patient Using a Bedpan

Background

- When the patient cannot be out of bed, use of a bedpan may be required.
- The two types of bedpans are:
 - A fracture pan, which is a shallow bedpan that is used for patients with hip or back fractures or to promote comfort in patients who may have to lie flat or are unable to raise their buttocks off the bed. Fracture bedpans are placed with the handle toward the patient's feet.
 - A regular bedpan, which has higher sides and is more uniquely shaped, similar to a standard toilet seat; it allows the patient to be raised to a more normal position for elimination.

Procedural Concerns

- Always wear gloves when assisting a patient with elimination.
- Place a waterproof pad on the bed.
- The patient must be properly positioned, with buttocks centered on the bedpan.
- If the patient is unable to assist with lifting/movement, roll the patient to one side and place the bedpan on the bed, then roll the patient onto the bedpan.
- Elevate the head of the bed, using the Fowler position if it can be tolerated by the patient.
- Do not leave the bedpan in place for longer than 10 minutes; doing so will promote or exacerbate pressure injuries and/or skin breakdown.
- After bedpan removal, provide perineal care and hand hygiene for the patient.

- Remove gloves and perform personal hand hygiene.

Documentation Concerns

- Document patient intake and output.
- Note the patient's tolerance of the procedure.
- Record skin assessment details.

Preserving skin integrity and preventing pain with required positioning are important. Sitting on a bedpan is uncomfortable because the pressure points rest on the hard surface. Time on the bedpan is limited, to prevent skin breakdown and decreased sphincter control. Leaving the patient on the bedpan longer than 10 minutes can result in skin breakdown and pressure injury formation (Box 40.5).

Box 40.5

Ethical, Legal, and Professional Practice

Care of the Patient With Altered Elimination

The nurse is responsible for providing competent care to the patient to reduce risk for infection and maintain skin integrity.

- Length of time a patient is left on the bedpan can contribute to pressure injuries. Answer the call bell promptly for the patient with issues pertaining to bowel elimination.
- After elimination, wash the area with soap and water and thoroughly dry to help prevent skin breakdown. Apply barrier cream to the skin if there is a risk for breakdown.
- The patient who is incontinent is exposed to moisture and bacteria and requires frequent assessment of skin integrity.
- The nurse is responsible for monitoring and identifying an alteration in elimination. Failure to identify alterations may hold the nurse liable for negligent nursing practice.

Maintain the patient's privacy during bowel elimination. Pull the curtain closed around the patient. Close bathroom doors. Make certain that treatment routines do not interfere with the patient's routine. Cover the patient with bed linens to maintain comfort and dignity. Ensure that the patient has access to the call light and toilet paper.

Bedpans are assigned for use by a single patient but are washed and disinfected after each use. Always perform hand hygiene and use gloves when handling a bedpan.

Safe Practice Alert

Wear appropriate personal protective equipment (PPE) when cleaning a bedpan. Gloves are always worn when handling a soiled bedpan. If there is a possibility of splashing during the cleaning procedure, PPE should include gloves, a gown, and a mask with an eye shield.

Bedside Commode

The bedside commode is a portable chair with a toilet seat and a receptacle beneath that can be emptied (Fig. 40.7). It is used most often with adult patients who can get out of bed but have difficulty with ambulation. Safety is a consideration in moving the patient to the commode.

FIGURE 40.7 Bedside commode. (From Sorrentino, S. A., & Remmert, L. [2017]. *Mosby's textbook for nursing assistants* [9th ed.]. St. Louis: Elsevier.)

Early Ambulation

Exercise is important in maintaining GI function. Early ambulation after surgery or an illness stimulates peristalsis and helps maintain function. Therefore the patient is encouraged to be out of bed as soon as possible.

Bowel Patterns

For the patient experiencing bowel elimination problems, a return to previous level of function is the optimal goal. To achieve that goal, additional assistance may be needed in the form of bowel training programs, elimination schedules, and medications.

Antidiarrheal Medications

Antidiarrheal medications are used to slow the motility of the intestine or promote the absorption of excess fluid in the intestine. Antidiarrheal medications are available as over-the-counter products. The most effective agents, however, are prescription opiate agents such as loperamide and diphenoxylate-atropine, which decrease intestinal muscle tone to slow the passage of feces. These drugs are given for 48 to 72 hours. Caution is used with opiates that are habit-forming, such as diphenoxylate-atropine. The cause of the diarrhea must be determined.

Laxatives and Stool Softeners

Cathartics and laxatives may be prescribed for a patient who is unable to empty the bowel normally. Although the two terms often are used interchangeably, *cathartics* induce defecation with a stronger effect on the intestines. Laxatives have a milder action, producing soft or liquid stools. Any laxative or cathartic is contraindicated in patients with nausea, vomiting, or undiagnosed abdominal pain. The chronic use of laxatives can weaken the natural response of the bowels, resulting in rebound constipation.

Laxative suppositories are more effective than their oral counterparts because of their stimulant effect on the rectal mucosa. A rectal **suppository** is a drug delivery system that is inserted into the rectum, where it dissolves for medication absorption through the rectal mucosa. The nurse ensures that the suppository is placed in contact with the mucosa and not in stool that is in the rectum. Laxative suppositories work to soften the stool and distend the rectum. These suppositories take approximately 30 minutes to work; therefore the patient should plan accordingly (see [Box 35.12](#) for more information on rectal suppository administration).

4. Identify three interventions that the nurse should expect to implement for T. S., and give the rationale for each.

Enemas

An **enema** is the introduction of solutions into the rectum and sigmoid colon via the anus ([Skill 40.1](#)). The increase in the volume of fluid rapidly distends the colon and irritates the intestinal mucosa lining, stimulating complete evacuation of the lower intestinal tract.

Common uses of enemas include relief of constipation, removal of impacted feces, emptying of the bowel before diagnostic tests or surgery, and beginning a program of bowel training. Enemas can be used to instill medications. Several types of enema solutions are used today ([Table 40.2](#)).

TABLE 40.2**Types of Enemas**

TYPE OF ENEMA	DESCRIPTION	VOLUME	USES
Cleansing enemas		120-1000 mL	Empty the bowel and remove feces through instillation of fluid. Primary action: Peristalsis stimulation.
Hypertonic	Work by osmotic pressure, drawing fluid out of interstitial spaces into the colon, which then fills with fluids and distends.		
Isotonic	Work by expanding the colon, thus promoting peristalsis.		
Oil retention enemas	The feces absorb the oil and become softer and easier to pass. The patient must retain the enema for 1-3 hours for the best possible results.	120-150 mL	Lubricate the rectum and colon.
Medication enemas	The patient must retain the enema so that the medication has time to work.	Prescribed amount	Antibiotic or anthelmintic enemas used to treat local infections such as bacteria, worms, and parasites are types of retention enemas.
Carminative enemas		60-80 mL	Provide relief from gastric distention by stimulating peristalsis to improve passage of flatus.
Return-flow enemas		100-200 mL of solution, administered and then drained from the rectum (often repeated until drainage is clear)	Provide relief from gastric distention by stimulating peristalsis to improve passage of flatus.

Nasogastric Intubation

Nasogastric (NG) intubation is necessary when the patient needs decompression of the GI tract, administration of medication or enteral feedings, compression of internal hemorrhage, or gastric lavage. An NG tube is a pliable tube that is inserted through the nasopharynx into the stomach (see [Chapter 30](#), Skill 30.1). The several types of NG tubes available can be broadly categorized as small-bore tubes or large-bore tubes.

Large-bore tubes, size 12 Fr and larger, are used for decompression, removal of gastric secretions, and lavage. They are used in conditions in which peristalsis is absent, such as surgery, trauma, infections, or obstruction. The common types of large-bore tubes are the Salem sump and Levin tubes (Fig. 40.8). The Salem sump tube is preferred for gastric decompression because it has two lumens, one of which serves as an air vent that connects with the second lumen, which is used for suction of gastric contents. When the main lumen is connected to suction, the other provides a continuous air vent.

FIGURE 40.8 Large-bore nasogastric tubes. (A) Levin tube. (B) Salem sump tube. (From Silvestri, L. A. [2017]. *Saunders comprehensive review for the NCLEX-RN™ examination* [7th ed.]. St. Louis: Elsevier.)

Irrigation (**lavage**) of the stomach is performed in cases of active bleeding, poisoning, and gastric dilation. Large-bore tubes, including the Salem sump, Levin, and Ewald tubes, are used for this purpose. For more information on insertion and use of NG tubes (see [Chapter 30](#)).

Ostomy Care

Ostomy appliances are used to protect skin, collect drainage, and control odor. Pouching systems may include a one-piece or two-piece appliance consisting of a skin barrier or wafer and a collection pouch (Fig. 40.9). The pouch attaches to the abdomen by the wafer and collects the stool output. The barrier or wafer protects the skin from the fecal output. Drainable pouches are used when the pouch needs to be emptied frequently (Skill 40.2). Skin-barrier preparation wipes, sprays, and powders may be applied before the wafer to protect the skin from effluent and further seal the device (Zeigler & Min, 2017).

FIGURE 40.9 Ostomy supplies. (Copyright Mosby's Clinical Skills: Essentials Collection.)

A patient with an ostomy in place will need to learn self-care, and it is crucial that this is begun in the acute care setting (Box 40.6). A wound ostomy continence nurse (WOCN) is consulted early to promote self-care and teach the meticulous regimen necessary to prevent skin damage and infection (Fig. 40.10). The WOCN is certified in the management of patients who have had some type of bowel or bladder diversion. This nurse specialist's areas of expertise include bowel and bladder control and associated skin care issues.

Box 40.6

Interprofessional Collaboration and Delegation

Multidisciplinary Care for Patients With Bowel Elimination Problems

- Patients who are about to undergo ostomy surgery and patients with new ostomy placement should have a consultation with a wound ostomy continence nurse (WOCN). This nurse specialist is certified as an expert in the care of patients with wounds, ostomies, and incontinence.
- Nutrition counseling assists in planning a diet to manage elimination issues.
- Mental health professionals are consulted if issues such as anxiety and depression are affecting the patient's elimination patterns.
- The primary care provider is consulted for prescriptions and diagnostic evaluation.

FIGURE 40.10 (A) Stoma with intact skin. (B) Stoma with excoriated skin. (From Evans, S. R. T. [2009]. *Surgical pitfalls*. Philadelphia: Saunders.)

Self-esteem and a positive body image are important to promote in a patient with an ostomy, and emotional support is needed preoperatively and postoperatively. To address body image and self-esteem concerns, the nurse must recognize the extent of the impact of the ostomy surgery on the patient. The situation in which the ostomy is placed may affect how the patient perceives it. Patients are given the opportunity to express their feelings about their surgery, the changes in their body, and their self-image.

Presence of an ostomy may cause disturbed body image, especially if it is permanent. Patients may perceive the ostomy as invasive and disfiguring. A well-placed stoma, however, does not usually interfere with the patient's activity and can be concealed with clothing. Foul odors, spillage or leakage of liquid stools, and inability to regulate bowel movements increase the loss of self-esteem. Patients may have difficulty maintaining or initiating normal sexual relations. Odor control

is essential to maintenance of self-esteem, and many ostomy appliances are available that assist with odor control (Box 40.7). Patients should begin to assist the WOCN in caring for the ostomy as soon as possible. Involvement in this process helps the patient build confidence and regain control. Refer patients to colostomy support groups such as the United Ostomy Association or the National Foundation for Ileitis and Colitis.

Box 40.7

Home Care Considerations

Patient Education in Colostomy and Ileostomy Care

- Family and significant others are included in ostomy teaching, because this may facilitate the patient's readiness to learn.
- If the patient is apprehensive about touching or looking at the stoma, start slowly and encourage active participation in ostomy care.
- Patients are given a teaching manual with step-by-step instructions, complete with illustrations, and supplemented with DVDs and access to websites.
- Evaluate the patient's home toileting facilities; note the location and availability.
- If the patient consumes gas-producing foods, it may be necessary to manually expel (“burp”) trapped air from the bag.
 - In a private setting, the patient can undo the clasp on the flap of the bag and allow the air to be released from the bag.
 - Foods that tend to form gas, such as most beans, broccoli, Brussels sprouts, cabbage, carbonated beverages such as soda and beer, eggs, fish, garlic, onions, some spices, and deep-fried or fatty foods, may be limited or avoided to help control gas and odors.
- Many products are created with an odor barrier film so that odor is contained within the pouch. Commercial deodorizing disks are available.
- Limiting odor-producing foods and emptying the pouch regularly can help reduce odor.
- Some ostomy products have a filter to allow air but not odors to escape from the pouch.

Qsen Focus!

Patient-centered care empowers the nurse to examine barriers to active involvement of patients in their own ostomy self-care and to value an active partnership with patients and their families in planning, implementation, and evaluation of care.

Evaluation

Evaluation of the goals and outcomes for the patient with bowel elimination problems is important. Whether the goals include a return to normal bowel function or maintaining existing function within the parameters of the patient's condition, it is important for the nurse to determine whether they have been met and, if not, why.

If the goals have not been met, the nurse reviews the plan of care and considers revising interventions related to bowel elimination. The patient's current food and fluid intake, medication use, activity level, and knowledge are reviewed to determine the effects on GI function. It is important to include the patient during changes in the plan of care. The interim steps may need to be reevaluated and readjusted continuously.

Qsen Focus!

Monitoring the outcomes of patient care allows the care providers to improve quality patient outcomes.

Skill 40.1 Administering an Enema

Purpose

Enemas are used to:

- Promote bowel cleansing
- Relieve constipation
- Empty the bowel for diagnostic testing or surgery
- Begin a bowel training program

Resources

- Noncommercial preparation:
 - Enema bag
 - Tubing
 - Clamp
 - Rectal tube (usually 22 to 30 Fr)
 - 750 to 1000 mL of appropriate warmed solution (slightly warmer than body temperature or 100° to 105° F)
- *or* commercial prepackaged enema
- Water-soluble lubricant
- Waterproof, absorbent pads
- Toilet tissue
- Basin
- Washcloths, towels
- Clean gloves
- Bedpan, commode, or toilet
- Container for disposal of equipment
- Nonskid footwear

Interprofessional Collaboration and Delegation

- Administration of an enema may be delegated to unlicensed assistive personnel (UAP) without a nurse's assistance in some agencies after assessment of the patient has been completed by the nurse. Check with state licensing regulations and facility policies and procedures.
- UAP should report any of the following to the nurse:
 - Changes in vital signs
 - Abdominal pain, cramping, or distention
 - Rectal bleeding
 - Difficulties in performing the procedure or other concerns verbalized by the patient
- UAP also should be instructed in:
 - Appropriate positioning
 - Appropriate equipment usage
 - Appropriate documentation

Evidence-Based Practice

- [Pegram, Bloomfield, and Jones \(2008\)](#) reiterate that documentation and evaluation of enema effectiveness are imperative, because findings usually affect further treatments or diagnostic tests. The amount and characteristics of stool are documented after an enema.
- Fecal impaction can be a complication of constipation, especially in the elderly. Impacted stool might be softened with the use of an enema, particularly an enema containing mineral oil ([Toner, 2012](#)).

Special Circumstances

1. **Assess:** Does the patient demonstrate any contraindications for enema use, such as increased intracranial pressure, glaucoma, or recent rectal or prostate surgery?
Intervention: Do not perform the procedure; notify the PCP.
2. **Assess:** Has an assessment been made of the patient's abdomen and of external sphincter control, hemorrhoids, and mobility?
Intervention: The assessment serves two functions:
 - It allows the caregiver to verify that an appropriate enema solution will be used, provides information needed to prepare for the procedure, and confirms the need for the procedure.
 - It establishes a baseline against which findings on subsequent assessments may be compared to determine the effectiveness of the treatment.
3. **Assess:** What position may be used if the patient is unable to be placed in the left side-lying (Sims) position or has poor sphincter control?
Intervention: Position patient in the dorsal recumbent position on a bedpan.
4. **Assess:** What should be done if the patient's abdomen becomes distended or rigid, if changes in vital signs occur, or if bleeding is noted?
Intervention: Stop the procedure immediately.
 - Reassess the patient.
 - Notify the PCP of the findings.
5. **Assess:** What should the caregiver do if the patient complains of abdominal pain or cramping during instillation?
Intervention: Slow the rate of instillation, and reassess the patient.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.
- III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of

microorganisms.

IV. Maintain standard precautions.

Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient, using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Administering an Enema

Follow preprocedure steps I through VIII.

1. If the procedure will be performed while the patient is in bed, raise the bed to working height, and lower the side rails on the right side of the bed only, keeping the left top side rail elevated.

STEP 1 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- Setting the bed at the correct working height prevents provider discomfort and possible injury.*
2. Adhere to the Rights of Medication Administration (see [Box 35.4](#)).
Avoid possible medication errors and promote patient safety by adhering to the Rights of Medication Administration.
 3. Follow the principles described in [Box 35.12](#) throughout this skill.
 4. Place the patient in the left side-lying (Sims) position with right knee flexed, with waterproof padding under the patient.

STEP 4 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- Lying on the left side promotes the flow of solution to the colon by gravity, is the optimal positioning for the procedure, reduces strain on the caregiver, and promotes patient comfort. The waterproof padding protects linens.*
5. Make sure a bedpan, commode, or toilet is accessible before beginning. Prepare the enema:
 - a. If it is a noncommercial preparation, warm the solution from the hospital pharmacy by placing the bag in a basin of warm water. (If it was not provided in a bag, use warm tap water to directly fill the enema bag.) Prime the tubing to remove air, and clamp the tubing.
 - b. If it is a commercial preparation, verify the order and inspect the container for the expiration date and any noticeable holes and or damage. Expel any air from the container.
 - c. Apply clean gloves.
Using warm solution prevents abdominal cramping (as would be caused by cold solution) or burning (if hot solution is used). Prime the tube to avoid air infusion, which would cause abdominal distention. Verifying the

accuracy of the dose avoids possible medication errors by adhering to the Rights of Medication Administration.

6. Lubricate 6 to 8 cm (3 to 4 inches) of the tip of the rectal tubing or commercial applicator.

STEP 6 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Using lubricant prevents trauma to mucosal tissues and aids insertion.

7. Help the patient relax by instructing the patient to breathe slowly in and out through the mouth. Insert the tip of the tubing or applicator:
 - a. Separate buttocks, and locate the anus.
 - b. Insert the tip of the tubing/applicator slowly and smoothly 6 to 8 cm (3 to 4 inches) toward the umbilicus.

STEP 7B (Copyright Mosby's Clinical Skills: Essentials Collection.)

- c. Hold the tubing/applicator in place.

Using a slow and smooth motion prevents trauma to the mucosal tissues and prevents perforation of the bowel.

Holding the tip in place prevents expulsion of the tubing/applicator via normal contraction of the bowel.
8. Administer the enema:
 - a. For a noncommercial preparation, begin by holding the solution at the level of the patient's hip, unclamp the tubing, and raise the enema bag approximately 12 to 18 inches to adjust the flow by gravity so that it

flows slowly for 5 to 10 minutes, holding the tubing in place until the enema is complete.

STEP 8A (Copyright Mosby's Clinical Skills: Essentials Collection.)

- b. For a commercial preparation, squeeze the tube/bottle slowly and evenly to expel the contents.

STEP 8B (Copyright Mosby's Clinical Skills: Essentials Collection.)

Holding the tubing in place prevents expulsion of solution via stimulation of the bowel and peristalsis from rapid instillation. The enema is administered slowly to prevent distention.

9. Remove the tubing/applicator, covering it with a paper towel as it is being removed.
Using the paper towel protects the linens from soiling and reduces the spread of microorganisms.
10. Provide the following instructions to the patient:
 - a. Retain the solution as long as possible until patient has the urge to defecate (generally 5 to 15 minutes, but the actual time varies depending on the solution ordered and the patient's reaction).
 - b. Do not flush the toilet if the patient is using it to expel the solution.
Retaining the solution for at least the minimal time allows optimal results. Not flushing the toilet will allow the nurse to assess the outcome of the procedure.
11. Apply nonskid footwear on the patient and assist the patient to the bathroom or onto a bedpan.
Nonskid footwear prevents slipping.

12. Provide perineal care if needed.

Keeping the perineal area clean and dry prevents skin breakdown.

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Skill 40.2 Ostomy Care

Purpose

- An ostomy pouch effectively collects fecal material (effluent).
- Changing the ostomy pouch is critical to:
 - Maintain skin integrity
 - Assess stoma healing and integrity
 - Prevent odors
 - Promote comfort
 - Maintain or increase self-esteem and dignity

Resources

- Pouch:
 - One-piece with attached skin barrier *or*
 - Two-piece ostomy pouch system with separate pouch and skin barrier in the correct size
- Clamp (for drainable pouch; with use of a disposable, closed-end pouch, no clamp is needed)
- Ostomy measurement tool (included in box with ostomy system)
- Ostomy deodorant
- Stoma paste/stoma adhesive/barrier paste
- Tape
- Gauze pads
- Washcloths
- Towels
- Waterproof pads
- Basin
- Bedpan
- Graduated container

- Scissors
- Pen
- Clean gloves

Interprofessional Collaboration and Delegation

- Changing the pouch of a new ostomy or care of an ostomy with complications may not be delegated to unlicensed assistive personnel (UAP).
- Changing the pouch of an established ostomy may be delegated to UAP without a nurse's assistance, after initial assessment of the patient has been completed. Check with state licensing and facility policy and procedure.
- UAP should report any of the following to the nurse:
 - Pain before, during, or after the procedure, either verbalized by the patient or manifested as grimacing or other physical responses
 - Sores, wounds, irritations, or lesions noted
 - Output volume and consistency
 - Difficulties in performing the procedure
- UAP should be instructed in the:
 - Appropriate pouch
 - Appropriate skin barriers
 - Appropriate procedural implementations
 - Appropriate documentation
- Collaborate with wound ostomy continence nurse (WOCN) if available within the facility.
- Collaborate and coordinate the procedure with the PCP or surgeon rounds if dressings or other

surgical implementations need to be examined and/or changed.

Evidence-Based Practice

- WOCNs and teams are specialists with in-depth training in wound and ostomy care, along with knowledge of the specialized products available to treat and prevent complications. Evidence in the United States and Canada has shown that employing and collaborating with WOCNs for care of this specialized population not only are beneficial for patient outcomes but also improve staff education and treatment practices, as well as return on investment in the form of an economical advantage in terms of insurance reimbursement for facilities. It is imperative that the nurse work closely with the WOCN, if available, to promote optimal safe, high-quality patient care ([Harris & Shannon, 2008](#); [Jankowski, 2010](#)).
- Soap should not be used to clean the stoma or peristomal area. It can dry the skin and cause complications. Warm water only should be used, along with an adhesive remover if obvious residue remains ([Collier, 2016](#)).
- Evidence-based studies on optimal pouch wear time are lacking. It is imperative to be vigilant with assessment of the pouch fitting, stoma, and peristomal skin area. Changing the pouch when not necessary can contribute to the risk for associated skin damage. Reported wear times depend on skin condition and changes in stoma size and shape ([Miller, Pearsall, Johnston, et al., 2017](#)).

- It is important to take into account the psychological and coping factors of the patient with an ostomy in providing care related to the ostomy appliances. The nurse should assess and incorporate self-image education and promotion during such care. With a more positive body image, the patient is more likely to engage in self-care and health promotion techniques, ultimately leading to better health outcomes (Ercolano, Grant, Krouse et al., 2016). In a recent study (Miller, Pearsall, Johnston, et al., 2017) the Stoma Quality of Life Index (SQLI) was used every 3 months for 1 year after the procedure and noted that quality-of-life scores were higher when care was provided by a stoma care nurse. The SQLI measures self-sufficiency, acceptance of the stoma, improved personal relationships, and activities (Miller, Pearsall, Johnston, et al., 2017).
- The opening in the skin barrier ostomy wafer should closely match the size of the stoma so that drainage from the stoma, or effluent, does not come into contact with skin. Skin barrier pastes and powders may be used before application of the wafer to further protect the skin (Zeigler & Min, 2017).

Special Circumstances

1. **Assess:** What are the findings on assessment of the stoma?

Intervention: Check for color, moisture, trauma, healing, and swelling.

- A normal stoma should be moist, reddish pink, and “budding” slightly above skin level.
- Dry and purple-black tissue without bleeding indicates necrosis.
- Assess for circulation and edema.
- Notify the PCP.

- Whitish areas indicate fungal infection. Notify the PCP.
 - Open areas, rash, and bleeding may indicate an allergy or a chemical or mechanical reaction. Notify the PCP.
 - If the edges of the stoma are more than “budding” (i.e., are protruding into the pouch):
 - Place the patient supine for 30 minutes.
 - If the site does not return to normal, notify the WOCN and/or the PCP.
 - For a new stoma, the following must be checked:
 - If no flatulence or fecal drainage has occurred by the third day, notify the PCP.
 - Measure the stoma with each assessment to ensure proper equipment sizing secondary to swelling. It takes 6 to 8 weeks for swelling to decrease completely.
 - The opening around the appliance should be less than $\frac{1}{8}$ inch to:
 - Ensure proper fitting of the equipment
 - Prevent trauma and skin breakdown
 - Facilitate drainage into pouch
2. **Assess:** Does the patient have an established ostomy with the current pouch intact?
- Intervention:** Assess the stoma.
- If there are no complications:
 - The pouching system may stay in place for 3 to 7 days.
 - UAP may be delegated to perform care, in accordance with state and facility guidelines.
 - If there are complications, a pouch change may be required.
 - Make more frequent assessments, and change the pouch as soon as it is not adhering correctly.
 - Leakage is caustic to the skin and stoma; it indicates a need for a different type of pouch or sealant and may require the application of a skin barrier.
 - Consult a WOCN.
 - Care may not be delegated to UAP if there are complications.

3. **Assess:** Is the ostomy new?
Intervention: Assess the incision, and ensure that placement of the equipment/pouch around the incision will prevent trauma.
 - Ensure accurate measurements are taken. The stoma takes 6 to 8 weeks to shrink to normal size.
 - Notify the PCP or the WOCN of any complications or signs or symptoms of infection.
4. **Assess:** After removal of a used pouch, do some skin barrier fragments remain on the patient's skin?
Intervention: Use adhesive remover.
 - If the skin barrier is not removed, it can cause skin breakdown and trauma.
 - Do not routinely use adhesive remover.
 - Rinse the site with warm water and pat the site dry with a towel.
 - Do not use alcohol-based products, towelettes, or premoistened products; all of these interfere with skin barrier adhesive.
5. **Assess:** Is odor or excessive gas a problem?
Intervention: Apply ostomy deodorant, or consider switching appliances.
 - Use only a small amount of deodorant, and do not use homemade mixtures.
 - Appliances with a vent or filter may be a better choice. Consult a WOCN.
6. **Assess:** Does the patient have excessive output?
Intervention: Empty the ostomy bag when it is one-third to one-half full.
 - Consider switching to a specialty high-output pouch.
 - Consult a WOCN.

Preprocedure

- I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.
- II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.

III. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

IV. Maintain standard precautions.

Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient, using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Changing a Pouch

Follow preprocedure steps I through VIII.

1. Raise the bed to working height, and lower the side rails as appropriate and safe.

Setting the bed at the correct working height prevents provider discomfort and possible injury.

2. The best timing for changing an ostomy pouch is before a meal but not immediately before it.

Changing the pouch is best performed when the abdomen is comfortable and nondistended, and peristalsis is normal rather than hyperactive. Avoid changing immediately before meals to avoid

decreasing the patient's appetite with residual odors from the pouch change.

3. Have the patient in the supine or semi-Fowler position, if possible, with a towel or waterproof pad around the area. Alternatively, the patient may stand or sit over the toilet. *The supine or semi-Fowler position facilitates application; the skin should be taut. Using a towel or pad protects the skin and linens.*
4. Apply clean gloves. Perform an assessment of the stoma, skin, and fit of the pouch. *Using gloves reduces the spread of microorganisms. The assessment may indicate a need for different appliances or products. Intact drainable pouches may remain in place for up to 7 days.*
5. If the patient is using a closed-end pouch, go to Step 6. If the patient is using a drainable pouch, empty the pouch.
 - a. Position the patient over a toilet, bedpan, or graduated container.
 - b. Open the clamp, but save it for reuse.
 - c. Empty the entire contents of the pouch, and measure the volume, if required. Observe the stool characteristics.
 - d. Clean the end of the pouch if needed and reclamp it (see Step 14, later).
 - e. Determine if the pouch needs to be changed. If so, continue to Step 6. If not, go to Step 11.
 - f. Remove and dispose of gloves, perform hand hygiene, and apply a new clean pair of gloves. *Positioning over a toilet or bedpan helps prevent effluent from spilling on the patient during the procedure; effluent is caustic and can break down the skin. Proper disposal of waste prevents the spread of microorganisms and reduces the risk for infection and contamination.*
6. Remove the used pouch:

STEP 6 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Apply clean gloves

- b. Gently and smoothly push the skin away from the wafer that holds the pouch, keeping the skin taut.
 - c. Dispose of the wafer and pouch (if the pouch is not being reused) per facility policies and procedures.
 - d. Remove and dispose of gloves, perform hand hygiene, and apply a new clean pair of gloves.
- Careful removal of the pouch prevents skin breakdown and trauma, keeps the caustic effluent away from the skin, and prevents patient discomfort. Proper disposal of waste prevents the spread of microorganisms, reduces the risk for infection, and prevents contamination.*

7. Cleanse the area around the stoma:

- a. Apply clean gloves. Use warm water and a washcloth to gently clean the area. Do not use premoistened cloths or towelettes.
- b. Pat the skin dry with a towel.
- c. Place gauze over the stoma if the effluent is liquid or drains continuously.

Proper cleansing prevents skin breakdown and promotes adherence of the appliance to the skin. Because the stoma is vascular, gentle cleansing prevents bleeding. The stoma contains few nerves, so the patient may not feel trauma. Patting the area dry prevents abrasion. Gauze prevents effluent from leaking onto the skin during the procedure.

8. If skin protectant has been ordered or is needed, apply a 2-inch area around the stoma and allow it to completely dry.

Only use skin protectant if needed. It helps prevent skin breakdown and trauma. The skin protectant must be dry for the pouch to adhere properly to the skin and to avoid leaks.

STEP 9 (Copyright Mosby's Clinical Skills: Essentials Collection.)

9. Measure the stoma to verify the correct size appliance will be used.

- a. Check the manufacturer directions.
- b. Use the measuring guide that is included in the box.
- c. Remove and dispose of gloves, perform hand hygiene, and apply a new clean pair of gloves.

*Take careful measurements to ensure accuracy and prevent leakage. (Leakage may cause skin breakdown and trauma.)
Manufacturers produce various appliances to meet individual needs for optimal outcomes, so it is essential to follow the directions for the specific appliance.*

10. Prepare the pouch by cutting a stoma opening in the back of the wafer/flange:

- a. The cut should be $\frac{1}{16}$ to $\frac{1}{8}$ inch larger than the stoma.
- b. Use the ostomy measurement guide.
- c. If measurements are printed on the back of the pouch or wafer/flange, cut the opening to the appropriate size.

STEP 10C (Copyright Mosby's Clinical Skills: Essentials Collection.)

- d. If measurements are not provided, center the template over the wafer and trace the correct size; then cut the pouch.

STEP 10D (Copyright Mosby's Clinical Skills: Essentials Collection.)

Too large of an opening permits leakage, and too small of an opening irritates the stoma. Use the correct size to prevent leakage, irritation, and skin breakdown.

11. Apply the pouch.

- a. For a one-piece system: remove the backing or apply stoma adhesive and allow it to dry. Remove the gauze from the stoma. Center the opening over the stoma, and secure it in place, smoothing the appliance from the stoma outward and ensuring that the seal is complete all around the stoma.

STEP 11A (Copyright Mosby's Clinical Skills: Essentials Collection.)

- b. For a two-piece system, apply the wafer/flange first, ensure it is properly adhered to the skin, and snap on the pouch.
- c. Hold a gloved hand over the wafer or have the patient hold a hand over the wafer.

Secure the pouch in place to prevent leakage and skin breakdown. The back of the pouch or wafer flange acts as a protective skin barrier. A stoma adhesive or barrier paste assists as a skin barrier. The skin barrier must dry completely for it to be effective (incomplete drying interferes with the adherence of the appliance to the skin). The body heat from a hand will help the wafer seal to the skin.

12. Assess the seal:
 - a. Fill in any leaks with barrier paste.
 - b. Maintain pressure to gently hold the pouch in place while the paste dries.
 - c. Allow the paste to dry completely.
Complete the seal to prevent leakage and skin breakdown from caustic effluents. The barrier paste must dry completely for it to be effective.
13. Gently tug on the pouch to ensure that it is securely attached.
Verify the seal adhered to prevent leakage and skin breakdown from caustic effluents.
14. If it is a drainable pouch, close the bottom of the pouch by folding it up once and applying the clamp; verify the clamp has snapped shut. Alternatively, follow the manufacturer directions.

STEP 14 (Copyright Mosby's Clinical Skills: Essentials Collection.)

Seal the bottom of the pouch securely to prevent leakage and skin breakdown.

15. Remove and dispose of gloves, perform hand hygiene.

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach for the patient.

Precautions are taken to maintain patient safety. Top side rails aid in positioning and turning. Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Summary of Learning Outcomes

LO 40.1 *Describe the anatomy and physiology of the GI tract and the processes involved in formation, storage, and elimination of waste products:* The GI tract runs from the mouth to the anus. A bolus of food moves from the mouth through the esophagus to the stomach. It then travels through the small intestine into the large intestine, where nutrients and electrolytes, especially sodium and chloride, are absorbed from digested food. Water is absorbed from indigestible food residue. Waste from the body is eliminated through the formation of feces and expelled from the body by way of the rectum and anus.

LO 40.2 *Identify common alterations in bowel elimination:* Diarrhea, constipation, and bowel diversions are the most common alterations in bowel elimination.

LO 40.3 *Integrate components of a comprehensive assessment of the patient to identify issues with bowel elimination:* By understanding normal elimination physiology, the nurse can conduct an in-depth focused assessment of elimination and a physical examination to evaluate alterations in elimination patterns, recent changes, and factors that influence defecation. The nurse understands that the complications of altered elimination include fluid and electrolyte imbalances, body image issues, alterations in skin integrity, imbalanced nutrition, activity intolerance, and pain.

LO 40.4 *Identify nursing diagnoses related to bowel elimination:* Nursing diagnoses related to bowel

elimination include *Constipation, Bowel Incontinence, Diarrhea*, and being at risk for these diagnoses.

Nursing diagnoses that are not directly related to elimination but might be included in the care plan for a patient with bowel changes include: *Disturbed Body Image, Risk for Impaired Skin Integrity, Fluid Imbalance, Impaired Self Toileting, Acute Pain, and Chronic Pain*

LO 40.5 *Outline goals for patients experiencing alterations in bowel elimination*: Patient goals are focused on maintaining current level of function or returning the patient to optimal bowel function.

LO 40.6 *Implement and evaluate interventions to maintain normal bowel elimination*: By prioritizing the nursing diagnoses related to elimination, the nurse collaborates on a plan of care for the patient and provides interventions based on short-term and long-term goals, with the ultimate aim of returning the patient to an optimal state of health. Ostomy care and teaching of self-care for new ostomy patients constitute a priority nursing intervention. Evaluation and modification of the plan of care are ongoing.

Review Questions

1. A patient is being discharged from the hospital with a new ileostomy. The patient expresses concern about caring for the ostomy. Before hospital discharge, it is most important for the nurse to coordinate with which member of the health care team?
 - a. Home care nurse
 - b. Wound ostomy continence nurse
 - c. Registered dietitian
 - d. Primary care provider
2. The nurse is assigned the care of a patient for whom a cleansing enema has been ordered. What information is most important for the nurse to know before administration of the enema?
 - a. The proper way to position the patient
 - b. Signs and symptoms of intolerance to the procedure
 - c. Vital signs before the procedure
 - d. History of surgery of the anus or rectum
3. To prevent constipation in an inactive patient, which early interventions should the nurse implement?
(Select all that apply.)
 - a. Stool softener administration
 - b. Enema administration
 - c. Increasing the fiber in the diet
 - d. Increasing physical activity
 - e. Increasing fluid intake

4. While performing an abdominal assessment on an unconscious patient, the nurse notes presence of an ostomy. The fecal output is liquid in consistency, with a pungent odor, from the stoma that is located in the upper right quadrant of the abdomen. What type of ostomy does the patient have?
 - a. Descending colostomy
 - b. Ureterostomy
 - c. Ileostomy
 - d. Ascending colostomy
5. The teaching plan for a patient with diarrhea should include which intervention?
 - a. Drinking at least eight glasses of fluid each day
 - b. Eating foods low in sodium and potassium
 - c. Limiting the amount of soluble fiber in the diet
 - d. Eliminating whole-wheat and whole-grain breads and cereal
6. The nurse knows that the teaching for a patient who was recently diagnosed with constipation has been effective if the patient's meal request specifies which food choice?
 - a. Hot dog on a bun
 - b. Grilled chicken
 - c. Tuna sandwich on white bread
 - d. Spinach salad with dressing
7. A 40-year-old patient complains of 4 days of frequent loose stools with abdominal cramping. What is the priority nursing diagnosis for this patient?
 - a. *Impaired Skin Integrity*

- b. *Fluid Imbalance*
 - c. *Acute Pain*
 - d. *Self-Care Deficit* (i.e., toileting)
8. A patient is scheduled for a colonoscopy. After preprocedure teaching by the nurse, the patient demonstrates understanding when he makes which statement?
- a. "I can have coffee the morning of the procedure."
 - b. "I should drink a red sports drink the day before to stay hydrated."
 - c. "I should drink clear liquids for 2 days before the procedure."
 - d. "I will be able to drive home immediately after the procedure."
9. Which nursing intervention is included for a patient experiencing diarrhea?
- a. Limiting fluid intake to 1000 mL/day
 - b. Administering a cathartic suppository
 - c. Increasing fiber in the diet
 - d. Limiting exercise
10. When administering a cleansing enema, which techniques should the nurse use? (*Select all that apply.*)
- a. Assist the patient to a left side-lying (Sims) position.
 - b. Add room-temperature solution to enema bag.
 - c. Lubricate 2 to 4 cm (1 to 2 inches) of tip of rectal tube with lubricating jelly.
 - d. Raise container, release clamps, and allow solution to fill tubing before administration.

e. Clamp tubing after solution is instilled

CHAPTER 41

Urinary Elimination

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 41.1 Describe the anatomy and physiology of the urinary system.
- LO 41.2 Describe abnormal patterns of urinary elimination, including causative factors.
- LO 41.3 Complete a comprehensive assessment of the patient with urinary elimination problems.
- LO 41.4 Identify nursing diagnoses related to urinary elimination.
- LO 41.5 Create collaborative patient-centered care plans for patients experiencing alterations in urinary elimination.
- LO 41.6 Implement interventions to address altered elimination concerns and evaluate their effectiveness.

KEY TERMS

- anuria, p. 1035**
- dialysis, p. 1035**
- dysuria, p. 1036**
- enuresis, p. 1037**
- functional incontinence, p. 1037**
- hematuria, p. 1036**
- hemodialysis, p. 1035**

Case Study

Annette James (A. J.) is an obese 31-year-old woman who comes into the primary care center with complaints of frequency, urgency, burning on urination, and lower abdominal pain rated as 4 on a 0-to-10 scale. Her vital signs are T 38.8° C (101.9° F), P 106 and regular, R18 and unlabored, and BP 140/85.

Significant assessment findings include a history of multiple and frequent bladder infections, occasional spotting between periods, right ovarian cyst removal 2 years ago, multiple sexual encounters with her partner in the past 3 weeks, and suprapubic tenderness on palpation. Based on diagnostic test results, A. J. is prescribed an antibiotic, nitrofurantoin (100 mg PO q 6 h), and the urinary tract analgesic phenazopyridine (2 tablets PO q 8 h PRN) for a bladder infection and told to return to the clinic in a month for a follow-up appointment.

Refer back to this case study to answer the critical-thinking exercises throughout the chapter.

Regular elimination of liquid waste products is an essential body function and is critical to healthy living. Social, cultural, and physical requirements factor into personal urinary elimination habits; therefore privacy and emotional needs, in addition to physical needs, must be addressed to ensure proper care of patients with urinary elimination concerns.

Urine elimination depends on factors such as food consumption, fluid intake, medications, and fluid loss through breathing and perspiration. Healthy adults eliminate approximately 1400 mL of urine each day (Lewis, Bucher, Heitkemper et al., 2017). Effective elimination of liquid waste

material requires proper functioning of the organs of the urinary tract, including the kidneys, ureters, urinary bladder, and urethra, as well as the muscles of the pelvic floor (Fig. 41.1).

Understanding normal anatomy and physiology related to the urinary system is essential for the nurse to provide optimal care.

FIGURE 41.1 Organs of the urinary system. (From Patton, K. T., & Thibodeau, G. A. [2016]. *Anatomy and physiology* [9th ed.]. St. Louis: Elsevier.)

LO 41.1 Normal Structure and Function of the Urinary System

Nutrients from food are used by the body to maintain all organ functions. The kidneys excrete and reabsorb water and electrolytes from the body. The urinary system controls the composition of blood by removing waste products such as **urea** and conserving useful substances. Urea is produced when protein-rich foods are digested. The urinary system helps control blood pressure and plays a crucial role in electrolyte and acid-base balance. The online animation demonstrates how the urinary system works. 

Kidneys

The kidneys are the major excretory organs of the body. The two kidneys are located bilaterally below the ribs toward the middle of the back. They filter liquid waste from the blood, balance electrolytes in the blood, regulate blood volume and pressure, produce erythropoietin for red blood cell formation, synthesize vitamin D to help control calcium levels, and maintain the acid-base balance of the extracellular fluid (Patton & Thibodeau, 2016).

Urine is formed by tiny filtering units called **nephrons**, which are the functional units of the kidney. Studies have indicated that the average number of nephrons varies greatly in humans, ranging from 200,000 to approximately 2 million (Rosenblum, Pal, & Reidy, 2017). Each nephron consists of the renal corpuscle and a small tube called the renal tubule. The renal corpuscle is made up of a network of blood capillaries called the glomerulus, which is surrounded by the Bowman capsule. The renal tubule is composed of the proximal tubule, the loop of Henle, and the distal convoluted tubule (Patton & Thibodeau, 2016).

Urine formation is a result of three processes. *Filtration* initially occurs in the glomerulus as fluid moves across a membrane as the result of a pressure difference. *Reabsorption* occurs in the renal tubule as most of the filtrate moves back into the blood. At this point waste products, excess solutes, and small amounts of water are not reabsorbed but are secreted. As tubular *secretion* takes

place, urine is produced. Urea, water, and other waste substances form urine as they pass through the nephrons down the renal tubules (Patton & Thibodeau, 2016). The online animation demonstrates urine formation. 

Ureters

After exiting the kidneys, urine is carried to the bladder by narrow tubes called the ureters. The ureter wall muscles continually tighten and relax, forcing urine downward. If urine is retained in the kidney or backflows from the bladder toward the kidneys, the patient becomes susceptible to kidney infections.

Bladder and Urethra

From the ureters the urine flows slowly into the bladder, located below the umbilicus and above the symphysis pubis in the lower abdomen, for storage. The bladder walls relax and expand to store urine, and contract and flatten to empty urine through the urethra. Sphincter muscles at the base of the bladder help keep urine from leaking by closing tightly like a rubber band around the opening of the bladder. The urethra transports urine from the bladder to outside the body for elimination and bladder emptying.

The innervation of the bladder signals when it is time to urinate and empty the bladder. This impulse is referred to as **urge or urgency**. The brain signals the bladder muscles to tighten and the sphincter muscles to relax, which squeezes urine out of the bladder through the urethra. When all of the signals occur in the correct order, normal **micturition**, or urination, occurs.

Normal Urine Characteristics

Urine can be produced in small or large amounts. It can be dilute or very concentrated. Normal urine is sterile. Urine contains fluids, salts, and waste products, but it is free of bacteria, viruses, and fungi. The amount of urine that an adult passes per day is dependent on the amount of fluids consumed, medications, medical conditions, and dietary intake, such as salt (Lewis, Bucher, Heitkemper et al., 2017). During the night, urine

formation decreases to approximately half of what is produced in the daytime.

LO 41.2 Altered Structure and Function of the Urinary System

Except for developmental factors associated with age and pregnancy, altered urinary elimination generally is due to some degree of urinary retention or loss of voluntary control of voiding (ability to empty the bladder). Psychosocial factors, food and fluid intake, surgical and diagnostic procedures, pathologic conditions such as hypertension and arteriosclerosis, and urinary tract infections (UTIs) all can affect the structure or function of the urinary system. These factors may alter the volume or characteristics of the urine produced or the effectiveness of excretion.

Abnormal Urination Patterns

Abnormal patterns of urination fall into several categories related to failure of the kidneys to produce or excrete more than 50 to 100 mL of urine in 24 hours (anuria), a reduced volume of urine typically greater than 100 and less than 500 mL in 24 hours (oliguria), excessive production and excretion of urine (polyuria), excessive urination at night (nocturia), painful urination (dysuria), and blood in the urine (hematuria). Urinary **incontinence**, the inability to control urination, is prevalent, particularly in women, and can greatly affect quality of life. Urinary retention is the inability to empty the bladder fully and generally is caused by an obstruction or neurologic disorder, enlarged prostate gland, or infection, among other factors.

