Women requesting epidural analgesia in labor will do so when they feel they need pain relief, and for some it might be quite early in their labor. Epidural analgesia for labor and birth involves the injection of a local anesthetic agent (e.g., lidocaine or bupivacaine) and an opioid analgesic agent (e.g., morphine or fentanyl) into the lumbar epidural space. A small catheter is then passed through the epidural needle to provide continuous access to the epidural space for maintenance of analgesia throughout labor and birth (Fig. 14.11). Epidural analgesia does increase the duration of the second stage of labor and may increase the rate of instrument-assisted vaginal deliveries as well as that of oxytocin administration (Camorcia, 2015). Approximately 60% of laboring women in the United States receive an epidural for pain relief during labor, but one in eight women who have an epidural during labor still need to use other methods of pain relief In urban areas, many hospitals approach 90% use of epidurals (Capogna, 2015b).

An epidural involves the injection of a drug into the epidural space, which is located outside the dura mater between the dura and the spinal canal. The epidural space is typically entered through the third and fourth lumbar vertebrae with a needle, and a catheter is threaded into the epidural space. An epidural can be used for both vaginal and cesarean births. It has evolved from a regional block producing total loss of sensation to analgesia with minimal blockade. The effectiveness of epidural analgesia depends on the technique and medications used. Theoretically, epidural local anesthetics could block all labor pain if used in large volumes and high concentrations. However, pain relief is balanced against other goals such as walking during the first stage of labor, pushing effectively in the second stage, and minimizing maternal and fetal side effects.

An epidural is contraindicated for women with a previous history of spinal surgery or spinal abnormalities, coagulation defects cardiac disease, obesity, infections, and hypovolemia. It also is contraindicated for the woman who is receiving anticoagulation therapy.

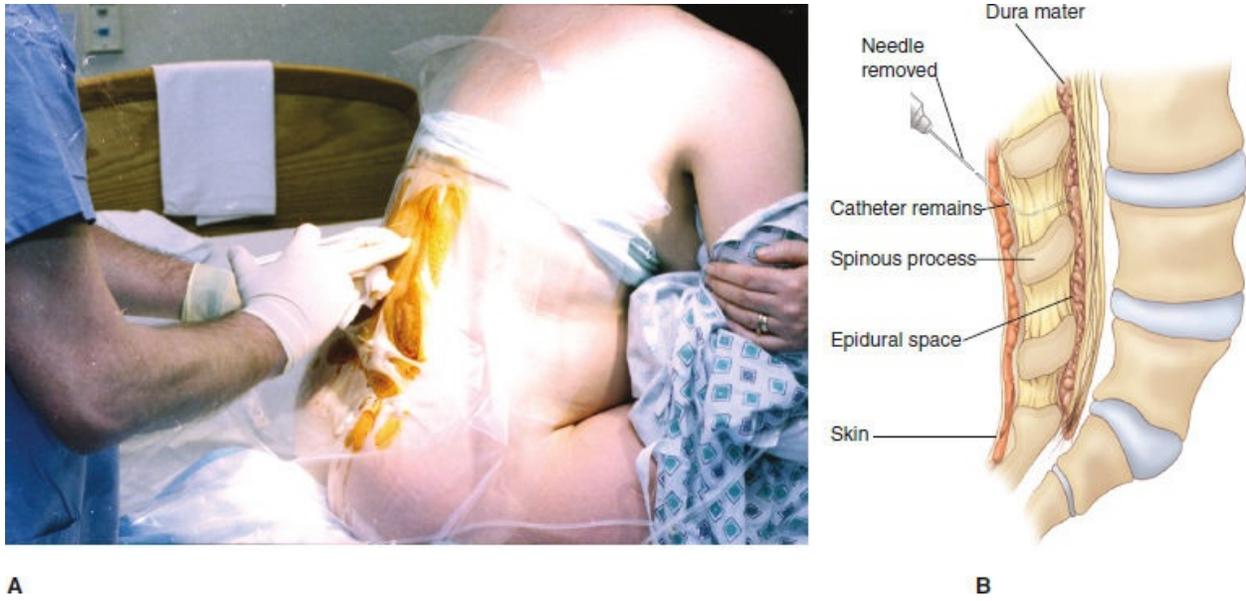
Complications include nausea and vomiting, hypotension, fever, pruritus, intravascular injection, maternal fever, allergic reaction, and respiratory depression. Effects on the fetus during labor include fetal distress secondary to maternal hypotension (Ibrahim et al., 2015). Ensuring that the woman avoids a supine position after an epidural catheter has been placed will help to minimize hypotension.


FIGURE 14.11 Epidural catheter insertion. **A.** A needle is inserted into the epidural space. **B.** A catheter is threaded into the epidural space; the needle is then removed. The catheter allows medication to be administered intermittently or continuously to relieve pain during labor and childbirth.

The addition of opioids, such as fentanyl or morphine, to the local anesthetic helps decrease the amount of motor block obtained. Continuous infusion pumps can be used to administer the epidural analgesia, allowing the woman to be in control and administer a bolus dose on demand (Patkar et al., 2015).

COMBINED SPINAL–EPIDURAL ANALGESIA

Another epidural technique is combined spinal–epidural (CSE) analgesia. This technique involves inserting the epidural needle into the epidural space and subsequently inserting a small-gauge spinal needle through the epidural needle into the subarachnoid space. An opioid, without a local anesthetic, is injected into this space. The spinal needle is then removed and an epidural catheter is inserted for later use.

CSE is advantageous because of its rapid onset of pain relief (within 3 to 5 minutes) that can last up to 3 hours. It also allows the woman's motor function to remain active. Her ability to bear down during the second stage of labor is preserved because the pushing reflex is not lost, and her motor power remains intact. The CSE technique provides greater flexibility and reliability for labor than either spinal or epidural analgesia alone (Stocks & Griffiths, 2015). When compared with traditional epidural or spinal analgesia, which often keeps the

woman lying in bed, CSE allows her to ambulate ("walking epidural"). A recent Cochrane review contrasting the CSE analgesia approach with traditional and low-dose epidural analgesia in labor identified that CSE analgesia was associated with a greater incidence of pruritus, but a lower incidence of urinary retention and need for rescue analgesia, than epidural along. In addition, CSE analgesia had a faster onset of pain relief, and there were no differences in labor outcomes (Heesen et al., 2015). Ambulating during labor provides several benefits: it may help control pain better, shorten the first stage of labor, increase the intensity of the contractions, and decrease the possibility of an operative vaginal or cesarean birth.

Although women can walk with CSE, they often choose not to because of sedation and fatigue. Often health care providers do not encourage or assist women to ambulate for fear of injury. Nurses need to evaluate for ambulation safety that includes no postural hypotension and normal leg strength by demonstrating a partial knee bend while standing; they also need to assist with ambulation at all times (Capogna, 2015b). Currently, anesthesiologists are performing walking epidurals using continuous infusion techniques as well as CSE and client-controlled epidural analgesia (Grant et al., 2015).

Complications include maternal hypotension, intravascular injection, accidental intrathecal blockade, postdural puncture headache, pruitis, inadequate or failed block, maternal fever, and pruritus. Hypotension and associated FHR changes are managed with maternal positioning (semi-Fowler's position), intravenous hydration, and supplemental oxygen (Ibrahim et al., 2015).

Consider This

When I was expecting my first child, I was determined to put my best foot forward and do everything right. I was an experienced OB nurse, and in my mind doing everything right was expected behavior. I was already 2 weeks past my calculated due date and I was becoming increasingly worried. That particular day I went to work with a backache but felt no contractions.

I managed to finish my shift but felt completely wiped out. As I walked to my car outside the hospital, my water broke and I felt the warm fluid run down my legs. I went back inside to be admitted for this much-awaited event.

Although I had helped thousands of women go through their childbirth experience, I was now the one in the bed and not standing alongside it. My husband and I had practiced our breathing techniques to cope with the discomfort of labor, but this "discomfort" in my mind was more than I could tolerate. So despite my best intentions of doing everything right, within an hour I begged for a painkiller to ease the pain. While the medication took the edge off my pain, I still felt every contraction and truly now appreciate the meaning of the word "labor." Although I wanted to use natural childbirth without any medication, I know that I was a full participant in my son's birthing experience, and that is what "doing everything right" was for me!

Thoughts: Doing what is right varies for each individual, and as nurses we need to support whatever that is. Having a positive outcome from the childbirth experience is the goal; the means it takes to achieve it is less important. How can nurses support women in making their personal choices to achieve a healthy outcome? Are any women "failures" if they ask for pain medication to tolerate labor? How can nurses help women overcome this stigma of being a "wimp"?

PATIENT-CONTROLLED EPIDURAL ANALGESIA

Patient-controlled epidural analgesia (PCEA) involves the use of an indwelling epidural catheter with an infusion of medication and a programmed pump that allows the woman to control the dosing. This method allows the woman to have a sense of control over her pain and reach her own individually acceptable analgesia level. When compared with traditional epidural analgesia, PCEA provides equivalent analgesia with lower anesthetic use, lower rates of supplementation, and higher client satisfaction (Van De Velde, 2015).

With PCEA, the woman uses a handheld device connected to an analgesic agent that is attached to an epidural catheter. When she pushes the button, a bolus dose of agent is administered via the catheter to reduce her pain. This method allows her to manage her pain at will without having to ask a staff member to provide pain relief. Evidence supports the use of PCEA which appears to result in greater maternal satisfaction and lower overall medication use (Sng et al., 2015).

LOCAL INFILTRATION

Local infiltration involves the injection of a local anesthetic, such as lidocaine,

into the superficial perineal nerves to numb the perineal area. This technique is done by the physician or midwife just before performing an episiotomy or before suturing a laceration. Local infiltration does not alter the pain of uterine contractions, but it does numb the immediate area of the episiotomy or laceration. Local infiltration does not cause side effects for the woman or her newborn.

PUDENDAL NERVE BLOCK

A pudendal nerve block refers to the injection of a local anesthetic agent (e.g., bupivacaine, ropivacaine) into the pudendal nerves near each ischial spine. It provides pain relief in the lower vagina, vulva, and perineum (Fig. 14.12).

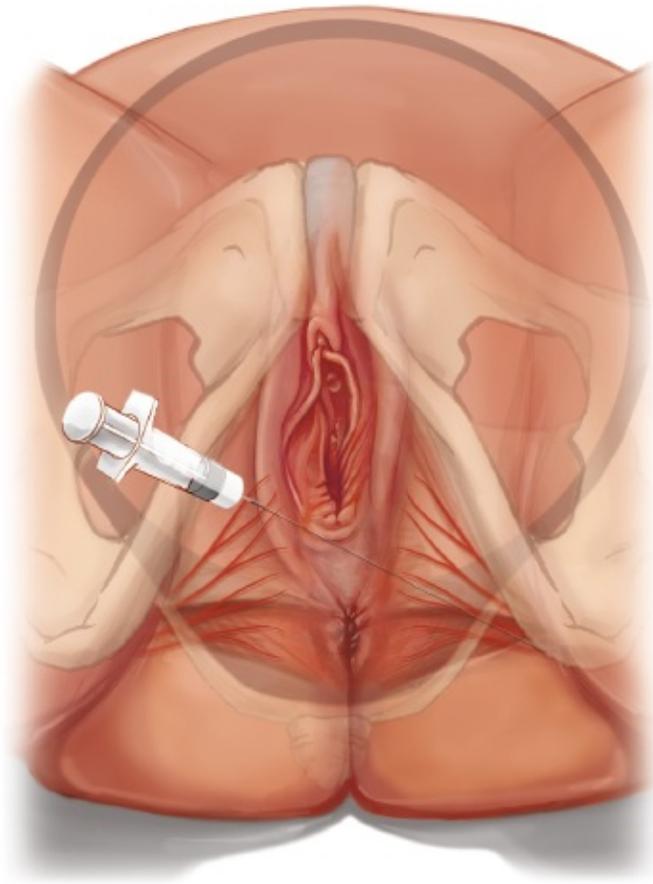
A pudendal block is used for the second stage of labor, an episiotomy, or an operative vaginal birth with outlet forceps or vacuum extractor. It must be administered about 15 minutes before it would be needed to ensure its full effect. A transvaginal approach is generally used to inject an anesthetic agent at or near the pudendal nerve branch. Neither maternal nor fetal complications are common.


FIGURE 14.12 Pudendal nerve block.

SPINAL (INTRATHECAL) ANALGESIA/ANESTHESIA

The spinal (intrathecal) pain management technique involves injection of an anesthetic "caine" agent, with or without opioids, into the subarachnoid space to provide pain relief during labor or cesarean birth. The subarachnoid space is a fluid-filled area located between the dura mater and the spinal cord. Spinal anesthesia is frequently used for elective and emergent cesarean births. The contraindications are similar to those for an epidural block. Adverse reactions for the woman include hypotension and spinal headache.

The subarachnoid injection of opioids alone, a technique termed intrathecal narcotics, has been gaining popularity since it was introduced in the 1980s. A narcotic is injected into the subarachnoid space, providing rapid pain relief while still maintaining motor function and sensation (Sng, Kwok, & Sia, 2015). An intrathecal narcotic is given during the active phase (more than 5 cm of dilation) of labor. Compared with epidural blocks, intrathecal narcotics are easy to administer, require a smaller volume of medication, produce excellent muscular relaxation, provide rapid-onset pain relief, are less likely to cause newborn respiratory depression, and do not cause motor blockade (Badve & Vallejo, 2015). Although pain relief is rapid with this technique, it is limited by the narcotic's duration of action, which may be only a few hours and not last through the labor. Additional pain measures may be needed to sustain pain management.

General Anesthesia

General anesthesia is typically reserved for emergency cesarean births when there is not enough time to provide spinal or epidural anesthesia or if the woman has a contraindication to the use of regional anesthesia. It can be started quickly and causes a rapid loss of consciousness. General anesthesia can be administered by intravenous injection, inhalation of anesthetic agents, or both. Commonly, thiopental, a short-acting barbiturate, or propofol is given intravenously to produce unconsciousness. This is followed by administration of a muscle relaxant. After the woman is intubated, nitrous oxide and oxygen are administered. A volatile halogenated agent may also be administered to produce amnesia (Cheng & Caughey, 2015a).

All anesthetic agents cross the placenta and affect the fetus. The primary

complication with general anesthesia is fetal depression, along with uterine relaxation and potential maternal vomiting and aspiration. General anesthesia complications are usually due to maternal aspiration or the inability to intubate the woman. The incidence of these complications has decreased greatly as a result of improved techniques (Hawkins, 2015).

Although the anesthesiologist or nurse anesthetist administers the various general anesthesia agents, the nurse needs to be knowledgeable about the pharmacologic aspects of the drugs used and must be aware of airway management. Ensure that the woman is not taking anything by mouth (NPO) and has a patent intravenous line. In addition, administer a nonparticulate (clear) oral antacid (e.g., Bicitra or sodium citrate) or a proton pump inhibitor (Protonix) as ordered to reduce gastric acidity. Assist with placement of a wedge under the woman's right hip to displace the gravid uterus and prevent vena cava compression in the supine position. Once the newborn has been removed from the uterus, assist the perinatal team in providing supportive care.

NURSING CARE DURING LABOR AND BIRTH

Childbirth, a physiologic process that is fundamental to all human existence, is one of the most significant cultural, psychological, spiritual, and behavioral events in a woman's life. Although the act of giving birth is a universal phenomenon, it is a unique experience for each woman. Continuous evaluation and appropriate intervention for women during labor are essential to promoting a positive outcome for the family.

The nurse's role in childbirth is to ensure a safe environment for the mother and her newborn. Nurses begin evaluating the mother and fetus during the admission procedures at the health care agency and continue to do so throughout labor. It is critical to provide anticipatory guidance and explain each procedure (fetal monitoring, intravenous therapy, medications given and expected reactions) and what will happen next. This will prepare the woman for the upcoming physical and emotional challenges, thereby helping to reduce her anxiety. Acknowledging members of her support system (family or partner) helps allay their fears and concerns, thereby assisting them in carrying out their supportive role. Knowing how and when to evaluate a woman during the various stages of labor is essential for all labor and birth nurses to ensure a positive maternal experience and a healthy newborn.

A major focus of care for the woman during labor and birth is assisting her with maintaining control over her pain, emotions, and actions while being an active participant. Nurses can help and support women to be actively involved in their childbirth experience by allowing time for discussion, offering companionship, listening to worries and concerns, paying attention to the woman's emotional needs, and offering information to help her understand what is happening in each stage of labor.

Nursing Management During the First Stage of Labor

Depending on how far advanced the woman's labor is when she arrives at the facility; the nurse will determine assessment parameters of maternal-fetal status and plan care accordingly. The nurse will provide high-touch, low-tech supportive nursing care during the first stage of labor when admitting the woman and orienting her to the labor and birth suite. The nurse is usually the primary gatekeeper of observations, interventions, treatments, and often the management of labor in the inpatient perinatal setting. Nursing care during this stage will include taking an admission history (reviewing the prenatal record); checking the results of routine laboratory tests and any special tests such as chorionic villi sampling, amniocentesis, genetic studies, and biophysical profile done during pregnancy; asking the woman about her childbirth preparation (birth plan, classes taken, coping skills); and completing a physical assessment of the woman to establish baseline values for future comparison.

Key nursing interventions include:

• Identifying the estimated date of birth from the client and the prenatal chart

• Validating the client's prenatal history to determine fetal risk status

• Determining fundal height to validate dates and fetal growth

• Performing Leopold's maneuvers to determine fetal position, lie, and presentation

• Checking FHR

• Performing a vaginal examination (as appropriate) to evaluate effacement and dilation progress

• Instructing the client and her partner about monitoring techniques and equipment

• Assessing fetal response and FHR to contractions and recovery time

• Interpreting fetal monitoring strips

• Checking FHR baseline for accelerations, variability, and decelerations

• Repositioning the client to obtain an optimal FHR pattern

• Recognizing FHR problems and initiating corrective measures

• Checking amniotic fluid for meconium staining, odor, and amount

• Comforting client throughout testing period and labor

• Documenting times of notification for team members if problems arise

• Knowing appropriate interventions when abnormal FHR patterns present

• Supporting the client's decisions regarding intervention or avoidance of intervention

• Assessing the client's support system and coping status frequently

In addition to these interventions to promote optimal outcomes for the mother and fetus, the nurse must document care accurately and in a timely fashion. Accurate and timely documentation helps to decrease professional liability exposure, minimize the risk of preventable injuries to women and infants during labor and birth, and preserve families (Simpson, 2015). Guidelines for recording care include documenting:

• All care rendered, to prove that standards were met

• Conversations with all providers, including notification times

• Nursing interventions before and after notifying provider

• Use of the chain of command and response at each level

• All flow sheets and forms, to validate care given

• All education given to client and response to it

• Facts, not personal opinions

• detailed descriptions of any adverse outcome

• Initial nursing assessment, all encounters, and discharge plan

• All telephone conversations (Callahan, 2016).

This standard of documentation is needed to prevent or defend against litigation, which is prevalent in the childbirth arena.

Assessing the Woman Upon Admission

The nurse usually first comes in contact with the woman either by phone or in person. The nurse should ascertain whether the woman is in true or false labor and whether she should be admitted or sent home. Upon admission to the labor and birth suite, the highest priorities include assessing FHR, assessing cervical dilation/effacement, and determining whether membranes have ruptured or are

intact. These assessment data will guide the critical thinking in planning care for the client.

If the initial contact is by phone, establish a therapeutic relationship with the woman. Speaking in a calm caring tone facilitates this. Nurses providing a telephone triage service need to have sufficient clinical experience and have clear lines of responsibility to enable sound decision making. When completing a phone assessment, include questions about the following:

• Estimated date of birth, to determine if term or preterm

• Fetal movement (frequency in the past few days)

• Other premonitory signs of labor experienced

• Parity, gravida, and previous childbirth experiences

• Time from start of labor to birth in previous labors

• Characteristics of contractions, including frequency, duration, and intensity

• Appearance of any vaginal bloody show

• Membrane status (ruptured or intact)

• Presence of supportive adult in household or if she is alone

When speaking with the woman over the telephone, review the signs and symptoms that denote true versus false labor, and suggest various positions she can assume to provide comfort and increase placental perfusion. Also suggest walking, massage, and taking a warm shower to promote relaxation. Outline what foods and fluids are appropriate for oral intake in early labor. Throughout the phone call, listen to the woman's concerns and answer any questions clearly.

Reducing the risk of liability exposure and avoiding preventable injuries to mothers and fetuses during labor and birth can be accomplished by adhering to two basic tenets of clinical practice: (1) use applicable evidence and/or published standards and guidelines as the foundation of care, and (2) whenever a clinical choice is presented, choose client safety (Miller, 2014). With these two tenets in mind, advise the woman on the phone to contact her health care provider for further instructions or to come to the facility to be evaluated, since ruling out true labor and possible maternal-fetal complications cannot be done accurately over the phone. Additional nursing responsibilities associated with a phone assessment include:

• Consulting the woman's prenatal record for parity status, estimated date of birth, and untoward events

• Calling the health care provider to inform him or her of the woman's status

• Preparing for admission to the perinatal unit to ensure adequate staff assignment

• Notifying the admissions office of a pending admission

If the nurse's first encounter with the woman is in person, an assessment is completed to determine whether she should be admitted to the perinatal unit or sent home until her labor advances. Recent research findings suggest that women admitted before active labor are approximately twice as likely to be augmented with oxytocin and give birth via cesarean when compared with women admitted in active labor (Neal et al., 2014). Nurses need to make careful assessment of labor progression *prior* to labor admission to decrease early admissions and to improve labor safety and birth outcomes.

Entering a facility is often an intimidating and stressful event for women since it is an unfamiliar environment. Giving birth for the first time is a pivotal event in the lives of most women. Therefore, demonstrate respect when addressing the client; listen carefully and express interest and concern. Nurses must value and respect women and promote their self-worth and sense of control by allowing them to participate in making decisions. Allowing them a fair amount of autonomy in their childbirth decisions, supporting their personal worth, knowing them holistically, and using caring communication will increase client satisfaction (Ivory, 2014).

An admission assessment includes maternal health history, physical assessment, fetal assessment, laboratory studies, and assessment of psychological status. Usually the facility has a form that can be used throughout labor and birth to document assessment findings (Fig. 14.13).

MATERNAL HEALTH HISTORY AND CULTURAL ASSESSMENT

A maternal health history should include typical biographical data such as the woman's name and age and the name of the delivering health care provider. Other information that is collected includes reason for admission, such as labor, cesarean birth, or observation for a complication; the prenatal record data, including the estimated date of birth, a history of the current pregnancy, and the results of any laboratory and diagnostic tests, such as blood type, Rh status, and group B streptococcal status; past pregnancy and obstetric history; past health history and family history; prenatal education; list of medications; risk factors

such as diabetes, hypertension, and use of tobacco, alcohol, or illicit drugs; pain management plan; history of potential domestic violence; history of previous preterm births; allergies; time of last food ingestion; method chosen for infant feeding; name of birth attendant (MD or midwife)(s) and pediatrician.

Ascertaining this information is important so that an individualized plan of care can be developed for the woman. If, for example, the woman's due date is still 2 months away, it is important to establish this information so interventions can be initiated to arrest the labor immediately or notify the intensive perinatal team to be available. In addition, if the woman has diabetes, it is critical to monitor her glucose levels during labor, to prepare for a surgical birth if dystocia of labor occurs, and to alert the newborn nursery of potential hypoglycemia in the newborn after birth. By collecting important information about each woman they care for, nurses can help improve the outcomes for all concerned.

Be sure to observe the woman's emotions, support system, verbal interaction, cultural background and language spoken, body language and posture, perceptual acuity, and energy level. This psychosocial information provides cues about the woman's emotional state, culture, and communication systems. For example, if the woman arrives at the labor and birth suite extremely anxious, alone, and unable to communicate in English, how can the nurse meet her needs and plan her care appropriately? It is only by assessing each woman physically and psychosocially that the nurse can make astute decisions regarding proper care. In this case, an interpreter would be needed to assist in the communication process between the staff and the woman to initiate proper care.

> ### BOX 14.2
>
> #### QUESTIONS FOR PROVIDING CULTURALLY COMPETENT CARE DURING LABOR AND BIRTH
>
> • Where were you born? How long have you lived in the United States?
> • What languages do you speak and read?
> • Who are your major support people?
> • What are your religious practices?
> • How do you view childbearing?
> • Are there any special precautions or restrictions that are important?
> • Is birth considered a private or a social experience?
> • How would you like to manage your labor discomfort?
> • Who will provide your labor support?
>
> Adapted from Bowers, P. (2015). Cultural perspectives in childbearing. Nursing Spectrum. Retrieved from http://ce.nurse.com/ce263-60/cultural-perspectives-in-childbearing; and Anderson, L. (2014). Cultural competence in the nursing practice. Nursetogether. Retrieved from http://www.nursetogether.com/cultural-competence-in-the-nursing-practice

It is important to acknowledge and try to understand the cultural differences in women with cultural backgrounds different from that of the nurse. Attitudes toward childbirth are heavily influenced by the culture in which the woman has been raised. As a result, within every society, specific attitudes and values shape the woman's childbearing behaviors. Be aware of what these are. When carrying out a cultural assessment during the admission process, ask questions (Box 14.2) to help plan culturally competent care during labor and birth.

PHYSICAL EXAMINATION

The physical examination typically includes a generalized assessment of the woman's body systems, including hydration status, vital signs, auscultation of heart and lung sounds, and measurement of height and weight. The physical examination also includes the following assessments:

1. Pain level and coping behaviors demonstrated
2. Uterine activity, including contraction frequency, duration, and intensity
3. Fetal status, including heart rate, position, and station
4. Cervical dilation and degree of effacement
5. Status of membranes (intact or ruptured)
6. Assess vital signs: temperature, pulse, respirations & blood pressure
7. Perform Leopold's maneuvers to determine fetal lie
8. Fundal height measurement
9. Ability to ambulate safely

These assessment parameters form a baseline against which the nurse can compare all future values throughout labor. The findings should be similar to those of the woman's prepregnancy and pregnancy findings, with the exception of her pulse rate, which might be elevated secondary to her anxious state with beginning labor.

LABORATORY STUDIES

On admission, laboratory studies typically are done to establish a baseline. Although the exact tests may vary among facilities, they usually include a urinalysis via clean-catch urine specimen and complete blood count. Blood typing and Rh factor analysis may be necessary if the results of these are unknown or unavailable. In addition, if the following test results are not included in the maternal prenatal history, it may be necessary to perform them at this time. They include syphilis screening, hepatitis B (HbsAg) screening, group B streptococcus, human immune deficiency virus (HIV) testing (if woman gives consent), and possible drug screening if the history is positive.

Group B streptococcus (GBS) is a gram-positive organism that colonizes in the female genital tract and rectum and is present in 10% to 30% of all healthy women (King et al., 2015). These women are asymptomatic carriers but can cause GBS disease of the newborn through vertical transmission during labor and horizontal transmission after birth. The mortality rate of infected newborns varies according to time of onset (early or late). Risk factors for GBS include maternal intrapartum fever, prolonged ruptured membranes (>12 to 18 hours), previous birth of an infected newborn, and GBS bacteriuria in the present pregnancy.

The Centers for Disease Control and Prevention (CDC), ACOG and the American Academy of Pediatrics have guidelines that advised universal screening of pregnant women at 35 to 37 weeks' gestation for GBS and intrapartum antibiotic therapy for GBS carriers. These new guidelines reaffirmed the major prevention strategy—universal antenatal GBS screening and intrapartum antibiotic prophylaxis for culture-positive and high-risk women. Also included are new recommendations for laboratory methods for identification of GBS colonization during pregnancy, algorithms for screening and intrapartum prophylaxis for women with preterm labor and premature rupture of membranes, updated prophylaxis recommendations for women with a penicillin allergy, and a revised algorithm for the care of newborn infants (Centers for Disease Control and Prevention [CDC], 2014). Maternal infections associated with GBS include acute chorioamnionitis, endometritis, and urinary tract infection. Neonatal clinical manifestations include pneumonia and sepsis. Identified GBS carriers receive intravenous antibiotic prophylaxis (penicillin G

or ampicillin) at the onset of labor or ruptured membranes.

The ACOG, CDC, AWHONN and the United States Preventive Services Task Force all recommend that all pregnant women be offered a screening test for HIV antibodies on their first prenatal visit, again during the third trimester if engaging in high-risk behaviors, and on admission to the labor and birth area. The CDC estimates that 50,000 individuals contract HIV in the United States each year, and 250,000 individuals have undiagnosed HIV infections (CDC, 2015).

If her HIV status is not documented, the woman being admitted to the labor and birth suite should have rapid HIV testing done. To reduce perinatal transmission, women who are HIV-positive are given zidovudine (2 mg/kg intravenously over an hour, and then a maintenance infusion of 1 mg/kg per hour until birth) or a single 200-mg oral dose of nevirapine at the onset of labor; the newborn is given zidovudine orally (2 mg/kg body weight every 6 hours) and should be continued for 6 weeks (Verklan & Walden, 2014). To further reduce the risk of perinatal transmission, ACOG and the United States Public Health Service recommend that women who are infected with HIV and have plasma viral loads of more than 1,000 copies/mL be counseled regarding the benefits of elective cesarean birth. In the absence of any medical intervention, the rate of vertical transmission of HIV to the fetus can range from 15% to 45% (Ashimi et al., 2015).

Additional interventions to reduce the transmission risk would include avoiding use of a scalp electrode for fetal monitoring or doing a scalp blood sampling for fetal pH, delaying amniotomy, encouraging formula feeding after birth, and avoiding invasive procedures such as forceps or vacuum-assisted devices. The nurse stresses the importance of all interventions and the goal to reduce transmission of HIV to the newborn.

Continuing Assessment During the First Stage of Labor

After the admission assessment is complete and the woman and her support person have been orientated to the room, equipment, and procedures, assessment continues for changes that would indicate that labor is progressing as expected. Assess the woman's knowledge, experience, and expectations of labor. Typically, blood pressure, pulse, and respirations are assessed every hour during the latent phase of labor unless the clinical situation dictates that vital signs be taken more frequently. During the active and transition phases, they are assessed every 30

minutes. The temperature is taken every 4 hours throughout the first stage of labor and every 2 hours after membranes have ruptured to detect an elevation indicating an ascending infection.

Vaginal examinations are performed periodically to track labor progress. This assessment information is shared with the woman to reinforce that she is making progress toward the goal of birth. Uterine contractions are monitored for frequency, duration, and intensity every 30 to 60 minutes during the latent phase, every 15 to 30 minutes during the active phase, and every 15 minutes during transition. Note the changes in the character of the contractions as labor progresses, and inform the woman of her progress. Continually determine the woman's level of pain and her ability to cope and use relaxation techniques effectively.

When the fetal membranes rupture, spontaneously or artificially, assess the FHR and check the amniotic fluid for color, odor, and amount. Assess the FHR intermittently or continuously via electronic monitoring. During the latent phase of labor, assess the FHR every 30 to 60 minutes; in the active phase, assess FHR at least every 15 to 30 minutes. Also, be sure to assess the FHR before ambulation, before any procedure, and before administering analgesia or anesthesia to the mother. Table 14.3 summarizes assessments for the first stage of labor.

Remember Sheila from the chapter-opening scenario? What is the nurse's role with Sheila in active labor? What additional comfort measures can the labor nurse offer Sheila?

Nursing Interventions

Nursing interventions during the admission process should include:

- Asking about the client's expectations of the birthing process
- Providing information about labor, birth, pain management options, and relaxation techniques
- Presenting information about fetal monitoring equipment and the procedures needed
- Monitoring FHR and identifying patterns that need further intervention
- Monitoring the mother's vital signs to obtain a baseline for later comparison

- Reassuring the client that her labor progress will be monitored closely and nursing care will focus on ensuring fetal and maternal well-being throughout

As the woman progresses through the first stage of labor, nursing interventions include:

- Encouraging the woman's partner to participate
- Keeping the woman and her partner up to date on the progress of the labor
- Orienting the woman and her partner to the labor and birth unit and explaining all of the birthing procedures
- Providing clear fluids (e.g., ice chips) as needed or requested
- Maintaining the woman's parenteral fluid intake at the prescribed rate if she has an IV
- Initiating or encouraging comfort measures, such as backrubs, cool cloths to the forehead, frequent position changes, ambulation, showers, slow dancing, leaning over a birth ball, side-lying, or counterpressure on lower back (Teaching Guidelines 14.1)

TABLE 14.3 SUMMARY OF ASSESSMENTS DURING THE FIRST STAGE OF LABOR

Assessments[a]	Latent Phase (0–3 cm)	Active Phase (4–7 cm)	Transition (8–10 cm)
Vital signs (BP, pulse, respirations)	Every 30–60 min	Every 30 min	Every 15–30 min
Temperature	Every 4 hr; more frequently if membranes are ruptured	Every 4 hr; more frequently if membranes are ruptured	Every 4 hr; more frequently if membranes are ruptured
Contractions (frequency, duration, intensity)	Every 30–60 min by palpation or continuously if EFM	Every 15–30 min by palpation or continuously if EFM	Every 15 min by palpation or continuously if EFM
Fetal heart rate	Every hour by Doppler or continuously by EFM	Every 30 min by Doppler or continuously by EFM	Every 15–30 min by Doppler or continuously by EFM
Vaginal examination	Initially on admission to determine phase and as needed based on maternal cues to document labor progression	As needed to monitor labor progression	As needed to monitor labor progression
Behavior/psychosocial	With every client encounter: talkative, excited, anxious	With every client encounter: self-absorbed in labor; intense and quiet now	With every client encounter: discouraged, irritable, feels out of control, declining coping ability

[a]The frequency of assessments is dictated by the health status of the woman and fetus and can be altered if either one of their conditions changes.
EFM, electronic fetal monitoring.

Teaching Guidelines 14.1

POSITIONING DURING THE FIRST STAGE OF LABOR

- Walking with support from the partner (adds the force of gravity to contractions to promote fetal descent)
- Slow-dancing position with the partner holding the woman (adds the force of gravity to contractions and promotes support from and active participation of your partner)
- Side lying with pillows between the knees for comfort (offers a restful position and improves oxygen flow to the uterus)
- Semi-sitting in bed or on a couch leaning against the partner (reduces back pain because fetus falls forward, away from the sacrum)
- Sitting in a chair with one foot on the floor and one on the chair (changes pelvic shape)
- Leaning forward by straddling a chair, a table, or a bed or kneeling over a

birth ball (reduces back pain, adds the force of gravity to promote descent; possible pain relief if partner can apply sacral pressure)

- Encourage any position of comfort the woman choses to labor in and give birth.

- Sitting in a rocking chair or on a birth ball and shifting weight back and forth (provides comfort because rocking motion is soothing; uses the force of gravity to help fetal descent)

- Lunge by rocking weight back and forth with foot up on chair during contraction (uses force of gravity by being upright; enhances rotation of fetus through rocking)

- Open knee–chest position (helps to relieve back discomfort) (Gizzo et al., 2014; Tharpe et al., 2016).

- Encouraging the partner's involvement with breathing techniques
- Assisting the woman and her partner to focus on breathing techniques
- Informing the woman that the discomfort will be intermittent and of limited duration; urging her to rest between contractions to preserve her strength; and encouraging her to use distracting activities to lessen the focus on contractions
- Changing bed linens and gown as needed
- Keeping the perineal area clean and dry
- Supporting the woman's decisions about pain management
- Monitoring maternal vital signs frequently and reporting any abnormal values
- Ensuring that the woman takes deep cleansing breaths before and after each contraction to enhance gas exchange and oxygen to the fetus
- Educating the woman and her partner about the need for rest and helping them plan strategies to conserve strength
- Monitoring FHR for baseline, accelerations, variability, and decelerations
- Checking on bladder status and encouraging voiding at least every 2 hours to make room for birth
- Repositioning the woman as needed to obtain optimal heart rate pattern
- Communicating requests from the woman to appropriate personnel
- Respecting the woman's sense of privacy by covering her when appropriate

- Offering human presence by being present with the woman, not leaving her alone for long periods
- Being patient with the natural labor pattern to allow time for change
- Encouraging maternal movement throughout labor to increase the woman's level of comfort
- Dimming the lights in the room when pushing and request softened voices be used to maintain a calm and centered ambiance
- Reporting any deviations from normal to the health care professional so that interventions can be initiated early to be effective (Green, 2016; Lucas et al., 2015; Nagtalon-Ramos, 2014).

See Nursing Care Plan 14.1.

Nursing Management During the Second Stage of Labor

Management of the second stage of labor often follows tradition-based routines rather than evidence-based practices. Current evidence for management of the second stage of labor supports the practices of delayed pushing, spontaneous (nondirected) pushing, and maternal choice positions (Cox & King, 2015). To be able to help women through the second stage of labor requires the nurse to have a comprehensive understanding of physiology and be aware of the latest evidence-based research and apply it to practice (Green, 2016).

Nursing care during the second stage of labor focuses on supporting the woman and her partner in making active decisions about her care and labor management, implementing strategies to prolong the early passive phase of fetal descent, supporting involuntary bearing-down efforts, providing instruction and assistance, and using maternal positions that can enhance descent and reduce pain (King et al., 2015). Women in the past gave birth unaided by following their bodies signals to birth their babies, so the role of the nurse should be to support the woman in her choice of pushing method and to encourage confidence in her maternal instinct of when and how to push.

In the absence of any complications, nurses should not be controlling this stage of labor, but empowering women to achieve a satisfying experience. The primary rationale for directing women to push is to shorten the second stage of labor. Common practice in many labor units is still to coach women to use closed glottis pushing with every contraction, starting at 10 cm of dilation, a practice that is not supported by research. Research suggests that directed pushing during the second stage may be accompanied by a significant decline in fetal pH and may cause maternal muscle and nerve damage if done too early (Reed, 2015). Shortening the phase of active pushing and lengthening the early phase of passive descent can be achieved by encouraging the woman not to push until she has a strong desire to do so and until the descent and rotation of the fetal head are well advanced. Effective pushing can be achieved by assisting the woman to assume a more upright or squatting position. Supporting spontaneous pushing and encouraging women to choose their own method of pushing should be accepted as best clinical practice (Cheng & Caughey, 2015b).

NURSING CARE PLAN 14.1

Overview of a Woman in the Active Phase of the First Stage of Labor

Candice, a 23-year-old gravida 1, para 0 (G1,P0), is admitted to the labor and birth suite at 39 weeks' gestation having contractions of moderate intensity every 5 to 6 minutes. A vaginal examination reveals that her cervix is 80% effaced and 5 cm dilated. The presenting part (vertex) is at 0 station and her membranes ruptured spontaneously 4 hours ago at home. She is admitted and an intravenous line is started for hydration and vascular access. An external fetal monitor is applied. FHR is 140 bpm and regular. Her partner is present at her bedside. Candice is now in the active phase of the first stage of labor, and her assessment findings are as follows: cervix dilated 7 cm, 80% effaced; moderate to strong contractions occurring regularly, every 3 to 5 minutes, lasting 45 to 60 seconds; at 0 station on pelvic examination; FHR auscultated loudest below umbilicus at 140 bpm; vaginal show—pink or bloody vaginal mucus; currently apprehensive, inwardly focused, with increased dependency; voicing concern about ability to cope with pain; limited ability to follow directions.

NURSING DIAGNOSIS: Anxiety related to labor and birth process and fear of the unknown related to client's first experience

Outcome Identification and Evaluation
The client will remain calm and in control as evidenced by ability to make decisions and use positive coping strategies.

Interventions: *Promoting Positive Coping Strategies*
• Provide instruction regarding the labor process to allay anxiety.
• Orient the woman to the physical environment and equipment as necessary to keep her informed of events.
• Encourage verbalization of feelings and concerns to reduce anxiety.
• Listen attentively to woman and partner to demonstrate interest and concern.
• Inform woman and partner of standard procedures/processes to ensure adequate understanding of events and procedures.
• Frequently update woman of progress and labor status to provide positive

reinforcement for actions.
- Reinforce relaxation techniques and provide instruction if needed to aid in coping.
- Encourage participation of the partner in the coaching role; role-model to facilitate partner participation in labor process to provide support and encouragement to the client.
- Provide a presence and remain with the client as much as possible to provide comfort and support.

NURSING DIAGNOSIS: Acute pain related to uterine contractions and stretching of the cervix and birth canal

Outcome Identification and Evaluation
The client will maintain a tolerable level of pain and discomfort as evidenced by statements of pain relief, pain rating of 2 or less on pain rating scale, and absence of adverse effects in client and fetus from analgesia or anesthesia.

Interventions: *Providing Pain Relief*
- Monitor vital signs, observe for signs of pain, and have client rate pain on a scale of 0 to 10 to provide baseline for comparison.
- Encourage client to void every 1 to 2 hours to decrease pressure from a full bladder.
- Assist woman to change positions frequently to increase comfort and promote labor progress.
- Encourage use of distraction to reduce focus on contraction pain.
- Suggest pelvic rocking, massage, or back counter pressure to reduce pain.
- Assist with use of relaxation and breathing techniques to promote relaxation.
- Use touch appropriately (backrub) when desired by the woman to promote comfort.
- Integrate use of nonpharmacologic measures for pain relief, such as warm water, birthing ball, or other techniques to facilitate pain relief.
- Administer pharmacologic agents as ordered when requested to control pain.
- Provide reassurance and encouragement between contractions to foster self-esteem and continued participation in labor process.

NURSING DIAGNOSIS: Risk of infection related to multiple vaginal examinations following rupture of membranes and tissue trauma

Outcome Identification and Evaluation
The client will remain free of infection as evidenced by the absence of signs and symptoms of infection, vital signs and FHR within acceptable parameters, lab test results within normal limits, and clear amniotic fluid without odor.

Interventions: *Preventing Infection*
• Monitor vital signs (every 2 hours after rupture of membranes [ROM]) and FHR frequently as per protocol to allow for early detection of problems; report fetal tachycardia (early sign of maternal infection) to ensure prompt treatment.
• Provide frequent perineal care and pad changes to maintain good perineal hygiene.
• Change linens and woman's gown as needed to maintain cleanliness.
• Ensure that vaginal examinations are performed only when needed to prevent introducing pathogens into the vaginal vault.
• Monitor lab test results such as white blood cell count to assess for elevations indicating infection.
• Use aseptic technique for all invasive procedures to prevent infection transmission.
• Carry out good handwashing techniques before and after procedures and use standard precautions as appropriate to minimize risk of infection transmission.
• Document amniotic fluid characteristics—color, odor—to establish baseline for comparison.

Perineal lacerations or tears can occur during the second stage when the fetal head emerges through the vaginal introitus. The extent of the laceration is defined by depth: a first-degree laceration extends through the skin; a second-degree laceration extends through the muscles of the perineal body; a third-degree laceration continues through the anal sphincter muscle; and a fourth-degree laceration also involves the anterior rectal wall. Special attention needs to be paid to third- and fourth-degree lacerations to prevent fecal incontinence.

Risks for third- or fourth-degree lacerations included nulliparity, being Asian or Pacific Islander, increased birth weight of newborn, operative vaginal birth, episiotomy, and longer second stage of labor. Increasing body mass index was associated with fewer lacerations (Sides et al., 2015). The primary care provider should repair any lacerations during the third stage of labor.

An **episiotomy** is an incision made in the perineum to enlarge the vaginal outlet and theoretically to shorten the second stage of labor. Alternative measures such as warm compresses and continual massage with oil have been successful in stretching the perineal area to prevent cutting it. Certified nurse midwives can cut and repair episiotomies, but they frequently use alternative measures if possible.

Take Note!

Restrictive use of episiotomy has been recommended by ACOG given the risks of the procedure and unclear benefits of routine use (Friedman et al., 2015).

The midline episiotomy has been the most commonly used one in the United States because it can be easily repaired and causes the least amount of pain. The application of warmed compresses and/or intrapartum perineal massage is associated with a decrease in trauma to the perineal area and reduced the need for an episiotomy (Green, 2016). Routine episiotomy has declined since liberal usage has been discouraged by ACOG, except to avoid several maternal lacerations or to expedite difficult births Anal sphincter laceration rates with spontaneous vaginal delivery have decreased, likely reflecting the decreased usage of episiotomy. The decline in operative vaginal delivery corresponds with a sharp increase in cesarean births, which may indicate that health care providers are favoring cesarean births for difficult births (Faisal-Cury et al., 2015). Figure 14.14 shows episiotomy locations.

Continuous Assessment During the Second Stage of Labor

Assessment is continuous during the second stage of labor. Hospital policies dictate the specific type and timing of assessments, as well as the way in which they are documented. Assessment involves identifying the signs typical of the second stage of labor, including:

- Increase in apprehension or irritability
- Spontaneous rupture of membranes
- Sudden appearance of sweat on upper lip
- Increase in blood-tinged show
- Low grunting sounds from the woman
- Complaints of rectal and perineal pressure
- Beginning of involuntary bearing-down efforts

Other ongoing assessments include the contraction frequency, duration, and intensity; maternal vital signs every 5 to 15 minutes; fetal response to labor as indicated by FHR monitor strips; amniotic fluid for color, odor, and amount when membranes are ruptured; and the copying status of the woman and her partner (Table 14.4).

Assessment also focuses on determining the progress of labor. Associated signs include bulging of the perineum, labial separation, advancing and retreating of the newborn's head during and between bearing-down efforts, and **crowning** (fetal head is visible at vaginal opening; Fig. 14.15).

A vaginal examination is completed to determine if it is appropriate for the woman to push. Pushing is appropriate if the cervix has fully dilated to 10 cm and the woman feels the urge to do so.

Nursing Interventions

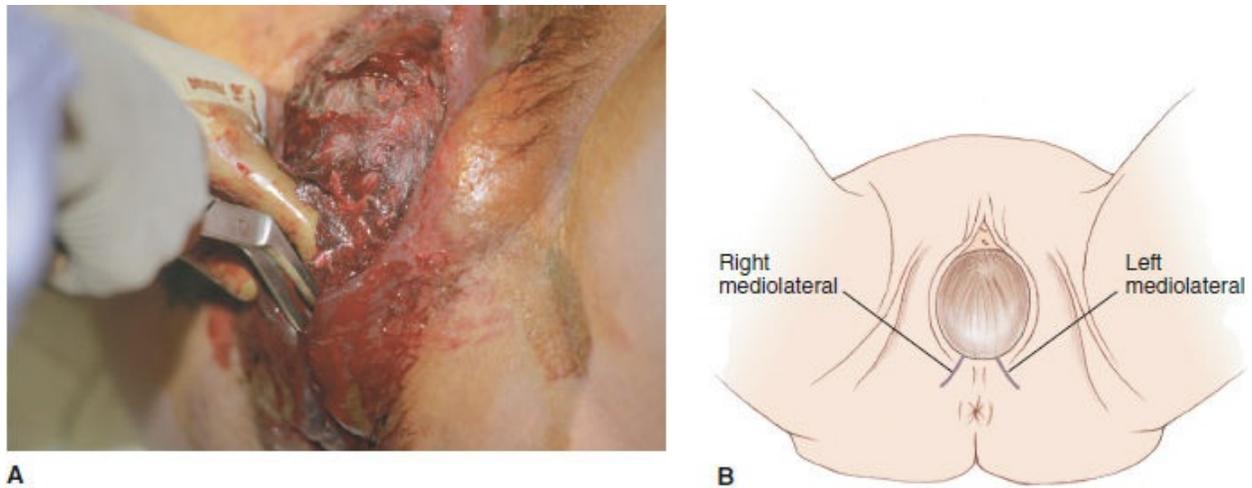
Nursing interventions during this stage focus on motivating the woman, assisting with positioning and encouraging her to put all her efforts to pushing this newborn to the outside world, and giving her feedback on her progress. If the woman is pushing without progress, suggest that she keep her eyes open during the contractions and look toward where the newborn is coming out. Changing positions frequently will also help in making progress. Positioning a mirror so the woman can visualize the birthing process and how successful her pushing efforts are can help motivate her.