Anuria

Anuria is the failure of the kidneys to produce or excrete urine. Anuria occurs as a result of any process that limits effective blood flow through the kidneys. Diagnosis of anuria is made when a catheter is passed into the bladder or a bladder scan is conducted and no urine is present. Inadequate flow or complete obstruction by anything (such as stones or tumors) that blocks both ureters and the bladder or obstructs the urethra can lead to an anuric

state, resulting in acute or chronic renal failure. Acute anuria is life-threatening and requires emergent investigation to determine the cause. As waste accumulates, the patient becomes at risk for coma or death.

Depending on the severity of anuria and the alterations in the patient's fluid and electrolyte levels, artificial filtering of waste products using renal dialysis may be necessary. **Dialysis** is a technique by which fluids and molecules pass through an artificial semipermeable membrane and are filtered by means of osmosis. The online animation demonstrates the process of dialysis.®

During **hemodialysis**, the patient's blood flows continually from the body through vascular catheters to the dialysis machine. The blood then goes through the machine's filters, and ultrafiltrate (a liquid from which the blood cells and the blood proteins have been filtered out) is created (Lewis, Bucher, Heitkemper et al., 2017). The frequency of hemodialysis depends on patient status. Once patients with chronic renal failure begin hemodialysis, they typically are required to undergo treatments three times per week or more often. Hemodialysis treatments most often are performed on an outpatient basis (Fig. 41.2).

FIGURE 41.2 Patient with chronic renal failure undergoing hemodialysis at an outpatient clinic. (Copyright Thinkstock.com.)

Peritoneal dialysis is performed by instilling dialysis solution into the patient's abdominal cavity through an external catheter

(Fig. 41.3). After the solution rests within the peritoneal cavity for a prescribed period, the solution is removed from the body through the catheter. In peritoneal dialysis, the abdominal cavity functions as the dialyzing membrane through which fluid and molecules are exchanged and toxic substances are removed from the body. The online animation demonstrates peritoneal dialysis.📺

FIGURE 41.3 Peritoneal dialysis (From Lewis, S. L., Bucher, L., Heitkemper, M. M., et al. [2017]. *Medical-surgical nursing: Assessment and management of clinical problems* [10th ed.]. St. Louis: Elsevier.)

Oliguria

Oliguria is defined as reduced urine volume less than 1 mL/kg/h in an infant, less than 0.5 mL/kg/h in children or adults, or less than 500 mL/day in adults (Eachempati, 2017). Oliguria is a symptom of acute or chronic renal failure, which can be classified as prerenal, renal, or postrenal failure. Prerenal failure occurs as a result of reduction in blood flow to the kidneys. Causes of prerenal failure include dehydration, vascular collapse, and low cardiac output. Structural issues with the kidneys, from primary glomerular diseases or vascular lesions, result in renal failure. Postrenal failure is related to a mechanical or functional obstruction of the flow of urine. Oliguria is most easily observed

by the nurse through frequent monitoring of the patient's urinary output. Signs and symptoms of oliguria vary according to the underlying cause. The patient may be breathless, with pale, clammy, and cool skin, and have a low blood pressure; there may be signs of edema or anemia; and changes in the heart rhythm, hepatomegaly, and hypertension may be present (Eachempati, 2017; Murphy & Byrne, 2010).

The management of oliguria includes treatment for any reversible causes. If the intravascular volume is low, fluids should be administered for restoration. Fluid balance should be monitored and maintained with electrolyte monitoring and correction. Input and output should be recorded, along with daily weights. Potassium retention is common in renal failure. Potassium levels need to be monitored, and dialysis may be initiated to reduce serum potassium levels to less than 5.5 mmol/l (Abuelo, 2018). Potassium intake should be limited until urine flow is reestablished. Dialysis may be required until the kidneys recover. The overall goal of dialysis is to remove toxins and to maintain fluid, electrolyte, and acid-base balance.

Safe Practice Alert

Measuring and recording intake and output (I&O) constitute an essential part of care for a majority of hospitalized patients, especially those experiencing fluid retention or excretion problems. Patients with acute or chronic renal failure may be placed on stringent fluid intake restriction, with orders for the nurse to maintain meticulous I&O records.

Polyuria

Polyuria is an excessive volume of urine formed and excreted each day. For an adult, this would be 2500 mL or more of urine per day. Polyuria may be caused by consumption of a large amount of fluids, especially fluids that contain caffeine or alcohol, which have a natural diuretic effect; ingestion of too much salt or glucose; use of diuretic medications; diabetes; imaging tests that involve contrast media or dye; or other disease processes.

Nocturia

Nocturia is excessive urination at night. The affected person may awaken several times during the night to urinate, which can disrupt the sleep cycle. Normally, urine decreases in amount and becomes more concentrated at night. Most people can sleep 6 to 8 hours without having to urinate. Nocturia commonly is seen in men with benign prostatic hyperplasia (BPH) and in postmenopausal women because of decreased bladder tone. It also may be associated with the use of medications such as diuretics, as well as with UTIs, congestive heart failure, cystitis (inflammation of the bladder), and diabetes. Drinking too much fluid before bedtime and sleep disorders also may have an effect. The patient with nocturia should be encouraged to maintain a diary of fluid intake, frequency of urination, urine output, and daily weights, taken at the same time on the same scale, to help determine an appropriate treatment regimen.

Dysuria

Painful urination, known as **dysuria**, may result from a number of factors, including bladder or UTI, cystitis, sexually transmitted disease, yeast infection, kidney or bladder stones, prostatic enlargement, malignancy, and allergic or irritant reaction to soaps, vaginal lubricants, spermicides, contraceptive foams and sponges, tampons, and toilet paper. Patients with dysuria often complain of burning that follows urination. Often a delay in initiating voiding or hesitancy is associated with dysuria (Michels & Sands, 2015).

Hematuria

Hematuria is the abnormal presence of red blood cells in the urine. The bleeding can originate at any point along the urinary tract. Both gross, or visible, and microscopic hematuria may represent serious underlying disease. The color of the urine does not reflect the degree of blood loss. Causes of hematuria include irritation or inflammation of the mucosa and invasion by bacteria. Malignancy, renal stones, trauma, infection, medications, tumors of the kidney, renal cysts, infarction, and arteriovenous

malformations (AVM, abnormal connections between arteries and veins) may contribute to hematuria.

Urinary Incontinence

Urinary incontinence is the inability to control the passage of urine. It is prevalent in the United States, affecting up to 51% of adult women and 16% of men, with risk factors including diabetes and obesity (Markland, Goode, Redden et al., 2010; Saiki & Meize-Grochowski, 2017). Affected individuals may have intermittent or complete inability to hold urine.

Urinary incontinence can be divided into several types. **Stress incontinence** is loss of urine control during activities that increase intraabdominal pressure, such as coughing, sneezing, laughing, or exercise. **Urge incontinence** involves a sudden strong urge to void, followed by rapid bladder contraction. The affected person does not have enough time for toileting between recognition of the urge to urinate and the onset of voiding. **Mixed incontinence** is a combination of both stress and urge incontinence. **Functional incontinence** refers to lack of urine control in the absence of any abnormalities of the urinary tract; it occurs when some physical limitation in functioning, such as difficulty with clothing fasteners or impaired mobility, hinders reaching the toilet before voiding occurs. **Overflow incontinence** is seen in patients who are unable to empty the bladder completely, resulting in a constant dribbling of urine or increased frequency of urination. Overflow incontinence results from weakened muscles of the bladder, which may be a consequence of certain pathologic conditions. **Temporary incontinence** can occur in association with factors such as severe constipation, infections in the urinary tract or vagina, or medication usage.

Urinary incontinence most frequently is seen in elderly people, although not all elderly people become incontinent. Women are more likely than men to suffer from it. Urinary incontinence contributes to decreased physical activity in women, leading to an increased incidence of obesity and diabetes (Norton, Pruski, Konkel et al., 2017). Infants and children are not considered incontinent until after toilet training is well established. Occasional accidents (unintentional instances of incontinence) are considered normal for children to have until about age 5 years.

Causes of acute urinary incontinence include extended bed rest, medications, increased amount of urine, mental confusion, pregnancy, prostate infection or inflammation, stool impaction, and UTIs. Chronic urinary incontinence issues may be related to bladder cancer, bladder spasms, depression, enlarged prostate, neurologic conditions, pelvic prolapse in woman, pelvic floor muscle damage that may occur with a hysterectomy, spinal injuries, or weakness of the bladder sphincter.

Urinary Retention

Urinary retention is the inability of the bladder to empty. It is caused by an obstruction in the urinary tract or by a neurologic disorder. The patient with chronic urinary retention has difficulty starting a stream of urine or emptying the bladder. Once started, the urine flow is weak. Chronic urinary retention causes mild but constant discomfort. During episodes of acute urinary retention, the patient is unable to urinate despite a full bladder. In another presentation, the patient may express the need to urinate frequently and when finished still feel urge. Dribbling may occur between trips to bathroom because the bladder is constantly full. Acute urinary retention is a medical emergency necessitating prompt medical intervention.

Conditions that contribute to urinary retention include vaginal childbirth, infections of the brain or spinal cord, diabetes, stroke, neurologic disorders, heavy metal poisoning, pelvic injury or trauma, prostate enlargement, infection, surgery, bladder stones, bladder tumors, rectocele, cystocele, constipation, urethral stricture, and medications such as antihistamines, anticholinergics, antispasmodics, and tricyclic antidepressants.

Factors Affecting Urinary Elimination

The ability to urinate is influenced by a variety of factors ([Box 41.1](#)). These include privacy issues and embarrassment, the effect of specific medications and foods, fluid intake, ambulatory ability, muscle tone that influences the frequency of voiding, the amount of urine produced, the color and other characteristics of the urine, the time of voiding, and voluntary control over actual urination. The cause of **enuresis**, the involuntary passing of urine, may be structural or pathologic, although it may be related to nonurinary

problems such as constipation, stress, and illness. Pathologic and surgical conditions may affect the process of urination temporarily or permanently.

Box 41.1

Diversity Considerations

Life Span

- Urinary patterns change over the course of a lifetime.

Age

- Full bladder control is attained between the ages of 3 and 5 years, although nighttime control may not occur until the age of 4 to 5 years.
- Loss of muscle tone in the bladder in older adults contributes to incontinence and frequency. Nocturia is common as well. The bladder does not empty as efficiently in older adults.
- Childbirth and gravity tend to weaken the pelvic floor, potentially leading to stress incontinence in older adult women.

Pregnancy

- During pregnancy, the growing fetus compromises bladder space and compresses the bladder, resulting in urinary frequency. Poor abdominal muscle tone also contributes to frequency.
- A 30% to 50% increase in circulatory volume occurs during pregnancy, which increases renal workload and output.
- The hormone relaxin, produced during pregnancy, causes relaxation of the bladder sphincter ([Sizer, 2014](#)).

Gender

- Enlargement of the prostate in men 40 years of age and older may lead to urinary frequency, hesitancy, and retention.
- Urinary tract infections (UTIs) are more prevalent in females because of their shorter urethra and because women experience a decrease in pelvic area muscle tone with age and childbirth.

Culture

- Studies indicate that minority women are less likely to seek professional help to treat urinary infection than women from Western cultures (Kang, 2015).
- In some cultures, it is inappropriate for a member of the opposite sex to care for a patient. Nurses should develop care plans to reflect cultural sensitivity to the needs of patients and their families.
- Immigrants face tremendous obstacles to seeking treatment for urinary concerns including language and cultural barriers and lack of health insurance (Kang, 2015). Sensitivity to the unique needs of patients is essential for accurate assessment and treatment.

Disability

- Total or partial disability may lead to urinary incontinence or retention.
- Paraplegics can be taught to empty the bladder using straight catheterization, to avoid urinary retention, which may lead to UTIs.
- Lack of privacy in hospitals and assisted care facilities can contribute to incontinence or retention.
- Insufficient time taken to void can lead to changes in urinary elimination patterns.

Morphology

- Pressure of the abdomen lying on the bladder in the obese person can lead to inadequate bladder emptying and incontinence.

QSEN Focus!

During the initial patient interview ask questions about the patient's urinary system function in a non-judgmental manner to establish trust and increase patient comfort.

Developmental Factors

Individual control of urination changes with age. The infant has no urinary control, and the young child will not gain control until between the ages of 2 and 5 years (Walle, Rittig, Tekgul et al., 2017). Preschoolers may have acquired the ability of independent toileting; however, accidents may occur and enuresis may be an issue until the age of approximately 5 years. By school age, the child's elimination patterns should be well established. Nocturnal enuresis (bedwetting) is commonly seen in children until full bladder control is established and should not be considered a problem until after the age of 5 years. Nocturnal enuresis in children over the age of 5 may be due to high urine production during the night, small bladder capacity, or a problem awakening from sleep (Arda, Cakiroglu, & Thomas, 2016).

Elderly people are at risk for elimination problems secondary to age-related decreased function of the kidneys. Urgency and frequency often are reported as the muscles supporting the bladder weaken. Retention of urine may lead to nocturia. Prostate enlargement that causes narrowing of the urethra may impair the ability of male patients to completely empty the bladder. Residual urine may predispose the elderly patient to bladder infections.

Psychosocial Factors

Many people consider urination a private matter and have established behaviors or habits that are associated with voiding. Alterations in the patient's elimination patterns produce anxiety and contribute to an inability to relax the muscles necessary to initiate voiding. Patients may voluntarily suppress the urge to

void secondary to other circumstances, such as unavailability of toileting facilities. These behaviors have been shown to increase the risk for incontinence and UTI.

Food and Fluid Intake

Changes in the patient's eating or drinking pattern can disrupt normal urination. Dehydration may lead to diminished urinary output. Decreased or excessive fluid intake may change the color, odor, or quantity of urine produced. Dietary changes, such as the intake of different food, can cause changes in the color or odor of the urine.

Medication

Certain drugs may alter the production, formation, concentration, clarity, and color of urine. Medications that affect the autonomic nervous system may interfere with the urination process, causing urinary retention. Blood pressure medications, specifically diuretics, change the ratio of water and electrolyte reabsorption within the kidneys, which will alter the concentration of urine.

Muscle Tone

Muscle tone plays a direct role in filling and emptying of the bladder. Poor muscle tone affects the ability of the bladder to contract and expand completely. Changes in the muscle tone of the pelvic floor can alter sphincter control, causing urine leakage.

Surgical and Diagnostic Procedures

Surgical and diagnostic procedures may alter the formation, concentration, color, and passage of urine. Ability to pass urine can be affected by swelling of surrounding tissues. Postoperative bleeding can change the color and quantity of the urine. Anesthesia contributes to urine retention by decreasing awareness of the need to void.

Pathologic Conditions

Diseases of the kidneys may reduce the production of urine. Heart and circulatory disorders can lead to diminished blood flow to the kidneys, affecting urine production. Calculi may obstruct the ureter, blocking the flow of urine. Dehydration causes water retention, resulting in decreased urinary output. Some pathologic conditions can result in bladder removal. In such instances, urine will need to be diverted from the urinary tract to exit the body.

Urinary Tract Infections

Urinary tract infections (UTIs) are the result of bacteria in the urine. Infection occurs when bacteria from the digestive tract, usually *Escherichia coli*, invade the urethra and multiply. UTI is one of the most common health care–associated infections (Centers for Disease Control and Prevention [CDC], 2018). Between 2 and 3 million emergency department visits in the United States are due to UTI symptoms, and over 150 million people contract UTIs each year worldwide (Flores-Mireles, Walker, Caparon, & Hultgren, 2015). UTI can occur in anyone. Females are more vulnerable than males, with the rate of occurrence gradually increasing with age. The rate for women is believed to be elevated because the female urethra is significantly shorter than that of the male and is located near sources of bacteria (the anus and vagina). The shorter urethra also contributes to the risk for infection associated with sexual intercourse. UTIs in women account for over 6 million patient visits to primary care providers (PCPs) annually in the United States (Brusch, Bavaro, Cunha, & Tessler, 2017).

People with a greater potential for infection include those with any abnormality of the urinary tract that obstructs the flow of urine, those with catheters in place, those who have difficulty voiding, and elderly people with bladder control loss. Diabetes or other diseases that suppress the immune system increase the risk for UTI.

Urinary Diversion

A **urinary diversion** is a surgical procedure performed when bladder function is impaired owing to trauma or disease involving the bladder, the distal ureters, or, rarely, the urethra. The diversion may be temporary or permanent and can be

classified as continent or incontinent. With cutaneous urinary diversion, urine exits the body through a stoma created on the abdomen (Fig. 41.4). With incontinent diversions (ileal conduits, ureterostomies, and other urostomies), an appliance, or bag, must be worn to collect urine as it is excreted from the body. For cutaneous continent diversions (Kock pouch, Mainz pouch, Indiana pouch), a collection reservoir is surgically created using a segment of the intestine; the patient then needs to catheterize the reservoir through a cutaneous stoma every 4 to 6 hours to drain stored urine. The orthotopic bladder substitute (i.e., ileal neobladder) is the most common continent diversion performed today because it most closely resembles the original bladder in both location and function. With this type of urinary diversion, a segment of the intestine is used as a urinary reservoir and is anastomosed (connected) to the patient's native urethra. An orthotopic neobladder eliminates the need for a cutaneous urinary collection device and, in some cases, the need for intermittent catheterization. The type of urinary diversion performed depends on a combination of clinical factors and patient preference.

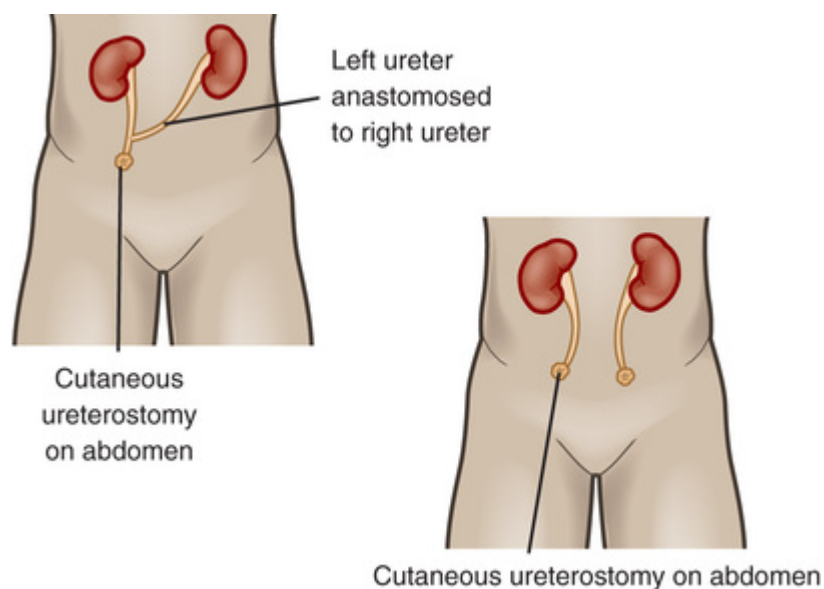

FIGURE 41.4 Cutaneous urinary diversion. (From Lewis, S. L., Bucher, L., Heitkemper, M. M., et al. [2017]. *Medical-surgical nursing: Assessment and management of clinical problems* [10th ed.]. St. Louis: Elsevier.)

LO 41.3 ♦ Assessment

Open-ended as well as focused questions can be useful in obtaining essential information about the patient's urinary concerns and function. A variety of questions guide the interview aspect of the assessment phase.

During the initial assessment, directed at gathering basic subjective and objective data, the patient's physical and mental abilities must be considered, prioritization of immediate problems identified, and relief of symptoms addressed before a full evaluation is undertaken. Signs of distress and the patient's orientation to his or her circumstances should be noted. Changes in mental status may be a symptom of elevated nitrogenous wastes in the blood secondary to kidney dysfunction. Frequent urination and burning during micturition are classic symptoms of UTI. Fatigue is a frequent complaint of patients with kidney disorders.

After completion of a focused interview, including past and present health history, the nurse needs to conduct a physical inspection of the abdomen. Inspection of the urine also is done to evaluate the patient's hydration status and identify changes related to the use and effects of medications and illnesses. A discussion with the patient focusing on urinary elimination patterns and abnormalities may be difficult, because elimination often is regarded as a private matter; however, it must be done. Refer to [Box 41.2](#) for health assessment questions to include in the patient's health history interview.

Box 41.2

Health Assessment Questions

- Have you ever been diagnosed with kidney or bladder disease?
- Have you ever had surgery or experienced trauma to the urinary system?
- Have you ever had a urinary tract or kidney infection?

- Do you have a family history of kidney disease or urinary problems?
- Do you have any physical problems that may affect the urinary tract, such as high blood pressure, diabetes, kidney stones, multiple sclerosis, Parkinson disease, spinal cord injury, or stroke? If so, have you noticed or experienced any problems with urinary retention?
- Have you experienced changes in your normal urination pattern? If so, have they caused you embarrassment or anxiety, for how long?
- Are you able to control the flow of urine when you urinate?
- Do you ever have to get up at night to urinate?
- Do you have difficulty starting or stopping your flow of urine?
- Have you noticed difficulty initiating the stream of urine? Voiding in small amounts?
- Do you feel the need to void more frequently than in the past?
- Have you noticed any changes in the quality, quantity, color, or odor of the urine? If so, for how long?
- Do you take any vitamins or medications such as antibiotics or diuretics or eat any particular foods that might cause changes in the characteristics of your urine?
- Do you work in an environment or industry that exposes you to harsh chemicals?
- Do you experience pain, burning, itching, or other discomfort associated with urination or pain in the sides of your back or abdomen? If so, describe and rate the pain on a scale of 0 to 10.
- For female patients: How do you cleanse after urination, bowel movements, or intercourse?

Abdominal Assessment

After explaining to the patient what to expect during the abdominal assessment, the nurse should assess the general appearance of the abdomen for dry skin to help determine hydration status and to identify masses, indentations, and scars.

Inspection and Auscultation

The abdomen is inspected for skin color, contour, symmetry, and distention while the patient is in the supine position. Normally, the abdomen is not distended and is symmetric and free of bruises, masses, and swelling. A distended bladder may be visible in the suprapubic area. A bladder scan can be conducted by the nurse with hand-held ultrasound equipment to quickly determine the extent of urinary retention (Fig. 41.5). Abdominal distention may be seen in conditions such as polycystic kidney disease, pyelonephritis, ascites, and pregnancy. In addition, auscultation of the left and right renal arteries is performed to assess circulation sounds. Normally, no sounds are heard.

FIGURE 41.5 Determining the level of urinary retention by ultrasound scanning of the bladder can prevent unnecessary catheterization. (Copyright Verathon, Inc. Used with permission.)

Palpation and Percussion

Palpation of the bladder is conducted to determine symmetry, location, size, and sensation. Light palpation should be performed over the lower abdomen. The abdomen should be soft and nondistended. Deep palpation, which can be done to outline the

shape of the bladder, usually is performed by the patient's PCP. Using a bimanual technique, the PCP will attempt to palpate the kidneys, which rarely are palpable unless they are enlarged from tumors, cysts, or hydronephrosis. Palpation of an enlarged kidney may be painful for the patient.

Assessment by a PCP may include blunt or indirect percussion to further assess the kidneys. The patient should feel no pain or tenderness with pressure or percussion. Pain or discomfort during or after percussion is suggestive of kidney disease. Percussion of the bladder determines location and degree of fullness.

Inspection of Urine

Color

Normal urine color ranges from pale yellow to amber. Common causes of urine discoloration are medications, vitamins (such as vitamin B), foods (such as asparagus or elderberries), and food dyes. Urine color may be altered by certain health problems. Concentrated urine is darker (deep amber) and may be the result of dehydration, low fluid intake, or reduced urine production. Dilute urine ranges in color from clear to pale straw and may be a consequence of excessive fluid intake or the inability of the kidneys to concentrate urine. Red or pink urine may be associated with bleeding, strenuous exercise, UTI, enlarged prostate, kidney or bladder stones, kidney disease, or cancer.

Food

Foods such as beets, blackberries, and rhubarb may discolor the urine pink or red; carrots and carrot juice may turn it orange. Brown or tea-colored urine is associated with consumption of fava beans and aloe. Asparagus consumption may result in green urine ([Harvard Women's Health Watch, 2018](#)).

Medication

Certain medications can affect the color of urine. Antimalarial drugs, laxatives, and metronidazole may cause the urine to turn brown or tea-colored. Rifampin, warfarin, and phenazopyridine may turn the urine orange. Blue or green urine can be seen in

patients receiving medications such as cimetidine, indomethacin, or promethazine ([Harvard Women's Health Watch, 2018](#)).

Pathologic Conditions

Patients with hypercalcemia may have blue-green urine. Those with liver failure from hepatitis and cirrhosis may have brown to tea-colored urine. Severe dehydration can cause urine to range between dark yellow-orange and tea color.

Clarity

Urine normally is clear. Cloudy urine may indicate the presence of bacteria, blood, sperm, crystals, or mucus. After bladder or kidney surgery, patients may excrete bloody urine containing clots. These patients typically require **irrigation** (flushing) of the bladder using a three-way catheter to prevent potential blockage.

Odor

Normal urine usually does not smell very strong. Dehydration may increase the odor of urine as more waste is excreted in smaller volume. Foods (most notably asparagus), genetics, and some diseases are associated with a change in the odor of urine. In uncontrolled diabetes, the urine can have a sweet, fruity odor, whereas in infections, a strong, unpleasant odor may be evident.

Amount

The amount of urine that a patient eliminates can vary, depending on factors such as fluid intake, dehydration, and retention. The normal urinary output is approximately equal to fluid intake. Adult urinary output of approximately 0.5 mL/kg/h is considered normal ([Eachempati, 2017](#)).

Safe Practice Alert

Output of less than 30 mL/h may indicate decreased renal perfusion and should be reported to the patient's PCP immediately.

1. Identify three assessment questions that the nurse should ask A. J. to further investigate her chief complaint.

Laboratory Tests

Common tests to evaluate urinary function include measurement of blood urea nitrogen (BUN) and serum creatinine levels to determine kidney function, urinalysis, urine culture to determine the cause of a UTI, and 24-hour urine collection to measure creatinine clearance.

Blood Urea Nitrogen and Creatinine

Blood levels of urea and creatinine are used to evaluate renal function. Urea is the end product of protein metabolism and is measured as BUN. Creatinine is a waste product that is produced in the blood as a by-product of muscle metabolism.

BUN concentration is a measure of the urea level in the blood. Urea is cleared by the kidney, and levels may be increased in the patient who is dehydrated or who has a disease that compromises the function of the kidney. Normal values for BUN in the blood are 7 to 20 mg/dL. Elevated levels may indicate kidney injury or disease as well as conditions such as diabetes, high blood pressure, blockage of the urinary tract, a high-protein diet, severe burns, gastrointestinal bleeding, or problems such as dehydration or heart failure, which affect blood flow. Medications also may elevate BUN levels. Low BUN values may be caused by a low-protein diet, malnutrition, liver damage, or drinking excessive amounts of liquids. No pretest preparation is required; however, medications, such as certain antibiotics, corticosteroids, and diuretics, may affect test results.

Creatinine is filtered along with other waste products from the blood by the kidney and eliminated in the urine. It is made at a

steady rate, and levels are not affected by diet or by normal physical activities. The patient with kidney damage has decreased urinary creatinine but increased serum levels. The amount of creatinine in the blood is directly related to muscle mass; generally, creatinine levels are higher in men than in women. Normal values of serum creatinine are 0.6 to 1.2 mg/dL for women and 0.8 to 1.4 mg/dL for men.

BUN and serum creatinine are viewed in relationship to each other. Sudden rises in BUN-to-creatinine ratios occur in acute kidney failure associated with shock, dehydration, or severe gastrointestinal bleeding. Low BUN-to-creatinine ratios are seen in patients on low-protein diets or those with severe muscle injury, cirrhosis of the liver, or syndrome of inappropriate antidiuretic hormone (SIADH).

Urinalysis

Urinalysis is an assessment of the urine at a single point in time. Urinalysis is a screening tool for UTI, kidney disease, and other conditions. Single samples can be used for detection or measurement of bacteria, glucose, white blood cells, red blood cells, proteins, and other substances. Urinalysis samples are collected by having the patient void in a specimen cup, or samples may be taken using catheterization. Only small samples of urine (10 to 15 mL) are required for urinalysis testing.

Specific Gravity

Urinalysis for specific gravity monitors the balance of water and solutes (solid matter) in urine. Normal specific gravity in an adult is 1.005 to 1.030. The higher the level of specific gravity, the more solid material is contained in the urine. Fluid intake has a direct relationship to specific gravity. If large volumes of water are consumed, dilute urine is produced, which has a low specific gravity. Specific gravity is high in conditions of dehydration.

pH

The acid-base balance in the body is determined by pH, which reflects the acidity or alkalinity of the urine. Urine normally is slightly acidic, with an average pH of 6. Urine with a pH of 4 is very acidic. A pH of 7 is neutral, and a pH of 9 is very alkaline.

The pH is useful in determining the kidneys' response to acid-base imbalances. In metabolic acidosis, the urine pH decreases as the kidneys excrete hydrogen ions; in metabolic alkalosis, pH of the urine increases. Maintaining a healthy pH helps prevent formation of kidney stones.

Urine for Protein

Normally, urine does not contain protein. Protein molecules generally are too large to escape from the glomerulus capillaries into filtrate. Protein in the urine may be associated with fever, vigorous exercise, pregnancy, and some diseases, such as kidney disease. In conditions such as glomerulonephritis (inflammation of the glomeruli of the kidney), the cell membrane can become permeable and allow proteins to cross.

Glucose

Normal urine contains very little to no glucose. The urine glucose concentration is used to screen for diabetes and to assess glucose tolerance. Glucose in the urine may be a sign of kidney damage or disease. Urine glucose levels are not an adequate measure of blood glucose levels. In the uncontrolled diabetic patient, glucose may appear in the urine.

Ketones

The presence of ketones in the urine (ketonuria) indicates that fat has broken down for energy. Ketones are normally not passed in the urine. Large amounts of ketones in the urine may indicate diabetic ketoacidosis. A diet low in sugars and carbohydrates, prolonged fasting or starvation, and vomiting also may be associated with ketonuria.

Microscopic Analysis

For microscopic analysis, urine is spun in a centrifuge and sediment settles at the bottom. The sediment is then spread on a slide and checked for red or white blood cells, casts, plugs, or crystals. The presence of crystals in the urine may indicate that stones are present. Bacteria, yeasts, and parasites are not normally present in urine and, when present, usually indicate infection.

Suspected Urinary Tract Infection

If a UTI is suspected, urine may be checked for nitrates. Nitrate levels increase when bacteria are present. A leukocyte esterase test determines the level of white blood cells in the urine; elevated levels indicate presence of a UTI.

Culture and Sensitivity Testing

Urine culture and sensitivity testing are performed for diagnosis of a UTI. Urine in the bladder normally is sterile; it does not contain bacteria or organisms. If organisms grow in the culture, sensitivity testing is performed to determine the appropriate antibiotic for treatment.

Twenty-Four-Hour Urine Collection

A 24-hour urine collection usually is performed to determine the amount of creatinine cleared through the kidneys (see [Chapter 34, Skill 34.2: Urine Specimen Collection](#)). This timed specimen also is used to measure levels of protein, hormones, minerals, and other chemical compounds in the urine. Creatinine clearance, which measures how well creatinine is removed from the blood by the kidneys, provides information about kidney function. Factors or conditions that may interfere with the accuracy of a 24-hour urine collection include failure to include some portion of the output, continuing the collection beyond 24 hours, spilling the specimen, inability to keep the specimen cool, and previous ingestion of certain foods or medications.

Preparation is not required before initiation of a 24-hour urine collection. The time of the patient's first morning void is the best start time for the 24-hour specimen collection. The first voided specimen is not saved; all urine produced after the first (discarded) specimen is collected in a special opaque container and kept cool. At the completion of the 24 hours, the first voided specimen of the second day (if the collection was started in the morning) is included in the specimen, and the container is transported to the laboratory for analysis. The 24-hour urine collection may be performed on an outpatient or inpatient basis.

Diagnostic Examinations

In more complicated situations, additional tests may be needed to obtain a more thorough assessment of the urinary system. Diagnostic procedures may be invasive or noninvasive. These tests may require some preparation on the part of the patient before testing. An adequate understanding of each procedure is necessary for the nurse providing care for patients with urologic difficulties to assist them through the diagnostic process.

Ultrasound Assessment of the Bladder or Kidneys

An ultrasound scan may be performed to assess the size, shape, and location of the kidneys; with use of specialized ultrasound technology, blood flow can be monitored during the procedure. Ultrasound studies may be safely conducted in pregnant women and in patients who have allergies to contrast media, because no radiation or contrast dyes are used. Factors or conditions that interfere with ultrasound results include severe obesity, recent barium studies, and excessive flatus or intestinal gas. Generally, no patient preparation such as fasting or sedation is required. If the bladder is to be studied, the patient will be required to drink fluid and refrain from voiding before the procedure. The ultrasound examination itself causes no pain; however, the patient may complain of discomfort from lying still with a full bladder for the duration of the procedure.

Kidney, Ureter, and Bladder X-ray Study

A kidney, ureter, and bladder (KUB) study is a diagnostic x-ray image centered on the iliac crest, typically used to investigate gastrointestinal conditions such as a bowel obstruction or gallstones. It also can detect the presence of kidney stones. In addition, KUB studies are used to assess positioning of indwelling devices such as ureteral stents. A ureteral stent is an indwelling tube placed in the ureter, at a point between the kidney and the bladder. Stents are placed to prevent or treat obstruction of the urine flow through the ureter.

Intravenous Pyelography

An intravenous pyelogram (IVP) is an x-ray study of the kidneys, the bladder, the ureters, and the urethra. The images show the size, shape, and position of the urinary tract. The procedure for IVP involves the injection of contrast material into a vein. X-ray images are then taken at timed intervals. An IVP commonly is performed to identify kidney stones, tumors, or infection; to measure the size of a tumor of the urinary tract; and to look for urinary tract damage after injury. Contraindications for IVP include pregnancy, severe kidney disease, metformin use within 48 hours ([Burchum & Rosenthal, 2016](#)), and an allergy to iodine. The patient should not eat or drink for 8 to 12 hours before the test and may need a laxative or enema to ensure that the bowels are empty. Risks involved with IVP are allergic reactions to the contrast material and sudden kidney failure associated with conditions such as diabetes, kidney disease, sickle cell disease, and pheochromocytoma (a rare adrenal gland tumor), as well as medications that affect the kidney ([Mayo Clinic Staff, 2018](#)).

Computed Tomography

Computed tomography (CT) is used to diagnose kidney stones, bladder stones, or blockage of the urinary tract. Contrast media may be used during the procedure to help identify blockages, growths, infections, or other diseases. The patient may be required to have nothing by mouth for 8 to 12 hours before the test and may be prescribed a laxative or enema. A sedative may be given to help the patient relax before the procedure. The scan usually takes 30 to 60 minutes but may take up to 2 hours, during which time the patient must lie still. After the procedure, the patient is instructed to increase fluid intake to flush out any contrast material that was given.

Cystoscopy

Cystoscopy is an examination of the bladder and urethra through a cystoscope, which is inserted into the urethra and advanced into the bladder. The procedure permits visualization of areas that do not show up well on x-ray images. Cystoscopy is performed to determine the cause of hematuria, dysuria, incontinence, frequency, urgency, or retention. Cystoscopy is used additionally in the diagnosis of conditions that cause blockage of the urethra,

as well as for treatment of urinary tract problems. Biopsy of tissues and removal of small stones or growths also can be performed using cystoscopy. Local, spinal, or general anesthesia may be used for the procedure. The patient should take nothing by mouth 8 to 12 hours before the test in case general anesthesia needs to be administered. The entire examination may take up to 45 minutes. The patient may experience a burning sensation and the urge to urinate during the procedure, and lying on the table can become uncomfortable. Risks associated with the test include those associated with anesthesia, temporary swelling of the urethra, difficulty urinating, and mild infection. Puncture of the urethra or bladder is a rare complication. After the procedure, the patient is instructed to increase fluid intake to minimize burning and prevent UTI. Pink-tinged urine commonly is seen for several days after cystoscopy, particularly if a biopsy is performed.

2. What diagnostic studies are most likely to be performed in evaluating A. J.? Give the rationale for each study.

LO 41.4 ♦ Nursing Diagnosis

Data obtained during assessment of the patient's urinary elimination function and patterns may reveal existing and potential problems. Accurate assessment and clustering of the data are crucial to identifying the defining characteristics of impaired elimination and determining the appropriate nursing diagnoses for the patient. [International Classification for Nursing Practice \(ICNP\)](#) nursing diagnoses associated with urinary elimination concerns include:

Impaired Urination

- Supporting Data: Microorganisms in the urinary tract, urgency, frequency, reports of burning with urination

Urinary Retention

- Supporting Data: Postanesthesia state, absent urinary output, lower abdominal distention, residual urine evident on bladder scan

Impaired Self-Toileting

- Supporting Data: Neuromuscular impairment, right-sided paralysis, inability to perform proper toileting hygiene, inability to manipulate clothing during toileting

Stress Incontinence of Urine, Functional Incontinence of Urine, Urge Incontinence of Urine, and Reflex Incontinence of Urine are each separate nursing diagnoses. Each of the incontinence diagnoses addresses the unique patient needs associated with that specific type of incontinence. The supporting data for each diagnosis are type-specific and allow for selection of individualized nursing interventions.

Although not directly related to urinary elimination, nursing diagnoses such as *Risk for Impaired Skin Integrity, Risk for Infection, Disturbed Body Image, Difficulty Coping, and Pain* may be appropriately assigned to patients experiencing urinary elimination concerns.

LO 41.5 ♦ Planning

Goals for the resolution of elimination problems are structured around maintaining normal elimination patterns, returning to previous levels of function, preventing associated risks, or coping with an altered pattern (Table 41.1). The nurse and the patient should work collaboratively with other members of the health care team to create individualized goals specific for the diagnosis and prioritized according to the patient's need, which may initially have a psychosocial focus (Box 41.3). Expected outcomes are related to satisfactory management of incontinence, complete emptying of the bladder, and independent management of toileting tasks. Short-term goals may include the following:

TABLE 41.1
Care Planning

ICNP NURSING DIAGNOSIS WITH SUPPORTING DATA	NURSING OUTCOME CLASSIFICATION (NOC)	NURSING INTERVENTION CLASSIFICATION (NIC)
<i>Impaired Urination</i> Microorganisms in the urinary tract Urgency Frequency Reports of burning with urination	<i>Urinary elimination</i> Absence of urinary frequency	<i>Urinary elimination management</i> Instruct patient to monitor for signs and symptoms of urinary tract infection.

(Eds.) (2018). *Nursing outcomes classification (NOC)* (6th ed.). St. Louis: Mosby. ICNP is owned and copyrighted by the International Council of Nurses (ICN). Reproduced with permission of the copyright holder.

Box 41.3

Interprofessional Collaboration and Delegation

Multidisciplinary Care for Patients With Elimination Needs

- Unlicensed assistive personnel (UAP) often aid patients in toileting. The nurse must communicate necessary actions, such as measuring the amount of urine, noting its color, and determining the frequency of urination. The nurse must stress to the UAP the necessity of documenting voiding patterns.
- Nurse continence specialists may need to be consulted to teach pelvic floor exercises.
- Physical therapists can design a plan to increase overall muscle strength.
- Depending on physical limitations, the family may need to alter the home environment to accommodate the patient's elimination needs.
- In some settings, UAP may be permitted to insert a urinary catheter, but it is not routine practice. The UAP may assist with positioning the patient, focusing lighting, maintaining patient position, and providing comfort measures.

- Patient will report resolution of UTI symptoms within 5 days of taking prescribed antibiotic treatment.
- Patient will spontaneously empty bladder completely without assistance within 12 hours after surgery.
- Patient will effectively wipe self with left hand after urination within 5 days.

Long-term goals associated with urinary elimination concerns may include:

- Patient will report no UTIs having occurred since last outpatient visit 12 months ago.

- Patient will not exhibit signs of urinary retention during a bladder scan at 6 month surgical follow-up appointment.
- Patient will demonstrate ability to safely perform toileting tasks without assistance within 9 months of developing right-sided paralysis secondary to a severe cerebrovascular accident.

The conceptual care map for A. J. can be found at <http://evolve.elsevier.com/YoostCrawford/fundamentals/>. It is partially completed to indicate how to use the map as a learning tool. Formulate A. J.'s care plan using the example conceptual care maps shown in **Chapters 8 and 25 to 33**.

LO 41.6 ♦ Implementation and Evaluation

The implementation phase of the nursing process involves interventions that assist the patient in achieving the goals, including, but not limited to, continence, complete emptying of the bladder, and self-care in toileting. The focus of each goal is directly related to the identified nursing diagnosis, which in turn determines what interventions are most appropriate for each patient. The nurse must focus on activities that will help the patient with compromised urinary elimination return to the normal state of function or adapt to changes in the state of function. Nursing interventions to help patients achieve urinary continence and complete emptying of the bladder and independent toileting include promoting adequate fluid intake, teaching self-care activities, and assisting with voiding. Collaborative interventions require the assistance of the PCP or other professionals, such as a physical therapist or nutritionist.

Ongoing assessment and follow-up are needed to ensure quality in the care provided and determine the need for further nursing interventions. Patient education is crucial for maintaining urinary tract health ([Box 41.4](#)). Before leaving the acute care facility, the patient needs to demonstrate understanding and competency in assessment of the qualities and characteristics of urine, home catheterization, toileting, fluid intake, and preventing UTIs. An additional important topic for patient education is the relationship between poor hygiene and occurrence of UTIs. Proper hand hygiene can prevent the spread of infection; proper perineal care techniques can prevent cross contamination with bacteria from the anal region. Female patients should be taught pelvic muscle exercises ([Kegel exercises](#)), which help strengthen and maintain pelvic floor muscles, thus aiding in the prevention of some types of incontinence.

Box 41.4

Patient Education and Health Literacy

Adapting Teaching to Patient Needs

- Instruct patients and families on safe transfer techniques for people with limited mobility needing voiding assistance.
- Instruct patients to respond promptly to urge, to avoid urinary retention and reduce infection risk.
- Emphasize the importance of maintaining fluid intake to help flush the urinary system.
- Instruct patients to promptly report pain or burning on urination; changes in urine color, odor, or clarity; or changes in voiding patterns.
- Reinforce proper aseptic technique with female patients, including washing front to back to maintain perineal cleanliness and voiding after intercourse. Remind male patients to retract foreskin, if present, to thoroughly wash the urinary meatus. Be sure to stress the importance of drying the area thoroughly to prevent skin breakdown or irritation.
- Teach proper care of indwelling catheters and the perineal area, including emptying and cleaning the device, maintaining a closed system, and bladder irrigation, if necessary.
- Arrange for a wound ostomy continence nurse (WOCN) to teach patients with a urinary diversion appropriate care for the stoma, drainage devices, and skin.
- Teach patients the importance of taking medications as prescribed. Instruct patients and families in desired or adverse drug effects that may influence the urinary elimination pattern. Stress the importance of maintaining fluid intake or restrictions based on medication requirements.

QSEN Focus!

Discussing reliable resources for patient and family referrals will promote informed decision making and support for caregivers after discharge.

3. List a minimum of three topics that the nurse should discuss with A. J. before discharging her from the clinic. Include content that the nurse should cover under each topic.

It is necessary to ensure that preparations for the patient's return home have been made before discharge (Box 41.5). The home should be assessed for accessibility of toileting facilities and associated safety issues. The nurse should facilitate the acquisition of needed supplies and equipment and expedite necessary referrals.

Box 41.5

Home Care Considerations

Necessary Elimination Resources

- Assessing the home for safety issues related to urinary elimination is important. The patient must have ready access to toilet facilities. Adequate lighting should be ensured.
- Necessary assistive and safety equipment, such as grab bars and raised toilet seats, should be in place in the home before discharge, as needed. Bedpans and a bedside commode, if warranted, should be in the home ahead of time.
- Supplies necessary for catheterization and catheter care, urinary diversions, and incontinence care should be purchased.
- Appropriate referrals to home health or social services should be made before discharge. Services such as those of home health aides for assistance with activities of daily living (ADLs) should be confirmed.
- Community resources such as the United Ostomy Association and the National Association for Continence

should be identified for patients and their families.

Safe Practice Alert

The home environment should be assessed for factors that may interfere with toileting. Impractical distance to the toilet, inefficient physical layout of the toileting facilities, clutter, stairways, rugs, and inadequate lighting may put ambulatory patients at safety risk.

Promoting Normal Urinary Patterns in a Health Care Facility

Generally, every patient in a health care facility experiences an alteration in the pattern of elimination. Many people follow routines to promote voiding, but in the health care facility, conflicts with a person's normal routine are common. For example, bed rest, medication use, prescribed medical therapies, and privacy issues can alter the patient's pattern. Proper integration of the patient's habits into daily care will aid in preventing problems with elimination.