FIGURE 14.14 Location of an episiotomy. **A.** Midline episiotomy. **B.** Right and left mediolateral episiotomies.

TABLE 14.4 Summary of Assessments During the Second, Third, and Fourth Stages of Labor

Assessments[a]	Second Stage of Labor (Birth of Neonate)	Third Stage of Labor (Placenta Expulsion)	Fourth Stage of Labor (Recovery)
Vital signs (BP, pulse, respirations)	Every 5–15 min	Every 15 min	Every 15 min
Fetal heart rate	Every 5–15 min by Doppler or continuously by EFM	Apgar scoring at 1 and 5 min	Newborn—complete head-to-toe assessment; vital signs every 15 min until stable
Contractions/uterus	Palpate every one	Observe for placental separation	Palpating for firmness and position every 15 min for first hour
Bearing down/ pushing	Assist with every effort	None	None
Vaginal discharge	Observe for signs of descent— bulging of perineum, crowning	Assess bleeding after expulsion	Assess every 15 min with fundus firmness
Behavior/ psychosocial	Observe every 15 min: cooperative, focus is on work of pushing newborn out	Observe every 15 min: often feelings of relief after hearing newborn crying; calmer	Observe every 15 min: usually excited, talkative, awake; needs to hold newborn, be close, and inspect body

[a]The frequency of assessments is dictated by the health status of the woman and fetus and can be altered if either one of their conditions changes.
EFM, electronic fetal monitoring.
Adapted from Holvey, N. (2014). Supporting women in the second stage of labor. *British Journal of Midwifery, 22*(3), 182–186; American Hospital Association. (2014). RNs role in labor and delivery. Retrieved from http://www.aha.org/search?q=RNs+role+in+labor+and+delivery&start-date; and Wenner, L. (2015). It's the little things. *Nursing for Women's Health, 19*(2), 203–204.

FIGURE 14.15 Crowning.

During the second stage of labor, an ideal position would be one that opens the pelvic outlet as wide as possible, provides a smooth pathway for the fetus to descend through the birth canal, takes advantage of gravity to assist the fetus to descend, and gives the mother a sense of being safe and in control of the labor process (Capogna, 2015a). Some suggestions for positions in the second stage include:

- Lithotomy with feet up in stirrups: most convenient position for caregivers, although EBP findings do not support this position physiologically
- Semi-sitting with pillows underneath knees, arms, and back
- Lateral/side-lying with curved back and upper leg supported by partner
- Sitting on birthing stool: opens pelvis, enhances the pull of gravity, and helps with pushing
- Squatting/supported squatting: gives the woman a sense of control
- Kneeling with hands on bed and knees comfortably apart

Other important nursing interventions during the second stage include:
- Providing continuous comfort measures such as mouth care, encouraging position changes, changing bed linen and underpads, and providing a quiet,

focused environment

• Instructing the woman on the following bearing-down positions and techniques:

  • Pushing only when she feels an urge to do so

  • Delaying pushing for up to 90 minutes after complete dilation

  • Using abdominal muscles when bearing down

  • Using short pushes of 6 to 7 seconds

  • Focusing attention on the perineal area to visualize the newborn

  • Relaxing and conserving energy between contractions

  • Pushing several times with each contraction

  • Pushing with an open glottis and slight exhalation (Petrocnik & Marshall, 2015)

• Continuing to monitor contraction and FHR patterns to identify problems

• Providing brief, explicit directions throughout this stage

• Continuing to provide psychosocial support by reassuring and coaching

• Facilitating the upright position to encourage the fetus to descend

• Continuing to assess blood pressure, pulse, respirations, uterine contractions, bearing-down efforts, FHR, and coping status of the client and her partner

• Providing pain management if needed

• Providing a continuous nursing presence

• Offering praise for the client's efforts

• Preparing for and assisting with delivery by:

  • Notifying the health care provider of the estimated time frame for birth

  • Preparing the delivery bed and positioning client

  • Preparing the perineal area according to the facility's protocol

  • Offering a mirror and adjusting it so the woman can watch the birth

  • Explaining all procedures and equipment to the client and her partner

  • Setting up delivery instruments needed while maintaining sterility

  • Using standard precautions during the birthing process to avoid body fluid splashes

  • Recording the time of birth, time of placenta, and type of birth

- Receiving newborn and transporting him or her to a warming environment, or covering the newborn with a warmed blanket on the woman's abdomen
- Providing initial care and assessment of the newborn (see the Birth section that follows)

Sheila is completely dilated now and experiencing the urge to push. How can the nurse help Sheila with her pushing efforts? What additional interventions can the labor nurse offer Sheila now? In addition to encouraging Sheila to rest between pushing and offering praise for her efforts, what is the nurse's role during the birthing process?

BIRTH

The second stage of labor ends with the birth of the newborn. The maternal position for birth varies from the standard lithotomy position to side-lying to squatting to standing or kneeling, depending on the birthing location, the woman's preference, and standard protocols. Once the woman is positioned for birth, cleanse the vulva and perineal areas. The primary health care provider then takes charge after donning protective eyewear, masks, gowns, and gloves and performing hand hygiene.

Once the fetal head has emerged, the primary care provider explores the fetal neck to see if the umbilical cord is wrapped around it. If it is, the cord is slipped over the head to facilitate delivery. As soon as the head emerges, the health care provider suctions the newborn's mouth first (because the newborn is an obligate nose breather) and then the nares with a bulb syringe to prevent aspiration of mucus, amniotic fluid, or meconium (Fig. 14.16). The umbilical cord is double-clamped and cut between the clamps by the birth attendant or the woman's partner if desired. With the first cries of the newborn, the second stage of labor ends. For care of the woman undergoing a surgical birth, the reader is referred to Chapter 21.

In addition to encouraging Sheila to rest between pushing and offering praise for her efforts, what is the nurse's role during the birthing process?

IMMEDIATE CARE OF THE NEWBORN

Once birth takes place, the newborn is placed under a radiant warmer, dried, assessed, wrapped in warmed blankets, and placed on the woman's abdomen for warmth and closeness. In some health care facilities, the newborn is placed on the woman's abdomen immediately after birth and covered with a warmed blanket without being dried or assessed. In either scenario, the stability of the newborn dictates the location of aftercare. The nurse can also assist the mother with breast-feeding her newborn for the first time.

FIGURE 14.16 Suctioning the newborn immediately after birth.

Assessment of the newborn begins at the moment of birth and continues until the newborn is discharged. Drying the newborn and providing warmth to prevent heat loss by evaporation is essential to help support thermoregulation and provide stimulation. Placing the newborn under a radiant heat source and putting on a stockinette/knitted cap will further reduce heat loss after drying.

Assess the newborn by assigning an Apgar score at 1 and 5 minutes. The Apgar score assesses five parameters—(1) heart rate (absent, slow, or fast),

(2)respiratory effort (absent, weak cry, or good strong yell), (3) muscle tone (limp, or lively and active), (4) response to irritation stimulus, and (5) color—that evaluate a newborn's cardiorespiratory adaptation after birth. The parameters are arranged from the most important (heart rate) to the least important (color). The newborn is assigned a score of 0 to 2 in each of the five parameters. The purpose of the Apgar assessment is to evaluate the physiologic status of the newborn; see Chapter 18 for additional information on Apgar scoring.

Secure two identification bands on the newborn's wrist and ankle that match the band on the mother's wrist to ensure the newborn's identity. This identification process is completed in the birthing suite before anyone leaves the room. Some health care agencies also take an early photo of the newborn for identification in the event of abduction (National Center for Missing and Exploited Children [NCMEC], 2015).

FIGURE 14.17 An example of a security sensor applied to a newborn's arm.

Other types of newborn security systems can also be used to prevent abduction. Some systems have sensors that are attached to the newborn's identification bracelet or cord clamp. An alarm is set off if the bracelet or clamp activates receivers near exits. Others have an alarm that is activated when the sensor is removed from the newborn (Fig. 14.17). Even with the use of electronic sensors, the parents, nursing staff, and security personnel are responsible for prevention strategies and ensuring the safety and protection of all

newborns (NCMEC, 2015). Nurses can help in preventing newborn abduction by educating parents about abduction risks, using identically numbered bands on the baby and parents, by instructing couples to keep their newborn in their direct line of vision within their hospital room at all times, taking color photographs of the infant, wearing color photograph ID badges themselves, discouraging parents/families from publishing birth notices in the public media with mother's name and address, controlling access to nursery/postpartum unit with locked doors, and utilizing infant security tags or abduction alarm systems (NCMEC, 2015).

> *Sheila gave birth to a healthy 7-lb, 7-oz baby girl. She is eager to hold and nurse her newborn. What is the initial care of the newborn? How can the nurse meet the needs of both the newborn and Sheila, who is exhausted but eager to bond with her newborn?*

Nursing Management During the Third Stage of Labor

During the third stage of labor, strong uterine contractions continue at regular intervals under the continuing influence of oxytocin. The uterine muscle fibers shorten, or retract, with each contraction, leading to a gradual decrease in the size of the uterus, which helps shear the placenta away from its attachment site. The third stage is complete when the placenta is delivered. Nursing care during the third stage of labor primarily focuses on immediate newborn care and assessment and observing for signs of placental separation, being available to assist with the delivery of the placenta, recording the time of expulsion and inspecting it for intactness. The nurse should also be assessing by palpating the uterus before and after placental expulsion.

Three hormones play important roles in the third stage. During this stage the woman experiences peak levels of oxytocin and endorphins, while the high adrenaline levels that occurred during the second stage of labor to aid with pushing begin falling. The hormone oxytocin causes uterine contractions and helps the woman to enact instinctive mothering behaviors such as holding the newborn close to her body and cuddling the baby.

Skin-to-skin contact immediately after birth and the newborn's first attempt at breast-feeding further augment maternal oxytocin levels, strengthening the uterine contractions that will help the placenta to separate and the uterus to contract to prevent hemorrhage. Endorphins, the body's natural opiates, produce an altered state of consciousness and aid in blocking out pain. In addition, the drop in adrenaline level from the second stage, which had kept the mother and baby alert at first contact, causes most women to shiver and feel cold shortly after giving birth.

Take Note!

A crucial role for nurses during this time is to protect the natural hormonal process by ensuring unhurried and uninterrupted contact between mother and newborn after birth, providing warmed blankets to prevent shivering, and allowing skin-to-skin contact with initial breast-feeding.

Continuing Assessment During the Third Stage of Labor

Assessment during the third stage of labor includes:

• Monitoring placental separation by looking for the following signs:

• Firmly contracting uterus

• Change in uterine shape from discoid to globular ovoid

• Sudden gush of dark blood from vaginal opening

• Lengthening of umbilical cord protruding from vagina

• Examining placenta and fetal membranes for intactness the second time (the health care provider assesses the placenta for intactness the first time) (Fig. 14.18)

• Assessing for any perineal trauma, such as the following, before allowing the birth attendant to leave:

• Firm fundus with bright-red blood trickling: laceration

• Boggy fundus with red blood flowing: uterine atony

• Boggy fundus with dark blood and clots: retained placenta

• Inspecting the perineum for condition of episiotomy, if performed

• Assessing for perineal lacerations and ensuring repair by birth attendant

Nursing Interventions

Interventions during the third stage of labor include:

• Describing the process of placental separation to the couple

• Instructing the woman to push when signs of separation are apparent

• Administering an oxytocic agent if ordered and indicated after placental expulsion

• Providing support and information about episiotomy and/or laceration if applicable

• Cleaning and assisting client into a comfortable position after birth, making sure to lift both legs out of stirrups (if used) simultaneously to prevent strain

• Assess the woman's knowledge of breast-feeding to determine educational needs

• Instruct her about latching on, positioning, infant sucking and swallowing

- Repositioning the birthing bed to serve as a recovery bed if applicable

- Assisting with transfer to the recovery area if applicable

- Providing warmth by replacing warmed blankets over the woman

- Applying an ice pack to the perineal area to provide comfort to episiotomy if indicated

- Explaining what assessments will be carried out over the next hour and offering positive reinforcement for actions

- Ascertaining any needs

- Monitoring maternal physical status by assessing:

  - Vaginal bleeding: amount, consistency, and color

  - Vital signs: blood pressure, pulse, and respirations taken every 15 minutes

  - Uterine fundus, which should be firm, in the midline, and at the level of the umbilicus

- Recording all birthing statistics and securing primary caregiver's signature

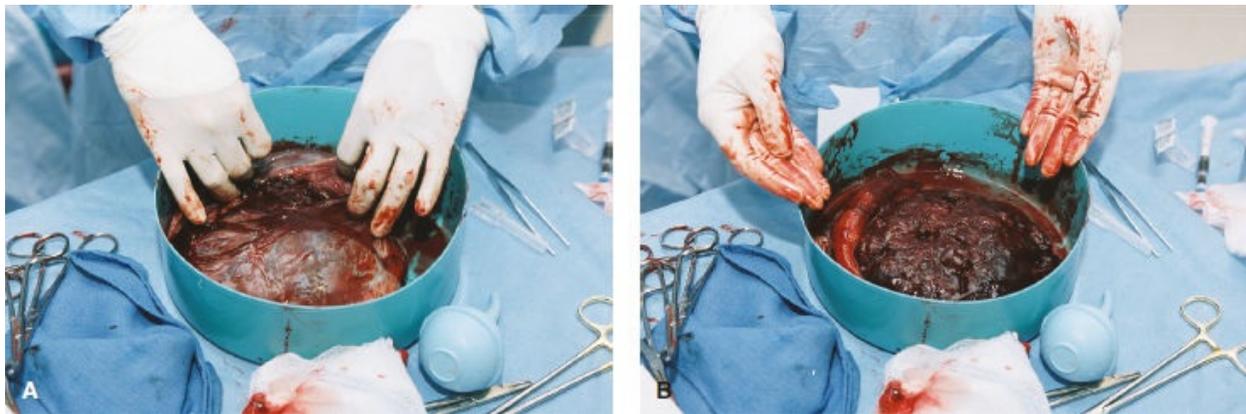
- Documenting birthing event in the birth book (official record of the facility that outlines every birth event), detailing any deviations


FIGURE 14.18 Placenta. **A.** Fetal side. **B.** Maternal side.

Nursing Management During the Fourth Stage of Labor

The fourth stage of labor begins after the placenta is expelled and lasts up to 4 hours after birth, during which time recovery takes place. This recovery period may take place in the same room where the woman gave birth, in a separate recovery area, or in her postpartum room. During this stage, the woman's body is beginning to undergo the many physiologic and psychological changes that occur after birth. The focus of nursing management during the fourth stage of labor involves frequent close observation for hemorrhage, provision of comfort measures, and promotion of family attachment.

Assessment

Assessments during the fourth stage center on the woman's vital signs, status of the uterine fundus and perineal area, comfort level, lochia amount, and bladder status. During the first hour after birth, vital signs are taken every 15 minutes, then every 30 minutes for the next hour if needed. The woman's blood pressure should remain stable and within normal range after giving birth. A decrease may indicate uterine hemorrhage; an elevation might suggest preeclampsia.

The pulse usually is typically slower (60 to 70 bpm) than during labor. This may be associated with a decrease in blood volume following placental separation. An elevated pulse rate may be an early sign of blood loss. The blood pressure usually returns to its prepregnancy level and therefore is not a reliable early indicator of shock. Fever is indicative of dehydration (less than 100.4°F or 38°C) or infection (above 101°F), which may involve the genitourinary tract. Respiratory rate is usually between 16 and 24 breaths per minute and regular. Respirations should be unlabored unless there is an underlying preexisting respiratory condition.

Assess fundal height, position, and firmness every 15 minutes during the first hour following birth. The fundus needs to remain firm to prevent excessive postpartum bleeding. The fundus should be firm (feels like the size and consistency of a grapefruit), located in the midline and below the umbilicus. If it is not firm (boggy), gently massage it until it is firm (see Nursing Procedure 22.1 for more information). Once firmness is obtained, stop massaging.

Take Note!

If the fundus is displaced to the right of the midline, suspect a full bladder as the cause.

The vagina and perineal areas are quite stretched and edematous following a vaginal birth. Assess the perineum, including the episiotomy if present, for possible hematoma formation. Suspect a hematoma if the woman reports excruciating pain or cannot void or if a mass is noted in the perineal area. Also assess for hemorrhoids, which can cause discomfort.

Assess the woman's comfort level frequently to determine the need for analgesia. Ask the woman to rate her pain on a scale of 1 to 10; it should be less than 3. If it is higher, further evaluation is needed to make sure there aren't any deviations contributing to her discomfort.

Assess vaginal discharge (lochia) every 15 minutes for the first hour and every 30 minutes for the next hour. Palpate the fundus at the same time to ascertain its firmness and help to estimate the amount of vaginal discharge. In addition, palpate the bladder for fullness, since many women receiving an epidural block experience limited sensation in the bladder region. Voiding should produce large amounts of urine (diuresis) each time. Palpating the woman's bladder after each voiding helps in assessing it and ensuring complete emptying. A full bladder will displace the uterus to either side of the midline and potentiate uterine hemorrhage secondary to bogginess.

Nursing Interventions

Nursing interventions during the fourth stage might include:

• Providing support and information to the woman regarding episiotomy repair and related pain relief and self-care measures

• Applying an ice pack to the perineum to promote comfort and reduce swelling

• Assisting with hygiene and perineal care; teaching the woman how to use the perineal bottle after each pad change and voiding; helping the woman into a new gown

• Monitoring for return of sensation and ability to void (if regional anesthesia was used)

- Encouraging the woman to void by ambulating to the bathroom, listening to running water, or pouring warm water over the perineal area with the peribottle
- Monitoring vital signs and fundal and lochia status every 15 minutes and documenting them
- Assessing for postpartum hemorrhage and urinary retention via uterine palpation
- Promoting comfort by offering analgesia for afterpains and warm blankets to reduce chilling
- Offering fluids and nourishment if desired
- Encouraging parent–infant attachment by providing privacy for the family
- Being knowledgeable about and sensitive to typical cultural practices after birth
- Assisting and encouraging the mother to nurse, if she chooses, during the recovery period to promote uterine firmness (the release of oxytocin from the posterior pituitary gland stimulates uterine contractions)
- Teaching the woman how to assess her fundus for firmness periodically and to massage it if it is boggy
- Describing the lochia flow and normal parameters to observe for postpartum
- Teaching safety techniques to prevent newborn abduction
- Demonstrating the use of the portable sitz bath as a comfort measure for her perineum if she had a laceration or an episiotomy repair
- Explaining comfort/hygiene measures and when to use them
- Assisting with ambulation when getting out of bed for the first time
- Providing information about the routine on the mother–baby unit or nursery for her stay
- Observing for signs of early parent–infant attachment: fingertip touch to palm touch to enfolding of the infant (Leonard, 2015; Green, 2016).

The nurse's role in labor and birth is a privileged one, supporting women at one of their most vulnerable times—childbirth. The nurse's focus during this time should be on supporting, protecting, advocating and empowering women. The nurse should also provide informational support, which would allow the woman to realize her aspirations and goals by making decisions through

informed choice. Nurses make a long-term difference in the lives of childbearing women with small things they do for their clients that make a big difference to them.

KEY CONCEPTS

- A nurse provides physical and emotional support during the labor and birth process to assist a woman to achieve her goals.
- When a woman is admitted to the labor and birth area, the admitting nurse must assess and evaluate the risk status of the pregnancy and initiate appropriate interventions to provide optimal care for the client.
- Completing an admission assessment includes taking a maternal health history; performing a physical assessment on the woman and fetus, including her emotional and psychosocial status; and obtaining the necessary laboratory studies.
- The nurse's role in fetal assessment for labor and birth includes determining fetal well-being and interpreting signs and symptoms of possible compromise. Determining the fetal heart rate (FHR) pattern and assessing amniotic fluid characteristics are key.
- FHR can be assessed intermittently or continuously. Although the intermittent method allows the client to move about during labor, the information obtained intermittently does not provide a complete picture of fetal well-being from moment to moment.
- Assessment parameters of the FHR are classified as baseline rate, baseline variability, and periodic changes in the rate (accelerations and decelerations).
- The nurse monitoring the laboring client needs to be knowledgeable about which category the FHR pattern is in so that appropriate interventions can be instituted.
- For a Category III FHR pattern, the nurse should notify the health care provider about the pattern and obtain further orders, making sure to document all interventions and their effects on the FHR pattern.
- In addition to interpreting assessment findings and initiating appropriate inventions for the laboring client, accurate and timely documentation must be carried out continuously.
- Today's women have many safe nonpharmacologic and pharmacologic choices

for the management of pain during childbirth. They may be used individually or in combination to complement one another.

- Nursing management for the woman during labor and birth includes comfort measures, emotional support, information and instruction, advocacy, and support for the partner.

- Nursing care during the first stage of labor includes taking an admission history (reviewing the prenatal record), checking the results of routine laboratory work and special tests done during pregnancy, asking the woman about her childbirth preparation (birth plan, classes taken, coping skills), and completing a physical assessment of the woman to establish baseline values for future comparison.

- Nursing care during the second stage of labor focuses on supporting the woman and her partner in making decisions about her care and labor management, implementing strategies to prolong the early passive phase of fetal descent, supporting involuntary bearing-down efforts, providing support and assistance, and encouraging the use of maternal positions that can enhance descent and reduce the pain.

- Nursing care during the third stage of labor primarily focuses on immediate newborn care and assessment and being available to assist with the delivery of the placenta and inspecting it for intactness.

- The focus of nursing management during the fourth stage of labor involves frequently observing the mother for hemorrhage, providing comfort measures, and promoting family attachment.

Chapter WORKSHEET

MULTIPLE CHOICE QUESTIONS

1. When a client in labor is fully dilated, which instruction would be most effective to assist her in encouraging effective pushing?

   a. Hold your breath and push through entire contraction.

   b. Use chest-breathing with the contraction.

   c. Pant and blow during each contraction.

   d. Wait until you feel the urge to push.

2. During the fourth stage of labor, the nurse assesses the woman at frequent intervals after giving childbirth. What assessment data would cause the nurse the most concern?

   a. Moderate amount of dark red lochia drainage on peripad

   b. Uterine fundus palpated to the right of the umbilicus

   c. An oral temperature reading of 100.6° F

   d. Perineal area bruised and edematous beneath her ice pack

3. When managing a client's pain during labor, nurses should:

   a. Make sure the agents given do not prolong labor

   b. Know that all pain relief measures are similar

   c. Support the client's decisions and requests

   d. Not recommend nonpharmacologic methods

4. When caring for a client during the active phase of labor without continuous electronic fetal monitoring, the nurse would intermittently assess FHR every:

   a. 15 to 30 minutes

   b. 5 to 10 minutes

   c. 45 to 60 minutes

d. 60 to 75 minutes

5. The nurse notes the presence of transient fetal accelerations on the fetal monitoring strip. Which intervention would be most appropriate?

a. Reposition the client on the left side.

b. Begin 100% oxygen via face mask.

c. Document this as indicating a normal pattern.

d. Call the health care provider immediately.

6. By the end of the second stage of labor, the nurse would expect which of the following events? The

a. cervix is fully dilated and effaced

b. placenta is detached and expelled

c. fetus is born and on mother's chest

d. woman to request pain medication

7. Which of the following practices would not be included in a physiologic birth?

a. Early induction of labor <39 weeks gestation

b. Freedom of movement for the laboring woman

c. Continuous presence and support throughout labor

d. Encouraging spontaneous pushing when urge felt

CRITICAL THINKING EXERCISE

1. A 20-year-old primigravida at term, comes to the birthing center in active labor (dilation 5 cm and 80% effaced, –1 station) with ruptured membranes. She states she wants an "all-natural" birth without medication. Her partner is with her and appears anxious but supportive. On the admission assessment, this client's prenatal history is unremarkable; vital signs are within normal limits; FHR via Doppler ranges between 140 and 144 bpm and is regular.

a. Based on your assessment data and the woman's request not to have medication, what nonpharmacologic interventions could you offer her?

b. What positions might be suggested to facilitate fetal descent?

2. Several hours later, the client complains of nausea and turns to her partner and angrily tells him to not touch her and to go away.

a. What assessment needs to be done to determine what is happening?

b. What explanation can you offer this client's partner regarding her change in behavior?

STUDY ACTIVITIES

1. Share experiences within a post clinical conference group regarding the pain management interventions of the clients to which you were assigned. Compare and evaluate the effectiveness of different methods used, maternal behavior observed, and neonatal outcome in terms of Apgar scores.

2. On the fetal heart monitor, the nurse notices an elevation of the fetal baseline with the onset of contractions. This elevation would describe _____.

3. Compare and contrast a local birthing center to a community hospital's birthing suite in terms of the pain management techniques and fetal monitoring used.

4. Select a childbirth website for expectant parents and critique the information provided in terms of its educational level and amount of advertising.

BRINGING IT ALL TOGETHER: CASE STUDY

A 30-year old woman at term presents to the emergency room with abdominal pain. This is her first pregnancy and she is accompanied by her partner and her very anxious sister. She is 40 weeks and 6 days based on her last ultrasound. All pregnancy blood tests have been normal. Earlier in the day she had a mucus-like dark red discharge followed by the onset of irregular period-type cramps. Two hours ago she felt a gush of clear fluid from her vagina and since then she has felt miserable. She took two Tylenol at home for the pain, but she is now in distress and came to the hospital for assessment.

ASSESSMENT

On examination, she is comfortable between pains. Her blood pressure is 130/80 and pulse is 100 bpm. Fetal movement is felt by the nurse. FHR is 142 bpm.

Fundal height upon palpation is 37 cm and in a cephalic presentation. Speculum exam shows clear fluid pooled in the posterior vaginal fornix. A ferning pattern is present when fluid is placed on a glass slide. The vaginal exam reveals the cervix to be fully effaced and 4cm dilated. The fetal head is 2 cm above the ischial spines. There is no fetal caput or molding felt during the vaginal exam.

Go to thePoint to find questions to consider about this case.

Postpartum Period

15

Postpartum Adaptations

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Examine the systemic physiologic changes occurring in the woman after childbirth.
2. Determine the psychological changes that occur in women in the postpartum period.
3. Relate effective maternal self-care measures to be implemented in the postpartum period.
4. Integrate dimensions of postpartum care for the multicultural family.
5. Plan postpartum nursing care with interventions to foster maternal/infant bonding.
6. Assess the phases of maternal role adjustment and accompanying behaviors.
7. Analyze the psychological adaptations occurring in the mother's partner after childbirth.

> *Betsy had been home only 3 days when she called the OB unit where she had given birth and asked to speak to the lactation consultant. She reported pain in both breasts. Her nipples were tender due to frequent breast-feeding and she described her breasts as heavy, hard, and swollen.*

Words of Wisdom

A new mother's expectations are seen through rose-colored glasses, and at times her fantasy is better than the reality.

INTRODUCTION

The postpartum period is a critical transitional time for a woman, her newborn, and her family on physiologic and psychological levels. The **puerperium** period begins after the delivery of the placenta and lasts approximately 6 weeks. During this period the woman's body begins to return to its prepregnant state, and these changes generally resolve by the sixth week after giving birth. However, the postpartum period can also be defined to include the changes in all aspects of the mother's life that occur during the first year after a child is born. Some believe that the postpartum adjustment period lasts well into the first year, making the fourth phase of labor the longest. Keeping this in mind, the true postpartum period may last between 9 and 12 months as the mother works to lose the weight she gained while pregnant, adjusts psychologically to the changes in her life, and takes on the new role of mother.

Nurses caring for childbearing families should consider all aspects of culture, including communication, space, and family roles. Communication encompasses an understanding of not only a person's language, and loudness of speech, but also the meaning of touch and gestures. The concept of personal space and the dimensions of comfort zones differ from culture to culture. Touching, placing clients in proximity to others, and taking away personal possessions can reduce a client's personal security and heighten her anxiety. Nurses must be sensitive to how people respond when being touched and should refrain from touching if the client's response indicates that it is unwelcome. Cultural norms also have an impact on family roles, expectations, and behaviors associated with a member's position in the family. For example, culture may influence whether a man actively participates in the pregnancy and childbirth. Maternity health care professionals in the United States expect men to be involved, but this role expectation may conflict with that of many of the diverse groups now living in the United States. Mexican Americans, Arab Americans, Asian Americans, and Orthodox Jewish Americans, for example, usually view the birthing experience as a woman's affair (Purnell, 2014).

Our major role as nurses is to provide safe and evidence-based care to promote optimal birth outcomes for all women, regardless of their cultural background. Nurses need to remember that there is more than one way to provide this care. Nurses are important cultural brokers as they welcome women

and their families into our obstetrical units, where nurses share with those families one of the most intimate experiences of their lives (Bowers & Ceballos, 2015).

This chapter describes the major physiologic and psychological changes that occur in a woman after childbirth. Various systemic adaptations take place throughout the woman's body. In addition, the mother and the family adjust to the new addition psychologically. The birth of a child changes the family structure and the roles of the family members. The adaptations are dynamic and continue to evolve as physical changes occur and new roles emerge.

MATERNAL PHYSIOLOGIC ADAPTATIONS

During pregnancy, the woman's entire body changed to accommodate the needs of the growing fetus. After birth, the woman's body once again undergoes significant changes in all body systems to return her body to its prepregnant state.

Reproductive System Adaptations

The reproductive system goes through tremendous adaptations to return to the prepregnancy state. All organs and tissues of the reproductive system are involved. The female reproductive system is unique in its capacity to remodel itself throughout the woman's reproductive life. The events after birth, with the shedding of the placenta and subsequent uterine involution, involve substantial tissue destruction and subsequent repair and remodeling. For example, the woman's menstrual cycle, interrupted during pregnancy, will begin to return several weeks after childbirth, if the woman is not breast-feeding. Ovulation can return any time, thus breast-feeding should not be considered as a safe contraceptive and other methods should be used to prevent pregnancy. The uterus, which has undergone tremendous expansion during pregnancy to accommodate progressive fetal growth, will return to its prepregnant size over several weeks. The mother's breasts have grown to prepare for lactation and do not return to their prepregnant size as the uterus does.

Uterine Involution

The uterus returns to its normal size through a gradual process of **involution**, which involves retrogressive changes that return it to its nonpregnant size and condition. Involution involves three retrogressive processes:

1. Contraction of muscle fibers to reduce those previously stretched during pregnancy
2. Catabolism, which shrinks enlarged, individual myometrial cells
3. Regeneration of uterine epithelium from the lower layer of the decidua after the upper layers have been sloughed off and shed during lochial discharge (Mattson & Smith, 2016).

The uterus, which weighs approximately 1,000 g (2.2 lb) soon after birth, undergoes physiologic involution as it returns to its nonpregnant state. Approximately 1 week after birth, the uterus shrinks in size by 50% and weighs about 500 g (1 lb); at the end of 6 weeks, it weighs approximately 60 g (2 oz), about the weight before the pregnancy (Jordan et al., 2014) (Fig. 15.1). During the first few days after birth, the uterus typically descends from the level of the umbilicus at a rate of 1 cm (1 fingerbreadth) per day. By 3 days, the fundus lies 2

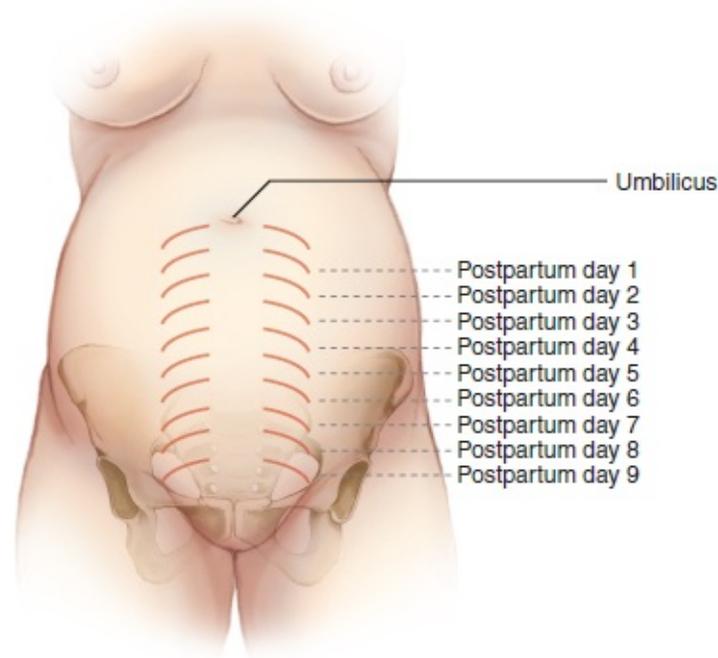
to 3 fingerbreadths below the umbilicus (or slightly higher in multiparous women). By the end of 10 days, the fundus usually cannot be palpated because it has descended into the true pelvis.


FIGURE 15.1 Uterine involution.

If these retrogressive changes do not occur as a result of retained placental fragments or infection, then subinvolution of the uterus typically results (delayed or absent involution). Subinvolution is generally responsive to early diagnosis and treatment. Factors that facilitate uterine involution include complete expulsion of amniotic membranes and placenta at birth, a complication-free labor and birth process, breast-feeding, and early ambulation. Factors that inhibit involution include a prolonged labor and difficult birth, incomplete expulsion of amniotic membranes and placenta, uterine infection, overdistention of uterine muscles (such as by multiple gestation, hydramnios, or a large singleton fetus), a full bladder (which displaces the uterus and interferes with contractions), anesthesia (which relaxes uterine muscles), and close childbirth spacing (frequent and repeated distention decreases tone and causes muscular relaxation).

LOCHIA

Lochia is the vaginal discharge that occurs after birth and continues for approximately 4 to 8 weeks. It results from involution, during which the superficial layer of the decidua basalis becomes necrotic and is sloughed off. Immediately after childbirth, lochia is bright red and consists mainly of blood, fibrinous products, decidual cells, and red and white blood cells. The lochia from the uterus is alkaline but becomes acidic as it passes through the vagina. It is roughly equal to the amount occurring during a heavy menstrual period. The average amount of lochial discharge is 240 to 270 mL (8 to 9 oz) (Bope & Kellerman, 2015).

Women who have had cesarean births tend to have less flow because the uterine debris is removed manually along with delivery of the placenta. Lochia is present in most women for at least 3 weeks after childbirth, but it persists in some women for as long as 6 weeks.

Lochia passes through three stages:

• *Lochia rubra* is a deep-red mixture of mucus, tissue debris, and blood that occurs for the first 3 to 4 days after birth. As uterine bleeding subsides, it becomes paler and more serous.

• *Lochia serosa* is the second stage. It is pinkish brown and is expelled 3 to 10 days postpartum. Lochia serosa primarily contains leukocytes, decidual tissue, red blood cells, and serous fluid.

• *Lochia alba* is the final stage. The discharge is creamy white or light brown and consists of leukocytes, decidual tissue, and reduced fluid content. It occurs from days 10 to 14 but can last 3 to 6 weeks postpartum in some women and still be considered normal.

Lochia at any stage should have a fleshy smell; an offensive odor usually indicates an infection, such as endometritis.

Take Note!

A danger sign is the reappearance of bright-red blood after lochia rubra has stopped. Reevaluation by a health care provider is essential if this occurs.

AFTERPAINS

Part of the involution process involves uterine contractions. Subsequently, many

women are frequently bothered by painful uterine contractions termed *afterpains*. All women experience afterpains, but they are more acute in multiparous and breast-feeding women secondary to repeated stretching of the uterine muscles from multiple pregnancies or stimulation during breast-feeding with oxytocin released from the pituitary gland. Primiparous women typically experience mild afterpains because their uterus is able to maintain a contracted state. Breast-feeding and administration of exogenous oxytocin both cause powerful and painful uterine contractions. Afterpains usually respond to oral analgesics.

![notepad icon] *Take Note!*

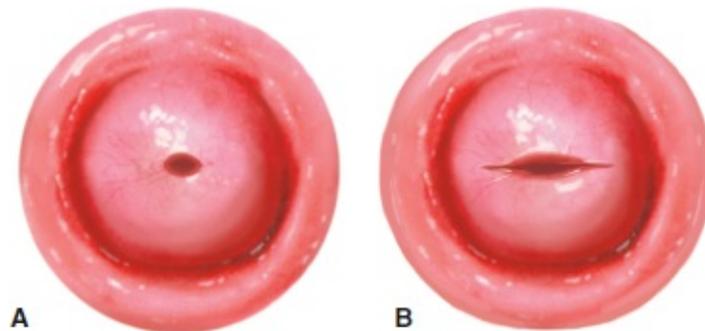
Afterpains are usually stronger during breast-feeding because oxytocin released by the sucking reflex strengthens the contractions. Mild analgesics can reduce this discomfort.


FIGURE 15.2 Appearance of the cervical os. **A.** Before the first pregnancy. **B.** After pregnancy.

Cervix

The cervix typically returns to its prepregnant state by week 6 of the postpartum period. The cervix gradually closes but never regains its prepregnant appearance. Immediately after childbirth, the cervix is shapeless and edematous and is easily distensible for several days. The internal cervical os gradually closes and returns to normal by 2 weeks, whereas the external os widens and never appears the same after childbirth. The external cervical os is no longer shaped like a circle, but instead appears as a jagged slit-like opening, often described as a "fish mouth" (Fig. 15.2).

Vagina

Shortly after birth, the vaginal mucosa is edematous and thin, with few rugae. As ovarian function returns and estrogen production resumes, the mucosa thickens and rugae return in approximately 3 weeks. The vagina gapes at the opening and is generally lax. The vagina returns to its approximate prepregnant size by 6 to 8 weeks postpartum but will always remain a bit larger than it had been before pregnancy.

Normal mucus production and thickening of the vaginal mucosa usually return with ovulation. The vagina gradually decreases in size and regains tone over several weeks. By 3 to 4 weeks, the edema and vascularity have decreased. The vaginal epithelium is generally restored by 6 to 8 weeks postpartum (Mattson & Smith, 2016). Localized dryness and coital discomfort (dyspareunia) usually plague most women until menstruation returns. Water-soluble lubricants can reduce discomfort during intercourse.

Perineum

The perineum is often edematous and bruised for the first day or two after birth. If the birth involved an episiotomy or laceration, complete healing may take as long as 4 to 6 months in the absence of complications at the site, such as hematoma or infection. The muscle tone may or may not return to normal, depending on the extent of injury to muscle, nerve, and connecting tissues (Spiliolpoulos & Mastrogiannis, 2014). Perineal lacerations may extend into the anus and cause considerable discomfort for the mother when she is attempting to defecate or ambulate. The presence of swollen hemorrhoids may also heighten discomfort. Local comfort measures such as ice packs, pouring warm water over the area via a peribottle, witch hazel pads, anesthetic sprays, and sitz baths can relieve pain.

Supportive tissues of the pelvic floor are stretched during the childbirth process, and restoring their tone may take up to 6 months. Pelvic relaxation can occur in any woman experiencing a vaginal birth. Nurses should encourage all women to practice pelvic floor muscle training exercises (PFMT) to improve pelvic floor tone, strengthen the perineal muscles, and promote healing. See Evidence-Based Practice 15.1

 Take Note!

Failure to maintain and restore perineal muscular tone leads to urinary incontinence later in life for many women.

Cardiovascular System Adaptations

The cardiovascular system undergoes dramatic changes after birth. During pregnancy, the heart is displaced slightly upward and to the left. This reverses as the uterus undergoes involution. Cardiac output remains high for the first few days postpartum and then gradually declines to nonpregnant values within 3 months of birth.

Blood volume, which increases substantially during pregnancy, drops rapidly after birth and returns to normal within 4 weeks postpartum. The decrease in both cardiac output and blood volume reflects the birth-related blood loss (an average of 500 mL with a vaginal birth and 1,000 mL with a cesarean birth). The cardiac output deceases to prelabor values 24 to 72 hours postpartum, rapidly falls over the next two weeks and usually returns to nonpregnant levels within 6 to 8 weeks postpartum. Blood plasma volume is further reduced through diuresis, which occurs during the early postpartum period (Cheng & Caughey, 2015). Despite the decrease in blood volume, the hematocrit level remains relatively stable and may even increase, reflecting the predominant loss of plasma. Thus, an acute decrease in hematocrit is not an expected finding and may indicate hemorrhage.

Concept Mastery Alert

Prioritizing Postpartum Vital Signs

It is not uncommon for women to have a temperature elevation up to 100.4°F in the first 24 hours postpartum. There may also be a slight decrease in blood pressure. The nurse should be most concerned about a blood pressure elevation because preeclampsia may occur during the early postpartum period.

EVIDENCE-BASED PRACTICE 15.1 PELVIC FLOOR MUSCLE TRAINING VERSES NO TREATMENT, OR

INACTIVE CONTROL TREATMENTS, FOR URINARY INCONTINENCE IN WOMEN

Stress incontinence is the involuntary leakage of urine with a physical activity that increases intra-abdominal pressure such as coughing or sneezing. This incontinence can occur after childbirth secondary to perineal trauma. Pelvic floor muscle training (PFMT) is the most common intervention for women that experience stress urinary incontinence. The objective of this study was to determine the effects of PFMT for women with urinary incontinence when compared with no treatment, placebo, or other inactive control treatments.

STUDY

Randomized or quasi-randomized trials in women experiencing stress incontinence were reviewed. Twenty-one trials involving 1281 women met the inclusion criteria. Women with stress urinary incontinence who were in the PFMT groups were 8 times more likely than the controls to report that they were cured (46/82 (56.1%) versus 5/83 (6.0%), RR 8.38, 95% CI 3.68 to 19.07) and 17 times more likely to report cure or improvement (32/58 (55%) versus 2/63 (3.2%), RR 17.33, 95% CI 4.31 to 69.64). In trials in women with any type of urinary incontinence, PFMT groups were also more likely to report cure, or more cure and improvement than the women in the control groups, although the effect size was reduced. Women with stress urinary incontinence were also more satisfied with the active treatment, while women in the control groups were more likely to seek further treatment. Women treated with PFMT leaked urine less often, lost smaller amounts on the short office-based pad test, and emptied their bladders less often during the day.

Findings

The review of trials found that PFMT (muscle-clenching exercises) helps women cure and improve stress urinary incontinence in particular, and all types of incontinence.

Pulse and Blood Pressure

The increase in cardiac output and stroke volume during pregnancy begins to diminish after birth once the placenta has been delivered. This decrease in cardiac output is reflected in bradycardia (40 to 60 bpm) for up to the first 2 weeks postpartum. This slowing of the heart rate is related to the increased blood that flows back to the heart and to the central circulation after it is no longer perfusing the placenta. This increase in central circulation brings about an increased stroke volume and allows a slower heart rate to provide ample maternal circulation. Gradually, cardiac output returns to prepregnant levels by 3 months after childbirth (Mahendru et al., 2014).

Tachycardia (heart rate above 100 bpm) in the postpartum woman warrants further investigation. It may indicate hypovolemia, dehydration, or hemorrhage. However, because of the increased blood volume during pregnancy, a considerable loss of blood may be well tolerated and not cause a compensatory cardiovascular response such as tachycardia. In most instances of postpartum hemorrhage, blood pressure and cardiac output remain increased because of the compensatory increase in heart rate. Thus, a decrease in blood pressure and cardiac output are not expected changes during the postpartum period. Early identification is essential to ensure prompt intervention.

Blood pressure falls mostly in the first 2 days and then increases 3 to 7 days after childbirth; and returns to prepregnancy levels by 6 weeks (Parpaglioni, 2015). A significant increase accompanied by headache might indicate preeclampsia and requires further investigation. Decreased blood pressure may suggest an infection or a uterine hemorrhage.

Coagulation

Normal physiologic changes of pregnancy, including alterations in hemostasis that favor coagulation, reduced fibrinolysis, and pooling and stasis of blood in the lower limbs, place women at risk for blood clots. These changes, which usually return to prepregnant levels after 3 weeks of postpartum, are important for minimizing blood loss at childbirth. Smoking, obesity, immobility, and postpartum factors such as infection, bleeding, and emergency surgery (including emergency cesarean section) also increase the risk of coagulation disorders (Creasy et al., 2014).

Clotting factors that increased during pregnancy tend to remain elevated during the early postpartum period. Giving birth stimulates this hypercoagulability state further. As a result, these coagulation factors remain elevated for 2 to 3 weeks postpartum (King et al., 2015). This hypercoagulable state, combined with vessel damage during birth and immobility, places the woman at risk for thromboembolism (blood clots) in the lower extremities and the lungs.

Blood Cellular Components

Red blood cell production ceases early in the puerperium, causing mean hemoglobin and hematocrit levels to decrease slightly in the first 24 hours. During the next 2 weeks, both levels rise slowly. The white blood count, which increases in labor, remains elevated for first 4 to 6 days after birth but then falls to 6,000 to 10,000/mm^3. This white blood cell elevation can complicate a diagnosis of infection in the immediate postpartum period.

Urinary System Adaptations

Pregnancy and birth can have profound effects on the urinary system. During pregnancy, the glomerular filtration rate and renal plasma flow increase significantly. Both usually return to normal by 6 weeks after birth. There is a gradual return of bladder tone and normal size and function of the bladder, ureters, and renal pelvis, all of which were dilated during pregnancy.

Many women have difficulty feeling the sensation to void after giving birth if they received an anesthetic block during labor (which inhibits neural functioning of the bladder) or if they received oxytocin to induce or augment their labor (antidiuretic effect). These women will be at risk for incomplete emptying, bladder distention, difficulty voiding, and urinary retention. In addition, urination may be impeded by:

• Perineal lacerations

• Generalized swelling and bruising of the perineum and tissues surrounding the urinary meatus

• Hematomas

• Decreased bladder tone as a result of regional anesthesia

• Diminished sensation of bladder pressure as a result of swelling, poor bladder tone, and numbing effects of regional anesthesia used during labor (Bope & Kellerman, 2015).

Difficulty voiding can lead to urinary retention, bladder distention, and ultimately urinary tract infection. Urinary retention and bladder distention can cause displacement of the uterus from the midline to the right and can inhibit the uterus from contracting properly, which increases the risk of postpartum hemorrhage. Urinary retention is a major cause of uterine atony, which allows excessive bleeding. Frequent voiding of small amounts (less than 150 mL) suggests urinary retention with overflow, and catheterization may be necessary to empty the bladder to restore tone.

Postpartum diuresis occurs as a result of several mechanisms: the large amounts of intravenous fluids given during labor, a decreasing antidiuretic effect of oxytocin as its level declines, the buildup and retention of extra fluids during pregnancy, and a decreasing production of aldosterone—the hormone that decreases sodium retention and increases urine production (Evans & De Franco,

2014). All of these factors contribute to rapid filling of the bladder within 12 hours of birth. Diuresis begins within 12 hours after childbirth and continues throughout the first week postpartum. Normal function returns within a month after birth (Cunningham et al., 2014).

Consider This

Have you ever felt like a real idiot by not being able to complete a simple task in life? I had a beautiful baby boy after only 6 hours of labor. My epidural worked well and I actually felt very little discomfort throughout my labor. Because it was in the middle of the night when they brought me to my postpartum room, I felt a few hours of sleep would be all I needed to be back to normal. During an assessment early the next morning, the nurse found my uterus had shifted to the right from my midline, and I was instructed to empty my bladder. I didn't understand why the nurse was concerned about where my uterus was located and, besides, I didn't feel any sensation of a full bladder. But I did get up anyway and tried to comply. Despite all the nurse's tricks of running the faucet for sound effects, in addition to having warm water poured over my thighs via the peribottle, I was unable to urinate. How could I not accomplish one of life's simplest tasks?

Thoughts: Women who receive regional anesthesia frequently experience reduced sensation to their perineal area and do not feel a full bladder. The nursing assessment revealed a displaced uterus secondary to a full bladder. What additional "tricks" can be used to assist this woman to void? What explanation should be offered to her regarding why she is having difficulty urinating?

Gastrointestinal System Adaptations

The gastrointestinal system quickly returns to normal after birth because the gravid uterus is no longer filling the abdominal cavity and producing pressure on the abdominal organs. Progesterone levels, which caused relaxation of smooth muscle during pregnancy and diminished bowel tone, also are declining.

Regardless of the type of delivery, most women experience decreased bowel tone and sluggish bowels for several days after birth. Decreased peristalsis occurs in response to analgesics, surgery, diminished intra-abdominal pressure, low-fiber diet, insufficient fluid intake, and diminished muscle tone. In addition, women with an episiotomy, perineal laceration, or hemorrhoids may fear pain or damage to the perineum with their first bowel movement and may attempt to delay it. Subsequently, constipation is a common problem during the postpartum period. A stool softener can be prescribed for this reason.

Most women are hungry and thirsty after childbirth, commonly related to nothing-by-mouth (NPO) restrictions and the energy expended during labor. Their appetite returns to normal immediately after giving birth.

 Take Note!

Anticipate the woman's need to replenish her body with food and fluids, and provide both soon after she gives birth.

Musculoskeletal System Adaptations

The effects of pregnancy on the muscles and joints vary widely. Musculoskeletal changes associated with pregnancy, such as increased ligament laxity, weight gain, change in the center of gravity, and carpal tunnel syndrome, revert back during the postpartum period. During pregnancy, the hormones relaxin, estrogen, and progesterone relax the joints. After birth, levels of these hormones decline, resulting in a return of all joints to their prepregnant state, with the exception of the woman's feet. Parous women will note a permanent increase in their shoe size (Jordan et al., 2014).

Woman commonly experience fatigue and activity intolerance and have a distorted body image for weeks after birth secondary to declining relaxin and progesterone levels, which cause hip and joint pain that interferes with ambulation and exercise. Good body mechanics and correct positioning are important during this time to prevent low back pain and injury to the joints. Within 6 to 8 weeks after delivery, joints are completely stabilized and return to normal.

During pregnancy, stretching of the abdominal wall muscles occurs to accommodate the enlarging uterus. This stretching leads to a loss in muscle tone and possibly separation of the longitudinal muscles (rectus abdominis muscles) of the abdomen. Separation of the rectus abdominis muscles, called diastasis recti, is more common in women who have poor abdominal muscle tone before pregnancy. After birth, muscle tone is diminished and the abdominal muscles are soft and flabby. Specific exercises are necessary to help the woman regain muscle tone. Fortunately, diastasis responds well to exercise, and abdominal muscle tone can be improved. (See Chapter 16 for more information about exercises to improve muscle tone.)

Take Note!

If rectus muscle tone is not regained through exercise, support may not be adequate during future pregnancies.

Integumentary System Adaptations

Another system that experiences lasting effects of pregnancy is the integumentary system. As estrogen and progesterone levels decrease, the darkened pigmentation on the abdomen (linea nigra), face (melasma), and nipples gradually fades. Some women experience hair loss during pregnancy and the postpartum periods. Approximately 90% of hairs are growing at any one time, with the other 10% entering a resting phase. Because of the high estrogen levels present during pregnancy, an increased number of hairs go into the resting phase, which is part of the normal hair loss cycle. The most common period for hair loss is within 3 months after birth, when estrogen returns to normal levels and more hairs are allowed to fall out. This hair loss is temporary, and regrowth generally returns to normal levels in 4 to 6 months in two thirds of women and by 15 months in the remainder, although hair may be less abundant than before pregnancy (King et al., 2015).

Striae gravidarum (stretch marks) that developed during pregnancy on the breasts, abdomen, and hips gradually fade to silvery lines. However, these lines do not disappear completely. Although many products on the market claim to make stretch marks disappear, their effectiveness is highly questionable.

The profuse diaphoresis (sweating) that is common during the early postpartum period is one of the most noticeable adaptations in the integumentary system. Many women will wake up drenched with perspiration during the puerperium. This postpartum diaphoresis is a mechanism to reduce the amount of fluids retained during pregnancy and restore prepregnant body fluid levels. It can be profuse at times. It is common, especially at night during the first week after birth. Reassure the client that this is normal and encourage her to change her gown to prevent chilling.

Respiratory System Adaptations

Respirations usually remain within the normal adult range of 16 to 24 breaths per minute. As the abdominal organs resume their nonpregnant position, the diaphragm returns to its usual position. Anatomic changes in the thoracic cavity and rib cage caused by increasing uterine growth resolve quickly. As a result, discomforts such as shortness of breath and rib aches are relieved. Tidal volume, minute volume, vital capacity, and functional residual capacity return to prepregnant values, typically within 1 to 3 weeks of birth (Mattson & Smith, 2016).

Endocrine System Adaptations

The endocrine system rapidly undergoes several changes after birth. Levels of circulating estrogen and progesterone drop quickly with delivery of the placenta. Decreased estrogen levels are associated with breast engorgement and with the diuresis of excess extracellular fluid accumulated during pregnancy (Creasy et al., 2014). Estrogen is at its lowest level a week after birth. For the woman who is not breast-feeding, estrogen levels begin to increase by 2 weeks after birth. For the breast-feeding woman, estrogen levels remain low until breast-feeding frequency decreases.

Other placental hormones (human chorionic gonadotropin [hCG], human placental lactogen [hPL], progesterone) decline rapidly after birth. The hCG levels are nonexistent at the end of the first postpartum week, and hPL is undetectable within 1 day after birth (Mattson & Smith, 2016). Progesterone levels are undetectable by 3 days after childbirth, and production is reestablished with the first menses. Prolactin is a hormone secreted by the anterior pituitary gland involved with lactation and reproduction. Prolactin levels decline within 2 weeks for the woman who is not breast-feeding, but remain elevated for the lactating woman (Jin et al., 2015).

Weight Loss After Childbirth

For all women of reproductive age, excessive weight gain and postpartum weight retention can increase their risk of obesity. Breast-feeding has been shown to have many health benefits for both mother and infant; however, its role in postpartum weight loss is unclear. More research studies are needed to reliably assess the impact of breast-feeding on postpartum weight management (Neville et al., 2014).

The rate and amount of weight loss in the postpartum period seem to be determined by the same factors that determine weight loss at any point in a woman's life, including existing weight/body mass index (BMI), diet, age, and activity level (Nascimento et al., 2014). Thus, there is benefit from overall lifestyle interventions on weight loss in postpartum women which include exercise plus dietary changes to achieve their weight reduction goals. See Evidence-Based Practice 15.2.

> *Think back to Betsy, the woman experiencing painful changes in her breasts. What is Betsy describing to the lactation consultant? Why has the condition of her breasts changed compared with when she was in the hospital?*

EVIDENCE-BASED PRACTICE 15.2 REDUCING POSTPARTUM WEIGHT RETENTION AND IMPROVING BREAST-FEEDING OUTCOMES IN OVERWEIGHT WOMEN: A PILOT RANDOMIZED CONTROLLED TRIAL

Women naturally gain weight during pregnancy and many gradually lose it afterward. Some women, though, find it difficult to lose the pregnancy-related weight during the postpartum period and there is concern that this may be a health risk. The retention of weight gained during pregnancy may contribute to obesity. Obesity in the general population increases the risk of diabetes, heart disease, and high blood pressure. It is suggested that women who return to their prepregnancy weight by about 6 months after childbirth have a lower risk of being overweight 10 years later. Weight gain is also associated with

lower rates of breast-feeding initiation and duration. The purpose of this randomized study was to help women reduce their postpartum weight retention and improve breast-feeding outcomes.

STUDY

Thirty-six women with a BMI of >25 were recruited, stratified by BMI and randomized to one of three groups with follow-up to 6 months postpartum. Women received a dietary intervention with or without breast-feeding support from a lactation consultant. All participants initiated breast-feeding, but the group that had lactation support had a longer duration of breast-feeding than the group without the lactation support. In addition, the women with longer breast-feeding duration, also loss the most weight during the 6-month period.

Findings

The study provided evidence to support the feasibility of providing overweight and obese women with targeted dietary advice and breast-feeding support to improve weight and breast-feeding outcomes.

Nursing Implications

Based on the findings of this study, nurses can recommend to their postpartum mothers desiring to lose their pregnancy weight should be encouraged to breast-feed and sustain it for at least 6 months to lose their pregnancy weight gained. Research findings associate breast-feeding with postpartum weight loss due to the increase in women's metabolic rates which burn calories. This information should be reported to postpartum mothers desiring to lose weight and breast-feed. Overall, if gained weight through the pregnancy isn't lost, their risk of cardiovascular diseases, diabetes, hypertension, and cancer will be increased as they age. The weight loss will help prevent these conditions or at the very least reduce their risks.

Global Health of Childbearing Women

Globalization has changed our society in numerous ways, yet the health of women is remaining stagnant or growing worse in many parts of the world. Many women in developing counties are denied their fundamental right to enjoy a complete state of health as defined by the World Health Organization (Boyd-Judson & James, 2014). More than half a million women die each year from complications during and after childbirth (bleeding and infections), the vast majority of them in Africa and Asia (Webber & Chirangi, 2014).

Women throughout the world continue to face enormous obstacles in attempting to access obstetric care. Skilled attendance at childbirth is critical for decreasing maternal and neonatal mortality, yet many women in developing countries give birth outside health facilities, without skilled help. Nurses throughout the world can help advocate for cost-effective, evidence-based interventions to prevent and battle complications from childbirth to save women's lives. The challenge is to guarantee that every pregnant woman who needs care gets it. Nurses can make a difference outside their own country's borders by advocating for all international women through their governmental

political systems and encouraging those governments to offer help and save lives.

Lactation

Lactation is the secretion of milk by the breasts. It is thought to be brought about by the interaction of progesterone, estrogen, prolactin, and oxytocin. Breast milk typically appears within 4 to 5 days after childbirth.

BREAST-FEEDING

Breast-feeding is a dynamic process, which requires coupling between periodic motions of the infant's jaws, undulation of the tongue, and breast milk ejection reflex. All mechanisms must be coordinated to be successful. All major health organizations recommend breast-feeding. The American Academy of Pediatrics recommends exclusive breast-feeding for 6 months, followed by the introduction of appropriate complementary foods and continued breast-feeding to 1 year and beyond (American Academy of Pediatrics [AAP], 2015). This recommendation is considered to be the standard of care today. Nurses have an important role in promoting, supporting, and protecting breast-feeding. Proper positioning, latching-on, sucking, and swallowing are the foundation for successful breast-feeding. Although breast-feeding is recommended by international and national organizations, the nurse must respect and support all mothers in either of the infant feeding methods chosen.

During pregnancy, the breasts increase in size and functional ability in preparation for breast-feeding. Estrogen stimulates growth of the milk collection (ductal) system, whereas progesterone stimulates growth of the milk production system. Within the first month of gestation, the ducts of the mammary glands grow branches, forming more lobules and alveoli. These structural changes make the breasts larger, more tender, and heavy. Each breast gains nearly 1 lb in weight by term, the glandular cells fill with secretions, blood vessels increase in number, and the amounts of connective tissue and fat cells increase (Engel et al., 2015).

Prolactin from the anterior pituitary gland, secreted in increasing levels throughout pregnancy, triggers the synthesis and secretion of milk after the woman gives birth. During pregnancy, prolactin, estrogen, and progesterone cause synthesis and secretion of *colostrum*, which contains protein and carbohydrate but no milk fat. It is only after birth takes place, when the high

levels of estrogen and progesterone are abruptly withdrawn, that prolactin is able to stimulate the glandular cells to secrete milk instead of colostrum. This takes place within 4 to 5 days after giving birth.

Oxytocin acts so that milk can be ejected from the alveoli to the nipple. Therefore, sucking by the newborn will release milk. A decrease in the quality of stimulation causes a decrease in prolactin surges and thus a decrease in milk production. Prolactin levels increase in response to nipple stimulation during feedings. Prolactin and oxytocin result in milk production if stimulated by sucking (Stuebe et al., 2015) (Fig. 15.3). If the stimulus (sucking) is not present, as with a woman who is not breast-feeding, breast engorgement and milk production will subside within days postpartum.

Skin-to-skin contact during the first hour following birth is the gold standard to initiate breast-feeding, if the mother decides this is the method of feeding for her newborn. Researchers realized that a newborn's instinct was to seek nourishment after birth. They move on their mother's abdomen up to her breast instinctively. Researchers term this movement the *breast crawl* that helps initiate breastfeeding immediately after childbirth. This instinct occurs when a newborn, left undisturbed and skin-to-skin on the mother's trunk following birth, moves toward her mother's breast for the purpose of locating and self-attaching for the first feeding. From there, the newborn uses leg and arm movements to propel her/himself toward the breast. Upon reaching the sternum, the newborn will bounce her/his head up and down and side to side. As the newborn approaches the nipple, her/his mouth opens and, after several attempts, latch-on and suckling take place. Newborns have senses and skills that enable early initiation of feeding at the breast. Nurses can help facilitate the breast crawl as a continuation of the birthing process. Nurses have a responsibility to promote the health of their childbearing families and provide evidence-based care. Encouraging use of the breast crawl can be the first step in health promotion for every newborn (Zanardo & Straface, 2015).

Breast milk production can be summarized as follows:

• Prolactin levels increase at term with a decrease in estrogen and progesterone levels.

• Estrogen and progesterone levels decrease after the placenta is delivered.

• Prolactin is released from the anterior pituitary gland and initiates milk production.

• Oxytocin is released from the posterior pituitary gland to promote milk let-

down.

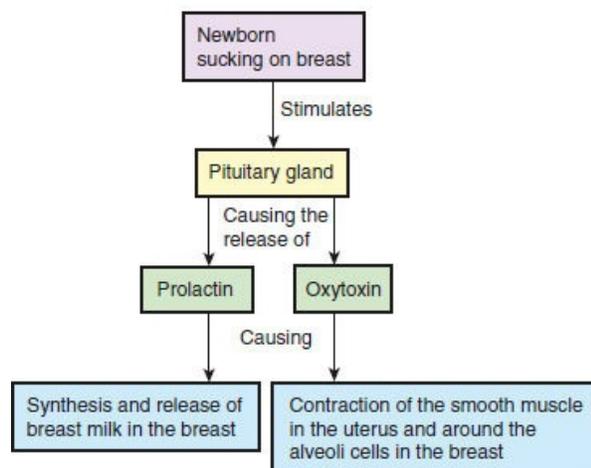
- Infant sucking at each feeding provides continuous stimulus for prolactin and oxytocin release (Wambach & Riordan, 2014).


FIGURE 15.3 Physiology of lactation.

Typically, during the first 2 days after birth, the breasts are soft and nontender. The woman also may report a tingling sensation in both breasts, which is the "let-down reflex" that occurs immediately before or during breast-feeding. After this time, breast changes depend on whether the mother is breast-feeding or taking measures to prevent lactation.

Engorgement is a postnatal physiologic painful condition in which distension and swelling of the breast tissue occurs as a result of an increase in blood and lymph supply as a precursor to lactation (Fig. 15.4). Breast engorgement usually peaks in 3 to 5 days postpartum and usually subsides within the following 24 to 36 hours (Alekseev, Vladimir, & Nadezhda, 2015). Engorgement can occur from infrequent feeding or ineffective emptying of the breasts and typically lasts about

24 hours. Breasts increase in vascularity and swell in response to prolactin 2 to 4 days after birth. If engorged, the breasts will be hard and tender to touch. They are temporarily full, tender, and very uncomfortable until the milk supply is ready. Frequent emptying of the breasts helps to minimize discomfort and resolve engorgement. Standing in a warm shower or applying warm compresses immediately before feedings will help to soften the breasts and nipples in order to allow the newborn to latch on more easily.

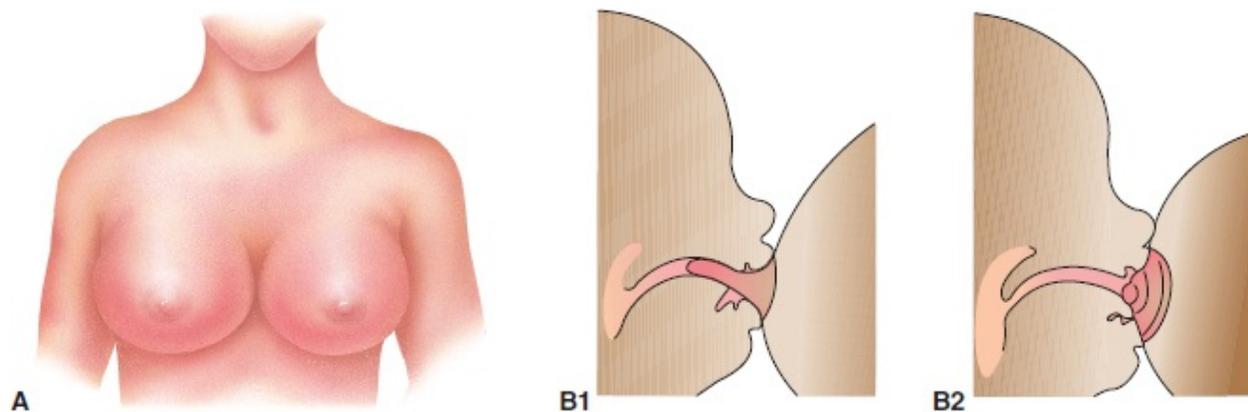
Treatments to reduce the pain of breast engorgement include heat or cold applications, cabbage leaf compresses, breast massage and milk expression, ultrasound, breast pumping, and anti-inflammatory agents (King et al., 2015). A nonprescription anti-inflammatory medication can also be taken for the breast discomfort and swelling resulting from engorgement. These measures will also enhance the let-down reflex. Between feedings, applying cold compresses to the breasts helps to reduce swelling. To maintain milk supply, the breasts need to be stimulated by a nursing infant, a breast pump, or manual expression of the milk (Fig. 15.5).


FIGURE 15.4 A. Image of engorged breasts. Note swelling and inflammation of both breasts. **B.** Breast engorgement can disrupt breast-feeding: (1) When sucking at a normal breast, the infant's lips compress the areola and fit neatly against the sides of the nipple. The infant also has adequate room to breathe. (2) When a breast is engorged, however, the infant has difficulty grasping the nipple and breathing ability is compromised. (From Pillitteri, A. [2014]. *Maternal and child nursing.* (7th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Remember Betsy, with the breast discomfort? The lactation consultant explained that she was experiencing normal breast engorgement and offered several suggestions to help her. What relief measures might she have

suggested? What reassurance can be given to Betsy at this time?

SUPPRESSING LACTATION

Various pharmacologic and nonpharmacologic interventions have been used to suppress lactation after childbirth and relieve associated symptoms. Despite the large volume of literature on the subject, there is currently no universal guideline on the most appropriate approach for suppressing lactation in postpartum women (Cunningham et al., 2014). It is estimated that more than 30% of women in the United States do not breast-feed their infants, and a larger proportion discontinues breast-feeding within 2 weeks of childbirth (Senie, 2014). Although physiologic cessation of lactation eventually occurs in the absence of physical stimulus such as infant suckling, a large number of women experience moderate to severe milk leakage and discomfort before lactation ceases.

FIGURE 15.5 Nurse instructs the new breast-feeding mother about use of a breast pump. (Copyright B. Proud.)

Up to two thirds of non-breast-feeding women experience moderate to severe engorgement and breast pain when no treatment is applied (Spencer, 2015). If a woman does not desire to breast-feed, some relief measures include wearing a tight, supportive bra 24 hours daily, applying ice to her breasts for approximately 15 to 20 minutes every other hour, avoiding sexual stimulation, and not stimulating the breasts by squeezing or manually expressing milk from the nipples. In addition, avoiding exposing the breasts to warmth (e.g., a hot shower) will help relieve breast engorgement. In women who are not breast-feeding,

engorgement typically subsides within 2 to 3 days with application of these measures.

Ovulation and Return of Menstruation

Changing hormone levels constantly interact with one another to produce bodily changes. Four major hormones are influential during the postpartum period: estrogen, progesterone, prolactin, and oxytocin. Estrogen plays a major role during pregnancy, but levels drop profoundly at birth and reach their lowest level a week into the postpartum period. Progesterone quiets the uterus to prevent a preterm birth during pregnancy, and its increasing levels during pregnancy prevent lactation from starting before birth takes place. As with estrogen, progesterone levels decrease dramatically after birth and are undetectable 72 hours after birth. Progesterone levels are reestablished with the first menstrual cycle (Creasy et al., 2014).

During the postpartum period, oxytocin stimulates the uterus to contract during the breast-feeding session and for as long as 20 minutes after each feeding. Oxytocin also acts on the breast by eliciting the milk let-down reflex during breast-feeding. Prolactin is also associated with the breast-feeding process by stimulating milk production. In women who breast-feed, prolactin levels remain elevated into the sixth week after birth (Bope & Kellerman, 2015). The levels of prolactin fluctuate in proportion to nipple stimulation. Prolactin levels decrease in nonlactating women, reaching prepregnant levels by the third postpartum week. High levels of prolactin have been found to delay ovulation by inhibiting ovarian response to follicle-stimulating hormone (Bernard et al., 2015).

The timing of first menses and ovulation after birth differs between women who are breast-feeding and women who are not breast-feeding. For nonlactating women, menstruation may resume as early as 7 to 9 weeks after giving birth, but the majority take up to 3 months, with the first cycle being anovulatory (Barrett et al., 2014). The return of menses in the lactating woman depends on breast-feeding frequency and duration. It can return any time after childbirth, depending on whether the woman is exclusively breast-feeding or supplementing with formula.

Take Note!

Ovulation may occur before menstruation. Therefore, breast-feeding is not a totally reliable method of contraception unless the mother exclusively breast-feeds, has had no menstrual period since giving birth, and whose infant is younger than 6 months old (Alexander et al., 2014).

> *Betsy tries several of the measures the lactation consultant suggested to relieve her breast discomfort, but is still having heaviness and pain. She feels discouraged and tells the nurse she is thinking of reducing her breast-feeding and using formula to feed her newborn. Is that a good choice? Why or why not? What interventions will help Betsy get through this difficult time?*

CULTURAL CONSIDERATIONS FOR THE POSTPARTUM PERIOD

Cultures vary in their postpartum beliefs, practices, and customs. Nurses practice in an increasingly multicultural society. Therefore, they must be open, respectful, nonjudgmental, and willing to learn about ethnically diverse populations. Although childbirth and the postpartum period are unique experiences for each individual woman, how the woman perceives and makes meaning of them is culturally defined. Somali women are highly regarded in Somali society for their roles as mothers. Postpartum women stay at home and refrain from sexual activity for 40 days. At the end of 40 days, there is a celebration and this typically marks the first time the mother and infant have left their home since childbirth. The majority of Somalian and Arab women breast-feed and do so for extended periods of time (Wojnar & Narruhn, 2016). Nurses need to offer early breast feeding instruction to support their efforts while still in the hospital setting before discharge.

Balance of Hot and Cold

Two areas that are significantly different from Western culture involve beliefs about the balance of hot and cold and confinement after childbirth. Vietnamese women view the postpartum period as a cold state (duong) and protect themselves through warmth. Cultural practices include warm water for hygiene and stimulation of lactation, consuming warm foods, and staying indoors. In the United States, childbearing and recovery are viewed as healthy states and mothers receive little formal support for both their recovery and infant care. In China, childbearing and postpartum are viewed as states which disturb the normal health balance between yin and yang. In order to restore balance in health, postpartum women engage in practices for a month related to the maternal role, physical activity, maintenance of body warmth, and certain food consumption that will restore their balance. Recent research findings in a small sample of Chinese women found that postpartum confinement negatively correlated with aerobic endurance and positively correlated with depression. These findings may challenge the assumption that practices of confinement are healthy for Chinese women's recovery after childbirth (Liu, Maloni, & Petrini, 2014).

For many cultures, good health requires the balancing of hot and cold substances. Because childbirth involves the loss of blood, which is considered hot, the postpartum period is considered cold, so the mother must balance that with the intake of hot food. Foods consumed should be hot in nature, and cold foods, such as fruits and vegetables, avoided. Western practices frequently use cold packs or sitz baths to reduce perineal swelling and discomfort. These practices are not acceptable to women of many cultures and can be viewed as harmful. Hot–cold beliefs are common among Latin American, African, and Asian people (Purnell, 2014).

To reduce infant and mother vulnerability and potential illness, women may practice a month-long confinement period after childbirth. During this confinement period, new mothers rest and recuperate. The postpartum period is a time to avoid cold—both in temperature and foods. Women are kept warm, stay inside to prevent becoming chilled, bathe infrequently, and avoid exercise (Rice & Manderson, 2014).

Postpartum Cultural Beliefs

With increasing multiculturalism in the United States, understanding various cultures' views of the postnatal period as it relates to their recovery and well-being after childbirth is important for all nurses. Postpartum nurses need to understand these diverse cultural beliefs and provide creative strategies for encouraging hygiene (sponge baths, perineal care), exercise, and balanced nutrition, while remaining respectful of the cultural significance of these practices. The best approach is to ask each woman to describe what cultural practices are important to her and plan accordingly.

PSYCHOLOGICAL ADAPTATIONS

The process of becoming a mother requires extensive psychological, social, and physical work. Women experience heightened vulnerability and face tremendous challenges as they make this transition. Nurses have a remarkable opportunity to help women learn, gain confidence, and experience growth as they assume the mother identity.

The transition to parenthood, while an exciting time to celebrate the life of their child, causes parents to face new challenges such as physical exhaustion, role overload, and less time for themselves and their partners (Velotti, Castellano, & Zavattini, 2015). Mothers' and fathers' experiences of pregnancy are necessarily different, and this difference continues after childbirth as they both adjust to their new parenting roles. Many couples struggle to adapt to parenthood. Parenting involves caring for infants physically and emotionally to foster the growth and development of responsible, caring adults. A substantial body of research finds no biologic-based differences between mothers and fathers in sensitivity to infants, capacity to provide care or acquisition of parenting skills. Within 15 minutes of holding a newborn, men experience raised levels of oxytocin, cortisol, and prolactin. The increased levels of these nurturing hormones are the same in men and women exposed to infants (Davies, 2015). Other members of the newborn's family, such as siblings and grandparents, also experience changes related to the birth of the newborn (see Chapter 16). Early parent–infant contact after birth improves attachment behaviors.

Parental Attachment Behaviors

The postpartum period is a unique time distinguished by the inseparable relationship parents have with their newborn. To enable an attachment to be built, closeness of this family unit is essential. **Attachment** is the formation of a relationship between a parent and his or her newborn through a process of physical and emotional interactions. Attachment between a woman and her newborn has lifelong implications (King et al., 2015). Maternal attachment has the potential to affect both child development and parenting. The bond between a parent and their newborn is one of strength, power, and potential. Attachment begins before birth, during the prenatal period where acceptance and nurturing of the growing fetus takes place. It continues after giving birth as parents learn to recognize their newborn's cues, adapt to the newborn's behaviors and responses, and meet their newborn's needs.

Several factors take place during the early postpartum period that can have a large influence on the attachment/bonding that occurs during this time. Oxytocin plays an essential role in the chemistry aspect of bonding, and its effects can be enhanced by skin-to-skin contact, breast-feeding, eye contact, social vocalizations, maternal and milk odors, which are soothing for the newborn, and newborn message during the first postpartum hour (Buckley, 2015; Hutcheson & Cheeseman, 2015).

Early and sustained contact between newborns and their parents is vital for initiating their relationship.

Nurses play a crucial role in assisting the attachment process by promoting early parent–newborn interactions. In addition, nurses can facilitate skin-to-skin contact (kangaroo care) by placing the infant onto the bare chests of mothers and fathers to enhance parent–newborn attachment. This activity will enable them to get close to their newborn and experience an intense feeling of connectedness and evoke feelings of being nurturing parents. Encouraging breast-feeding is another way to foster attachment between mothers and their newborns. Finally, nurses can encourage nurturing activities and contact such as touching, talking, singing, comforting, changing diapers, feeding—in short, participating in routine newborn care.

The process of attachment is complex and is influenced by many factors including environmental circumstances, the newborn's health status, and the quality of nursing care (Buckley, 2015). Nurses need to minimize parent–

newborn separation by promoting parent–newborn interactions through kangaroo care, breast-feeding, and participation in their newborn care. Nurses who provide positive psychosocial support and clear communication to parents will help support the attachment process within family units.

Maternal Psychological Adaptations

Childbirth is supposed to be the most joyous period in a woman's life and involves the almost spiritual experience of giving birth and being able to give life to another being. For many, this can be a life-changing event and through the centuries has been anticipated with excitement and joy and has even been referred to as a blessing. In reality, childbirth and child rearing are very stressful, financially challenging, and emotionally demanding.

Mood Disorders

Many people consider childbirth a time of happiness and well-being, but it is common for women to experience changes in their mood during this time. This may include being fatigued, irritable or worried, and frequently these mood symptoms become severe enough to need medical intervention. In the postpartum period, mood disorders can be divided into three distinct entities in ascending order of severity: maternal (baby) blues, postpartum depression, and psychosis. These disorders, however, have not been clearly demarcated and it is a matter of much debate whether they are discrete disorders or a single disorder that ranges along a continuum of severity (Finley & Brizendine, 2015).

Up to 85% of new mothers suffer from the short-lived postpartum mood disorder termed "baby blues" or maternal blues, which are characterized by mild depressive symptoms, anxiety, irritability, mood swings, lose their appetite, have trouble sleeping, tearfulness (often for no discernible reason), increased sensitivity, and fatigue (Flynn, 2015). The "blues" typically peak on postpartum days 4 and 5, may last hours to days, and usually resolve by day 10. Although these symptoms may be distressing, they do not reflect psychopathology, and they typically do not affect the mother's ability to function and care for her child.

For additional information, see Chapter 22.

Phases of Maternal Adaptation to Parenthood

Parenthood is a highly anticipated and positive event for most women. Society has constructed many ideal images of motherhood, giving standards for women to live up to, and frequently setting them up for disappointment. Most women are able to experience this mismatch between their ideal and actual self and adapt with minimal discrepancy (Adams, 2015). The woman experiences a

variety of responses as she adjusts to a new family member and to postpartum discomforts, changes in her body image, and the reality of change in her life. In the early 1960s, Reva Rubin identified three phases that a mother goes through to adjust to her new maternal role. Rubin's maternal role framework can be used to monitor the client's progress as she "tries on" her new role as a mother. The absence of these processes or inability to progress through the phases satisfactorily may impede the appropriate development of the maternal role (Rubin, 1984). Although Rubin's maternal role development theories are of value, some of her observations regarding the length of each phase may not be completely relevant for the contemporary woman of the 21st century. Today, many women know their infant's gender, have "seen" their fetus in utero through four-dimensional ultrasound, and have a working knowledge of childbirth and child care. They are less passive than in years past and progress through the phases of attaining the maternal role at a much faster pace than Rubin would have imagined. Still, Rubin's framework is timeless for assessing and monitoring expected role behaviors when planning care and appropriate interventions.

TAKING-IN PHASE

The **taking-in phase** is the time immediately after birth when the client needs sleep, depends on others to meet her needs, and relives the events surrounding the birth process. This phase is characterized by dependent behavior. During the first 24 to 48 hours after giving birth, mothers often assume a very passive role in meeting their own basic needs for food, fluids, and rest, allowing the nurse to make decisions for them concerning activities and care. They spend time recounting their labor experience to anyone who will listen. Such actions help the mother integrate the birth experience into reality—that is, the pregnancy is over and the newborn is now a unique individual, separate from herself. When interacting with the newborn, new mothers spend time claiming the newborn and touching him or her, commonly identifying specific features in the newborn, such as "he has my nose" or "his fingers are long like his father's" (Fig. 15.6).

Take Note!

The taking-in phase typically lasts 1 to 2 days and may be the only phase observed by nurses in the hospital setting because of the shortened postpartum stays that are the norm today.

FIGURE 15.6 Mother bonding with newborn during the taking-in phase.

TAKING-HOLD PHASE

The **taking-hold phase**, the second phase of maternal adaptation, is characterized by dependent and independent maternal behavior. This phase typically starts on the second to third day postpartum and may last several weeks.

As the client regains control over her bodily functions during the next few days, she will be taking hold and becoming preoccupied with the present. She will be particularly concerned about her health, the infant's condition, and her ability to care for her or him. She demonstrates increased autonomy and mastery of her own body's functioning, and a desire to take charge with support and help from others. She will show independence by caring for herself and learning to care for her newborn, but she still requires assurance that she is doing well as a mother. She expresses a strong interest in caring for the infant by herself.

LETTING-GO PHASE

In the **letting-go phase**, the third phase of maternal adaptation, the woman reestablishes relationships with other people. She adapts to parenthood through her new role as a mother. She assumes the responsibility and care of the newborn with a bit more confidence now (Edelman, Kudzma, & Mandle, 2014). The focus of this phase is to move forward by assuming the parental role and to separate herself from the symbiotic relationship that she and her newborn had during pregnancy. She establishes a lifestyle that includes the infant. The mother

relinquishes the fantasy infant and accepts the real one.

Nurses have recognized the importance of the process of becoming a mother (BAM) to maternal–infant nursing since Rubin's report on maternal role attainment (MRA). Mothers' perceptions of their competence or confidence, or both, in mothering and their expressions of love for their infants included age, relationship with the father, socioeconomic status, birth experience, experienced stress, available support, personality traits, self-concept, child-rearing attitudes, role strain, health status, preparation during pregnancy, relationships with own mother, depression, and anxiety. Infant variables identified as influencing MRA/BAM include appearance, responsiveness, temperament, and health status (DiPietro et al., 2015). More current research has led to renaming the four stages a woman progresses through in establishing a maternal identity in BAM:

1. Commitment, attachment to the unborn baby, and preparation for delivery and motherhood during pregnancy

2. Acquaintance/attachment to the infant, learning to care for the infant, and physical restoration during the first 2 to 6 weeks following birth

3. Moving toward a new normal

4. Achievement of a maternal identity through redefining self to incorporate motherhood (around 4 months). The mother feels self-confident and competent in her mothering and expresses love for and pleasure interacting with her infant (Mercer & Walker, 2006)

The woman's work in the first stage is to make a commitment to the pregnancy and to the safe birth and care of her unborn child. This commitment is associated with a positive adaptation to motherhood. During the second stage while the mother is placing the infant in her family context and learning how to care for her infant, her attachment and attitude toward her infant, and her self-confidence or sense of competence in mothering, or both, consistently indicate an interdependence of these two variables. The nursing care provided during the first two stages is especially important in assisting mothers as they begin to mother. Follow-up is needed as mothers move toward a new normal and recognize a transformation of self in BAM can continue to reinforce their capabilities (Mercer, 2006).

To foster maternal role attainment, three specific interventions for nurses were identified in a review of the literature (Ferrarello & Hatfield, 2014). First, instructions about infant care and the infant's capabilities are more effective if

they are specifically focused on that particular mother's infant. Second, mothers prefer live classes rather than videotapes so they can ask questions. In short, interactive nurse–client relationships are associated with positive maternal growth. Third, identifying barriers that reduce skin-to-skin periods of mother-to-infant during the postpartum hospital stay and intervening to reduce them have implications for both maternal role development and breast-feeding success, if she has chosen this method. Providing times for skin-to-skin mother and infant contact has a positive impact on the long-term health of both. Nurses who interact with clients long term during pregnancy, childbirth and during well child care help build maternal competence. Pregnancy, birth, and becoming a mother collectively represent a critical period of physical and emotional upheaval in a woman's life. The need for a holistic care approach that supports the emotional and physical health of the dyad is imperative (Spiteri et al., 2014).

Transition to motherhood theories (Rubin and Mercer) describe women in a prescribed role; that of being a mother and indeed a predetermined type of mother. In that sense transition to motherhood theory is baby-centered. New theories need to be developed that are woman-centered and conceptualize the woman as an embodied self who is powerful in her own life.

Partner Psychological Adaptations

For partners, whether they are husbands, significant others, boyfriends, same-sex life partners, or just friends, becoming a parent or just sharing the childbirth experience can be a perplexing time as well as a time of great change. This transition is influenced by many factors, including participation in childbirth, relationships with significant others, competence in child care, the family role organization, the individual's cultural background, and the method of infant feeding.

The transition from being merely a partner to being a parent can propel many partners to reorganize their lifestyles. During the postpartum period, partners frequently find themselves struggling to balance personal and work needs with the new demands of parent status and their new self-image. The complexities of the transitional process involved in forging a parenthood identity can be viewed at three different levels: readjustment to a new self-image, formation of a triadic family relationship, and adaptation to redefining themselves and their relationship with their partner: the "more united tag team" (Halford, Petch, & Creedy, 2015).

Nurses can play a key role in supporting a partner's transition to parenthood by keeping partners informed about birth and postpartum routines, reporting on their newborn's health status, and reviewing infant development. They can also contribute by creating participative space for new partners during the postpartum period. This can be achieved, for example, by helping partners take on their new role by supporting and promoting their degree of involvement in the process. They can also be encouraged to actively participate in caring for, and maintaining contact with, their newborns.

Take Note!

Most research findings stress the importance of early contact between the partner or significant other and the newborn, as well as participation in infant care activities, to foster the relationship (Nolan, 2015).

Infants have a powerful effect on their parents and others, who become intensely involved with them (Fig. 15.7). The father's or significant other's

developing bond with the newborn—a time of intense absorption, preoccupation, and interest—is called *engrossment*.

Engrossment

Engrossment is characterized by seven behaviors:

1. Visual awareness of the newborn—the partner perceives the newborn as attractive, pretty, or beautiful.

2. Tactile awareness of the newborn—the partner has a desire to touch or hold the newborn and considers this activity to be pleasurable.

3. Perception of the newborn as perfect—the partner does not "see" any imperfections.

4. Strong attraction to the newborn—the partner focuses all attention on the newborn when they are in the room.

5. Awareness of distinct features of the newborn—the partner can distinguish his/her newborn from others in the nursery.

6. Extreme elation—the partner feels a "high" after the birth of his/her child.

7. Increased sense of self-esteem—the partner feels proud, "bigger," more mature, and older after the birth of his/her child (Sears & Sears, 2015).

FIGURE 15.7 Engrossment of the father and his newborn.

Frequently, partners are portrayed as well-meaning but bumbling when caring for newborns. However, they have their own unique way of relating to their newborns and can become as nurturing as mothers. A partner's nurturing responses may be less automatic and slower to unfold than a mother's, but they are capable of a strong bonding attachment to their newborns (Sears & Sears, 2015). Encouraging partners to express their feelings by seeing, touching, and holding their son or daughter and by cuddling, talking to, and feeding him or her will help to cement this new relationship. Reinforcement of this engrossing behavior helps partners to make a positive attachment during this critical period.

Three-Stage Role Development Process

Similar to mothers, partners also go through a predictable three-stage process during the first 3 weeks as they too "try on" their roles as parents. The three stages are expectations, reality, and transition to mastery (Sears & Sears, 2015).

STAGE 1: EXPECTATIONS

New partners pass through stage 1 (expectations) with preconceptions about what home life will be like with a newborn. Many partners may be unaware of the dramatic changes that can occur when this newborn comes home to live with them. For some, it is an eye-opening experience.

STAGE 2: REALITY

Stage 2 (reality) occurs when partners realize that their expectations in stage 1 are not realistic. Their feelings change from elation to sadness, ambivalence, jealousy, and frustration. Many wish to be more involved in the newborn's care and yet do not feel prepared to do so. Some find parenting fun but at the same time do not feel fully prepared to take on that role.

Partner's stress, irritability and frustration in the days, weeks, and months after the birth of their child can turn into depression, just like new maternal experience. Unfortunately, partners rarely discuss their feelings or ask for help, especially during a time when they are supposed to be the "strong one" for the new mother. Depression in partners can cause marital conflicts, reckless or violent behavior, withdrawn parental interactions with the newborn, poor job performance, and substance abuse. In addition, paternal depression following childbirth can have a detrimental effect on a couple's relationship, the parent–child relationship, and on their children's future development (Sethna et al.,

2015).

Risk factors for partner postpartum depression include previous history of depression, financial problems, a poor relationship with his/her partner, and an unplanned pregnancy. Symptoms of depression appear 1 to 3 weeks after birth and can include feelings of being very stressed and anxious, being discouraged, fatigued, resentment toward the infant and the attention he or she is getting, and headaches. Partners experiencing these symptoms should understand that it is not a sign of weakness and professional help can be helpful for them.

STAGE 3: TRANSITION TO MASTERY

In stage 3 (transition to mastery), the partner makes a conscious decision to take control and be at the center of his/her newborn's life regardless of his/her preparedness. This adjustment period is similar to that of the mother's letting-go phase, when she incorporates the newest member into the family.

KEY CONCEPTS

- The puerperium period refers to the first 6 weeks after delivery. During this period, the mother experiences many physiologic and psychological adaptations to return her to the prepregnant state.

- Involution involves three processes: contraction of muscle fibers to reduce stretched ones, catabolism (which reduces enlarged, individual cells), and regeneration of uterine epithelium from the lower layer of the decidua after the upper layers have been sloughed off and shed in lochia.

- Lochia passes through three stages: lochia rubra, lochia serosa, and lochia alba during the postpartum period.

- Maternal blood plasma volume decreases rapidly after birth and returns to normal within 4 weeks postpartum.

- Reva Rubin (1984) identified three phases the mother goes through to adjust to her new maternal role: the taking-in, taking-hold, and letting-go phase.

- The transition to fatherhood is influenced by many factors, including participation in childbirth, relationships with significant others, competence in child care, the family role organization, the father's cultural background, and the method of infant feeding.

- Like mothers, partners go through a predictable three-stage process during the first 3 weeks as they too "try on" their roles as f partners. The three stages

include expectations, reality, and transition to mastery.

CHAPTER **WORKSHEET**

MULTIPLE CHOICE QUESTIONS

1. Postpartum breast engorgement occurs 48 to 72 hours after giving birth. What physiologic change influences breast engorgement?

    a. An increase in blood and lymph supply to the breasts

    b. An increase in estrogen and progesterone levels

    c. Colostrum production increases dramatically

    d. Fluid retention in the breasts due to the intravenous fluids given during labor

2. In the taking-in maternal role phase described by Rubin (1984), the nurse would expect the woman's behavior to be characterized as which of the following?

    a. Gaining self-confidence

    b. Adjusting to her new relationships

    c. Being passive and dependent

    d. Resuming control over her life

3. The nurse is explaining to a postpartum woman 48 hours after her giving childbirth that the after-pains she is experiencing can be the result of which of the following?

    a. Abdominal cramping is a sign of endometriosis

    b. A small infant weighing less than 8 lb

c. Pregnancies that were too closely spaced

d. Contractions of the uterus after birth

4. The nurse would expect a postpartum woman to demonstrate lochia in which sequence?

a. Rubra, alba, serosa

b. Rubra, serosa, alba

c. Serosa, alba, rubra

d. Alba, rubra, serosa

5. The nurse is assessing Ms. Smith, who gave birth to her first child 5 days ago. What findings by the nurse would be expected?

a. Cream-colored lochia; uterus above the umbilicus

b. Bright-red lochia with clots; uterus 2 fingerbreadths below umbilicus

c. Light pink or brown lochia; uterus 4 to 5 fingerbreadths below umbilicus

d. Yellow, mucousy lochia; uterus at the level of the umbilicus

6. Prioritize the postpartum mother's needs 4 hours after giving birth by placing a number 1, 2, 3, or 4 in the blank before each need.

a. _____ Learn how to hold and cuddle the infant.

b. _____Watch a baby bath demonstration given by the nurse.

c. _____ Sleep and rest without being disturbed for a few hours.

d. _____ Interaction time (first 30 minutes) with the infant to facilitate bonding.

7. Immediately after childbirth in the recovery area, the nurse observes the mother's partner's fascination and interest in the new son. This behavior is often termed:

a. Attachment

b. Engrossment

c. Bonding

d. Temperament

8. After the nurse provides instructions to a postpartum woman about postpartum

blues, which statement would indicate understanding of it? I will

a. "Need to take medication daily to treat the anxiety and sadness."

b. "Call the OB support line only if I start to hear voices."

c. "Contact my doctor if I become dizzy and fell nauseated."

d. "Feel like laughing one minute and crying the next minute."

CRITICAL THINKING EXERCISE

1. A new nurse assigned to the postpartum mother–baby unit makes a comment to the oncoming shift that, a 25-year-old primipara, seems lazy and shows no initiative in taking care of herself or her baby. The nurse reported that this new mother talks excessively about her labor and birth experience and seems preoccupied with herself and her needs, not her newborn's care. She wonders if something is wrong with this mother because she seems so self-centered and has to be directed to do everything.

a. Is there something "wrong" with Ms. Griffin's behavior? Why or why not?

b. What maternal role phase is being described by the new nurse?

c. What role can the nurse play to support the mother through this phase?

2. A primipara gave birth to a healthy baby boy yesterday. Her partner seemed elated at the birth, calling their friends and family on his cell phone minutes after the birth. He passed out cigars and praised his wife for her efforts. Today, when the nurse walked into their room, her partner seemed very anxious around his new son and called for the nurse whenever the baby cried or needed a diaper change. He seemed standoffish when asked to hold his son, and he spent time talking to other fathers in the waiting room, leaving his wife alone in the room.

a. Would you consider Mr. Lenhart's paternal behavior to be normal at this time?

b. What might Mr. Lenhart be feeling at this time?

c. How can the nurse help this new father adjust to his new role?

STUDY ACTIVITIES

1. Find an Internet resource that discusses general postpartum care for new

mothers who might have questions after discharge. Evaluate the web site's information as to how credible, accurate, and current the information is.

2. Prepare a teaching plan for new mothers, outlining the various physiologic changes that will take place after discharge.