Safe Practice Alert

Medications such as diuretics may cause frequency or urgency, potentially compromising patient safety. Instruct patients who are on fall precautions to ask for assistance before ambulation.

Bedpan and Urinal

The patient who is unable to ambulate to the bathroom may require the use of a bedpan or urinal. For many patients, this can be an uncomfortable and embarrassing procedure. Many patients require privacy and an unhurried time to void. Pulling the bedside curtain closed, allowing for adequate time for the patient to void, and encouraging the patient to be in the most normal position possible on the bedpan will help promote elimination.

The bedpan may be warmed before use, because a cold bedpan can cause contraction of the perineal muscles with consequent

inhibition of voiding. A high Fowler position increases the intraabdominal pressure and helps stimulate voiding, and flexion of the hip and knees simulates the normal position for a woman. A small pillow or rolled towel placed behind the patient's back will increase comfort. Use of a fracture bedpan is recommended for patients who must remain positioned at an angle less than 30 degrees from horizontal.

Urinals generally are for male use. Urinals for women are available as well, but these rarely are used in the hospital setting (Fig. 41.6). The urinal can be used while the patient is standing, sitting, or lying down. Box 41.6 outlines the procedure.

FIGURE 41.6 Male urinals are more commonly used in the acute care setting, although urinals for both females (A) and males (B) are available.

Box 41.6

Nursing Care Guideline

Assisting a Patient With a Urinal

Background

- Routine urination and complete emptying of the bladder will prevent many complications.

- Encourage routine use of the urinal for male patients who are unable to ambulate to the bathroom.

Procedural Concerns

- Patient positioning for using a urinal may be:
 - In bed, where the patient may be:
 - Side-lying *or*
 - Supine *or*
 - Supine with the head of the bed elevated
 - Sitting on the side of the bed *or*
 - Standing
- Apply clean gloves before placing the urinal.
- Place the urinal between the patient's legs, with the penis completely in the urinal.

(Copyright Mosby's Clinical Skills: Essentials Collection.)

- Provide privacy, with the call light within reach of the patient.
- Remove the urinal after 10 minutes (whether or not urination has occurred) to prevent skin breakdown.
- Provide for patient hand hygiene.
- Assist the patient with cleansing, as needed.
- Implement personal hand hygiene before and after helping the patient with the urinal.

Documentation Concerns

- Document the quantity, color, quality, and odor of the urine.
- Note the stream characteristics.
- Monitor frequency of urination.

To maintain asepsis, hospitalized patients are provided with a bedpan, urinal, or both for personal use that is marked with their name or room number. The bedpan typically is stored in the bathroom. A urinal should be stored out of sight but within reach. It should be kept separate from other equipment used for hygienic care, and aseptic practices prohibit its being kept on the floor, under the bed, or on the over-bed table. Bedpans and urinals should be rinsed thoroughly after each use.

Bedside Commode

A bedside commode is a chair with a toilet seat top that has a container underneath to collect urine or stool for the patient who is unable to ambulate to the bathroom. The container is removed for emptying and cleaning. A bedside commode is more conducive to elimination than a bedpan. Use of a bedside commode may be appropriate if the patient is weak or unsteady, is at risk for falling, or becomes short of breath when ambulating. It should not be used for the patient who is unable to stand, who is maintained on strict bed rest, or who independently cannot sit up safely.

Although a bedside commode is not disposable, each hospitalized patient is provided with one for individual use to maintain asepsis; it is cleaned and sanitized between users. The bedside commode container should be emptied and rinsed between each use. Privacy can be an issue with the bedside commode; pulling the privacy curtain and avoiding disruptions are essential.

Privacy

If possible, the patient should be given time and privacy to void. Many patients have difficulty voiding in the presence of others. As noted, pulling the bedside curtain and avoiding disruptions

will help promote elimination. Visitors should be asked to leave the area. If possible, the patient should be provided the use of a private room. If the patient needs to be monitored more closely for safety reasons while using a bedpan or urinal, the nurse should remain at the bedside facing slightly away from the patient and use a cover sheet to allow for privacy.

It may be helpful to provide sensory stimuli that will assist the patient to relax, such as applying warm compresses or blankets to the lower abdomen. Turning on running water within hearing distance of the patient may stimulate urge and mask the sound of voiding. These types of interventions help relieve physical and emotional discomfort.

Toileting Schedule

Determining the patient's toileting pattern may assist the person with urinary elimination. The patient should be encouraged to void at regular intervals whether urge is felt or not. The patient with functional incontinence benefits from bladder training that includes a toileting schedule, which helps improve general control over urination ([Palmer & Willis-Gray, 2017](#)). Create a specific routine based on the patient's normal toileting pattern, then monitor and document episodes of incontinence, looking for patterns. First, establish voiding opportunities on a regular schedule: on awakening, every 1 to 2 hours during the day, before bedtime, and every 4 hours at night; and then gradually increase the time intervals between. Variations to this schedule can be made for bladder retraining to slowly increase the amount of fluid retained and for habit training. Prompted voiding also may be encouraged as the patient develops control.

Fluid Intake

Increasing fluid intake will promote urine production in the patient without renal or cardiac dysfunction. A normal daily intake of 1500 to 2000 mL of fluids usually is adequate to maintain normal micturition. The patient with a history of UTI or renal calculi should increase that intake to approximately 2400 mL for flushing of the urinary tract and prevention of stone formation ([Pendick, 2018](#)). Although it is important to increase fluid intake,

to minimize nocturia, encourage the patient to stop drinking fluids at least 2 hours before bedtime.

Safe Practice Alert

Dehydration can pose a risk for patients trying to control incontinence problems by avoiding adequate fluid consumption. Dehydration may affect the patient's mental status, further contributing to risk.

Monitoring Intake and Output

For most hospitalized patients, not just those with urinary concerns, it is necessary to monitor and record patient intake and output. Recording of fluid (I&O) can be delegated to qualified unlicensed assistive personnel (UAP), if the nurse takes ultimate responsibility to make sure the intervention is completed satisfactorily. While evaluating I&O, the nurse should always take into consideration whether the patient has recently undergone surgery, is receiving medications that influence fluid I&O, or has a medical condition such as kidney or heart failure that affects fluid balance.

Intake includes all food and oral fluids as well as tube feedings and intravenous fluids. In most facilities, solid food intake is documented as an estimated percentage of a meal consumed (e.g., 85% of lunch). Oral fluids are recorded in milliliter (mL) amounts for the size of the container from which they are consumed. A list of volumes for various containers used in a facility, such as coffee cup = 240 mL, juice glass = 120 mL, and water pitcher = 900 mL, should be available for reference before documentation of oral intake. Ice chips are documented as approximately half of their volume. The volume of tube feedings and intravenous therapies (both maintenance and piggyback) are noted on the can or bag in which they are supplied. Regardless of how liquid intake is “consumed,” it is recorded in milliliters.

Output is measured by collecting fluid and drainage from bedpans, urinals, urinary catheters, drains, ostomy bags, nasogastric tubes, or collection devices commonly referred to as urine “hats” placed in the front of a toilet or bedside commode

(Fig. 41.7). All liquid secretions are measured in milliliters (mL) using a disposable graduated container, which is washed after each use. Each time output receptacles are emptied, the volume is carefully documented. Liquids that are measured and recorded as output include urine, liquid feces, vomitus, blood, and nasogastric and drainage excretions (including those from chest tubes). Irrigation fluid introduced through nasogastric or gastric tubes and catheters should be measured during instillation and subtracted from output before documentation. If a patient is extremely diaphoretic, that is noted, despite its being immeasurable.

FIGURE 41.7 Urine hats are used to monitor urinary output in ambulatory patients. All liquid output is measured in a disposable graduated container to ensure accuracy of output records.

Safe Practice Alert

Urine color, clarity, and odor should be assessed before disposal. Urine quantity must be measured before it is discarded to ensure accurate intake and output records.

Once I&O is recorded, the balance is calculated and documented for assessment. This allows all members of the health care team to determine if a patient has a positive or negative I&O balance. If the patient has consumed more fluid than has been excreted, the balance is positive. When the patient excretes or loses more fluid than what is consumed, the balance is considered negative (Table 41.2).

TABLE 41.2

Sample Intake and Output Calculation

POSITIVE BALANCE	NEGATIVE BALANCE
Intake	Intake
Oral fluid = 700 mL	Oral fluid = 100 mL
Intravenous fluid = 1250 mL	Tube feeding = 480 mL
<i>8-hour intake total</i> = 1950 mL	<i>8-hour intake total</i> = 580 mL
Output	Output
Urine = 940 mL	Urine = 640 mL
Vomitus = 50 mL	Hemovac drainage = 400 mL
<i>8-hour output total</i> = 990 mL	<i>8-hour output total</i> = 1040 mL
Input and output balance: +960	Input and output balance: -460

Kegel Exercises

Kegel exercises are recommended to help keep the female pelvic floor toned, which reduces the risk for incontinence. If performed correctly and regularly, Kegel exercises have been shown to strengthen the pelvic floor muscles that support the uterus, bladder, and bowel (Box 41.7). If the patient has difficulty performing Kegel exercises, biofeedback training may be used. A small monitoring probe is inserted into the patient's vagina or rectum, or small electrodes are placed outside the area, and when the patient contracts the pelvic floor muscles successfully, a measurement will show on the monitor. When Kegel exercises are performed regularly, improvement normally is seen in approximately 8 to 10 weeks.

Box 41.7

Nursing Care Guideline

Kegel Exercise Techniques

Background

- Kegel exercises also are known as pelvic floor exercises.
- They improve muscle tone in the pelvic floor, which helps prevent stress incontinence.
- Exercises can be done while the person is sitting or standing.

Procedural Concerns

Instruct the patient to:

- Tighten the circumvaginal muscles, anal sphincter, and urinary sphincter together for 3 or 4 seconds without tightening the leg muscles or buttocks.
- When the exercises are practiced during urination, the patient should be able to completely stop the flow of urine if they are being performed properly.
- Relax the muscles for 30 seconds, and immediately retighten the muscle group.
- Repeat the sequence of 10 times for each set, and do five sets per day.
- Increase gradually to three sets of five contractions, each held for 10 seconds with a 10-second rest. Rest for 30 seconds between each set.
- Perform one or two sets per week.

Documentation Concerns

- Document that patient education was provided.

Prevention of Urinary Tract Infections

Prevention is key to controlling UTIs, especially in women prone to infection. Nurses need to be proactive in instructing all patients, especially those who have experienced UTIs in the past, about ways to prevent infection or recurrence. Patients should be

encouraged to avoid wearing tight-fitting clothing, which can irritate the urethra and prevent ventilation of the perineal area. The patient should drink at least eight 8-ounce glasses of water per day to flush the urinary tract. It is important that the patient urinate when the urge is felt; in people who frequently hold urine, a higher incidence of infection has been reported ([Bardsley, 2014](#)). Women and girls should wipe front to back in the perineal area after urination or defecation, to prevent possible entry of bacteria from the gastrointestinal tract into the urethra. Urination right after sexual intercourse may help prevent UTIs as well. Showers are the preferred method of bathing for the patient prone to development of UTI, because bacteria in bathwater can readily enter the urethra. Likewise, it is important that the patient avoid the use of bubble baths, bath bombs, soaps, powders, and sprays in the perineal area, because they may cause inflammation and encourage bacterial growth. Good perineal hygiene, which includes cleansing the urethral meatus after each voiding or bowel movement, is essential. The genital area also should be cleansed before sexual intercourse.

Treatment for a UTI requires antibiotics, and the patient often will achieve symptom relief within 1 or 2 days of treatment. However, patients should be instructed to finish their antibiotics even after they are feeling better. Prophylactic (preventive) or short-term suppressive antibiotic therapy is sometimes prescribed for patients with recurrent UTIs. Long-term suppressive therapy is not recommended because of potential development of antibiotic resistance. Kidney infections may require several weeks of antibiotic treatment to resolve. Severely ill patients may require hospitalization with intravenous antibiotics. The use of a heating pad, drinking plenty of water, urinary tract analgesic medication, and avoidance of caffeine, alcohol, and spicy foods will help promote symptom relief.

Over 67% of UTIs are the result of catheterization ([Clayton, 2017](#)). This clear-cut connection makes avoiding the use of indwelling catheters a primary consideration in UTI prevention. Nurses should be aware of and follow care guidelines if catheterization is required.

QSEN Focus!

To enhance quality of care, use quality improvement data to identify concerns or decreases in urinary catheter infection rates.

Urinary Catheterization

Urinary catheterization most often is performed by introducing a catheter into the patient's urethra to reach the bladder. For urethral catheterization, any of four different kinds of catheters—straight, Foley, triple-lumen, and coudé—may be used (Fig. 41.8). *Straight catheters* are single-lumen devices, designed for one-time or short-term catheterization. The catheter is left in place only long enough to drain the patient's bladder. The procedure may be performed to (1) obtain samples of urine for analysis, (2) diagnose infection or kidney dysfunction, (3) drain residual urine found during a bladder scan, (4) empty a continent urinary diversion, or (5) drain the bladder of a paraplegic or quadriplegic who has lost the ability to urinate naturally.

FIGURE 41.8 Urinary catheters. (A) Straight. (B) Foley. (C) Triple lumen. (D) Coudé. (Modified from Wein, A. J. [2007]. *Campbell-Walsh urology* [9th ed.]. Philadelphia: Saunders.)

Foley and coudé catheters are double-lumen *indwelling catheters*. One lumen is for filling a balloon at the tip of the catheter to “anchor” it in place and the other is for draining urine. Coudé catheters are a special type of double-lumen, indwelling catheter that are slightly stiff and bent at the end, allowing the catheter to pass more easily through a partially constricted urethra. They are used mostly in men experiencing prostate enlargement or benign prostatic hyperplasia (BPH). Coudé catheters may need to be placed using a metal wire introducer. Placement using an introducer typically is performed by a physician or the patient's urologist, to avoid damaging urethral tissue. Both Foley and coudé catheters are designed to be left in place, draining the bladder continuously or intermittently for an extended period of hours, days, or weeks. [Skill 41.1](#) reviews the procedure for insertion and care of a urinary catheter.

Triple-lumen catheters are used for bladder irrigation. The triple-lumen design allows sterile irrigation fluid to be introduced into the bladder to provide localized antibiotic treatment or to drain

blood and blood clots after surgical or diagnostic procedures ([Skill 41.2](#)).

Despite its multiple applications, in addition to being the primary cause of UTIs, urinary catheterization may lead to blockages and trauma to the urethra. Research has identified only the following six indications for which indwelling catheter use is appropriate:

1. Relief of acute urinary obstruction or retention
2. Preventing contamination during complex surgical procedures
3. Accurate measurement of urine in critically ill patients
4. Maintaining dry tissue during perineal or sacral wound healing in incontinent patients
5. Optimal management of patients who are immobilized for an extended period
6. Support of patient comfort at the end of life

When catheterization is necessary, the smallest-suitable device should be used to reduce the risk of UTI ([CDC, 2017](#); [Panchisin, 2016](#)). Current research is inconclusive as to the value of silver alloy catheters or silver-impregnated catheters for the reduction of infections ([Clayton, 2017](#)). Use of aseptic technique and sterile equipment is necessary during insertion of all types of urinary catheters ([CDC, 2017](#)). It is best to maintain a closed system throughout the period in which the indwelling catheter is in place, to prevent the introduction of microorganisms into the bladder. Indwelling urinary catheters should be placed only when indicated and should be removed as soon as medically possible ([Box 41.8](#)).

Box 41.8

Nursing Care Guideline

Discontinuing an Indwelling Catheter

Background

- Indwelling catheters are a primary source of urinary tract infections (UTIs) and should be removed as soon as medically possible.
- The Centers for Disease Control and Prevention (CDC) has issued guidelines for insertion, use, and removal to aid in decreasing catheter-associated UTIs.
- The patient may experience burning and difficulty voiding, as well as frequency or retention, after removal.

Procedural Concerns

- Identify the patient.
- Explain the procedure to the patient.
- Perform hand hygiene and don clean gloves.
- Empty the urinary collection drainage bag.
- Measure urinary output for documentation.
- Obtain urine specimen, if ordered.
- Remove the catheter from the anchoring device.
- Place a disposable waterproof pad under the area from which the catheter is being removed.
- Check the balloon volume noted on the balloon port.
- Withdraw fluid from the balloon:
 - Connect a sterile syringe to the balloon port.
 - Allow fluid to flow into the syringe.
 - If needed, pull back on the plunger of the syringe to ensure the balloon is fully deflated.
 - Remove the syringe.
- Remove the catheter slowly and smoothly as the patient exhales, placing it lightly on the disposable waterproof pad.
- Ensure that the catheter and the balloon are both intact.
- Dispose of the catheter and waterproof pad.
- Clean the perineal area.
- Remove gloves.
- Perform hand hygiene.
- Monitor the patient's output closely.

- If the patient is urinating only small quantities, assess for bladder distention.
- If the patient has not urinated during the 6 to 8 hours after removal of the catheter:
 - Assess for urinary retention via bladder scan.
 - Notify the primary care provider (PCP).
 - Intermittent catheterization with a straight catheter or reinsertion of an indwelling catheter may be necessary.

Documentation Concerns

- Record urinary output.
- Document any difficulties with performing the procedure, as well as the patient's response to the procedure.
- Note any patient education that was done.
- Record the findings of the urinary assessment after catheter removal, including:
 - The quantity of urine, and frequency of urination
 - The color, odor, consistency, and amount (COCA) of the urine
- Include any difficulty encountered by the patient with urinary retention and/or bladder distention.

Evidence-Based Practice

- The longer a urinary catheter is in place, the greater the risk is for a UTI ([Clayton, 2017](#)).
- The difference between clamping and unclamping an indwelling catheter before removal is not found to be significant in relationship to recatheterization rates, urine retention, and the incidence of UTI ([Wang et al., 2016](#)).

Routine Catheter Care

Once a catheter is placed, the urethral meatus should be cleansed with soap and water once or twice daily. The use of antiseptics for cleansing is not recommended ([Association for Professionals in](#)

Infection Control and Epidemiology [APIC], 2014). Catheter bags should be consistently kept below the level of the bladder, to prevent backflow leading to catheter-acquired urinary tract infection (CAUTI) (Box 41.9).

Box 41.9

Evidence-Based Practice and Informatics

Urinary Catheter Infection Prevention

It is imperative that catheter bags be kept below the level of the bladder at all times to prevent reflux of urine into the bladder, which may lead to infection (Clayton, 2017).

- When transferring patients with indwelling catheters horizontally from bed to cart, keep the catheter bag below the level of the patient's legs to prevent urine backflow. Do not place the catheter bag on the patient's abdomen or legs during transfer.
- When positioning the catheter bag for a patient lying or sitting in bed, make sure the bag is hung on the bed frame and not the side rail, even if the rail is in low position. The side rail may be inadvertently raised at any time with the catheter bag attached, causing a reflux of urine. Never place the catheter bag on the floor.

Preconnected closed-drainage urinary catheterization systems should be used to reduce risk for interruption of the system by staff or the patient's family. Routine irrigation of the indwelling catheter is not recommended for UTI prevention. Arbitrary and routine intervals for changing catheters are not recommended. Catheters should be changed if debris or encrustation of the catheter is noted. Catheter bags should be emptied when two-thirds full.

Suprapubic Catheters

Surgical placement of a suprapubic catheter may be undertaken if urethral catheterization is either contraindicated or unsuccessful. Men and women with urethral obstructions or injuries and men with prostate cancer and BPH are most often candidates for this type of catheter. Suprapubic catheters are placed with use of local or general anesthesia through the abdominal wall approximately 4 to 5 cm above the symphysis pubis and secured with sutures (Fig. 41.9). Urine drains through the suprapubic catheter into an attached bag secured to the patient's leg or abdomen.

FIGURE 41.9 Suprapubic catheter in place without a dressing. (From Perry, A. G., Potter, P. A., Ostendorf, W. R. et al. [2018]. *Clinical nursing skills and techniques* [9th ed.]. St. Louis: Elsevier.)

Patients with suprapubic catheters are encouraged to drink plenty of fluid, to maintain hydration and promote urinary excretion. Care should include daily cleansing around the catheter site with soap and water. Patients should be instructed to avoid the use of creams or lotions around the site. The nurse should assess for any seepage around the site and for signs of infection such as redness or discharge. Documentation should include site appearance; the color, volume, and characteristics of excreted urine; and patient tolerance of the catheter if it is newly placed.

External Female Catheters

To reduce CAUTIs in women, updated external female catheters are being introduced in the clinical setting. Some external catheter designs attach around the genital area with adhesive, and drain into an attached, small collection bag. Newer external female catheters use wicking material placed between the labia and gluteal folds, with tubing attached to low continuous suction to drain excreted urine. [Fig. 41.10](#) shows one type of external female catheter currently in use.

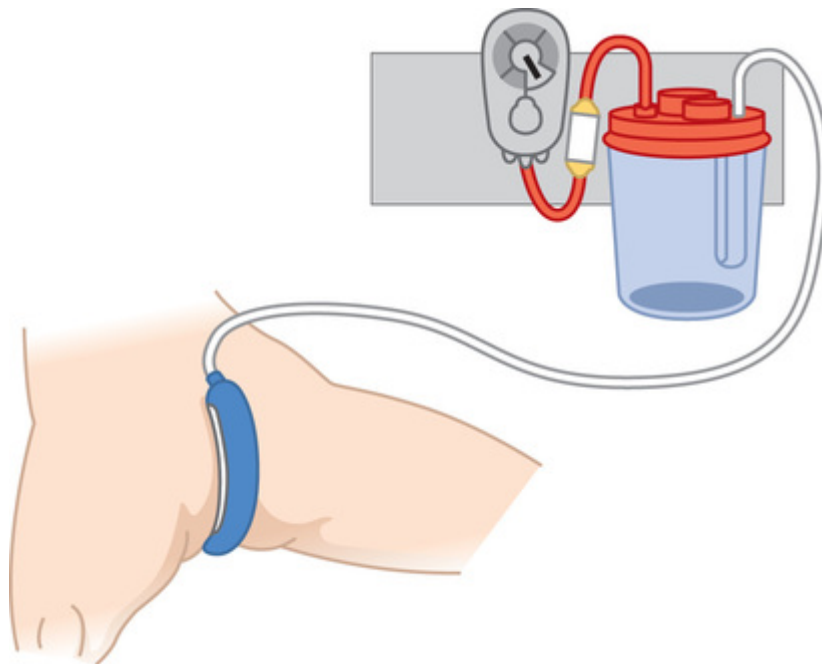

FIGURE 41.10 External female catheter attached to wall suction. (Copyright 2018 C. R. Bard, Inc. Used with permission.)

External Male Catheters

Various external male catheters are available today, including specialty styles that fit over just the head of the penis ([Fig. 41.11](#)) and the more common condom catheters that are applied over the tip and shaft of the penis. External male catheters that are attached only to the head of the penis are especially helpful for uncircumcised men or those with a retracted penis. External catheter use is less likely to lead to bacteriuria, UTI, and death than use of indwelling catheters in patients who retain urine. Use of condom catheters, however, is not without risk. Skin necrosis,

penile strangulation, urethrocutaneous fistulas, dermatitis, skin erosion, pain, and localized infection have been reported. Male patients report that condom catheters are more comfortable and less painful than indwelling urethral catheters (Vigil & Hickling, 2016).

FIGURE 41.11 Specialty external male catheter that only attaches to the head of the penis. (Courtesy BioDerm Inc., Largo, Florida.)

Hand hygiene should be performed before and after catheter care. A new condom catheter should be placed daily, along with assessment for potential complications. Perform perineal care while the condom catheter is off. Use a clean washcloth with soap and water, and pull back the foreskin if the patient is uncircumcised. Rinse and dry the penis, and pull the foreskin down over the head of the uncircumcised penis to prevent swelling before placing a new catheter. [Box 41.10](#) reviews the procedure.

Box 41.10

Nursing Care Guideline

Applying a Condom Catheter

Background

- A condom catheter (also known as an external catheter, urinary or penile sheath, or a Texas catheter) may be used as an incontinence solution for the male patient.
- It consists of a condom device with a drainage collection tube that connects to a urinary collection drainage bag.

(Copyright Mosby's Clinical Skills: Essentials Collection.)

- The catheter is sealed with an adhesive at the base of the penis. It is imperative to monitor the penis for circulatory and integumentary problems while the device is in place.

Procedural Concerns

- Identify the patient.

- Assess skin integrity before applying the device. Do not apply the device if skin changes are noted.
- Perform hand hygiene.
- Don clean gloves.
- Trim the pubic hair as needed to aid in proper placement and prevent complications.
- Wash the penis and allow it to dry.
- Apply the catheter: Roll it down over the penis, leaving 1 to 2 inches at the tip of the penis to:
 - Prevent irritation
 - Allow for urine flow
- Hold the bottom of the catheter on the shaft of the penis for 10 to 15 seconds to:
 - Allow the adhesive to bind
 - Prevent skin breakdown and other complications during use
- Connect the drainage tubing to the urinary collection drainage bag.
- Dispose of gloves and equipment and perform hand hygiene.

Documentation Concerns

- Record any difficulties encountered with placing the catheter.
- Document urine output and the quantity, color, and odor of the urine.
- Document neurovascular monitoring of the penis.

Evidence-Based Practice

- Urinary tract infection and urethral damage are less common with condom catheters than indwelling catheters ([Vigil & Hickling, 2016](#))
- It is important to recognize that without proper care and routine assessment, condom catheters can cause skin breakdown and other complications that can lead to external infections. Use of silicone instead of latex condom catheters is preferred to facilitate visualization for assessment of the

penile shaft on a routine basis, and to prevent possible allergic reactions ([Smart, 2014](#)).

Perineal Care

Skin care is important in patients with urinary elimination issues, including those with indwelling catheters, to help prevent infection. Urine is very irritating to the skin. When urine accumulates on the skin, it is converted to ammonia, which causes the skin to remain moist and possibly become macerated (softened and broken down). The patient is at risk for skin breakdown, ulceration, and infection. Frequent perineal care is necessary, although use of harsh soaps, bubble baths, powder, or sprays, which can irritate the urethra, leading to inflammation and infection, should be avoided. The perineal area should be cleansed frequently with soap and water or no-rinse cleansers and dried thoroughly. In female patients, cleansing is done from front to back, especially after defecation. Skin should be checked regularly for redness or signs of breakdown. Skin protectants, such as Baza Protect Moisture Barrier Cream, may be used to help prevent breakdown or heal affected areas. Specialty incontinence pads that draw moisture away from the surface of the skin may be used for the incontinent patient.

Urinary Diversion Care

Special procedures are required for the care of a patient with a urinary diversion (i.e., ileal conduit [urostomy] or continent urinary diversion) to maintain skin integrity and prevent infection ([Box 41.11](#)). Patients should be encouraged to provide their own urinary diversion care as much as possible. However, in some cases, the nurse will need to assist those requiring help due to physical limitations or self-image issues. Patients who have recently undergone diversion surgery will require a demonstration and patient education on how best to manage and care for their specific type of urinary diversion. In some health care facilities, a wound ostomy continence nurse (WOCN) will be assigned to help with patient education. Sensitivity to patient concerns related to self-image is imperative. Participation in a support group of other people with urinary diversions may be helpful in addressing individual patient concerns.

Box 41.11

Nursing Care Guideline

Urinary Diversion Care

Background

- Various disease processes or disorders, such as cancers, spinal cord injury, or renal calculi, may necessitate the ureters to be diverted externally from the meatus of the bladder to the abdominal wall.
- Types:
 - An ileal conduit (urostomy) is the most common incontinent urinary diversion.
 - A section of small bowel is resected.
 - The ureters are connected to the resected small bowel.
 - The small bowel resection is brought to the abdominal wall.
 - A stoma is created in the abdominal wall.
 - Urine drains through the stoma into a collection bag/device.
 - An ileal neobladder is the most common continent urinary diversion.
 - A section of intestine is used to create a pouch to hold urine.
 - A stoma is created in the abdominal wall.
 - The patient catheterizes the stoma to drain the urine, if necessary.
- Referral to or consultation with a wound ostomy continence nurse (WOCN) may be necessary.

Procedural Concerns

- With the urinary diversion conduit:
 - The collection device usually has a face plate that ensures a good fit around the stoma so that it does

- not leak.
- Some patients use a belt with the device/bag.
- With catheterization and a stoma:
 - Assess the normal frequency of catheterization and catheter size.
 - Assess stoma condition (for color, moisture, and skin condition).
 - Check for mucus in the urine (mucus may be normal).
- To reduce odor, empty the collection device at least every 4 to 6 hours.
- The peristomal area can be washed with mild soap and water during the patient's bath.
- Inspect devices and equipment for patency.
- Monitor the stoma for any changes.
 - Potential complications include skin breakdown, ulcerations, and even necrosis.
 - Routine assessment, together with consultation with a WOCN, is an essential component of stoma care, with implementation of appropriate interventions to prevent infection.

Documentation Concerns

- Document patient urinary intake and output.
- Note stoma condition and skin appearance.
- Record color, odor, consistency, and amount (COCA) of urine

Obtaining Urine Specimens

The nurse is responsible for collecting urine specimens. Specimens may be collected for routine urinalysis by having the patient void into a specimen cup or into a clean urinal or bedpan. For culture and sensitivity testing, urine is collected by the clean-catch, or midstream, method, using a sterile specimen cup. Specimens also can be obtained by performing straight catheterization using sterile technique or by removal of a specimen from the tubing of an indwelling catheter or urinary diversion collection bag. Care

needs to be taken to ensure that the specimen is not contaminated. See [Chapter 34, Skill 34.2: Urine Specimen Collection](#) for additional information and the procedures related to specimen collection.

Evaluation

Patient goals or outcomes are evaluated to determine their achievement and documented as met, partially met, or unmet. Interventions are evaluated to determine their effectiveness. Care plans are continued, modified, or discontinued, depending on the patient's achievement of the established goal or outcome. The overall aim is to return patients to their previous state of health or to assist patients and families to adapt to functional changes. Sharing evaluation findings with patients helps them recognize goal achievement and move closer to healthy urinary elimination patterns regardless of previous challenges. Prevention of kidney disease, UTIs, and secondary complications such as skin breakdown related to incontinence is a primary concern, whether the patient is in a health care facility or at home. Paying careful attention to detail related to the urinary elimination patterns of patients and providing preventive patient education will help promote positive outcomes. Although the subject often is considered personal, discussions regarding urinary elimination should be encouraged by nurses, to help identify potential problems early and to prevent deterioration of kidney function requiring ongoing lifestyle changes.

SKILL 41.1 Urinary Catheterization: Insertion and Care

Purpose

Urinary catheters are used to:

- Accurately monitor urinary output
- Assess bladder function
- Obtain urine specimens
- Relieve bladder distention and discomfort
- Allow for healing after surgical procedures
- Irrigate the bladder
- Instill medications into the bladder
- Manage urinary incontinence
- Manage urinary retention

Resources

- Foley catheter insertion kit (verify that all listed items are available):
 - Sterile fenestrated drape
 - Sterile field square drape
 - Sterile gloves
 - Lubricant
 - Antiseptic cleansing solution (povidone-iodine [Betadine] wipes, or swabs)
 - Cotton balls (if antiseptic solution is provided)
 - Forceps (if antiseptic solution is provided)

- Prefilled sterile syringe with sterile water
- Catheter (of the correct size)
- Tubing and collection drainage bag
- Leg securing device
- Straight catheter insertion kit:
 - All of the above, except the tubing and collection drainage bag and the leg securing device
 - Drainage collection container (tray from kit)
- Extra sterile gloves (if desired)
- Extra sterile catheter (correct size and type, if desired)
- Clean gloves
- Bath blanket (privacy draping)
- Washcloth, towel, and/or perineal wipes
- Specimen cup, if needed

Interprofessional Collaboration and Delegation

- Inserting a straight catheter may be delegated to unlicensed assistive personnel (UAP) without a nurse's assistance after assessment of the patient, depending on the laws governing the institution's policies and procedures and provided that the UAP has received the appropriate specialized training.
- UAP should report any of the following to the nurse:

- Patient reports of pain before, during, or after the procedure
- Sores, wounds, irritations, or lesions noted
- Difficulties encountered while performing the procedure
- UAP should be instructed in:
 - Sterile technique
 - Appropriate procedure and timing
 - Required documentation

Evidence-Based Practice

- To prevent catheter-associated urinary tract infections (CAUTIs), catheters should be inserted based on practice guidelines and removed as quickly as possible. Most indwelling catheters can be removed on the first day after surgery; however, exact timing for removal based on the type of surgery is not definitive based on current research ([Clayton, 2017](#)).
- Anchoring the catheter to the patient's leg minimizes pain, reduces the incidence of infection and skin damage and helps prevent the catheter from dislodging ([Panchisin, 2016](#)).
- Intermittent catheterization should be considered as an alternative to placing an indwelling catheter to lower the risk for CAUTI ([APIC, 2014](#)).

Special Circumstances

1. **Assess:** Is resistance being encountered with insertion of the catheter?

Intervention:

- Pull back the catheter, and attempt a gentle reinsertion/repositioning.
 - Ensure proper lubrication has been applied to the catheter.
 - Ensure insertion is into the urinary meatus if the patient is female.
 - With gentle pressure, grasp and straighten the male penis, holding it at approximately a 45-degree angle from the abdomen, if resistance is met.
 - Check that the smallest appropriate catheter size is being used.
 - It may be necessary to contact the patient's physician or urologist, per facility policy, to insert a coude catheter if resistance is persistent.
2. **Assess:** What should be checked if no urinary drainage is seen on insertion of the catheter?

Interventions: Assess the catheter, its placement, and the urinary system.

- Verify correct placement:
 - For a female patient, if the catheter has been placed erroneously into the vagina, keeping the catheter there while inserting another sterile catheter into the urinary meatus may avoid inadvertent reinsertion into the vagina.
 - For a male patient, the catheter may not move past the prostate. A special coude catheter with a stiffer, bent tip may be required.
- Check the quantity and time of the last void or catheterization, and check the volume of intake.
- Ask the patient to cough; this increases pressure, which may promote urine flow.

- Ask the patient to take a deep breath in and out to relax the abdominal muscles.
 - Check the catheter itself for kinks or other possible obstruction.
 - Assess the bladder for distention; perform a bladder scan if necessary and equipment is available.
 - Push the catheter in slightly and rotate it; the catheter may not quite be fully inside the bladder, or the opening may be up against the bladder wall.
 - Pull the catheter out slightly and rotate it; the catheter may be above the level of urine, or the opening may be blocked.
 - Initially drainage may have occurred, but sediment may have been present.
 - Assess the appearance of the urine.
 - Send a specimen to the laboratory for analysis if warranted.
 - Notify the primary care provider (PCP), and obtain orders as needed.
 - Irrigation may be needed.
3. **Assess:** Has urethral discharge been noted when caring for the catheter?
- Intervention:** Urethral discharge may be indicative of infection.
- Ensure catheter care with soap and warm water is performed routinely.
 - Observe the urinary output and document. Obtain a urine specimen if needed.
 - Communicate the urethral discharge during report, notify the PCP, and document the findings.
 - Continue monitoring and documentation; the possibility of a CAUTI must be kept in mind.
4. **Assess:** Has the catheter been dislodged?
- Intervention:** Notify the PCP to determine the need for reinsertion of the catheter.
- Assess the patient for trauma, and treat if necessary.

- Inspect catheter to determine whether it is intact.
 - Monitor urinary output.
5. **Assess:** Does your facility allow lidocaine 2% gel (a local anesthetic) to be used as a lubricant?
- Intervention:** Check for patient allergy to lidocaine. If none, obtain and substitute lidocaine 2% gel in place of the lubricant in the kit for male catheter insertion.
6. **Assess:** Was sterile equipment contaminated?
- Intervention:** Obtain another sterile catheter before attempting placement again.
- Continuing with the procedure would increase the risk for the patient contracting a CAUTI.
 - Communicate with the patient throughout the procedure.
7. **Assess:** Does the patient perform home catheterization using clean technique?
- Intervention:** Per the recommendations to prevent CAUTIs, aseptic technique with sterile equipment should be used in the acute care setting.
- The clean technique is used for chronic, intermittent catheterizations in the home setting:
 - Catheters are washed and reused.
 - The caregiver washes his or her hands with soap and water, and then dons clean gloves.
 - Daily and as-needed cleaning of the perineal area is performed.

Preprocedure

I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.

II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.

III. Perform hand hygiene.

Frequent hand hygiene prevents the spread of microorganisms.

IV. Maintain standard precautions.

Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.

V. Introduce yourself.

Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.

It is important to maintain patient dignity.

VII. Identify the patient, using two identifiers.

Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.

The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Insertion: Female

Follow preprocedure steps I through VIII.

1. If you are right-handed, work from the side of the bed closer to the patient's right side; if you are left-handed, work from the side of the bed closer to the patient's left side.

Using the appropriate hand promotes optimal placement of the

catheter and decreases the likelihood of breaking sterile technique.

2. Place the patient in the dorsal recumbent position.
Alternatively, use the Sims (or side-lying) position, with the patient's upper leg flexed at the hip.
This position provides for maximum patient comfort while facilitating insertion of the catheter and minimizing the risk for trauma with insertion.
3. Place a waterproof pad under the patient's buttocks and drape the patient with a bath blanket for privacy, exposing only the perineum.
A waterproof pad protects bed linens from becoming soiled, and draping helps maintain patient dignity and ease anxiety.
4. Clean the perineal area and dry it thoroughly with a towel.
Proper cleaning should be used to prevent the spread of microorganisms into the urinary tract, where they may cause infection.
5. After removing your gloves, wash hands before proceeding.
Hand hygiene is essential before initiating a sterile procedure.
6. Prepare a sterile field and organize supplies.
 - a. Use the outer plastic wrapping/container from the kit as a waste disposal receptacle; place it on the bed in a location away from the sterile field (ideally, to the side of the sterile field).
Alternatively, use a small bag or trash can at the side of the bed.
 - b. Apply sterile gloves.
 - c. Place the sterile drape under the buttocks and the fenestrated drape over the perineum.
 - d. If using cotton balls in a kit with antiseptic solution, open the solution and pour it over the cotton balls. Place the forceps nearby.
 - e. Lubricate 1 to 2 inches of the catheter tip.

STEP 6E (Copyright Mosby's Clinical Skills: Essentials Collection.)

- f. If a specimen is needed, open a new sterile specimen container; if it is not needed, remove the specimen container from the sterile field. *Use a sterile field to maintain sterile procedure. Prepare and organize supplies to facilitate the procedure. Place the waste receptacle (for disposing of items during the procedure) at a location that will not contaminate the sterile field. Lubrication prevents trauma by facilitating insertion of the catheter.*
7. If the patient is to have an indwelling catheter:
 - a. Remove the cap from the prefilled syringe.
 - b. Attach the syringe to the injection port.
 - c. If the manufacturer instructions do *not* require a testing balloon, go to step 7d. If testing the balloon *is* required, inject the fluid amount indicated on the injection port or in the manufacturer instructions, and observe the balloon for inflation and leaks. Withdraw the fluid and observe the balloon for complete deflation. *Prepare and test equipment (if required) to facilitate the procedure; many silicone catheters are pretested during manufacturing, and testing them a second time may result in stretching or damaging the balloon. Balloons without manufacturer pretesting may have faults or be damaged, so testing before insertion of the catheter prevents unnecessarily repeated procedures. Damaged balloons may cause trauma to the tissues in the bladder or urinary tract.*
 - d. Leave the syringe attached.
8. Designate your nondominant hand as the clean hand. If you are right-handed, use your left hand to hold the labia open. If you are left-handed, use your right hand to hold

the labia open and expose the urethral meatus. Do not release the labia. Keep the clean, nondominant hand in place throughout the remainder of the procedure.

Using the appropriately designated hand maintains sterile procedure and reduces microorganism transmission. Holding the labia open facilitates placement of the catheter; releasing the labia prematurely causes contamination of the urinary meatus and the catheter before insertion.

9. Designate the dominant hand as the sterile hand. Use this hand to pick up antiseptic cleaning swab or the forceps; the forceps will be used to pick up cotton balls soaked in antiseptic solution.

STEP 9 (Copyright Mosby's Clinical Skills: Essentials Collection.)

10. Cleanse the urinary/vaginal area:
 - a. Use one cotton ball or swab per wipe.
 - b. Wipe from front to back (i.e., from anterior end of the labia toward the rectum), using a new cotton ball or swab for each wipe in the following sequence: right labial fold, left labial fold, then directly over the urinary meatus.

STEP 10B (Copyright Mosby's Clinical Skills: Essentials Collection.)

- c. Discard each cotton ball or swab in the waste receptacle immediately after use.
Cleansing from the least-contaminated to the most-contaminated areas while using a fresh cotton ball or swab for each pass maintains sterile procedure, reduces the number of microorganisms in the area where the procedure will take place, avoids introducing microorganisms from the more contaminated area to the cleaner area, and prevents infection.

11. Using your sterile hand, pick up the catheter, ensure that the tip is sufficiently covered in lubricant, and coil the distal end of the catheter in your hand.
Using the sterile hand maintains sterile procedure. Lubrication prevents trauma by facilitating insertion. Coiling the catheter in your sterile hand reduces risk for contamination.

12. Insert the catheter:
 - a. Have the patient bear down.
 - b. Insert the tip of the catheter into the urethral meatus; insertion should be for 2 to 3 inches or until urine appears.

STEP 12B (Copyright Mosby's Clinical Skills: Essentials Collection.)

- c. Insert the catheter an additional 1 to 2 inches after urine appears.
- d. Release the labia.

Bearing down relaxes the external sphincter, which assists with insertion and reduces discomfort. Initial insertion length approximates the female urethral length (which usually is 1.5 to 2 inches). The additional 1 to 2 inches of insertion ensures the catheter is firmly placed in the bladder.

13. If a urine specimen is needed, allow urine to flow into the sterile specimen container. If an indwelling catheter is being placed and the collection bag is already attached, wait to obtain a sterile specimen from the collection port on the side of the drainage tubing until after completing the catheterization procedure.

Once an indwelling catheter is attached to the collection bag, it should not be detached. Maintaining a closed system is recommended to prevent CAUTIs.

14. If an indwelling catheter was inserted, inflate the balloon (or attach the sterile water syringe to the injection port and inflate the balloon, if not already in place); gently tug on the catheter.

STEP 14 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Connect the tubing.
- b. Secure the catheter with nonallergenic tape or leg securing device.

STEP 14B (Copyright Mosby's Clinical Skills: Essentials Collection.)

- c. Hang the collection drainage bag from the bed frame.

STEP 14C (Copyright Mosby's Clinical Skills: Essentials Collection.)

Balloons are meant to be inflated with the amount of sterile water marked on the side of the injection port. Tugging gently on the catheter ensures that the balloon rests at the bladder opening. Securing the catheter reduces risk for damage to urinary tissues and inadvertent removal. The collection drainage bag should be consistently maintained below the level of the bladder to prevent backflow of urine and the potential introduction of bacteria into the bladder. Hanging the bag from the bed frame and not the side rail will help keep the catheter stable and the bag consistently below the bladder.

15. If a straight catheter was inserted, allow complete drainage or drain 1000 mL, clamp the tubing, and wait slightly before additional urine is allowed to drain. Remove the catheter after the bladder is emptied.
Draining an overdistended bladder too quickly may induce spasms, preventing complete emptying of urine. In patients with spinal cord injuries, rapid decompression of urine may cause hypotension.
16. Reposition the patient for comfort. Dispose of catheterization equipment.

Follow postprocedure steps I through VII.

Insertion: Male

Follow preprocedure steps I through VIII.

1. If you are right-handed, work from the side of the bed closer to the patient's right side; if you are left-handed, work from the side of the bed closer to the patient's left side.
Using the appropriate hand promotes optimal placement of the catheter and decreases the likelihood of breaking sterile technique.
2. Position the patient in the supine position, with his thighs slightly apart.
Patient position provides for maximal patient comfort while facilitating insertion of the catheter and minimizing the risk for trauma with insertion.
3. Place a waterproof pad under the patient's buttocks and drape the patient with a bath blanket for privacy, exposing only the penis.
A waterproof pad protects bed linens from becoming soiled, and draping helps maintain patient dignity and ease anxiety.
4. Provide perineal care.
Proper cleaning should be used to prevent the spread of microorganisms into the urinary tract, where they may cause infection.
5. After removing your gloves, wash hands before proceeding.

Hand hygiene is essential before initiating a sterile procedure.

6. If your facility does not allow lidocaine gel injections, proceed to step 7 (next). If it is allowed, inject the lidocaine in accordance with the PCP order and facility policies and procedures:
 - a. Usually 10 to 15 mL of gel is used.
 - b. Inject approximately 10 mL of the gel directly into the urethra.
 - c. Wipe the shaft from the glans toward the testicles.
 - d. Wait 2 minutes before insertion of the catheter.

Lidocaine provides for greater patient comfort during the procedure. Wiping the shaft of penis in downward direction helps spread medication throughout the urinary tract. The peak analgesia effect of lidocaine gel is obtained at 2 to 5 minutes.

7. Follow steps 6 and 7 for “Insertion: Female, placing the fenestrated drape over the penis.”
8. Position the penis upright with your nondominant hand, which is designated as your clean hand. (If you are right-handed, your left hand will be your clean hand; if you are left-handed, the right hand will be your clean hand.)
 - a. If the patient is uncircumcised, use your clean hand to retract the foreskin and hold it in the retracted position.
 - b. If the patient is circumcised, use the thumb and index finger of your clean hand to hold the penis below the glans.
 - c. Do *not* release the positioning or the foreskin until after the catheter is inserted.

Uncircumcised males have extra skin covering the urethral meatus and glans; this foreskin must be retracted for cleansing to reduce the number of microorganisms and prevent them from entering the urinary tract. The upright penis position straightens the urethra and facilitates insertion. Releasing the position and foreskin will cause contamination of the urethral meatus and the catheter before insertion.
9. Wipe from the urethral meatus outward to the base of glans:

STEP 9 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Use a new swab or cotton ball for each wipe.
 - b. Discard cotton balls or swabs, as used, in the appropriate waste receptacle.
 - c. Repeat the process for a total of three times.
Cleansing from the least-contaminated to the most-contaminated areas while using a fresh cotton ball or swab for each pass maintains sterile procedure, reduces the number of microorganisms in the area where the procedure will take place, and prevents infection.
10. Use your dominant hand, designated as your sterile hand, to pick up the catheter, ensure that 5 to 8 inches of the tip is sufficiently covered with lubricant, and coil the distal end of the catheter in your hand.
Use the dominant hand to prevent unintentional contamination. Lubrication prevents trauma by facilitating insertion. Coiling the catheter in your sterile hand reduces risk for infection.
11. Insert the catheter:

STEP 11 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. Have the patient bear down.
- b. Insert the tip of the catheter into the urethral meatus while gently rotating the catheter; insertion should be for 7 to 9 inches or until urine appears.
- c. Insert the catheter to the bifurcation ports after urine appears.
- d. Lower the penis, but keep the catheter secure with your clean hand.

Bearing down relaxes the external sphincter, which assists with insertion and reduces discomfort. Initial insertion length is approximately the male urethral length (which varies). Gentle rotation of the catheter may cause less discomfort for the patient. Inserting the additional length ensures that the catheter is firmly placed in the bladder. Lowering the penis assists the flow of urine via gravity.

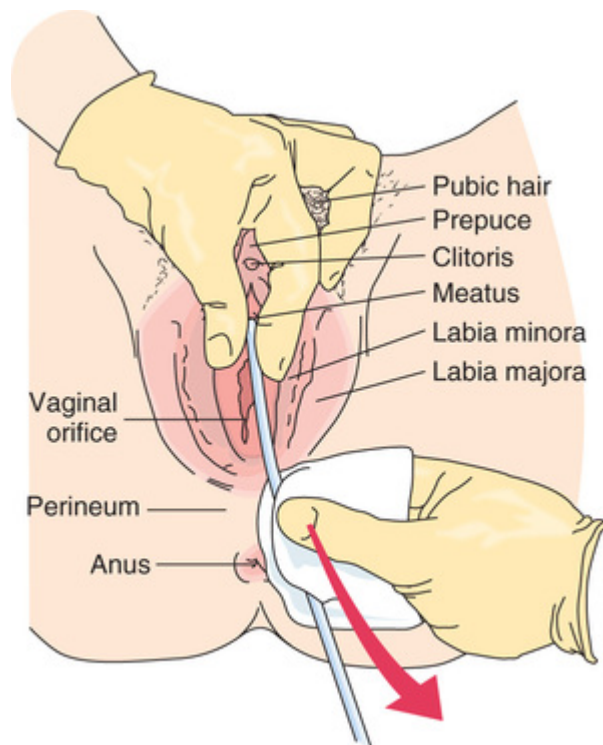

12. Replace foreskin for the uncircumcised male.
13. Follow steps 13 to 16 for Insertion: Female.

Follow postprocedure steps I through VI.

Catheter Care: Indwelling

Follow preprocedure steps I through VIII.

1. Follow steps 1 to 3 for Insertion: Female or Insertion: Male.
2. Clean the perineal area.
Using the appropriate cleansing technique reduces the number of microorganisms, prevents microorganisms from entering the urinary tract, and prevents infection.
3. For female patients, hold the labia open, and hold the catheter. For male patients, retract the foreskin if needed; hold the penis and catheter.
Hold the catheter in place to avoid unintentionally dislodging it.
4. Clean the catheter from the urethral meatus downward at least 4 inches with soap and water daily.

STEP 4 (From Sorrentino and Remmert, 2019.)

Washing should proceed from the least-contaminated to the most-contaminated area, to prevent the spread of microorganisms and avoid infection.

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach of the patient.

Precautions are taken to maintain patient safety.

Top side rails aid in positioning and turning.

Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Step 4 figure from Sorrentino, S. A., & Remmert, L. (2019).
Mosby's essentials for nursing assistants (6th ed.). St. Louis: Elsevier.

SKILL 41.2 Closed Bladder Irrigation

Purpose

Bladder irrigation is performed to:

- Maintain patency of catheters
- As a postoperative procedure for genitourinary surgeries
- Decrease genitourinary complications (such as infections)

Resources

- Intermittent and continuous irrigation methods:
 - Sterile irrigation solution, per order (room temperature)
 - Antiseptic wipes
 - Catheter clamp for catheter/tubing
 - Clean gloves
 - Waterproof pad
- Intermittent method:
 - Clean gloves
 - Sterile irrigation kit containing the following items (or assemble separately):
 - Graduated container (sterile)
 - Sterile irrigation syringe (60 mL)
- Continuous method:
 - Irrigation tubing (optional Y connector)

- Intravenous (IV) pole
- Label for irrigation solution bag

Interprofessional Collaboration and Delegation

- Bladder irrigation may not be delegated to unlicensed assistive personnel (UAP) without a nurse's assistance. UAP helping care for the patient should report any of the following to the nurse:
 - Patient complaints of pain before or after the procedure
 - Clots noted in output
 - Change in color, odor, consistency, or amount (COCA) of output
 - Sores, wounds, irritations, or lesions noted
 - Fever or other changes in vital signs

Evidence-Based Practice

- “Unless obstruction is anticipated (e.g., as might occur with bleeding after prostate or bladder surgery), bladder irrigation is not recommended. Routine irrigation of the bladder with antimicrobials is not recommended” ([Gould, Umscheid, Agarwal, et al., 2017](#), p. 44).

Special Circumstances

1. **Assess:** Is the wrong catheter currently in use for a patient needing a bladder irrigation procedure?
Intervention: Change the catheter to the correct type.
 - A single-lumen catheter or straight catheter without a balloon can be used for intermittent bladder irrigation.
 - A double-lumen catheter may be used for:
 - Intermittent irrigation *or*
 - Continuous irrigation with a sterile Y connector
 - A triple-lumen catheter is the best choice for closed continuous irrigation.
2. **Assess:** Have you observed bladder distention or the presence of clots, sediment, or mucus in the tubing?
Intervention: Any of these factors may indicate clogged tubing, bleeding, or tissue sloughing.
 - Check whether output is greater than intake.
 - Check the tubing for patency.
 - Verify that the tubing is placed below the level of the bladder.
 - Milk the tubing, if doing so will not further irritate or damage fragile tissue:
 - Starting at the point at which the tubing exits the patient, squeeze the tubing and release it.
 - Repeat the process while moving along the tube, progressing downward from the patient toward the collection device.
 - Be careful not to tug on the catheter or dislodge it.
 - Milking may release a clot or blockage in the tubing.
 - An alcohol wipe on the outside of the tubing may augment this technique.
3. **Assess:** Is the patient experiencing bladder spasms or discomfort?
Intervention: Check the temperature of the irrigation solution; cold solutions may cause spasms.

4. **Assess:** What should be done if the irrigation solution does not flow easily with gentle pressure during intermittent irrigation?

Intervention: Reposition the syringe and check the catheter placement in the bladder.

Preprocedure

I. Check PCP orders and the patient care plan.
Knowledge of patient-specific orders is critical for safe patient care.

II. Gather supplies and equipment.
Preparing for the patient encounter saves time and promotes patient trust.

III. Perform hand hygiene.
Frequent hand hygiene prevents the spread of microorganisms.

IV. Maintain standard precautions.
Use of the correct personal protective equipment (PPE) is required whenever contact with bodily fluids is possible, to reduce the transfer of pathogens.

V. Introduce yourself.
Initial communication establishes the role of the nurse and begins a professional relationship.

VI. Provide for patient privacy.
It is important to maintain patient dignity.

VII. Identify the patient, using two identifiers.
Identifying a patient involves scanning barcodes or comparing the patient's stated name and birthdate to information on the patient's wristband or health record. The correct person must receive the correct treatment.

VIII. Explain the procedure to the patient.
The nurse has a responsibility to inform a patient before initiating care. Information may ease patient anxiety and facilitate cooperation.

Procedure

Intermittent Method

Follow preprocedure steps I through VIII.

1. Empty the drainage bag; accurately measure the amount of urine, noting characteristics of the urine; and document.
Obtaining a volume measurement before performing the procedure provides a baseline assessment. Emptying the drainage bag allows space for the solution drainage and permits accurate assessment of volume and characteristics of output.
2. Verify whether sufficient length of catheter is available to work with, from the anchoring device to the injection port:
 - a. If sufficient length is available, leave the catheter anchored.
 - b. If there is insufficient length, remove the catheter from the anchoring device and be cautious when working with the catheter.
Sufficient length guards against inadvertently dislodging the catheter.
3. Place a waterproof pad under the catheter at the injection port and point at which the catheter and tubing join.
The pad protects the linens and helps maintain skin integrity by keeping the patient as dry as possible.
4. Put on clean gloves and pour sterile solution into the sterile container.
Use appropriate sterile procedures to maintain sterility within the bladder, thereby avoiding infection.
5. Draw solution into the irrigation syringe from the sterile container using aseptic technique:
 - a. Place the tip of the syringe into the sterile solution.

- b. Pull back on the plunger of the syringe to withdraw the prescribed volume of sterile solution.
 - c. Cap the syringe tip or place a blunt-tip needle on the syringe.
Using aseptic technique reduces the transmission of microorganisms.
6. Clamp the catheter tubing below the specimen port.
Clamping in this manner allows the solution to flow into the bladder and prevents the solution from draining into the bag.
7. Clean the specimen or injection port with an antiseptic wipe, in accordance with facility policies and procedures.
Cleaning with antiseptic reduces the spread of microorganisms and the risk for infections.
8. Connect the syringe to the specimen port:

STEP 8 (Copyright Mosby's Clinical Skills: Essentials Collection.)

- a. For a needleless catheter system (Luer-Lok), twist the syringe onto the port.
 - b. For a needle system, insert the needle (or blunt-tipped cannula) at a 30-degree angle, with the bevel in the direction of the bladder.
Using the appropriate method to attach the syringe prevents possible provider injury. The angle of the needle avoids damage to the catheter/specimen port system and allows the solution to flow toward the bladder.
9. Inject the solution slowly, smoothly, and steadily.
This injection technique decreases the risk for trauma and dislodges clots and sediment.
10. Verify whether the instilled solution is to remain in the bladder for a set amount of time:

- a. If not, withdraw the syringe, insert a new catheter plug, if needed, and remove the clamp to allow the irrigation solution to flow into the collection bag.
- b. If a solution dwell time has been prescribed, withdraw the syringe and keep the clamp on the catheter tubing until the end of the designated period before releasing the clamp and emptying the bladder.
- c. Secure the catheter again before leaving the patient's bedside.

Removing the clamp allows drainage by gravity. Securing the catheter reduces the risk for damage to urinary tissues and inadvertent removal of the catheter.

Follow postprocedure steps I through VI.

Continuous Method

Follow preprocedure steps I through VIII.

1. Follow steps 1 to 3 for Intermittent Method.
2. Insert the spike on the irrigation tubing into the port on the irrigation solution bag using an aseptic technique.
 - a. Hang the solution bag on the IV pole.
 - b. Prime the tubing.
 - c. Clamp the tubing.

Use aseptic technique to prevent the spread of microorganisms.
3. Ensure the solution bag is properly labeled as bladder irrigation solution.

Proper labeling prevents adverse events and medical errors.
4. Securely attach tubing:
 - a. If attaching to a triple-lumen catheter, clean the irrigation port with an antiseptic wipe.
 - b. If attaching to a double-lumen catheter, add a sterile Y connector, and clean the connector with an antiseptic wipe.

Cleaning with antiseptic reduces the spread of

microorganisms and the risk for infections, while maintaining sterile procedure.

5. Calculate the drip rate.

Ensure accuracy and compliance with the PCP order.

6. Open the clamps, and ensure that the fluid is instilling properly.

STEP 6 (From Perry et al., 2018.)

Proper instilling decreases the risk for trauma, bladder distention, injury, and discomfort.

7. Note the volume of irrigation solution, determine the appropriate rate for instillation, and pay attention to the period the solution is to remain in the bladder, if at all. *Irrigation fluid may be ordered to run into the bladder and right back out, or it may be ordered to remain for a matter of minutes before draining.*
8. Observe color and quality of output from irrigation. *Record presence of clots, sediment, or blood. Assessment of output is required to determine the effectiveness of the irrigation.*
9. Document output and patient tolerance of the procedure. *Documentation ensures accurate intake and output totals.*

Records should include patient response to care.

Follow postprocedure steps I through VI.

Postprocedure

I. Return the bed to its lowest position, raise the top side rails, and verify that the call light is within reach of the patient.

Precautions are taken to maintain patient safety.

Top side rails aid in positioning and turning.

Raising four side rails is considered a restraint.

II. Assess for additional patient needs and state the time of your expected return.

Meeting patient needs and offering self promote patient satisfaction and build trust.

III. Properly dispose of PPE.

Gloves, gowns, and masks must be appropriately discarded to prevent the spread of microorganisms.

IV. Clean or dispose of equipment if it was in contact with the patient; see specific manufacturer instructions.

Disinfection eliminates most microorganisms from inanimate objects.

V. Perform hand hygiene.

Frequent hand hygiene prevents the spread of infection.

VI. Document the date, time, assessment, procedure, and patient's response to the procedure.

Accurate documentation is essential to communicate patient care and to provide legal evidence of care.

Step 6 figure from Perry, A. G., Potter, P. A., & Ostendorf, W. R., et al. (2018). *Clinical nursing skills and techniques* (9th ed.). St. Louis: Elsevier.

Summary of Learning Outcomes

LO 41.1 *Describe the anatomy and physiology of the urinary system:* The kidneys, located bilaterally below the ribs toward the middle of the back, filter liquid waste from the blood, help control acid-base balance, regulate blood volume and pressure, and contribute to other critical functions of the body. The ureters, bladder, and urethra, located below the kidneys down to the urethral sphincter, work together with the kidneys to eliminate liquid waste from the body.

LO 41.2 *Describe abnormal patterns of urinary elimination, including causative factors:* Changes in body pH, the use of medications, contrast media used in diagnostic procedures, and surgical alterations may have a significant impact on functioning of the urinary system. Alterations in urinary elimination may have a profound psychological effect on the patient.

LO 41.3 *Complete a comprehensive assessment of the patient with urinary elimination problems:* Accurate assessment and evaluation of urinary system health is necessary for maintenance of urinary health and early identification of alterations. A thorough patient interview, physical examination, and diagnostic testing are often required to determine the cause of urologic concerns.

LO 41.4 *Identify nursing diagnoses related to urinary elimination:* Nursing diagnoses related directly to urinary elimination are *Impaired Urination, Urinary Retention, and Impaired Self-Toileting.*

LO 41.5 *Create collaborative patient-centered care plans for patients experiencing alterations in urinary elimination:* Patient goals, established collaboratively with the patient and with other health care professionals during the planning stage of nursing process, should address the degree of dysfunction, establish priority for care measures related to elimination, and focus on the return or adaptation of urinary function to as close to normal as possible.

LO 41.6 *Implement interventions to address altered elimination concerns and evaluate their effectiveness:* Specific nursing interventions, such as increased patient fluid intake, proper perineal care, and toileting schedules, may help prevent kidney stone formation, urinary tract infection, urinary incontinence, and urinary retention. Urinary catheterization may be required when elimination patterns and function are altered, but should be performed only when less invasive methods fail. Urinary diversions are surgically performed to drain urine when the bladder is removed. The effectiveness of interventions can be determined on the basis of whether patients

return to their previous state of health or adapt successfully to functional changes.

Review Questions

1. A patient with an indwelling catheter reports a need to void. What is the priority intervention for the nurse to perform?
 - a. Check to see if the catheter is patent.
 - b. Reassure the patient that it is not possible to void while catheterized.
 - c. Catheterize the patient again with a larger gauge catheter.
 - d. Notify the primary care provider.
2. Which nursing instruction is correct when a urine specimen is collected for culture and sensitivity testing from a patient without a urinary catheter?
 - a. Tell the patient to void and pour the urine into a labeled specimen container.
 - b. Ask the patient to void first into the toilet, stop midstream, and finish voiding into the sterile specimen container.
 - c. Instruct the patient to discard the first void and collect the next void for the specimen.
 - d. Have the patient keep all voided urine for 24 hours in a chilled, opaque collection container.
3. A female patient has had frequent urinary tract infections. Which statement by the patient indicates that the nurse's teaching on prevention has been effective?

- a. "I will limit my fluid intake to 40 ounces per day."
 - b. "I will use only organic bath bombs when bathing."
 - c. "I will wait to wear my tight jeans until after my urine is clear."
 - d. "I will wipe from the front to back after voiding."
4. A patient is scheduled for an intravenous pyelogram (IVP). Which piece of data would be most important to know before the procedure is carried out?
- a. Urinalysis negative for sugar and acetone
 - b. History of allergies
 - c. History of a recent thyroid scan
 - d. Frequency of urination
5. When emptying a patient's catheter drainage bag, the nurse notes that the urine appears to be discolored. The nurse understands that what factors may change the color of urine? (*Select all that apply.*)
- a. Taking the urinary tract analgesic phenazopyridine
 - b. A diet that includes a large number of beets or blackberries
 - c. An enlarged prostate or kidney stones

- d. High concentrations of bilirubin secondary to liver disease
 - e. Increased carbohydrate intake
6. What self-care measure is most important for the nurse to include in the teaching plan for a patient who will be discharged with a urostomy?
- a. Change the appliance before going to bed.
 - b. Cut the wafer 1 inch larger than the stoma.
 - c. Cleanse the peristomal skin with mild soap and water.
 - d. Use firm pressure to attach the wafer to the skin.
7. An indwelling catheter is ordered for a postoperative patient who is unable to void. What is the primary concern of the nurse performing the procedure?
- a. Teaching deep-breathing techniques
 - b. Maintaining strict aseptic technique
 - c. Medicating the patient for pain before the procedure
 - d. Positioning the patient for comfort during the procedure
8. The nurse is assessing a patient with an indwelling catheter and finds that the catheter is not draining and the patient's bladder is distended. What action should the nurse take next?

- a. Notify the primary care provider.
 - b. Assess the tubing for kinks and ensure downward flow.
 - c. Change the catheter as soon as possible.
 - d. Aspirate the stagnant urine in the catheter for culture.
9. The nurse is placing an indwelling catheter in a female patient. The nurse accidentally inserts the catheter into the vagina. What is the next action for the nurse to implement?
- a. Collect a urine specimen and notify the primary care provider (PCP).
 - b. Leave the catheter in place and insert a new catheter into the urethra.
 - c. Remove the catheter from the vagina and place it into the urethra.
 - d. Ask another nurse to attempt the catheterization of the patient.
10. Which nursing intervention would be the highest priority when caring for a patient complaining of voiding small amounts of urine in relation to his fluid intake?
- a. Placing a disposable waterproof pad on the patient's bed before he goes to sleep.
 - b. Documenting in the patient's electronic health record that he is complaining of anuria.

- c. Notifying the patient's primary care provider (PCP) of the need for intermittent catheterization.
- d. Palpating the patient's bladder for distention before scanning for possible retention.

CHAPTER 42

Death and Loss

LEARNING OUTCOMES

Comprehension of this chapter's content will provide students with the ability to:

- LO 42.1 Describe the process of grief, loss, and bereavement.
- LO 42.2 Discuss dysfunctional loss and grieving.
- LO 42.3 Identify factors affecting the grief and bereavement process.
- LO 42.4 Perform a nursing assessment of patients and their families who are experiencing loss, death, grief, and bereavement.
- LO 42.5 Select nursing diagnoses appropriate for people experiencing death and the grieving process.
- LO 42.6 Plan appropriate goals and outcomes for dying patients and their families.
- LO 42.7 Implement and evaluate nursing care plans with nursing interventions appropriate for patients and families experiencing death and grief.
- LO 42.8 Examine the effects death and loss may have on nurses.
- LO 42.9 Explore the role of the nurse in organ donation.

Case Study

Shirley Richardson (S. R.) is a 64-year-old hospice patient being cared for at home with the support of the hospice agency staff. She has a 4-year history of colon cancer with metastasis. She underwent surgery, radiation therapy, and various chemotherapy regimens over the last 4 years, until tumor growth continued despite the treatments. Chemotherapy was discontinued 2 months ago, and the metastasis accelerated.

S. R.'s pain is being controlled by morphine sublingual drops. She is weak but able to use the bedside commode with assistance of one person. She requires assistance with activities of daily living (ADLs). Her husband of 41 years helps her during most of the day, but a hospice aide comes in daily for bathing. The hospice nurse visits three times per week. The family has declined hospice spiritual care because they are active with a church. The couple's grown son lives within 30 minutes and visits at least weekly but is busy with his own family and work. Their daughter lives 6 hours away and has been in touch only a couple of times during her mother's illness. When S. R. is awake, the couple often reminisces, looks at old photos of their family, and talks about funeral plans.

As S. R.'s condition begins to deteriorate rapidly, the hospice nurse assesses her and tells Mr. R. that he should let the children know that their mother will probably live only a few more days. Mr. R. agrees to call his children and is openly crying while the nurse comforts him and sits quietly with him. They begin to plan S. R.'s care for her final days.

Refer back to this case study to answer the critical-thinking questions throughout the chapter.

Death, loss, grief, and bereavement are a part of life for all people. To experience life itself, we must experience loss and grief. This chapter describes various types of loss, the stages of grief and bereavement, and nursing care of the patient and family experiencing loss, grief, and death. Death is a universal aspect of the human experience. Nurses in any setting must be prepared to care for patients who are dying and their families, and for others who are experiencing loss and grief. Through compassionate care, knowledge of the dying process, and excellent skills of communication, quality care can be achieved for patients and families at the time of death or loss.

LO 42.1 Grief, Loss, and Bereavement

Loss and grief are a normal part of human existence. Everyone, at various stages in life, will experience loss with the accompanying grief response. The terminology describing loss and grief is defined in this section, in which theories or stages of the grieving process also are explored. People cope with various types of loss and experience grief in a very individualized manner. Nurses are instrumental in assisting this coping process, because they provide comfort and support to patients and families experiencing loss and grief.

Loss

Many definitions of *loss* can be found in the nursing literature. **Loss** often is defined as the absence of something to which the affected person has formed an attachment and can involve people, places, or things. Examples are loss of a family member to death, loss of a body part to disease or accident, loss of health or independence to illness or old age, loss of financial stability to catastrophe, and even loss of choice to dementia or other illness that affects cognition. Loss is a separation from someone or something that is of personal importance. The meaning of loss is determined by the person affected by it; thus loss is a subjective experience.

Loss and the resulting grieving process are experienced by everyone over the course of a lifetime. Developmental life changes may be associated with significant losses, which can include moving out of a parental home, changing jobs, loss of a job, retirement, change in friendships, loss of a pet, or loss of a dream for self or family. The nature of loss varies widely: Death, the effects of acute or chronic illness, changes in physical or mental health status, a decrease in self-esteem, loss of hopes, and loss of personal possessions all may precipitate a grief response, discussed next.

Grief

Loss elicits a grief response that often is determined by the value placed on the person, place, or thing that is lost. **Grief** is described as the emotional response to a loss. It is the set of individualized and deeply personal feelings and responses experienced with real, perceived, or anticipated loss (Kissane, 2011). Grief produces feelings including anger, frustration, loneliness, sadness, guilt, regret, a sense of resolution, and peace. As noted, specific feelings attached to the grief response are extremely subjective and vary in nature and intensity over time and from person to person. As the significance of the loss increases, a deeper level of grief along with more acute feelings of loss can be expected.

Feelings of loss and grief after a death are experienced over the affected person's lifetime. People who have suffered loss related to a death are faced with a reemergence of the sensations of grief for years after the initial loss. These feelings often return on the anniversary of the loss or death, and at other special times, such as birthdays, holidays, family celebrations, graduations, and other developmental milestones in the lives of families. Reminders of the loss, even years later, can elicit the grief response. The reminders include people, places, sights, and sounds, such as hearing a favorite song or visiting a vacation destination. The strength and intensity of the emotions experienced during the grieving process will diminish over time, but the feelings never completely go away. It is important for the grieving person to understand that these feelings are a normal part of the grieving process and that measures can be taken to promote coping during these times. Reminiscing about the loved one and talking about the loss to family and friends can provide a positive focus during the grieving process. Rituals and development of new traditions help keep the memory of the deceased alive in a positive manner.

Theories and Stages of Grief

Grief is described according to its characteristics, signs and symptoms, and responses to the loss that the person is experiencing. Normal grief is described as feelings, behaviors, and reactions to loss; it can be physical, emotional, cognitive, and behavioral in nature (Table 42.1). An important nursing consideration is that active grieving can take months to years, with significant variability in how it progresses.

TABLE 42.1**Reactions to Loss**

AFFECTED DOMAIN	SIGNS AND SYMPTOMS
Physical	Tightness in the chest and throat Oversensitivity to noise Breathlessness Muscular weakness Lack of energy Fatigue Sleep disturbances Changes in appetite
Emotional	Numbness Loneliness Sadness Sorrow Guilt Shock Anxiety Depression Anger Agitation Lack of interest or motivation Lower level of patience or tolerance
Cognitive	Preoccupation with the deceased Forgetfulness Preoccupation with the loss Inability to concentrate Inability to retain information Disorganization Feeling confused
Behavioral	Crying Insomnia Restlessness Withdrawal Irritability Apathy Impaired work performance

Certain patterns or similarities in the grieving process have been identified over time. Such work has led to the perspective that grief is a process with a probable course toward resolution of the identified loss. Several theorists, including Kübler-Ross, Bowlby, and Sheldon, have identified stages and tasks of grief and grieving, which are outlined in [Table 42.2](#). [Kübler-Ross \(2003\)](#) first identified five stages of grief while working with patients who were diagnosed with a serious or terminal illness and who were

dying. These stages were later adapted to apply to people who have experienced other types of loss. The stages Kübler-Ross described are still considered today by both researchers and clinicians attempting to gain a full appreciation of the experience and emotions of people who are dying and of those suffering grief and loss. Stages identified by [Bowlby \(1982\)](#) begin with numbness as an initial reaction to loss and proceed to reorganization and then recovery. [Sheldon's \(1998\)](#) stages include initial shock, grief, despair, and adjustment. Each of these theories specifies stages and goals for achievement at each stage as people move successfully through the process of grieving.

TABLE 42.2**Theories and Stages of Grief and Loss**

THEORY	STAGE	CHARACTERISTICS
Kübler-Ross's (2003) five stages of grief	Denial	<ul style="list-style-type: none"> • A temporary defense to assist in the coping process • The dying person: <i>"No, it can't be me!"</i> • The person experiencing loss: <i>"He did not die in an accident!"</i>
	Anger	<ul style="list-style-type: none"> • Occurs after denial when true realization of the circumstances of the loss begin to emerge • The dying person: <i>"Why me? This is not fair."</i> • The person experiencing loss: <i>"Whose fault is it? I am going after them!"</i>
	Bargaining	<ul style="list-style-type: none"> • Beginning understanding of the loss with the hope that negotiation can change the circumstances • The dying person: <i>"I will change my ways and behave if I can live longer. I just want to live!"</i> • The person experiencing loss: <i>"I will do anything to have him back."</i>
	Depression	<ul style="list-style-type: none"> • Understanding of the certainty of impending death or loss occurs, and the process of grieving, which includes crying and sadness, is able to begin • The dying person: <i>"It doesn't matter anymore. I am going to die anyway."</i> • The person experiencing loss: <i>"It doesn't matter anymore. He is gone and not going to return. Why live?"</i>
	Acceptance	<ul style="list-style-type: none"> • Coming to terms with the reality of the loss • The dying person: <i>"Somehow this is going to be okay."</i> • The person experiencing loss: <i>"Life will go on somehow!"</i>
Bowlby's (1982) model of grief	Shock and numbness	Describes the time immediately after the loss, when the bereaved person feels numb; this is thought to be a natural defense mechanism that allows the person to survive the emotional response to the loss
	Searching and yearning	Time when the grieving person longs for the deceased and when emotions, such as anger, fear, anxiety, and confusion may occur
	Disorganization and despair	Yearning for the deceased decreases, whereas apathy, withdrawal, and anguish begin to surface
	Reorganization	A new state of normal begins with a decreased intensity of the negative emotions related to the loss, and a sense of enjoyment of life begins to return
Sheldon's (1998) stages of grief	Initial shock	<ul style="list-style-type: none"> • <i>Common emotions and experiences:</i> Numbness, disbelief, relief • <i>Task:</i> Accept the reality of the loss

THEORY	STAGE	CHARACTERISTICS
	Pangs of grief	<ul style="list-style-type: none"> • <i>Common emotions and experiences:</i> Sadness, anger, guilt, feelings of vulnerability and anxiety, regret, insomnia, social withdrawal, transient auditory and visual hallucinations of the dead person, restlessness, searching behavior • <i>Task:</i> Experience the pain of grief
	Despair	<ul style="list-style-type: none"> • <i>Common emotions and experiences:</i> Loss of meaning and direction in life • <i>Task:</i> Adjust to an environment in which the deceased is missing
	Adjustment	<ul style="list-style-type: none"> • <i>Common emotions and experiences:</i> Develop new relationships or interests • <i>Task:</i> Emotionally relocate the deceased to an important but not central place in bereaved person's life and move on

Research continues related to theories of grief and their application to various patient populations and different types of loss. In addition, none of these theorists would suggest a stepwise progression through the stages of loss and grief as they are outlined. These stages are to be regarded simply as a guide to understanding the process of grief, with no specific timeline detailing when people “should be” in a certain stage or “should” move from one stage to the next. Nurses need to understand these stages, and the feelings and emotions that are common in each stage, so that nursing interventions can be focused on the stage that a patient is experiencing, or the task that the person is attempting to complete related to the process of grief.

Anticipatory Grief

[Lindemann \(1944\)](#) coined the term *anticipatory grief*. This term is used in nursing in the context of caring for dying patients and their families. **Anticipatory grief** is defined as the cognitive, affective, cultural, and social reactions to an *expected death*, felt by the patient as well as family members and friends. This type of grief is experienced before an actual loss occurs and can arise when a person is initially diagnosed with an acute illness, chronic disease, or terminal disease.

Nursing interventions for anticipatory grieving include provision of emotional support with a positive presence, active listening, and reassurance while encouraging verbalization of the anticipated loss. Reminiscence and life review ([Butler, 1963](#)) are

used to assist those experiencing anticipatory grief with the realization that death is approaching. During the dying process, many people develop a sense of their own mortality and impending death, and they often contemplate their life. This sense of mortality allows the dying person and significant others to look back and reassess their lives in view of imminent death. Butler views life review as a process essential to resolve potential conflicts, which may assist in the process of accepting death.

Mourning

Mourning is the outward, social expression of loss. It is demonstrated on an individual basis related to the person's cultural norms, customs, rituals, traditions, and religious or spiritual beliefs. Life experiences and personality traits influence the outward expression of loss.

Nurses working with patients experiencing grief and loss should be aware of cultural characteristics of grief, mourning, death, and loss. Assessment of a person's cultural beliefs related to death rituals, common responses to death and grief, meaning of the afterlife, disposition of the body after death, and any other practices specific to the culture or religion is the responsibility of the nurse. Individualized assessment of each family's beliefs of death and the dying process are necessary to consider while developing nursing interventions and communication strategies (Fig. 42.1).

FIGURE 42.1 The nurse assesses the family's beliefs about death.

An overview of the beliefs of several cultural and religious groups regarding death and dying, as well as grief and bereavement, is shown in [Box 42.1](#). Assessment of personal knowledge, as well as a willingness to learn about various religious and cultural responses to death, loss, grief, and bereavement, allows the practicing nurse to provide care that is culturally competent and sensitive to the needs of the patient and their families. For more information about the health beliefs of common world religions, see [Chapter 22](#).

Box 42.1

Diversity Considerations

Culture, Ethnicity, and Religion

African American

- Friends and family often gather at the home of the deceased to offer support and share in the grief process.
- Funeral director and clergy may help plan the wake. Music and singing are common.
- Visitation may take place at a funeral home followed by a religious service in a place of worship and the gravesite.
- A meal is often shared after the wake and funeral.

Asian American

- Consider practices of the various cultural backgrounds: Chinese, Korean, Japanese, Vietnamese, and Laotian.
- Respect may be shown for the body by providing warm clothes for the burial.
- A shrine to the deceased may be displayed in the home.

European American

- Friends and family often gather at the home of the deceased following the death to offer support and share in the grief process.
- Funeral director and clergy may assist in planning the funeral and burial.
- Visitation at a funeral home followed by a religious service in a place of worship, as well as the gravesite, is common.

Hispanic/Latino American

- Diverse cultural backgrounds in this population.
- The rosary may be said, often at the home of the deceased.
- Many Hispanic survivors commemorate the loss of a loved one with a promise or commitment that is taken very seriously.

Native American

- Different tribes have different belief systems.
- The Medicine Man or spiritual leader may moderate the funeral service.
- Some tribes call on their ancestors to come to join the deceased to help with the transition.

Buddhism

- Family may bring religious implements (such as, incense, flowers, fruit, prayer beads, or images of Buddha) and may request a teacher or monk.
- Incense may be lit in the room.
- Family may wash the body. Cremation is preferred.

Christianity

- Family may request a visit from a minister or priest for prayers.
- Sacrament of the Sick may be administered by a Catholic priest.
- Funeral director and minister or priest may help the family plan the services.
- Friends call on family at a funeral home. There is usually a religious service after calling hour at the funeral home or in a place of worship, as well as at graveside.
- Cremation and burial both are acceptable.
- Organ donation and autopsy may be permissible.

Hinduism

- Priest, family, and friends may visit.
- Grief may be visually displayed.
- Family may wash the body.
- Cremation may be preferred with ashes scattered in sacred rivers.

Islam

- Family and friends may visit to provide emotional support.
- Body is treated with respect. After death, body may be moved to face Mecca.
- Autopsy may be conducted only for medical or legal reasons.
- Ritualistic washing of the body may be performed by a person of the same gender.
- Burial takes place as soon as possible.

Judaism

- Visitors may include family, friends, the rabbi, and possibly 10 men from the synagogue; prayers for the sick.
- Body is treated with respect. Autopsy is discouraged.
- Burial takes place as quickly as possible. Embalming is discouraged. Cremation is not appropriate.

Adapted from End of Life Nursing Education Consortium (ELNEC) Graduate Training Program (2005, 2018): Module 4: *Cultural Considerations in End of Life*, and End of Life Nursing Education (ELNEC) Consortium Core Curriculum (2011, 2018): Module 5: *Cultural and Spiritual Considerations in End of Life Care*.

Tasks of Mourning

Worden (2008) describes the process of grief and mourning as a series of tasks. The first task is to accept the reality of the loss, because the feelings of shock and disbelief that occur during the initial stage of grieving are the most common emotions felt by those experiencing a loss. Disbelief is replaced by the reality of the actual loss. The second task occurs as the grieving person begins to work through the pain of grief, experiencing the physical, emotional, cognitive, and behavioral responses common to the grieving process. Adjusting to an environment in which the deceased is missing includes rearranging, restructuring, and redefining the roles that person had in the life of the person experiencing the loss. This process of adjustment relates to the emotional, physical, financial, and other existing roles that the dying person once had in the life of the survivor who is grieving. Making life adjustments is necessary as implications of the loss are recognized and dealt with over a period of time. The final task is to emotionally relocate the deceased and move on with life. This task begins the resolution stage of the initial loss. At this time, people who are grieving accept that the deceased person is really gone and become less conscious of the loss and less preoccupied with the deceased. This final task allows survivors to reinvest energy in other relationships and move on with life while still maintaining the deceased person's presence in memories and through religious faith.

Bereavement

The term **bereavement** includes both grief and mourning, and can be described as the inner feelings and outward expressions that people experiencing loss are demonstrating. Bereavement has been described as a “period of time” that the person experiencing the loss feels the pain of the loss, experiences the grieving process, and begins to adjust to life without the person, place, or thing that has been lost.

1. Which type of grief is Mr. R. experiencing right now? What type of grief reaction would the nurse expect from Mr. R. after his wife's death?

Nursing Knowledge Necessary for Care of the Dying Patient and the Patient's Family

[Field and Cassel \(1997\)](#), through the Committee on Care at the End-of-Life of the Institute of Medicine (now National Academy of Medicine), identified four areas of knowledge and skill that health care professionals need to provide high-quality end-of-life care. These areas are scientific and clinical knowledge, interpersonal skills, sound ethical and professional principles, and skills of organization. All members of the health care team must have the necessary knowledge and skills to promote high-quality care for dying patients in a safe and effective manner at the end of life.

Scientific and Clinical Knowledge

Scientific and clinical knowledge that relates to the underlying disease process and the biologic basis of dying related to specific illness and injury is an essential component of nursing care at the

end of life. Assessment of symptoms at the end of life that occur with individual disease processes will allow the nurse to rapidly respond to potentially difficult and distressing problems. Valid and reliable assessment tools are available for health care providers and allow efficient evaluation of a patient's condition. Understanding the pathophysiology, physiologic, and emotional aspects of pain is essential, because pain is the most common symptom in the dying process. Understanding of the treatment of pain and other symptoms requires knowledge of pharmacology for effective treatment to promote high-quality care at the end of life. In addition, understanding the effects as well as limits of life-prolonging interventions is necessary while educating patients and families about options for care.

Interpersonal Skills

Interpersonal skills include the ability to listen to patients and families, as well as other members of the health care team. Empathy and sensitivity to religious, ethnic, and individual differences in care and treatment will enhance effective communication. Being able to convey difficult or upsetting news and providing information related to prognosis and options for treatment allow the patient and family the ability to make informed decisions. Effective communication is important in understanding and managing the response of patients and families to loss and the dying process.

Ethical and Professional Principles

Ethical principles include doing good and avoiding harm. Determining and respecting patient and family preferences are essential at the end of life. Professional activities include acting as a role model while demonstrating clinical proficiency, integrity, and compassion. Other concerns about end-of-life care are delineated in [Box 42.2](#).

Box 42.2

Ethical, Legal, and Professional Practice

Decisions at End-of-Life

- All patients need to consider whether potential burdens of treatment outweigh the benefits. Nurses assist patients and their families in the decision to continue or forego treatment by providing factual information. Quality-of-life issues are evaluated and determined.
- Patient self-determination and informed decision making are key aspects of end-of-life care. Nurses can advocate for patients to ensure that they are aware of their options for care that include interventions, treatments, anticipated outcomes, as well as risk and benefits of any decision made concerning medical care.
- Decision-making capacity is determined on an individual basis. Each person who is making a decision related to end-of-life care must be declared able to make an informed decision based on rational thought and decision-making abilities.
- The decision to withhold or withdraw treatment is a difficult decision that many patients, as well as families, make as they consider treatment options. Quality-of-life considerations are taken into account during these potentially difficult times.
- Assisted suicide and euthanasia are not legal (except in a few states where assisted suicide is viewed as medical treatment if provided by a physician for a terminally ill patient) or accepted practice by health care organizations in the United States. If patients or families request assisted suicide in an effort to hasten death, the patient and family needs a comprehensive assessment to determine their mental status, level of comfort, and goals for end-of-life care.
- The [American Nurses Association \(2013\)](#) position statement on Euthanasia, Assisted Suicide, and Aid in Dying prohibits nurses' participation in assisted suicide and euthanasia. Such activities would be a violation of the ethics of the profession.

Patients or families may insist on futile medical care. Futile care is described as treatment that will not change the course of the disease process and offers no hope of survival. If futile efforts at

sustaining life put the patient in jeopardy of further harm, nursing communication with the patient, family, and other members of the health care team can enhance the decision-making process and allow for a dignified death (Box 42.3).

Box 42.3

■ Interprofessional Collaboration and Delegation

End-of-Life Care

- Nurses can facilitate shared decision making about end-of-life care as patients and families interact with various members of the health care team in either acute care or long-term care settings, or when receiving hospice care. Research is being conducted exploring the roles, establishing policies, and formalizing the structure of interprofessional teams to enhance end-of-life care across the life span (Van Humbeek, Dillen, Peers, et al, 2016). Collaboration during the decision-making process is essential for high-quality end-of-life care.
- Patients and families need consistent information and communication about options for care, treatment measures, and prognosis. Nurses are in the most advantageous position to enhance communication through collaborative efforts with the primary care provider (PCP) and other members of the health care team.
- Nurses are integral members of the health care team. Interdisciplinary care requires the nurse to act independently and also to delegate tasks as appropriate so that high-quality care measures are met for the dying patient, as well as the family.
- Unlicensed assistive personnel (UAP) provide assistance with activities of daily living (ADLs).
- Social workers provide assistance with referrals to agencies, especially if the dying patient is being discharged to home or a care facility.

- Patients seek control of symptoms in all domains of quality of life. The nurse's role is to meet the needs of the patient in a safe and timely manner.

LO 42.2 Dysfunctional Loss and Grief

There are several circumstances during which loss or grief is dealt with in a dysfunctional manner. When the bereaved person is unable to progress through the stages of grief, complicated grief occurs. Another type of dysfunctional grief is disenfranchised grief.

Complicated Grief

Complicated grief, also called *unresolved grief*, occurs when the affected person is not able to progress through the normal stages of grieving. It is characterized by distressing symptoms lasting at least 6 months after the death of a significant person. This type of grief is described in the *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)* ([American Psychiatric Association, 2013](#)). Risk for complicated grief increases when death follows trauma, suicide, homicide, or any other sudden and unexpected death. The pain and sadness after a loss are never completely resolved, and the grieving process is so severe that it does not allow a person to continue normal life processes. Symptoms of complicated grief include intense longing for the deceased, denial of the death or sense of disbelief, imagining that the loss has not occurred, searching for the person in familiar places, extreme anger or bitterness over the loss, and avoiding things that are reminders of the loss. Daily life routines are not maintained, and the person's emotional as well as physical health becomes threatened.

Four types of complicated grief have been identified:

- **Chronic grief** is characterized by grief reactions that do not diminish over time and continue for an indefinite period or very long period of time.
- **Delayed grief** is characterized by suppression of the grief reaction while the

grieving person consciously or unconsciously avoids the pain that has occurred with the loss.

- **Exaggerated grief** occurs when the survivor is overwhelmed by grief and cannot function in daily life. In such instances, the affected person may use self-destructive behaviors, such as drugs or alcohol, as a coping mechanism. The potential for suicide with exaggerated grief cannot be overlooked by the health care team.
- The final type of complicated grief is described as **masked grief** and occurs when the behaviors of the survivor interfere with normal functioning, but that person is not aware that these behaviors are concealing the actual grieving process.

Complicated grief reactions are uncharacteristic of the normal grief process and may include a greater intensity of denial, anger, or shock; verbalization of helplessness or hopelessness; panic attacks; substance abuse; or chronic depression. Complicated grief can lead to long-lasting physical problems and serious mental health issues.

2. What type of grief reaction would the nurse expect from the couple's two children?

Disenfranchised Grief

Disenfranchised grief was defined by **Doka (2002)** as any loss that is not validated or recognized. This type of grief is encountered when a loss happens that cannot be openly acknowledged or publicly shared by the grieving person. It occurs when society does not want to acknowledge the grief, or does not know how to deal with the loss or with the response of the grieving person. Persons at risk for this type of grief include ex-spouses, ex-partners, friends, lovers, mistresses, co-workers, mothers of stillborn babies, and even those who have terminated a pregnancy. Disenfranchised grief can complicate grieving and stress, because the loss is not grieved in a manner that is beneficial or advantageous to the afflicted person.

LO 42.3 Factors Affecting the Process of Grief and Bereavement

Various identified factors have an effect on each person's grieving process. The intensity of the emotional and physical responses to loss varies according to the factors described. It is essential to recognize that people experience grief and loss in their own way, with their own set of coping skills, which include life experiences, cultural norms, religious beliefs, and spiritual practices. Factors related to grief and bereavement include the importance that was attributed to the loss, the circumstances of the death, and the nature of the relationship to the deceased.

Age of the Bereaved and Age of the Deceased

Chronologic age has an impact on the process of grief and bereavement, as well as the age of a person at the time of their death. As people age and gain valuable life experiences, their ability to adapt to loss and grief evolves. Life events that occur over time can promote the person's ability to cope with loss. Coping strategies are adapted over a lifetime as knowledge and experience expand. With age come wisdom and experience, which help the person through the process of grief and bereavement.