3. The term that describes the return of the uterus to its prepregnant state is

   _____.

4. A deviated fundus to the right side of the abdomen would indicate a

   _____.

BRINGING IT ALL TOGETHER: CASE STUDY

A 29-year-old married Latina mother of four children lived with her migrant husband and his parents in a small rural border town. She had given birth to her fourth child 7 weeks ago. She now had four children in the past four years. Her pregnancy, labor, and birth had been uneventful, and an untrained neighbor woman helped conduct the home birth. Because pregnancy was viewed as a normal occurrence that did not require any medical attention, she did not receive any prenatal care for any of her four pregnancies. For the first month after birth, she felt normal, but then began to exhibit restless and anxious behavior. She became isolated from her family, stopped speaking to them, and ceased to care for her newborn or other children. Her family wondered about her isolation, but seemed indifferent to her condition, as they were all busy with their own lives. One day when all of her family members and her children had gone to work in the fields, she ended her life.

Go to thePoint to find questions to consider about this case.

Nursing Management During the Postpartum Period

KEY TERMS

attachment
bonding
en face position
pelvic floor exercises
peribottle
postpartum blues
sitz bath

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Characterize the normal physiologic and psychological adaptations to the postpartum period.
2. Determine the parameters that need to be assessed during the postpartum period.
3. Compare and contrast bonding to the attachment process.
4. Select behaviors that enhance or inhibit the attachment process.
5. Outline nursing management for the woman and her family during the postpartum period.
6. Examine the role of the nurse in promoting successful breast-feeding.
7. Plan areas of health education needed for discharge planning, home care, and follow-up.

> *A 24-year-old Muslim primipara has just been admitted to the postpartum unit. Her husband sits at the bedside, but doesn't seem to provide her any physical or emotional support after her lengthy labor and difficult birth.*

Words of Wisdom

Parenting is an intimate, interactive, continuous, lifelong process.

INTRODUCTION

The postpartum period is a time of major adjustments and adaptations not just for the mother, but for all members of the family. It is during this time that parenting starts and a relationship with the newborn begins. A positive, loving relationship between parents and their newborn promotes the emotional well-being of all. This relationship endures and has profound effects on the child's growth and development.

 Take Note!

Parenting is a skill that is often learned by trial and error, with varying degrees of success. Successful parenting, a continuous and complex interactive process, requires the parents to learn new skills and to integrate the new member into the family.

Once the infant is born, each system in the mother's body takes several weeks to return to its nonpregnant state. The physiologic changes in women during the postpartum period are dramatic. Nurses should be aware of these changes and should be able to make observations and assessments to validate normal occurrences and detect any deviations.

This chapter describes the nursing management of the woman and her family during the postpartum period. (See Chapter 21 for a detailed discussion of the postpartum care of the woman undergoing a surgical birth.) Nursing management during the postpartum period focuses on assessing the woman's ability to adapt to the physiologic and psychological changes occurring at this time (see Chapter 15 for a detailed discussion of these adaptations). The chapter outlines physical assessment parameters for new mothers and newborns. It also focuses on bonding and attachment behaviors; nurses need to be aware of these behaviors so they can perform appropriate interventions. Family members are also assessed to determine how well they are making the transition to this new stage.

Based on assessment findings, the nurse plans and implements care to address the family's needs. Steps to address physiologic needs such as comfort, self-care,

nutrition, and contraception are described. Ways to help the woman and her family adapt to the birth of the newborn are also discussed (Fig. 16.1). Because of today's shortened lengths of stay, the nurse may be able to focus only on priority needs and may need to arrange for follow-up in the home to ensure that all the family's needs are met.

SOCIAL SUPPORT AND CULTURAL CONSIDERATIONS

In addition to physical assessment and care of the woman in the postpartum period, strong social support is vital to help her integrate the baby into the family. A key to providing effective postpartum care is to understand the woman in her social and cultural context so that all care provided is culturally competent and sensitive. In today's mobile society, extended families may live far away and may be unable to help care for the new family. As a result, many new parents turn to health care providers for information as well as physical and emotional support during this adjustment period. Nurses can be an invaluable resource by serving as mentors, teaching about self-care measures and baby care basics, and providing emotional support. Nurses can "mother" the new mother by offering physical care, emotional support, information, and practical help. The nurse's support and care through this critical time can increase the new parents' confidence, giving them a sense of accomplishment in their parenting skills. One important intervention during the postpartum period is promotion of breast-feeding. *Healthy People 2020* includes breast-feeding as a goal for maternal, infant, and child health (U.S. Department of Health and Human Resources [USDHHS], 2010).

FIGURE 16.1 Parents and grandmother interacting with the newborn.

As in all nursing care, nurses should provide culturally competent care during

the postpartum period. The nurse should engage in ongoing cultural self-assessment and overcome any stereotypes that perpetuate prejudice or discrimination against any cultural group (Bowers & Ceballos, 2015). Providing culturally competent nursing care during the postpartum period requires time, open-mindedness, and patience. The global migration of diverse populations presents nurses with the challenge of providing care to unprecedented numbers of clients and their families with health care beliefs and practices that differ from their own. Sensitivity cannot be assumed; it needs to be nurtured and developed. The skill set needed by nurses to provide culturally competent care to postpartum clients and their families include understanding their beliefs, experiences, and family environment; facilitating their language through appropriate use of interpreters so that the information provided can be understood; and compassionately respecting clients and their human rights. The Chinese culture values traditions and the involvement of elders in the extended family. Some Chinese women living in the United States practice transnational parenting, a process of sending their American-born child to China to be raised by the extended family there. This obviously has implications for breast-feeding success among these mothers (Lee & Brann, 2015). To promote positive outcomes, the nurse should be sensitive to the woman's and family's culture, religion, and ethnic influences (see "Providing Optimal Cultural Care" in the Nursing Interventions section).

HEALTHY PEOPLE 2020 • 16.1

Objective	Nursing Significance
Increase the proportion of mothers who breast-feed their babies.	Will provide infants with the most complete form of nutrition, improving their health, growth and development, and immunity.
Increase the number of mothers who breast-feed ever from a baseline of 74% to 81.9%.	Will improve maternal health via breast-feeding's beneficial effects.
Increase the number of mothers who breast-feed at 6 months from a baseline of 43.5% to 60.6%.	Will increase the rate of breast-feeding, particularly among low-income and certain racial and ethnic populations who are less likely to begin breastfeeding in the hospital or to sustain it through the infant's first year.
Increase the number of mothers who breast-feed at 1 year from a baseline of 22.7% to 34.1%.	
Increase the number of mothers who breast-feed exclusively through 3 months from a baseline of 33.6% to 46.2%.	
Increase the number of mothers who breast-feed exclusively through 6 months from a baseline of 14.1% to 25.5%.	

Healthy People objectives based on data from http://www.healthypeople.gov.

Remember the couple introduced at the beginning of the chapter? When the postpartum nurse comes to examine Raina, her husband quickly leaves the

room and returns a short time later after the examination is complete. How do you interpret his behavior toward his wife? What might you communicate to this couple?

NURSING ASSESSMENT IN THE POSTPARTUM PERIOD

Many adaptations and adjustments must be made to accommodate the new family member. The nurse's focus is on assistance for families to maximize their adjustment, surveillance for maladaptation, and education, consultation, collaboration as needed. Comprehensive nursing assessment begins within an hour after the woman gives birth and continues through discharge.

Take Note!

Nurses need a firm grasp of normal findings to be able to recognize abnormal findings and intervene appropriately.

This postpartum assessment includes vital signs and physical and psychosocial assessments. It also includes assessing the parents and other family members, such as siblings and grandparents, for attachment and bonding with the newborn. Although the exact protocol may vary among facilities, postpartum assessment typically is performed as follows:

• During the first hour: every 15 minutes

• During the second hour: every 30 minutes

• During the first 24 hours: every 4 hours

• After 24 hours: every 8 hours (Jordan et al., 2014; Mattson & Smith, 2016).

During each assessment, keep in mind risk factors that may lead to complications, such as infection or hemorrhage, during the recovery period (Box 16.1). Early identification is critical to ensure prompt intervention.

The postpartum period is a time of transition for women. The end of the pregnancy and childbirth initiates physiologic changes as many body systems return to their nonpregnant state. Nurses need to be aware of the normal physiologic and psychological changes that take place in clients' bodies and minds in order to provide comprehensive care during the postpartum period. In addition to client and family teaching, one of the most significant responsibilities

of the postpartum nurse is to recognize potential complications after childbirth.

As with any assessment, always review the woman's medical record for information about her pregnancy, labor, and birth. Note any preexisting conditions, any complications that occurred during pregnancy, labor, birth, and immediately afterward, and any treatments provided.

Postpartum assessment of the mother typically includes vital signs, pain level, epidural site inspection for infection, and a systematic head-to-toe review of body systems. The acronym **BUBBLE-EEE**—**b**reasts, **u**terus, **b**ladder, **b**owels, **l**ochia, **e**pisiotomy/perineum/epidural site, **e**xtremities, and **e**motional status—can be used as a guide for this head-to-toe review (Cunningham et al., 2014).

BOX 16.1

FACTORS INCREASING A WOMAN'S RISK FOR POSTPARTUM COMPLICATIONS

Risk Factors for Postpartum Infection

• Operative procedure (forceps, cesarean birth, vacuum extraction)

• History of diabetes, including gestational-onset diabetes

• Prolonged labor (more than 24 hours)

• Use of indwelling urinary catheter

• Anemia (hemoglobin < 10.5 mg/dL)

• Multiple vaginal examinations during labor

• Prolonged rupture of membranes (>24 hours)

• Manual extraction of placenta

• Compromised immune system (HIV positive)

Risk Factors for Postpartum Hemorrhage

• Precipitous labor (less than 3 hours)

• Uterine atony

• Placenta previa or abruptio placenta

• Labor induction or augmentation

• Operative procedures (vacuum extraction, forceps, cesarean birth)

• Retained placental fragments

• Prolonged third stage of labor (more than 30 minutes)

• Multiparity, more than three births closely spaced

• Uterine over distention (large infant, twins, hydramnios)

While assessing the woman and her family during the postpartum period, be alert for danger signs (Box 16.2). Notify the primary health care provider immediately if any are noted.

Vital Signs Assessment

Obtain vital signs and compare them with the previous values, noting and reporting any deviations. Vital sign changes can be an early indicator of complications.

Temperature

Use a consistent measurement technique (oral, axillary, or tympanic) to get the most accurate readings. Typically, the new mother's temperature during the first 24 hours postpartum is within the normal range or a low-grade elevation. Some women experience a slight fever, up to 100.4° F (38° C), during the first 24 hours. This elevation may be the result of dehydration because of fluid loss during labor. Temperature should be normal after 24 hours with replacement of fluids lost during labor and birth (Green, 2016).

A temperature above 100.4° F (38° C) at any time or an abnormal temperature after the first 24 hours may indicate infection and must be reported. Abnormal temperature readings warrant continued monitoring until an infection can be ruled out through cultures or blood studies. An elevated temperature can identify maternal sepsis, which results in significant maternal morbidity and mortality worldwide. To improve the outcome, it is essential that nurses be vigilant in obtaining accurate values and monitoring their client's temperature.

Pulse

Pulse rates of 60 to 80 beats per minute (bpm) at rest are normal during the first week after birth. This pulse rate is called puerperal bradycardia. During pregnancy, the heavy gravid uterus causes a decreased flow of venous blood to the heart. After giving birth, there is an increase in intravascular volume. The cardiac output is most likely caused by an increased stroke volume from the venous return now. The elevated stroke volume leads to a decreased heart rate (Creasy et al., 2014). Tachycardia in the postpartum woman can suggest anxiety, excitement, fatigue, pain, excessive blood loss or delayed hemorrhage, infection, or underlying cardiac problems. Any pulse rate higher than 100 bpm warrants further investigation to rule out complications.

Respirations

Respiratory rates in the postpartum woman should be within the normal range of 12 to 20 bpm at rest. Pulmonary function typically returns to the prepregnant state after childbirth when the diaphragm descends and the organs revert to their normal positions. Any change in respiratory rate out of the normal range might indicate pulmonary edema, atelectasis, a side effect of epidural anesthesia, or pulmonary embolism and must be reported. Lungs should be clear on auscultation.

Blood Pressure

Assess the woman's blood pressure and compare it with her usual range. Report any deviation from this range. Immediately after childbirth, the blood pressure should remain the same as during labor. An increase in blood pressure could indicate gestational hypertension, whereas a decrease could indicate shock or orthostatic hypotension or dehydration, a side effect of epidural anesthesia. Blood pressure readings should not be higher than 140/90 mm Hg or lower than 85/60 mmHg (King et al., 2015). Blood pressure also may vary based on the woman's position, so assess blood pressure with the woman in the same position every time. Be alert for orthostatic hypotension, which can occur when the woman moves rapidly from a lying or sitting position to a standing one.

Pain

Pain, the fifth vital sign, is assessed along with the other four parameters.

Question the woman about the type of pain and its location and severity. Have the woman rate the pain using a numeric scale from 0 to 10 points. Nursing care should focus on providing comfort measures to ease pain which might include perineal care, clean gown, mouth care, providing warm blankets, ensuring adequate fluid intake to facilitate healing, reposition frequently, and encouraging rest between assessments (Nagtalon-Ramos, 2014).

Many postpartum orders will have the nurse premedicate the woman routinely for afterbirth pains rather than wait for her to experience them first. The goal of pain management is to have the woman's pain scale rating maintained between 0 and 2 points at all times, especially after breast-feeding. This can be accomplished by assessing the woman's pain level frequently and preventing pain by administering analgesics. If the woman has severe pain in the perineal region despite use of physical comfort measures, check for a hematoma by inspecting and palpating the area. If one is found, notify the health care provider immediately.

Physical Examination

Physical examination of the postpartum woman focuses on assessing the breasts, uterus, bladder, bowels, lochia, episiotomy/perineum and epidural site and extremities.

Breasts

Inspect the breasts for size, contour, asymmetry, engorgement, or erythema. Check the nipples for cracks, redness, fissures, or bleeding, and note whether they are erect, flat, or inverted. Flat or inverted nipples can make breast-feeding challenging for both mother and infant. Cracked, blistered, fissured, bruised, or bleeding nipples in the breast-feeding woman are generally indications that the baby is improperly positioned on the breast. Palpate the breasts lightly to ascertain if they are soft, filling, or engorged, and document your findings. For women who are not breast-feeding, use a gentle, light touch to avoid breast stimulation, which would exacerbate engorgement.

Lactogenesis (the onset of milk secretion) is initially triggered by the delivery of the placenta, which results in falling levels of estrogen and progesterone, with the continued presence of prolactin. If the mother is not breast-feeding, the prolactin levels fall and return to normal levels within 2 to 3 weeks. As milk is starting to come in, the breasts become firmer; this is charted as "filling." Engorged breasts are hard, tender, and taut. Ask the woman if she is having any nipple discomfort. Palpate the breasts for any nodules, masses, or areas of warmth, which may indicate a plugged duct that may progress to mastitis if not treated promptly. Any discharge from the nipple should be described and documented if it is not colostrum (creamy yellow) or foremilk (bluish white). Over the first week, the breast milk matures and contains all necessary nutrients in the neonatal period. The breast milk continues to change throughout the period of breast-feeding to meet the changing demands of the growing infant.

Uterus

Assess the fundus (top portion of the uterus) to determine the degree of uterine involution. If possible, have the woman empty her bladder before assessing the fundus and auscultate her bowel sounds prior to uterine palpation. If the client has had a cesarean birth and has a patient-controlled anesthesia (PCA) pump,

instruct her to self-medicate prior to fundal assessment to decrease her discomfort.

Using a two-handed approach with the woman in the supine position with her knees flexed slightly and the bed in a flat position or as low as possible, palpate the abdomen gently, feeling for the top of the uterus while the other hand is placed on the lower segment of the uterus to stabilize it (Fig. 16.2).

The fundus should be midline and should feel firm. A boggy or relaxed uterus is a sign of uterine atony (loss of muscle tone in the uterus). This can be the result of bladder distention, which displaces the uterus upward and to the right, or retained placental fragments. Either situation predisposes the woman to hemorrhage.

Once the fundus is located, place your index finger on the fundus and count the number of fingerbreadths between the fundus and the umbilicus (1 fingerbreadth is approximately equal to 1 cm). One to 2 hours after birth, the fundus typically is between the umbilicus and the symphysis pubis. Approximately 6 to 12 hours after birth, the fundus usually is at the level of the umbilicus. If the fundal height is above the umbilicus, which would be an abnormal finding, investigate this immediately to prevent excessive bleeding. Frequently the woman's bladder is full, thus displacing the uterus up and to either side of the midline. Ask the woman to empty her bladder and reassess the uterus again.

Normally, the fundus progresses downward at a rate of one fingerbreadth (or 1 cm) per day after childbirth and should be nonpalpable by 10 to 14 days postpartum. By day 14, the uterus has descended below the rim of the symphysis pubis and is no longer palpable (Cunningham et al., 2014). On the first postpartum day, the top of the fundus is located 1 cm below the umbilicus and is recorded as u/1. Similarly, on the second postpartum day, the fundus would be 2 cm below the umbilicus and should be recorded as u/2, and so on. Health care agencies differ according to how fundal heights are charted, so follow their protocols for this. If the fundus is not firm, gently massage the uterus using a circular motion until it becomes firm.

Bladder

Considerable diuresis—as much as 3,000 mL/day—begins within 12 hours after childbirth and continues for several days. A single voiding may be 500 mL or more. By 21 days postpartum, the diuresis is usually complete (Jordan et al., 2014). However, many postpartum women do not sense the need to void even if their bladder is full. In this situation the bladder can become distended and

displace the uterus upward and to the side, which prevents the uterine muscles from contracting properly and can lead to excessive bleeding. Urinary retention as a result of decreased bladder tone and emptying can lead to urinary tract infections. It is imperative that nurses monitor clients for signs of urinary tract infections, including fever, urinary frequency and/or urgency, difficult or painful urination, and tenderness over the costovertebral angle (Wilson et al., 2015). Women who received regional anesthesia during labor are at risk for urinary tract infections due to continuous urinary catheterization to prevent urinary retention during labor, which is thought to delay fetal descent. They also experience difficulty voiding and loss of sensation and must wait until it returns to feel a full bladder which might be several hours after childbirth.

Assess for voiding problems by asking the woman the following questions:

• Have you (voided, urinated, gone to the bathroom) yet?

• Have you noticed any burning or discomfort with urination?

• Do you have any difficulty passing your urine?

• Do you feel that your bladder is empty when you finish urinating?

• Do you have any signs of infection such as urgency, frequency, or pain?

• Are you able to control the flow of urine by squeezing your muscles?

• Have you noticed any leakage of urine when you cough, laugh, or sneeze?

Assess the bladder for distention and adequate emptying after efforts to void. Palpate the area over the symphysis pubis. If empty, the bladder is not palpable. Palpation of a rounded mass suggests bladder distention. Also percuss the area: a full bladder is dull to percussion. If the bladder is full, lochia drainage will be more than normal because the uterus cannot contract to suppress the bleeding.

Take Note!

Note the location and condition of the fundus; a full bladder tends to displace the uterus up and to the right.

After the woman voids, palpate and percuss the area again to determine adequate emptying of the bladder. If the bladder remains distended, the woman may be retaining urine in her bladder, and measures to initiate voiding should be

instituted. Be alert for signs of infection, including infrequent or insufficient voiding (less than 200 mL), discomfort, burning, urgency, or foul-smelling urine (Mattson & Smith, 2016). Document all urine output.

Bowels

Spontaneous bowel movements may not occur for 1 to 3 days after giving birth because of a decrease in muscle tone in the intestines as a result of elevated progesterone levels. Normal patterns of bowel elimination usually return within a week after birth (Verghese, Futaba, & Latthe, 2015). Often women are hesitant to have a bowel movement due to pain in the perineal area resulting from an episiotomy, lacerations, or hemorrhoids. Some are fearful that they may "rip their stitches" should they strain. Nurses should reassure their clients that stool softeners and/or laxatives to treat constipation have been prescribed for them to reduce discomfort.

Inspect the woman's abdomen for distention, auscultate for bowel sounds in all four quadrants prior to palpating the uterine fundus, and palpate for tenderness. The abdomen typically is soft, nontender, and nondistended. Bowel sounds are present in all four quadrants. Ask the woman if she has had a bowel movement or has passed gas since giving birth, because constipation is a common problem during the postpartum period and many women do not offer this information unless asked about it. Normal assessment findings are active bowel sounds, passing gas, and a nondistended abdomen.

Lochia

Assess lochia in terms of amount, color, odor, and change with activity and time. To assess how much a woman is bleeding, ask her how many perineal pads she has used in the past 1 to 2 hours and how much drainage was on each pad. For example, did she saturate the pad completely, or was only half of the pad covered with drainage? Ask about the color of the drainage, odor, and the presence of any clots. Lochia has a definite musky scent, with an odor similar to that of menstrual flow without any large clots (fist size). Foul-smelling lochia suggests an infection, and large clots suggest poor uterine involution, necessitating additional intervention.

To determine the amount of lochia, observe the amount of lochia saturation on the perineal pad and relate it to time (Fig. 16.3). Also, take into consideration the specific type of peripad used, because some are more absorbent than others.

Lochia flow will increase when the woman gets out of bed (lochia pools in the vagina and the uterus while she is lying down) and when she breast-feeds (oxytocin release causes uterine contractions). A woman who saturates a perineal pad within 30 to 60 minutes is bleeding much more than one who saturates a pad in 2 hours.

FIGURE 16.3 Assessing lochia.

Typically, the amount of lochia is described as follows:

- *Scant:* a 1- to 2-in lochia stain on the perineal pad or approximately a 10-mL loss
- *Light or small:* an approximately 4-inch stain or a 10- to 25-mL loss
- *Moderate:* a 4- to 6-in stain with an estimated loss of 25 to 50 mL
- *Large or heavy:* a pad is saturated within 1 hour after changing it (Bope & Kellerman, 2015)

The total volume of lochial discharge varies in women based on their parity, but the amount decreases daily. Check under the woman, by turning her to either side, to make sure additional blood is not hidden and not absorbed on her perineal pad. This also a good time to assess for the presence and condition of hemorrhoids since the nurse is visually inspecting the perineum.

Report any abnormal findings, such as heavy, bright-red lochia with large tissue fragments or a foul odor. If excessive bleeding occurs, the first step would be to massage the boggy fundus until it is firm to reduce the flow of blood.

Document all findings.

Women who had a cesarean birth will have less lochia discharge than those who had a vaginal birth, but stages and color changes remain the same. Although the woman's abdomen will be tender after surgery, the nurse must palpate the fundus and assess the lochia to make sure they are within the normal range and that there is no excessive bleeding.

Anticipatory guidance to give the woman at discharge should include information about lochia and the expected changes. Urge the woman to notify her health care provider if lochia rubra returns after the serosa and alba transitions have taken place. This is abnormal and may indicate subinvolution or that the woman is too active and needs to rest more. Lochia is an excellent medium for bacterial growth. Explain to the woman that frequent changing of perineal pads, continued use of her peribottle for rinsing her perineal area, and hand hygiene before and after pad changes are important infection control measures.

Episiotomy/Perineum and Epidural Site

If the woman has an episiotomy, which is not routinely done currently, to assess the episiotomy and perineal area, position the woman on her side with her top leg flexed upward at the knee and drawn up toward her waist. If necessary, use a penlight to provide adequate lighting during the assessment. Wearing gloves and standing at the woman's side with her back to you, gently lift the upper buttock to expose the perineum and anus (Fig. 16.4). Inspect the episiotomy for irritation, ecchymosis, tenderness, or hematomas. Assess for hemorrhoids and their condition.

During the early postpartum period, the perineal tissue surrounding the episiotomy is typically edematous and slightly bruised. The normal episiotomy site should not have redness, discharge, or edema. The majority of healing takes place within the first 2 weeks, but it may take 4 to 6 months for the episiotomy to heal completely (King et al., 2015).

Lacerations to the perineal area sustained during the birthing process that were identified and repaired also need to be assessed to determine their healing status. Lacerations are classified based on their severity and tissue involvement:

- *First-degree laceration:* involves only skin and superficial structures above muscle
- *Second-degree laceration:* extends through perineal muscles
- *Third-degree laceration:* extends through the anal sphincter muscle
- *Fourth-degree laceration:* continues through anterior rectal wall

Assess the episiotomy and any lacerations at least every 8 hours to detect hematomas or signs of infection. Large areas of swollen, bluish skin with complaints of severe pain in the perineal area indicate pelvic or vulvar hematomas. Redness, swelling, increasing discomfort, or purulent drainage may indicate infection. Both findings need to be reported immediately.

A white line running the length of the episiotomy is a sign of infection, as is swelling or discharge. Severe, intractable pain, perineal discoloration, and ecchymosis indicate a perineal hematoma, a potentially dangerous condition. Report any unusual findings. Ice can be applied to relieve discomfort and reduce edema; sitz baths also can promote comfort and perineal healing (see "Promoting Comfort" in the Nursing Interventions section).

If the woman has had an epidural during her labor, assessment of the epidural wound site is important as well as checking for any side effects of the medication injected such as itching, nausea and vomiting, or urinary retention. Visual inspection of the epidural site and an accurate documentation of intake and output are essential.

Extremities

Pregnancy is associated with an increased risk of venous thromboembolism (VTE), which includes pulmonary embolism and deep vein thrombosis. During

pregnancy, the state of hypercoagulability protects the mother against excessive blood loss during childbirth and placental separation. However, this hypercoagulable state can increase the risk of thromboembolic disorders during pregnancy and postpartum. Three factors predispose women to thromboembolic disorders during pregnancy: stasis (compression of the large veins because of the gravid uterus), altered coagulation (state of pregnancy), and localized vascular damage (may occur during the birthing process). All of these factors increase the risk of clot formation and having it travel to the lungs.

While inspecting the woman's extremities, also determine the degree of sensory and motor function return (recovery from anesthesia) by asking the woman if she feels sensation at various areas the nurse touches and also by observing her ambulation stability.

Take Note!

Pulmonary embolism occurs in up to 3 per 1000 births and is a major cause of maternal mortality (Kim et al., 2015).

Pulmonary emboli typically result from dislodged deep vein thrombi in the lower extremities. Risk factors associated with thromboembolic conditions include:
• Anemia
• Diabetes mellitus
• Cigarette smoking
• Obesity
• Preeclampsia
• Hypertension
• Severe varicose veins
• Pregnancy
• Multiple pregnancies
• Cardiovascular disease
• Sickle cell disease
• Postpartum hemorrhage

• Oral contraceptive use

• Cesarean birth

• Severe infection

• Previous thromboembolic disease

• Multiparity

• Bed rest or immobility for 4 days or more

• Advanced maternal age > 35 years (Kline & Kabrhel, 2015)

Because of the subtle presentation of thromboembolic disorders, the physical examination may not be enough to detect them. An accurate diagnosis of pulmonary embolism is needed because it requires (1) prolonged therapy (≤ 9 months of heparin during pregnancy), (2) prophylaxis during future pregnancies, and (3) avoidance of oral contraceptive pills. The woman may report lower extremity tightness or aching when ambulating that is relieved with rest and elevation of the leg. Edema in the affected leg (typically the left), along with warmth and tenderness, and a low-grade fever may also be noted. A duplex ultrasound (two-dimensional ultrasound and Doppler ultrasound that compresses the vein to assess for changes in venous flow) in conjunction with the physical findings frequently is needed for a conclusive diagnosis (Sucker & Zotz, 2015).

Women with an increased risk for this condition during the postpartum period should wear antiembolism stockings or use sequential compression devices to reduce the risk of venous stasis by preventing blood from pooling in the calves of the legs. Encouraging the client to ambulate after childbirth reduces the incidence of thrombophlebitis.

Psychosocial Assessment

Psychosocial assessment of the postpartum woman focuses on emotional status and bonding and attachment.

Emotional Status

Assess the woman's emotional status by observing how she interacts with her family, her level of independence, energy levels, eye contact with her infant (within a cultural context), posture and comfort level while holding the newborn, and sleep and rest patterns. Be alert for mood swings, irritability, or crying episodes.

> *Remember Raina and her "quiet" husband, the Muslim couple? The postpartum nurse informs Raina that her doctor, Nancy Schultz, has been called away for emergency surgery and won't be available the rest of the day. The nurse explains that Dr. Robert Nappo will be making rounds for her. Raina and her husband become upset. Why? Is culturally competent care being provided to this couple?*

Bonding and Attachment

Nurses can be instrumental in promoting attachment by assessing attachment behaviors (positive and negative) and intervening appropriately if needed. Nurses must be able to identify any family discord that might interfere with the attachment process. Remember, however, that mothers from different cultures may behave differently from what is expected in your own culture. For example, Native American mothers tend to handle their newborns less often and use cradle boards to carry them. Native American mothers and many Asian American mothers delay breast-feeding until their milk comes in, because colostrum is considered harmful for the newborn (Bowers & Ceballos, 2015). Do not assume that different behavior is wrong.

Meeting the newborn for the first time after birth can be an exhilarating experience for parents. Although the mother has spent many hours dreaming of her unborn and how he or she will look, it is not until after birth that they meet face to face. They both need to get to know one another and to develop feelings

for one another.

Bonding is the close emotional attraction to a newborn by the parents that develops during the first 30 to 60 minutes after birth. It is unidirectional, from parent to infant. It is thought that optimal bonding of the parents to a newborn requires a period of close contact within the first few minutes to a few hours after birth. Bonding is really a continuation of the relationship that began during pregnancy (Sears & Sears, 2015a). It is affected by a multitude of factors, including the parent's socioeconomic status, family history, role models, support systems, cultural factors, and birth experiences. The mother initiates bonding when she caresses her infant and exhibits certain behaviors typical of a mother tending her child. The infant's responses to this, such as body and eye movements, are a necessary part of the process. During this initial period, the infant is in a quiet, alert state, looking directly at the holder.

 Take Note!

The length of time necessary for bonding depends on the health of the infant and mother, as well as the circumstances surrounding the labor and birth (Tester-Jones et al., 2015).

Attachment is the development of strong affection between an infant and a significant other (mother, father, sibling, and caretaker). This attachment is reciprocal; both the significant other and the newborn exhibit attachment behaviors. The attachment relationship formed between the infant and primary caregiver influences the child's view of the world and future relationships (Sette, Coppola, & Cassibba, 2015). This tie between two people is psychological rather than biologic, and it does not occur overnight. The process of attachment follows a progressive or developmental course that changes over time. Attachment is an individualized and multifactorial process that differs based on the health of the infant, the mother, environmental circumstances, and the quality of care the infant receives. The newborn responds to the significant other by cooing, grasping, smiling, and crying. Nurses can assess for attachment behaviors by observing the interaction between the newborn and the person holding him or her (Mattson & Smith, 2016). It occurs through mutually satisfying experiences. Maternal attachment begins during pregnancy as the result of fetal movement and maternal fantasies about the infant and continues through the birth and

postpartum periods. Attachment behaviors include seeking, physical caretaking behaviors, emotional attentiveness to infant's needs, staying close to, touching, kissing, cuddling, choosing the ***en face*** (face-to-face) **position** while holding or feeding the newborn, expressing pride in the newborn and exchanging gratifying experiences with the infant (McComish, 2015). In a high-risk pregnancy, the attachment process may be complicated by premature birth (lack of time to develop a relationship with the unborn baby) and by parental stress due to the fetal and/or maternal vulnerability.

Bonding is a vital component of the attachment process and is necessary in establishing parent–infant attachment and a healthy, loving relationship. During this early period of acquaintance, mothers touch their infants in a very characteristic manner. Mothers visually and physically "explore" their infants, initially using their fingertips on the infant's face and extremities and progressing to massaging and stroking the infant with their fingers. This is followed by palm contact on the trunk. Eventually, mothers draw their infant toward them and hold the infant (Fig. 16.5).

Generally, research on attachment has found that the process is similar for partners as for mothers, but the pace may be different. Like mothers, partners manifest attachment behaviors during pregnancy. Indeed, Baltes et al. (2014) found that the best predictors of early postnatal attachment for fathers or significant others were those who viewed the paternal caregiving role as important and also had greater marital quality. Higher levels of paternal sensitivity were associated with better infant–father attachment. Becoming a father or significant partner requires the person to build on the experiences he/she has had throughout childhood and adolescence. Fathers or significant other partners develop an emotional tie with their infants in a variety of ways. They seek and maintain closeness with the infant and can recognize characteristics of the infant. Another study further described paternal attachment as a permanent, cyclical concept characterized by changes in response to the child's developmental stage. When children have a secure, supportive, and sensitive relationship with their fathers or mother's significant other, they are generally better adjusted than those that have a nonsupportive relationship (Lickenbrock & Braungart-Rieker, 2015).

FIGURE 16.5 En face position.

Attachment is a process; it does not occur instantaneously, even though many parents believe in a romanticized version of attachment, which happens right after birth. A delay in the attachment process can occur if a mother's physical and emotional states are adversely affected by exhaustion, pain, and the absence of a support system; if she has an infant in NICU and is separated from it; or had a traumatic birth experience, anesthesia, or an unwanted outcome, such as an ill infant (Lee et al., 2014).

Take Note!

Touch is a basic instinctual interaction between a parent and his or her infant and has a vital role in the infant's early development. Parents provide a variety of tactile stimulation while addressing their infant's daily care routines (Hugill, 2015).

The developmental task for the infant is learning to differentiate between trust and mistrust. If the mother or caretaker is consistently responsive to the infant's care, meeting the baby's physical and psychological needs, the infant will likely learn to trust the caretaker, view the world as a safe place, and grow up to be secure, self-reliant, trusting, cooperative, and helpful. However, if the infant's needs are not met, the child is more likely to face developmental delays, neglect,

and child abuse (Klebanov & Travis, 2015).

   "Becoming" a parent may take 4 to 6 months. The transition to parenthood, according to Mercer (2006), involves four stages:

1. Commitment, attachment, and preparation for an infant during pregnancy

2. Acquaintance with and increasing attachment to the infant, learning how to care for the infant, and physical restoration during the first weeks after birth

3. Moving toward a new normal routine in the first 4 months after birth

4. Achievement of a parenthood role around 4 months

   The stages overlap, and the timing of each is affected by variables such as the environment, family dynamics, and the partners (Mercer, 2006).

FACTORS AFFECTING ATTACHMENT

Attachment behaviors are influenced by three major factors:

1. Parents' background (includes the care that the parents received when growing up, cultural practices, relationship within the family, experience with previous pregnancies and planning and course of events during pregnancy, postpartum depression)

2. Infant (includes the infant's temperament and health at birth)

3. Care practices (the behaviors of physicians, midwives, nurses, and hospital personnel, care and support during labor, first day of life in separation of mother and infant, and rules of the hospital or birthing center) (Lewis & Rudolph, 2014).

   Attachment occurs more readily with the infant whose temperament, health, appearance, and gender fit the parent's expectations. If the infant does not meet these expectations, attachment can be delayed (Lickenbrock & Braungart-Rieker, 2015).
   Factors associated with the health care facility or birthing unit can also hinder attachment. These include:

• Separation of infant and parents immediately after birth and for long periods during the day

• Policies that discourage unwrapping and exploring the infant

• Intensive care environment, restrictive visiting policies

• Staff indifference or lack of support for parent's caretaking attempts and abilities

Grief After Delivery of a Child with Special Needs

It is important for the mother to visit the child in the special care nursery, but the priority is to assist the mother in dealing with the grief that accompanies giving birth to a child with special needs. The mother must first mourn the loss of the "perfect child."

CRITICAL ATTRIBUTES OF ATTACHMENT

The terms *bonding* and *attachment* are often used interchangeably, even though they involve different time frames and interactions. Attachment stages include proximity, reciprocity, and commitment.

Proximity refers to the physical and psychological experience of the parents being close to their infant. This attribute has three dimensions:

1. *Contact:* The sensory experiences of touching, holding, and gazing at the infant are part of proximity-seeking behavior.

2. *Emotional state:* The emotional state emerges from the affective experience of the new parents toward their infant and their parental role.

3. *Individualization:* Parents are aware of the need to differentiate the infant's needs from themselves and to recognize and respond to them appropriately, making the attachment process also, in some way, one of detachment.

Reciprocity is the process by which the infant's abilities and behaviors elicit parental response. Reciprocity is described by two dimensions: complementary behavior and sensitivity. Complementary behavior involves taking turns and stopping when the other is not interested or becomes tired. An infant can coo and stare at the parent to elicit a similar parental response to complement his or her behavior. Parents who are sensitive and responsive to their infant's cues will promote their development and growth. Parents who become skilled at recognizing the ways their infant communicates will respond appropriately by

smiling, vocalizing, touching, and kissing.

   Commitment refers to the enduring nature of the relationship. The components of this are twofold: centrality and parent role exploration. In centrality, parents place the infant at the center of their lives. They acknowledge and accept their responsibility to promote the infant's safety, growth, and development. Parent role exploration is the parents' ability to find their own way and integrate the parental identity into themselves (Sears & Sears, 2015b).

POSITIVE AND NEGATIVE ATTACHMENT BEHAVIORS

Positive bonding behaviors include maintaining close physical contact, making eye-to-eye contact, speaking in soft, high-pitched tones, and touching and exploring the infant. Table 16.1 highlights typical positive and negative attachment behaviors.

NURSING INTERVENTIONS

In terms of postpartum hospital stays today, "less is more." If the woman had a vaginal delivery, she may be discharged within 48 hours or sooner. If she had a cesarean birth, she may remain hospitalized for up to 72 hours. This shortened stay leaves little time for nurses to prepare the woman and her family for the many changes that will occur when she returns home (see Nursing Care Plan 16.1). Research shows that mothers feel unprepared, uninformed, and unsupported during the postpartum period as they struggle with physical and emotional issues, infant caregiving, breast-feeding concerns, and lifestyle adjustments (Walker, Murphey, & Nichols, 2015). Nurses need to focus on: pain and discomfort, immunizations, nutrition, activity and exercise, infant care, lactation instruction, discharge teaching, sexuality and contraception, and follow-up with the limited time they have with their clients. Planning home visits to reinforce postpartum instructions may enhance maternal-infant wellness (see Evidence-Based Practice 16.1).

TABLE 16.1 Positive and Negative Attachment Behaviors

	Positive Behaviors	Negative Behaviors
Infant	Smiles; is alert; demonstrates strong grasp reflex to hold parent s finger; sucks well, feeds easily; enjoys being held close; makes eye-to-eye contact; follows parent's face; appears facially appealing; is consolable when crying	Feeds poorly, regurgitates often; cries for long periods, colicky and inconsolable; shows flat affect, rarely smiles even when prompted; resists holding and closeness; sleeps with eyes closed most of time; stiffens body when held; is unresponsive to parents; doesn't pay attention to parents' faces
Parent	Makes direct eye contact; assumes *en face* position when holding infant; claims infant as family member, pointing out common features; expresses pride in infant; assigns meaning to infant's actions; smiles and gazes at infant; touches infant, progressing from fingertips to holding; names infant; requests to be close to infant as much as allowed; speaks positively about infant	Expresses disappointment or displeasure in infant; fails to "explore" infant visually or physically; fails to claim infant as part of family; avoids caring for infant; finds excuses not to hold infant close; has negative self-concept; appears uninterested in having infant in room; frequently asks to have infant taken back to nursery to be cared for; assigns negative attributes to infant and calls infant inappropriate, negative names (e.g., frog, monkey, tadpole)

Take Note!

Always adhere to standard precautions when providing direct care to reduce the risk of disease transmission.

Providing Optimal Cultural Care

As the face of America is becoming more diverse, nurses must be prepared to care for childbearing families from various cultures. In many cultures, women and their families are cared for and nurtured by their community for weeks and even months after the birth of a new family member. Overall, the culturally competent care for all childbearing families include understanding of traditional folk beliefs; involvement and support by family members; respect; presence of a significant other; breast-feeding and eating healthy; observing the principles of hot and cold; avoidance of sexual intercourse postnatally; encouragement; empowerment; their spiritual dimensions as important; avoidance of evil spirits; and the hope that nurses will anticipate the needs of the mother and infant (McFarland & Wehbe-Alamah, 2015). Box 16.3 highlights some of the major cultural variants during the postpartum period.

EVIDENCE-BASED PRACTICE 16.1 ENHANCING NEONATAL WELLNESS WITH HOME VISITATION

STUDY

According to the AAP, there is sufficient evidence that breast-feeding provides the best nutrition for newborns and should be continued for the first 6 months followed by continued breast-feeding during the first year or more, as solid foods are introduced. The purpose of this study was to measure the effectiveness of home visits by RNs on neonatal wellness as measured by the continuance of breast-feeding at 6 months, reduce readmissions for newborn jaundice and identify any maternal or newborn health issues. The home visits were made on days three and seven after discharge from the hospital. A complete physical assessment on both mother and infant was performed at each home visit.

Findings

The study used a longitudinal, mixed method, within-subject design involving 1705 participants. Quantitative data were compared to regional and national benchmarks. Qualitative data from study participant interviews were analyzed to identify common themes. The data indicated the home visits did help mothers to continue to breast-feed longer when compared to the regional and national statistics and the home visits also effectively identified newborn jaundice with a reduction in the average length of stay for infants readmitted in comparison to benchmarks.

Nursing Implications

The study's results reinforce the need for extended breast-feeding support beyond the hospital setting discharge for new mothers to continue to breast-feed longer. New mothers need to have access to community-based interventions after discharge to reinforce their postpartum education. Nurses can be instrumental in making referrals for home visitations to promote the safe transition from the hospital to the home.

NURSING CARE PLAN 16.1

Overview of the Postpartum Woman

A 26-year-old G2P2, is a client on the mother–baby unit after giving birth to a term 8-lb, 12-oz baby boy yesterday. The night nurse reports that she has an episiotomy, complains of a pain rating of 7 points on a scale of 1 to 10, is having difficulty breast-feeding, and had heavy lochia most of the night. The nurse also reports that the client seems focused on her own needs and not on those of her infant. Assessment this morning reveals the following:

   B: **Breasts** are soft with colostrum leaking; nipples cracked
   U: **Uterus** is one fingerbreadth below the umbilicus; deviated to right
   B: **Bladder** is palpable; client states she hasn't been up to void yet
   B: **Bowels** have not moved; bowel sounds present; passing flatus
   L: **Lochia** is moderate; peripad soaked from night accumulation
   E: **Episiotomy** site intact; swollen, bruised; hemorrhoids present
   E: **Extremities**; no edema over tibia, no warmth or tenderness in calf
   E: **Emotional status** is "distressed" as a result of discomfort and fatigue

NURSING DIAGNOSIS: Impaired tissue integrity related to episiotomy

Outcome Identification and Evaluation

The client will remain free of infection, without any signs and symptoms of infection, and exhibit evidence of progressive healing as demonstrated by clean, dry, decreased/absent edema, and an intact episiotomy site.

Interventions: *Promoting Tissue Integrity*

• Monitor episiotomy site for redness, edema, warmth or discharge *to identify infection.*
• Assess vital signs at least every 4 hours *to identify changes suggesting infection.*
• Apply ice pack to episiotomy site *to reduce swelling.*
• Instruct client on use of sitz bath *to promote healing, hygiene, and comfort.*
• Encourage frequent perineal care and peripad changes *to prevent infection.*
• Recommend ambulation *to improve circulation and promote healing.*
• Instruct client on positioning *to relieve pressure on perineal area.*

• Demonstrate use of anesthetic sprays *to numb perineal area.*

NURSING DIAGNOSIS: Pain related to episiotomy, sore nipples, and hemorrhoids

Outcome Identification and Evaluation
The client will experience a decrease in pain as evidenced by reporting that her pain has diminished to a tolerable level and rating it as 2 points or less.

Interventions: *Providing Pain Relief*
• Thoroughly inspect perineum to rule out hematoma as cause of pain.
• Administer analgesic medication as ordered as needed to promote comfort.
• Carry out comfort measures to episiotomy as outlined earlier to reduce pain.
• Explain discomforts and reassure the client that they are time limited to
   assist in coping with pain.
• Apply Tucks® to swollen hemorrhoids to induce shrinkage and reduce pain.
• Suggest frequent use of sitz bath to reduce hemorrhoid pain.
• Administer stool softener and laxative to prevent straining with first bowel
   movement.
• Observe positioning and latching-on technique while breast-feeding. Offer
   suggestions based on observations to correct positioning/latching on to
   minimize trauma to the breast.
• Suggest air-drying of nipples after breast-feeding and use of plain water to
   prevent nipple cracking.
• Teach relaxation techniques when breast-feeding to reduce anxiety and
   discomfort.

NURSING DIAGNOSIS: Risk for ineffective coping related to mood alteration and pain

Outcome Identification and Evaluation
The client will cope with mood alterations, as evidenced by positive statements about newborn and participation in newborn care.

Interventions: *Promoting Effective Coping*
• Provide a supportive, nurturing environment and encourage the mother to
   vent her feelings and frustrations *to relieve anxiety*.

- Provide opportunities for the mother to rest and sleep *to combat fatigue.*
- Encourage the mother to eat a well-balanced diet *to increase her energy level.*
- Provide reassurance and explanations that mood alterations are common after birth secondary to waning hormones after pregnancy *to increase the mother's knowledge.*
- Allow the mother relief from newborn care *to afford opportunity for self-care.*
- Discuss with partner expected behavior from mother and how additional support and help are needed during this stressful time *to promote partner's participation in care.*
- Make appropriate community referrals for mother–infant support *to ensure continuity of care.*
- Encourage frequent skin-to-skin contact and closeness between mother and infant *to facilitate bonding and attachment behaviors.*
- Encourage client to participate in infant care and provide instructions as needed *to foster a sense of independence and self-esteem.*
- Offer praise and reinforcement of positive mother–infant interactions *to enhance self-confidence in care.*

Nurses need to remember that childbearing practices and beliefs vary from culture to culture. To provide appropriate nursing care, the nurse should determine the client's preferences before intervening. Cultural practices may include dietary restrictions, certain clothes, taboos, activities for maintaining mental health, and the use of silence, prayer, or meditation. Restoring health may involve taking folk medicines or conferring with a tribal healer. A language barrier might interfere with communication between the woman and health providers, followed by health care provider's lack of cultural sensitivity, leading to a woman's reluctance in using health services (Santiago & Figueiredo, 2015). Providing culturally diverse care within our global community is challenging for all nurses, because they must remember that one's culture cannot be easily summarized in a reference book, but must be viewed through one's own life experiences.

The Muslim woman and her husband are upset at the thought of having a

male doctor care for her because Muslim women are very modest and prefer having a same-sex care provider. What should the nurse do in this situation?

BOX 16.3

CULTURAL INFLUENCES DURING THE POSTPARTUM PERIOD

African American

• Mother may share care of the infant with extended family members.

• Experiences of older women within the family influence infant care.

• Mothers may protect their newborns from strangers for several weeks.

• Mothers may not bathe their newborns for the first week. Oils are applied to skin and hair to prevent dryness and cradle cap.

• Silver dollars may be taped over the infant's umbilicus in an attempt to flatten the slightly protruding umbilical stump.

• Sleeping with parents is a common practice.

Amish

- Women consider childbearing their primary role in society.
- They generally oppose birth control.
- Pregnancy and childbirth are considered a private matter; they may conceal it from public knowledge.
- Women typically do not respond favorably when hurried to complete a self-care task. Nurses need to take cues from women indicating their readiness to complete morning self-care activities.

Appalachian

- Infant colic is treated by passing the newborn through a leather horse's collar or administering weak catnip tea.

- An *asafetida* bag (a gum resin with a strong odor) is tied around the infant's neck to ward off disease.

- Women may avoid eye contact with nurses and health care providers.

- Women typically avoid asking questions even though they do not understand directions.

- The grandmother may rear the infant for the mother.

Filipino American

• Grandparents often assist in the care of their grandchildren.

• Breast-feeding is encouraged, and some mothers breast-feed their children for up to 2 years.

• Women have difficulty discussing birth control and sexual matters.

• Strong religious beliefs prevail and bedside prayer is common.

• Families are very close-knit and numerous visitors can be expected at the hospital after childbirth.

Japanese American

- Cleanliness and protection from cold are essential components of newborn care. Nurses should bathe the infant daily.
- Newborns routinely are not taken outside the home because it is believed that they should not be exposed to outside or cold air. Infants should be kept in a quiet, clean, warm place for the first month of life.
- Breast-feeding is the primary method of feeding.
- Many women stay in their parents' home for 1 to 2 months after birth.
- Bathing the infant can be the center of family activity at home.

Mexican American

- The newborn's grandmother lives with the mother for several weeks after birth to help with housekeeping and child care.

- Most women will breast-feed for more than 1 year. The infant is carried in a *rebozo* (shawl) that allows easy access for breast-feeding.

- Women may avoid eye contact and may not feel comfortable being touched by a stranger. Nurses need to respect this feeling.

- Some women may bring religious icons to the hospital and may want to display them in their room.

Muslim

- Modesty is a primary concern; nurses need to protect the client's modesty.
- Muslims are not permitted to eat pork; check all food items before serving.
- Muslims prefer a same-sex health care provider; male–female touching is prohibited except in an emergency situation.
- A Muslim woman stays in the house for 40 days after birth, being cared for by the female members of her family.
- Most women will breast-feed, but religious events call for periods of fasting, which may increase the risk of dehydration or malnutrition.
- Women are exempt from obligatory five-times-daily prayers as long as lochia is present.
- Extended family is likely to be present throughout much of the woman's hospital stay. They will need an empty room to perform their prayers without having to leave the hospital.

Native American

- Women are secretive about pregnancies and do not reveal them early.
- Touching is not a typical female behavior and eye contact is brief.
- They resent being hurried and need time for sitting and talking.
- Most mothers breast-feed and practice birth control.

(2014). *Cultural competencies of nurses: Impact on health and illness* (2nd ed.). Burlington, MA: Jones & Bartlett Learning; and Andrews, M. M., & Boyle, J. S. (2012). *Transcultural concepts in nursing care* (6th ed.). Philadelphia, PA: Wolters Kluwer Health.

Promoting Comfort

The postpartum woman may have discomfort and pain from a variety of sources, such as an episiotomy, perineal lacerations, backache as a result of the epidural, pain from a full bladder, an edematous perineum, inflamed hemorrhoids, engorged breasts, afterbirth pains secondary to uterine contractions in breast-feeding and multiparous mothers, and sore nipples if breast-feeding. Relieving the underlying problem is the first step in pain management. Most practices traditionally employed for postpartum discomforts are not evidence based, so both nonpharmacologic and pharmacologic measures are often used in tandem (King et al., 2015).

Applications of Cold and Heat

COLD

Commonly, an ice pack is the first measure used after a vaginal birth to relieve perineal discomfort from edema, an episiotomy, or a laceration. An ice pack seems to minimize edema, reduce inflammation, decrease capillary permeability, and reduce nerve conduction to the site. It is applied during the fourth stage of labor and can be used for the first 24 hours to reduce perineal edema and to prevent hematoma formation, thus reducing pain and promoting healing. Ice packs are wrapped in a disposable covering or clean washcloth and are applied to the perineal area. Usually the ice pack is applied intermittently for 20 minutes and removed for 10 minutes. Many commercially prepared ice packs are available, but a surgical glove filled with crushed ice and covered can also be used if the mother is not allergic to latex. Ensure that the ice pack is changed frequently to promote good hygiene and to allow for periodic assessments.

HEAT

The **peribottle** is a plastic squeeze bottle filled with warm tap water that is sprayed over the perineal area after each voiding and before applying a new perineal pad. Usually the peribottle is introduced to the woman when she is assisted to the bathroom to freshen up and void for the first time—in most instances, once vital signs are stable after the first hour. Provide the woman with instructions on how and when to use the peribottle. Reinforce this practice each

time she changes her pad, voids, or defecates, making sure that she understands to direct the flow of water from front to back. The woman can take the peribottle home and use it over the next several weeks until her lochia discharge stops. The peribottle can be used by women who had either vaginal or cesarean births to provide comfort and hygiene to the perineal area.

After the first 24 hours, a **sitz bath** with room temperature water may be prescribed and substituted for the ice pack to reduce local swelling and promote comfort for an episiotomy, perineal trauma, or inflamed hemorrhoids. The change from cold to room temperature therapy enhances vascular circulation and healing. When compared with an infrared light to promote healing and reduce perineal pain, sitz baths were significantly more effective in promoting episiotomy wound healing (Sukhwinder et al., 2014). Before using a sitz bath, the woman should cleanse the perineum with a peribottle or take a shower using mild soap.

FIGURE 16.6 Sitz bath setup.

Most health care agencies use plastic disposable sitz baths that women can take home. The plastic sitz bath consists of a basin that fits on the commode; a bag filled with warm water is hung on a hook and connected via a tube onto the front of the basin (Fig. 16.6). Teaching Guidelines 16.1 highlights the steps in

using a sitz bath.

Advise the woman to use the sitz bath several times daily to provide hygiene and comfort to the perineal area. Encourage her to continue this measure after discharge. Some facilities have hygienic sitz baths called Suri-Gators in the bathroom that spray an antiseptic, water, or both onto the perineum. The woman sits on the toilet with legs apart so that the nozzle spray reaches her perineal area.

Keep in mind that tremendous hemodynamic changes are taking place within the mother during this early postpartum period, and her safety must be a priority. Fatigue, blood loss, the effects of medications, and lack of food may cause her to feel weak when she stands up. Assisting the woman to the bathroom to instruct

her on how to use the peribottle and sitz bath is necessary to ensure her safety. Many women become light-headed or dizzy when they get out of bed and need direct physical assistance. Staying in the woman's room, ensuring that the emergency call light is readily available, and being available if needed during this early period will ensure safety and prevent accidents and falls.

Recent reviews of the use of postpartum local cooling and warming interventions for perineal pain found limited evidence supporting their effectiveness. Additional studies are needed in the area of perineal pain and healing in order to develop evidence-based interventions in the future (Mooventhan & Nivethitha, 2014).

Topical Preparations

Several treatments may be applied topically for temporary relief of perineal pain and discomfort. One such treatment is a local anesthetic spray such as benzocaine topical. These agents numb the perineal area and are used after cleansing the area with water via the peribottle and/or a sitz bath.

Postpartum women are predisposed to hemorrhoid development due to pressure during vaginal birth, constipation, relaxation of the smooth muscles in vein walls, and impaired blood return, all related to increased pressure from the heavy gravid uterus. Nonpharmacologic measures to reduce hemorrhoid discomfort include ice packs, ice sitz baths, and application of cool witch hazel pads, such as Tucks®. The pads are placed at the rectal area, between the hemorrhoids and the perineal pad. These pads cool the area, help relieve swelling, and minimize itching. Pharmacologic methods used to reduce hemorrhoid pain include local anesthetics (dibucaine) or steroids (hydrocortisone acetate). Prevention or correction of constipation, encouraging the use of the sidelying position, proper toileting habits, assuming positions that minimize putting pressure on the hemorrhoids, and not straining during defecation will be helpful in reducing discomfort (King et al., 2015).

Nipple pain is difficult to treat, although a wide variety of topical creams, ointments, and gels are available to do so. This group includes beeswax, glycerin-based products, petrolatum, lanolin, and hydrogel products. Many women find these products comforting. Beeswax, glycerin-based products, and petrolatum all need to be removed before breast-feeding. These products should be avoided in order to limit infant exposure because the process of removal may increase nipple irritation. Applying expressed breast milk to nipples and

allowing it to dry has been suggested to reduce nipple pain. Usually the pain is due to incorrect latch-on and/or removal of the nursing infant from the breast. Early assistance with breast-feeding to ensure correct positioning can help prevent nipple trauma.

Analgesics

Analgesics such as acetaminophen and oral nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen or naproxen are prescribed to relieve mild postpartum discomfort. For moderate to severe pain, a narcotic analgesic such as codeine or oxycodone in conjunction with aspirin or acetaminophen may be prescribed. Instruct the woman about adverse effects of any medication prescribed. Common adverse effects of oral analgesics include dizziness, light-headedness, nausea and vomiting, constipation, and sedation (Skidmore-Roth, 2015).

   Also inform the woman that the drugs are secreted in breast milk. Nearly all medications that the mother takes are passed into her breast milk; however, the mild analgesics (e.g., acetaminophen or ibuprofen) are considered relatively safe for breast-feeding mothers (King et al., 2015). Administering a mild analgesic approximately an hour before breast-feeding will usually relieve afterpains and/or perineal discomfort.

Assisting With Elimination

The bladder is edematous, hypotonic, and congested immediately postpartum. Consequently, bladder distention, incomplete emptying, and inability to void are common. A full bladder interferes with uterine contraction and may lead to hemorrhage, because it will displace the uterus out of the midline. Encourage the woman to void. Often, assisting her to assume the normal voiding position on the commode facilitates this. If the woman has difficulty voiding, pouring warm water over the perineal area, hearing the sound of running tap water, blowing bubbles through a straw, taking a warm shower, drinking fluids, providing her with privacy, or placing her hand in a basin of warm water may stimulate voiding. If these actions do not stimulate urination within 4 to 6 hours after giving birth, catheterization may be needed. Palpate the bladder for distention and ask the woman if she is voiding in small amounts (less than 100 mL) frequently (retention with overflow). If catheterization is necessary, use sterile technique to reduce the risk of infection.

Decreased bowel motility during labor, high iron content in prenatal vitamins, postpartum fluid loss, and the adverse effects of pain medications and/or anesthesia may predispose the postpartum woman to constipation. In addition, the woman may fear that bowel movements will cause pain or injury, especially if she had an episiotomy or a laceration that was repaired with sutures.

Usually a stool softener, such as docusate, with or without a laxative might be helpful if the client has difficulty with bowel elimination. Other measures, such as ambulating and increasing fluid and fiber intake, may also help. Nutritional instruction might include increasing fruits and vegetables in the diet; drinking plenty of fluids (8 to 12 cups daily) to keep the stool soft; drinking small amounts of prune juice and/or hot liquids to stimulate peristalsis; eating high-fiber foods such as bran cereals, whole grains, dried fruits, fresh fruits, and raw vegetables; and walking daily.

Promoting Activity, Rest, and Exercise

The postpartum period is an ideal time for nurses to promote the importance of physical fitness, help women incorporate exercise into their lifestyle, and encourage them to overcome barriers to exercise. The lifestyle changes that occur postpartum may affect a woman's health for decades. Early ambulation is encouraged to reduce the risk of thromboembolism and to improve strengthening.

Many changes occur postpartum, and caring for a newborn alters the woman's eating and sleeping habits, work schedules, and time allocation. Postpartum fatigue is common during the early days after childbirth, and it may continue for weeks or months. Having adequate sleep is critical for new mothers because shorter sleep time, a high percentage of sleep disturbances, and greater fatigue are associated with depressive symptoms in postpartum women (Bhati & Richards, 2015). Working partners with newborns experience fatigue during early parenthood and are unable to recover due to interrupted and poor sleep patterns. This sleep deficit can compromise their work safety (Parfitt & Ayers, 2014). For women, it affects the mother's relationships with significant others and her ability to fulfill household and child care responsibilities. Be sure that the mother recognizes her need for rest and sleep and is realistic about her expectations. Some suggestions include the following:

• Nap when the infant is sleeping, because getting uninterrupted sleep at night is difficult.

• Reduce participation in outside activities and limit the number of visitors.

• Determine the infant's sleep–wake cycles and attempt to increase wakeful periods during the day so the baby sleeps for longer periods at night.

• Eat a balanced diet to promote healing and to increase energy levels.

• Share household tasks to conserve your energy.

• Ask the father or other family members to provide infant care during the night periodically so that mothers can get an uninterrupted night of sleep, if they are not breast-feeding.

• Review your family's daily routine and see if you can "cluster" activities to conserve energy and promote rest.

The demands of parenthood may reduce or prevent exercise in even the most committed person. A targeted exercise program and proper body mechanics can help new mothers deal with the physical challenges of motherhood. Emphasize the benefits of a regular exercise program, which include:

• Helps the woman to lose pregnancy weight

• Reduces the risk of obesity later in life

• Increases overall postpartum well-being

• Increases energy level so the woman can cope with her new responsibilities

• Speeds the return to prepregnant size and shape

• Reduces risk of postpartum depression

• Reduces risk of constipation

• Reduces mental fatigue

• Provides an outlet for stress (Covan, 2015)

Overweight and obesity are epidemic in the United States. Obesity is a risk factor for numerous conditions, including diabetes, hypertension, high cholesterol, stroke, heart disease, cancer and arthritis. More than one third of American women are overweight (ACOG, 2014). Although the average gestational weight gain is small (approximately 25 to 35 lb), excess weight gain and failure to lose weight after pregnancy are important predictors of long-term obesity. The postpartum period is a vulnerable time for excessive weight retention, particularly for the increasing number of women who are overweight at the start of their pregnancy and subsequently find it difficult to lose the additional weight gained during pregnancy. Breast-feeding and exercise may help to control weight in the long term (Neville et al., 2014).

 Take Note!

Women who are unable to return to a healthy weight by 6 months postpartum increase their risk factors for the development of chronic diseases including metabolic syndrome, obesity, and cardiovascular disease (Brekke et al., 2014). Encourage women to lose their pregnancy weight by 6 months postpartum, and refer those who don't to community weight-loss programs.

The postpartum woman may face some obstacles to exercising, including physical changes (ligament laxity), competing demands (newborn care), lack of information about weight retention (inactivity equates to weight gain), and stress incontinence (leaking of urine during activity).

A healthy woman with an uncomplicated vaginal birth can resume exercise in the immediate postpartum period. Advise the woman to start slowly and increase the level of exercise over a period of several weeks as tolerated. Infant strollers/carriers may be an option for some women, allowing them to walk with their newborns for exercise. Jogging strollers can be used later when the infant is 6 to 12 months old and can hold his or her head up. Also, exercise videos and home exercise equipment allow mothers to work out while the newborn naps.

Exercising after giving birth promotes feelings of well-being and restores muscle tone lost during pregnancy. Routine exercise should be resumed gradually, beginning with pelvic floor exercises on the first postpartum day and, by the second week, progressing to abdominal, buttock, and thigh-toning exercises. Most postpartum women fail to meet national guidelines for physical activity which may elevate their risk for morbidity and contribute to the intergenerational impact of obesity on their offspring (Downs, Evenson, & Chasan-Taber, 2014). Walking is an excellent form of early exercise as long as the woman avoids jarring and bouncing movements, because joints do not stabilize until 6 to 8 weeks postpartum. Exercising too much too soon can cause the woman to bleed more and her lochia may return to bright red. If this occurs, instruct the woman to stop exercising and rest lying down until the bleeding slows. This increase in bleeding should be a warning to the woman that she is over doing it and needs to slow down her exercise routine.

Recommended exercises for the first few weeks postpartum include abdominal breathing, head lifts, modified sit-ups, double knee roll, and pelvic tilt (Teaching Guidelines 16.2). The number of exercises and their duration is gradually increased as the woman gains strength.

Teaching Guidelines 16.2

POSTPARTUM EXERCISES

Abdominal Breathing

1. While lying on a flat surface (floor or bed), take a deep breath through your nose and expand your abdominal muscles (they will rise up from your midsection).
2. Slowly exhale and tighten your abdominal muscles for 3 to 5 seconds.
3. Repeat this several times.

Head Lift

1. Lie on a flat surface with knees flexed and feet flat on the surface.
2. Lift your head off the flat surface, tuck it onto your chest, and hold for 3 to 5 seconds.
3. Relax your head and return to the starting position.
4. Repeat this several times.

Modified Sit-Ups

1. Lie on a flat surface and raise your head and shoulders 6 to 8 inc so that your outstretched hands reach your knees.
2. Keep your waist on the flat surface.
3. Slowly return to the starting position.
4. Repeat, increasing in frequency as your comfort level allows.

Double Knee Roll

1. Lie on a flat surface with your knees bent.
2. While keeping your shoulders flat, slowly roll your knees to your right side to touch the flat surface (floor or bed).
3. Roll your knees back over your body to the left side until they touch the opposite side of the flat surface.
4. Return to the starting position on your back and rest.
5. Repeat this exercise several times.

Pelvic Tilt

1. Lie on your back on a flat surface with your knees bent and your arms at your side.
2. Slowly contract your abdominal muscles while lifting your pelvis up toward the ceiling.
3. Hold for 3 to 5 seconds and slowly return to your starting position.

4. Repeat several times.

Remember that cultures have different attitudes toward exercise. Some cultures (e.g., Haitian, Arab American, Chinese, and Mexican) expect new mothers to observe a specific period of bed rest or activity restriction; thus, it would be inappropriate to recommend active exercise during the early postpartum period (Bowers & Ceballos, 2015).

Preventing Stress Incontinence

Fifty percent of all parous women develop some degree of pelvic prolapse in their lifetime that is associated with stress incontinence. Stress incontinence causes reduced quality of life and withdrawal from fitness and exercise activities typically. Research suggests that having a vaginal delivery results in direct pelvic muscle trauma and disruption of fascial supports, and also causes damage to the levator ani muscle and pudendal nerve injury. Offering pelvic floor muscle exercise instruction to all women during their first pregnancy and again after having a vaginal birth is recommended by the National Institute for Health and Care Excellence (NICE) guidelines. Nurses can offer them as a first-line intervention in the prevention of urinary incontinence postpartum (Hall & Woodward, 2015). The more vaginal deliveries a woman has had, the more likely she is to have stress incontinence. Stress incontinence can occur with any activity that causes an increase in intra-abdominal pressure. Postpartum women might consider low-impact activities such as walking, biking, swimming, or low-impact aerobics so they can resume physical activity while strengthening the pelvic floor.

Suggestions to prevent stress incontinence are:

• Start a regular program of pelvic floor muscle exercises after childbirth.

• Lose weight if necessary; obesity is associated with stress incontinence.

• Avoid smoking; limit intake of alcohol and caffeinated beverages, which irritate the bladder.

• Adjust fluid intake to produce a 24-hourly urine output of 1,000 to 2,000 mL.

• Use either an intravaginal or intra-urethral device that puts pressure onto the urethra so that urine will not leak when bladder pressure rises (Laliberte, 2015).

Pelvic floor exercises (Kegel exercises) help to strengthen the pelvic floor muscles if done properly and regularly (Ciaghi, Bianco, & Guarese, 2015). These pelvic floor strengthening exercises were originally developed by Dr. Arnold Kegel in the 1940s as a method of controlling incontinence in women after childbirth. The principle behind these exercises is that strengthening the muscles of the pelvic floor improves urethral sphincter function.

While providing postpartum care, instruct women on primary prevention of

stress incontinence by discussing the value and purpose of pelvic floor muscle exercises. Approach the subject sensitively, avoiding the term *incontinent*. The terms *leakage, loss of urine,* or *bladder control issues* are more acceptable to most women.

Take Note!

When properly performed, pelvic floor exercises have been effective in preventing or improving urinary continence (Jones & Hawkes, 2015).

Women can perform pelvic floor exercises, doing ten 5-second contractions, whenever they change diapers, talk on the phone, or watch TV. Teach the woman to perform pelvic floor exercises properly; help her to identify the correct muscles by trying to stop and start the flow of urine when sitting on the toilet (Teaching Guidelines 16.3). Pelvic floor exercises can be done without anyone knowing.

Teaching Guidelines 16.3

PERFORMING PELVIC FLOOR MUSCLE EXERCISES

1. Identify the correct pelvic floor muscles by contracting them to stop the flow of urine while sitting on the toilet.
2. Repeat this contraction several times to become familiar with it.
3. Start the exercises by emptying the bladder.
4. Tighten the pelvic floor muscles and hold for 10 seconds.
5. Relax the muscle completely for 10 seconds.
6. Perform 10 exercises at least three times daily. Progressively increase the number that you perform.
7. Perform the exercises in different positions, such as standing, lying, and sitting.
8. Keep breathing during the exercises.

9. Don't contract your abdominal, thigh, leg, or buttocks muscles during these exercises.

10. Relax while doing pelvic floor exercises and concentrate on isolating the right muscles.

11. Attempt to tighten your pelvic muscles before sneezing, jumping, or laughing.

12. Remember that you can perform these exercises anywhere without anyone noticing.

Assisting With Self-Care Measures

Demonstrate and discuss with the woman ways to prevent infection during the postpartum period. Because she may experience lochia drainage for as long as a month after childbirth, describe practices to promote well-being and healing. These measures include:

• Frequently change perineal pads, applying and removing them from front to back to prevent spreading contamination from the rectal area to the genital area.

• Avoid using tampons after giving birth to decrease the risk of infection.

• Shower once or twice daily using a mild soap. Avoid using soap on nipples.

• Use a sitz bath after every bowel movement to cleanse the rectal area and relieve enlarged hemorrhoids.

• Use the peribottle filled with warm water after urinating and before applying a new perineal pad.

• Avoid tub baths for 4 to 6 weeks, until joints and balance are restored, to prevent falls.

• Wash your hands before changing perineal pads, after disposing of soiled pads, and after voiding (Mattson & Smith, 2016).

   To reduce the risk of infection at the episiotomy site, reinforce proper perineal care with the client, showing her how to rinse her perineum with the peribottle after she voids or defecates. Stress the importance of always patting gently from front to back and washing her hands thoroughly before and after perineal care. For hemorrhoids, have the client apply witch hazel-soaked pads (Tucks®), ice packs to relieve swelling, or hemorrhoidal cream or ointment if ordered.

Ensuring Safety

One of the safety concerns during the postpartum period is orthostatic hypotension. When the woman rapidly moves from a lying or sitting position to a standing one, her blood pressure can suddenly drop, causing her pulse rate to increase. She may become dizzy and faint. Be aware of this problem and initiate the following safeguards:

• Check blood pressure first before ambulating the client.

• Elevate the head of the bed for a few minutes before ambulating the client.

• Have the client sit on the side of the bed for a few moments before getting up.

• Help the client to stand up, and stay with her.

• Ambulate alongside the client and provide support if needed.

• Frequently ask the client how her head feels.

• Stay close by to assist if she feels light-headed.

Additional topics to address orthostatic hypotension that may concern infant safety include instructing the woman to place the newborn back in the crib on his or her back if she is feeling sleepy to prevent a fall. If the woman falls asleep while holding the infant, she might drop him or her. Also, instruct mothers to keep the door to their room closed when their infant is in their room with them. They should check the identification of anyone who enters their room or who wants to take the infant out of the room. This will prevent infant abduction.

Counseling About Sexuality and Contraception

Pregnancy and childbirth are special periods in a woman's life that involve significant physical, hormonal, psychological, social, and cultural changes that may influence her own sexuality as well as the health of a couple's sexual relationship. This is often a time period filled with excitement, changes, and challenges. Mothers often face changes in their own sexuality in their adjustment to motherhood. Sexuality is an important part of every woman's life. Women want to get back to "normal" as soon as possible after giving birth, but a couple's sexual relationship cannot be isolated from the psychological and psychosocial adjustments that both partners are going through.

Childbirth is a significant life transition that has a measurable impact on postpartum women's sexual function. There are physical (perineal pain), psychological (depression), and contextual factors (motherhood) that contribute to the change in many women's sex lives after experiencing childbirth. Postpartum women may hesitate to resume sexual relations for a number of reasons. Many postpartum women have fatigue, weakness, loss of sexual desire, perception of decreased attractiveness, change in body appearance, vaginal bleeding, perineal discomfort, hemorrhoids, sore breasts, decreased vaginal lubrication resulting from low estrogen levels, and dyspareunia. Fatigue, the physical demands made by the infant, and the stress of new roles and responsibilities may stress the emotional reserves of couples. New parents may not get much privacy or rest, both of which are necessary for sexual pleasure (Whittock, 2015).

Men may feel they now have a secondary role within the family, and they may not understand their partner's daily routine. The delicate nature of postpartum sexuality makes it difficult for couples to discuss. These issues, combined with the woman's increased investment in the mothering role, can strain the couple's sexual relationship.

Although couples are reluctant to ask, they often want to know when they can safely resume sexual intercourse after childbirth. Typically, sexual intercourse can be resumed once bright-red bleeding has stopped and the perineum is healed from an episiotomy or lacerations. This is usually by the third to the sixth week postpartum. However, there is no set, prescribed time at which to resume sexual intercourse after childbirth. There is no scientific basis for the traditional recommendation to delay sexual activity until the six week postpartum check-up.

Each couple must set their own time frame when they feel it is appropriate to resume sexual intercourse. Despite fears and myths about sexual activity during pregnancy, maintaining a couple's sexual interactions throughout pregnancy and the postpartum period can promote sexual health and well-being and a greater depth of intimacy.

Postpartum sexual health and sexual problems are common, which receive little attention from health care providers during the postpartum period, need to be addressed (Halford, Petch, & Creedy, 2015). When counseling the couple about sexuality, determine what knowledge and concerns the couple have about their sexual relationship. Inform the couple that fluctuations in sexual interest are normal. Reassure the breast-feeding mother that she may notice a let-down reflex during orgasm and find her breasts are very sensitive when touched by her partner. Also inform the couple about how to prevent discomfort. Precoital vaginal lubrication may be impaired during the postpartum period, especially in women who are breast-feeding. Use of water-based gel lubricants (K-Y® jelly, Astroglide) can help. Pelvic floor exercises, in addition to preventing stress incontinence, can also enhance sensation.

Initiation of contraception during the postpartum period is important to prevent unintended pregnancy and short birth intervals, which can lead to negative health outcomes for mother and infant. Contraceptive options should be included in the discussions with the couple so that they can make an informed decision before resuming sexual activity. Many couples are overwhelmed with the amount of new information given to them during their brief hospitalization, so many are not ready for a lengthy discussion about contraceptives. Presenting a brief overview of the options, along with literature, may be appropriate. It may be suitable to ask them to think about contraceptive needs and preferences and advise them to use a barrier method (condom with spermicidal gel or foam) until they choose another form of contraception. This advice is especially important if the follow-up appointment will not occur for 4 to 6 weeks after childbirth, because many couples will resume sexual activity before this time. Some postpartum women ovulate before their menstrual period returns and thus need contraceptive protection to prevent another pregnancy.

Recently, the CDC assessed evidence regarding the safety of estrogen-containing contraceptive methods use during the postpartum period. They recommend that postpartum women not use combined hormonal contraceptives during the first 21 days after childbirth because of the high risk for VTE during this period. During days 21 to 42 postpartum, women without risk factors for

VTE generally can initiate estrogen-containing contraceptives, but women with risk factors for VTE (e.g., previous VTE or recent cesarean delivery) generally should not use these methods. After 42 days postpartum, no restrictions on the use of combined hormonal contraceptives based on postpartum status apply (Centers for Disease Control and Prevention [CDC], 2015a).

Open and effective communication is necessary for effective contraceptive counseling so that information is clearly understood. Provide clear, consistent information appropriate to the woman and her partner's language, culture, and educational level. This will help the couple select the best contraceptive method. Research supports that postpartum education about contraception leads to more contraception use and fewer unplanned pregnancies and that both short-term and multiple-contact interventions had effects. The use of contraceptives was highest when contraceptive counseling was provided prenatally and again in the postpartum period (Zapata et al., 2015).

Promoting Maternal Nutrition

The postpartum period can be a stressful one for myriad reasons, such as fatigue, the physical stress of pregnancy and birth, and the nonstop work required to take care of the newborn and to meet the needs of other family members. As a result, the new mother may ignore her own nutrition needs. Whether she is breast-feeding or bottle-feeding, encourage the new mother to take good care of herself and eat a healthy diet so that the nutrients lost during pregnancy can be replaced and she can return to a healthy weight. In general, nutrition recommendations for the postpartum woman include the following:

• Eat a wide variety of foods with high nutrient density.

• Eat meals that require little or no preparation.

• Avoid high-fat fast foods.

• Drink plenty of fluids daily—at least 2,500 mL (approximately 84 oz).

• Avoid fad weight-reduction diets and harmful substances such as alcohol, tobacco, and drugs.

• Avoid excessive intake of fat, salt, sugar, and caffeine.

• Eat the recommended daily servings from each food group (Box 16.4).

Nutrition for the Breast-Feeding Mother

The breast-feeding mother's nutritional needs are higher than they were during pregnancy. The mother's diet and nutritional status influence the quantity and quality of breast milk. Recently, the American Academy of Pediatrics (2014a) recommended that breast-feeding women consume foods that contain iodine, an element that is crucial to healthy brain development and may be lacking in their present diets. Iodine is necessary to produce thyroid hormone, which in turn helps brain development. To meet the needs for breast milk production, the woman's nutritional needs increase as follows:

• *Calories:* +500 cal/day for the first and second 6 months of lactation

• *Protein:* +20 g/day, adding an extra 2 cups of skim milk

• *Calcium:* +400 mg daily—consumption of four or more servings of milk

• *Iodine:* 290 μg daily—dairy products, seafood and iodized salt

- *Fluid:* +2 to 3 quarts of fluids daily (milk, juice, or water); no sodas

Recommendations for the Lactating Woman from the Food Guide *MyPlate*

• Fruits: 4 servings

• Vegetables: 4 servings

• Milk: 4 to 5 servings

• Bread, cereal, pasta: 12 or more servings

• Meat, poultry, fish, eggs: 7 servings

• Fats, oils, and sweets: 5 servings (Dudek, 2014).

> **General Dietary Guidelines for Americans from the Food Guide on _MyPlate_ (for the Nonlactating Woman)**
>
> • Fruits: Make half of your plate fruits and vegetables.
>
> • Vegetables: Eat red, orange, and dark-green vegetables.
>
> • Milk: Switch to skim milk or 1%.
>
> • Breads, grains, and cereals should be whole grains.
>
> • Meat, poultry, fish, eggs: Eat seafood twice a week and beans, which are high in fiber.
>
> • Eat the right amount of calories for you; enjoy your food, but eat less.
>
> • Be physically active your way in activities that you enjoy.
>
> • Fats, oils, and sweets: Cut back on these.
>
> • Use food labels to help you make better choices (U. S. Department of Agriculture [USDA] & U.S. Department of Health and Human Services [USDHHS], 2014).

Some foods eaten by the breast-feeding mother may affect the flavor of the breast milk or cause gastrointestinal problems for the infant. Not all infants are affected by the same foods. It is suggested that the mother identify the food item that may be causing a problem for the infant and reduce or eliminate her intake of it.

Nutritional needs for breast-feeding mothers are based on the nutritional content of breast milk and the energy expended to produce it. If intake of calories exceeds the energy expended, weight gain occurs. The highest incidence of obesity in women occurs during the childbearing years. Women need to be made aware that weight gained during their reproductive years will have a negative impact on their health as they age. Nurses can assist women in their postpartum weight management program by assessing their readiness to change to lose their pregnancy weight gain; assessing their breast-feeding status, dietary intake, and activity levels; and assessing them for stress and depressive symptoms, which might hinder their weight loss (Green, 2016).

During a woman's brief stay in a health care facility, she may demonstrate a healthy appetite and eat well. Nutritional problems usually start at home when the mother needs to make her own food selections and prepare her own meals. This is a crucial area to address during follow-up.

Supporting the Woman's Choice of Infant Feeding Method

The AAP, WHO, ANA, IOA, USDHHS, ADA, and USPSTF have all released position statements in support of breast-feeding and nurses, should be encouraging it as part of evidence-based practice (Edelman, Kudzma, & Mandle, 2014). Although there is considerable evidence that breast-feeding has numerous health benefits for both mother and infant, many mothers choose to feed their infants formula for the first year of life. Nurses must be able to deliver sound, evidence-based information to help the new mother choose the best way to feed her infant and must support her in her decision. Research findings indicate that parents do listen to nurse's instruction on feeding practices (Stagg & Ustianov, 2015). Many factors affect a woman's choice of feeding method, such as culture, employment demands, support from significant others and family, and knowledge base. Although breast-feeding is encouraged, be sure that couples have the information they need to make an informed decision. Whether a couple chooses to breast-feed or bottle-feed the newborn, support and respect their choice.

Women Who Should Not Breast-Feed

Certain women should not breast-feed. Drugs such as antithyroid drugs, antineoplastic drugs, alcohol, herpes infection on the breasts, or street drugs (methamphetamines, cocaine, PCP, marijuana) enter the breast milk and would harm the infant, so women taking these substances should not breast-feed. To prevent HIV transmission to the newborn, women who are HIV positive should not breast-feed. Other contraindications to breast-feeding include a newborn with an inborn error of metabolism such as galactosemia or phenylketonuria (PKU), active tuberculosis, or a mother with a serious mental health disorder that would prevent her from remembering to feed the infant consistently (Denne, 2015).

Providing Assistance With Breast-Feeding and Bottle-Feeding

First-time mothers often have many questions about feeding, and even women who have had experience with feeding may have questions. Regardless of

whether the postpartum woman is breast-feeding or bottle-feeding her newborn, she can benefit from instruction.

PROVIDING ASSISTANCE WITH BREAST-FEEDING

The AAP (2014b) recommends breast-feeding for all full-term newborns. Exclusive breast-feeding is sufficient to support optimal growth and development for approximately the first 6 months of life. Breast-feeding should be continued for at least the first year of life and beyond for as long as mutually desired by mother and child. Educating a mother about breast-feeding will increase the likelihood of a successful breast-feeding experience.

At birth, all newborns should be quickly dried, assessed, and, if stable, placed immediately in uninterrupted skin-to-skin contact (kangaroo care) with their mother. This is good practice whether the mother is going to breast-feed or bottle-feed her infant. Numerous benefits of kangaroo care have been reported related to physiological (thermoregulation, cardiorespiratory stability), behavioral (sleep, breast-feeding duration, and degree of exclusivity), domains, as an effective therapy to relieve procedural pain, and improve neurodevelopment. In addition, kangaroo care provides the newborn with optimal physiologic stability, warmth, and opportunities for the first feed (Campbell-Yeo et al., 2015).

The benefits of breast-feeding for infants are clear (see Chapter 18). To promote breast-feeding, the Baby-Friendly Hospital Initiative, an international program of the World Health Organization and the United Nations International Children's Emergency Fund (UNICEF), was started in 1991. This global health promotion initiative was put forth to improve maternal-infant health by improving rates of exclusive breast-feeding. As part of this program, the hospital or birth center should take the following 10 steps to provide "an optimal environment for the promotion, protection, and support of breast-feeding":

1. Have a written breast-feeding policy that is communicated to all staff.

2. Educate all staff to implement this written policy.

3. Inform all women about the benefits and management of breast-feeding.

4. Show all mothers how to initiate breast-feeding within 30 minutes of birth.

5. Give no food or drink other than breast milk to all newborns.

6. Demonstrate to all mothers how to initiate and maintain breast-feeding.

7. Encourage breast-feeding on demand.

8. Allow no pacifiers to be given to breast-feeding infants.

9. Establish breast-feeding support groups and refer mothers to them.

10. Practice rooming-in 24 hours daily (Cleminson et al., 2015; CDC, 2015a; World Health Organization [WHO], 2014a).

The nurse is responsible for protecting, promoting and supporting breast-feeding when appropriate. For the woman who chooses to breast-feed her infant, the nurse or lactation consultant will need to spend time instructing her about how to do so successfully. Many women have the impression that breast-feeding is simple. Although it is a natural process, women may experience some difficulty in breast-feeding their newborns. Nurses can assist mothers in smoothing out this transition. Assist and provide one-to-one instruction to breast-feeding mothers, especially first-time breast-feeding mothers, to ensure correct technique. Suggestions are highlighted in Teaching Guidelines 16.4 (see Evidence-Based Practice 16.2).

 Take Note!

Some newborns "latch on and catch on" right away, and others take more time and patience. Inform new mothers about this to reduce their frustration and uncertainty about their ability to breast-feed.

Tell mothers that they need to believe in themselves and their ability to accomplish this task. They should not panic if breast-feeding does not go smoothly at first; it takes time and practice. Additional suggestions to help mothers relax and feel more comfortable breast-feeding, especially when they return home, include the following:

• Select a quiet corner or room where you won't be disturbed.

• Use a rocking chair to soothe both you and your infant.

• Take long, slow deep breaths to relax before nursing.

• Drink while breast-feeding to replenish body fluids.

• Listen to soothing music while breast-feeding.

• Cuddle and caress the infant while feeding.

• Set out extra cloth diapers within reach to use as burping cloths.

- Allow sufficient time to enjoy each other in an unhurried atmosphere.

- Involve other family members in all aspects of the infant's care from the start.

- Contact a local La Leche or Nursing Mother's group for continued guidance/support.

EVIDENCE-BASED PRACTICE 16.2 NURSES IMPROVING THE HEALTH OF MOTHERS AND INFANTS BY DANCING THE 10 STEPS TO SUCCESSFUL BREAST-FEEDING

STUDY

The Baby Friendly Hospital Initiative has gained momentum in the United States in recent years. The principles of it are evidence-based and that promoting breast-feeding improves health outcomes and neurocognitive development in infants. The purpose of this study was to implement the Ten Steps to Successful Breast-feeding and see if the rates and duration of breast-feeding improved. The implementation strategies included assessment of current practices, identification of barriers and opportunities, and strategies to support changes in 89 hospitals that participated. The initiative was to increase the number of Baby Friendly designated hospitals over a 2-year process-improvement time frame.

Findings

Results included heightened professional environment of competence, enhanced delivery of client centered care, improved health of mothers and infants, increased client satisfaction, and achievement of benchmarks. The implementation of the Ten Steps to Successful Breast-feeding resulted in improved rates of breast-feeding in all 89 hospitals.

Nursing Implications

This study demonstrated the positive effect of a nurse-led initiative that improved the continuum of care for mothers and infants from the prenatal period through post discharge community care. Nurses can be instrumental by applying principles of evidence-based practices and bring forth change within their health care agencies to improve the outcomes for mothers and their infants.

Teaching Guidelines 16.4

BREAST-FEEDING SUGGESTIONS

1. Explain that breast-feeding is a learned skill for both parties.
2. Offer a thorough explanation about the procedure.
3. Instruct the mother to wash her hands before starting.
4. Inform her that her afterpains will increase during breast-feeding.
5. Make sure the mother is comfortable (pain-free) and not hungry.
6. Tell the mother to start the feeding with an awake and alert infant showing hunger signs.
7. Assist the mother to position herself correctly for comfort.
8. Urge the mother to relax to encourage the let-down reflex.
9. Guide the mother's hand to form a "C" to access the breast with thumb on top and other four fingers under the breast.
10. Have the mother lightly tickle the infant's upper lip with her nipple to stimulate the infant to open the mouth wide.
11. Aid her in helping the infant to latch on by bringing the infant rapidly to

the breast with a wide-open mouth.

12. Show her how to check that the newborn's mouth position is correct, and tell her to listen for a sucking noise.

13. Demonstrate correct removal from the breast, using her finger to break the suction.

14. Instruct the mother on how to burp the infant before changing from one breast to another.

15. Show her different positions, such as cradle and football holds and side-lying positions (see Chapter 18).

16. Reinforce and praise the mother for her efforts.

17. Allow ample time to answer questions and address concerns.

18. Refer the mother to support groups and community resources.

Because obesity in America is increasing in all walks of life, it is important for nurses to be knowledgeable about how it impacts breast-feeding and ways to support the obese mother. Research shows that mothers who are obese (BMI > 30) are less likely to initiate lactation, have difficulties with latching on, have delayed lactogenesis, experience mechanical challenges, and are prone to early cessation of breast-feeding (Shannon, Chao, & Ramos, 2015). Obesity rates are highest among African American women, who have the lowest rate of breast-feeding initiation and shortest duration when compared with Hispanic and White women. Women who are overweight and obese have lowered prolactin responses to infant sucking, thus milk production may be inhibited. Lactation plays a significant role in preventing future obesity in both the mother and the infant (Masho, Cha, & Morris, 2015).

Nurses can assist in managing obesity-related lactation challenges by keeping the mother and newborn together to facilitate early and frequent sucking to trigger prolactin and oxytocin production, which will help negate the obesity-related blunting of the prolactin response. Suggesting a sandwich technique to insert the mother's breast into the newborn's mouth to elicit sucking might be helpful for the mother with large breasts. In the sandwich technique, the mother is taught to grasp her breast by making a "C" with her thumb and index finger. The thumb stabilizes the top of the breast while the remaining four fingers support her breast from below. Massage or pumping the breast may soften and extend the nipple for easier infant latch-on. In short, nurses can make a difference by observing lactation, assessing infant hydration and satisfaction, and reassuring the mother about her breast-feeding capacity.

PROVIDING ASSISTANCE WITH BOTTLE-FEEDING

If the mother or couple has chosen to bottle-feed their newborn, the nurse should respect and support their decision. Discuss with the parents what type of formula they will use. Commercial formulas are classified as cow's milk-based (Enfamil, Similac), soy protein-based (Isomil, Prosobee, Nursoy), or specialized or therapeutic formulas for infants with protein allergies (Nutramigen, Pregestimil, Alimentum). Commercial formulas can also be purchased in various forms: powdered (must be mixed with water), condensed liquid (must be diluted with equal amounts of water), ready to use (poured directly into bottles), and prepackaged (ready to use in disposable bottles).

Breast milk is a dynamic fluid with compositional changes occurring throughout the period of lactation that reflects the growth rate and developmental needs of the infant. Infant formula, in contrast, has a static composition, intended to meet the nutritional requirements of infants from birth to 12 months of age (Lönnerdal & Hernell, 2015). Nurses need to bring this information to the attention of mothers who choose to formula feed their infants that changes may be needed in different stages of growth to meet the nutritional needs of their infant.

Newborns need about 108 cal/kg or approximately 650 cal/day (Dudek, 2014). Therefore, explain to parents that a newborn will need 2 to 4 ounces to feel satisfied at each feeding. Until about age 4 months, most bottle-fed infants need six feedings a day. After this time, the number of feedings declines to accommodate other foods in the diet, such as fruits, cereals, and vegetables (Dudek, 2014). For more information on newborn nutrition and bottle feeding, see Chapter 18.

When teaching the mother about bottle-feeding, provide the following guidelines:

• Wash hands with soap and water and dry using a clean or disposable cloth.

• Make sure all bottles, nipples and other utensils are clean.

• Make feeding a relaxing time, a time to provide both food and comfort to your newborn.

• Use the feeding period to promote bonding by smiling, singing, making eye contact, and talking to the infant.

• Powdered formula mixes more easily and the lumps dissolve faster if you use room-temperature water.

- Store any formula prepared in advance in the refrigerator to keep bacteria from growing.
- Do not microwave formula; the microwave won't heat it evenly, causing hot spots.
- Always hold the newborn when feeding. Never prop the bottle.
- Use a comfortable position when feeding the newborn. Place the newborn in your dominant arm, which is supported by a pillow. Or have the newborn in a semi-upright position supported in the crook of your arm. (This position reduces choking and the flow of milk into the middle ear.)
- Tilt the bottle so that the nipple and the neck of the bottle are always filled with formula. This prevents the infant from taking in too much air.
- Stimulate the sucking reflex by touching the nipple to the infant's lips.
- Refrigerate any powdered formula that has been combined with tap water.
- Discard any formula not taken; do not keep it for future feedings.
- Burp the infant frequently, and place the baby on his or her back for sleeping.
- Use only iron-fortified infant formula for the first year (Moses, 2014).

Teaching About Breast Care

Regardless of whether or not the mother is breast-feeding her newborn, urge her to wear a very supportive, snug bra 24 hours a day to support enlarged breasts and promote comfort. A woman who is breast-feeding should wear a supportive bra throughout the lactation period. A woman who is not nursing should wear it until engorgement ceases, and then should wear a less restrictive one. The bra should fit snugly while still allowing the mother to breathe without restriction. All new mothers should use plain water to clean their breasts, especially the nipple area; soap is drying and should be avoided.

Assessing the Breasts

Instruct the mother how to examine her breasts daily. Daily assessment includes the milk supply (breasts will feel full as they are filling), the condition of the nipples (red, bruised, fissured, or bleeding), and the success of breast-feeding. The fullness of the breasts may progress to engorgement in the breast-feeding mother if feedings are delayed or breast-feeding is ineffective. Palpating both breasts will help identify whether the breasts are soft, filling, or engorged. A similar assessment of the breasts should be completed on the nonlactating mother to identify any problems, such as engorgement or mastitis.

Alleviating Breast Engorgement

Breast engorgement usually occurs during the first week postpartum. It is a common response of the breasts to the sudden change in hormones and the presence of an increased amount of milk. Reassure the woman that this condition is temporary and usually resolves within 72 hours.

ALLEVIATING BREAST ENGORGEMENT IN THE BREAST-FEEDING WOMAN

If the mother is breast-feeding, encourage frequent feedings, at least every 2 to 3 hours, using manual expression just before feeding to soften the breast so the newborn can latch on more effectively. Advise the mother to allow the newborn to feed on the first breast until it softens before switching to the other side. See Chapter 18 for more information on alleviating breast engorgement and other common breast-feeding concerns.

ALLEVIATING BREAST ENGORGEMENT AND SUPPRESSING LACTATION IN THE BOTTLE-FEEDING WOMAN

If the woman is bottle-feeding, explain that breast engorgement is a self-limiting phenomenon that disappears as increasing estrogen levels suppress milk formation (i.e., lactation suppression). Encourage the woman to use ice packs, to wear a snug, supportive bra 24 hours a day, and to take mild analgesics such as acetaminophen. Encourage her to avoid any stimulation to the breasts that might foster milk production, such as warm showers or pumping or massaging the breasts. Medication is no longer given to hasten lactation suppression because these agents had limited effectiveness and adverse side effects. Teaching Guidelines 16.5 provides tips on lactation suppression.

Teaching Guidelines 16.5

SUPPRESSING LACTATION

1. Wear a supportive, snugly fitting bra 24 hours daily, but not one that binds the breasts too tightly or interferes with your breathing.

2. Suppression may take 5 to 7 days to accomplish.

3. Take mild analgesics to reduce breast discomfort.

4. Let shower water flow over your back rather than your breasts.

5. Avoid any breast stimulation in the form of sucking or massage.

6. Drink to quench your thirst. Restricting your fluid intake will not dry up your milk.

7. Reduce your salt intake to decrease fluid retention.

8. Use ice packs or cool compresses (e.g., cool cabbage leaves) inside the bra to decrease local pain and swelling; change them every 30 minutes (King et al., 2015).

Promoting Family Adjustment and Well-Being

The postpartum period involves extraordinary physiologic, psychological, and sociocultural changes in the life of a woman and her family. Adapting to the role of a parent is not an easy process. The postpartum period is a "getting-to-know-you" time when parents begin to integrate the newborn into their lives as they reconcile the fantasy child with the real one. This can be a very challenging period for families. Nurses play a major role in assisting families to adapt to the changes, promoting a smooth transition into parenthood. Appropriate and timely interventions can help parents adjust to the role changes and promote attachment to the newborn (Fig. 16.7).