Losses are experienced by people across the life span. Each stage of life brings specific developmental tasks and different challenges related to loss, grief, and bereavement. Coping strategies and the process of grief and bereavement differ for each age group and developmental level or stage of life. Resources, such as the National Hospice and Palliative Care Organization (NHPCO), provide information for nurses, clients (including children), and their families ([NHPCO, 2017a](#)).

Adults work through the process of grieving as outlined by the theorists identified in this chapter. They often feel intense emotions while working toward resolution of the loss. Coping styles vary considerably in the adult population. Loss and grief in the older adult population need to be examined, particularly in view of the continued growth of this population. Older adults experience a myriad of losses throughout a lifetime. Many such

losses occur during the process of growing older, such as the potential loss of function or of the ability to perform activities of daily living (ADLs).

Gender and gender role differences related to loss, grief, and bereavement have been hypothesized in various types of research during the past 50 years. No definitive findings have been established through research to date. It is thought that gender does have an impact on grief and bereavement, because men and women experience grief differently in relation to how they express, and manage or adapt to loss and grief. Some societies teach that it is not acceptable for males to express emotions; it is more acceptable for women to demonstrate strong emotions when grieving.

Loss of a child often produces an intense grieving process for parents. Many people in Western societies have a greater sense of acceptance and understanding of death when the deceased is an older adult who has “lived a long and good life.” The death of someone who is close in age to the survivor may affect the grieving process because it is a reminder of personal mortality.

Health Status of the Survivor

Physical and emotional health influence the grieving process. Optimal physical and psychological health results in a greater capacity to cope with loss. When the survivor has acted as the caregiver for any length of time, the person's own needs for health care often have been neglected. Once the grieving process begins, undiagnosed and untreated health problems can become a major concern.

Cognitive Status of the Survivor

People with diminished cognitive function have different needs during the time of bereavement and are considered a vulnerable population in the context of loss and grief. Older adults with cognitive impairment, such as dementia, will have difficulty processing their loss and may even forget that they have lost a loved one to death. In addition, families may have difficulty grieving when they are asked on a regular basis about the deceased and why the deceased is not available.

Relationship to the Deceased

The relationship of the survivor to the deceased, and the type and quality of their relationship, will affect the grieving process. Examples of difficult losses with the potential for complicated grief are miscarriage, loss of a child, and loss of a first-degree relative or spouse.

For other people experiencing loss, the nature of the relationship may be more distant, so that the sensations associated with grief and bereavement are minimized. Examples are minor grief reactions to the loss of an ex-spouse or an abusive spouse and to the loss of a family member or friend who has been absent from the life of the survivor. The quality or value of the relationship has an impact on the grief felt by the bereaved.

Coping Styles and Concurrent Stressors

Coping skills have an impact on the process of grief and bereavement. These include both past and present coping skills, as well as healthy versus unhealthy patterns of coping. People who have lived through previous loss will have used various coping skills and thus have an array of strategies available for dealing with a current loss. Accepting support and expressing emotions are healthy coping strategies. Coping styles that include suppressing feelings or avoidance of difficult situations by running away may ultimately result in a prolonged and more painful experience of loss.

Loss is a stressor, and concurrent stressors have an impact on the grieving process. The process of bereavement is multiplied with an increased number of stressors and may be extended or interrupted. Stressors in daily life are numerous and can include family issues, caregiving concerns, financial problems, workplace demands, and lack of a support system. Multiple stressors can complicate the grieving process, resulting in a crisis situation.

Available Support Systems

Social support is essential during the process of grieving. Sources of support include family members and friends, fellow members of a religious or spiritual community, and support groups for people who have experienced a similar loss. Professional

counseling with a grief counselor is an option to recommend for people experiencing intense emotions that have not abated despite use of other sources of support.

Socioeconomic Status

The implications of financial circumstances cannot be overlooked when working with the grieving person and the family. Availability of funds has an effect on the grieving process due to the cost of necessary services. Funerals are expensive, and many families do not have the resources necessary to provide the proper or desired burial for their loved one. In addition, the death of a loved one may mean loss of income for surviving family members. People with higher levels of education and higher incomes have demonstrated a greater ability to obtain necessary support throughout the process of grieving.

Religion and Spirituality

Religious or spiritual beliefs have an impact on ability to cope with death and loss. Many people derive strength from their religious or spiritual beliefs, customs, and rituals. They find comfort and support in counsel from their religious and spiritual leaders. The grieving process is made less painful as meaning is found in the midst of loss. Others feel that God is punishing them when something bad happens in their lives. Anger toward God may lead to feelings of guilt and even greater anguish over the loss.

Type of Loss

Loss related to a suicide often leads bereaved family and friends to feel shame, fear, guilt, rejection, and anger. Shame is a common feeling for these suicide survivors due to the societal stigma of suicide. Nurses can review the events leading up to the death, to help the survivor understand that the suicide was actually a long-term process and not just a singular event. Families are encouraged to talk about the death together. When survivors feel that anxiety, depression, and a suicidal tendency are familial traits, fear of another family member's having such traits may intensify the loss. Denial includes the potential need to disguise

the real cause of the death, which complicates the grieving process. Guilt may include the potential for self-blame or a feeling of moral failure. Anger arising as an emotional response to this type of loss frequently is misdirected at the deceased, evoking a further sense of guilt.

When a loss is because of a murder or other wrongful death, the survivor's personal sense of security is threatened and a sense of control is lost. Grief reactions usually are severe, intense, exaggerated, and complicated. It is difficult to comprehend the loss after a murder has occurred, which complicates the grieving process. Survivors may experience a sense of vulnerability or fear of being murdered. Revengeful thoughts can bring normal anger to a point of rage. Interaction with law enforcement officials, the court system, and news media may complicate the grieving process while the survivor becomes a victim to the intrusion of outside forces.

Complicated Loss

Many conditions or situations are recognized to complicate the grief process. **Complicated loss** occurs with a sudden death, a violent or traumatic death, multiple deaths, loss that is related to a social stigma, and with the death of a young person. Sudden death does not allow the survivor time to prepare for the impending loss, and this type of event can leave the survivor with a sense of feeling out of control and wondering about the meaning of the death and even of life. Any violent or traumatic death (such as a suicide, homicide, or accident) can lead to a sense of shock and disbelief that is a normal part of the grieving process but is much stronger with a violent type of loss. When people experience a series of losses, the ability to grieve becomes difficult, because the emotions may leave a person feeling numb. This type of loss may include multiple losses over time or the loss that occurs when several people are killed in one accident. The age of the deceased can result in complicated loss, especially with the death of a child or of someone close to the survivor's own age.

Complicated loss can occur with a catastrophic event (such as a natural disaster, or loss of the home and its contents), violent acts (such as murder, rape, war, or bombings), or other events (such as the September 11, 2001 attack on New York's World Trade Center

towers and the Pentagon in Washington, DC). These losses may involve violation of basic human rights and can affect an individual person, a family unit, or an entire nation. During this time of loss, symbolic losses can include a loss of security, trust, liberty, and pursuit of happiness.

Loss of a house to a fire involves loss of the home and its contents, loss of personal control of security, and loss of past lifestyle. Emotional stresses of this type of loss include a sense of powerlessness, the horror at witnessing suffering, and possibly the difficulty of identifying victims. Complicated loss associated with catastrophe typically leaves a visual as well as a cognitive imprint, with reminders often encountered on a daily basis.

The experience of miscarriage or stillbirth affects not only the mother but also other members of the grieving family. Parents and other relatives are asked to say goodbye before they have said hello ([Humphrey & Zimpfer, 2007](#)), and hopes and plans for a new family member cannot be realized. This type of loss is considered a complicated loss in that the bereaved are grieving a dream. Often, however, the mother is left to grieve this loss essentially alone because she, unlike the father or any other member of the family, started the attachment process to the baby during the pregnancy, with development of a unique physical bond. Her feelings and experiences during the period of loss and bereavement will therefore differ ([O'Leary, 2004](#)). For the mother, grief may be experienced physically as a sense of acute emptiness, aching arms, and a potential sense of unreality. Emotional symptoms may include sadness, anger, guilt, depression, a sense of "what might have been," and a potential sense of failure. For effective grieving to occur, parents need to be allowed to see and hold the infant if possible. This may include dressing and rocking the baby and selecting clothes for the funeral ([Humphrey & Zimpfer, 2007](#)).

LO 42.4 ♦ Assessment

Assessment of grieving is customized for each circumstance. Asking both focused and open-ended questions will give the nurse information on how to best support and care for dying persons and their loved ones (Box 42.4).

Box 42.4

Health Assessment Questions

Assessment of the Grieving Individual and Family

- What are you feeling right now? Are there other feelings that you have been experiencing?
- How are you coping with these feelings?
- Do you have other stressors or concerns in addition to this loss?
- Have you coped with a loss in the past?
- Who is able to support you during this very difficult time?
- Is this loss affecting your physical health? Do you have concerns about your physical health?
- What are your needs from the health care team?

Assessment of Anticipatory Grief

- Will your loved one's death result in loss of financial support?
- Are you and your family having difficulty making decisions?
- Are there other losses that you are still dealing with?
- Has your loved one's diagnosis or determined prognosis been recent (less than 6 months)?
- Has the illness been of long duration (greater than 12 months)?

- Have you had suicidal thoughts or do you feel unable to cope with this crisis?

Assessment of Potential Dysfunctional Grieving

- Do you feel that your support system is inadequate?
- Are you using more alcohol, tobacco, drugs, or prescribed medications?
- Do you have more difficulty sleeping than usual?
- Have you lost or gained weight?
- Has your grief subsided or intensified in the last few weeks?
- Are you able to carry out your day-to-day activities including work, social commitments, and household responsibilities?
- Do you have new health concerns?

General Assessment

Grief assessment should include the patient, family members, and significant others. Assessment of grief within a family system includes understanding relationships within the family and where support can be obtained for the individual members. A functional family (one that is characterized by love, mutual respect, and support among its individual members) is better prepared to deal with the feelings, stresses, and changes that occur during the time of loss.

Assessment of the Caregiver

Persons providing care for those at the end of life experience stressors related to the role of provider of care. Many caregivers do not care for themselves while they are caring for a loved one who is dying. Assessment of the needs of the caregiver is an essential component of the nursing care that is provided to patients. Caregivers need to take steps to preserve their own health and well-being ([Mayo Clinic, 2018](#)). The caregiver assessment includes:

- General health checkup

- Focused assessment of physical, mental, or emotional symptoms
- Assessment of nutritional status
- Sleep evaluation
- Examination of the caregiver's ability to maintain work and family roles
- Maintenance of dental and visual health
- Assessment of social network
- Evaluation of support systems

Signs and symptoms of caregiver stress include feeling tired and overwhelmed, getting too much or not enough sleep, and significant weight gain or loss. Caregivers may lose interest in activities they formerly enjoyed ([Mayo Clinic, 2018](#)).

Assessment Tools

Specific tools for assessment of grief are available from the Toolkit of Instruments to Measure End of Life Care: Grief and Bereavement, which was developed as a project funded by the Robert Wood Johnson Foundation. Common assessment parameters pertinent to nursing included in these tools are consideration of the relationship to the deceased (and the quality of that relationship), type of loss (sudden or expected, traumatic or disease based), current coping strategies, available support systems, health status (physical as well as emotional), religious or spiritual beliefs, any concurrent stressors, financial or socioeconomic status, history of previous loss, family assessment, and satisfaction with current relationships ([Brown University Medical School, 2004](#)).

Physical Assessment of the Dying Patient

Caring for patients who are dying requires excellent skills of physical assessment. Many families of patients who are dying ask the nurse, “When is death going to occur?” Although nurses are not in a position to predict the time of death, knowledge of the physical signs and symptoms of death will allow the nurse to

support families when death appears imminent. Physical symptoms at the end of life include weakness and fatigue, increased drowsiness, and sleeping more and responding less. A decrease in oral intake and a decrease in the swallow reflex may occur. Surges of energy may occur as the dying person begins to make the transition to death. Changes in bowel and bladder elimination are common and include constipation, diarrhea, and potential incontinence. Patients and families need to know that these are normal changes, and education about these changes will enhance coping abilities during the time of anticipatory grief.

Signs and Symptoms of Impending Death

Universal manifestations of imminent death include a decrease in urine output, cold and mottled extremities, and changes in vital signs, in that the blood pressure decreases and heart rate often increases but can decrease. Changes in breathing patterns, with the occurrence of periods of apnea that increase as the body shuts down, and apparent respiratory congestion or the “death rattle” from the inability to swallow secretions are common manifestations of impending death.

Signs and Symptoms of Death

Signs and symptoms of actual death include absence of heartbeat and respirations, an involuntary release of stool and or urine, lack of any response to verbal or tactile stimuli, and a drop in body temperature as the body begins to cool. This cooling is called **algor mortis**, or cooling after death. The eyes may remain open, the jaw will drop as the mouth appears to be open, and the color of the skin becomes pale and then bluish (**livor mortis**) as blood settles. After a period of time, **rigor mortis**, or stiffening of the joints of the body, will set in.

LO 42.5 ♦ Nursing Diagnosis

Common International Classification for Nursing Practice (ICNP) nursing diagnoses that grieving persons may experience are:

Grief

- Supporting Data: Anticipated death of spouse; crying when told that wife will live only a few more days

Chronic Sadness

- Supporting Data: Continued sadness and depression after amputation of left leg as a result of a motorcycle accident, statements of fear, helplessness, hopelessness, low self-esteem, continued self-blame

Death Anxiety

- Supporting Data: Beginning understanding of terminal diagnosis and prognosis of less than 6 months to live, statement of fear of dying, fear of suffering while dying, fear of leaving family members at the time of death, a feeling of powerlessness over the dying process

3. Identify an appropriate nursing diagnosis for Mr. R., and give reasons why it is appropriate.

LO 42.6 ♦ Planning

Examples of goals or outcome statements related to the sample nursing diagnoses listed in the Nursing Diagnosis section include (Table 42.3):

TABLE 42.3
Care Planning

ICNP NURSING DIAGNOSIS WITH SUPPORTING DATA	NURSING OUTCOME CLASSIFICATION (NOC)	NURSING INTERVENTION CLASSIFICATION (NIC)
<i>Grief</i> Anticipated death of spouse Crying when told that wife will live only a few more days	<i>Coping</i> Uses effective coping strategies	<i>Grief Work Facilitation</i> Support progression through personal grieving stages

From Butcher, H. K., Bulechek, G. M., Dochterman, J. M., et al. (Eds.). (2018). *Nursing interventions classification (NIC)* (7th ed.). St Louis: Mosby; Moorhead, S., Swanson, E., Johnson, M., et al. (Eds.). (2018). *Nursing outcomes classification (NOC)* (6th ed.). St. Louis: Mosby; ICNP is owned and copyrighted by the International Council of Nurses (ICN). Reproduced with permission of the copyright holder.

- Husband will express his feelings toward the anticipated loss of his wife during her last few days.
- Patient will identify personal strengths within 1 month of amputation.
- Patient will accept assistance from friends, family, and significant others during the process of grief within 2 weeks of diagnosis.

LO 42.7 ♦ Implementation and Evaluation

Providing nursing care to dying patients and their families can be a challenging as well as a rewarding responsibility. It is important for the nurse to develop trust and rapport while using skills of therapeutic communication to acknowledge their experience of loss.

Care of the Dying Patient and the Patient's Family

People who are grieving need to know that they are heard and understood as they are trying to make sense of the loss and the emotions of grief. Providing education about the stages of grief will assist in the provision of appropriate nursing interventions, because communication techniques vary according to the stage of grief. Simply understanding that what they are feeling is normal can assist in the grieving process. Encouraging healthy behaviors (such as exercise, rest and sleep, adequate diet, journaling, stress-relieving techniques, and other healthy coping mechanisms identified by the affected person) will facilitate movement toward resolution of the loss.

An important nursing intervention is listening while patients or their families tell the story of their loss, because verbalization of the loss allows the process of bereavement to begin. Including the entire family or significant others in the assessment and planning of nursing interventions for grief and bereavement is essential, both because grief work involves the entire family and because family dynamics affect each person's grieving process ([Becvar, 2003](#)). Using community resources and making appropriate referrals may help enhance coping while providing the grieving person with additional and ongoing sources of support.

Advance Directives for End of Life

Advance directives are legal documents that allow people to communicate their wishes about what type of medical care they

would like to receive at the end of life. It is a nursing responsibility to be aware of types of advance directives available and to discuss the options with patients and families. A copy of the patient's advance directives should be part of the medical records. Advance directives are discussed in greater detail in [Chapter 11](#).

Hospice and Palliative Care

Some confusion has arisen among the general public as well as health care providers about the difference between hospice and palliative care. *Palliative care* includes hospice care, but not all palliative care is considered hospice care. *Hospice care* is provided to patients with a life expectancy of 6 months or less who decide to forego curative treatment. Palliative care begins at the time of a diagnosis and includes curative measures.

Hospice

Hospice is defined by the NHPCO as a program that provides comfort and supportive care for terminally ill patients and their families, either directly or on a consulting basis with the patient's physician or another community agency. The whole family is considered the unit of care, and care extends through their period of mourning ([NHPCO, 2017b](#)). When the patient or a surrogate decision maker accepts or chooses the hospice benefit, curative treatments are no longer a focus of care. The goal becomes symptom control and quality-of-life measures. It is important for nurses to understand that patients who choose the hospice benefit can live longer than 6 months and remain on the hospice program. Medicare benefits include an initial 90-day benefit period, a second 90-day benefit period, and then unlimited 60-day benefit periods so long as progression of the terminal illness is documented. Patients who enter a hospice program and later decide that they want to pursue treatment for a cure can revoke the hospice benefit and seek curative treatment.

The care provided by hospice occurs in various settings with a focus on symptom control and with the understanding that dying is a part of the normal life cycle. Care is provided to patients and families in the home, residential or long-term care facilities, dedicated inpatient settings, designated hospital beds, and

prisons, and even to homeless populations (Box 42.5). Several tools are used to assist members of the health care team determine prognosis. General tools include the Karnofsky Performance Scale, the Palliative Performance Scale, and the Functional Assessment Staging Tool (FAST). These guidelines assess functional status, such as ambulation and self-care, nutritional intake, evidence of disease, cognitive function, and level of consciousness.

Box 42.5

Home Care Considerations

Hospice Care in the Home

Patients receiving hospice in the home require skilled, knowledgeable nurses to provide a high level of care, because many needs are specific for the dying patient and the family of that patient. Care includes:

- Assessment of safety in the home related to the physical as well as social environment
- Physical as well as psychosocial assessment conducted in an independent and thorough manner
- Coordination with all members of the health care team
- Education of family care providers so that they are able to provide the necessary physical care
- Demonstration of safe use of equipment in the home and provision of necessary services

Hospice care is provided by an interprofessional team that includes nurses, physicians, pharmacists, social workers, spiritual care providers, massage therapists, art therapists, and music therapists. Physical therapy or occupational therapy may be included in the individualized plan of care if the patient's goal is to regain strength to improve quality of life. Care includes durable medical equipment, medications related to the terminal illness, respite care, homemaker services, home health services, and volunteer services (Fig. 42.2). Grief and bereavement services are

recognized as a core component of any hospice or palliative care program, according to the [National Consensus Project for Quality Palliative Care \(2013\)](#). These services are available for at least 13 months after the death of the patient, and risk assessments are routinely conducted.

FIGURE 42.2 A hospice patient is cared for at home.

Palliative Care

Palliative care emerged in response to the needs of patients who were not terminally ill but needed high-quality symptom control for a serious or life-threatening illness. This type of care is appropriate for anyone who has a chronic, debilitating condition.

The World Health Organization ([WHO, 2017](#)) describes **palliative care** as “an approach that improves the quality of life of patients (adults and children) and their families who are facing problems associated with life-threatening illness. It prevents and relieves suffering through the early identification, correct assessment and treatment of pain and other problems, whether physical, psychosocial or spiritual.”

Palliative care provides relief from pain and other distressing symptoms, affirms life and regards dying as a normal process, intends to neither hasten nor postpone death, integrates the psychological and spiritual aspects of patient care, and offers a support system to help patients live as actively as possible until death. Palliative care includes hospice care along with curative measures. Palliative care is appropriate early in the course of

illness. It is used in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy, and includes those interventions needed to manage distressing clinical complications.

Interventions for Symptom Management at the End of Life

Effective symptom management at the end of life is essential to meet the care needs of patients and families specific to this period. The [City of Hope Pain and Palliative Care Resource Center \(2014\)](#) has identified four domains of quality of life that are significant to people facing the end of life ([Fig. 42.3](#)). Attention to management of the physical symptoms common at the end of life will improve quality of life for the patient, who can then expect to maintain an optimal level of psychological, social, and spiritual well-being.

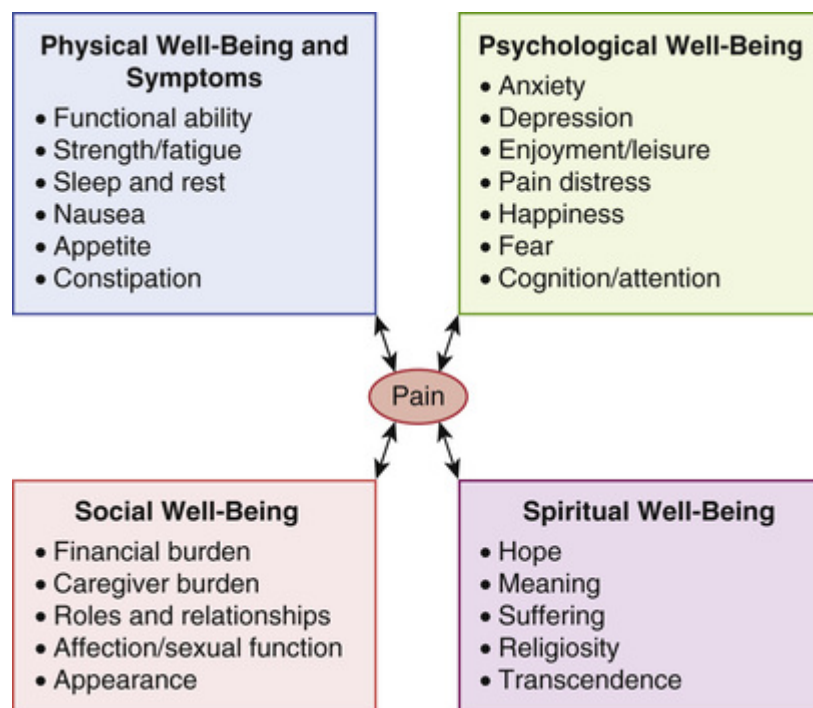

FIGURE 42.3 Quality-of-life model. (From Betty Ferrell, PhD, FAAN, and Marcia Grant, DNSc, FAAN, City of Hope Medical Center, Duarte, CA.)

Adequate control of symptoms at the end of life requires ongoing assessment and evaluation of interventions. Common physical and psychological symptoms at the end of life include

pain, dyspnea, anorexia and cachexia, constipation, diarrhea, nausea and vomiting, fatigue, anxiety, and depression. Nurses need to be knowledgeable in the management of these symptoms. Aggressive management of symptoms will promote a peaceful death for the patient and facilitates the grieving process for the surviving family members.

Safe Practice Alert

Families need a great deal of education and support if distressing symptoms are present. Education and support to the patient, as well as the family, are essential as nurses work promptly to control patient symptoms with pharmacologic and nonpharmacologic measures.

Care of the Dying Patient

In the delivery of care for a dying person, the patient and family are considered the unit of care. The provision of nursing care to the dying patient may occur in any setting, including acute care, long-term care, and home care.

The Care Environment

The provision of a supportive environment is essential in caring for the dying patient. Patients are encouraged to bring some of their favorite belongings with them if they are not at home. These may include a pillow, blanket, stuffed animal, photographs, or other treasured mementos. Photographs provide comfort to the dying person, as well as the family, allow life review to occur, help families reminisce, and facilitate nurses' knowledge of the family dynamics. A major benefit of having photos of the dying person is that nurses can see that person as once-healthy with a lifetime of experiences that does not include only illness and approaching death.

Allowing pets to visit brings comfort and companionship. Families are allowed unrestricted visiting hours, time for privacy, and space necessary for closeness and intimacy. Interventions to provide a supportive environment for the dying patient and

family require the nurse to be creative while advocating for patient and family needs and choices.

For the person who is “actively dying,” a change of setting, such as transfer from a nursing home to a hospital, or from a hospital to a hospice facility, can be disruptive and distressing. The setting is changed only if the patient or family requests a change. If the person prefers to die at home, for example, that request would be honored. Patients and families are given options for where they want the death to occur, and the nurse provides support while advocating for the wishes of the patient and family.

Each member of the health care team ensures that diagnostic tests and procedures are conducted only if treatment measures will be implemented. Vital signs may not be necessary unless they are being obtained to update a family member about a dying patient's status.

Communication With Dying Patients and Their Families

Open and honest communication is essential as death is approaching. Informed decision making is a necessary requirement in an effort to gain trust of the patient and family. It is only through honest communication that is sensitive, caring, and compassionate that trust is facilitated and high-quality care is provided (Box 42.6). Information at the end of life is given in simple, uncomplicated terms while avoiding overloading or overwhelming the patient or family members. The provision of simple answers to questions that consider the patient's and family members' understanding and readiness for information is essential. Family members often are tired, have difficulty concentrating, and cannot focus on information that is provided to them. The nurse may need to answer the same questions while providing information repeatedly so that the family can integrate what they are learning as the patient's condition changes. Patients may be aware that they are dying and ask the nurse about the dying process. Nurses need to be honest while exploring any potential concerns or fears that the patient may be having.

Box 42.6

Evidence-Based Practice and Informatics

Recommendations for Patients in End-of-Life Intensive Care Unit

- Recommendations for end-of-life care in the intensive care unit have been published by the Agency for Healthcare Research and Quality that relate to not only physical care of the dying patient but also the need for improved communication.
- Consideration of the value of family conferences as a tool for communication, interdisciplinary team rounds, and development of an environment that supports open communication are described.

More information is provided in a published consensus statement by the American College of Critical Care Medicine, which is available at <https://www.ncbi.nlm.nih.gov/pubmed/?term=18431285>.

Qsen Focus!

Through patient-centered care of dying patients and their families the nurse demonstrates understanding of pain and suffering; assesses the extent of the pain and suffering, as well as the levels of physical and emotional comfort; and recognizes the specific beliefs of patients and families.

Providing education and accurate information as death approaches is an essential component of nursing care at the end of life. Honest and factual information can empower patients and families. Educational needs of patients and families are noted in [Box 42.7](#).

Box 42.7

Patient Education and Health Literacy

End-of-Life Care

- Teach patients and families the signs and symptoms of the dying process in terms that they can understand. Knowing what to expect can empower family caregivers during this very difficult time.
- Explain measures used to control symptoms and to maintain quality of life for the patient. Knowing that efforts are being made to keep their loved one comfortable can decrease the stress family members may feel while caring for the dying person.
- Provide assurance that members of the health care team are available and ready to provide assistance and support.
- Educate caregivers about how to provide physical care measures to allow the family to provide safe care in a manner that will allow comfort for the patient, as well as the family.

When a person is imminently dying, the family may want to be at the bedside constantly. This period often is termed the *death vigil*. Other families may be uncomfortable being with the dying person for very personal reasons. Fear often is a common feeling for families who have not faced death or who have experienced death in a detrimental manner. Common fears include fear of being alone with the patient, fear of their loved one having a painful or otherwise symptomatic death, fear that they will witness suffering, and fear of not knowing if the patient has actually died. Families who are fearful need an increased level of support by various members of the interdisciplinary team. Increased presence of family members, friends, and spiritual support will help allay some of these fears. It is the responsibility of the nurse to reassure the family that the patient will be kept as comfortable as possible. The nurse serves as a role model for how and when to implement effective end-of-life caregiving measures.

Safe Practice Alert

Be aware that families may react with anger and fear as their loved one is dying. Nurses should ensure their own safety in any environment in which they practice. Always be aware of the potential for aggressive behaviors, and bring a calm and reassuring manner to interactions with patients, as well as their families.

It can be a very difficult but necessary task for the nurse to communicate to families that their loved one has died. Telling the family that the patient has died is done in an open and honest manner with compassion and support. Providing information in small amounts, repeatedly if necessary, allows the family to process that information. Many families are shocked and overwhelmed at the time of death and will need time to process that death has just occurred. If the family is expecting the death, they may have been prepared in advance through the process of anticipatory grieving. Family members may feel numb and lost at this time; the nurse assists them in understanding what they need to do after the death. It is helpful for the nurses to ask what family members are capable of doing at that point—for example, making telephone calls to other family members.

Care of the Patient WHO Is Imminently Dying

Care of the patient who is imminently, or actively, dying demands the most basic nursing care measures provided with a high level of caring and compassion. Gentle bathing is necessary, with perineal care performed on a regular basis unless symptoms, such as pain or shortness of breath, are intolerable. Oral care is essential, because many dying patients breathe through the mouth. Use of a moistening agent and care of the lips to prevent dryness will promote comfort. Turning and repositioning are necessary to prevent skin breakdown, which could result in pain and discomfort. If the patient is agitated or restless, decreasing environmental stimuli while playing soothing music may promote a sense of peace and comfort. The most important intervention is to ensure that symptoms are controlled. Frequent and attentive assessment to ongoing or new symptoms with prompt intervention will promote comfort and prevent any undue distress or suffering.

Symptom management and keeping a dying patient comfortable are priority nursing goals. Pain medication is given as needed, often in the form of sublingual drops or suppositories. Supplemental oxygen may help a patient who is struggling to maintain oxygenation. Patients who experience nausea or vomiting are treated with medication in suppository form. Use of complimentary and alternative therapies (such as guided imagery, massage, distraction techniques, and herbal therapies) may be helpful.

Patients who are actively dying may lose the ability to swallow, and secretions may build up, causing congestion and difficulty breathing. Secretions can be controlled through medications to decrease oral and respiratory secretions, and suctioning if it does not cause the patient undue distress.

4. What nursing interventions are appropriate for the couple during S. R.'s last few days?

Nearing Death Awareness

Nearing death awareness has been described as a special communication of the dying, which occurs when patients are approaching death or imminently dying. Not all people will have this experience, but the nurse must be aware of the signs that nearing death awareness is occurring. People who are experiencing nearing death awareness may appear confused and report speaking to or seeing already deceased persons, such as a parent or spouse. Many people in this state describe spiritual beings and bright lights, together with a sense of peace and beauty. Making hand gestures, such as reaching or picking, or holding unseen objects is common. Nurses caring for patients exhibiting these signs should not assume that they are confused or hallucinating or having a reaction to medications. Many

professionals experienced in the field of end-of-life care have witnessed these signs and believe that the dying person is undergoing a transition from this life to the next. The person may actually be trying to communicate his or her experience to the family or health care providers. This conveyed experience often is viewed as a type of symbolic communication, perhaps trying to ask for permission to die or resolving previous conflicts. *Final Gifts: Understanding the Special Awareness, Needs, and Communications of the Dying* by Maggie Callanan and Patricia Kelley (1992) describes this process.

It is important to recognize that these experiences can be comforting to the dying patient, and nurses should not contradict or argue with the person. It is imperative to simply be present with the person, listen, and be open to any attempts to communicate. It is acceptable to ask gentle questions, such as “What are you seeing?” or “How does that make you feel?” Having an open discussion with the family while describing what is occurring may provide further insight to the nurse as the health care provider, as well as promoting a sense of understanding and acceptance for the family.

If a death is expected, such as with a terminal illness, the final days or hours before a person dies may be one of the most significant events that the dying person and loved ones experience. It is a time to say goodbye and complete end-of-life or life-closure tasks. Nurses facilitate this process as they provide care, education, support, and advocacy during this time. The goal is to provide dignified end-of-life care to patients and their families in any practice setting.

Postmortem Care: Care of the Patient at the Time of Death

The procedure to pronounce death begins with identifying the patient. The nurse notes the general appearance of the body, lack of reaction to verbal or tactile stimuli, lack of response of the pupils to light, absence of a pulse on palpation or a heartbeat on auscultation, no blood pressure, and no audible respirations on auscultation of the lungs. If family members are present, they may be reassured to watch the nurse assess for signs of death as a sense of reality of the actual death is determined. Once death has

been confirmed, the nurse, in any setting, determines that the death occurred without “unusual circumstances.” Any signs of foul play or of suicide or missing medications are reported to the appropriate authorities, which may include the police and the coroner. Documentation of the time of death includes the patient's name, the time the call was made to the appropriate health care provider to give notification of the death, and actual findings on the physical examination. The physician caring for the patient and other health care providers involved in the patient's care are notified as well.

Nurses need to be aware of the policies and procedures at their individual places of employment related to pronouncement of death and the actions that need to be taken at the time of death. Each state has practice guidelines that determine who can pronounce death. If the patient is an organ donor, it is necessary to follow policies and procedures appropriate to the organ(s) donated. In addition, if an autopsy is going to be performed as required by law or family request, any invasive tubes or lines must remain in the body. Such devices include intravenous (IV) lines, nasogastric (NG) tubes, tracheostomy appliances, endotracheal tubes, Foley catheters, drainage tubes, and any other invasive device that was used before death.

After death in any setting, any medical equipment or tubes in the body are removed from the room unless an autopsy is to be performed. Any unnecessary items from prior care of the patient are removed from the room, and the room is cleaned. Bathing and dressing the body demonstrate respect and dignity for the deceased and help the family in the grieving process. Proper positioning of the body and covering the body appropriately after death demonstrate respect, because a peaceful last impression of the deceased is important for the family. At this time, it is necessary to ask the family if any special religious or cultural practices need to be followed. Physical care of the body may be dictated by cultural practices. [Box 42.8](#) details preparing a body for the morgue.

Box 42.8

Nursing Care Guideline

Preparing a Body for the Morgue

Background

- Policy regarding postmortem care differs among states and between facilities. Be sure to be familiar with your institution's policy and procedures before care of the body after death.
- It is imperative that the body be treated with the same respect and dignity given during life.
- Care of the body postmortem can be delegated to unlicensed assistive personnel (UAP) with appropriate education regarding institution procedures.
- Dependent on culture, family may wish to take part in final care. Assist the family in appropriate postmortem care as necessary.

Procedural Concerns

Positioning

- The body is placed in a supine position (on the back) in normal anatomic position, to prevent abnormal pooling of the blood.
 - Arms at side (palms down) or across the abdomen
 - Head/shoulders elevated on one pillow (to prevent discoloration of the face secondary to blood pooling)
- Dentures and or other prosthetics are inserted if available to maintain normal anatomic appearance.
- Close the eyes and hold them closed for several seconds so that they remain shut.
- Jewelry is removed (with the exception of a wedding ring, which often is taped in place); check institution policy for specific details.

Medical Tubes/Paraphernalia

- Policies regarding medical equipment (such as, intravenous [IV] lines, nasogastric [NG] tubes, chest tubes, or endotracheal tubes) vary among institutions/states.
 - Some require they remain in/attached to the body exactly as they were at the time of death
 - Some states/institutions allow the medical paraphernalia to be cut to a specified length but require that the tubes still remain in place.
 - Still other facilities/states may allow them to be removed completely.
- Remove any extraneous movable equipment from the room out of respect for the family viewing the body.

Washing the Body

- The family may wish to participate in this procedure or may complete this procedure in private. Health care personnel should abide by their wishes as much as possible.
- Clean any soiled areas on the body (a full bath is not necessary).
- Place absorbent pads under the buttocks (when the muscles relax, urine and feces will be expelled).
- Apply a clean gown.
- Brush the patient's hair.
- Replace and straighten top sheets.
- Remove any soiled linens from the room.

Religious Concerns

- Certain religions may require a specialized person to perform this portion of the procedure, whereas other religions might forbid washing of the body. Accommodation of the family's religious wishes should be made if possible. Regardless, the mortician will ultimately wash the body.
- After the family has left the hospital or health care facility, the body may be wrapped in a **shroud**, a cloth, sheet, or bag, for transportation to the morgue or funeral home.

Documentation Concerns

- Ensure that the death certificate has been signed.
- Follow through with any organ donation arrangements. Ensure adherence to institutional and state policy and procedures.

Identification

- The hospital identification (ID) band is left in place. Many facilities require additional ID; check with institution procedure/policy for specific information, but common locations for ID tags or labels are the ankle/foot and the outer shroud in which the body is wrapped for transport. Personal items not taken by the family are identified and documented.
- Appropriately document all of the procedural applications in a final note on the patient's chart. In addition, be sure to include to whom any personal items were dispersed, the time of body transfer, and any other special circumstances.

Care of the Family at the Time of Death

Skills of interpersonal communication, which include empathy, unconditional positive regard, genuineness, attention, and listening skills, are essential at this time. Nurses must be comfortable “being with” the dying patient and family. Being present, by being in the room or close to the area and through active listening, is an essential part of caring for those at the end of life.

Collaborative care is necessary, because care for the dying is an interdisciplinary activity. Identifying which members of the health care team have developed relationships with the family during the illness and supporting their continued involvement with the family after the death of the patient can allow for enhanced grieving, both for the family and for the health care provider. Continued therapeutic communication by physicians, nurses, social workers, chaplains, and even dietary and housekeeping staff can assist the family in the grieving process.

Another important nursing intervention is to provide the family time with the deceased so that they can say goodbye and begin to let go. Nurses can offer to call for spiritual support in accordance with the wishes of the family. Pastoral care assists in the decision-making process about funeral arrangements as necessary. If the death is expected, funeral arrangements may have already been made, and the funeral home may be contacted by telephone or other means by the nurse or the family.

Bereavement Support

After a death, bereavement support begins immediately. The nurse begins by providing support and compassion, while being present with active listening. Assessment of grief reactions and risk factors for complicated grief is completed at this time. Follow-up bereavement support is provided by phone calls, cards, and possible attendance at funeral services, depending on the care setting. If the bereaved are in need of further support, referral to community bereavement resources (such as, hospice or other support groups) is necessary.

Death of an infant or child is an extremely difficult experience for many parents and families. At the time of death, babies are wrapped snugly in a blanket, and parents are encouraged to hold their child. Siblings are allowed to participate in this process as well. Consideration should be given that the loss of an unborn child may elicit the same response from the family as the death of a newborn. Some states, including New Jersey, have introduced legislation that requires bereavement services to be offered to the family of an infant lost perinatally after 22 weeks gestation (Donaldson, 2016).

When children are close to the deceased, caregivers are encouraged to openly and honestly answer any questions they may have. The child's responses to the loss are evaluated while determining if the child should attend the funeral. If young children are going to attend the funeral, they need to be prepared for what they will see, who will be there, what they may feel, how they may see other people grieving, and what they will be doing during the time that they are at the funeral. It is essential to explain to the child what the body will look like, and the fact that the deceased will not talk, move, or breathe.

Health care providers often fear expressing emotions in front of their patients and families. This fear causes many to avoid discussing potentially difficult topics that are essential to end-of-life care. Nurses and others who work with dying patients need an outlet to express their emotions. For more information, see [“The Nurse: Experiences of Caring for the Dying”](#) section later in this chapter. Some health care providers experience a sense of guilt or failure when they cannot cure their patients, which may lead to lack of communication related to needs at the end of life. Other common fears are because of the uncertainty of making a prognosis and determining appropriate treatment measures for individual patients.

Effective communication includes the need for the powerful skill of listening. Sensitive listening requires energy and involvement and being present physically, mentally, and emotionally.

Evaluation

Evaluation of the nursing care provided to the grieving patient and family, or to the dying patient and family, focuses on the consideration of the goals of that person and the family unit. Careful attention to the specific loss, related factors, and risk factors for potential decreased quality of life are important considerations. People who are grieving need to demonstrate that they can talk about the meaning of their loss, use available support systems, and deal with the loss as they move through the stages of grief. Identification of feelings, any change in health, and effective coping strategies are essential to the grieving process. A return to life and a level of functioning, physically, socially, emotionally, and spiritually, that existed before the loss is evaluated.

For those who are experiencing death anxiety, an ability to discuss their concerns about their death and feelings associated with dying are findings that demonstrate effective nursing interventions and individual coping. Goal setting and gaining a realistic perspective related to the disease process and prognosis are indicators of development toward meeting the goals of nursing care and quality end-of-life care.

LO 42.8 the Nurse: Experiences of Caring for the Dying

In a majority of health care settings, nurses will experience death and loss. Many nurses experience a multitude of losses in their clinical practice, and possibly in their personal lives. Cumulative loss is a succession of loss experienced by nurses who work with those who are dying. When the nurse is exposed to frequent loss and death, available time may be inadequate to resolve grief issues of one patient before another patient dies. Accumulation of loss can result in unresolved grief and potential chronic grief and bereavement (Vachon & Huggard, 2010).

Working with dying patients can create a personal sense of loss and fear about the nurse's own mortality. Some nurses develop defense mechanisms to cope with loss and grief in the practice setting. These defenses allow the nurse to temporarily alleviate the discomfort caused by death and dying. Focusing only on physical care needs while overlooking the emotional or psychosocial nature of nursing care allows a nurse to avoid uncomfortable feelings and fears. These behaviors result in emotional distancing, avoidance, and potential withdrawal from dying patients and their families when supportive care from the nurse is most needed.

A nurse's comfort level with dying patients and families is affected by personality; past experience with loss and grief; and cultural, social, and spiritual belief systems. To effectively care for the dying, nurses need to explore their personal feelings regarding death. Self-exploration and reflection through personal death awareness exercises and discussion of beliefs concerning life and death with friends, peers, co-workers, and pastoral care workers will promote an understanding and acceptance of death as a part of life. Nurses should be aware of their own fears, feelings, responses, and reactions to death and dying so that they have the ability to communicate effectively and to convey caring, acceptance, and respect for patients and families who are experiencing death, loss, and grief. Verbalization of feelings to others and expression of emotions help nurses process their own reactions to the grieving process.

Nurses who experience cumulative losses need to have support systems in place and be able to explore and express their feelings associated with anxiety, loss, and grief. Oncology nurses and those nurses working where there is an increased incidence of death may need additional ongoing support (deWit & Kumajai, 2017). Health care workers' ability to manage grief associated with death may be overlooked with the assumption that they are professionals that know how to cope (Cheung, Kwok, & Desmond, 2016). Effective support systems may be formal, informal, or spiritual, or may be in the form of continuing education in end-of-life care (Vachon & Huggard, 2010). Self-care is an important aspect of the nurse's overall health and ability to handle the stressors of working with the dying patient. Proper diet, exercise, sleep, time for relaxation, and vacations all are aspects of self-care that will strengthen the nurse's ability to continue providing effective care.

LO 42.9 The Role of the Nurse in Organ Donation

Nurses have a role in many aspects of organ donation. Recognizing a potential situation in which organ donation may be a possibility, working collaboratively with the patient/family and other interprofessionals throughout the process. Many health care organizations have an organ donation coordinator or liaison who will act as a resource to the nurse and the rest of the interprofessional team. It is imperative that the nurse is aware of the basic guidelines that warrant a patient's organs viable for transplant so that should the situation arise, the nurse can take the appropriate action by following facility policy. Some organs that may be considered for donation include bone, cartilage, eyes/corneas, fascia, heart, kidneys, liver, and skin ([Lifebanc, 2018](#)).

Summary of Learning Outcomes

LO 42.1 *Describe the process of grief, loss, and bereavement:* Loss is determined by the affected person and is a subjective experience that elicits a grief response. Grief is the emotional response to loss while mourning is considered the outward signs of grief demonstrated by the person based on his or her personal, cultural, and religious or spiritual beliefs. Bereavement is the feelings and expressions that people experiencing loss demonstrate.

LO 42.2 *Discuss dysfunctional loss and grieving:* Dysfunctional loss and grieving include complicated grief, which occurs when a person does not progress through the normal stages of grief, and disenfranchised grief when a person cannot openly grieve a loss.

LO 42.3 *Identify factors affecting the grief and bereavement process:* Various factors including developmental level, gender, socioeconomic status, religion and spirituality, health status of the survivor, the relationship to the deceased and the strength of that relationship, coping styles, concurrent stressors, available support systems, and the type of loss experienced affect the grief and bereavement process.

LO 42.4 *Perform a nursing assessment of patients and their families who are experiencing loss, death,*

grief, and bereavement: Nurses must assess individual patients, as well as families, during the grieving process. Valid and reliable tools have been developed that will allow a complete and thorough assessment.

LO 42.5 *Select nursing diagnoses appropriate for people experiencing death and the grieving process:* Nursing diagnoses for grief and death include: *Grief, Chronic Sadness, and Death Anxiety.*

LO 42.6 *Plan appropriate goals and outcomes for dying patients and their families:* Goals for dying patients and their families relate to the specific nursing diagnosis and to the stage of grieving.

LO 42.7 *Implement and evaluate nursing care plans with nursing interventions appropriate for patients and families experiencing death and grief:* Nursing care for patients and families experiencing death and loss is individualized. Therapeutic communication, being present for the patient and family, treating symptoms that cause discomfort, and educating the patient and family are all part of nursing care. Evaluation of the care plan is ongoing, because changes may occur rapidly when a patient is near death.

LO 42.8 *Examine the effects death and loss may have on nurses:* Nurses experience death and loss on a recurring basis while providing care in most any health care setting. Working with dying patients requires nurses to develop their own awareness and understanding of death and dying, as well as loss and grief.

LO 42.9 *Explore the role of the nurse in organ donation:* Nurses, as a part of the interprofessional team, collaborate, screen, and support situations in which organ donation may be possible.

Review Questions

1. While caring for a female patient with advanced multiple sclerosis, the nurse is discussing the difference between hospice and palliative care. Which statement by the patient indicates understanding of the difference between hospice care and palliative care?
 - a. "I will need to get hospice care if I want my symptoms controlled."
 - b. "I can get palliative care right now—even though I am not going to die anytime soon."
 - c. "My doctor has to make the decision if I have hospice care."
 - d. "I can't get any other treatments, even if they are experimental if I choose palliative care."
2. The nurse is orienting new staff to a clinical unit that provides palliative care. A new employee asks what "grief" is exactly. Which statement indicates that the nurse has correctly defined grief?
 - a. The emotional response to a loss
 - b. The outward, social expression of a loss
 - c. The depression felt after a loss
 - d. The loss of a possession or loved one
3. The nurse has been caring for a 65-year-old male patient who has just died. In planning for follow-up bereavement care, the nurse knows

that which person is at risk for disenfranchised grief?

- a. A daughter who lives in a different state
- b. The son who was with the client when he died
- c. An estranged ex-wife of the patient who lives nearby
- d. The 16-year-old grandchild of the patient

4. The mother of two children, 8 and 10 years of age, has just experienced the death of her mother, the children's grandmother. The mother is concerned about the emotional impact attending the funeral may have on her children. She asks the nurse what she should do in relation to her children attending the funeral. What is the nurse's best response?

- a. "Take them to the funeral—they need closure, and seeing their grandma in the casket will assist them in knowing that she has died and will not return. Many children attend funerals in today's society."
- b. "Do not take them to the funeral—they are too young to be exposed to the emotions that are demonstrated at funerals. Many children who attend funerals have adverse psychological reactions."
- c. "Talk to your children about how they feel about attending the funeral and encourage them to ask questions and talk about their concerns. If they want to go, they will need to

be prepared for what will happen at the funeral.”

- d. “Talk to your children about what your mother meant to you and how much she cared for them as her grandchildren, and then see if they really want to attend the funeral. If they want to go it is okay to take them.”
5. The nurse has been caring for a patient who has just died. What is the preferred outcome in caring for the body after death?
- a. Make sure the body is sent to the morgue within an hour after death.
 - b. Have the family members participate in the bathing and dressing of the deceased.
 - c. Notify in person or by phone all family and team members immediately after the patient's death.
 - d. Demonstrate respect for the body and provide a clean, peaceful impression of the deceased for the family.
6. Several theorists have identified stages of the grieving process. The nurse understands these stages and knows that people progress through them in an individualized manner. Which statements are true regarding the steps of the grieving process? *Select all that apply.*
- a. There is a definite “timetable” or period of time specific to each stage of the grieving

process.

- b. Nursing interventions are generalized across all stages of the grieving process.
 - c. Tasks to be achieved at each stage have been identified by each theorist.
 - d. There is a common stepwise progression through each stage of the grieving process.
 - e. Not all individuals will experience all stages of grief.
7. Which statement is true regarding advance directives?
- a. Advance directives apply only when the person has a chronic illness.
 - b. Advance directives should be drawn up by family members of people who are incompetent.
 - c. Discussion of advance directives is a nursing responsibility.
 - d. Advance directives should be kept in a safety deposit box until the person dies.
8. In which scenario is hospice care provided?
- a. Only in the homes of the terminally ill
 - b. For any terminal illness that requires symptom control
 - c. For cancer patients only in their last weeks of life

- d. Only in hospital settings based on the seriousness of the illness
9. In caring for a dying patient, what is an appropriate nursing action to increase family involvement?
- a. Insisting that all bedside care be performed by the family
 - b. Asking family members what they would like to do for their loved one and allowing them to participate
 - c. Expecting the family to be able to perform the patient's daily needs and to meet them consistently
 - d. Refusing all assistance from the family, to decrease family stress
10. The nurse cares for dying patients and understands that "nearing death awareness" is a phenomenon evident by which patient statement(s)? *Select all that apply.*
- a. "Where are my shoes? I need to get ready for the trip."
 - b. "Is my daughter from California going to come and visit before I die?"
 - c. "When do you think that I am going to die?"
 - d. "I was just talking to my daughter (deceased)."
 - e. "How much longer can I live without food or water?"

APPENDIX A

Abbreviations, Roots, Prefixes, and Suffixes

Commonly Used Abbreviations

Abbreviation	Definition
ac	before meals
ACLS	advanced cardiac life support
ad lib	as desired
ADA	American Diabetes Association; Americans with Disabilities Act
ADD	attention deficit disorder
ADLs	activities of daily living
Afib	atrial fibrillation
AIDS	acquired immunodeficiency syndrome
ALS	advanced life support; amyotrophic lateral sclerosis
AM, a.m.	morning
AMI	acute myocardial infarction
ASD	atrial septal defect
AST	aspartate aminotransferase (formerly SGOT)
AV	arteriovenous; atrioventricular
BCLS	basic cardiac life support
BE	barium enema
BID, bid, b.i.d.	twice a day (bis in die)
BM	bowel movement
BMI	body mass index
BMR	basal metabolic rate
BP	blood pressure
BPH	benign prostatic hypertrophy
bpm	beats per minute
BPM	breaths per minute
BR	bedrest
BRP	bathroom privileges
BS	bowel sounds
BSA	body surface area
BSC	bedside commode
BSE	breast self-examination
BUN	blood urea nitrogen
Bx	biopsy
Ā	with
C	centigrade
CABG	coronary artery bypass graft
CAD	coronary artery disease
CAT	computerized (axial) tomography scan
CBC	complete blood count
CCU	coronary care unit; critical care unit
CF	cystic fibrosis
CHD	congenital heart disease; coronary heart disease
CK	creatinine kinase
CMV	cytomegalovirus
CNS	central nervous system; clinical nurse specialist
c/o	complaint of
CO	carbon monoxide; cardiac output

Abbreviation	Definition
CO ₂	carbon dioxide
COPD	chronic obstructive pulmonary disease
COX	cyclooxygenase
CP	cerebral palsy
CPAP	continuous positive airway pressure
CPK	creatine phosphokinase
CPR	cardiopulmonary resuscitation
CSF	cerebrospinal fluid
CT	computed tomography
CVA	cerebrovascular accident; costovertebral angle
CVP	central venous pressure
D&C	dilation (dilatation) and curettage
dc, DC, D/C	discontinue
DIC	disseminated intravascular coagulation
diff	differential blood count
DKA	diabetic ketoacidosis
dL	deciliter
DM	diabetes mellitus; diastolic murmur
DNA	deoxyribonucleic acid
DNR	do-not-resuscitate
DOA	dead on arrival
DOB	date of birth
DOE	dyspnea on exertion
DPT	diphtheria-pertussis-tetanus
DRG	diagnosis-related group
DSM-5	<i>Diagnostic and Statistical Manual of Mental Disorders</i>
DT	delirium tremens
DVT	deep vein thrombosis
D ₅ W	dextrose 5% in water
Dx	diagnosis
EBV	Epstein-Barr virus
ECG, EKG	electrocardiogram; electrocardiograph
ECHO	echocardiography, echocardiogram
ECT	electroconvulsive therapy
ED	emergency department
EDD	estimated date of delivery
EEG	electroencephalogram; electroencephalograph
EENT	eye, ear, nose, and throat
ELISA	enzyme-linked immunosorbent assay
EMG	electromyogram
EMS	emergency medical service
EMT	emergency medical technician
ENT	ear, nose, and throat
EBP	evidence-based practice
ER	emergency room (hospital)
ERV	expiratory reserve volume
ESR	erythrocyte sedimentation rate

Abbreviation	Definition
ESRD	end-stage renal disease
ET	endotracheal tube
ETOH	ethyl alcohol
F	Fahrenheit
FBS	fasting blood sugar
FEV	forced expiratory volume
FH, Fhx	family history
FHR	fetal heart rate
FOB	foot of bed
FTT	failure to thrive
fx	fracture
GB	gallbladder
GC	gonococcus; gonorrheal
GI	gastrointestinal
GSW	gunshot wound
gtt	drops (guttae)
GU	genitourinary
Gyn	gynecology
H&P	history and physical
HA	headache
HAV	hepatitis A virus
Hb, HGB	hemoglobin
HBV	hepatitis B virus
HCG	human chorionic gonadotropin
HCO ₃	bicarbonate
HCT	hematocrit
HDL	high-density lipoprotein
HEENT	head, eye, ear, nose, and throat
HF	heart failure
HIV	human immunodeficiency virus
HOB	head of bed
h/o	history of
HOH	hard of hearing
H ₂ O	water
H ₂ O ₂	hydrogen peroxide
HR, hr	heart rate; hour
HSV	herpes simplex virus
HT, ht, hgt	height
HTN	hypertension
hx, Hx	history
I&O	intake and output
IBW	ideal body weight
ICNP	International Classification for Nursing Practice
ICP	intracranial pressure
ICU	intensive care unit
Ig	immunoglobulin
IM	intramuscular

Abbreviation	Definition
INR	international normalized ratio
IUD	intrauterine device
IV	intravenous
IVP	intravenous pyelogram; intravenous push
IVPB	intravenous piggyback
KCl, K	potassium chloride
KG, kg	kilogram
KUB	kidney, ureter, and bladder
KVO	keep vein open
L	Liter; left
lab	laboratory
lb, #	pound
L&D	labor and delivery
LDL	low-density lipoprotein
LE	lower extremity; lupus erythematosus
LMP	last menstrual period
LOC	level of consciousness
LP	lumbar puncture
LR	lactated Ringer's
LTG	long-term goal
LVH	left ventricular hypertrophy
MAP	mean arterial pressure
mcg	microgram
MD	muscular dystrophy
MDI	medium-dose inhalant; metered-dose inhaler
mEq	milliequivalent
mg	milligram
MI	myocardial infarction
mL, ml	milliliter
mm Hg	millimeters of mercury
MMR	maternal mortality rate; measles-mumps-rubella
MRI	magnetic resonance imaging
MVA	motor vehicle accident
N/A	not applicable
NaCl, Na	sodium chloride
NANDA-I	North American Nursing Diagnosis Association–International
NAS	no added salt
N&V, N/V	nausea and vomiting
NG	nasogastric
NIC	<i>Nursing Interventions Classification</i>
NICU	neonatal intensive care unit
NKA	no known allergies
NKDA	no known drug allergies
NOC	<i>Nursing Outcomes Classification</i>
NPO	nothing by mouth (non per os)
NSAID	nonsteroidal antiinflammatory drug
NSG, nsg	nursing

Abbreviation	Definition
NSR	normal sinus rhythm
O ₂	oxygen
OB	obstetrics
OBS	organic brain syndrome
OOB	out of bed
OR	operating room
OTC	over-the-counter
oz	ounce
̄	after
PAC	premature atrial contraction
PACU	postanesthesia care unit
PALS	pediatric advanced life support
pc	after meals
PCA	patient-controlled analgesia
PCP	primary care provider
PE	physical examination; pulmonary embolism
PEEP	positive end-expiratory pressure
PERRLA	pupils equal, regular, react to light and accommodation
PET	positron emission tomography
PICC	peripherally inserted central catheter
PID	pelvic inflammatory disease
PKU	phenylketonuria
p.m.	evening
PMH	past medical history
PMI	point of maximal impulse
PMN	polymorphonuclear neutrophil leukocytes (polys)
PMS	premenstrual syndrome
PO	orally (per os); by mouth
POD	postoperative day
PRN	as required (pro re nata); as needed
pt	pint
PT	prothrombin time; physical therapy
PTT	partial thromboplastin time
PVC	premature ventricular contraction
q	every
Qh, qhr	every hour
qid	four times a day
qt	quart
R	respiration; right
RBC	red blood cell
RDA	recommended daily/dietary allowance
RDS	respiratory distress syndrome
Rh	rhesus factor in blood
RNA	ribonucleic acid
R/O	rule out
ROM	range of motion
ROS	review of systems

Abbreviation	Definition
RR	recovery room; respiratory rate
R/T	related to
RX, Rx	prescription
̄	without
SCD	sequential compression device
SGOT	serum glutamic oxaloacetic transaminase
SGPT	serum glutamic pyruvic transaminase
SIDS	sudden infant death syndrome
SLE	systemic lupus erythematosus
SOB	shortness of breath
S/P, s/p	status post
s/s	signs and symptoms
Staph	staphylococcus
stat	immediately (statim)
STD	sexually transmitted disease
STG	short-term goal
STI	sexually transmitted infection
Strep	streptococcus
Sx	symptoms
T	temperature; thoracic
T&A	tonsillectomy and adenoidectomy
TB	tuberculosis
TBL, tbsp, T	tablespoon
TENS	transcutaneous electrical nerve stimulation
TIA	transient ischemic attack
tid	three times a day
TMJ	temporomandibular joint
TPN	total parenteral nutrition
TPR	temperature, pulse, and respiration
TSE	testicular self-examination
TSH	thyroid-stimulating hormone
tsp, t	teaspoon
Tx	treatment
UA	urinalysis
UAP	unlicensed assistive personnel
URI	upper respiratory infection
UTI	urinary tract infection
VC	vital capacity
vol	volume
VS, v.s.	vital signs
VSD	ventricular septal defect
VTE	venous thromboembolism
WBC	white blood cell
WNL	within normal limits
WT, wt, wgt	weight

NOTE: Abbreviations in common use can vary widely from place to place. Each institution's list of acceptable abbreviations is the best authority for its records.

From *Mosby's dictionary of medicine, nursing, and health professions*, ed 10, St. Louis, 2017, Elsevier.

Roots

Root	Definition
aden/o	gland
adip/o, lip/o, steat/o	fat
albin/o, leuk/o, leuc/o	white
angi/o, vas/o	vessel
anter/o	front, before
arteri/o	artery
arthr/o	joint
audi/o	hearing
blast/o	embryonic
brachi/o	arm
bronch/o	airway
carcin/o	cancer
cardi/o	heart
cephal/o	head
cerebr/o, encephal/o	brain
cervic/o	neck
chol/e	bile, gall
cholecyst/o	gallbladder
chondr/o	cartilage
cirrh/o, jaund/o, xanth/o	yellow
cleid/o	clavicle
col/o	colon
colp/o	vagina
cost/o	rib
crani/o	skull
crypt/o	hidden
cutane/o, dermat/o, derm/o	skin
cyan/o	blue
cyst/o	urinary bladder, cyst
cyt/o	cell
dactyl/o	finger or toe
elast/o	elastic
enter/o	intestines
erythem/o, erythr/o, rube/o	red
gastr/o	stomach or ventral
glomerul/o	glomerulus
gloss/o	tongue
gon/o	genitals
gynec/o, gyn/o	female
hem/o, hemat/o	blood
hepat/o	liver
hist/o	tissue
hol/o	entire, complete
home/o	like, similar
hydr/o	water, liquid, hydrogen
hypn/o	sleep

Root	Definition
hyster/o, metr/o	uterus
idi/o	distinct, unknown
ile/o	ileum
ili/o	ilium, flank
irid/o	iris of the eye
kerat/o	horny substance, cornea
labi/o	lip, labial
lact/o	milk, lactic acid
laryng/o	larynx
later/o	side or lateral
lith/o	stone
lymph/o	lymph
mamm/o, mast/o	breast
medi/o	middle
medull/o	medulla
melan/o	black, darkness
men/o	menses
menig/o	meninges
my/o	muscle
myel/o	spinal cord, marrow
myring/o	eardrum
nas/o, rhin/o	nose
necr/o	death
nephr/o	kidney
neur/o	nerve, nervous tissue
nucle/o	nucleus
ocul/o, ophthalm/o	eye
odont/o	teeth
onc/o	tumor, mass
onych/o	nail
oophor/o, ovari/o	ovary
orchid/o	testicle
oste/o	bone
ot/o	ear
path/o	disease
ped/o	foot, children
phag/o	ingestion, eating
phleb/o	vein
pneum/o	air, breath
poster/o	behind, posterior
proct/o	anus, rectum
proxim/o	near
psych/o	mind, mental
py/o	pus
pyel/o	pelvis
pylor/o	pylorus
rachi/o	spine

Root	Definition
radi/o	radioactive
ren/o	kidney
salping/o	tube
scler/o	hard
splen/o	spleen
squam/o	scale
thorac/o	chest, chest wall
thromb/o	blood clot
tox/o	poison
trache/o	trachea, windpipe
trich/o	hair
ur/o	urine
ureter/o	ureter
urethr/o	urethra
ventr/o	abdomen, ventral
vesic/o	bladder, vesicle
viscer/o	body organs

Prefixes

Prefix	Definition
a-	before, without
ab-	away from
acu-	clarity, sharpness
ad-	toward
all-, allo-	divergence
ambi-	both
an-	not, without
ante-	before
anti-	against
arch-, arche-, archi-	first, beginning
aur-, auro-	ear
auto-	self
bar-, baro-	weight, pressure
bi-, di-, diplo-	two, double
bili-	bile
bio-	life
brady-	slow
bucco-	cheek
caud-	tail
chemo-	chemical
circum-	around
co-	together
contra-, counter-	against
cryo-	cold
de-	from, removal
demi- hemi-, semi-	half
dia-	through
dis-	removal, separation
duct-	carry
dys-	abnormal, difficult, painful
ecto-	outside
endo-, ento-, im-, in-, intra-	within
epi-	upon, over
episio-	perineum
esthesi-	sensation, feeling
etio-	causation
eu-	normal, good, true
ex-	out
exo-	outside of
extra-	outside, in addition to
fasci-, fascio	fibrous membrane, band
fibro-	fibrous tissue
hetero-	other, different
homo-, homeo-	same
hyper-	high, increased, above
hypo-, sub-	under, decreased

Prefix	Definition
iatro-	medicine, healing
immuno-	free from, immune
in-, im-	not
infra-, sub-	below, under
inter-	between
intra-	within
intro-	on the inside
iso-	equal, same
juxta-	near
macro-	large
mal-	bad, poor
megalo-	abnormally large
meso-	middle
meta-	beyond, over
micro-	abnormally small
mono-, uni-	one
multi-	many
neo-	new
nocto-	night
non-	not
oligo-	little
oo-	egg
ortho-	straight, correct
pan-	all
para-	beside, near
per-	by, through
peri-	around
poly-	many
post-	after, behind
pre-, pro-	before, in front of
prim-	first
pseudo-	false
quad-	four
re-	back, again
retro-	backward, behind
super-	above, excessive
supra-	above
syn-, sym-	together
tachy-	fast
trans-	through, across
tri-	three
ultra-	beyond
un-	not

Suffixes

Suffix	Definition
-ac, -al, -ary, -eal, -ic, -ory, -ous	pertaining to
-acro	extremity, extreme point
-agogue	producer, secretor
-agra	sudden, severe pain
-algia, dynia	pain
-ase	enzyme
-asis, -ia, -ism, -osis	condition
-asthenia	weakness
-ather, -athero	fatty plaque
-cardia	action of the heart
-cardio	heart
-cele	swelling, hernia
-centesis	puncture of a cavity
-cide	destroying, killing
-clysis	washing, flushing
-crine	secrete
-crit	separate
-cyte	cell
-desis	binding, fixation
-ectasis	expansion, dilation
-ectomy	cutting out
-emia	blood condition
-form	in the shape of
-gen, -genic	produce, production
-gram	writing, record
-graph	instrument used to write or record
-graphy	process of writing or recording
-iatic	medicine
-ics	body of knowledge
-itis	inflammation
-lith	stone
-logy	study of
-lysis	dissolving, separating
-malacia	softening
-megaly	abnormal enlargement
-meter	measuring instrument
-metry	to measure
-odynia	pain
-oid	resembling
-ole, -ule	small
-oma	tumor
-para	to bear, give birth
-pathy	disease, feeling
-penia	deficiency
-pexy	surgical fixation
-phagia	eating, ingestion

Suffix	Definition
-phasia	speech
-philia, -phile, -philic	affinity for
-plasia	formation, molding
-plasty	plastic repair
-plegia	paralysis
-pnea	breathing
-poiesis	growth, formation
-rrhage, -rrhagia, -rrhagy	burst forth
-rrhaphy	surgical repair
-rrhea	flow, discharge
-rrhexis	rupture
-scope	instrument for viewing
-scopy	visual examination
-stasis	stoppage of flow
-stenosis	narrowing
-stomy	surgical opening
-tome, -tomy	cutting
-tripsy	crushing
-trophy	nutrition, growth
-tropia, -tropic	deviation from normal, have influence on
-uria	presence of a substance in urine

APPENDIX B

Helpful Hints for Answering NCLEX-Style Questions

Compiled from National Council of State Boards of Nursing. (2018). *Alternate item formats FAQs*. Retrieved from <https://www.ncsbn.org/9010.htm>

Dickison, P. (2018). *Next generation NCLEX (NGN) overview*. Special session presented at the NLN Education Summit 2018, Chicago, IL.

Mastering the ability to analyze NCLEX-style questions is one of the greatest challenges new nursing students face as they begin their professional education. It requires strong foundational knowledge in the physical and social sciences and nursing, as well as advanced critical thinking skills and sound clinical judgment. Most nursing students enter college highly qualified with a history of excellent grades, so they initially focus more on grades than the much more important issues of learning and patient safety. Ultimately, nursing students must overcome the tendency to focus on their GPA and instead concentrate more on understanding, applying, and synthesizing nursing content to provide safe, patient-centered care.

NCLEX questions focus primarily on the responsibilities of the nurse and how those relate to providing comprehensive, informed care. There are a variety of item formats that will appear on the 2019–2021 NCLEX-RN licensing exams. Although research is currently being conducted on new alternative item formats, no additional or different types of questions are anticipated to appear on the NCLEX-RN exam until 2022, at the earliest (Dickison, 2018). Next Generation NCLEX (NGN) up-to-date resources can be accessed at <https://www.ncsbn.org/11435.htm>. Types of NCLEX exam questions (National Council of State Boards of Nursing, 2018) include the following:

- Multiple-choice with only one correct answer out of four possible options

- Multiple-response that require students to choose one, more than one, or all of the possible options
- Ranked, priority-based that ask students to put a list in order of importance in a given situation
- Fill-in-the-blank or “hot spot” that require calculation of a dosage or identification on an illustration
- Medical record review that present a patient problem to solve
- Audio and graphics that ask for an aural or visual review of content prior to selecting the best answer

This appendix seeks to provide fundamentals-of-nursing students with strategies for answering multiple-choice questions correctly.

Most faculty-developed NCLEX-style exam questions focus on some aspect of the nursing process. They expect the student to know what data are significant in a given situation or what additional information is needed. Some questions ask the student to prioritize care. Others ask about what can be delegated, or what interventions should be implemented. Still others require students to identify how best to evaluate changes in a patient's condition or situation. NCLEX-style questions contain a stem (the actual question), the correct response (answer), and various numbers of distractors (incorrect responses) if they are multiple-choice or multiple-response test items.

Some general guidelines for answering NCLEX-style multiple-choice questions include the following:

- Read the stem and the response options of the question through once, without answering the question. Read the stem again, and underline,

circle, or note key words that provide a context in which the item is to be answered. Read the possible responses, and cross out or ignore any that are obviously not correct. Then reread the stem a third time to determine which of the responses is **best in the identified situation** before choosing an answer.

- Eliminate all responses that contain information you recognize as incorrect before selecting an answer.
- Avoid reading into the stem of the question by assuming additional information that is not in the test item.
- Look for similarity in the response options provided for multiple-choice questions. When only one response is to be chosen, selecting an answer that is the same as another option worded differently is obviously going to be wrong.
- Note qualities of the patient or subject of the question, such as patient age, disease process, diagnostic test, or specific circumstance (i.e., preoperative status).
- Answer questions according to book, class, or laboratory instructional materials rather than by referencing experiences with relatives, friends, or from observing nurses or unlicensed assistive personnel (UAP) in the clinical setting.
- Focus on key words or phrases in the stem that indicate timing or importance. These may include first, immediately, urgent, most critical,

best, next, of greatest concern, or highest priority.

- If there is an indication of priority, use Maslow's hierarchy-of-needs theory or the ABCs of health care facility cardiopulmonary resuscitation (CPR) to decide on the correct response.
- Remember that physiological needs are the first priority according to Maslow, followed by safety, love and belonging, esteem, and self-actualization. See [Fig. 1.6](#) and [Table 8.1](#) in the text for further information on Maslow's theory as it relates to nursing.

Examples

1. Which action would the nurse undertake **first** when beginning to **formulate a patient's plan of care**?
 - a. List possible treatment options
 - b. Identify realistic outcome indicators
 - c. Consult with health care team members
 - d. Rank patient concerns from assessment data

*In this question, the key word is **first**, indicating a need to pay attention to timing, and the focus is **formulating a patient's care plan**. All of the responses are actions that the nurse may undertake; however, the question is asking which action comes **first**.*

The correct response is **d**. Prioritizing or ranking patient needs precedes the identification of outcome indicators, consulting with team members, or consulting with interdisciplinary team members.

2. A patient is being discharged from the hospital with a new ileostomy. The patient expresses **concern about caring for the ostomy**. Before hospital discharge, it is **most important** for the nurse to coordinate with which member of the health care team?
- Wound ostomy continence nurse
 - Home healthcare nurse
 - Primary care provider
 - Registered dietitian

*Key phrases in this stem are **most important** and **concern about caring for the ostomy**. These indicate a need to address priority and focus on a specific patient circumstance.*

The correct answer is **a**. The wound ostomy continence nurse (WOCN) is the most important person to contact to schedule teaching sessions and follow-up care. This nurse specialist is certified in the treatment of patients who have a bowel or bladder diversion. Although team input is important, the contribution of the WOCN is paramount to help the patient achieve competence and comfort with self-care before discharge.

- In most cases, avoid responses that include the words “always” or “never” or those that imply limits with words, such as “all” or “only.” Each patient situation is unique and requires the nurse to determine what is most appropriate in that specific context.
- Exceptions to this may be safety-related circumstances such as the following:
 - “Always” is appropriate in a situation such as checking patient identity before administering medications.
 - “Never” is applicable if a student is asked about giving a medication by a

route that is not recommended or safe.

Other than in these types of safety situations, options with the words “always” or “never” are rarely correct.

Examples

1. What would be the **best** therapeutic response to a patient who expresses **indecision** about recommended chemotherapy treatments?
 - a. “Can you tell me why you are undecided?”
 - b. “It is always a good idea to have chemotherapy.”
 - c. “What are you thinking about the treatments at this point?”
 - d. “You should follow whatever your health care provider recommends.”

*The key words in this question stem are **best** and **indecision**. Response **b** can immediately be omitted as a response option because it contains the word **always** in what is not specifically a safety-related circumstance.*

The correct response is **c**. Asking open-ended questions allows patients to share freely on a subject. “Why” questions, using closed-ended questions, and giving advice (such as, “It is always a good idea to have chemotherapy.”) are all examples of nontherapeutic communication that limit patient reflection and sharing on topics of concern.

2. In which scenario is **hospice care** provided?
 - a. Only in the homes of the terminally ill
 - b. For any terminal illness that requires symptom control
 - c. For cancer patients only in their last weeks of life
 - d. In critical care units for the seriously ill

*This question focuses on a specific context (**hospice care**), and two of the distractors contain the word*

only, which is restrictive and not applicable. Those two possible responses can be omitted immediately.

The correct answer is **b**. Hospice care is provided in a variety of settings, including home care, freestanding inpatient units, hospitals, long-term care facilities, and prisons, as well as to the homeless, for patients with any disease or illness that has been determined to be life-limiting (prognosis of 6-month survival). Any patient who is experiencing symptoms—physical, psychological, or spiritual—can benefit from hospice support and symptom control at the end of life.

- If there is a response that refers to assessment, that most often will be the correct answer. Assessment is the first step of the nursing process that guides the actions of the health care team. The item response may not use the word “assess” specifically, but may use words or phrases (such as look for, observe, listen, check, verify, identify, recognize, determine, note, gather, or collect).
- Before selecting a response that is similar to “Notify the patient's primary care provider,” consider if any of the other options indicates a nursing action that would provide pertinent patient data that should be collected or addressed before calling the physician or nurse practitioner.

Examples

1. While auscultating a patient's lungs, the nurse notes diminished breath sounds at the base of the right lung. What action should the nurse take next?
 - a. Refer the patient for a chest x-ray.

- b. Listen to the base of the patient's left lung.
- c. Palpate the patient's lung fields bilaterally.
- d. Notify the patient's primary care provider (PCP).

*This question illustrates the concepts of recognizing alternative words for assessment (in this case, **listen**) and **an action that should be carried out before notifying the patient's PCP.***

The correct response is **b**. When auscultating a patient's lungs, the nurse should follow a pattern that compares lung fields side to side in each area, making listening to the base of the patient's left lung the next step for this nurse to take. Referring the patient for an x-ray, palpating the patient's lung fields, and notifying the patient's physician might be indicated later, depending on the outcome of the full respiratory assessment.

2. The nurse is caring for a 6-year-old patient in the emergency department who just had a full left leg cast placed for a fracture. As the nurse is reviewing the discharge instructions with the patient's mother, she states, "You don't have to go over those. I'll read them at home." What should the nurse do?

- a. Contact the nurse practitioner or physician immediately.
- b. Consider the possibility of health literacy limitations and assess further.
- c. Stop the teaching, because the mother obviously has taken care of casts before.
- d. Explain to the mother that reading the instructions with her and her child is required.

*This question illustrates an **alternative wording for PCP** and actually uses the word "**assess**," even though it is not the first word in the answer.*

The correct response is **b**. The patient's mother may have limited reading skills or health literacy and should be further assessed. Contacting the nurse practitioner or physician in this situation would not be appropriate, because ensuring that the patient and family understand discharge instructions is the

responsibility of the nurse. Assuming that the mother has taken care of casts in the past may be inaccurate. Stating that reading the instructions with the nurse is a requirement does not ensure that the patient or mother comprehend the instructions.

Ultimately the keys to analyzing and answering NCLEX-style multiple choice questions are as follows:

1. Knowing foundational information
2. Determining the subject, focus, and/or circumstance of the stem
3. Recognizing the priority, context, and nuances of each possible response

Practice taking as many NCLEX-style questions as possible. Mastering the art of applying nursing knowledge to patient care situations enhances your clinical decision-making skills and enables you to provide safe patient care now and for the rest of your nursing career!

Glossary

abnormal reactive hyperemia The persistent redness that occurs during a stage I pressure ulcer due to excessive vasodilation caused by pressure.

absorption Movement of smaller elements through the walls of the digestive tract and into the blood. The passage of a drug from the administration site into the bloodstream.

abstinence Voluntarily avoidance of sexual intercourse.

abuse Offensive, harmful, or injurious act toward an individual that can pose a direct safety threat. The four major types of abuse are physical, psychological/emotional, sexual, and financial.

accidents Incidents that occur at random and may be unavoidable.

accommodation Changing the pattern of behavior when encountering new similar objects. The ability of the eyes to focus on near objects.

accountability The concept of being answerable for one's actions.

acculturation Cultural change achieved through the exchange of cultural features resulting from firsthand contact between groups.

accuracy To represent something in a true and correct way.

acid A chemical that releases hydrogen ions.

activated partial thromboplastin time Coagulation blood test used to detect bleeding disorders caused by abnormalities of the intrinsic clotting system and to monitor the effectiveness of heparin therapy.

active listening A specific communication technique in which one fully concentrates on what the other is saying in a conscious

effort to fully understand the other.

active range of motion Demonstration of full, independent movement of each joint.

active transport The movement of a solute from areas of lower to higher concentration that requires energy.

activities of daily living (ADLs) Activities that include bathing, mouth care, grooming, toileting, dressing, and eating.

acute illness An illness typically characterized by an abrupt onset and short duration (<6 months).

acute pain Pain that lasts for less than 6 months.

acute wound A wound that progresses through the phases of wound healing in a rapid, uncomplicated manner.

adaptation The process of adjusting schemes in response to stimuli within the environment.

adaptive cognition The idea that thought is more responsive to context and less constrained by the need to find only one answer to a question.

addiction A psychological or emotional dependence on a prescribed medication or illicit drug.

a-delta fibers Large-diameter, myelinated fibers with rapid conduction that cause sharp, acute pain.

adjuvant medications Medications that work synergistically with standard pain medications to enhance pain relief and to treat the side effects of the medications.

advance directives Consists of three documents: (1) living will, (2) durable power of attorney, and (3) health care proxy, commonly referred to as a *durable power of attorney for health care*.

Advanced Practice Registered Nurse (APRN) A registered nurse who has met advanced educational and clinical practice requirements at a minimum of a master's level and provides at least some level of direct care to patient populations.

adventitious breath sounds Abnormal sounds that originate in the lungs and airways.

adverse effects Severe, unintended, unwanted, and often unpredictable drug reactions.

advocacy Supporting or promoting the interests of others or of a cause greater than oneself.

advocate Someone who supports and promotes the interests of others.

aerobic exercise Physical activity that requires increased work by the heart and lungs for oxygen metabolism to produce energy.

afebrile Maintaining normal body temperature between 36.5° to 37.5° C (97.6° to 99.6° F).

affective domain A form of learning that recognizes the emotional component of integrating new knowledge.

afterload The resistance that has to be exceeded for the ventricle to eject the blood during systole.

agents of disease Causes of a disease.

agnostic A person who believes that the nature or existence of God is unknowable.

airborne transmission Microorganisms are dispersed by air currents and inhaled or deposited on the skin of a susceptible host.

airway obstruction A potentially life-threatening emergency caused by blockage of the pharynx either by the tongue or another object.

alanine aminotransferase (ALT) An enzyme found primarily in the liver and also found in the kidneys, heart, and skeletal muscle.

albinism A congenital loss of pigmentation characterized by a generalized lack of melanin pigment in the eyes, skin, and hair or, in rare instances, in the eyes alone.

albumin The major plasma protein, primarily responsible for maintaining fluid balance by providing colloidal osmotic pressure in the blood.

aldosterone A hormone that acts on the distal convoluted tubule of the kidney to increase the reabsorption of water and sodium back into the bloodstream.

algor mortis A drop in body temperature as the body begins to cool after death.

alkaline phosphatase (ALP) An enzyme found primarily in the liver levels, which is a useful indicator of liver and bone disease.

allergic reactions Unpredictable immune responses to medications.

allostasis The means by which homeostasis is reestablished. Its purpose is to assist the body in maintaining stability.

alopecia Permanent or temporary hair loss.

Alzheimer's disease The most common type of dementia, in which protein fragments called amyloid plaques build up between the nerve cells of the brain, blocking electrical and chemical connections between neurons.

Ambu bag Resuscitator bag that is used to assist ventilation.

ambulatory care Care that takes place in a physician's office or outpatient clinic.

amino acids The “building blocks” of proteins that must be consumed in food every day.

amyloid plaques Protein fragments.

anabolism The use of energy to change simple materials into complex body substances and tissue.

anaerobic exercise Physical activity that does not require oxygen metabolism.

analgesic Pain-reducing medication.

analytic epidemiology Generates a hypothesis of why the disease might be occurring in the community and then tests the hypothesis.

anaphylactic reaction A severe allergic reaction.

anastomosis The surgical joining of two structures such as ducts, blood vessels, or bowel segments.

anesthesia An inhaled or injected pharmacologic agent that makes the patient insensitive to pain and sensation during a procedure or surgery.

anger An emotion that involves antagonism toward another person or situation. It is evoked when an individual feels wronged.

angina pectoris The crushing chest pain that is the first indication of an oxygen-deprived heart.

angioplasty The balloon surgery that flattens fatty deposits to open blood flow in blocked arteries.

anonymity A person's identity or personal information is not known.

anorexia A loss of appetite by patients experiencing illness or side effects from allergies, medications, or treatments, such as chemotherapy, that suppresses the desire to eat.

anorexia nervosa A very serious disorder in which the person exhibits life-threatening practices as a result of an altered mental state. There is a distortion of body image with the intense fear of gaining weight or being viewed as "fat," despite the fact that the individual's weight is less than healthy or normal.

anorgasmia Inability to achieve orgasm.

anosmia The complete loss of the sense of smell.

antagonism A drug's effect is decreased by taking it with another substance.

anthropometry The study of measurements of the human body.

antibodies Immunoglobulin molecules that recognize foreign invaders.

anticipatory grief The cognitive, affective, cultural, and social reactions to an expected death, felt by the patient as well as family members and friends.

antidiuretic hormone A hormone secreted by the pituitary gland that maintains serum osmolality by controlling the amount of water excreted in the urine.

antiembolism hose Tightly fitting elastic stockings that are used to promote blood flow of venous return and prevent edema in the lower extremities, deep vein thrombosis, venous stasis, and pulmonary emboli.

antigen Protein molecules on the surface of foreign invaders or nonliving substances such as toxins, chemicals, drugs, or particles that trigger the immune response.

anuria The failure of the kidneys to excrete urine.

anxiety A response to stress that causes apprehension or uncertainty. There are various levels and types of anxiety.

aphasia Speech or language impairment.

apical pulse A central pulse that can be auscultated over the apex of the heart at the point of maximal impulse.

APIE note Adds *A*, assessment, combining subjective and objective data, to the PIE (problem, intervention, and evaluation) format.

apnea An absence of breathing; brain damage occurs after 4 to 6 minutes of apnea.

applied research Testing the application of theories in different situations with different populations.

approximated Brought together.

arrhythmia An irregular heartbeat that can prevent the heart from pumping adequate blood.

arterial blood gas (ABG) A diagnostic test that examines arterial blood to assess a patient's oxygenation status and acid–base balance.

ascites An abnormal collection of fluid in the peritoneal cavity.

asepsis Freedom from and prevention of disease-causing contamination.

aspartate aminotransferase (AST) An enzyme found primarily in the heart, liver, and muscle that is released after cell death or injury.

aspiration Inhalation of fluid or foreign matter into the lungs and bronchi.

assault A threat of bodily harm or violence caused by a demonstration of force by the potential perpetrator. A feeling of imminent harm or feeling of immediate danger must exist for assault to be claimed.

assertiveness The ability to express ideas and concerns clearly while respecting the thoughts of others.

assessment The organized and ongoing appraisal of a patient's well-being.

assimilation Attempting to use a new object in the same way that more familiar objects are used. The process by which individuals from one cultural group merge with, or blend into, a second group.

asthma A chronic respiratory disorder characterized by airway spasms, bronchial narrowing or obstruction, mucus accumulation, and airway inflammation.

atelectasis The collapse of all or part of the lung.

atheist A person who believes that a god or higher powers do not exist.

atherosclerosis The buildup of plaque in coronary arteries around the heart.

atrial natriuretic peptide A hormone secreted by cells in the atrium of the heart in response to an increase in blood pressure causing an increase in glomerular filtration rate, which leads to increased excretion of water in urine.

atrophy Wasting away of muscles; a decrease in size.

auricle The outer ear.

auscultation Listening, with the assistance of a stethoscope, to sounds within the body.

auscultatory gap During blood pressure measurement, absence of Korotkoff sounds noted in some patients after the initial systolic pressure.

autocratic leader A leader who exercises strong control over subordinates. This type of leader assumes that followers are motivated by external forces such as the need for approval by the supervisor and the need to avoid punishment.

autonomy The freedom to make decisions supported by knowledge and self-confidence.

axilla Armpit.

bacteria Single-cell organisms that are capable of causing disease, but that also live on and in the skin, eyes, nose, mouth, upper throat, lower urethra, small intestine, and large intestine as normal flora.

bar-code medication administration (BCMA) After using a portable scanner to sign into the electronic medication administration record (eMAR) by scanning his or her identification badge, the nurse then electronically scans the bar codes on the patient's wristband and the drug to determine that the right patient is getting the right drug and dose at the right time. An alert on the eMAR signals a potential error, and it is the nurse's responsibility to verify all information before administering the medication to the patient.

basal metabolic rate (BMR) The minimum amount of energy required to maintain body functions at rest while awake.

bases Substances that accept hydrogen ions.

basic metabolic panel A commonly ordered diagnostic test that measures electrolytes, carbon dioxide, glucose, and renal function.

basic research Research conducted to generate theories.

basophils A type of white blood cell that is involved in the inflammatory response to injury.

battery Actual physical harm caused to another person.

Behavioral Risk Factor Surveillance System (BRFSS) An ongoing, state-based, random-digit-dialed telephone survey of the noninstitutionalized U.S. population over 18 years old. BRFSS collects data on health risk behaviors and preventive health services related to leading causes of death.

behavioral theories Theories that assume that leaders learn certain behaviors. These theories focus on what leaders do rather than on what characteristics they innately possess.

beliefs A mental representation of reality or a person's perceptions about what is right, true, or real or what the person expects to happen in a given situation.

beneficence Doing good; nurses demonstrate beneficence by acting on behalf of others and placing priority on the needs of others rather than on personal thoughts and feelings.

bereavement The inner feelings and outward expressions that people experiencing loss demonstrate.

bias An inclination or tendency toward favoritism or partiality.

Bier block A regional anesthetic involving injection of an agent into the venous circulation of an extremity.

bilirubin A component of bile that is synthesized in the liver, spleen, and bone marrow.

bingeing The intake of excessive amounts of food, as many as 2000 to 3000 calories at one time.

bioburden Bacterial load.

bioethics The study of ethical and philosophic issues in biology and medicine.

biopsy Removal of a sample of cells to detect cancer.

bioterrorism The deliberate release of biological agents such as bacteria, viruses, and other germs to cause illness or death in people, animals, or plants.

bisexual An individual who is emotionally or sexually attracted to people of either sex.

blog A type of social media that is usually maintained by an individual and has regular entries of commentary, descriptions of events, or other material such as graphics or videos.

blood pressure The measurable pressure of blood within the systemic arteries.

blood urea nitrogen A kidney function test that measures urea in the blood.

body mass index (BMI) Measurement of a person's body fat based on a formula that uses height and weight.

borborygmi Hyperactive bowel sounds audible without a stethoscope.

bradycardia A slow heart rate of less than 60 beats per minute in the adult.

bradypnea A decrease in respiratory rate to less than 10 breaths per minute (BPM) in the adult.

brain natriuretic peptide (BNP) A hormone produced by myocardial cells and released from the ventricle during times of increased pressure or overload such as in heart failure.

breadth To consider a topic, problem, issue, etc. from every relevant viewpoint.

bronchodilators Oral or inhaled medications that increase the diameter of the bronchioles, which decreases wheezing and

improves oxygenation.

bruit An abnormal swooshing sound audible on auscultation over an aneurysm, the carotid artery, or an arteriovenous (AV) fistula.

bruxism The clenching of teeth or the grinding of teeth from side to side that occurs during sleep.

buccal Medication administered against the mucous membrane of the cheek.

bulimia nervosa An eating disorder that involves an obsession with bingeing followed by purging. In an effort not to gain weight from the excessive amount of food eaten, the person may use self-induced vomiting or excessive exercise.

bureaucratic leader A leader that assumes that followers are motivated by external forces. This type of leader relies on policies and procedures to direct goals and work processes.

burnout Mental or physical exhaustion due to constant stress or activity.

C fibers Smaller, unmyelinated fibers with slow conduction that cause a diffuse, dull, and longer-lasting pain.

cachexia Physical wasting.

capillary closing pressure The minimum pressure required to collapse a capillary.

capillary refill An indication of peripheral blood perfusion, measured in seconds.

carbohydrates Chemical substances compiled from carbon, hydrogen, and oxygen molecules.

carbon monoxide A colorless, odorless gas that can cause sudden illness and even death.

cardiac murmurs Blowing or swishing sounds heard on systole or diastole, caused by increased or abnormal blood flow through the valves of the heart.

cardiac output Calculated by multiplying the heart rate in beats per minute (beats/min) times stroke volume in liters per beat.

caring Having concern or regard for that which affects the welfare of another.

case law Judicial decisions from individual court cases. It was historically referred to as “common law.”

case manager Coordinator of care.

catabolism The breaking down of substances from complex to simple, resulting in a release of energy.

cataplexy The sudden loss of voluntary muscle tone.

cataracts A condition that causes the lens of the eye to become cloudy and impair vision.

cathartics Strong laxatives that stimulate evacuation of the bowel by causing a change in gastrointestinal transit time.

cellular immunity A defense by the white blood cells—lymphocytes—in response to foreign microorganisms.