For couples who already have children, the addition of a new member may bring role conflict and challenges. The nurse should provide anticipatory guidance about siblings' responses to the new baby, increased emotional tension, child development, and meeting the multiple needs of the expanding family. Although the multiparous woman has had experience with newborns, do not assume that her knowledge is current and accurate, especially if some time has elapsed since her previous child was born. Reinforcing information is important for all families.

Promoting Parental Roles

Parents' roles develop and grow when they interact with their newborn (see Chapter 15 for information on maternal and paternal adaptation). The pleasure they derive from this interaction stimulates and reinforces this behavior. With repeated, continued contact with the newborn, parents learn to recognize cues and understand the newborn's behavior. This positive interaction contributes to family harmony.

Nurses need to know the stages parents go through as they make their new parenting roles fit into their life experience. Assess the parents for attachment behaviors (normal and deviant), adjustment to the new parental role, family member adjustment, social support system, and educational needs. To promote parental role adaptation and parent–newborn attachment, provide the following nursing interventions:

• Provide as many opportunities as possible for parents to interact with their newborn. Encourage parents to explore, hold, and provide care for their

newborn. Praise them for their efforts.

FIGURE 16.7 Examples of family members carrying out roles to promote adjustment and well-being. **A.** An aunt admiring the newest member of the family. **B.** A father holding his newborn closely on his chest. **C.** Grandparents welcoming the newest little one to the family circle.

- Model behaviors by holding the newborn close, calling the newborn's name, and speaking positively.

- Speak directly to the newborn in a calm voice, while pointing out the newborn's positive features to the parents.
- Evaluate the family's strengths and weaknesses and readiness for parenting.
- Assess for risk factors such as lack of social support and the presence of stressors.
- Observe the effect of culture on the family interaction to determine healthy family dynamics.
- Monitor parental attachment behaviors to determine whether alterations require referral. Positive behaviors include holding the newborn closely or in an *en face* position, talking to or admiring the newborn, or demonstrating closeness. Negative behaviors include avoiding contact with the newborn, calling it names, or showing a lack of interest in caring for the newborn (see Table 16.1).
- Monitor the parents' coping behaviors to determine alterations that need intervention. Positive coping behaviors include positive conversations between the partners, both parents wanting to be involved with newborn care, and lack of arguments between the parents. Negative behaviors include not visiting, limited conversations or periods of silence, and heated arguments or conflict.
- Identify the support systems available to the new family and encourage them to ask for help. Ask direct questions about home or community support. Make referrals to community resources to meet the family's needs.
- Arrange for community home visits in high-risk families to provide positive reinforcement of parenting skills and nurturing behaviors with the newborn.
- Provide anticipatory guidance about the following before discharge to reduce the new parents' frustration:

  - Newborn sleep–wake cycles (they may be reversed)
  - Variations in newborn appearance and developmental milestones (growth spurts)
  - How to interpret crying cues (hunger, wet, discomfort) and what to do about them
  - Sensory enrichment/stimulation (colorful mobile)
  - Signs and symptoms of illness and how to assess for fever
  - Important phone numbers, follow-up care, and needed immunizations
  - Physical and emotional changes associated with the postpartum period

- Need to integrate siblings into care of the newborn; stress that sibling rivalry is normal and offer ways to reduce it
- Ways to make time together for the couple

In addition, nurses can help fathers to feel more competent in assuming their parental role by teaching and providing information (Fig. 16.8). Education can dispel any unrealistic expectations they may have, helping them to cope more successfully with the demands of fatherhood and thereby fostering a nurturing family relationship.

Explaining Sibling Roles

It can be overwhelming to a young child to have another family member introduced into his or her small, stable world. Although most parents try to prepare siblings for the arrival of their new little brother or sister, many young children experience stress. They may view the new infant as competition, or fear that they will be replaced in the parents' affection. All siblings need extra attention from their parents and reassurance that they are loved and important. Many parents need reassurance that sibling rivalry is normal. Suggest the following to help parents minimize sibling rivalry:

FIGURE 16.8 Father participating in newborn care.

- Expect and tolerate some regression (thumb sucking, bedwetting).
- Explain childbirth in an appropriate way for the child's age.
- Encourage discussion about the new infant during relaxed family times.

- Encourage the sibling(s) to participate in decisions, such as the baby's name and toys to buy.
- Take the sibling on a tour of the maternity suite.
- Buy a T-shirt that says "I'm the [big brother or big sister]."
- Spend "special time" with the child.
- Read with the child. Some suggested titles include: *Things to Do With a New Baby* (Ormerod, 1984); *Betsy's Baby Brother* (Wolde, 1975); *The Berenstain Bears' New Baby* (Berenstain, 1974); and *Mommy's Lap* (Horowitz & Sorensen, 1993).
- Plan time for each child throughout the day.
- Role-play safe handling of a newborn, using a doll. Give the preschooler or school-age child a doll to care for.
- Encourage older children to verbalize emotions about the newborn.
- Purchase a gift that the child can give to the newborn.
- Purchase a gift that can be given to the child by the newborn.
- Arrange for the child to come to the hospital to see the newborn (Fig. 16.9).
- Move the sibling from his or her crib to a youth bed months in advance of the birth of the newborn.
- Show the older sibling photos of the baby growing in mommy's belly. Let them pat the baby beneath the bulge, talk to baby, and feel the baby kick.
- Make the older sibling feel important by giving them a title "mommy's helper."
- Encourage grandparents to pay attention to the older child when visiting.
- Tell the older sibling that their friends come and go, but siblings are forever.
- Encourage "Do unto others as you would have them do unto you" (Sears & Sears, 2015c).

FIGURE 16.9 Sibling visitation.

🌸 *Consider This*

Katie and Molly have been excited about having a new baby sister ever since they were told about their mother's pregnancy. The 6-year-old twins are eagerly looking out the front window, waiting for their parents to bring their new sister, Jessica, home. The girls are big enough to help their mother care for their new sibling, and for the past few months they have been fixing up the new nursery and selecting baby clothes. They practiced diapering their dolls—their mother was specific about not using any powder or lotion on Jessica's bottom—and holding them correctly to feed them bottles. Finally, their mother arrives home from the hospital with Jessica in her arms!

The girls notice that their mother is very protective of Jessica and watches them carefully when they care for her. They fight over the opportunity to hold her or feed her. What is special to both of them is the time they spend alone with their parents. Although a new family member has been added, the twins still feel special and loved by their parents.

Thoughts: Bringing a new baby into an established family can cause conflict and jealousy. What preparation did the older siblings have before Jessica arrived? Why is it important for parents to spend time with each sibling separately?

Discussing Grandparents' Role

Grandparents can be a source of support and comfort to the postpartum family if effective communication skills are used and roles are defined. The grandparents' role and involvement will depend on how close they live to the family, their willingness to become involved, and cultural expectations of their role. Just as parents and siblings go through developmental changes, so too do grandparents. These changes can have a positive or negative effect on the relationship.

Newborn care, feeding, and child-rearing practices have changed since the grandparents raised the parents. New parents may lack parenting skills but nonetheless want their parents' support without criticism. A grandparent's "take-charge approach" may not be welcome by new parents who are testing their own parenting roles, and family conflict may ensue. However, many grandparents respect their adult children's wishes for autonomy and remain "resource people" for them when requested.

Take Note!

Grandparents' involvement can enrich the lives of the entire family if accepted in the right context and dose by the family.

Nurses can assist in the grandparents' role transition by assessing their communication skills, role expectations, and support skills during the prenatal period. Find out whether the grandparents are included in the couple's social support network and whether their support is wanted or helpful. If they are, and it is, then encourage the grandparents to learn about the parenting, feeding, and child-rearing skills their children have learned in childbirth classes. This information is commonly found in "grandparenting" classes, which introduce new parenting concepts and bring the grandparents up to date on today's childbirth practices.

Teaching About Postpartum Blues

The postpartum period is typically a happy yet stressful time, because the birth of an infant is accompanied by enormous physical, social, and emotional changes. The postpartum woman may report feelings of emotional lability, such as crying one minute and laughing the next (see Chapter 15 for postpartum blues discussion). Although postpartum blues is usually benign and self-limited, these mood changes can be frightening to the woman. It is prudent to ask two questions—about having pleasure and interest in things, or feeling predominately down, depressed, or hopeless. Once postpartum blues are determined to be the likely cause of her mood symptoms, the nurse can offer anticipatory guidance that these mood swings are commonly experienced and usually resolve spontaneously within a week and offer reassurance. Women should also be counseled to seek further evaluation if these moods do not resolve within two weeks, as postpartum depression may be developing (King et al., 2015).

 Take Note!

Postpartum blues have been regarded as brief, benign, and without clinical significance, but several studies have proposed a link between blues and subsequent depression in the 6 months following childbirth (Cristescu et al., 2015).

Postpartum blues require no formal treatment other than support and reassurance because they do not usually interfere with the woman's ability to function and care for her infant. Nurses can ease a mother's distress by encouraging her to vent her feelings and by demonstrating patience and understanding with her and her family. Suggest that getting outside help with housework and infant care might help her to feel less overwhelmed until the blues ease. Provide telephone numbers she can call when she feels down during the day. Making women aware of this disorder while they are pregnant will increase their knowledge about this mood disturbance, which may lessen their embarrassment and increase their willingness to ask for and accept help if it does occur.

The postpartum woman also is at risk for postpartum depression and

postpartum psychosis; these conditions are discussed in Chapter 22.

Preparing for Discharge

The World Health Organization (WHO) recommends that the length of stay in the health care facility should be individualized for each mother and baby, but should be at least 24 hours after birth (2014b). A shortened hospital stay may be indicated if the following criteria are met:

• Mother is afebrile and vital signs are within normal range.

• Lochia is appropriate amount and color for stage of recovery.

• Hemoglobin and hematocrit values are within normal range.

• Uterine fundus is firm; urinary output is adequate.

• ABO blood groups and RhD status are known and, if indicated, anti-D immunoglobulin has been administered.

• Surgical wounds are healing and no signs of infection are present.

• Mother is able to ambulate without difficulty.

• Food and fluids are taken without difficulty.

• Self-care and infant care are understood and demonstrated.

• Family or other support system is available to care for both.

• Mother is aware of possible complications (WHO, 2014b).

Providing Immunizations

Prior to discharge, check the immunity status for rubella for all mothers and give a subcutaneous injection of rubella vaccine if they are not serologically immune (titer less than 1:8). Be sure that the client signs a consent form to receive the vaccine. The rubella vaccine should not be given to any woman who is immune compromised, and the immune status of her close contacts needs to be determined before any vaccine is administered to her to prevent a more virulent case of the vaccine-preventable illness or potential death. With the recent increase in the number of pertussis in infants younger than three months of age, the CDC is also recommending vaccination with (Tdap) (combination of diphtheria, pertussis, and tetanus vaccines) for the mother during her postpartum stay (CDC, 2015b). Nursing mothers can be vaccinated because the live, attenuated rubella virus is not communicable. Inform all mothers receiving immunization about adverse effects (rash, joint symptoms, and a low-grade fever

5 to 21 days later) and the need to avoid pregnancy for at least 28 days after being vaccinated because of the risk of teratogenic effects (CDC, 2015b).

Rh Status

If the client is Rh negative, check the Rh status of the newborn. Verify that the woman is Rh negative and has not been sensitized, that her indirect Coombs' test (antibody screen) is negative, and that the newborn is Rh positive. Mothers who are Rh negative and have given birth to an infant who is Rh positive should receive an injection of Rh immunoglobulin within 72 hours after birth to prevent a sensitization reaction in the Rh-negative woman who received Rh-positive blood cells during the birthing process. Administering RhoGAM prevents initial isoimmunization in Rh-negative mothers by destroying fetal erythrocytes in the maternal system before maternal antibodies can develop and maternal memory cells become sensitized. This is a classic passive immunization technique. The usual protocol for the Rh-negative woman is to receive two doses of Rh immunoglobulin (RhoGAM), one at 28 weeks' gestation and the second dose within 72 hours after childbirth. The standard dose of Rho(D) immune globulin (RhoGAM) is 300 mcg given intramuscularly, which prevents the development of antibodies for an exposure of up to 15 mL of fetal red blood cells (King et al., 2015). A signed consent form is needed after a thorough explanation is provided about the procedure, including its purpose, possible adverse effects, and effect on future pregnancies.

RhoGam contains actual Rh antibodies produced by people who have become sensitized. It is therefore, a blood product. Each dose contains enough Anti-D to suppress the immune response of 15 mL of Rh positive red blood cells (Jordan et al., 2014). Jehovah's Witnesses and others who belong to religions prohibiting the use of blood products should consult their conscience and possibly ecclesiastical leaders about the use of RhoGam. Nurses need to respect whatever their decision is.

Ensuring Follow-Up Care

New mothers and their families need to be attended to over an extended period of time by nurses knowledgeable about mother care, infant feeding (breast-feeding and bottle-feeding), infant care, and nutrition. Although continuous nursing care stops on discharge from the hospital or birthing center, extended episodic nursing care needs to be provided at home. Some of the challenges

faced by families after discharge are described in Box 16.5.

Many new mothers are reluctant to "cut the cord" after their brief stay in the health care facility and need expanded community services. Women who are discharged too early from the hospital run the risk of uterine subinvolution, discomfort at an episiotomy or cesarean site, infection, fatigue, and maladjustment to their new role. Postpartum nursing care should include a range of family-focused care, including telephone calls, outpatient clinics, and home visits. Typically, public health nurses, community and home health nurses, and the health care provider's office staff will provide postpartum care after hospital discharge.

CHALLENGES FACING FAMILIES AFTER DISCHARGE

• Lack of role models for breast-feeding and infant care

• Lack of support from the new mother's own mother if she did not breast-feed

• Increased mobility of society, which means that extended family may live far away and cannot help care for the newborn and support the new family

• Feelings of isolation and limited community ties for women who work full time

• Shortened hospital stays: parents may be overwhelmed by all the information they are given in the brief hospital stay

• Prenatal classes usually focus on the birth itself rather than on skills needed to care for themselves and the newborn during the postpartum period

• Limited access to education and support systems for families from diverse cultures

Adapted from Bope, E., & Kellerman, R. (2015). *Conn's current therapy 2015*. Philadelphia, PA: Saunders Elsevier; and Bang, K., Huh, B., & Kwon, M. (2014). The effect of a postpartum nursing intervention program for immigrant mothers. *Child Health Nursing Research*, 20(1), 11–19.

PROVIDING TELEPHONE FOLLOW-UP

Telephone follow-up typically occurs during the first week after discharge to check on how things are going at home. Calls can be made by perinatal nurses within the agency as part of follow-up care or by the local health department nurses. One disadvantage of a phone call assessment is that the nurse cannot see the client and thus must rely on the mother or the family's observations. The experienced nurse needs to be able to recognize distress and give appropriate advice and referral information if needed.

PROVIDING OUTPATIENT FOLLOW-UP

For mothers with established health care providers such as private pediatricians

and obstetricians, visits to the office are arranged soon after discharge. For the woman with an uncomplicated vaginal birth, an office visit is usually scheduled for 4 to 6 weeks after childbirth. A woman who had a cesarean birth frequently is seen within 2 weeks after hospital discharge. Hospital discharge orders will specify when these visits should be made. Newborn examinations and further diagnostic laboratory studies are scheduled within the first week.

Take Note!

The hospital stay of the mother and her healthy term newborn should be long enough to allow identification of early problems and to ensure that the family is able and prepared to care for the infant at home (WHO, 2014b).

Outpatient clinics are available in many communities. If family members run into a problem, the local clinic is available to provide assessment and treatment. Clinic visits can replace or supplement home visits. Although these clinics are open during daytime hours only and the staff members are unfamiliar with the family, they can be a valuable resource for the new family with a problem or concern.

PROVIDING HOME VISIT FOLLOW-UP

Home visits are usually made within the first week after discharge to assess the mother and newborn. During the home visit, the nurse assesses for and manages common physical and psychosocial problems. In addition, the home nurse can help the new parents adjust to the change in their lives. The postpartum home visit usually includes the following:

- *Maternal assessment:* general well-being, vital signs, breast health and care, abdominal and musculoskeletal status, voiding status, fundus and lochia status, psychological and coping status, family relationships, proper feeding technique, environmental safety check, newborn care knowledge, and health teaching needed (Fig. 16.10 shows sample assessment forms.)

- *Infant assessment:* physical examination, general appearance, vital signs, home safety check, child development status, any education needed to improve parents' skills

The home care nurse must be prepared to support and educate the woman and her family in the following areas:

• Breast-feeding or bottle-feeding technique and procedures

• Appropriate parenting behavior and problem solving

• Maternal/newborn physical, psychosocial, and culture–environmental needs

• Emotional needs of the new family

• Warning signs of problems and how to prevent or eliminate them

• Sexuality issues, including contraceptive use

• Immunization needs for both mother and infant

• Family dynamics for smooth transition

• Links to health care providers and community resources

B

FIGURE 16.10 Sample postpartum home visit assessment form. **A.** Maternal assessment. **B.** Newborn

KEY CONCEPTS

- The transitional adjustment period between birth and parenthood includes education about baby care basics, the role of the new family, emotional support, breast-feeding or bottle-feeding support, and maternal mentoring.

- Sensitivity to how childbearing practices and beliefs vary for multicultural families and how best to provide appropriate nursing care to meet their needs are important during the postpartum period.

- A thorough postpartum assessment is key to preventing complications as is frequent hand hygiene by the nurse, especially between handling mothers and infants.

- The postpartum assessment that uses the acronym BUBBLE-EE (breasts, uterus, bowel, bladder, lochia, episiotomy/perineum/epidural site, extremities, and emotions) is a helpful guide in performing a systematic head-to-toe postpartum assessment.

- Lochia is assessed according to its amount, color, and change with activity and time. It proceeds from lochia rubra to serosa to alba.

- Because of shortened agency stays, nurses must use this brief time with the client to address areas of comfort, elimination, activity, rest and exercise, self-care, sexuality and contraception, nutrition, family adaptation, discharge, and follow-up.

- The AAP advocates breast-feeding for all full-term newborns, maintaining that, ideally, breast milk should be the sole nutrient for the first 6 months and continued with foods until 12 months of life or longer.

- Successful parenting is a continuous and complex interactive process that requires the acquisition of new skills and the integration of the new member into the existing family unit.

- Bonding is a vital component of the attachment process and is necessary in establishing parent–infant attachment and a healthy, loving relationship; attachment behaviors include seeking and maintaining proximity to, and exchanging gratifying experiences with, the infant.

- Nurses can be instrumental in facilitating attachment by first understanding attachment behaviors (positive and negative) of newborns and parents, and

intervening appropriately to promote and enhance attachment.
- New mothers and their families need to be attended to over an extended period of time by nurses knowledgeable about mother care, newborn feeding (breast-feeding and bottle-feeding), newborn care, and nutrition.

CHAPTER **WORKSHEET**

MULTIPLE CHOICE QUESTIONS

1. When assessing a postpartum woman, which of the following would lead the nurse to suspect postpartum blues?

    a. Panic attacks and suicidal thoughts

    b. Anger toward self and infant

    c. Periodic crying and insomnia

    d. Obsessive thoughts and hallucinations

2. Which of these activities would best help the postpartum nurse to provide culturally sensitive care for the childbearing family?

    a. Taking a transcultural course

b. Caring for only families of his or her cultural origin

c. Teaching Western beliefs to culturally diverse families

d. Educating himself or herself about diverse cultural practices

3. Which of the following suggestions would be most appropriate to include in the teaching plan for a postpartum woman who needs to lose weight?

a. Increase fluid intake and acid-producing foods in her diet.

b. Avoid empty-calorie foods, breastfeed, increase exercise.

c. Start a high-protein, low carbohydrate diet and restrict fluids.

d. Eat no snacks or carbohydrates after dinner.

4. After teaching a group of breast-feeding women about nutritional needs, the nurse determines that the teaching was successful when the women state that they need to increase their intake of which nutrients?

a. Carbohydrates and fiber

b. Fats and vitamins

c. Calories and protein

d. Iron-rich foods and minerals

5. Which of the following would lead the nurse to suspect that a postpartum woman was developing a complication?

a. Fatigue and irritability

b. Perineal discomfort and pink discharge

c. Pulse rate of 60 bpm

d. Swollen, tender, hot area on breast

6. Which of the following would the nurse assess as indicating positive bonding between the parents and their newborn?

a. Holding the infant close to the body

b. Having visitors hold the infant

c. Buying expensive infant clothes

d. Requesting that the nurses care for the infant

7. Which activity would the nurse include in the teaching plan for parents with a newborn and an older child to reduce sibling rivalry when the newborn is brought home?

a. Punishing the older child for bedwetting behavior

b. Sending the sibling to the grandparents' house

c. Planning a daily "special time" for the older sibling

d. Allowing the sibling to share a room with the infant

8. The major purpose of the first postpartum homecare visit is to:

a. Identify complications that require interventions

b. Obtain a blood specimen for PKU testing

c. Complete the official birth certificate

d. Support the new parents in their parenting roles

9. The nurse is instructing the postpartum client who plans to bottle-feed her newborn about measures to prevent breast engorgement when she is discharged. Which of the following measures should the nurse include in the teaching plan?

a. Decreasing her fluid intake for the first week at home

b. Wearing a tight-fitting supportive bra 24 hours daily

c. Take a diuretic to release the extra fluid in the breasts

d. Manually express the milk that is accumulating

10. A new mother was brought to the postpartum unit who gave birth 12 hours ago. Because this is her first child, which of the following goals by the nurse is most appropriate?

a. Early discharge for the mother and newborn

b. Rapid transition into her role of being a parent/caretaker

c. Minimal need for expression of her feelings now

d. Effective education of both parents before discharge

CRITICAL THINKING EXERCISES

1. As a nurse working on a postpartum unit, you enter the room of, a 22-year-old primipara, and find her chatting on the phone while her newborn is crying loudly in the bassinette, which has been pushed into the bathroom. You pick up and comfort the newborn. While holding the baby, you ask the client if she was aware her newborn was crying. She replies, "That's about all that monkey does since she was born!" You hand the newborn to her and she places the newborn on the bed away from her and continues her phone conversation.

   a. What is your nursing assessment of this encounter?

   b. What nursing interventions would be appropriate?

   c. What specific discharge interventions may be needed?

2. A 34-year-old single primipara, left the hospital after a 36-hour stay with her newborn son. She lives alone in a one-bedroom walk-up apartment. As the postpartum home health nurse visiting her 2 days later, you find the following:

   • Tearful client pacing the floor holding her crying son

   • Home cluttered and in disarray

   • Fundus firm and displaced to right of midline

   • Moderate lochia rubra; episiotomy site clean, dry, and intact

   • Vital signs within normal range; pain rating less than 3 points on scale of 1 to 10

   • Breasts engorged slightly; supportive bra on

   • Newborn assessment within normal limits

   • Distended bladder upon palpation; reporting urinary frequency

   a. Which of these assessment findings warrants further investigation?

   b. What interventions are appropriate at this time, and why?

   c. What health teaching is needed before you leave this home?

3. The nurse walks into the room of a 24-year-old primigravida. She asks the nurse to hand her the bottle sitting on the bedside table, stating, "I'm going to finish it off because my baby only ate half of it 3 hours ago when I fed him."

   a. What response by the nurse would be appropriate at this time?

   b. What action should the nurse take?

   c. What health teaching is needed for this new mother prior to discharge?

STUDY ACTIVITIES

1. Identify two questions that a nurse would ask a postpartum woman to assess for postpartum blues.

2. Find a web site that offers advice to new parents about breast-feeding. Critique the site, the author's credentials, and the accuracy of the content.

3. Outline instructions you would give to a new mother on how to use her peribottle.

4. Breast tissue swelling secondary to vascular congestion after childbirth and preceding lactation describes _____.

5. Listen to the postpartum story of one of your assigned clients and share it with your peers in class or as part of online discussion.

BRINGING IT ALL TOGETHER: CASE STUDY

A 26-year-old African American woman gave birth to a healthy term neonate yesterday and is preparing for discharge. The mother is illiterate and lives in a poor agricultural area of town not far from the hospital. This is her fourth infant in five years. The postpartum nurse comes into the room and observes that this mother has wrapped a piece of unclean cloth tightly around the infant's abdomen with a quarter which covers the cord stump. The take-home infant outfit is not clean and not appropriate for the weather conditions outside. The mother is waiting for a ride home from a friend. The postpartum nurse is here to provide her with discharge instructions.

ASSESSMENT

Client's general appearance is healthy, but appears fatigued. Vital signs are as follows: BP 120/74; Pulse 78; Temp 98.2F; Respirations 20 bpm. Her breasts are soft upon palpation, no engorgement present. She plans to bottle-feed her infant. Her abdominal exam is without significant findings and involution is proceeding normally. Fundus is at the level of the umbilicus and firm. Lochia rubra is moderate, with no clots. Voiding well and has had a bowel movement this morning. No episiotomy site to assess. Newborn physical exam was normal per pediatrician's notes.

Newborn Transitioning

KEY TERMS

cold stress
jaundice
meconium
neonatal period
neurobehavioral response
neutral thermal environment
periodic breathing
reflex
surfactant
thermoregulation

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Examine the major physiologic changes that occur as the newborn transitions to extrauterine life.
2. Determine the primary challenges faced by the newborn during the transition to extrauterine life.
3. Interpret the factors that influence the initiation of newborn respirations.
4. Compare and contrast the cardiovascular changes that take place from fetal circulation to extrauterine circulation after birth.
5. Relate three characteristics that predispose newborns to heat loss after birth.
6. Distinguish three primary immunoglobulins that help strengthen the newborn's immunologic system.
7. Differentiate the three behavioral patterns that newborns progress through after birth.
8. Assess the five typical behavioral responses triggered by external stimuli of the newborn.

The Healthy Start home care nurse reviewed the client's file in her car before she got out: 18-year-old primipara, 1 week postpartum with a term newborn girl weighing 7 lb. The new mother, Maria, greeted the nurse at the door and let her inside the house. After performing a postpartum assessment on Maria and an assessment of her newborn daughter, the nurse asked Maria if she had any questions or concerns. Maria's eyes welled up with tears: she is worried that her daughter can't see.

WOW

Words of Wisdom

Newborns can't always be judged by their outer wrapping; rather, we should focus on the awesome gift inside.

INTRODUCTION

When a child is born, the exhaustion and stress of labor are over for the parents, but now the newborn must begin the work of physiologically and behaviorally adapting to the new environment. The first 24 hours of life can be the most precarious (Swanson & Sinkin, 2015).

The **neonatal period** is defined as the first 28 days of life. It is a period of the most dramatic and rapid physiologic changes in humans. After birth, the newborn is exposed to a whole new world of sounds, colors, smells, and sensations. The newborn, previously confined to the warm, dark, wet intrauterine environment, is now thrust into an environment that is much brighter and cooler. As the newborn adapts to life after birth, numerous physiologic changes occur (Table 17.1).

Awareness of the adaptations that are occurring forms the foundation for providing support to the newborn during this crucial time. Physiologic and behavioral changes occur quickly during this transition period. Being aware of any deviations from the norm is crucial to ensure early identification and prompt intervention.

This chapter describes the physiologic changes of the newborn's major body systems. It also discusses the behavioral adaptations, including behavioral patterns and the newborn's behavioral responses, which occur during this transition period.

PHYSIOLOGIC TRANSITIONING

The adaptation from the intrauterine to extrauterine environment is complex and difficult, but required for all humans. Maternal medical and fetal conditions can have a profound effect on the successful transition. The mechanics of birth require a change in the newborn for survival outside the uterus. Immediately at birth, respiratory gas exchange, along with circulatory modifications, must occur to sustain extrauterine life. During this time, as newborns strive to attain homeostasis, they also experience complex changes in major organ systems. The newborn's most dramatic and most rapid extrauterine transitions occur in four interdependent areas: respiratory, circulatory, thermoregulation, and their ability to stabilize their blood glucose levels. All four areas must make successful transitions for the newborn to adapt to extrauterine life. Although the transition usually takes place within the first 6 to 10 hours of life, many adaptations take weeks to attain full maturity.

Cardiovascular System Adaptations

During fetal life, the heart relies on certain unique structures that assist it in providing adequate perfusion of vital body parts. The umbilical vein carries oxygenated blood from the placenta to the fetus. The ductus venosus allows the majority of the umbilical vein blood to bypass the liver and merge with blood moving through the vena cava, bringing it to the heart sooner. The foramen ovale allows more than half the blood entering the right atrium to cross immediately to the left atrium, bypassing the pulmonary circulation. The ductus arteriosus connects the pulmonary artery to the aorta, which allows bypassing of the pulmonary circuit. Only a small portion of blood passes through the pulmonary circuit for the main purpose of perfusion of the structure, rather than for oxygenation. The fetus depends on the placenta to provide oxygen and nutrients and to remove waste products.

TABLE 17.1 ANATOMIC AND PHYSIOLOGIC COMPARISON OF THE FETUS AND NEWBORN

Topic of Comparison	Fetus	Newborn
Respiratory system	Fluid-filled, high-pressure system causes blood to be shunted from the lungs through the ductus arteriosus to the rest of the body	Air-filled, low-pressure system encourages blood flow through the lungs for gas exchange; increased oxygen content of blood in the lungs contributes to the closing of the ductus arteriosus (becomes a ligament)
Site of gas exchange	Placenta	Lungs
Circulation through the heart	Pressures in the right atrium are greater than in the left, encouraging blood flow through the foreman ovale	Pressures in the left atrium are greater than in the right, causing the foreman ovale to close
Hepatic portal circulation	Ductus venosus bypasses; maternal liver performs filtering functions	Ductus venosus closes (becomes a ligament); hepatic portal circulation begins
Thermoregulation	Body temperature is maintained by maternal body temperature and the warmth of the intrauterine environment	Body temperature is maintained through a flexed posture and brown fat

Adapted from Sharma, A., Ford, S., & Calvert, J. (2014). Adaptation for life: A review of neonatal physiology. *Anesthesia & Intensive Care Medicine, 15*(3), 89–95; Stave, U. (2014). *Perinatal physiology*. New York, NY: Springer Publishers; and King, T. L., Brucker, M. C., Kriebs, J. M., Fahey, J. O., Gegor, C. L., & Varney, H. (2015). *Varney's midwifery*. (5th ed.). Burlington, MA: Jones & Bartlett Learning.

At birth, the circulatory system must switch from fetal to newborn circulation and from placental to pulmonary gas exchange. Successful transition from fetal to postnatal circulation requires increased pulmonary blood flow, removal of the

placenta, and closure of the intracardiac (foramen ovale) and extracardiac shunts (ductus venosus and ductus arteriosus). These changes are needed to equalize the right ventricular output with that of the left (Stark & Eichenwald, 2016). The physical forces of the contractions of labor and birth, mild asphyxia, increased intracranial pressure as a result of cord compression and uterine contractions, and the cold stress experienced immediately after birth lead to an increased release of catecholamines that is critical for the changes involved in the transition to extrauterine life. The increased levels of epinephrine and norepinephrine stimulate increased cardiac output and contractility, surfactant release, and promotion of pulmonary fluid clearance (Sharma, Ford, & Calvert, 2014).

Fetal to Neonatal Circulation Changes

Changes in circulation occur immediately at birth as the fetus separates from the placenta (Fig. 17.1). When the umbilical cord is clamped, the first breath is taken and the lungs begin to function. As a result, systemic vascular resistance increases and blood return to the heart via the inferior vena cava decreases. Concurrently with these changes, there is a rapid decrease in pulmonary vascular resistance and an increase in pulmonary blood flow (Cuneo, 2014). The foramen ovale functionally closes with a decrease in pulmonary vascular resistance, which leads to a decrease in right-sided heart pressures. An increase in systemic pressure, after clamping of the cord, leads to an increase in left-sided heart pressures. The ductus arteriosus, ductus venosus, and umbilical vessels that were vital during fetal life are no longer needed. Over a period of months these fetal vessels form nonfunctional ligaments.

Before birth, the foramen ovale allowed most of the oxygenated blood entering the right atrium from the inferior vena cava to pass into the left atrium of the heart. With the newborn's first breath, air pushes into the lungs, triggering an increase in pulmonary blood flow and pulmonary venous return to the left side of the heart. As a result, the pressure in the left atrium becomes higher than in the right atrium. The increased left atrial pressure causes the foramen ovale to close, thus allowing the output from the right ventricle to flow entirely to the lungs. With closure of this fetal shunt, oxygenated blood is now separated from nonoxygenated blood. The subsequent increase in tissue oxygenation further promotes the increase in systemic blood pressure and continuing blood flow to the lungs. The foramen ovale normally closes functionally at birth when left

atrial pressure increases and right atrial pressure decreases. Permanent anatomic closure, though, really occurs throughout the next several weeks.

During fetal life, the ductus arteriosus, located between the aorta and the pulmonary artery, protected the lungs against circulatory overload by shunting blood (right to left) into the descending aorta, bypassing the pulmonary circulation. Its patency during fetal life is promoted by continual production of prostaglandin E2 (PGE2) by the ductus arteriosus (van Vonderen et al., 2014). The ductus arteriosus becomes functionally closed within the first few hours after birth. Oxygen is the most important factor in controlling its closure. Closure depends on the high oxygen content of the aortic blood that results from aeration of the lungs at birth. At birth, pulmonary vascular resistance decreases, allowing pulmonary blood flow to increase and oxygen exchange to occur in the lungs. It occurs secondary to an increase in PO_2 coincident with the first breath and umbilical cord occlusion when it is clamped.

The ductus venosus shunted blood from the left umbilical vein to the inferior vena cava during intrauterine life. It closes within a few days after birth because this shunting is no longer needed as a result of activation of the liver. The activated liver now takes over the functions of the placenta (which was expelled at birth). The ductus venosus becomes a ligament in extrauterine life.

The two umbilical arteries and one umbilical vein begin to constrict at birth because with placental expulsion, blood flow ceases. In addition, peripheral circulation increases. Thus, the vessels are no longer needed and they too become ligaments. Successful transition and closure of the three fetal shunts creates a neonatal circulation where deoxygenated blood returns to the heart through the inferior and superior vena cava. Deoxygenated blood enters the right atrium then into the right ventricle and travels through the pulmonary artery to the pulmonary vascular bed. Oxygenated blood returns through pulmonary veins to the left atrium, the left ventricle, and through the aorta to the systemic circulation (Stave, 2014). Box 17.1 provides a summary of fetal to neonatal circulation.

Heart Rate

During the first few minutes after birth, the newborn's heart rate is approximately 110 to 160 bpm. Thereafter, it begins to decrease to an average of 120 to 130 bpm (Creasy et al., 2014). The newborn is highly dependent on heart rate for maintenance of cardiac output and blood pressure. Although blood

pressure is not taken routinely in the healthy term newborn, it is usually highest after birth and reaches a plateau within a week after birth. Cardiac defects may be identified in the newborn nursery by conducting a thorough and systematic physical assessment, including inspection, palpation, auscultation, and measurement of blood pressure and oxygen saturations. The ability of the nurse to identify irregular findings during physical assessment aids rapid identification and treatment.

B

FIGURE 17.1 Cardiovascular adaptations of the newborn. Note the changes in oxygenation between (**A**) prenatal circulation and (**B**) postnatal (pulmonary) circulation.

Transient functional cardiac murmurs may be heard during the neonatal period as a result of the changing dynamics of the cardiovascular system at birth (Fillipps & Bucciarelli, 2015).

The fluctuations in both the heart rate and blood pressure tend to follow the changes in the newborn's behavioral state. An increase in activity, such as wakefulness, movement, or crying, corresponds to an increase in heart rate and blood pressure. In contrast, the compromised newborn demonstrates markedly less physiologic variability overall. Tachycardia may be found with volume depletion, cardiorespiratory disease, drug withdrawal, and hyperthyroidism. Bradycardia is often associated with apnea and is often seen with hypoxia.

Blood Volume

The blood volume of the newborn depends on the amount of blood transferred from the placenta at birth. It is usually estimated to be 80 to 85 mL/kg of body weight in the term infant (Stave, 2014). However, the volume may vary by as much as 25% to 40%, depending on when clamping of the umbilical cord occurs. Early (before 30 to 40 seconds) or late (after 3 minutes) clamping of the umbilical cord changes circulatory dynamics during transition. Recent studies indicate that the benefits of delayed cord clamping include improving the newborn's cardiopulmonary adaptation, preventing iron-deficient anemia in full-term newborns without increasing hypervolemia-related risks and increased iron stores, increasing blood pressure, improving oxygen transport, and increasing red blood cell flow (McAdams, 2014). Although a tailored approach is required in the case of cord clamping, current available data suggests that delayed cord clamping offers the newborn many benefits physiologically, which include at least a 30% increase in blood volume for term infants and a 50% increase in preterm infants, improvement of systemic blood pressure, increase in the cerebral oxygen index, higher hemoglobin levels at 24 to 48 hours of age, and increased serum iron levels at 4 to 6 months (Kluckow & Hooper, 2015; Leslie, 2015). Cord blood has also been described as "nature's first stem cell transplant" because it possesses regenerative properties and can grow into different types of cells in the body (van Vonderen et al., 2014).

BOX 17.1

SUMMARY OF FETAL TO NEONATAL CIRCULATION

- Clamping umbilical cord at birth eliminates the placenta as a reservoir for blood.
- Onset of respirations causes a rise in PO_2 in the lungs and a decrease in pulmonary vascular resistance, *which…*
- Increases pulmonary blood flow and increases pressure in the left atrium, *which…*
- Decreases pressure in the right atrium of the heart, which causes closure of the foramen ovale (closes within minutes after birth secondary to a decreased pulmonary vascular resistance and increased left heart pressure).
- With an increase in oxygen levels after the first breath, an increase in systemic vascular resistance occurs, *which…*
- Decreases vena cava return, which reduces blood flow in the umbilical vein (constricts, becomes a ligament with functional closing).
- Closure of the ductus venosus (becomes a ligament) causes an increase in pressure in the aorta, which forces closure of the ductus arteriosus within 10 to 15 hours after birth.

Professional organizations American Academy of Pediatrics (AAP) (2013) and American College of Obstetricians & Gynecologists (ACOG) (2014) have released opinions that support delayed cord clamping for preterm infants, but endorse further research on this procedure for term infants. WHO (2014) released a report recommending delayed cord clamping for "all births" as a best practice. A recent Cochrane Review on term infants and timing of umbilical cord clamping reported that those with delayed cord clamping had up to a 60% increase in red blood cells, high hemoglobin levels, and higher iron levels at 4 to 6 months. Infants whose cords were clamped early were twice as likely to be iron deficit at 3 to 6 months (Leslie, 2015). So, at this time, there is no uniform agreement about this practice.

Blood Components

The fetus has more red blood cells per cubic millimeter than an adult and they have a greater affinity for oxygen at a lower oxygen pressure than adult red blood cells. Fetal red blood cells are larger in size when compared to an adult, thus each cell can carry more oxygen (Stave, 2014). After birth, the red blood cell count gradually increases as the cell size decreases, because the cells now live in an environment with much higher PO_2. A newborn's red blood cells have a life span of 80 to 100 days, compared with 120 days in adults.

Hemoglobin initially declines as a result of a decrease in neonatal red cell mass (physiologic anemia of infancy). Leukocytosis (elevated white blood cells) is present as a result of birth trauma soon after birth. The newborn's platelet count and aggregation ability are the same as those of adults.

The newborn's hematologic values are affected by the site of the blood sample (capillary blood has higher levels of hemoglobin and hematocrit compared with venous blood), placental transfusion (delayed cord clamping and normal shift of plasma to extravascular spaces, which causes higher levels of hemoglobin and hematocrit), and gestational age (increased age is associated with increased numbers of red cells and hemoglobin) (Andersson et al., 2014). Table 17.2 lists normal newborn blood values.

Respiratory System Adaptations

The newborn's transition from fetal to neonatal life includes aeration of the lungs, establishment of pulmonary gas exchange, and changing the fetal circulation into the adult type. Lung aeration leads to the establishment of functional residual capacity, allowing pulmonary gas exchange to start. The first breath of life is a gasp that generates an increase in transpulmonary pressure and results in diaphragmatic descent. Hypercapnia, hypoxia, and acidosis resulting from normal labor become stimuli for initiating respirations. Inspiration of air and expansion of the lungs allow for an increase in tidal volume (amount of air brought into the lungs). **Surfactant** is a surface tension–reducing lipoprotein found in the newborn's lungs that prevents alveolar collapse at the end of expiration and loss of lung volume. It lines the alveoli to enhance aeration of gas-free lungs, thus reducing surface tension and lowering the pressure required to open the alveoli. Normal lung function depends on surfactant, which permits a decrease in surface tension at end expiration (to prevent atelectasis) and an increase in surface tension during lung expansion (to facilitate elastic recoil on inspiration). Surfactant provides the lung stability needed for gas exchange. The newborn's first breath, in conjunction with surfactant, overcomes the surface forces to permit aeration of the lungs. The chest wall of the newborn is floppy because of the high cartilage content and poorly developed musculature. Thus, accessory muscles to help in breathing are ineffective.

TABLE 17.2 NORMAL NEWBORN BLOOD VALUES

Lab Data	Normal Range
Hemoglobin	16–18 g/dL
Hematocrit	46–68%
Platelets	150,000–350,000/µL
Red blood cells	4.5–7.0 (1,000,000/µL)
White blood cells	10–30,000/mm^3

(2014). *Fast facts for the neonatal nurse: A nursing orientation and care guide in a nutshell.* New York, NY: Springer.

One of the most crucial adaptations that the newborn makes at birth is adjusting from a fluid-filled intrauterine environment to a gaseous extrauterine environment. During fetal life, the lungs are expanded with an ultrafiltrate of the amniotic fluid. During and after birth, this fluid must be removed and replaced with air. Passage through the birth canal allows intermittent compression of the thorax, which helps eliminate the fluid in the lungs. Pulmonary capillaries and the lymphatics remove the remaining fluid.

If fluid is removed too slowly or incompletely (e.g., with decreased thoracic squeezing during birth or diminished respiratory effort), transient tachypnea (respiratory rate above 60 bpm) of the newborn occurs. Examples of situations involving decreased thoracic compression and diminished respiratory effort include cesarean birth and sedation in newborns. Research findings support the need for thoracic compression because the absence of the neonate's exposure to labor contractions, which may occur with cesarean births or heavy sedation during the labor process or general anesthesia administered during the surgical birth, is associated with an increased risk of transient tachypnea at term, with oxygen supplementation being needed for a longer duration (Hooper, Polglase, & Roehr, 2015).

Take Note!

A neonate born by cesarean section does not have the same benefit of the birth canal squeeze as does the newborn born by vaginal delivery. Closely observe the respirations of the newborn after cesarean delivery.

Lungs

Before the newborn's lungs can maintain respiratory function, the following events must occur:

• Initiation of respiratory movement

• Expansion of the lungs

• Establishment of functional residual capacity (ability to retain some air in the lungs on expiration)

• Increased pulmonary blood flow

• Redistribution of cardiac output (Bope & Kellerman, 2015)

Initial breathing is probably the result of a reflex triggered by pressure changes, noise, light, temperature changes, touching, compression of the fetal chest during the birthing process, and high carbon dioxide and low oxygen concentrations of the newborn's blood. Central chemoreceptors stimulated by hypoxia and hypercapnia further increase the respiratory drive. Many theories address the initiation of respiration in the newborn, but most are based on speculation from observations rather than on empirical research (Sharma et al., 2014). Research continues to search for answers to these questions.

Respirations

After respirations are established in the newborn, they are shallow and irregular, ranging from 30 to 60 breaths per minute, with short periods of apnea (less than 15 seconds). The newborn's respiratory rate varies according to his or her activity; the more active the newborn, the higher the respiratory rate, on average. Signs of respiratory distress to observe for include cyanosis, tachypnea, expiratory grunting, sternal retractions, and nasal flaring. Respirations should not be labored, and the chest movements should be symmetric. In some cases, **periodic breathing** may occur, which is the cessation of breathing that lasts 5 to 10 seconds without changes in color or heart rate (Davidson, 2014). Periodic breathing may be observed in newborns within the first few days of life and requires close monitoring.

Take Note!

Apneic periods lasting more than 15 seconds with cyanosis and heart rate changes require further evaluation (Mattson & Smith, 2015).

Body Temperature Regulation

Newborns are dependent on their environment for the maintenance of body temperature, much more so immediately after birth than later in life. One of the most important elements in a newborn's survival is obtaining a stable body temperature to promote an optimal transition to extrauterine life. On average, a newborn's temperature ranges from 97.9° to 99.7°F (36.6° to 37.6°C). Since newborns lose heat easily after birth, having skin-to-skin contact with their mothers is recommended as the initial method for maintaining newborn body temperature. Skin-to-skin contact should be the first line of treatment for hypothermia and as a measure to reduce discomfort from painful procedures. See Evidence-Based Practice 17.1.

Thermoregulation is the process of maintaining the balance between heat loss and heat production in order to maintain the body's core internal temperature. It is a critical physiologic function that is closely related to the transition and survival of the newborn. An appropriate thermal environment is essential for maintaining a normal body temperature. Compared with adults, newborns tolerate a narrower range of environmental temperatures and are extremely vulnerable to both under heating and overheating. Nurses play a key role in providing an appropriate environment to help newborns maintain thermal stability (Fig. 17.2).

FIGURE 17.2 Father and mother looking at their newborn after birth. Note the newborn's hat and warm blanket to preserve body heat.

Heat Loss

Newborns have several characteristics that predispose them to heat loss:

• Thin skin with blood vessels close to the surface

• Lack of shivering ability to produce heat until 3 months old

• Limited stores of metabolic substrates (glucose, glycogen, fat)

• Limited use of voluntary muscle activity or movement to produce heat

• Large body surface area relative to body weight

• Lack of subcutaneous fat, which provides insulation

• Little ability to conserve heat by changing posture (fetal position)

• No ability to adjust their own clothing or blankets to achieve warmth

• Inability to communicate that they are too cold or too warm

> **EVIDENCE-BASED PRACTICE 17.1 EFFECT OF EARLY MATERNAL/NEWBORN SKIN-TO-SKIN CONTACT AFTER BIRTH ON THE DURATION OF THIRD STAGE OF LABOR AND INITIATION OF BREAST-FEEDING**

STUDY

The holding of a newborn with vertical skin-to-skin contact typically in an upright position with the swaddled newborn on the chest of the mother, is commonly referred to as kangaroo care. It has been recommended that this skin-to-skin contact is a feasible, natural, and cost-effective intervention for breast-feeding initiation and thermoregulation. The aim of this study was to determine the effect of early maternal–newborn skin-to-skin contact after birth on the duration of the third stage of labor and initiation of breast-feeding.

Findings

A nonrandomized controlled clinical trial was conducted using a sample of 100 laboring women. The project included a study group (50) who had skin-to-skin contact and a control group (50) who received routine hospital care. Tools used to collect data included a structured interview, assessment of mothers during the third stage of labor, and an outcome assessment of first breast-feeding. The results revealed that success in first-time breast-feeding during the complete separation of the placenta and immediate contraction of the uterus was higher in the study group compared to the control group. There were statistically significant differences between the study and control groups in third stage of labor duration (9 minutes shorter), complete placental separation, and immediate contraction of the uterus or excessive bleeding. The study concluded that mothers who practice early mother/newborn skin-to-skin contact immediately after giving birth experienced a shorter third stage duration and early successful initiation of breast-feeding.