Centers for Medicare and Medicaid Services (CMS) The federal organization that certifies all Medicare- and Medicaid-participating hospitals.

central venous catheter A central venous access device that is inserted into a major vein in the arm or chest with the tip of the catheter lying in the superior vena cava, just outside the right atrium.

centration Focusing on only one aspect of an object.

cerebrovascular accident (CVA) Injury to the brain that occurs when an area of the brain is deprived of blood flow; also called a stroke.

cerumen Earwax.

chafing Inflammation of the skin due to friction.

channel A method of communication. Any of the five senses may be used as channels.

charting by exception (CBE) Documentation that records only abnormal or significant data. It reduces charting time by assuming certain norms. In this type of charting each facility must define what is normal. Any assessment finding outside normal is charted as an exception.

cheilitis Dry, cracked lips.

chemical restraint A medication that is administered to a patient to control behavior.

chemoreceptors Sensory nerve endings that react to chemicals.

chief complaint The patient's presenting problem, reason for seeking care.

cholesterol A waxy, fatlike substance found in all cells of the body.

chronic bronchitis A disorder associated with chronic obstructive pulmonary disease that is characterized by inflammation of the larger airways, increased production of mucus, and chronic cough.

chronic grief A type of complicated grief characterized by grief reactions that do not diminish over time and continue for a long time.

chronic illness Any condition characterized by a loss or abnormality of body function that lasts longer than 6 months and requires ongoing care.

chronic obstructive pulmonary disease (COPD) A general term used for a group of disorders characterized by impaired airflow in the lungs.

chronic pain Pain that lasts for longer than 6 months.

chronic wound A wound that fails to progress to healing in a timely manner, often remaining open for an extended period.

chyme Semiliquid product of digestion that travels from the stomach through the intestines.

cilia Tiny hairs lining the nasal passages.

circadian rhythms Day-night, 24-hour biological cycle.

circulating nurse A registered nurse who is the patient's advocate in the operating room and a liaison between scrubbed personnel and the surgical team.

circumcision Surgical removal of the foreskin of the penis that is considered a religious rite for those of the Jewish and Muslim faiths.

civil law Governs unjust acts against individuals, rather than federal or state crimes. In civil law, court judgments require the payment of restitution in the form of services or money to the victim or family members.

civility Acting politely, showing respect.

clarity To be easily understood, clear in thought or style.

Clinical Care Classification System System that provides nursing diagnosis taxonomies for electronic medical record (EMR) systems.

clinical manifestations Signs and symptoms.

clinical pathways Sometimes referred to as care pathways, care maps, or critical pathways, are multidisciplinary resources designed to guide patient care.

clinical research Research that is used when testing theories about the effectiveness of interventions.

clonus A repetitive vibratory contraction of the muscle that occurs in response to muscle and tendon stretch.

closed wound A wound in which the skin is still intact.

Clostridium difficile A bacterium that causes diarrhea and inflammation of the colon; often called "C. diff."

clustering Organizing patient assessment data into groupings with similar etiologies (underlying causes).

coanalgesic medications Medication that works synergistically with standard pain medications to enhance pain relief and to

treat side effects of the medication.

code of ethics A formalized statement that defines the values, morals, and standards guiding practice within a specific discipline or profession.

cognition Knowing influenced by awareness and judgment; it comprises skills that include language, calculation, memory, attention, reasoning, learning, problem solving, and decision making.

cognitive domain A form of learning based on knowledge and material that is remembered.

collaboration Two or more people work together toward a common goal. In nursing, collaboration occurs when RNs, UAP, LPN/LVNs, primary care providers, pharmacists, social workers, clergy, and therapists all interact productively to provide quality patient care.

collaborative nursing interventions Require consultation and coordination of patient care with a variety of members of the health care team.

colloids Substances that do not dissolve easily.

colonized wound A wound in which one or more organisms are present on the surface of the wound when a swab culture is obtained but there is no overt sign of an infection in the tissue below the surface.

colonoscopy A procedure performed through a scope to visualize inflamed tissue, ulcers, and abnormal growths in the anus, rectum, and colon.

colostomy Surgically created bowel diversion when a portion of the colon is brought through an opening created in the abdominal wall.

community-based nursing Care for individuals within specific areas such as schools, prisons, or businesses.

comorbid Two or more medical conditions existing simultaneously.

compassion The force that impels and empowers one to recognize, acknowledge, and act to alleviate human suffering.

compassion fatigue An extreme state of distress experienced as the progressive and cumulative result of exposure to stress in the therapeutic use of self in caring for others.

complicated grief Grief that does not progress through the normal stages.

complicated loss Loss that occurs with a sudden death, a violent or traumatic death, multiple deaths, loss that is related to a social stigma, and with the death of a young person.

computed tomography (CT) A radiologic procedure in which the use of a special scanner allows cross-sectional images of an organ to be visualized.

computer literacy Knowledge of computers and the ability to use them efficiently.

computerized provider order entry (CPOE) Orders are entered into a computer by clinicians and sent directly to the appropriate department.

conception The process of a sperm and an ovum uniting.

conceptual framework or model A collection of interrelated concepts that provides direction for nursing practice, research, and education. A conceptual model addresses the four concepts of the nursing metaparadigm: optimal functioning of the person or patient, how people interact with the environment, illness and health promotion, and nursing's role.

condom A thin rubber sheath that covers the penis to prevent sperm from entering the vagina.

cones A type of photoreceptors present in the retina that detect sharp, color images.

confidentiality The ethical principle that a health professional will hold secure all information relating to a patient unless the patient gives consent for disclosure.

connected health Tools under the telehealth umbrella that enables remote patient monitoring, patient education, lifestyle management, and biometric monitoring.

conservation The ability to recognize that objects remain the same even if they change in appearance.

consistency The measurement of organ location and size against the expected anatomic norm.

constipation Infrequent or difficult bowel movements, or having fewer than three bowel movements per week.

constitutional law Laws derived from a formal written constitution that defines the powers of government and the responsibilities of its elected or appointed officials.

contact One person's body surface touching the surface of another's body or an object.

contaminated wound A wound with bacteria present resulting from trauma, a break in sterile technique during surgery, or spillage of bowel contents or other bacteria-laden material during surgery.

continuous theories A theory of development that subscribes to the belief that development occurs in a smooth and gradual process from infancy to adulthood.

contraception Techniques used for birth control, to prevent pregnancy.

contracture Permanent fixation of a joint.

control group The group in an experiment that does not receive the treatment.

controlled substances Drugs with regulated manufacturing, prescribing, and dispensing requirements.

coping The dynamic cognitive and behavioral efforts to manage demands (internal or external) that are appraised as exceeding immediately available resources.

core temperature The temperature of deep tissues.

coronary artery disease Narrowing of the arteries by atherosclerosis, spasms, or congenital malformations.

correlational research Research used to explore a relationship between two variables.

C-reactive protein A protein produced by the liver in response to inflammation, tissue damage, and infection.

creatine kinase An enzyme found primarily in skeletal muscle, cardiac muscle, and brain tissue.

creatinine A waste product of skeletal muscle metabolism that is excreted via the kidneys.

creativity The ability to think differently.

crepitation (crepitus) Crackling or rubbing felt as a result of air in superficial tissues.

criminal law The body of state and federal laws written to prevent harm to the country, state, and individual citizens.

crisis intervention Short-term assistance provided to an individual with the goal of regaining equilibrium in a time of physical or emotional upheaval.

critical appraisal A balanced evaluation of the strengths and benefits as well as the weaknesses and flaws of the research.

critical closing pressure The minimum pressure required to collapse a capillary.

critical thinking A complex process that involves reflection while thinking to provide for a more clear, precise, accurate, relevant, consistent, and fair thought process.

Cross-Linking Theory of Aging The theory that suggests that, over time, protein fibers that make up the body's connective tissue form bonds, or crosslinks, with another, causing tissue to become less elastic and leading to negative outcomes such as loss of flexibility, clouding of the lens of the eye, clogged arteries, and damaged kidneys.

crystallized intelligence Skills that depend on accumulated knowledge, experience, good judgment, and mastery of social conventions.

crystalloids Solutes that dissolve easily in water.

cue A hint or an indication of a potential disease process or disorder.

cultural competence The complex integration of an individual's knowledge, attitudes, beliefs, skills, and encounters with those of persons from different cultures.

cultural openness A lifelong stance that promotes cultural self-awareness and continuing development of transcultural skills.

cultural sensitivity The recognition that there are differences among cultures.

culturally congruent care The use of culturally based knowledge in sensitive, creative, safe, and meaningful ways to promote the health and well-being of individuals or groups.

culture The learned, shared, and transmitted knowledge of values, beliefs, and ways of life of a particular group that are generally transmitted from one generation to another and influence the individual's thinking, decisions, and actions in patterned or certain ways. May change over time.

cyanosis Bluish discoloration of the skin and mucous membranes, caused by decreased oxygen levels in arterial blood.

dandruff Scaling and flaking of the skin of the scalp.

dangling Sitting up on the side of the bed prior to standing.

DAR note A charting format based on data collected about the patient problems, the action initiated, and the patient's response to the actions.

data Information collected by the researcher from the participants in the research and expressed either as numbers or words.

data analysis Specific procedures used to summarize the words or numbers and create a meaningful result for interpretation.

debridement The removal of necrotic tissue.

decision making Choosing a solution or answer from among different options; often considered a step in the problem-solving process.

decision support system (DSS) A computerized system that supports decision-making activities such as choosing appropriate diagnoses or medications and improving the quality of care through reminders and safe-practice alerts.

decode The receiver's interpretation of the message. Numerous factors may affect the ability of the receiver to accurately decode a message. The message may be misinterpreted if clarity is not sought and achieved by the receiver.

decussate To cross over.

dedication The ability to spend the time necessary to accomplish a task.

deductive reasoning Generating facts or details from a major theory, generalization, or premise (i.e., from general to specific).

deep vein thrombosis A blood clot that develops in peripheral circulation.

defamation of character Public statements made by an individual that are false and injurious to another person.

defecation The final act of digestion by which the solid, semisolid, or liquid waste is expelled by the body through the anus.

defense mechanisms Unconscious strategies that allow an individual to decrease or avoid unpleasant circumstances.

defining characteristics Cues or clusters of related assessment data that are signs, symptoms, or indications of an actual or health promotion nursing diagnosis.

dehiscence The partial or complete separation of the tissue layers during the healing process; usually occurs in connection with surgical incisions.

dehydration A hypertonic form of fluid volume deficit, which occurs with excessive loss of water or inadequate intake of fluid.

delayed grief A type of complicated grief characterized by suppression of the grief reaction while the grieving individual consciously or unconsciously avoids the pain that has occurred with the loss.

delegation A transfer of responsibility that gives a competent individual the authority to perform a selected nursing task in a specific situation.

delirium A reversible state of acute confusion characterized by a disturbance in consciousness or a change in cognition that develops over 1 to 2 days and is caused by a medical condition.

dementia A permanent decline in mental function over a period of time that is characterized by the decline in many cognitive abilities, including reasoning, use of language, memory, computation, judgment, and learning.

democratic leader A leader who believes that employees are motivated by internal means and want to participate in decision making. Views self as equal to followers.

dentures Artificial teeth.

deontology An ethical theory that stresses the rightness or wrongness of individual behaviors, duties, and obligations without concern for the consequences of specific actions.

dependent nursing interventions Tasks the nurse undertakes that are within the nursing scope of practice but require the order of a primary care provider (PCP) to be implemented.

dependent variable The outcome that is affected by manipulation of the independent variable.

depression A mood disorder characterized by a sense of hopelessness and persistent unhappiness.

depth Exploring a topic or problem below the surface to identify and manage related complexities.

dermis Thick, middle layer of skin between the epidermis and the deeper subcutaneous layer.

descriptive epidemiology Studies that are conducted once a disease is evident.

descriptive research Identifies data and characteristics about a population or phenomenon.

detumescence Loss of blood from erectile tissue.

development The increasing maturation of physical ability, thought processes, and behaviors over time.

diabetic retinopathy A complication of diabetes mellitus in which the blood vessels of the retina become damaged.

diagnosis label A concise term or phrase that represents a pattern of related clustered data.

dialysis A technique by which fluids and molecules pass through an artificial semipermeable membrane and are filtered via osmosis.

diaphragm A flexible, round rubber dome placed in the vagina for contraception.

diarrhea An intestinal disorder characterized by an abnormally high frequency and increased fluidity of fecal evacuations.

diastolic pressure The lowest pressure on arterial walls, which occurs when the heart rests.

diffusion The movement of solutes across a selectively permeable membrane from areas of higher concentration to areas of lower concentration until equilibrium has been reached.

digestion The breaking down of food into smaller particles of nutrients.

diplopia Double vision.

direct care Interventions that are carried out by having personal contact with patients.

discipline A specific field of study or branch of instruction or learning.

discontinuous theories A theory that describes development as progressing through a series of distinct and predictable stages triggered by inborn factors.

discrimination Policies and practices that harm a group and its members.

disenfranchised grief Any loss that is not validated or recognized, occurring when the loss cannot be openly acknowledged or publicly shared by the grieving individual.

disinfection The removal of pathogenic microorganisms.

dissemination The communication and distribution of research information and findings.

distress Stress that is beyond the ability of an individual to cope with or adapt to effectively.

distribution The process of delivering a medication to tissues, organs, and, ultimately, the specific site of action.

disuse osteoporosis Loss of bone mass due to lack of activity.

do-not-resuscitate (DNR) order Directions given by patients who are faced with life-threatening illness, or their designated family members acting as health care proxies, to refuse or limit extraordinary measures that may prolong the patient from experiencing natural death.

droplet transmission The mucous membranes of the respiratory tract (nose, mouth, or conjunctiva) are exposed to the secretions of an infected individual.

drug Any substance that either positively or negatively alters physiologic function.

drug incompatibility Mixing medications in a solution that causes precipitation, or combining a drug with another drug that causes an adverse chemical reaction.

drug tolerance An adaptation to medication, which eventually leads to less effective pain relief.

dualistic thinking Dividing information, values, and authority into right and wrong, good and bad, we and they.

durable power of attorney A legal document that allows a designated person to make legal decisions on behalf of an individual who is unable or not permitted to make legal decisions independently.

dyspareunia Painful intercourse.

dysphagia Difficulty swallowing.

dyspnea Difficult, labored breathing, usually with a rapid, shallow pattern and sometimes painful.

dysrhythmia An irregular rhythm in the pulse, caused by an early, late, or missed heartbeat.

dyssomnias Disorders associated with getting to sleep, staying asleep, or being excessively sleepy.

dysuria Painful urination.

early intervention Strategies introduced at the first detection of a possible health problem.

ecchymosis Bruising.

edema Swelling.

effleurage A massage technique that employs long hand movements along the length of the back muscles.

ego The part of the mind that functions in reality and allows people to seek out pleasure within the norms of society.

egocentric A stage of development in which children believe that everyone else sees the world exactly as they see it.

elective surgery A surgical procedure that is planned in advance and performed to improve the patient's quality of life.

electrical shock Energy that flows through the body, or a portion of the body, to the ground when a person comes in contact with an energy source.

electrocardiogram (ECG) A recording of the electrical current generated by the heart during depolarization and repolarization of the cardiac muscle.

electrolytes Positively or negatively charged ions that conduct electrical impulses across cells.

electronic health record (EHR) A longitudinal record of health that includes the information from both inpatient and outpatient episodes of health care from one or more care settings.

electronic infusion device Intravenous infusion pump used for a more precise delivery of intravenous fluids.

electronic medical record (EMR) A record of one episode of care, either an inpatient stay or an outpatient appointment.

embryo A developing zygote after 3 weeks up until 2 months after conception.

emergency surgery A surgical procedure that is unanticipated and is performed immediately to preserve the life of the patient, a body part, or body function.

emerging adulthood Prolonged transition phase between adolescence into adulthood.

emic A perspective that focuses on the local, indigenous, and insider's culture.

emotional intelligence The ability of individuals to monitor their own and others' feelings and emotions, discriminate among them, and use the information to guide both their thinking and actions.

emphysema A disorder associated with chronic obstructive pulmonary disease that is characterized by inflamed and damaged alveolar walls in the lungs.

encode The translation of the sender's thoughts and feelings into communication with a receiver.

enculturation The process whereby a culture is passed from generation to generation.

endoscopy An examination of the interior of an organ or cavity by means of a fiberoptic scope.

endotracheal tube Semirigid, curved airway tube with a cuff at the distal end that seals to prevent aspiration of gastric contents into the lung, allows positive pressure for ventilation, and keeps air from leaking out of the airway.

enema The introduction of solutions into the rectum and sigmoid colon via the anus.

enteral feeding Tube feeding.

enuresis The involuntary passing of urine.

environmental (extrinsic) factors Environmental variables such as food sources, vectors of disease, or socioeconomic influences.

enzymes Proteins responsible for catalyzing most chemical reactions in the body, such as digesting food and synthesizing new compounds.

eosinophils A type of white blood cell that destroys parasites and is involved in allergic reactions.

epidemiology The study of disease incidence and prevalence.

epidermis The outermost layer of the skin and the thinnest of the layers, which regenerates every 4 to 6 weeks.

epidural anesthesia A regional anesthesia in which an agent is injected into the epidural space through the lumbar or thoracic region.

epistaxis Nosebleed.

epithelial tissue Tissue that lines tubes, cavities, and the surface of the skin.

equilibration The process by which a balance between present understanding and new experiences is restored.

equilibrium Balance.

erectile dysfunction (ED) The inability to achieve or maintain a penile erection for sexual intercourse.

erythema Redness of the skin caused by congestion or dilation of the superficial blood vessels in the skin, signaling circulatory changes to an area.

erythrocytes Red blood cells.

eschar Necrotic tissue.

ethics The standards of moral conduct within a society. The main concepts in nursing ethics are accountability, advocacy, autonomy, beneficence, confidentiality, fidelity, justice, nonmaleficence, responsibility, and veracity.

ethnicity An individual's identification with or membership in a particular racial, national, or cultural group and observation of the group's customs, beliefs, and language.

ethnocentrism The belief that one's own culture is superior to that of another's while using one's own cultural values as the criteria by which to judge other cultures.

ethnography A focus on the sociology of meaning through close field observation of a sociocultural phenomenon.

etic A perspective that focuses on the outsider's world and especially on professional views.

etiologic factors Causes of a disease.

etiology The underlying cause of a patient problem or concern.

eupnea Normal respiration with a normal rate and depth for the patient's age.

eustress Motivational stress that is associated with effective coping and adaptation.

euthanasia The act of painlessly ending the life of another.

evaluation Examination of goal or outcome attainment by focusing on the patient and the patient's response to nursing interventions.

evidence-based practice (EBP) The integration of best research evidence with clinical expertise, patient values and needs, and the delivery of quality, cost-effective health care.

evisceration The total separation of the tissue layers, allowing the protrusion of visceral organs through the incision.

exacerbation Worsening of clinical manifestations.

exaggerated grief A type of complicated grief in which the survivor is overwhelmed by grief and cannot function in daily life.

excoriation An abrasion due to rubbing or scratching.

excretion A process that removes the less active drug or its metabolites.

experimental research Research that explores the causal relationships between variables.

extracellular fluid Body fluid that is outside the cells.

fairness Avoiding bias or prejudice and dealing with a situation in a just manner.

faith A belief beyond oneself that is based on trust and life experience rather than scientific data.

faith community nursing Spiritual care provided by registered nurses. Some roles of a faith community nurse are health advisor, health educator, advocate, liaison to faith and community resources, coordinator of volunteers, and developer of support groups.

falls Events in which an individual unintentionally and through the force of gravity drops to the ground, floor, or some other lower level.

false imprisonment The unauthorized restraint or detention of a person.

fat-soluble vitamins Vitamins A, D, E, and K are fat-soluble vitamins that are stored in the liver and fat tissue. Toxicity may result if excessive amounts are taken.

febrile Elevated body temperature.

fecal occult blood test A test that measures microscopic amounts of blood in the feces.

felony A serious crime that results in the perpetrator being imprisoned in a state or federal facility for more than 1 year.

fetus The term for an embryo beyond 2 months after conception.

fever A rise in body temperature above normal, caused by trauma or illness.

fiber A complex carbohydrate classified as either soluble or insoluble.

fiberoptics A system in which flexible glass or plastic fibers are used to transmit light around curves and corners, which allows direct visualization of the area of interest.

fibrinogen An essential component of blood clotting that converts into fibrin threads in the presence of ionized calcium.

fidelity Keeping promises or fulfilling agreements made with others.

fight-or-flight response A physiologic response to stress, whether physical or psychological, that activates the autonomic nervous system, resulting in an increase in heart rate, blood pressure, and respirations along with pupil dilation and a decrease in gastric motility and blood flow to the skin.

filtration The process by which fluid and solutes move together from an area of higher pressure to one of lower pressure.

first-order beliefs The foundation or the basis of an individual's belief system.

fistula Abnormal connections between two internal organs or between an internal organ and through the skin to the outside of the body.

flaccidity Lack of muscle tone.

flatulence The production of a mixture of gases in the intestine as by-products of the digestive process.

fluid intelligence The ability to detect relationships among stimuli, the speed with which information is analyzed, and the capacity of working memory.

fluid volume deficit A fluid imbalance that occurs with excessive loss or inadequate intake of fluid.

fluid volume excess A fluid imbalance that occurs when fluid intake exceeds output.

focused assessment An examination in which only specific, relevant areas are examined.

footdrop A common joint contracture that results in permanent plantar flexion.

forced expiratory flow (FEF) The maximal flow rate attained during the middle of the forced vital capacity maneuver.

forced expiratory volume in 1 second (FEV₁) The volume of air expelled in 1 second from the beginning of the forced vital capacity.

forced vital capacity (FVC) Part of pulmonary function tests that measures the volume of air the patient can forcefully expel after the maximum amount of air is breathed in.

formal leadership Leadership that is part of an official position, which may or may not be a management position.

fraction of inspired oxygen (FIO₂) The percentage of oxygen in inspired air.

free radicals Naturally occurring, highly reactive chemicals that form in the presence of oxygen and can cause harmful alterations in cellular function similar to those seen in aging.

friction Rubbing.

frostbite Ice crystals form inside the cells due to exposure to subnormal temperatures that may cause permanent circulatory and tissue damage.

full-thickness wound A wound that extends through the dermis to the subcutaneous layer and may extend farther, to the muscle, bone, or other underlying structures.

functional incontinence Lack of urine control in the absence of any abnormalities of the urinary tract.

functional residual capacity The volume of air that remains in the patient's lung after normal expiration.

fungi Single-cell organisms, such as yeast and mold, that are capable of causing infection.

futile care Care that is perceived as useless and that prolongs the time until death rather than restoring life.

gait The patient's manner of walking.

gamma-glutamyltransferase (GGT) An enzyme found primarily in the liver and biliary tract that assists in transporting amino acids across cell membranes.

gay The term most often associated with male homosexuality.

gender identity An individual's self-concept with respect to being a male or female.

gender role The outward behavior of a person as a male or female and the perception of what constitutes gender-appropriate actions.

general adaptation syndrome (GAS) The physical response to stress.

general anesthesia A combination of inhaled or intravenous anesthetic agent is used to cause central nervous system depression and put the patient in a drug-induced coma.

generalization Broad statements or ideas about people or things.

generalized anxiety disorder Unrealistic levels of worry and tension with or without an identifiable cause.

generativity Reaching out to others in ways that guide and give to the next generation.

generic name The official drug name assigned by the U.S. Adopted Names Council, which is simpler than the chemical name.

genetic vulnerability The risk for disease expression based on genotype.

gingivae Gums.

gingivitis Inflammation of the gums.

glaucoma A serious medical condition of the eye that causes increased intraocular pressure, which puts pressure on the optic nerve, leading to loss of peripheral visual fields and possibly blindness.

globulins Plasma proteins classified as alpha, beta, and gamma globulins; some function as antibodies, whereas others are responsible for enzymatic functions and the transport of lipids, iron, and copper in the blood.

grand theory A global conceptual framework that defines broad perspectives for nursing practice and provides ways of looking at nursing phenomena from a distinct nursing perspective.

granulation tissue New tissue that is beefy red in appearance that develops to fill a wound.

grief The emotional response to loss.

grounded theory research Research that attempts to derive a theory from the data collected in the research.

growth Increase in height and weight.

guarding Positioning to prevent movement of a painful body part.

gustation The sense of taste.

half-life The time it takes for the blood concentration of a drug to measure half of the original dose due to drug elimination.

halitosis Unpleasant breath odor.

handoff The real-time process of passing patient-specific information from one caregiver to another or among interdisciplinary team members to ensure continuity of care and patient safety. A handoff can be oral or written.

healing ridge A 1-cm-wide ridge or area of induration along an incision that indicates that collagen synthesis has taken place in a wound.

health belief model (HBM) A model developed by psychologists Hochbaum, Rosenstock, and Kegels that explores the relationship between patient attitudes and beliefs and how those factors predict health behavior.

health care disparity Inequality related to access, use, and quality of care.

health care documentation Any written or electronically generated information about a patient that describes the patient, the patient's health, and the care and services provided, including the dates of care and signature of the care giver.

health care proxy The specific durable power of attorney for medical care.

health care–associated infections (HAIs) Infections acquired while the patient is receiving treatment in a health care facility such as a hospital, long-term care facility, clinic, or primary care office.

health history Includes all pertinent information collected during initial or early contact with a patient that can guide the development of a patient-centered plan of care.

Health Insurance Portability and Accountability Act

(HIPAA) Act passed in 1996 that created federal standards for the protection of personal health information, whether conveyed orally or recorded in any form or medium. The act

clearly mandates that protected health information may be used only for treatment, payment, or health care operations. Nurses share the responsibility of preventing a breach of confidentiality.

health literacy The ability of the patient to understand and integrate health-related knowledge.

health promotion model (HPM) A health model by Pender that relies on the premise that a multidimensional interaction exists between an individual and the environment in which health promotion consists of a collection of behaviors directed at improving the individual's well-being.

health promotion Behavior motivated by the desire to increase well-being and optimize health status.

health promotion nursing diagnoses NANDA-I diagnostic labels that are clinical judgments concerning the motivation and desire of an individual, family, group, or community to increase well-being and to actualize human health potential.

health protection Includes intentional behaviors aimed at circumventing illness, detecting it early, and maintaining the best possible level of mental and physiologic function within the boundaries of illness.

health A state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity.

Healthy People 2020 An initiative designed to track, over 10-year increments, risk factors and personal behaviors related to physical activity, access to health services, tobacco use, substance use, responsible sexual behavior, mental health, immunizations, injury, and violence prevention.

heat exhaustion Profound sweating resulting in excessive water and electrolyte loss after environmental heat exposure.

heatstroke Prolonged exposure to the sun or high environmental temperatures overwhelm the body's heat-loss mechanisms. This health emergency has a high mortality rate.

hematuria Blood in the urine.

hemiparesis Weakness on one side of the body.

hemiplegia Paralysis of one side of the body.

Hemoccult A test for hidden blood in the stool.

hemodialysis Mechanical filtration of impurities and waste products from the blood of patients who have acute or chronic renal failure.

hemoglobin (Hgb) A protein primarily responsible for oxygen transport to and carbon dioxide transport from the erythrocytes.

hemolysis Red blood cell destruction.

hemolytic reactions The life-threatening destruction of red blood cells.

hemoptysis The presence of blood in the sputum.

hemorrhage A large amount of bleeding.

hemorrhoids Swollen and inflamed veins in the anus or lower rectum.

Hemovac drain A closed drainage system in which a soft drain is attached to a springlike suction device.

heterosexual A person who has sexual interest in or sexual intercourse exclusively with partners of the opposite sex.

high-density lipoprotein cholesterol (LDL) A lipoprotein that transports excess cholesterol from the tissues back to the liver, where it is broken down and excreted in bile.

higher-order beliefs Ideas derived from a person's first-order beliefs using inductive or deductive reasoning.

hirsutism A condition affecting both men and women in which hair growth on the upper lip, chin, and cheeks becomes excessive and vellus body hair becomes thicker and coarser.

historical research Research that studies historic documents to determine an accurate picture of a historical event or time period.

holistic health models Models based on the philosophy that a synergistic relationship exists between the body and the environment.

home health care nursing Care for a patient that takes place in a residential, home setting.

homeostasis The body's regulation of systems to maintain a steady state of equilibrium.

homocysteine An amino acid formed in the conversion of methionine to cysteine.

homosexual A person who has sexual interest in or sexual intercourse exclusively with members of his or her own sex.

hope A confident expectation.

hospice A program that provides comfort and supportive care for terminally ill patients and their families, either directly or on a consulting basis with the patient's physician or another community agency.

hospice care End-of-life care for the terminally ill.

host (intrinsic) factors Individual variables such as genetics, age, or gender.

host (reservoir) The source of infection; can be inanimate objects, human beings, and animals.

human subject An individual about whom an investigator conducting research obtains data through intervention or interaction with the individual or from identifiable private information such as a patient chart.

humanistic The promotion of human welfare.

humility The ability to recognize that no one is superior to another.

humoral immunity A defense system that involves antibodies and white blood cells that are produced to fight antigens, which allows the body to produce substances such as interferon and interleukin-1, which cause fever.

hydrocephalus An accumulation of cerebrospinal fluid in the ventricles of the brain.

hydrostatic pressure The force of the fluid pressing against the blood vessel that is controlled by the force of myocardial contraction, rate of contraction, and blood flow.

hygiene Practices such as cleanliness that promote and preserve health.

hypercalcemia Increased serum calcium level greater than 10.5 mg/dL.

hypercapnia High levels of carbon dioxide.

hyperchloremia Occurs when serum chloride levels go above 106 mEq/L and can be affected by dehydration and certain medication. Excessive infusion of normal saline intravenously also may cause hyperchloremia.

hyperglycemia Increased blood glucose levels.

hyperkalemia Increased serum potassium level greater than 5.0 mEq/L.

hyperlipidemia Elevation of plasma cholesterol, triglycerides, or both.

hypermagnesemia increased serum magnesium level greater than 2.1 mEq/L.

hybernemia Serum sodium levels greater than 145 mEq/L. This imbalance is due to either a greater loss of water compared to sodium or a greater intake of sodium.

hyperphosphatemia Increased serum phosphorus levels greater than 4.5 mg/dL.

hypersomnia Excessive daytime sleepiness lasting at least 1 month, causing impairment in occupational or other areas of a person's life.

hypertension Elevated blood pressure; it is the leading cause of cardiovascular disorders and the most important risk factor for stroke.

hyperthermia High body temperature.

hypertonic solution A solution with higher osmolarity than body fluids that pulls water from the cell to the extracellular fluid compartment, leading to cell shrinkage.

hypertonicity An increase in muscle tone.

hyperventilation Deep, rapid respirations often caused by stress or anxiety.

hypnotics Medications that induce unnatural sleep that disturbs rapid eye movement (REM) and non-rapid eye movement (NREM) sleep.

hypocalcemia Decreased serum calcium levels less than 9 mg/dL.

hypochloremia Occurs when serum chloride levels fall below 98 mEq/L and usually occurs with simultaneous shifts in water balance, sodium levels, or bicarbonate levels.

hypokalemia Decreased serum potassium level less than 3.5 mEq/L.

hypomagnesemia Decreased serum magnesium levels less than 1.3 mEq/L.

hyponatremia Occurs when the sodium level is decreased in relation to body water. It is defined as a serum level less than 135 mEq/L.

hypophosphatemia Decreased serum phosphorus levels less than 1.3 mEq/L.

hypothesis A statement about two or more variables and their relationship to each other.

hypotonic solution A solution with a lower osmolarity than body fluids that causes excess water to move into cells.

hypotonicity A decrease in muscle tone.

hypovolemia A decrease in fluid volume.

hypoxemia Low oxygen levels in the blood.

id The part of personality consisting of instincts, operating on an unconscious level not based in reality.

idiosyncratic reaction An unpredictable patient response to medication.

ileostomy A surgically created opening in the small intestine, usually at the end of the ileum.

illness A state of health characterized by a decrease or impairment in an individual's abilities to engage in physical or mental functioning that was previously experienced.

immune response The body's attempt to recognize and protect itself from substances that are foreign and harmful, triggered by an antigen.

immunization The process by which an individual develops immunity against a specific agent.

impaction The presence of a hard fecal mass in the rectum or colon that the patient is unable to expel.

implementation Initiation of appropriate interventions designed to meet the unique needs of each patient.

incidence Occurrence.

incontinence The loss of ability to voluntarily control urine or feces.

incontinence-associated dermatitis (IAD) Perineal inflammation and dermatitis caused by contact with urine or feces; the damage from moisture is confined to the more superficial layers.

independent nursing interventions Tasks within the nursing scope of practice that the nurse may undertake without a PCP order.

independent variable A concept that is thought to have an effect on another concept.

indirect care Nursing interventions that are performed to benefit patients but do not involve face-to-face nurse–patient contact.

inductive reasoning Using specific facts or details to make conclusions and generalizations; proceeding from specific to general.

infected wound A wound that shows clinical signs of infection, including redness, warmth, and increased drainage that may or may not be purulent (contain pus) and has a bacterial count in the tissue of at least 10^5 per gram of tissue sampled when cultured.

infection A disease state caused by an infectious agent that occurs when a pathogen multiplies in a susceptible host.

inferences Conclusions.

infertility When a couple has not conceived after 12 months of contraceptive-free intercourse if the female is under the age of 34 or after 6 months of contraceptive-free intercourse if the female is over the age of 35.

inflammatory phase The body's initial response to wounding of the skin that lasts about 3 days.

inflammatory response A local response to cellular injury or infection that causes capillary dilation and leukocyte infiltration.

informal leadership Emerges outside the structure of a formal position.

informatics A broad academic field encompassing artificial intelligence, cognitive science, computer science, information science, and social science.

information literacy The ability to recognize when information is needed and to locate, evaluate, and effectively use the needed information.

informed consent Permission granted by a patient after discussing each of the following topics with the physician, surgeon, or advanced practice nurse who will perform the surgery or procedure: (1) exact details of the treatment, (2) necessity of the treatment, (3) all known benefits and risks

involved, (4) available alternatives, and (5) risks of treatment refusal.

infrastructure One of the structural elements that keeps a culture strong; provides the basic necessities of life.

inhalation Medications taken into the body through the respiratory tract.

insomnia The most common dyssomnia; characterized by difficulty in falling asleep or staying asleep, sleep that is too light, or early morning awakenings.

inspection The use of vision, hearing, and smell to closely scrutinize physical characteristics of a whole person and individual body systems.

institutional review board A review committee established to help protect the rights and welfare of human research subjects.

instruments The data collection tools used to collect information.

integrity Aligning one's actions with one's stated values.

integumentary system The body system that includes skin, nails, hair, sweat glands, and sebaceous glands.

intentional injuries Injuries that result from deliberate acts of violence or abuse and often involve fatal consequences such as suicide and homicide.

intentional torts Wrongs committed by individuals who deliberately seek to injure or hurt another person.

intermittent infusion device A saline lock or prn adapter that allows periodic or emergency venous access.

International Classification for Nursing Practice

(ICNP) Provides an international standard that facilitates the description and comparison of nursing practice locally, regionally, nationally, and internationally.

international normalized ratio A coagulation blood test that is a standardized ratio to monitor the effect of anticoagulant therapy.

Internet The shared global computing network.

interpersonal communication Communication that takes place between a minimum of two people; it may be formal or informal and conversational, and it may or may not have a stated goal or purpose.

intersex A person who is born not fitting the characteristic definitions of male or female, based on the person's anatomy, chromosome makeup, or other related differences.

interstitial fluid Fluid between the cells of an organ or tissue.

intracellular fluid Body fluid that is within the cell.

intra dermal (ID) A shallow injection into the dermis skin layer, just under the epidermis.

intramuscular (IM) An injection into a muscle of adequate size to accommodate the amount and type of medication.

intraoperative phase The second phase of surgery that begins when the patient enters the operating room and ends when the patient is transferred to the postanesthesia care unit.

intrapersonal communication Communication that occurs within oneself, focuses on personal needs, and has the potential of having an impact on a person's well-being.

intrauterine device (IUD) A contraceptive device placed through the cervix into the uterus that may contain progesterone or copper, which changes the uterine lining, thus reducing the chance of implantation.

intravascular fluid Blood plasma.

intravenous (IV) An injection into a vein.

invasion of privacy Public disclosure of private information, use of a person's name or likeness without permission, intrusion into a person's place of solitude, and meddling into another's personal affairs.

irrigation Flushing with a solution.

ischemia Reduced blood flow.

isometric exercise Physical activity that requires tension and relaxation of muscles without joint movement.

isotonic exercise Active movement with constant muscle contraction.

isotonic solution A solution that has the same osmolarity as blood plasma.

Jackson-Pratt drain A closed drainage system in which a soft drain is attached to a bulblike suction device.

jaundice A yellow hue to the skin, mucous membranes, or eyes of both light- and dark-skinned individuals.

judgment The result or decision related to the processes of thinking and reasoning.

justice Acting fairly and equitably.

Kegel exercises An exercise that helps keep the female pelvic floor toned, which reduces the risk for incontinence.

ketones Organic chemical compounds that result from incomplete fat oxidation when carbohydrates are not available.

kilocalorie The amount of heat energy it takes to raise the temperature of 1000 g of water 1° C.

Korotkoff sounds The sounds for which the nurse listens when assessing blood pressure.

kwashiorkor A lack of protein accompanied by fluid retention.

kyphosis An outward curvature of the thoracic spine.

labyrinths The intricate communicating passageways that make up the inner ear.

lactation The production and release of milk by the breasts (mammary glands).

laissez-faire leader A leader who provides little or no direction to followers. The followers develop their own goals and make

their own decisions. Few policies and procedures are in place.

laryngospasm Causes the laryngeal muscle to briefly spasm, causing the patient to have trouble speaking and difficulty breathing.

lavage Irrigation of the stomach.

lead poisoning A public health issue that occurs when lead builds up in the blood over a period of months or years; it can affect all of the body systems.

leadership The ability to influence, guide, or direct others. Leadership focuses on relationships, using interpersonal skills to persuade others to work toward a common goal.

learning Acquiring knowledge or skills through instruction or experience.

lesbian A term exclusively associated with female homosexuality.

leukocytes White blood cells.

libel Written forms of defamation of character.

licensure The granting of a license, which provides legal permission to practice.

life expectancy The average number of years of life remaining at a given age.

lipids Fat found within the body, including true fats and oils such as fatty acids, cholesterol, and phospholipids.

listserv A computer program that automatically sends messages to multiple e-mail addresses on a mailing list.

literature review A critical analysis of current information on a specific subject that will be studied or discussed in a research project or scholarly article.

living will A document that specifies the treatment a person wants to receive in circumstances in which that person is unconscious or no longer capable of making decisions independently.

livor mortis The color of the skin becomes pale, then bluish after death.

local adaptation syndrome (LAS) Inflammation, reflexive response to pain, or hypoxia secondary to catecholamine release that results from the direct effect of stress on body tissues.

local anesthesia The regional application or injection of anesthetic drugs subcutaneously to a specific area of the body.

logic To have a mutually supporting and sensible combination of combined thoughts, whereby the conclusion follows from presented facts.

logrolling Moving the whole body as a unit in straight alignment.

long-term goals Goals that take weeks, months, or longer to achieve.

lordosis An inward lumbar curvature just above the buttocks area.

loss The absence of something or someone to which a person has formed an attachment.

low-density lipoprotein A lipoprotein that transports cholesterol from the liver to various parts of the body.

lymphocytes A type of white blood cell that recognizes foreign antigens, produces antibodies, and creates memory cells.

maceration Breakdown of the skin caused by fluid.

macronutrients Nutrients that are needed in large amounts.

macular degeneration Damage to the area of the retina that provides central vision leading to loss of vision in the central visual fields.

magnanimity Giving credit where credit is due.

magnetic resonance imaging (MRI) A superconducting magnet and radiofrequency waves cause hydrogen nuclei to emit

signals that are translated by a computer into a well-defined image of the structure.

major surgery A surgery in which there is a higher risk to the life of the patient and the surgery involves reconstruction or alteration of a body part.

malabsorption Problematic or inadequate absorption of nutrients in the intestinal tract.

malignant hyperthermia A rare, hereditary, and potentially life-threatening condition that can occur in susceptible individuals when inhaled general anesthesia is administered.

malnutrition An imbalance in the amount of nutrient intake and the body's needs.

malpractice Negligence committed by a person functioning within a professional role.

mammogram Soft tissue x-rays that allow visualization of the underlying breast tissue.

management The process of coordinating others and directing them toward a common goal. Management is focused on the task at hand.

marasmus A protein and caloric deficiency.

masked grief A type of complicated grief in which the behaviors of the survivor interfere with normal functioning, but the person is not aware that these behaviors are concealing the actual grieving process.

Maslow's hierarchy of needs A model used to understand the interrelationship between the elements of basic requirements for survival and the desires that drive personal growth and development.

mastication Chewing.

maturation phase The last phase of wound healing, which lasts for up to a year.

medical adhesive–related skin injuries (MARSI) Occur when superficial layers of skin are removed by medical adhesive, in which erythema and/or other manifestation of skin trauma or reaction, including formation of vesicles, bulla, skin erosion, and epidermal tears, persist longer than 30 minutes after removal of the adhesive. MARSI not only affects skin integrity but also causes pain, increases risk for infection, potentially increases wound size, and delays healing.

medical aid in dying When a person who is mentally competent with a prognosis of 6 months or less to live causes his or her own death by self-administering prescribed medication.

medical asepsis Clean technique used to prevent infection and break the chain of infection.

medical record A document with comprehensive information about a patient's health care encounter, as well as demographic, administrative, and clinical data. The record serves as the major communication tool between staff members and as a single data access point for everyone involved in the care of the patient. It is a legal document that must meet guidelines for completeness, accuracy, timeliness, accessibility, and authenticity.

medical device–related pressure injury Injury that results from the use of devices designed and applied for diagnostic or therapeutic purposes.

medication A drug specifically administered for its therapeutic effect on physiologic function.

medication administration record (MAR) A list of ordered medications, along with dosages and times of administration, on which the nurse initials medications given or not given. A paper MAR includes a signature section in which the nurse is identified by linking the initials used with a full signature.

medication error Any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the health care professional, patient, or consumer.

medication interaction A drug's action is modified by the presence of a certain food, herb, or another medication.

meditation Mindful reflection or contemplation; another form of intrapersonal communication. Some people use it regularly as a means of self-encouragement and reassurance.

menopause The permanent cessation of menstrual activity.

menstruation The female's cyclic periodic discharge of body fluid from the uterus during the reproductive years, from approximately 12 to 50 years of age.

message The content transmitted during communication.

meta-analysis An analysis that merges statistical results from related studies for the purpose of discovering similarities and differences between the studies.

metabolic acidosis High acid content in the blood, with a pH less than 7.35 and a bicarbonate level less than 21 mEq/L.

metabolic alkalosis An excess of bicarbonate ions, which raises the pH above 7.45 and bicarbonate levels greater than 28 mEq/L.

metabolism The process of chemically changing nutrients, such as fats and proteins, into end products that are used to meet the energy needs of the body or stored for future use, thereby helping maintain homeostasis in the body. The process by which a drug is altered to a less active form to prepare for excretion.

metaparadigm A global set of concepts that identify and describe the central phenomena of the discipline and explain the relationship among those concepts.

micronutrients Nutrients needed by the body in limited amounts.

micturition Urination.

middle-range theory A moderately abstract theory that has a limited number of variables. Middle-range theories are more concrete and narrowly focused on a specific condition or population than are grand theories.

milliequivalent The ability of cations to bond with anions to form molecules.

minerals Chemicals needed for energy, muscle building, nerve conduction, blood clotting, and immunity to diseases.

minor surgery Surgical alteration that is minimal with low risk to the life of the patient.

misdemeanor A crime of lesser consequence that is punishable by a fine or incarceration in a local or county jail for up to 1 year.

mixed incontinence A combination of both stress and urge incontinence.

mode of transmission The microorganism's form of transportation to travel from the source to the susceptible host.

moderate sedation Conscious sedation or an altered state of consciousness providing a moderate to deep level of sedation, amnesia, and analgesia that minimizes pain and discomfort achieved by use of pain medications and sedatives.

moisture-associated skin damage (MASD) Inflammation or skin erosion caused by prolonged exposure to a source of moisture (e.g., urine, stool, sweat, wound drainage, saliva, or mucus).

monocytes A type of white blood cell involved in phagocytosis; they become macrophages.

monounsaturated fatty acids Have only one double bond between per molecules and are components of triglycerides.

moral distress The anguish that health care professionals experience when their basic beliefs of what is right and wrong or ethical principles are challenged.

moral resilience A method for responding effectively to moral distress or ethical challenges; the capacity of an individual to sustain or restore his or her integrity in response to moral complexity, confusion, distress, or setbacks.

mourning The outward, social expression of loss.

mucous membranes Lining of the passages and cavities of the body, such as nasal, oral, vaginal, urethral, and anal areas.

mucus Fluid secreted by mucous membranes.

multimodal analgesia The use of more than one means for controlling pain.

multimodal learner A person who does best when more than one teaching strategy is used or who is able to adapt to a variety of teaching strategies.

myocardial infarction (MI) The blockage of blood flow to the coronary arteries of the heart.

myoglobin An oxygen-transporting and storage protein found in cardiac and skeletal muscle.

myopia Nearsightedness that causes a person to be able to see clearly only a short distance.

NANDA-I NANDA International, Inc., formerly the North American Nursing Diagnosis Association.

narcolepsy A chronic neurologic disorder caused by the brain's inability to regulate the sleep-wake cycle normally, resulting in an uncontrollable desire to sleep.

nasopharyngeal airway An airway placed through the nostril into the pharynx.

nature versus nurture The debate over whether development is predetermined at birth (nature) or whether the child's environment (nurture) controls how development progresses.

necrosis Death of cells, tissues, or organs.

negative reinforcement A form of learning that occurs when behavior results in the removal of an unpleasant stimulus, increasing the chance that the behavior will be repeated.

negative self-talk Internal conversation that is potentially harmful or destructive and may damage the ability of an individual to achieve his or her greatest potential or to overcome adversity.

negligence Creating a risk of harm to others by failing to do something that a “reasonable person” would ordinarily do or doing something that a “reasonable person” would ordinarily not do.

nephrons The tiny filtering units in the kidneys that form urine.

nerve block Regional anesthetic that is injected into a particular nerve, group of nerves, or surrounding tissue.

neurofibrillary tangles Twisted fragments of protein that clog the nerve cells, which interrupts nutrient delivery to brain cells.

neuropathic pain Pain that results from nerve injury; the pain continues even after the painful stimuli are gone.

neurotransmitters Inflammatory substances that are released into the extracellular space as a result of tissue damage.

neutrophils A type of white blood cell that acts as first defenders against bacterial and fungal infections, foreign antigens, and cell debris.

nits Lice eggs.

nociceptive pain The most common type of pain; occurs when nociceptors are stimulated in response to an injury or tissue damage from surgery or trauma or to inflammation.

nociceptors The free endings of afferent nerve fibers, which are sensitive to thermal, mechanical, or chemical stimuli.

nocturia Excessive urination at night.

nocturnal enuresis Bedwetting at night.

nonmaleficence “First, do no harm;” the avoidance of harm.

nonopioid analgesics Drugs that do not contain narcotics that are used in the treatment of many types of mild to moderate pain.

non-rapid eye movement (NREM) sleep The phases of sleep in which REM sleep does not occur, growth hormone is released to repair epithelial and brain cells, cell division for skin and bone marrow renewal occurs, and energy is conserved.

nonsteroidal antiinflammatory drugs (NSAIDs) Nonnarcotic drugs that do not contain steroids that are used in the treatment of many types of mild to moderate pain.

nontherapeutic communication Communication that can be hurtful and potentially damaging to interpersonal interaction. Changing the subject or sharing personal opinions serves to limit conversation between the nurse and the patient and discourages open conversation on sensitive topics.

nonverbal communication Wordless transmission of ideas in the form of body language, gestures, touch, attire, facial expressions, and eye contact.

NPO (nil per os) Nothing by mouth.

normal flora Non-disease-causing microorganisms, such as bacteria, fungi, and protozoa that live within or on the body.

nurse practice acts Laws that provide the scope of practice defined by each state or jurisdiction and are the legal limits of nursing practice. These acts are laws that the nurse must be familiar with to function in practice.

nursing The protection, promotion, and optimization of health and abilities, prevention of illness and injury, alleviation of suffering through the diagnosis and treatment of human response, and advocacy in the care of individuals, families, communities, and populations.

nursing diagnosis Identification of an actual or potential patient problem or response to a problem based on the clinical judgment of the nurse.

nursing informatics A specialty area of informatics that addresses the use of health information systems to support nursing practice.

nursing interventions classification (NIC) A comprehensive, research-based, standardized classification of multidisciplinary interventions and associated activities.

nursing minimum data set (NMDS) Standardized collection of essential nursing data used on a regular basis by the majority

of nurses in the delivery of care across settings.

nursing outcomes classification (NOC) Standardized vocabulary used for describing patient, family, or community responses to nursing interventions.

nursing presence The shared perception of human connectedness between a nurse and a patient.

nursing process The systematic method of critical thinking used by professional nurses to develop individualized plans of care and provide care for patients.

nursing theory A group of concepts that can be tested in practice and can be derived from a conceptual model.

nutrients The necessary substances obtained from ingested food that supply the body with energy; build and maintain bones, muscles, and skin; and aid in the normal growth and function of each body system.

nystagmus Rapid, shaking, involuntary movement of the eyes.

obesity Excessive accumulation of body fat that is the result of a person's energy intake consistently exceeding energy use. Body mass index (BMI) of ≥ 30 .

object permanence An object still exists even when it is out of sight.

objective data Data that can be measured or observed. The nurse's senses of sight, hearing, touch, and smell are used to collect objective data. Also called signs.

obstructive sleep apnea (OSA) Absence of breathing during sleep caused by collapse of the upper airway despite respiratory effort.

olfaction The sense of smell.

oliguria A reduced urine volume less than 1 mL/kg/h in an infant; less than 0.5 mL/kg/h in children; and less than 400 mL/day in adults.

oncotic pressure The presence of plasma proteins, specifically albumin; because these plasma proteins are too large to pass through the capillary membrane, they hold the fluid in the intravascular space.

onset of action The time the body takes to respond to a drug after administration.

open wound A wound characterized by an actual break in the skin's surface.

openness A leader's ability to listen to other points of view without prejudging them or shutting them down.

operant conditioning A form of learning based on reinforcement or punishment.

opioid analgesics The most effective agents for relief of moderate to severe pain. These narcotic drugs work by binding to the opioid receptors in the nervous system, which are sites of endorphin action.

opportunistic infections Harmless organisms that become pathogenic.

oral Mouth.

orthopnea Difficulty in breathing when in positions other than upright.

orthostatic hypotension A sudden drop of 20 mm Hg in systolic pressure and 10 mm Hg in diastolic pressure when the patient moves from a lying to sitting to standing position.

osmolality Ionic concentration.

osmolarity The number of osmols per liter of solvent.

osmoreceptor Receptors located in the hypothalamus, monitor the osmolarity of blood plasma.

osmosis The movement of water across cell membranes.

osmotic pressure The force created when two solutions of different concentrations are separated by a selectively

permeable membrane.

ossicles The three small bones in the middle ear.

ostomy A surgically created opening in the gastrointestinal, urinary, or respiratory organs that is exited onto the skin.

outcome identification Observable behaviors or actions that indicate attainment of a goal.

outcome indicators Criteria on which goal attainment is observed or measured.

overflow incontinence A condition in which a person is unable to empty the bladder completely, resulting in a constant dribbling of urine or frequency in urination.

oxygen saturation Amount of oxygen in the arterial blood.

pain threshold The point at which the brain recognizes the stimulus as pain.

pain tolerance The intensity or duration of pain that a patient is able or willing to endure.

palliative care Comfort care offered to patients at any stage of a serious illness.

pallor Pale skin tone that is usually uniformly disseminated throughout the skin surface. Pallor can be caused by illness, emotional shock or stress, decreased exposure to sunlight, anemia, or genetics.

palpation Physical examination using touch to assess body organs and skin texture, temperature, moisture, turgor, tenderness, and thickness.

papillary dermis Projections that provide the “stick” that anchors layers of the skin together, preventing them from sliding back and forth; also called rete ridges.

paracentesis A needle aspiration that involves removing fluid from the peritoneal cavity.

paralytic ileus The stoppage of peristalsis.

paraplegia Lower body paralysis.

parasite Organisms that live on or in other organisms and are capable of causing disease.

parasomnias Abnormal sleep behaviors.

parenteral Medication administration by injection or infusion.

paresthesia Numbness or tingling.

partial-thickness wound A wound that involves the epidermis and the dermis but does not extend through the dermis to the subcutaneous layer.

passive range of motion Passive movement of each joint of the body of another person to the point of resistance while evaluating the person's comfort level.

pathogen Any infectious, disease-causing agent; can include bacteria, viruses, fungi, and parasites.

pathologic bone fractures Spontaneous bone breaks without trauma.

patient interview A formal, structured discussion in which the nurse questions the patient to obtain demographic information, as well as data about current health concerns and past medical and surgical history.

patient-centered care Providing care that is respectful of, and responsive to, individual patient preferences, needs and values, and ensuring that patient values guide all clinical decisions.

patient-controlled analgesia (PCA) A system in which an electronically controlled infusion pump immediately delivers a prescribed amount of analgesic to the patient when he or she activates a button, without the need for a nurse to administer it.

peak plasma level The highest serum (blood) concentration of a drug.

pediculosis A contagious scalp infestation most commonly known as head lice.

Penrose drain An open drain that is a flexible piece of tubing, usually not sutured into place.

perception The way the brain perceives information.

percussion Tapping the patient's skin with short, sharp strokes that cause a vibration to travel through the skin and to the upper layers of the underlying structures.

perimenopause The phase before the onset of menopause and the first year after menopause.

perineal care Cleansing of the genital area, urinary meatus, and anus.

perioperative nursing The nursing specialty that provides for patients before, during, and after surgery.

perioperative period The three phases of surgery.

peripheral neuropathy Nerve damage away from the center of the body.

peripheral pulse Pulses that can be palpated over arteries located away from the heart.

peripherally inserted central catheter (PICC) A catheter inserted by a physician or specially trained nurse into the cephalic or basilic veins or antecubital space and threaded up until it rests in the superior vena cava right outside the right atrium. It can remain in place for weeks to months and does not have the risk for pneumothorax associated with its use; and it is associated with fewer catheter-related infections.

peristalsis Progressive wave action causing movement of contents through the gastrointestinal system.

peritoneal dialysis A procedure to remove waste products from the body of a patient in chronic renal failure that is performed by instilling dialysis solution into the patient's abdominal cavity through an external catheter.

personal protective equipment (PPE) The equipment that health care personnel use to protect against the spread of infection.

Gloves, masks, goggles, face shields, gowns, caps, and shoe coverings are all examples.

petechiae Tiny, dark red spots that indicate hemorrhage under the skin.

pétrissage A massage technique performed by using a kneading motion with the fingers and thumb along the patient's back and shoulders.

phantom pain Pain that occurs after an amputation when the brain continues to receive messages from the area of the amputation.

pharmacodynamics The process in which a medication interacts with the body's cells to produce a biologic response.

pharmacokinetics The study of how a medication enters the body, moves through the body, and is excreted.

phenomenologic research Research that explores the lived experiences of a specific group of people experiencing a similar event in their lives.

phenomenon An aspect of reality that can be observed or experienced.

philosophy A statement about the beliefs and values of nursing in relation to a specific phenomenon such as health.

phlebitis Inflammation of a vein.

physical assessment A comprehensive data collection followed by an extensive physical examination of every body system.

physical dependence Dependence on a medication that builds as the body becomes unable to function normally without the medication, reaching the point of withdrawal symptoms on abrupt cessation of the medication.

physical restraint A device, such as material or equipment attached or adjacent to the patient's body, used to restrict movement.

PICO An acronym used to formulate a research question that stands for: P: patient, population, or problem; I: intervention; C: comparison intervention; O: outcomes.

PIE note Used to document problem (*P*), intervention (*I*), and evaluation (*E*).

planning Phase of the nursing process during which the nurse prioritizes a patient's nursing diagnoses, establishes short- and long-term goals, chooses outcome indicators, and identifies interventions to address patient goals.

pleural effusion Fluid accumulation in the pleura of the lungs.

pneumonia Inflammation of the lungs usually caused by an infection or foreign material.

poisoning The intentional or unintentional ingestion, inhalation, injection, or absorption through the skin of any substance that is harmful to the body.

polyps Benign or malignant tissue growth in the colon.

polysomnography The recording of brain waves and other physiologic variables, such as muscle activity and eye movements, during sleep.

polyunsaturated fatty acids Fatty acids with multiple pairs of double carbon bonds.

polyuria An excessive volume of urine formed and excreted each day.

portal of entry The means by which the microorganism enters the susceptible host.

portal of exit The means by which the pathogen escapes from the reservoir or source of infection.

positive self-talk Internal conversation that provides motivation and encouragement; it may be used to build self-esteem and self-confidence.

postformal thought Cognitive development past Piaget's formal operational stage consisting of gradual change in thinking in

the face of reality and adult responsibility.

postoperative phase The third phase of surgery that begins when the patient is admitted to the postanesthesia care unit and ends when the patient has completely recovered from the surgical procedure, which in some cases is several months.

posttraumatic stress disorder (PTSD) A very serious mental health condition characterized by flashbacks and erratic behaviors that results from exposure to a horrifying experience. PTSD may develop when an individual's ability to cope is exceeded by the trauma that was experienced.

postural drainage A therapeutic way to position a patient to use gravity to help mobilize respiratory tract secretions.

prayer A form of meditation traditionally directed to a deity.

prealbumin A plasma protein synthesized by the liver and considered a precise measure of nutritional status.

precision To provide sufficient detail, resulting in the understanding of exactly what was meant.

preemptive analgesia The administration of medications prior to a painful event to minimize pain.

prejudice A preformed opinion, usually an unfavorable one, about an entire group of people that is based on insufficient knowledge, irrational feelings, or inaccurate stereotypes.

preload Amount of blood and pressure at the end of diastole.

preoperative The first phase of surgery that begins when the patient decides to have surgery and ends when the patient is taken to the operating room.

presbycusis Age-related hearing loss.

presbyopia Farsightedness, or an age-related decrease in the ability to focus on near objects.

prescription Medications dispensed by a pharmacist on receipt of written directions from a medical provider legally permitted to prescribe drugs.

pressure injury Damage to the skin caused by pressure in an area that may include soft tissue damage and is usually found over bony prominences.

prevalence Pervasiveness or extent of a disease.

preventive action A lifestyle change along with information gathering about a health topic that leads to actual change in behavior.

primary data Data that comes directly from the patient.

primary intention Wounds that tend to heal quickly and result in minimal scar formation because the edges of the skin can be brought together.

primary prevention The stage of an individual's health when it is possible to keep disease from becoming established, either by removing the potential causes or by increasing resistance.

privacy The right to be free from intrusion or disturbance in a person's private life or affairs.

problem solving A systematic, analytic approach to finding a solution.

problem-focused nursing diagnoses NANDA-I diagnostic labels that are clinical judgments about undesirable human responses to health conditions or life processes that occur in an individual, family, group, or community.

problem-oriented medical record (POMR) Integrates charting from the entire care team in the same section of the record. The POMR is usually structured to provide a focus for the documentation.

profession An occupation that requires at a minimum specialized training and a specialized body of knowledge.

proliferative phase A phase in wound healing that repairs the defect; fills the wound bed with new tissue, called granulation tissue; and resurfaces the wound with skin.

prophylactic An agent that prevents the spread of disease. A popular name for a condom.

proprioception An awareness of posture and movement.

positive reinforcement A form of learning that occurs when a behavior is met with a positive consequence increasing the likelihood of repeating the behavior.

prosthetic Artificial.

prothrombin time A coagulation blood test that detects bleeding disorders caused by abnormalities of the extrinsic clotting system, and used to monitor the effectiveness of anticoagulant therapy.

protocols Written plans that can be generalized to groups of patients with the same or similar clinical needs that do not require a physician's order.

proxemics The study of the spatial requirements of humans and animals.

pruritus Itching.

psychogenic pain Pain that is perceived by an individual but has no physical cause.

psychomotor domain A form of learning that incorporates physical movement and the use of motor skills into learning.

ptosis Abnormal drooping of the eyelid.

puberty A time of great change as a child matures into an adult, both physically and socially; also referred to as adolescence.

public health nursing Branch of nursing that examines the greater community as a whole—the city, county, state, nation, continent, world—and designs collaborative and interdisciplinary strategies to keep the population healthy by preventing or controlling disease and threats to human health.

pulmonary embolism (PE) A blood clot that detaches and lodges in the pulmonary artery.

pulse The palpable, bounding blood flow created by the contraction of the left ventricle of the heart.

pulse deficit The apical pulse rate exceeds the radial pulse rate.

pulse oximetry Measures the amount of oxygen available to tissues, is typically assessed with respirations.

purging Intentional vomiting.

purpura Bleeding underneath the skin.

purulent Containing pus.

quadriplegia Inability to move all four extremities.

qualitative research Research that focuses on personal beliefs, thoughts, and feelings that produces data in the form of comments or observations.

quantitative research Research that focuses on measurable, objective data that usually produces information in the form of numbers.

quasi-experimental research Research that examines a causal relationship between variables, but it may not meet the strict guidelines of experimental research.

questioning Someone who is unsure or exploring his or her sexual orientation or gender identity.

RACE A fire emergency response acronym. R: rescue all patients in immediate danger and move them to safe areas. A: activate the manual-pull station and/or fire alarm and have someone call 911. C: contain the fire by closing doors, confining the fire and preventing the spread of smoke. E: extinguish the fire if possible after all patients are removed from the area.

race A socially constructed concept that tends to group people by common descent, heredity, or physical characteristics.

racism A belief that race is the primary determinant of human traits and capacities and that racial differences produce an inherent superiority of a particular race.

radial pulse Palpated by placing the first two or three middle fingers of one hand over the radial artery at the groove along the radial, or thumb side, of the patient's inner wrist.

radiating pain Pain that extends to another area of the body.

radiography The use of x-rays to visualize bones, organs, and soft tissues for abnormalities.

range of motion Degrees of movement.

rapid eye movement (REM) sleep Quick scanning movements of the eyes that occur during sleep, associated with dreaming.

reasoning Logical thinking that links thoughts, ideas, and facts together in a meaningful way; used in scientific inquiry and problem solving.

rebound tenderness Discomfort experienced after stimulation is discontinued.

receiver The person who receives and decodes, or interprets, the communication.

referent The initiating event or thought that leads one person to interact with another, may be anything, including something related to one of the senses.

referred pain Pain that occurs in one area but hurts in another area, such as pain from a myocardial infarction or heart attack.

reflection The process of contemplating experiences, sometimes even life-changing experiences, and searching for meaning in those events.

regional anesthesia Anesthesia that disrupts the transmission of nerve impulses to a specific area of the body.

regulatory law Laws, established by administrative bodies, such as state boards of nursing, that outline how the requirements of statutory law will be met.

related factors The underlying cause or etiology of a patient problem.

relativist thinking The ability to recognize multiple, conflicting versions of “truth” representing legitimate alternatives occurring as adolescents become aware of the diversity of opinions on any topic.

relevance To focus on facts and ideas directly related and pertinent to the subject at hand.

religion Provides a structure for understanding spirituality and involves rites and rituals within a faith community.

remission A period of relief from symptoms during chronic illness.

renin-angiotensin system Regulates blood pressure and fluid balance through vasoconstriction and excretion or reabsorption of sodium.

replication Reproduction or duplication.

reservoir masks Masks that have a bag that inflates with oxygen and deliver higher levels of oxygen to a patient.

residual volume (RV) The amount of air remaining in the lungs after maximum expiration. The expected finding is 1.2 liters.

respiration The frequency of breaths per minute (BPM). One inhalation and one exhalation is one breath.

respiratory acidosis Arterial blood pH of less than 7.35, and the partial arterial pressure of carbon dioxide (PaCO₂) is increased to greater than 45 mm Hg. Usually the result of hypoventilation due to chest injury, asthma attack, brain injury, pulmonary edema, or medications.

respiratory alkalosis Arterial blood pH of greater than 7.45, and the partial arterial pressure of carbon dioxide (PaCO₂) is decreased to less than 35 mm Hg. Usually the result of hyperventilation or excess exhalation of carbon dioxide.

responsibility The concept of being dependable and reliable.

restless legs syndrome A familial sleep disorder characterized by disagreeable-feeling leg movements resulting from intense, abnormal, lower extremity sensations of crawling or tingling.

rete ridges Projections that provide the “stick” that anchors layers of the skin together, preventing them from sliding back and forth; also called papillary dermis.

retina Innermost layer of the eye that contains photoreceptors (rods and cones).

reversibility An important development in thinking patterns that enables older children and adults to change direction in their thinking to return to the starting point.

rigor mortis The stiffening of the joints of the body after death.

risk factor reduction The step-by-step improvement of individual health factors that, when combined, lower the likelihood of developing a certain disease.

risk factors Environmental, physical, psychological, or situational concerns that increase a patient's vulnerability to a potential problem or concern.

risk nursing diagnoses NANDA-I diagnostic labels that identify risk factors that are vulnerabilities of an individual, family, group, or community for developing negative human responses to health conditions or life processes.

rituals Formal, stylized, repetitive, and stereotyped actions performed in special places at special times.

rods Types of photoreceptors present in the retina that are sensitive to light and therefore provide vision in dim light.

role boundaries The limits and responsibilities of individuals within a given setting.

rule of descent The arbitrary assignment of a race to a person on the basis of a societal dictate that associates social identity with ancestry.

safety The condition of being free from physical or psychological harm and injury.

salivary glands Glands in the mouth secrete mucus, enzymes, and a watery fluid, which mix to form saliva.

sample The actual individuals in the population from whom the data will be collected.

sandwich generation Refers to middle-aged adults who are the caretakers of more than one generation of their families.

sanguineous Drainage that usually indicates bleeding and is bright red.

sarcopenia Loss of flesh; the process of decreasing muscle tissue (muscle mass) and muscle strength that begins in the 30s.

saturated fatty acids Contain as many hydrogen atoms as the carbon atoms can bond with and no double carbon bonds.

SBAR A communication format specifically suggested for use in nurse–physician interactions and as a handoff tool. Stands for Situation, Background, Assessment, Recommendation.

scar tissue An avascular mass of collagen that gives strength to the repaired wound.

scoliosis Sideways or S-shaped curvature of the spine that is always abnormal.

scrub nurse Specially trained nurse who prepares the surgical setup, handles instruments, maintains surgical asepsis while draping, and assists the surgeon by passing instruments, sutures, and supplies.

sebaceous glands Glands in the dermis that secrete an oily substance that keeps the hair and skin soft.

secondary data Information about a patient shared by family members, friends, or other members of the health care team.

secondary intention New tissue fills in from the bottom and sides of the wound until the wound bed is filled.

secondary prevention The stage of an individual's health when a disease process has evolved far enough that it is detectable by medical tests but the patient may still be asymptomatic.

secondary sleep disorders Sleep problems caused by underlying medical or psychiatric disorders.

sedation A state of calm or reduced anxiety.

selectively permeable membrane The cell membrane that allows water to move across but not the solutes.

self-actualization The highest level of optimal functioning that involves the integration of cognition, consciousness, and physiologic utility into a single entity.

self-concept The way in which individuals perceive unchanging aspects of themselves, such as social character or abilities, physical appearance, body image, and ways of thinking.

self-efficacy The belief in one's own ability to perform a task.

semicircular canal A second set of labyrinths in the inner ear with receptors that interpret the head's position.

sender The person who initiates and encodes the communication. Senders may be individuals or groups who have a message to share.

senescence Biological aging.

sensation A feeling, within or outside the body, of conditions resulting from stimulation of sensory receptors.

sense of coherence (SOC) A characteristic of personality that references one's perception of the world as comprehensible, meaningful, and manageable.

sensory adaptation Process by which some impulses are ignored by the brain during times of alertness because they are not prioritized as important.

sensory deprivation Decreased stimulation from the environment.

sensory overload An overabundance of stimuli from the environment and from internal sources such as pain.

sentinel event An unexpected occurrence involving death or serious physical or psychological injury or the risk of injury. Such events are called "sentinel" because they signal the need for immediate investigation and response.

sequential compression devices (SCDs) Inflatable sleeves that wrap around the legs of patients and are attached to an air source that inflates and deflates, creating a massaging action for the lower extremities.

seriation The ability to arrange things in a logical order.

serosanguineous Drainage that is pink to pale red and contains a mix of serous fluid and blood.

serous Drainage that contains clear, watery fluid from plasma.

sex Classification of male or female determined by the internal and external genitalia. The term often used to express “sexual intercourse.”

sexual orientation A person's attraction to his or her own sex, the opposite sex, or both sexes when choosing a sexual partner.

sexuality The collective characteristics that mark the differences between male and female.

sexually transmitted disease (STD) A disease acquired as a result of sexual intercourse or other intimate contact with an infected individual.

sexually transmitted infection (STI) An infection acquired as a result of sexual intercourse or other intimate contact with an infected individual without actual signs of disease.

shear The result of the relationship between friction and gravity; causes a hyperangulation and stretching of the blood vessels, damaging them and their ability to transport blood.

shock A life-threatening condition in which the circulatory system fails to maintain adequate perfusion to the vital organs.

short-term goals Goals that are achievable within less than a week.

shroud A cloth, sheet, or bag, for transportation of the body to the morgue or funeral home.

side effects Predictable but unwanted and sometimes unavoidable reactions to medications.

significance To concentrate on the most important information in one's reasoning and take into consideration the most important concepts, facts, or ideas.

signs Data that can be measured or observed. The nurse's senses of sight, hearing, touch, and smell are used to observe signs; also called objective data.

sinus tract A tunnel or narrow passageway extending outward from the edge of the wound.

situational theories The theory that leaders change their approach depending on the situation. The situation includes a number of factors, such as characteristics of the group, the type of business, and the economic climate.

sitz baths Baths for soaking a patient's perineal area.

Six Rights of Medication Administration The right drug, right dose, right time, right route, right patient, and right documentation.

skipped generation The parents of the approximately 4% to 5% of the child population in the United States who lives with grandparents and apart from parents.

slander Oral defamation of character.

sleep A naturally occurring altered state of consciousness regulated by the central nervous system.

sleep apnea Absence of breathing (apnea) or diminished breathing during sleep.

sleep deprivation A prolonged, inadequate quality and quantity of sleep.

smegma A whitish substance under the foreskin.

SOAP note A format for documentation. Stands for Subjective data, Objective data, Assessment, Plan.

SOAPIE note A format for documentation. Stands for Subjective data, Objective data, Assessment, Plan, Intervention, Evaluation.

SOAPIER note A format for documentation. Stands for Subjective data, Objective data, Assessment, Plan, Intervention, Evaluation, Revisions to plan.

social determinants of health Identifiable variables that affect health and wellness that are key components in guiding health promotion activities and preventive behaviors.

social media Include various online technologies such as Facebook, Twitter, and LinkedIn that allow people to communicate easily via the internet to share information and resources.

social structure One of three structural elements that keeps a culture strong; influences how people interact with one another.

socialization The process of being reared and nurtured within a culture and acquiring its characteristics.

solute Substances that dissolve in a liquid.

solvent The liquid a in which a solute dissolves.

somatic pain Pain that occurs with injury to skin, muscles, bones, and joints.

somnambulism Sleepwalking.

spasticity Increased muscle tone.

spinal anesthesia An anesthetic agent injected into the subarachnoid space.

spirit The expression of spirituality through a person's capability for thought, contemplation, and exploration of meaning and purpose in life.

spiritual care A mutual, purposeful, interactive process between a nurse and other members of the health care team, and a patient, which may include family, to promote the patient's spiritual health.

spiritual distress A disruption in a belief or value system.

spirituality The expression of meaning and purpose in life.

stage I pressure injury A wound resulting from pressure on tissue characterized by intact, nonblistered skin with nonblanchable erythema, or persistent redness, in the area that has been exposed to pressure.

stage II pressure injury A partial-thickness wound resulting from pressure on tissue that involves the epidermis and/or dermis but does not extend below the level of the dermis. It can present as a blister or open wound.

stage III pressure injury Full-thickness wound resulting from pressure on tissue that extends into the subcutaneous tissue but does not extend through the fascia to muscle, bone, or connective tissue.

stage IV pressure injury Full-thickness wound resulting from pressure on tissue that is deeper than a stage III pressure ulcer and involves exposure of muscle, bone, or connective tissue such as tendons or cartilage.

stages of illness model A model that best describes illness behavior and how individuals arrive at the coping mechanisms necessary for the management of disease conditions.

stagnation Self-centered and narcissistic.

stakeholder Someone who is an integral part of the process, either the end user of the process or anyone who may be affected by the process.

standardized nursing terminology A structured vocabulary that provides a common means of communication among nurses. A unified language classification system sometimes referred to as a taxonomy.

standards of care The minimum requirements for providing safe nursing care; federal and state laws, rules and regulations, accreditation standards, and institutional policies and procedures are used to formulate nursing standards of care.

standards The minimum set of criteria of practice.

standing orders Preapproved standardized order sets.

statutory law Laws created by legislative bodies such as the U.S. congress and state legislatures. State statutes must be consistent with all federal laws.

steatorrhea Fecal fat.

stenosis Narrowing.

stereotype An idea about a person, a group, or an event that is thought to be typical of all others in that category.

sterilization A process used to destroy all microorganisms, including their spores.

stimulus A change in the environment sufficient to evoke a response.

stoma The protuberance of the gastrointestinal, urinary, or respiratory organs through the skin.

strabismus Crossed eyes.

stratum corneum The outermost of the epidermal layers.

stratum germinativum The innermost of the epidermal layers.

stress A demand from the internal or external environment that exceeds the person's immediately available resources or ability to respond.

stress appraisal The process by which a person interprets a stressor as either a threat or a challenge.

stress incontinence A loss of urine control during activities that increase intraabdominal pressure, such as coughing, sneezing, laughing, or exercise.

stressor An event or stimulus that disrupts a person's sense of equilibrium.

striae Stretch marks resulting from pregnancy and weight loss or gain.

subcutaneous layer A layer of adipose tissue, or fat, that attaches the dermis to the underlying muscles and bone, delivers the blood supply to the dermis, provides insulation, and has a cushioning effect.

subcutaneous An injection into the subcutaneous tissue just below the skin.

subjective data Spoken information that is difficult to authenticate. Generally, subjective data are gathered during the interview process if patients are well enough to describe their symptoms.

sublingual Medication administration under the tongue.

substance use disorder A pattern of behaviors that range from misuse to dependency or addiction on alcohol, legal drugs, or illegal drugs; causes significant impairment such as disability; inability to fulfill work, home, or school responsibilities; or health problems.

suffocation A state in which air no longer reaches the lungs because of smothering, drowning, or choking, resulting in a loss of respiration.

sundowning A worsening of agitation and confusion in the evening.

superego The moral branch of personality, referred to as the conscience.

superficial wound A wound that involves only the epidermis.

superstructure One of three structural elements that keeps a culture strong; provides a belief system that helps people identify themselves, their society, and the world around them.

supervision Monitoring an activity being carried out by someone else and making sure that it is performed correctly.

suppositories A drug delivery system that is inserted into the rectum, where it dissolves for medication absorption by coming into contact with the rectal mucosa.

surgical asepsis Sterile technique used to prevent the introduction of microorganisms from the environment to the patient.

susceptible host Someone exposed to an infectious disease who is likely to contract the disease. Increased susceptibility is associated with people at the extremes of age, those who are nutritionally compromised, and those who have experienced recent trauma or surgery.

suspected deep tissue injury An area of intact skin that is purple or maroon or a blood-filled blister indicating damage under the skin.

sutures Threads or metal staples used to bring the edges of a wound together to speed wound healing and reduce scar formation.

symbols Signs, sounds, clothing, tools, customs, beliefs, rituals, and other items that represent meaningful concepts.

symptoms Subjective description of a disease process or problem by a patient.

synergistic effect The combined effect of substances is greater than the effect of either substance if taken alone.

systematic review Provides a comprehensive, unbiased analysis through the use of a strict scientific design to select and assess various related research studies.

systolic pressure The peak of the pressure wave on the arterial wall.

tachycardia An excessively fast heart rate (>100 bpm in the adult).

tachypnea An increase in respiratory rate to more than 24 BPM in the adult.

tactile fremitus A palpable vibration transmitted through the chest wall that occurs with the movement of the vocal cords during speech.

tactile Touch.

tapotement A massage technique that involves a tapping or percussion motion with the side of the palm or ulnar side of the hand.

target population (population of interest) Groups of individuals who are of concern or at risk for injury, disease, or disability, including those most vulnerable.

taxonomy A unified language classification system.

teaching Imparting knowledge or giving instruction.

telecommunications device for the deaf (TDD) An electronic device that sends text communications through a telephone line.

telehealth/telemedicine The use of the Internet to link medical experts with other clinicians, patients, or patient information, allowing for remote consultations with clear video images and high-fidelity links.

temperature The sensible heat of the human body.

temporary incontinence Urinary leakage that results from issues such as severe constipation, infections in the urinary tract or vagina, or medication usage.

tertiary intention A delay in wound healing between injury and closure.

tertiary prevention Occurs when a condition or illness is permanent and irreversible. The aim of care is to reduce the number and impact of complications and disabilities the individual experiences as a result of the disease process or medical condition.

The Joint Commission An independent, not-for-profit group in the United States that accredits hospitals and other health care-related agencies and focuses on the goal of patient safety.

therapeutic communication A beneficial, positive interaction that focuses on the patient in a nurse-patient interaction.

therapeutic effect The intended effect; the desired result or action of a medication.

thoracentesis A needle aspiration that removes fluid from the pleural space.

thrill Abnormal vibration felt on palpation over an aneurysm, the carotid artery, or an arteriovenous (AV) fistula.

thrombocytes Platelets.

thrombophlebitis Inflammation of the vein with the formation of a blood clot.

tinnitus Ringing in the ears.

tonicity The level of osmotic pressure of a solution.

toothette A disposable foam swab used for oral care.

topical Medication administration on the skin or mucous membranes.

topical anesthesia A type of local anesthesia applied to surface areas of the skin and mucous membranes, used to decrease discomfort.

torts Wrongs committed against another person that do not involve a contract.

tortuosity Bending and twisting.

total parenteral nutrition (TPN) Intravenous nutrition given through a peripherally inserted central catheter line or central venous catheter by means of an infusion pump. TPN may be the only feasible option for patients who do not have a functioning GI tract, or it may be given when patients are unable to ingest, digest, or absorb essential nutrients.

toxic effects The buildup of medication in the blood due to impaired metabolism and excretion or to an overdose.

toxins A wide variety of substances that can poison or harm a living organism or individual through mechanisms such as ingestion, inhalation, and environmental exposure.

tracheostomy tube A tube placed directly in the trachea through the neck to control the airway.

trade name A registered name assigned by the drug manufacturer; brand name.

trait theories Theory that assumes that leaders are born with the personality traits necessary for leadership, which few people were thought to possess.

transformational leaders Leaders who employ methods that inspire people to follow their lead. Transformational leaders work toward transforming an organization with the help of others.

transactional leaders Leaders who use reward and punishment to gain the cooperation of followers.

transcellular Extracellular fluid that is in cerebrospinal, synovial, peritoneal, pleura, and pericardial fluids.

transcendence The process of moving beyond who one is in the moment and toward who one will become in the future.

transcultural nursing A nursing specialty that seeks to address the multifaceted aspects of culture and ethnicity.

transdermal patch A topical preparation designed to deliver medication slowly for long-term systemic effects.

trans-fatty acids Composed of partially hydrogenated fatty acids, and saturated fats that are known to raise the body's total cholesterol.

transgendered A person who has a gender identity or gender perception different from the phenotypic gender.

transsexual A person who self-identifies as a member of the opposite sex. The sexual anatomy is not consistent with the gender identity.

transvestite A person who has the desire to dress in the clothes of and be accepted as a member of the opposite sex.

trapeze A triangular device suspended above the bed to assist with movement and transfers.

triglycerides The most abundant lipids in food. Although the intake of a limited amount of triglycerides is important, an excess can be unhealthy.

troponin I and troponin T Proteins found exclusively in cardiac muscle and released during myocardial damage.

trough The lowest serum level of the medication.

tubal ligation Female sterilization; the ligation of the fallopian tubes; the tubes are tied off or severed.

tunnel A narrow passageway extending outward from the edge of the wound.

turgor Tension due to fluid content.

ultrasound A procedure that provides visualization of soft tissue organs by recording and measuring the reflection of ultrasonic waves.

undermining An area of tissue loss present under intact skin, usually along the edges of the wound, forming a “lip” around the wound.

unintentional injuries Unplanned incidents causing injury such as falls, motor vehicle crashes, poisonings, drownings, fire-associated injuries, suffocation by ingested objects, and firearms.

unintentional poisoning Unplanned ingestion, inhalation, injection, or absorption through the skin of any substance harmful to the body.

unintentional torts Omissions or acts by individuals that cause unintended harm.

unstageable pressure injury A full-thickness wound in which the amount of necrotic or slough tissue in the wound bed makes it impossible to assess the depth of the wound or the involvement of underlying structures.

urea Waste products in the blood that are removed by the urinary system.

urge/urgency Innervation of the bladder that signals a person when it is time to urinate and empty the bladder.

urgent surgery Surgery that needs to be performed within the next 24 hours.

urinary diversion A surgical procedure performed when bladder function is impaired due to trauma or disease involving the bladder, distal ureters, and, rarely, urethra.

urinary incontinence Inability to control the passage of urine.

urinary retention Inability of the bladder to empty.

urinary tract infection Infection that occurs when bacteria, usually *Escherichia coli*, from the digestive tract invade the urethra and multiply.

urobilinogen Substance produced by the breakdown of bilirubin in the intestines.

utilitarianism An ethical theory in which behaviors are determined to be either right or wrong based on how they benefit the greater good.

vaginismus Contraction of the vaginal muscles to the degree that the penis cannot be inserted.

validation The process of gathering information to determine whether the information or data collected are factual and true.

validity The strength or the degree to which a concept, conclusion, or measurement is justifiable and corresponds accurately to the real world.

Valsalva maneuver Bearing down while holding the breath; usually done while defecating.

values clarification A process used to help individuals reflect on, clarify, and prioritize personal values to increase self-awareness or to make decisions.

values conflict When a person's values are inconsistent with his or her behaviors or when the person's values are not consistent with the choices that are available.

values system A set of somewhat consistent values and measures that are organized hierarchically into a belief system on the basis of a continuum of relative importance.

values Enduring ideas about what a person considers is good, best, and the right thing to do—and the bad, worst, and wrong thing to do—and about what is desirable or has worth in life.

variable A concept with different values that can be measured, manipulated, or controlled in the study.

vasectomy Male sterilization; the severing of the vas deferens, which carry sperm out of the testes.

vasoconstriction Narrowing of blood vessels throughout the body that increases arterial blood pressure.

vectors Insects or animals that carry pathogens from one host to another.

venipuncture Insertion of a needle directly into a vein.

venous thromboembolism (VTE) A condition in which a blood clot forms most often in the deep veins of the legs, groin, or arm (known as deep vein thrombosis, DVT) and may travel in the circulation, lodging in the lungs (known as a pulmonary embolism, PE).

veracity Truthfulness.

vertigo Disequilibrium, spinning sensation.

vibration External manipulation of the thorax by gently shaking a flat hand against the chest; used during postural drainage therapy.

virus The smallest microorganisms that are reproduced inside living cells and are responsible for causing many different types of disease.

visceral pain Pain that arises from the organs of the body and occurs in such conditions as appendicitis, pancreatitis, inflammatory bowel disease, bladder distention, and cancer.

vital signs (VS) A basic but very important component of the physiologic assessment of a patient; used to monitor the functioning of body systems. VS consist of body temperature (T), pulse (P), respirations (R), and blood pressure (BP).

vitamins Organic compounds that contribute to important metabolic and physiologic functions within the body.

vitiligo A loss of skin pigment.

vulnerable populations Those at high risk for a disease or problem.

water-soluble vitamins Vitamins that dissolve in the body and are excreted in the urine. They are easily destroyed by air, light, and cooking. Water-soluble vitamins must be ingested daily through dietary sources or supplements because they are not stored in the body. Examples are C and B complex vitamins.

wear-and-tear theory of aging A theory first introduced in 1882 by Dr. August Weismann, a German biologist, that aging occurs because the body wears out from hard use.

wellness The active process of self-care through being aware of and making choices toward a healthy life.

windshield survey An initial needs assessment that involves collecting data through observation of the community's geography, population, environment, industry, education, recreation, communication, transportation, and public services.

wound Disruptions in the skin's integrity that lead to a loss of the skin's normal functioning.

zygote A fertilized ovum; begins as a single cell.

Prefilled cartridge, [809–810](#)

Pregnancy

- bowel elimination and, [1012](#)
- diversity considerations in, [235b](#)
- substance abuse and, [24b](#)

Prejudice, [22–23](#), [381](#)

Preload, [913](#)

Premature ejaculation, [430](#)

Prenatal screening, [235b](#)

Preoperational stage, in Piaget's theory, [232](#)

Preoperative checklist, [895f](#)

Preoperative phase, of surgery, [875–876](#)

- altered structure and function during, [883](#)
- assessment in, [885–886](#), [886b](#)
- nursing interventions during, [889–892](#)

- informed consent in, 890–892, 893f
- pain management plan in, 890
- patient preparation in, 892
- preoperative teaching in, 889–890, 890b

Preoperative teaching, 889–890, 890b

Presbycusis, 689

Presbyopia, 342b, 690

Preschool child

- growth and development of, 240–241, 240b, 241b, 241f
 - across theories, 238t
- urinary elimination of, 1037

Prescription medications, 788–790, 788f, 789b, 789f, 790t

Presence, 30

Pressure injuries, 550

- prevention of, UAP supervision of, 566b

Pressure Ulcer Prevention and Treatment Guidelines, 608–610

Pressure ulcers, 550, 597–599

- classification of, 599–601
- deep tissue injury, 600–601, 600f
- duration of, 598
- friction and shear, 598
- intensity of, 597–598
- medical devices for, 598
- moisture and, 598
- nutrition, 599
- prevention of, UAP supervision of, 566b
- risk assessment for, 602, 602b
- sensory loss or immobility, 598
- sites of, 597f
- stage 1, 599, 599f
- stage 2, 599, 599f
- stage 3, 600, 600f
- stage 4, 600, 600f

- unstageable, [600](#), [600f](#)
- wound assessment for, [602–607](#)
 - conditions of wound edges and surrounding tissue in, [606](#)
 - drainage in, [602–606](#)
 - location in, [602](#)
 - patient response in, [606–607](#), [607b](#)
 - presence of undermining or tunneling, [602](#)
 - size in, [602](#)
 - skin hygiene and, [610](#)
 - tools for, assessment of wound healing and, [607](#)
 - wound bed in, [606](#)
- Pressure-reducing mattresses, [611](#), [611f](#)
- Pressure-relief ankle-foot orthotic (PRAFO) boots, [566](#)
- Prevalence, [416](#)
- Prevention, levels of, [216–217](#)
 - collaboration and delegation, [217b](#)
 - primary, [216](#)
 - secondary, [216–217](#)

Skills

- Skill 19.1 Measuring Body Temperature, [295](#)
- Skill 19.2 Assessing Pulses, [301](#)
- Skill 19.3 Assessing Respirations, [305](#)
- Skill 19.4 Assessing Pulse Oximetry, [307](#)
- Skill 19.5 Measuring Blood Pressure: Manual and Electronic, [310](#)
- Skill 25.1 Applying Physical Restraints, [465](#)
- Skill 26.1 Hand Hygiene, [487](#)
- Skill 26.2 Sterile Gloving, [489](#)
- Skill 26.3 Personal Protective Equipment, [492](#)
- Skill 26.4 Sterile Fields, [494](#)
- Skill 27.1 Bathing a Patient in Bed, [513](#)
- Skill 27.2 Perineal Care, [518](#)
- Skill 27.3 Foot and Hand Care, [521](#)
- Skill 27.4 Therapeutic Massage, [524](#)
- Skill 27.5 Hair Care, [527](#)
- Skill 27.6 Oral Hygiene, [530](#)
- Skill 27.7 Shaving a Male Patient, [535](#)
- Skill 27.8 Making an Occupied or Unoccupied Bed, [537](#)
- Skill 28.1 Manual Logrolling, [568](#)
- Skill 28.2 Ambulation With Assistive Devices, [571](#)
- Skill 28.3 Walking With Crutches, [576](#)
- Skill 28.4 Antiembolism Hose, [581](#)
- Skill 28.5 Sequential Compression Devices, [584](#)
- Skill 29.1 Irrigating a Wound, [621](#)

Skill 29.2 Changing a Sterile Dressing: Dry, Wet/Damp-to-Dry, [624](#)

Skill 29.3 Obtaining a Wound Culture Specimen, [630](#)

Skill 29.4 Negative-Pressure Wound Therapy, or Vacuum-Assisted Closure, [633](#)

Skill 29.5 Applying Wraps and Bandages, [637](#)

Skill 30.1 Insertion, Placement, and Removal of Nasogastric and Nasojejunal Tubes, [669](#)

Skill 30.2 Enteral Feedings via Nasogastric, Nasojejunal, and Percutaneous Endoscopic Gastrostomy Tubes, [676](#)

Skill 34.1 Blood Glucose Testing, [766](#)

Skill 34.2 Urine Specimen Collection, [769](#)

Skill 34.3 Stool Specimen Collection, [775](#)

Skill 35.1 Oral Medication Administration, [816](#)

Skill 35.2 Inhaled Medication Administration, [821](#)

Skill 35.3 Preparing Injections: Ampules, Multidose Vials, and Reconstituting Medications, [827](#)

Skill 35.4 Medication Administration: Mixing Insulin, [833](#)

Skill 35.5 Subcutaneous, Intramuscular, and Intradermal Injections, [836](#)

Skill 35.6 Administering Intravenous Medications and Intermittent Solutions, [843](#)

Skill 37.1 Surgical Scrub, Gowning, and Gloving, [903](#)

Skill 38.1 Tracheostomy, Nasotracheal, Nasopharyngeal, Oropharyngeal, and Oral

Suctioning, [932](#)
Skill 38.2 Tracheostomy Care, [938](#)
Skill 38.3 Care of Chest Tubes and Disposable
Drainage Systems, [942](#)
Skill 39.1 Starting a Peripheral Intravenous
Infusion, [992](#)
Skill 39.2 Maintaining a Peripheral Intravenous
Infusion, [995](#)
Skill 39.3 Central Line Dressing Change and
Care, [998](#)
Skill 40.1 Administering an Enema, [1023](#)
Skill 40.2 Ostomy Care, [1026](#)
Skill 41.1 Urinary Catheterization: Insertion and
Care, [1054](#)
Skill 41.2 Closed Bladder Irrigation, [1061](#)