Every newborn struggles to maintain body temperature from the moment of birth, when the newborn's wet body is exposed to the much cooler environment of the birthing room. The amniotic fluid covering the newborn cools as it evaporates rapidly in the low humidity and air conditioning of the room. The newborn's temperature may decrease 3 to 5 degrees within minutes after leaving the warmth of the mother's uterus (99.6°F [37.5°C]). The skin of newborns adjusts quickly to the challenging environmental conditions of extrauterine life. However, certain functions, for example, microcirculation, continue to develop even beyond the neonatal period (McCall et al., 2014).

Consider This

When I look down at my little miracle of life in my arms, I can't help but beam with pride at this great accomplishment. She seems so vulnerable and defenseless, and yet is equipped with everything she needs to survive at birth. When the nurse brought my daughter in for the first time after birth, I wanted to see and feel every part of her. Much to my dismay, she was wrapped up like a mummy in a blanket and she had a pink knit cap on her head. I asked the nurse why all the babies had to look like they were bound for the North Pole with all these layers on. Wasn't the nurse aware it was summertime and

probably at least 85 degrees outside?

The nurse explained that newborns lose body heat easily and need to be kept warm until their temperature stabilizes. Even though I wanted to get up close and personal with my baby, I decided to keep the pink polar bear outfit on her.

Thoughts: Newborns may be born with "everything they need to survive" on the outside, but they still experience temperature instability and lose heat through radiation, evaporation, convection, and conduction. Because the newborn's head is the largest body part, a great deal of heat can be lost if a cap is not kept on the head. What guidance can be given to this mother before discharge to stabilize her daughter's temperature while at home? What simple examples can be used to demonstrate your point?

The transfer of heat depends on the temperature of the environment, air speed, and water vapor pressure or humidity. Heat exchange between the environment and the newborn involves the same mechanisms as those with any physical object and its environment. Heat can be lost by four mechanisms including conduction (3%), convection (34%), evaporation (24%), and radiation (39%) (Sharma et al., 2014). Prevention of heat loss is a key nursing intervention (Fig. 17.3).

CONDUCTION

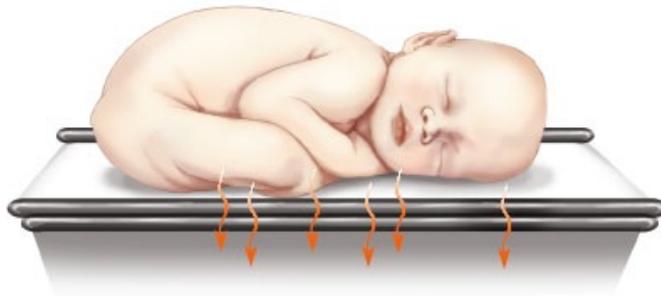
Conduction involves the transfer of heat from one object to another when the two objects are in direct contact with each other. Conduction refers to heat fluctuation between the newborn's body surface when in contact with other solid surfaces, such as a cold mattress, scale, or circumcision restraining board. Heat loss by conduction can also occur when touching a newborn with cold hands or when the newborn has direct contact with a colder object such as a metal scale. Using a warmed cloth diaper or blanket to cover any cold surface touching a newborn directly helps to prevent heat loss through conduction. Placing the newborn skin-to-skin with the mother also helps prevent heat loss through conduction.

CONVECTION

Convection involves the flow of heat from the body surface to cooler surrounding air or to air circulating over a body surface. An example of

convection-related heat loss would be a cool breeze that flows over the newborn. To prevent heat loss by this mechanism, keep the newborn out of direct cool drafts (open doors, windows, fans, air conditioners) in the environment, work inside an isolette as much as possible and minimize opening portholes that allow cold air to flow inside, and warm any oxygen or humidified air that comes in contact with the newborn. Using clothing and blankets in isolettes is an effective means of reducing the newborn's exposed surface area and providing external insulation. Also, transporting the newborn to the nursery in a warmed isolette, rather than carrying him or her, helps to maintain warmth and reduce exposure to the cool air.

EVAPORATION

Evaporation involves the loss of heat when a liquid is converted to vapor. Evaporative loss may be insensible (such as from skin and respiration) or sensible (such as from sweating). Insensible loss occurs, but the individual is not aware of it. Sensible loss is objective and can be noticed. It depends on air speed and the absolute humidity of the air. For example, when the baby is born, the body is covered with amniotic fluid. The fluid evaporates into the air, leading to heat loss. Heat loss via evaporation also occurs when bathing a newborn. Drying newborns immediately after birth with warmed blankets and placing a cap on their head will help to prevent heat loss through evaporation. In addition, drying the newborn after bathing will help prevent heat loss through evaporation. Promptly changing wet linens, clothes, or diapers will also reduce heat loss and prevent chilling.


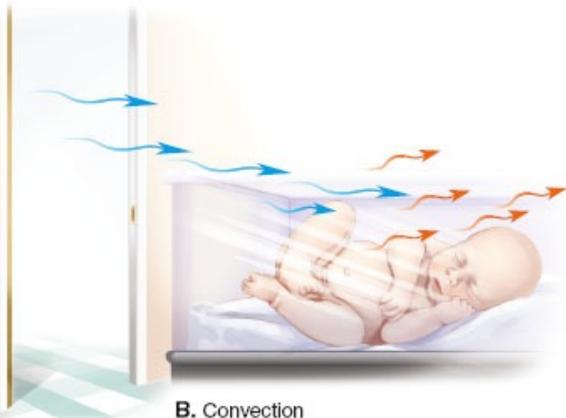


FIGURE 17.3 The four mechanisms of heat loss in the newborn. **A.** Conduction. **B.** Convection. **C.** Evaporation. **D.** Radiation.

RADIATION

Radiation involves the loss of body heat to cooler, solid surfaces that are in proximity but not in direct contact with the newborn. The amount of heat loss

depends on the size of the cold surface area, the surface temperature of the newborn's body, and the temperature of the receiving surface area. For example, when a newborn is placed in a single-wall isolette next to a cold window, heat loss from radiation occurs. Newborns will become cold even though they are in a heated isolette. To reduce heat loss by radiation, keep cribs and isolettes away from outside walls, cold windows, and air conditioners. Also, using radiant warmers for transporting newborns and when performing procedures that may expose the newborn to the cooler environment will help reduce heat loss.

A warmed transporter is an enclosed isolette on wheels. A radiant warmer is an open bed with a radiant heat source above. This type of environment allows health care providers to reach the newborn to carry out procedures and treatments.

Overheating

The newborn is also prone to overheating. Limited insulation and limited sweating ability can predispose any newborn to overheating. Control of body temperature is achieved via a complex negative feedback system that creates a balance between heat production, heat gain, and heat loss. The primary heat regulator is located in the hypothalamus and the central nervous system. The immaturity of the newborn's central nervous system makes it difficult to create and maintain this balance. Therefore, the newborn can become overheated easily. For example, an isolette that is too warm or one that is left too close to a sunny window may lead to hyperthermia. Although heat production can substantially increase in response to a cool environment, basal metabolic rate and the resultant heat produced cannot be reduced. Overheating increases fluid loss, the respiratory rate, and the metabolic rate considerably.

Thermoregulation

Humans have the ability to regulate their body temperature within a narrow range. Newborns have a decreased ability to regulate their body temperature, producing heat through nonshivering thermogenesis. Thermoregulation, the balance between heat loss and heat production, is related to the newborn's rate of metabolism and oxygen consumption. The newborn attempts to conserve heat and increase heat production by increasing the metabolic rate, increasing muscular activity through movement, increasing peripheral vasoconstriction, and assuming a fetal position to hold in heat and minimize exposed body surface

area.

Concept Mastery Alert

Effects of Cold Stress in the Newborn's Brown Fat Metabolism

The newborn first experiences an increase in norepinephrine in response to a cold environment. This then influences the triglycerides to stimulate brown fat metabolism.

An environment in which body temperature is maintained without an increase in metabolic rate or oxygen use is called a **neutral thermal environment**. Within a neutral thermal environment, the rates of oxygen consumption and metabolism are minimal, and internal body temperature is maintained because of thermal balance. A neutral thermal environment promotes growth and stability, conserves energy for basic bodily functions, and minimizes heat (energy) and water loss (Knobel, 2014). Because newborns have difficulty maintaining their body heat through shivering or other mechanisms, they need a higher environmental temperature to maintain a neutral thermal environment. If the environmental temperature decreases, the newborn responds by consuming more oxygen. The respiratory rate increases (tachypnea) in response to the increased need for oxygen. As a result the newborn's metabolic rate increases.

As noted earlier, the newborn's primary method of heat production is through nonshivering thermogenesis. This is a process in which brown fat (adipose tissue) is oxidized in response to cold exposure. Brown fat is a special kind of highly vascular fat found only in newborns. Brown adipose tissue is a unique tissue that is able to convert chemical energy directly into heat when activated by the sympathetic nervous system. It is produced during the third trimester; ordinarily disappears by 3 to 5 weeks after birth and is vital for thermogenesis. The brown coloring is derived from the fat's rich supply of blood vessels and nerve endings. These fat deposits, which are capable of intense metabolic activity—and thus can generate a great deal of heat—are found between the scapulae, axillae, at the nape of the neck, in the mediastinum, and in areas surrounding the kidneys and adrenal glands. Brown fat makes up about 6% of

term body weight in the full-term newborn (Betz & Enerback, 2015). When the newborn experiences a cold environment, norepinephrine is released. This in turn stimulates brown fat metabolism by breaking down triglycerides. Cardiac output increases, increasing blood flow through the brown fat tissue. Subsequently, this blood becomes warmed as a result of the increased metabolic activity of the brown fat (Fig. 17.4).

Newborns can experience heat loss through all four mechanisms, ultimately resulting in cold stress. **Cold stress** is excessive heat loss that requires a newborn to use compensatory mechanisms (such as nonshivering thermogenesis and tachypnea) to maintain core body temperature (Davidson, 2014). The consequences of cold stress can be quite severe. As the body temperature decreases, the newborn becomes less active, lethargic, hypotonic, and weaker. All newborns are at risk for cold stress, particularly within the first 12 hours of life. However, preterm newborns are at the greatest risk for cold stress and experience more profound effects than full-term newborns because they have fewer fat stores, poorer vasomotor responses, and less insulation to cope with a hypothermic event.

FIGURE 17.4 Areas of brown fat in a newborn.

Cold stress in the newborn can lead to the following problems if not reversed: depleted brown fat stores, increased oxygen needs, respiratory distress, increased glucose consumption leading to hypoglycemia, metabolic acidosis, jaundice, hypoxia, and decreased surfactant production (Mattson & Smith, 2015).

Nurses must be aware of the thermoregulatory needs of the newborn and must ensure that these needs are met to provide the newborn with the best start possible. Maintenance of temperature stability should be focused on preventative measures.

To minimize the effects of cold stress and maintain an NTE, the following interventions are helpful:

• Prewarming blankets and hats to reduce heat loss through conduction

• Keeping the infant transporter (warmed isolette) fully charged and heated at all times

• Drying the newborn completely after birth to prevent heat loss from evaporation

• Encouraging skin-to-skin contact with the mother if the newborn is stable

• Promoting early breast-feeding to provide fuels for nonshivering thermogenesis

• Using heated and humidified oxygen

• Always using radiant warmers and double-wall isolettes to prevent heat loss from radiation

• Deferring bathing until the newborn is medically stable, and using a radiant heat source while bathing (Fig. 17.5)

• Avoiding the placement of a skin temperature probe over a bony area or one with brown fat, because it does not give an accurate assessment of the whole body temperature (most temperature probes are placed over the liver when the newborn is supine or side-lying)

FIGURE 17.5 Bathing a newborn under a radiant warmer to prevent heat loss.

The preceding interventions allow the newborn to minimize his or her metabolic rate and oxygen consumption, thereby conserving vital energy stores required for optimum growth.

Hepatic System Function

The liver has an essential role in the synthesis, degradation, and regulation of pathways involved in the metabolism of carbohydrates, proteins, lipids, trace elements, and vitamins. At birth, the newborn's liver slowly assumes the functions that the placenta handled during fetal life. Most enzymatic pathways are present in the newborn, but are inactive at birth and generally become fully active at 3 months of age. These functions include blood coagulation, and also iron storage, carbohydrate metabolism, and conjugation of bilirubin, as discussed next. Glycogen reserves provide energy and may become depleted if the metabolic needs of the newborn increase, such as during cold or respiratory stress.

Iron Storage

As red blood cells are destroyed after birth, their iron is released and stored by the liver until new red cells need to be produced. Newborn iron stores are determined by total body hemoglobin content and length of gestation. If the mother's iron intake was adequate during pregnancy, sufficient iron has been stored in the newborn's liver for use during the first 6 months of age.

Carbohydrate Metabolism

Glucose is an essential fuel for brain metabolism. When the placenta is lost at birth, the maternal glucose supply is cut off. Initially, the newborn's serum glucose levels decline. Newborns must learn to regulate their blood glucose concentration and adjust to an intermittent feeding schedule. Usually, a term newborn's blood glucose level is 70% to 80% of the maternal blood glucose level at birth. Hypoglycemia is one of the most frequent problems encountered, and maintaining glucose homeostasis is one of the important physiologic events during the fetal-to-newborn transition. During the first 24 to 48 hours of life, as normal neonates transition from intrauterine to extrauterine life, their plasma glucose levels are usually lower than later in life (Thornton et al., 2015).

Glucose is the main source of energy for the first several hours after birth. With the newborn's increased energy needs after birth, the liver releases glucose from glycogen stores for the first 24 hours. Initiating early breast-feeding or bottle feeding helps to stabilize the newborn's blood glucose levels. No evidence

supports universal invasive routine measurement of glucose in healthy term newborns. Selective screening of at-risk newborns is more appropriate (Adamkin, 2015).

Bilirubin Conjugation

The liver is also responsible for the conjugation of bilirubin—a yellow-to-orange bile pigment produced by the breakdown of red blood cells. In utero, elimination of bilirubin in the blood is handled by the placenta and the mother's liver. However, once the cord is cut, the newborn must now assume this function.

Bilirubin normally circulates in plasma, is taken up by liver cells, and is changed to a water-soluble pigment that is excreted in the bile. This conjugated form of bilirubin is excreted from liver cells as a constituent of bile.

The principal source of bilirubin in the newborn is the hemolysis of erythrocytes. This is a normal occurrence after birth, when fewer red blood cells are needed to maintain extrauterine life. When red blood cells die after approximately 80 days of life, the heme in their hemoglobin is converted to bilirubin. Bilirubin is released in an unconjugated form called indirect bilirubin, which is fat soluble. Enzymes, proteins, and different cells in the reticuloendothelial system and liver process the unconjugated bilirubin into conjugated bilirubin or direct bilirubin. This form is water soluble and now enters the gastrointestinal system via the bile and is eventually excreted through feces. The kidneys also excrete a small amount.

Newborns produce bilirubin at a rate of approximately 6 to 8 mg/kg/day. This is more than twice the production rate in adults, primarily because of relative polycythemia and increased red blood cell turnover. Bilirubin production typically declines to the adult level within 10 to 14 days after birth (Bhutani et al., 2015). In addition, the metabolic pathways of the liver are relatively immature and thus cannot conjugate bilirubin as quickly as needed.

Failure of the liver cells to break down and excrete bilirubin can cause an increased amount of bilirubin in the bloodstream, leading to jaundice (Sharma et al., 2014). Bilirubin is toxic to the body and must be excreted. Blood tests ordered to determine bilirubin levels measure bilirubin in the serum. Total bilirubin is a combination of indirect (unconjugated) and direct (conjugated) bilirubin. When unconjugated bilirubin pigment is deposited in the skin and mucous membranes as a result of increased bilirubin levels, **jaundice**, also known as icterus, develops, with a yellowing of the skin, sclera, and mucous

membranes. Visible jaundice as a result of increased blood bilirubin levels occurs in more than half of all healthy newborns. Even in healthy term newborns, extremely elevated blood levels of bilirubin during the first week of life can cause bilirubin encephalopathy, a permanent and devastating form of brain damage (Wong & Bhutani, 2015).

Common risk factors for the development of jaundice include fetal–maternal blood group incompatibility, prematurity, asphyxia at birth, an insufficient intake of milk during breast-feeding, drugs (such as diazepam [Valium], oxytocin [Pitocin], sulfisoxazole/erythromycin [Pediazole], and chloramphenicol [Chloromycetin]), maternal gestational diabetes, infrequent feedings, male gender, trauma during birth, resulting in cephalhematoma, cutaneous bruising from birth trauma, polycythemia, previous sibling with hyperbilirubinemia, intrauterine infections such as TORCH (toxoplasmosis, other viruses, rubella, cytomegalovirus, herpes simplex viruses), and ethnicity such as Asian or Native American (Moses, 2015).

The causes of newborn jaundice can be classified into three groups based on the mechanism of accumulation:

1. Bilirubin overproduction, such as from blood incompatibility (Rh or ABO), drugs, trauma at birth, polycythemia, delayed cord clamping, and breast milk jaundice

2. Decreased bilirubin conjugation, as seen in physiologic jaundice, hypothyroidism, and breast-feeding

3. Impaired bilirubin excretion, as seen in biliary obstruction (biliary atresia, gallstones, neoplasm), sepsis, hepatitis, chromosomal abnormality (Turner syndrome, trisomies 18 and 21), and drugs (aspirin, acetaminophen, sulfa, alcohol, steroids, antibiotics) (Nagtalon-Ramos, 2014)

Jaundice in the newborn is discussed in more detail in Chapter 24.

Gastrointestinal System Adaptations

The full-term newborn has the capacity to swallow, digest, metabolize, and absorb food taken in soon after birth. At birth, the pH of the stomach contents is mildly acidic, reflecting the pH of the amniotic fluid. The once-sterile gut changes rapidly, depending on what feeding is received. Bowel sounds are normally heard shortly after birth, but may be hypoactive on the first day.

Mucosal Barrier Protection

Humans start their development in a sterile intrauterine environment, but from the very moment of birth all epithelial surfaces in direct contact with the environment (skin, respiratory, gastrointestinal, and urogenital tract) are colonized by microorganisms. An important adaptation of the gastrointestinal system is the development of a mucosal barrier to prevent the penetration of harmful substances (bacteria, toxins, and antigens) present within the intestinal lumen. At birth, the newborn must be prepared to deal with bacterial colonization of the gut. Colonization is dependent on oral intake. Nutrition, be it breast milk or formula, plays a major role in early colonization patterns in the neonatal gut. It usually occurs within 24 hours of age and is required for the production of vitamin K (Gritz & Bhandari, 2015). After birth, environmental, oral, and cutaneous microbes from the mother will be mechanically transferred to the newborn by several processes including suckling, kissing, and caressing. Thus, the proximity of the birth canal and the anus, as well as parental expression of neonatal care, are effective methods of ensuring transmission of microbes from one generation to the next. If harmful substances are allowed to penetrate the mucosal epithelial barrier under pathologic conditions, they can cause inflammatory and allergic reactions (Nylund et al., 2014).

Take Note!

Human breast milk provides a passive mechanism to protect the newborn against the dangers of a deficient intestinal defense system. It contains antibodies, viable leukocytes, and many other substances that can interfere with bacterial colonization and prevent harmful penetration.

Stomach and Digestion

The newborn must rapidly adapt from receiving all nutrient and energy requirements via the placenta to obtaining them orally after birth. The physiologic capacity of the newborn stomach is considerably less than its anatomic capacity. There is a rapid gain in physiologic capacity during the first 4 days of life. After the first 4 days, the anatomic and physiologic capacities more closely approximate each other. Researchers have found that for the first 24 hours after birth, the newborn's small stomach does not stretch to hold more, as it will within a day or two later (Batchelor, 2014). This explains the experience of countless hospital nurses who have learned the hard way that when newborns are fed an ounce or two by bottle during the first day of life, most of it tends to come right back up. The walls of the newborn stomach stay firm, expelling extra milk rather than stretching to hold it.

For bottle-fed newborns, small, frequent feedings set up a healthy eating pattern right from the start (breast-fed newborns self-regulate how much they consume). Experts now advise adults that it is healthier to eat smaller amounts more often and the same is true for babies and children. Coaxing an infant to take more milk leads to overfeeding. If feeling overfull at feedings becomes the norm for a young infant, this may lead to unhealthy eating habits that contribute to childhood and adult obesity later. Early onset obesity is a precursor to a life-long weight struggle and numerous comorbidities (Redsell et al., 2015; Reilly & Hughes, 2015).

The cardiac sphincter and nervous control of the stomach is immature, which may lead to uncoordinated peristaltic activity and frequent regurgitation. Immaturity of the pharyngoesophageal sphincter and absence of lower esophageal peristaltic waves also contribute to the reflux of gastric contents. Avoiding overfeeding and stimulating frequent burping may minimize regurgitation. Most digestive enzymes are available at birth, allowing newborns to digest simple carbohydrates and protein. However, they have limited ability to digest complex carbohydrates and fats, because amylase and lipase levels are low at birth. As a result, newborns excrete a fair amount of lipids, resulting in fatty stools.

Adequate digestion and absorption are essential for newborn growth and development. Normally, term newborns lose 5% to 10% of their birth weight as a result of insufficient caloric intake within the first week after birth, shifting of intracellular water to extracellular space, and insensible water loss. To gain

weight, the term newborn requires an intake of 108 kcal/kg/day from birth to 6 months of age. Understanding the role and importance of nutrition in early postnatal life on growth and development is vital, but how it links to later health has the potential of health benefits for all future generations (Robinson, 2015).

Bowel Elimination

The frequency, consistency, and type of stool passed by newborns vary widely. The evolution of a stool pattern begins with a newborn's first stool, which is meconium. **Meconium** is composed of amniotic fluid, shed mucosal cells, intestinal secretions, and blood. It is greenish black, has a tarry consistency, and is usually passed within 12 to 24 hours of birth. The first meconium stool passed is semisterile, but this changes rapidly with ingestion of bacteria through feedings. After feedings are initiated, a transitional stool develops, which is greenish brown to yellowish brown, thinner in consistency, and seedy in appearance. If breast-fed, the stools will resemble light mustard with seed-like particles. If formula-fed, the stools will be tan or yellow in color and firmer. The frequency of bowel movements varies widely from one infant to another.

Take Note!

Newborns that are fed early pass stools sooner, which helps to reduce bilirubin buildup (Mattson & Smith, 2015).

The last development in the stool pattern is the milk stool. Its characteristics differ in breast-fed and formula-fed newborns. The stools of the breast-fed newborn are yellow-gold, loose, and stringy to pasty in consistency, and typically sour-smelling. The stools of the formula-fed newborn vary depending on the type of formula ingested. They may be yellow, yellow-green, or greenish and loose, pasty, or formed in consistency, and they have an unpleasant odor.

Renal System Changes

A full complement of one million nephrons is present by 34 weeks gestation. The glomeruli and nephrons are functionally immature at birth, resulting in a reduced glomerular filtration rate (GFR) and limited concentrating ability. A limited ability to concentrate urine and the reduced GFR make the newborn susceptible to both dehydration and fluid overload (Sharma et al., 2014). Frequently the newborn's kidneys are described as immature, but they are able to carry out their usual responsibilities and can handle the challenge of excretion and maintaining acid–base balance. Only when the newborn is faced with unexpected imbalances of water, electrolytes, or a disruption of acid–base status secondary to a preterm birth or illness does it lack the ability to handle the body's fluid homeostasis. A newborn infant's body mass is 75% water, the highest proportion of body water at any stage of a person's life. The majority of term newborns void immediately after birth, indicating adequate renal function. Although the newborn's kidneys can produce urine, they are limited in their ability to concentrate it until about 3 months of age, when the kidneys mature more. Until that time, a newborn voids frequently and the urine has a low specific gravity (1.001 to 1.020). About six to eight voidings daily is average for most newborns; this indicates adequate fluid intake (Harshman & Brophy, 2014).

The renal cortex is relatively underdeveloped at birth and does not reach maturity until 12 to 18 months of age. The GFR is the amount of fluid filtered each minute by all the glomeruli of both kidneys and is one index of kidney function. At birth, the newborn's GFR is approximately 30% of normal adult values, reaching approximately 50% of normal adult values by the 10th day of life and full adult values by the first year of life (Chishti, 2014). The low GFR and the limited excretion and conservation capability of the kidney affect the newborn's ability to excrete salt, water loads, and drugs.

Take Note!

The possibility of fluid overload is increased in newborns; keep this in mind when administering intravenous therapy to a newborn.

Immune System Adaptations

Essential to the newborn's survival is the ability to respond effectively to hostile environmental forces. The newborn's immune system begins working early in gestation, but many of the responses do not function adequately during the early neonatal period. The newborn is protected from certain infections, in part because of maternal antibodies circulating in their system until about 6 months of age. Immunoglobulin G (IgG) crosses the placenta to the fetus while in utero. Newborns who are breast-fed receive antibodies from the breast milk, which includes IgE, IgA, IgM, and IgG (Nagtalon-Ramos, 2014). The risk of acquiring an infection is great because a newborn's immune system is immature and is not able to respond for long periods of time to fight infections. The intrauterine environment usually protects the fetus from harmful microorganisms and the need for defensive immunologic responses. With exposure to a wide variety of microorganisms at birth, the newborn must develop a balance between its host defenses and the hostile environmental organisms to ensure a safe transition to the outside world. Healthy infants begin to produce their own antibodies, starting at 2 to 3 months of age.

Responses of the immune system serve three purposes: defense (protection from invading organisms), homeostasis (elimination of worn-out host cells), and surveillance (recognition and removal of enemy cells). The newborn's immune system response involves recognition of the pathogen or other foreign material, followed by activation of mechanisms to react against and eliminate it. All immune responses primarily involve leukocytes (white blood cells).

The immune system's responses can be divided into two categories: natural and acquired immunity. These mechanisms are interrelated and interdependent; both are required for immunocompetency.

Natural Immunity

Natural immunity includes responses or mechanisms that do not require previous exposure to the microorganism or antigen to operate efficiently. Physical barriers (such as intact skin and mucous membranes), chemical barriers (such as gastric acids and digestive enzymes), and resident nonpathologic organisms make up the newborn's natural immune system. Natural immunity involves the most basic host defense responses: ingestion and killing of microorganisms by phagocytic

cells.

Acquired Immunity

Acquired immunity involves two primary processes: (1) the development of circulating antibodies or immunoglobulins capable of targeting specific invading agents (antigens) for destruction and (2) formation of activated lymphocytes designed to destroy foreign invaders. Acquired immunity is absent until after the first invasion by a foreign organism or toxin.

Immunologic ability depends heavily on immunoglobulins such as IgG, IgM, and IgA. The newborn depends largely on these three immunoglobulins for defense against microorganisms associated with illness. Newborns remain very susceptible to infections for months.

IgG is the major immunoglobulin and the most abundant, making up about 80% of all circulating antibodies (Martin, Fanaroff, & Walsh, 2014). It is found in serum and interstitial fluid. It is the only class able to cross the placenta, with active placental transfer beginning at approximately 20 to 22 weeks' gestation. IgG produces antibodies against bacteria, bacterial toxins, and viral agents.

IgA is the second most abundant immunoglobulin in the serum. IgA does not cross the placenta, and maximum levels are reached during childhood. This immunoglobulin is believed to protect mucous membranes from viruses and bacteria. IgA is predominantly found in the gastrointestinal and respiratory tracts, tears, saliva, colostrum, and breast milk.

Take Note!

A major source of IgA is human breast milk, so breast-feeding is believed to have significant immunologic advantages over formula feeding (Walker, 2014).

IgM is found in blood and lymph fluid and is the first immunoglobulin to respond to infection. It does not cross the placenta, and levels are generally low at birth unless a congenital intrauterine infection is present. IgM offers a major source of protection from blood-borne infections. The predominant antibodies formed during neonatal or intrauterine infection are of this class.

Integumentary System Adaptations

The newborn skin is critical to its transition from intrauterine to extrauterine environments and to the journey to self-sufficiency. The newborn's skin is a large organ, making up approximately 13% of body weight in contrast to 3% of body weight in an adult. It is sensitive, fragile, with a neutral pH on the surface, lower lipid content, and higher water content when compared with adults. Because of these characteristics, newborn skin is vulnerable to injury and infections (Visscher, et al., 2015). The most important function of the skin is to provide a protective barrier between the body and the environment. It limits the loss of water, prevents absorption of harmful agents, protects thermoregulation and fat storage, and protects against physical trauma. The epidermal barrier begins to develop during midgestation and is fully formed by about 32 weeks' gestation. Although the neonatal epidermis is similar to the adult epidermis in thickness and lipid composition, skin development is not complete at birth (King et al., 2015). Although the basic structure is the same as that of an adult, the less mature the newborn, the less mature the skin functions. Fewer fibrils connect the dermis and epidermis in the newborn compared with the adult. Also in a newborn, the risk of injury producing a break in the skin from the use of tapes and monitors and from handling is greater than for an adult. Improper handling of the newborn during daily skin care practices, such as bathing, can cause damage, prevent healing, and interfere with the normal maturation process.

Newborns vary greatly in appearance. Many of the variations are temporary and reflect the physiologic adaptations that the newborn is experiencing. Skin coloring varies, depending on the newborn's age, race, or ethnic group; temperature; and whether he or she is crying. Skin color changes with both the environment and health status. At birth, the newborn's skin is dark red to purple. As the newborn begins to breathe air his or her skin color changes to red. This redness normally begins to fade the first day.

Neurologic System Adaptations

The nervous system is immature and continues to develop to achieve a full complement of cortical and brainstem cells by 1 year of age. The brain increases its size threefold during the first year of life. The nervous system consists of the brain, spinal cord, 12 cranial nerves, and a variety of spinal nerves that come from the spinal cord. Neurologic development follows cephalocaudal (head-to-toe) and proximal–distal (center-to-outside) patterns. Myelin develops early on in sensory impulse transmitters. Thus, the newborn has an acute sense of hearing, smell, and taste. The newborn's sensory capabilities include:

• *Hearing*—well developed at birth, responds to noise by turning to sound.

• *Taste*—ability to distinguish between sweet and sour by 72 hours old.

• *Smell*—ability to distinguish between mother's breast milk and breast milk from others.

• *Touch*—sensitivity to pain, responds to tactile stimuli.

• *Vision*—is incomplete at birth. Maturation is dependent on nutrition and visual stimulation. Newborns have ability to focus only on close objects (8 to 10 inches away) with a visual acuity of 20/140; they can track objects in midline or beyond (90 inches). This is the least mature sense at birth. The ability to fix, follow, and be alert is indicative of an intact CNS (King et al., 2015).

Remember Maria, the new mother who is worried that her daughter can't see? What might the new mother notice about her daughter's behavior? What might be the new mother's expectations?

Congenital Reflexes

Successful adaptations demonstrated by the respiratory, circulatory, thermoregulatory, and musculoskeletal systems indirectly indicate the central nervous system's successful transition from fetal to extrauterine life, because the central nervous system plays a major role in all these adaptations. In the newborn, congenital reflexes are the hallmarks of maturity of the central nervous system, viability, and adaptation to extrauterine life.

The presence and strength of a reflex is an important indication of neurologic

development and function. A **reflex** is an involuntary muscular response to a sensory stimulus. It is built into the nervous system and does not need the intervention of conscious thought to take effect. The physical assessment of the neurologic system of the newborn includes evaluating the major reflexes (gag, Babinski, Moro, and Galant) and minor ones (finger grasp, toe grasp, rooting, sucking, head righting, stepping, and tonic neck).

To assess each reflex, the nurse progresses methodically, taking care to document each finding (Weber & Kelly, 2014). Many neonatal reflexes disappear with maturation, although some remain throughout adulthood. The arcs of these reflexes end at different levels of the spine and brain stem, reflecting the function of the cranial nerves and motor systems. The ways newborns blink, move their limbs, focus on a caretaker's face, turn toward sound, suck, swallow, and respond to the environment are all indications of their neurologic abilities. Congenital defects within the central nervous system are frequently not overt but may be revealed in abnormalities in tone, posture, or behavior (Davidson, 2014). Damage to the nervous system (birth trauma, perinatal hypoxia) during the birthing process can cause delays in the normal growth, development, and functioning of the newborn. Early identification may help to identify the cause and to start early intervention to decrease long-term complications or permanent sequelae.

Newborn reflexes are assessed to evaluate neurologic function and development. Absent or abnormal reflexes in a newborn, persistence of a reflex past the age when it is normally lost, or redevelopment of an infantile reflex in an older child or adult may indicate neurologic pathology. (See Chapter 18 for a description of newborn reflex assessment.)

The Healthy Start nurse explained to Maria that all newborns are born with some degree of myopia (inability to see distances) and that 20/20 vision is not generally achieved until 2 years of age. What developmental information should the nurse discuss with Maria?

BEHAVIORAL ADAPTATIONS

In addition to adapting physiologically, the newborn also adapts behaviorally. All newborns progress through a specific pattern of events after birth, regardless of their gestational age or the type of birth they experienced.

Behavioral Patterns

The newborn usually demonstrates a predictable pattern of behavior during the first several hours after birth, characterized by two periods of reactivity separated by a sleep phase. Behavioral adaptation is a defined progression of events triggered by stimuli from the extrauterine environment after birth.

FIGURE 17.6 The first period of reactivity is an optimal time for interaction.

First Period of Reactivity

The first period of reactivity begins at birth and may last from 30 minutes up to 2 hours. The newborn is alert and moving and may appear hungry. This period is characterized by myoclonic movements of the eyes, spontaneous Moro reflexes, sucking motions, chewing, rooting, and fine tremors of the extremities. Muscle tone and motor activity are increased (Healy & Fallon, 2014). Respiration and heart rate are elevated but gradually begin to slow as the next period begins.

This period of alertness allows parents to interact with their newborn and to enjoy close contact with their new baby (Fig. 17.6). The appearance of sucking and rooting behaviors provides a good opportunity for initiating breast-feeding. Many newborns latch on the nipple and suck well at this first experience.

Period of Decreased Responsiveness

At 30 to 120 minutes of age, the newborn enters the second stage of transition—

that of the *sleep period* or a decrease in activity. This phase is referred to as a period of decreased responsiveness. Movements are less jerky and less frequent. Heart and respiratory rates decline as the newborn enters the sleep phase. The muscles become relaxed, and responsiveness to outside stimuli diminishes. During this phase, it is difficult to arouse or interact with the newborn. No interest in sucking is shown. This quiet time can be used for both mother and newborn to remain close and rest together after labor and the birthing experience.

Second Period of Reactivity

The second period of reactivity begins as the newborn awakens and shows an interest in environmental stimuli. This period lasts 2 to 8 hours in the normal newborn (Davidson, 2014). Heart and respiratory rates increase. Peristalsis also increases. Thus, it is not uncommon for the newborn to pass meconium or void during this period. In addition, motor activity and muscle tone increase in conjunction with an increase in muscular coordination (Fig. 17.7).

FIGURE 17.7 Newborn during the second period of reactivity. Note the newborn's wide-eyed interest.

Interaction between the mother and the newborn during this second period of reactivity is encouraged if the mother has rested and desires it. This period also provides a good opportunity for the parents to examine their newborn and ask questions.

Take Note!

Teaching about feeding, positioning for feeding, and diaper-changing techniques can be reinforced during this time.

Behavioral Responses

Newborn development is a reflection of the dynamic relationship between endowment and environment. Newborns demonstrate several predictable responses when interacting with their environment. How they react to the world around them is termed a **neurobehavioral response**. It comprises predictable periods that are probably triggered by external stimuli. Expected newborn behaviors include orientation, habituation, motor maturity, self-quieting ability, and social behaviors. Any deviation in behavioral responses requires further assessment, because it may indicate a complex neurobehavioral problem.

Orientation

The response of newborns to stimuli is called *orientation.* They become more alert when they sense a new stimulus in their environment. Orientation reflects newborns' response to auditory and visual stimuli, demonstrated by their movement of head and eyes to focus on that stimulus. Newborns prefer the human face and bright shiny objects. As the face or object comes into their line of vision, newborns respond by staring at the object intently. Newborns use this sensory capacity to become familiar with people and objects in their surroundings.

Remember Maria, who was concerned about her newborn daughter's vision? She told the nurse that her daughter did not show any interest in her pastel-colored homemade mobile she had hung across the room from her crib. What suggestions can the nurse make to Maria regarding the placement of the mobile and the types and colors of objects used to promote orientation in her newborn daughter?

Habituation

Habituation is the newborn's ability to process and respond to visual and auditory stimuli. It is a measure of how well and appropriately an infant responds to the environment. Habituation is the ability to block out external stimuli after the newborn has become accustomed to the activity. During the first 24 hours after birth, newborns should increase their ability to habituate to

environmental stimuli and sleep. Habituation provides a useful indicator of their neurobehavioral intactness.

Motor Maturity

Motor maturity depends on gestational age and involves evaluation of posture, tone, coordination, and movements. These activities enable newborns to control and coordinate movement. When stimulated, newborns with good motor organization demonstrate movements that are rhythmic and spontaneous. Bringing the hand up to the mouth is an example of good motor organization. As newborns adapt to their new environment, smoother movements should be observed. Such motor behavior is a good indicator of the newborn's ability to respond and adapt accordingly; it indicates that the central nervous system is processing stimuli appropriately.

Self-Quieting Ability

Self-quieting ability (also called self-soothing) refers to newborns' ability to quiet and comfort themselves. Newborns vary in their ability to console themselves or to be consoled. "Consolability" is how newborns are able to change from the crying state to an active alert, quiet alert, drowsy, or sleep state. They console themselves by hand-to-mouth movements and sucking, alerting to external stimuli, and motor activity (Karp, 2014). Recent research outlines five things (the five "**S**'s") that parents can do to calm a fussy infant:

1. **S**waddling tightly
2. **S**ide/stomach position on the lap of the caretaker
3. **S**hushing loudly or continuous white noise
4. **S**winging using any rhythmic movement
5. **S**ucking (Karp, 2014)

Assisting parents to identify consoling behaviors to quiet their newborn if the newborn is not able to self-quiet is important.

Social Behaviors

Newborns begin extrauterine life able to engage in it with their sensory capabilities and communicate with their environment through a complex

repetoire of behaviors. Social behaviors include cuddling and snuggling into the arms of the parent when the newborn is held. Usually newborns are very sensitive to being touched, cuddled, and held. Cuddliness is very important to parents because they frequently gauge their ability to care for their newborn by the newborn's acceptance or positive response to their actions. This can be assessed by the degree to which the newborn nestles into the contours of the holder's arms. Most newborns cuddle, but some will resist. Assisting parents to assume comforting behaviors (e.g., by cooing while holding their newborn) and praising them for their efforts can help foster cuddling behaviors.

KEY CONCEPTS

- The neonatal period is defined as the first 28 days of life. As the newborn adapts to life after birth, numerous physiologic changes occur.

- At birth, the cardiopulmonary system must switch from fetal to neonatal circulation and from placental to pulmonary gas exchange.

- One of the most crucial adaptations that the newborn makes at birth is the adjustment of a fluid medium exchange from the placenta to the lungs and that of a gaseous environment.

- Neonatal red blood cells have a life span of 80 to 100 days in comparison with the adult red blood cell life span of 120 days. This difference in red blood cell life span causes several adjustment problems.

- Thermoregulation is the maintenance of balance between heat loss and heat production. It is a critical physiologic function that is closely related to the transition and survival of the newborn.

- The newborn's primary method of heat production is through nonshivering thermogenesis, a process in which brown fat (adipose tissue) is oxidized in response to cold exposure. Brown fat is a special kind of highly vascular fat found only in newborns.

- Heat loss in the newborn is the result of four mechanisms: conduction, convection, evaporation, and radiation.

- Responses of the immune system serve three purposes: defense (protection from invading organisms), homeostasis (elimination of worn-out host cells), and surveillance (recognition and removal of enemy cells).

- In the newborn, congenital reflexes are the hallmarks of maturity of the CNS,

viability, and adaptation to extrauterine life.

- The newborn usually demonstrates a predictable pattern of behavior during the first several hours after birth, characterized by two periods of reactivity separated by a sleep phase.

CHAPTER **WORKSHEET**

MULTIPLE-CHOICE QUESTIONS

1. When assessing the term newborn, the following are observed: newborn is

alert, heart and respiratory rates have stabilized, and meconium has been passed. The nurse determines that the newborn is exhibiting behaviors indicating:

a. Initial period of reactivity

b. Second period of reactivity

c. Decreased responsiveness period

d. Sleep period for newborns

2. A nurse observes a 3-day-old term newborn that is starting to appear mildly jaundiced. What might explain this condition?

a. Physiologic jaundice secondary to breast-feeding

b. Hemolytic disease of the newborn due to blood incompatibility

c. Exposing the newborn to high levels of oxygen

d. Overfeeding the newborn with too much glucose water

3. After teaching a group of nursing students about thermoregulation and appropriate measures to prevent heat loss by evaporation, which of the following student behaviors would indicate successful teaching?

a. Transporting the newborn in an isolette

b. Maintaining a warm room temperature

c. Placing the newborn on a warmed surface

d. Drying the newborn immediately after birth

4. After birth, the nurse would expect which fetal structure to close as a result of increases in the pressure gradients on the left side of the heart?

a. Foramen ovale

b. Ductus arteriosus

c. Ductus venosus

d. Umbilical vein

5. Which of the following newborns could be described as breathing normally?

a. Newborn A is breathing deeply, with a regular rhythm, at a rate of 20 bpm.

b. Newborn B is breathing diaphragmatically with sternal retractions, at a rate

of 70 bpm.

    c. Newborn C is breathing shallowly, with 40-second periods of apnea and cyanosis.

    d. Newborn D is breathing shallowly, at a rate of 36 bpm, with short periods of apnea.

6. When assessing a term newborn (6 hours old), the nurse auscultates bowel sounds and documents recent passing of meconium. These findings would indicate:

    a. Abnormal gastrointestinal newborn transition and needs to be reported

    b. An intestinal anomaly that needs immediate surgery

    c. A patent anus with no bowel obstruction and normal peristalsis

    d. A malabsorption syndrome, resulting in fatty stools

7. A nursing student questions the nursery nurse why they do not bathe the newborn immediately upon admission to the nursery observation area after birth. The nurse states that this would increase the risk of:

    a. Jaundice

    b. Infection

    c. Hypothermia

    d. Anemia

8. Because the newborn's red blood cells breakdown much sooner than those of an adult, what might result?

    a. Anemia

    b. Bruising

    c. Apnea

    d. Jaundice

9. The nurse performs a physical examination on a newborn 2 hours after birth. Which of the following findings indicate a need for a pediatric consultation? Select all that apply:

    a. Respiratory rate of 50 breaths per minute

    b. Intermittent episodes of apnea, lasting <10 seconds each

c. Absent Moro reflex when startled

d. Preauricular skin tag noted on left ear

e. White raised bumps noted on nose and face

f. Yellow blanching of the skin when pressure applied to the nose

CRITICAL THINKING EXERCISES

1. As the nurse manager, you have been orienting a new nurse in the nursery for the past few weeks. Although she has been demonstrating adequacy with most procedures, today you observe her bathing several newborns without covering them, weighing them on the scale without a cover, leaving the storage door open with the transporter nearby, and leaving the newborns' head covers and blankets off after showing them to family members through the nursery observation window.

   a. What is your impression of this behavior?

   b. What principles concerning thermoregulation need to be reinforced?

   c. How will you evaluate whether your instructions have been effective?

2. The most important adaptations for the newborn to make after birth are to establish respirations, make cardiovascular adjustments, and establish thermoregulation. Nursing care focuses on monitoring and supporting adjustments to extrauterine adaptation. Write appropriate nursing interventions to help achieve the following newborn adaptations:

   a. Respiratory adaptation

   b. Safety, including prevention of infection

   c. Thermoregulation

STUDY ACTIVITIES

1. While in the nursery clinical setting, identify the period of behavioral reactivity (first, inactivity, or second period) for two newborns born at different times. Share your findings during the post conference for that clinical day.

2. Dramatic changes occur in the cardiovascular system at birth. When the

umbilical cord is clamped and the placenta is separated, there is a resultant increase in systemic blood pressure and changes to the three major fetal shunts (ductus venosus, foramen ovale, and ductus arteriosus) occur. Outline what happens to cause their functional closures during this period of transition.

3. Find two web sites about the transition to extrauterine life that can be shared with other nursing students as well as nursery nurses. Critique the information presented in terms of how accurate and current it is.

4. The most common mechanism of heat loss in the newborn is _____.

5. The newborn creates heat in three ways—by shivering, through muscle activity, and through thermogenesis by the metabolism of brown adipose tissue. Which is the most effective?

BRINGING IT ALL TOGETHER: CASE STUDY

An 18-year-old woman gave birth to her first infant 3 days ago, but she does not smile when the *Healthy Start* nurse greets her at a home visit. The nurse questions her about what has happened since she was discharged from the hospital 2 days ago. She tells the nurse that her breasts are swollen, hot, and very painful when touched. She states she knows that breast-feeding is best for her child, but she is not sure she wants to continue to breast-feed because of the pain. Her infant is lying on the bare kitchen table in only a diaper crying.

ASSESSMENT

On examining the woman's breasts, the nurse finds that they are both very swollen and hot to the touch, but there is no redness or palpated lump. (The client bites her lip and a tear falls from her eye when the nurse palpates her breasts). Milk drips freely from both nipples. Temperature is 37.7°C. The nurse examines the infant girl weighing 2,580 g. Her extremities are cyanotic and cold to touch. The infant has lost 100 g since birth and appears hungry. The nurse requests the client to breast-feed her infant so that she can observe the infant, and finds that the infant is having trouble grasping the very swollen areola. When the infant finally latches on, she does not seem to suck very vigorously.

Go to thePoint to find questions to consider about this case.

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Perform the assessments needed during the immediate newborn period.
2. Employ interventions that meet the immediate needs of the term newborn.
3. Demonstrate the components of a typical physical examination of a newborn.
4. Distinguish common variations that can be noted during a newborn's physical examination.
5. Characterize common concerns in the newborn and appropriate interventions.
6. Compare the importance of the newborn screening tests.
7. Plan for common interventions that are appropriate during the early newborn period.
8. Analyze the nurse's role in meeting the newborn's nutritional needs.
9. Outline discharge planning content and education needed for the family with a newborn.

> ***Kelly,*** *a 16-year-old first-time mother, calls the hospital maternity unit 3 days after being discharged home. She tells the nurse that her newborn son "looks yellow, like a canary" and "isn't nursing well." She wonders what is wrong.*

WOW

Words of Wisdom

You can send a more powerful message with your actions and behavior than with words alone.

INTRODUCTION

Immediately after the birth of a newborn, all mother and father/support persons/significant others are faced with the task of learning and understanding as much as possible about caring for this new family member, even if the parents already have other children. In their new or expanded role as parents, they will face many demands and challenges. For most, this is a wonderful, exciting time filled with many discoveries and much information.

Mother and father/support persons or significant others learn as they watch the nurse interacting with their newborn. Nurses play a major role in teaching the newborn's caretakers about normal newborn characteristics and about ways to foster optimal growth and development. This role is even more important today because of limited hospital stays.

The newborn has come from a dark, small, enclosed space in the mother's uterus into the bright, cold, extrauterine environment. Nurses can easily forget that they are caring for a small human being who is experiencing his or her first taste of human interaction outside the uterus. The newborn period is an extremely important one, and two national health goals have been developed to address this critical period (see the *Healthy People 2020* feature; U.S. Department of Health and Human Services [USDHHS], 2010).

It is also easy to overlook the intensity with which mother and father/support persons/significant others and visitors observe the actions of nurses as they care for the new family member. Nurses need to serve as a model for giving nurturing care to newborns. This chapter provides information about assessment and interventions in the period immediately following the birth of a newborn and during the early newborn period.

NURSING MANAGEMENT DURING THE IMMEDIATE NEWBORN PERIOD

The period of transition from intrauterine to extrauterine life occurs during the first several hours after birth. During this time, the newborn is undergoing numerous adaptations, many of which are occurring simultaneously (see Chapter 17 for more information on the newborn's adaptation. The neonate's temperature, respiration, and cardiovascular dynamics stabilize during this period. Close observation of the newborn's status is essential. Careful examination of the newborn at birth allows for detection of anomalies, birth injuries, and disorders that can compromise adaptation to extrauterine life. Problems that occur during this critical time can have a lifelong impact.

HEALTHY PEOPLE 2020 • *18.1*

Objective	Nursing Significance
• Increase the proportion of mothers who breast-feed their babies during the early postpartum period from a baseline of 74% to 81.9%. • Increase the proportion of mothers who breast-feed at 6 months from a baseline of 43.5% to 60.6%. • Increase the proportion of mothers who breast-feed at 1 year from a baseline of 22.7% to 34.1%. • Ensure appropriate newborn bloodspot screening and follow-up testing. • Increase the number of states and the District of Columbia that verify through linkage with vital records that all newborns are screened shortly after birth for conditions mandated by their state-sponsored screening program. • Increase the proportion of screen-positive children who receive follow-up testing within the recommended time period. • (Developmental) Increase the proportion of children with a diagnosed condition identified through newborn screening who have an annual assessment of services needed and received. • Increase the proportion of newborns who are screened for hearing loss by no later than age 1 month, have audiologic evaluation by age 3 months, and are enrolled in appropriate intervention service no later than age 6 months.	• Will emphasize the importance of breast milk as the most complete form of nutrition for infants. • Will help promote infant health, growth, immunity, and development throughout the newborn and infant periods. • Will help foster early detection and prompt treatment for conditions, thereby lessening the incidence of illness, disability, and death associated with these conditions and their overall effects on the newborn, infant, and family.

Healthy People objectives based on data from http://www.healthypeople.gov.

Assessment

The initial newborn assessment is completed in the birthing area to determine whether the newborn is stable enough to stay with the parents or whether resuscitation or other immediate interventions are necessary. Recently, an easy, rapid newborn assessment tool, the RAPP, has been developed to enhance the nurse's ability to quickly and accurately assess the newborn's physiologic condition. The RAPP assessment (**r**espiratory **a**ctivity, **p**erfusion, and **p**osition) provides a method to swiftly evaluate the newborn's condition so that decisions can be made regarding newborn stability (Ludington-Hoe & Morgan, 2014). A second assessment may be performed within the first 2 to 4 hours, when the newborn is admitted to the nursery or the labor and birth room. A third assessment is usually completed before discharge, according to the hospital policy. The purpose of these assessments is to determine the newborn's overall health status, to provide information to the mother and father/support persons/significant others about their newborn, and to identify apparent physical abnormalities (Davidson, 2014).

During the initial newborn assessment, look for signs that might indicate a problem, including:

1. Nasal flaring

2. Chest retractions

3. Grunting on exhalation

4. Labored breathing

5. Generalized cyanosis

6. Abnormal breath sounds: rhonchi, crackles (rales), wheezing, and stridor

7. Abnormal respiratory rates (tachypnea, more than 60 breaths/minute; bradypnea, less than 25 breaths/minute)

8. Flaccid body posture

9. Pallor

0. Apneic episodes

1. Abnormal heart rates (tachycardia, more than 160 bpm; bradycardia, less than 100 bpm)

2. Abnormal newborn size: small or large for gestational age

If any of these findings is noted, medical intervention may be necessary.

Apgar Scoring

The **Apgar score**, introduced in 1952 by Dr. Virginia Apgar, is used worldwide to evaluate a newborn's physical condition at 1 minute and 5 minutes after birth. An additional Apgar assessment is done at 10 minutes if the 5-minute score is less than 7 points. The heart rate was found to be the most important diagnostic and prognostic of the five signs (Apgar, 2015). It can be used as a rapid method for assessing the survival of a neonate. Assessment of the newborn at 1 minute provides data about the newborn's initial adaptation to extrauterine life. Assessment at 5 minutes provides a clearer indication of the newborn's overall central nervous system status.

Five parameters are assessed with Apgar scoring. A quick way to remember the parameters of Apgar scoring is as follows:

• **A**: appearance (color)

• **P**: pulse (heart rate)

• **G**: grimace (reflex irritability)

• **A**: activity (muscle tone)

• **R**: respiratory (respiratory effort)

Each parameter is assigned a score ranging from 0 to 2 points. A score of 0 points indicates an absent or poor response; a score of 2 points indicates a normal response (Table 18.1). A normal newborn's score should be 8 to 10 points. The higher the score indicates the better condition of the newborn. If the Apgar score is 8 points or higher, no intervention is needed other than supporting normal respiratory efforts and maintaining thermoregulation. Scores of 4 to 7 points signify moderate difficulty and scores of 0 to 3 points represent severe distress in adjusting to extrauterine life. The Apgar score is influenced by the presence of infection, newborn maturity, mother's age, congenital anomalies, physiologic immaturity, maternal sedation via medications, labor management, and neuromuscular disorders (Rudiger & Konstantelos, 2015).

When the newborn experiences physiologic depression, the Apgar score characteristics disappear in a predictable manner: first the pink coloration is lost, next the respiratory effort, and then the tone, followed by the reflex irritability and finally heart rate (Apgar, 2015).

Take Note!

Although Apgar scoring is done at 1 and 5 minutes, it can also be used as a guide during the immediate newborn period to evaluate the newborn's status for any changes because it focuses on critical parameters that must be assessed throughout the early transition period.

Length and Weight

Parents are eager to know their newborn's length and weight. These measurements are taken soon after birth. A disposable tape measure or a built-in measurement board located on the side of some scales can be used. Length is measured from the head of the newborn to the heel with the newborn unclothed (Fig. 18.1). Because of the flexed position of the newborn after birth, place the newborn in a supine position and extend the leg completely when measuring the length. The expected length range of a full-term newborn is usually 44 to 55 cm (17 to 22 in). Molding can affect measurement (Weber & Kelley, 2014).

TABLE 18.1 APGAR SCORING FOR NEWBORNS

Parameter (Assessment Technique)	0 Point	1 Point	2 Points
Heart rate (auscultation of apical heart rate for 1 full minute)	Absent	Slow (<100 bpm)	>100 bpm
Respiratory effort (observation of the volume and vigor of the newborn's cry; auscultation of depth and rate of respirations)	Apneic	Slow, irregular, shallow	Regular respirations (usually 30–60 breaths/minute), strong, good cry
Muscle tone (observation of the extent of flexion in the newborn's extremities and newborn's resistance when the extremities are pulled away from the body)	Limp, flaccid	Some flexion, limited resistance to extension	Tight flexion, good resistance to extension with quick return to flexed position after extension
Reflex irritability (flicking of the soles of the feet or suctioning of the nose with a bulb syringe)	No response	Grimace or frown when irritated	Sneeze, cough, or vigorous cry
Skin color (inspection of trunk and extremities with the appropriate color for ethnicity appearing within minutes after birth)	Cyanotic or pale	Appropriate body color; blue extremities (acrocyanosis)	Completely appropriate color (pink on both trunk and extremities)

Data from Cunningham, F. G., Leveno, K. J., Bloom, S. L., Spong, C. Y., Dashe, J. S., Hoffman, B. L., et al. (2014). *William's obstetrics* (24th ed.). New York, NY: McGraw-Hill Medical; and Marcdante, K. J., & Kliegman, R. M. (2014). *Nelson essentials of pediatrics* (7th ed.). Philadelphia, PA: Elsevier Science Health.

Most often, newborns are weighed using a digital scale that reads the weight

in grams. Typically, the term newborn weighs 2,500 to 4,000 g (5 lb, 8 oz to 8 lb, 14 oz; Fig. 18.2). Birth weights less than 10% or more than 90% on a growth chart are outside the normal range and need further investigation. Weights taken at later times are compared with previous weights and are documented with regard to gain or loss on a nursing flow sheet. Newborns can lose up to 10% of their initial birth weight by 3 to 4 days of age secondary to loss of meconium, extracellular fluid, and limited food intake. This weight loss is usually regained by the 10th day of life (Fonseca et al., 2014).

FIGURE 18.1 Measuring a newborn's length.

Newborns can be classified by their birth weight regardless of their gestational age (American Academy of Pediatrics [AAP], 2015a) as follows:

• Low birth weight: >2,500 g (>5.5 lb)

• Very low birth weight: >1,500 g (>3.5 lb)

• Extremely low birth weight: >1,000 g (>2.5 lb)

Vital Signs

Heart rate and respiratory rate are assessed immediately after birth with Apgar scoring. Heart rate, obtained by taking an apical pulse for 1 full minute, typically is 110 to 160 bpm. Newborns' respirations are assessed when they are quiet or sleeping. Place a stethoscope on the right side of the chest and count the breaths for 1 full minute to identify any irregularities. The newborn respiratory rate is 30 to 60 breaths/minute with symmetric chest movement. Heart and respiratory rates are usually assessed every 30 minutes until stable for 2 hours after birth. Once stable, the heart rate and respiratory rates are checked every 8 hours. These assessment time frames may vary per hospital protocols, so nurses should follow

the facility's procedures (Nagtalon-Ramos, 2014).

FIGURE 18.2 Weighing the newborn. Note how the nurse guards the newborn with her hand to prevent falling.

Vital signs are assessed at birth, within 1 to 4 hours after birth according to hospital policy. Vital signs are used for identifying a variety of complications and for ensuring well-being of the newborn. In some health care agencies, temperatures are taken immediately after the Apgar score has been taken to allow for identification of hypothermia, which then requires a glucose check, but nurses need to follow their hospital protocols on this assessment timing. In term newborns, the normal axillary temperature range should be maintained at 97.7° to 99.5° F (36.5° to 37.5° C). Rectal temperatures are no longer taken because of the risk of perforation (AAP, 2015b). The thermometer or temperature probe is held in the midaxillary space according to manufacturer's directions and hospital protocol. Blood pressure is not usually assessed as part of a normal newborn examination unless there is a clinical indication or low Apgar scores. If assessed, an oscillometer (Dinamap) is used. The typical range is 50 to 75 mm Hg (systolic) and 30 to 45 mm Hg (diastolic). Crying, moving, and late clamping of the umbilical cord will increase systolic pressure (Weber & Kelley, 2014). Typical values for newborn vital signs are provided in Table 18.2.

Gestational Age Assessment

To determine a newborn's **gestational age** (the stage of maturity), physical signs and neurologic characteristics are assessed. Typically, gestational age is determined by using a tool such as the Ballard gestational age assessment or Ballard Scale. It determines a newborn's gestational age between 20 and 44 weeks. A score is assigned to the various parameters, and the total score

corresponds to a maturity rating in weeks of gestation (Fig. 18.3). This scoring system provides an objective estimate of gestational age by scoring the specific parameters of physical as well as neuromuscular maturity. Points are given for each assessment parameter, with a low score of –1 point or –2 points for extreme immaturity to 4 or 5 points for postmaturity. The scores from each section are added to correspond to a specific gestational age in weeks.

TABLE 18.2 NEWBORN VITAL SIGNS

Newborn Vital Signs	Ranges of Values
Temperature	97.7–99.5° F (36.5–37.5° C)
Heart rate (pulse) to 180 during crying	110–160 bpm; can increase
Respirations	30–60 breaths/minute at rest; will increase with crying
Blood pressure	50–75 mm Hg systolic, 30–45 mm Hg diastolic

Data from Moses, S. (2015). Pediatric vital signs. *Family Practice Notebook.* Retrieved from http://www.fpnotebook.com/cv/exam/pdtrcvtlsgns.htm; and Kliegman, R. M., Behrman, R. E., Jenson, H. B., & Stanton, B. F. (2014). *Nelson's textbook of pediatrics* (20th ed.). St. Louis, MO: Saunders Elsevier.

The physical maturity section of the examination is done during the first 2 hours after birth. The physical maturity assessment section of the Ballard examination evaluates physical characteristics that appear different at different stages depending on a newborn's gestational maturity. Newborns who are physically mature have higher scores than those who are not. The areas assessed on the physical maturity examination include:

- *Skin texture*—typically ranges from sticky and transparent to smooth, with varying degrees of peeling and cracking, to parchment-like or leathery with significant cracking and wrinkling
- *Lanugo*—soft downy hair on the newborn's body, which is absent in preterm newborns, appears with maturity, and then disappears again with postmaturity
- *Plantar creases*—creases on the soles of the feet, which range from absent to

covering the entire foot, depending on maturity (the greater the number of creases, the greater the newborn's maturity)

- *Breast tissue*—the thickness and size of breast tissue and areola (the darkened ring around each nipple), which range from being imperceptible to full and budding
- *Eyes and ears*—eyelids can be fused or open and ear cartilage and stiffness determine the degree of maturity (the greater the amount of ear cartilage with stiffness, the greater the newborn's maturity)
- *Genitals*—in males, evidence of testicular descent and appearance of scrotum (which can range from smooth to covered with rugae) determine maturity; in females, appearance and size of clitoris and labia determine maturity (a prominent clitoris with flat labia suggests prematurity, whereas a clitoris covered by labia suggests greater maturity)

The neuromuscular maturity section typically is completed within 24 hours after birth. Six activities or maneuvers that the newborn performs with various body parts are evaluated to determine the newborn's degree of maturity:

1. *Posture*—How does the newborn hold his or her extremities in relation to the trunk? The greater the degree of flexion, the greater the maturity. For example, extension of arms and legs is scored as 0 points and full flexion of arms and legs is scored as 4 points.

					TOTAL PHYSICAL MATURITY SCORE			

FIGURE 18.3 Gestational age assessment tool. The New Ballard Score (2014). Adapted from http://www.ballardscore.com

2. *Square window*—How far can the newborn's hands be flexed toward the wrist? The angle is measured and scored from more than 90 degrees to 0 degrees to determine the maturity rating. As the angle decreases, the newborn's maturity increases. For example, an angle of more than 90 degrees is scored as –1 point and an angle of 0 degrees is scored as 4 points.

3. *Arm recoil*—How far do the newborn's arms "spring back" to a flexed position? This measure evaluates the degree of arm flexion and the strength of recoil. The reaction of the arm is then scored from 0 to 4 points based on the degree of flexion as the arms are returned to their normal flexed position. The higher the points assigned, the greater the neuromuscular maturity (for example, recoil less than a 90-degree angle is scored as 4 points).

4. *Popliteal angle*—How far will the newborn's knees extend? The angle created when the knee is extended is measured. An angle of less than 90 degrees indicates greater maturity. For example, an angle of 180 degrees is scored as –1 point and an angle of less than 90 degrees is scored as 5 points.

5. *Scarf sign*—How far can the elbows be moved across the newborn's chest? An elbow that does not reach midline indicates greater maturity. For example, if the elbow reaches or nears the level of the opposite shoulder, this is scored as –1 point; if the elbow does not cross the proximate axillary line, it is scored as 4 points.

6. *Heel to ear*—How close can the newborn's feet be moved to the ears? This maneuver assesses hip flexibility: the lesser the flexibility, the greater the newborn's maturity. The heel-to-ear assessment is scored in the same manner as the scarf sign.

After the scoring is completed, the 12 scores are totaled and then compared with standardized values to determine the appropriate gestational age in weeks. Scores range from very low in preterm newborns to very high for mature and postmature newborns.

Typically newborns are also classified according to their gestational age as:

• *Preterm or premature*—born prior to 37 completed weeks' gestation, regardless of birth weight

• *Term*—born between 38 and 42 weeks' gestation

• *Post-term or postdates*—born after completion of week 42 of gestation

• *Postmature*—born after 42 weeks and demonstrating signs of placental aging

Using the information about gestational age and then considering birth weight, newborns can also be classified as follows:

• *Small for gestational age (SGA)* —weight less than the 10th percentile on standard growth charts (usually >5.5 lb)

- *Appropriate for gestational age (AGA)* —weight between 10th and 90th percentiles
- *Large for gestational age (LGA)* —weight more than the 90th percentile on standard growth charts (usually >9 lb)

Chapter 23 describes these variations in birth weight and gestational age in greater detail.

 Take Note!

Gestational age assessment is important because it allows the nurse to plot growth parameters and to anticipate problems related to prematurity, postmaturity, and growth abnormalities.

Nursing Interventions

During the immediate newborn period, care focuses on helping the newborn to make the transition to extrauterine life. The nursing interventions include maintaining airway patency, ensuring proper identification, administering prescribed medications, and maintaining thermoregulation.

Maintaining Airway Patency

Immediately after birth, a newborn is suctioned to remove fluids and mucus from the mouth and nose (Fig. 18.4). Typically, the newborn's mouth is suctioned first with a bulb syringe to remove debris and then the nose is suctioned. Suctioning in this manner helps prevent aspiration of fluid into the lungs by an unexpected gasp. Recent studies, along with recommendations from leading maternal health experts and the WHO, support using a towel to wipe secretions from the mouth and nose of newborns for stable newborns. Routine suctioning of the mouth and airways is not required. Despite evidence showing that the use of routine suctioning shows no benefit and may produce harm, the practice remains commonplace (Bond, 2015; Saugstad, 2015).

When suctioning a newborn with a bulb syringe, compress the bulb before placing it into the oral or nasal cavity. Release bulb compression slowly, making sure the tip is placed away from the mucous membranes to draw up the excess secretions. Remove the bulb syringe from the mouth or nose, and then, while holding the bulb syringe tip over an emesis basin lined with paper towel or tissue, compress the bulb to expel the secretions. Repeat the procedure several times until all secretions are removed or use a towel to wipe away secretions per hospital policy.

FIGURE 18.4 A newborn is suctioned by means of a bulb syringe to remove mucus from the mouth and nose. The head-down-and-to-the-side position facilitates drainage. Care is given with the infant under a radiant heat source. (Copyright Caroline Brown, RNC, MS, DEd.)

 Take Note!

Always keep a bulb syringe near the newborn in case he or she develops sudden choking or a blockage in the nose. It may be lifesaving.

Ensuring Proper Identification

Infant abduction continues to be a threat in hospitals and health care organizations across the country. The abduction by nonfamily members of newborns from health care facilities has clearly become a subject of concern for parents, maternal-child care nurses, health care security and risk management administrators, law enforcement officials, and the National Center for Missing & Exploited Children (NCMEC). Staff identification (ID) badges, training, video surveillance, access control and tagging systems can help prevent a newborn from being abducted from the hospital. Proactive security measures must become everyone's responsibility to ensure the safety of all newborns and their families in all hospital settings.

Before the newborn and family leave the birthing area, be sure that agency policy about identification has been followed. Typically, the mother, the newborn, and the father or any significant other or support person of the mother's choosing receive ID bracelets. The newborn commonly receives two ID bracelets, one on a wrist and one on an ankle. The mother receives a

matching one, usually on her wrist. The ID bands usually state name, gender, date and time of birth, and identification number. The same identification number is on the bracelets of all family members.

These ID bracelets are provided for the safety of the newborn and must be secured before the mother and newborn leave the birthing area. The ID bracelets are checked by all nurses to validate that the correct newborn is brought to the right mother if they are separated for any period of time (Fig. 18.5). They also serve as the official newborn identification and should be checked before initiating any procedure on that newborn and on discharge from the unit (NCMEC, 2015). Taking the newborn's picture within 2 hours after birth with a color camera or color video/digital image also helps prevent mix-ups and abduction. Many facilities use electronic devices that sound an alarm if a newborn is taken beyond a certain point on the unit or removed from the area.

FIGURE 18.5 The nurse checks the newborn's identification band against the mother's.

Newborns' footprints may also be taken, using a form that includes the mother's fingerprint, name, date, and time of the birth. Some states require footprints of the newborn, although many studies point out that birthing room staff does not take consistently legible footprints suitable for identification purposes (Goyal, Nagar, & Kumar, 2014). Many states have stopped requiring newborn footprints, and thus other means of identification are needed, such as collecting cord blood at the time of birth for DNA testing; facial biometric recognition, and live scans to capture digital forensic-quality prints that are suitable for identification purposes (Otsuka, 2014).

Prevention of infant abductions has been successful through a combination of

increased security measures in hospitals, including video cameras and alarm devices, and education of staff and parents about precautions to take while in the hospital. It is critical not to allow anyone without identification to take an infant for any reason and to keep the infant within the sight of the parent or nursery staff at all times. These measures should be largely invisible and create a sense of security rather than increasing parental fears about abduction.

Although infant abduction rates are rare, the safety and security of mothers and infants should remain a high priority for nurses. By being aware of physical security of maternity units, educating expectant parents on the methods used by potential abductors, and working with community resources, these tragic incidents can be prevented.

Administering Prescribed Medications

During the immediate newborn period, two medications are commonly ordered: vitamin K and eye prophylaxis with either erythromycin or tetracycline ophthalmic ointment (Drug Guide 18.1).

VITAMIN K

Prophylactic treatment of newborns with intramuscular vitamin K has been the standard of care for decades in the United States. Vitamin K, a fat-soluble vitamin, promotes blood clotting by increasing the synthesis of prothrombin by the liver. A deficiency of this vitamin delays clotting and might lead to hemorrhage. Newborns are at risk for vitamin K deficiency and subsequent bleeding unless supplemented at birth. Vitamin K deficiency is an acquired coagulopathy in newborn infants because of an accumulation of inactive vitamin K coagulation factors, which leads to an increased bleeding tendency. Supplementation of vitamin K at birth has been recommended in the United States since 1961 and successfully reduces the risk of bleeding in newborns (Bellini, 2015).

DRUG GUIDE 18.1 DRUGS FOR THE NEWBORN

Drug	Action/Indication	Nursing Implications
Phytonadione (vitamin K [Aqua-MEPHYTON, Konakion, Mephyton])	Provides the newborn with vitamin K (necessary for production of adequate clotting factors II, VII, IX, and X by the liver) during the first week of birth until newborn can manufacture it Prevents vitamin K deficiency bleeding (VKDB) of the newborn	• Administer within 1 to 2 hours after birth. • Give as an IM injection at a 90-degree angle into the outer middle third of the vastus lateralis muscle. • Use a 25-gauge, 5/8-in needle for injection. • Hold the leg firmly and inject medication slowly. • Adhere to standard precautions. • Assess for bleeding at injection site after administration.
Erythromycin ophthalmic ointment 0.5% or tetracycline ophthalmic ointment 1%	Provides bactericidal and bacteriostatic actions to prevent *Neisseria gonorrhoeae* and *Chlamydia trachomatis* conjunctivitis Prevents ophthalmia neonatorum	• Be alert for chemical conjunctivitis for 1 to 2 days. • Wear gloves, and open eyes by placing the thumb and finger above and below the eye. • Gently squeeze the tube or ampoule to apply medication into the conjunctival sac from the inner canthus to the outer canthus of each eye. • Do not touch the tip to the eye. • Close the eye to make sure the medication permeates. • Wipe off excess ointment after 1 minute.

Adapted from King, T. L., Brucker, M. C., Kriebs, J. M., Fahey, J. O., Gegor, C. L., & Varney, H. (2015). *Varney's midwifery* (5th ed.). Burlington, MA: Jones & Bartlett Learning; and Skidmore-Roth, L. (2015). *Mosby's 2015 nursing drug reference* (28th ed.). St. Louis, MO: Elsevier Health Sciences.

Generally, the bacteria of the intestine produce vitamin K in adequate quantities. However, the newborn's bowel is sterile, so vitamin K is not produced in the intestine until after microorganisms have been introduced, such as with the first feeding. Usually, it takes about a week for the newborn to produce enough vitamin K to prevent vitamin K deficiency bleeding. An oral vitamin K preparation is also being given to newborns outside the United States, but at least three doses are needed over a 1-month period (Abrams & Savelli, 2014).

The efficacy of vitamin K in preventing early vitamin K deficiency bleeding is firmly established and has been the standard of care since the AAP recommended it in the early 1960s. The AAP (2015c) recommends that vitamin K be administered to all newborns soon after birth in a single intramuscular dose of 0.5 to 1 mg (Fig. 18.6). The AAP also suggests that additional research is needed to validate the efficacy and safety of oral forms of vitamin K, which have been used in many parts of the world, but currently are not recommended in the United States.

EYE PROPHYLAXIS

All newborns in the United States, whether delivered vaginally or by cesarean

birth, must receive an installation of a prophylactic agent in their eyes within an hour or two of birth. This is mandated in all 50 states to prevent **ophthalmia neonatorum**, which can cause neonatal blindness (Centers for Disease Control and Prevent [CDC], 2015a). Ophthalmia neonatorum is a hyperacute purulent conjunctivitis occurring during the first 10 days of life. It is usually contracted during birth when the baby comes in contact with vaginal discharge of the mother infected with gonorrhea and chlamydia (CDC, 2015a). Most often both eyelids become swollen and red with purulent discharge.

FIGURE 18.6 The nurse administers vitamin K IM to the newborn.

FIGURE 18.7 The nurse administers eye prophylaxis.

Prophylactic agents that are currently recommended (and in most states legally required) include erythromycin 0.5% ophthalmic ointment or tetracycline 1% ophthalmic ointment in a single application. Silver nitrate solution was

formerly used but has little efficacy in preventing chlamydial eye disease (Moore & MacDonald, 2015).

Regardless of which agent is used, instillation should be done as soon as possible after birth (Fig. 18.7). If instillation is delayed to allow visualization and bonding, the nursery staff should make sure the agent is administered when the newborn reaches the nursery for observation and assessment.

Inform all parents about the eye treatment, including why it is recommended, what problems may arise if the treatment is not given, and possible adverse effects of the treatment.

Take Note!

Ophthalmia neonatorum is a severe form of conjunctivitis caused by chlamydia and/or gonococcal infections that is potentially a blinding condition in newborns.

Maintaining Thermoregulation

Newborns have trouble regulating their temperature; especially during the first few hours after birth (see Chapter 17 for a complete discussion). Therefore, maintaining body temperature is crucial.

Concept Mastery Alert

Use of a Radiant Heater in Preventing Newborn Heat Loss

A 1-day-old infant should have adequate thermoregulation to remain out of the radiant heater. The best way to prevent heat loss is to ensure that the infant does not come in contact with cold surfaces.

Assess body temperature frequently during the immediate newborn period. The baby's temperature should be taken every 30 minutes for the first 2 hours or until the temperature has stabilized, and then every 8 hours until discharge or follow hospital protocols (King et al., 2015). Commonly a thermistor probe (automatic sensor) is attached to the newborn to record body temperature on a

monitoring device. The probe is taped to the newborn's abdomen, usually in the right upper quadrant, which allows for position changes without having to readjust the probe. The other end of the thermistor probe is inserted into the radiant heat control panel. Temperature parameters are set on an alarm system connected to the heat panel that will sound if the newborn's temperature falls out of the set range. Check the probe connection periodically to make sure that it remains secure. Remember the potential for heat loss in newborns, and perform all nursing interventions in a way that minimizes heat loss and prevents hypothermia.

Axillary temperatures can also be used to assess the newborn's body temperature. Place a thermometer under the newborn's axilla and place the arm over the chest to keep the thermometer in place and provide comfort to the newborn.

Nursing interventions to help maintain body temperature include:

- Dry the newborn immediately after birth to prevent heat loss through evaporation.
- Wrap the baby in warmed blankets to reduce heat loss via convection.
- Skin-to-skin contact with mother as soon as stabilized.
- Use a warmed cover on the scale to weigh the unclothed newborn.
- Warm stethoscopes and hands before examining the baby or providing care.
- Avoid placing newborns in drafts or near air vents to prevent heat loss through convection.
- Delay the initial bath until the baby's temperature has stabilized to prevent heat loss through evaporation.
- Avoid placing cribs near cold outer walls to prevent heat loss through radiation.
- Put a cap on the newborn's head after it is thoroughly dried after birth.
- Place the newborn under a temperature-controlled radiant warmer (Fig. 18.8).

NURSING MANAGEMENT DURING THE EARLY NEWBORN PERIOD

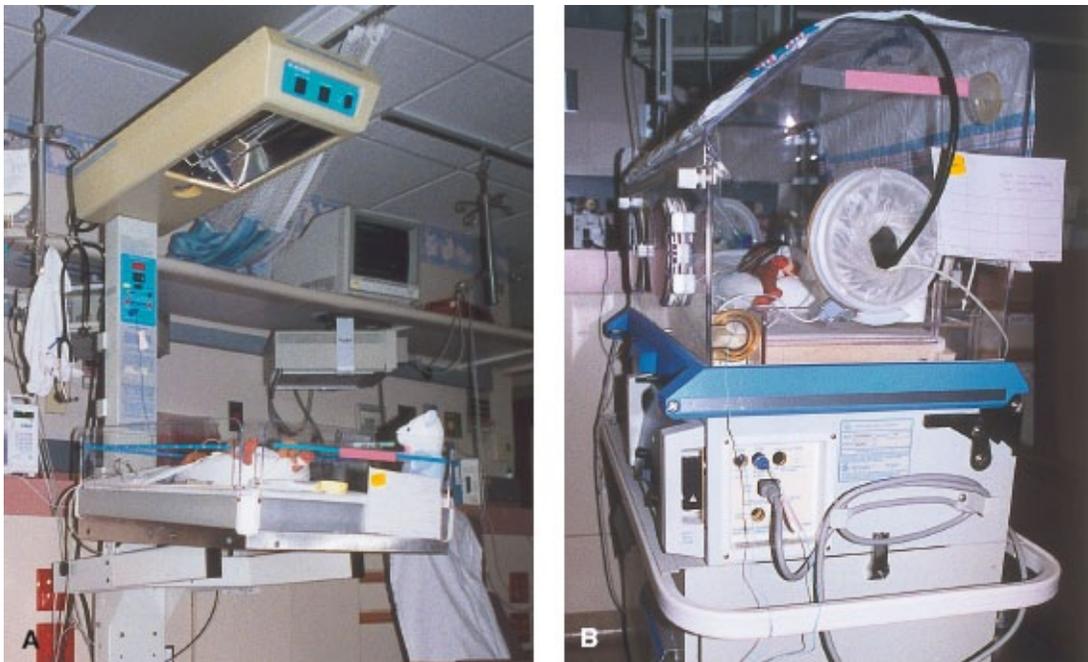
The early newborn period is a time of great adjustment for both the mother and the newborn; both of them are adapting to many physiologic and psychological changes. In the past, mothers and newborns remained in the health care facility while these dramatic changes were taking place, with nurses and doctors readily available. However, today shorter hospital stays are the norm, and new mothers can easily be overwhelmed by having to go through all of these changes in such a short time: the woman gives birth, experiences marked physiologic and psychological changes, and must adapt to her newborn and learn the skills needed to care for herself and the baby, all within 24 to 48 hours.


FIGURE 18.8 Maintaining thermoregulation. **A.** Radiant warmer. **B.** Isolette.

The nurse's role is to assist the mother and her newborn through this dramatic transition period. The newborn needs continued health assessment, and the mother needs to be taught to care for the new baby. At discharge, the new mother may panic and feel insecure about her role as a primary caretaker. Nurses play a major role in promoting the newborn's transition by providing ongoing

assessment and care and in promoting the woman's confidence by serving as a role model and teaching about proper newborn care.

Assessment

The newborn requires ongoing assessment after leaving the birthing area to ensure that his or her transition to extrauterine life is progressing without problems. The nurse uses the data gathered during the initial assessment as a baseline for comparison.

Perinatal History

Pertinent maternal and fetal data are vital to formulate a plan of care for the mother and her newborn. Historical information is obtained from the medical record and from interviewing the mother. Review the maternal history because it provides pertinent information, such as the presence of certain risk factors that could affect the newborn. Keep in mind that a comprehensive maternal history may not be available, especially if the mother has had limited or no prenatal care. Historical information usually includes the following:

• Mother's name, medical record number, blood type, serology result, rubella and hepatitis status, and history of substance abuse

• Other maternal tests that are relevant to the newborn and care, such as human immunodeficiency virus (HIV) and group B streptococcus status

• Intrapartum maternal antibiotic therapy (type, dose, and duration)

• Maternal illness that can affect the pregnancy, evidence of chorioamnionitis, maternal use of medications such as steroids

• Prenatal care, including timing of first visit and subsequent visits

• Risk for blood group incompatibility, including Rh status and blood type

• Fetal distress or any nonreassuring fetal heart rate patterns during labor

• Known inherited conditions such as sickle cell anemia and phenylketonuria (PKU)

• Birth weights of previous live-born children, along with identification of any newborn problems

• Social history, including tobacco, alcohol, and recreational drug use

• History of depression or domestic violence

• Cultural factors, including primary language and educational level

- Pregnancy complications associated with abnormal fetal growth, fetal anomalies, or abnormal results from tests of fetal well-being
- Information on the progress of labor, birth, labor complications, duration of ruptured membranes, and presence of meconium in the amniotic fluid
- Medications given during labor, at birth, and immediately after birth
- Time and method of delivery, including presentation and the use of forceps or a vacuum extractor
- Status of the newborn at birth, including Apgar scores at 1 and 5 minutes, the need for suctioning, weight, gestational age, vital signs, and umbilical cord status
- Medications administered to the newborn
- Postbirth maternal information, including placental findings, positive cultures, and presence of fever

Newborn Physical Examination

The initial newborn physical examination, which may demonstrate subtle differences related to the newborn's age, is carried out within the first 24 hours after birth. For example, a newborn who is 30 minutes old has not yet completed the normal transition from intrauterine to extrauterine life, and thus variability may exist in vital signs and in respiratory, neurologic, gastrointestinal, skin, and cardiovascular systems. Therefore, a comprehensive examination should be delayed until after the newborn has completed the transition.

The physical examination should not be initiated if the newborn is crying or appears to be upset. Instead, it is best to postpone the assessment until the newborn is calm. In a quiet newborn, begin the examination with the least invasive and noxious elements of the examination (auscultation of heart and lungs). Then examine the areas most likely to irritate the newborn (e.g., examining the hips and eliciting the Moro reflex). A general visual assessment provides an enormous amount of information about the well-being of a newborn. Initial observation gives an impression of a healthy (stable) versus an ill newborn and a term versus a preterm newborn.

A typical physical examination of a newborn includes a general survey of skin color, posture, state of alertness, head size, overall behavioral state, respiratory status, gender, and any obvious congenital anomalies. Check the overall appearance for anything unusual. Then complete the examination in a systematic

fashion.

Remember Kelly, who called the home health nurse and said her newborn son "looks like a canary"? What additional information is needed about the baby? What might be causing his yellow color?

ANTHROPOMETRIC MEASUREMENTS

Shortly after birth, after the gender of the child is revealed, most women and their partners/significant others want to know the vital statistics of their newborn —length and weight—to report to their family and friends. Additional measurements, including head and chest circumference, are also taken and recorded. Abdominal measurements are not routinely obtained unless there is a suspicion of pathology that causes abdominal distention. The newborn's progress from that point onward will be validated based on these early measurements. These measurements will be compared with future serial measurements to determine growth patterns, which are plotted on growth charts to evaluate normalcy. Therefore, accuracy is paramount.

Length. The average length of most newborns is 50 cm (20 in), but it can range from 44 to 55 cm (17 to 22 in). Measure length with the unclothed newborn lying on a warmed blanket placed on a flat surface with the knees held in an extended position. Then run a tape measure down the length of the newborn— from the head to the soles of the feet—and record this measurement in the newborn's record (see Fig. 18.1).

Weight. At birth the average newborn weighs 3,400 g (7.5 lb), but normal birth weights can range from 2,500 to 4,000 g (5 lb, 8 oz to 8 lb, 14 oz). Newborns are weighed immediately after birth and then daily. Newborns usually lose up to 6% of their birth weight within the first few days of life, but regain it in approximately 10 days.

Newborns are weighed on admission to the nursery or are taken to a digital scale to be weighed and returned to the mother's room. First, balance the scale if it is not balanced. Place a warmed protective cloth or paper as a barrier on the scale to prevent heat loss by conduction; recalibrate the scale to zero after applying the barrier. Next, place the unclothed newborn in the center of the scale. Keep a hand above the newborn for safety (see Fig. 18.2).

Weight is affected by racial origin, genetics, maternal age, size of the parents, maternal nutrition, maternal weight prenatally, and placental perfusion (Tawia & McGuire, 2014). Weight should be correlated with gestational age. A newborn who weighs more than normal might be LGA or an infant of a diabetic mother; a newborn who weighs less than normal might be SGA, preterm, or have a genetic syndrome. It is important to identify the cause for the deviation in size and to monitor the newborn for complications common to that etiology.

Head Circumference. The average newborn head circumference is 32 to 38 cm (13 to 15 in). Measure the circumference at the head's widest diameter (the occipitofrontal circumference). Wrap a flexible or paper measuring tape snugly around the newborn's head and record the measurement (Fig. 18.9A).

Take Note!

Head circumference may need to be remeasured at a later time if the shape of the head is altered from birth.

FIGURE 18.9 **A.** Measuring head circumference. **B.** Measuring chest circumference.

The head circumference should be approximately one fourth of the newborn's length or about half the infant's body length plus 10 cm. Expected head circumference for a term infant is between 32 and 37 cm (12.5 to 14.5 in) (Nagtalon-Ramos, 2014). A small head might indicate microcephaly caused by rubella, toxoplasmosis, or SGA status; an enlarged head might indicate hydrocephalus or increased intracranial pressure. Both need to be documented and reported for further investigation.

Chest Circumference. The average chest circumference is 30 to 36 cm (12 to 14 in). It is generally equal to or about 2 to 3 cm less than the head circumference (Weber & Kelley, 2014). Place a flexible or paper tape measure around the unclothed newborn's chest just below the nipple line without pulling it taut (see Fig. 18.9B).

The head and chest circumferences are usually equal by about 1 year of age.

VITAL SIGNS

In the newborn, temperature, pulse, and respirations are monitored frequently and compared with baseline data obtained immediately after birth. Generally, vital signs (excluding blood pressure) are taken:

• On admission to the nursery or in the labor and birth room after the woman/parents are allowed to hold and bond with the newborn

• Once every 30 minutes until the newborn has been stable for 2 hours

• Then once every 4 to 8 hours until discharge (Davidson, 2014)

Blood pressure is not routinely assessed in a normal newborn unless the baby's clinical condition warrants it. This schedule can change depending on the baby's health status.

Obtain a newborn's temperature by placing an electronic temperature probe in the midaxillary area or by monitoring the electronic thermistor probe that has been taped to the abdominal skin (applied when the newborn was placed under a radiant heat source). Monitor the newborn's temperature frequently per hospital protocol for changes until it stabilizes. If the temperature is higher, adjust the environment, such as removing some clothing or blankets. If the temperature is lower, check the radiant warmer setting or add a warmed blanket. Report any abnormalities to the primary health care provider if simple adjustments to the environment do not change the baby's temperature.

Obtain an apical pulse by placing the stethoscope over the fourth intercostal space on the chest. Listen for a full minute, noting rate, rhythm, and abnormal sounds such as murmurs. In the typical newborn, the heart rate is 120 to 160 bpm, with wide fluctuations with activity and sleep. Sinus arrhythmia is a normal finding. Murmurs detected during the newborn period do not necessarily indicate congenital heart disease, but they need to be evaluated further if they persist. Also palpate the apical, femoral, and brachial pulses for presence and equality (Fig. 18.10). Report any abnormalities to the primary health care provider for evaluation.

Assess respirations by observing the rise and fall of the chest for 1 full minute.

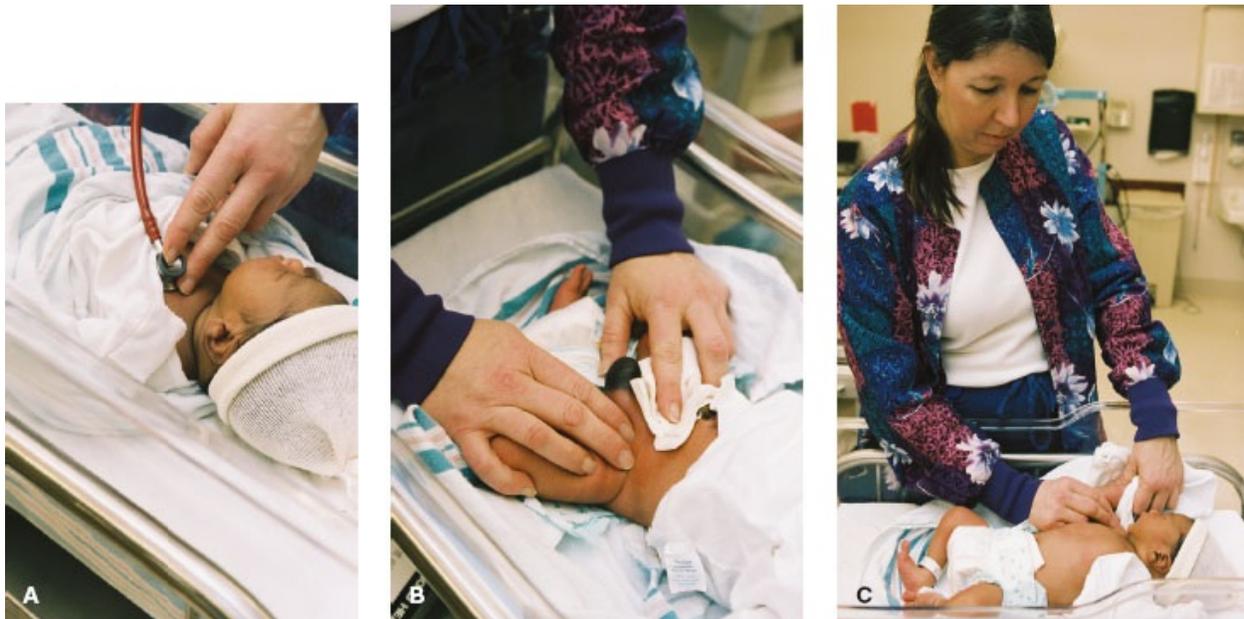
Respirations should be symmetric, slightly irregular, shallow, and unlabored at a rate of 30 to 60 breaths/minute. The newborn's respirations are predominantly diaphragmatic, but they are synchronous with abdominal movements. Also auscultate breath sounds. Note any abnormalities, such as tachypnea, bradypnea, grunting, gasping, periods of apnea lasting longer than 20 seconds, asymmetry or decreased chest expansion, abnormal breath sounds (rhonchi and crackles), or sternal retractions. Some variations might exist early after birth, but if the abnormal pattern persists, notify the primary health care provider.


FIGURE 18.10 Assessing the newborn's vital signs. **A.** Assessing the apical pulse. **B.** Palpating the femoral pulse. **C.** Palpating the brachial pulse.

SKIN

The newborn's skin is similar in structure to the adult's, but many of the functions are not fully developed. Observe the overall appearance of the skin, including color, texture, turgor, and integrity. The newborn's skin should be smooth and flexible, and the color should be consistent with genetic background.

Skin Condition and Color. Check skin turgor by pinching a small area of skin over the chest or abdomen and note how quickly it returns to its original position. In a well-hydrated newborn, the skin should return to its normal position immediately. Skin that remains "tented" after being pinched may indicate dehydration. A small amount of lanugo (fine downy hair) may be

observed over the shoulders and on the sides of the face and upper back. There may be some cracking and peeling of the skin. The skin should be warm to the touch and intact.

The newborn's skin often appears blotchy or mottled, especially in the extremities. Persistent cyanosis of fingers, hands, toes, and feet with mottled blue or red discoloration and coldness is called **acrocyanosis** (Fig. 18.11). It may be seen in newborns during the first few weeks of life in response to exposure to cold. Acrocyanosis is normal and intermittent. Any change in color of the newborn skin needs further investigation.

Newborn Skin Variations. While assessing the skin, make note of any rashes, ecchymoses or petechiae, nevi, or dark pigmentation. Skin lesions can be congenital or transient; they may be a result of infection or may result from the mode of birth. If any of them are present, observe the anatomic location, arrangement, type, and color. Bruising may result from the use of devices such as a vacuum extractor during delivery. Petechiae may be the result of pressure on the skin during the birth process. Forceps marks may be observed over the cheeks and ears. A small puncture mark may be seen if internal fetal scalp electrode monitoring was used during labor.

Common skin variations include vernix caseosa, stork bites or salmon patches, milia, Mongolian spots, erythema toxicum, harlequin sign, nevus flammeus, and nevus vasculosus (Fig. 18.12).

FIGURE 18.11 Acrocyanosis. This commonly appears on the feet and hands of babies shortly after birth. This infant is a 32-week newborn. (From Fletcher M. [1998]. *Physical diagnosis in neonatology*. Philadelphia, PA: Lippincott-Raven Publishers.)

FIGURE 18.12 Common skin variations. **A.** Stork bite. **B.** Milia. **C.** Mongolian spots. **D.** Erythema toxicum. **E.** Nevus flammeus (port-wine stain). **F.** Strawberry hemangioma.

Vernix caseosa is a thick white substance that protects the skin of the fetus. It is formed by secretions from the fetus's oil glands and is found during the first 2 or 3 days after birth in body creases and the hair. It does not need to be removed because it will be absorbed into the skin.

Stork bites or salmon patches are superficial vascular areas found on the nape of the neck, on the eyelids, and between the eyes and upper lip (see Fig. 18.12A). The name comes from the marks on the back of the neck where, as myth goes, a stork may have picked up the baby. They are caused by a concentration of immature blood vessels and are most visible when the newborn is crying. They are considered a normal variant, and most fade and disappear completely within the first year.

Milia are multiple pearly-white or pale yellow unopened sebaceous glands frequently found on a newborn's nose. They may also appear on the chin and forehead (see Fig. 18.12B). They form from oil glands and disappear on their own within 2 to 4 weeks. When they occur in a newborn's mouth and gums, they are termed **Epstein's pearls**. They occur in approximately 80% of newborns. As most lesions break spontaneously within the first few weeks of life, no therapy is indicated (El-Radhi, 2015).

Mongolian spots are benign blue or purple splotches that appear solitary on the lower back and buttocks of newborns, but may occur as multiple over the legs and shoulders (see Fig. 18.12C). They tend to occur in African American, Asian, Hispanic, and Indian newborns but can occur in dark-skinned newborns of all races. The spots are caused by a concentration of pigmented cells and usually disappear spontaneously within the first 4 years of life. They should not be confused with bruises caused by trauma (Silverberg, 2015).

Erythema toxicum (newborn rash) is a benign, idiopathic, generalized, transient rash that occurs in up to 70% of all newborns during the first week of life. It consists of small papules or pustules on the skin resembling flea bites. It is often mistaken for staphylococcal pustules. The rash is common on the face, chest, and back (see Fig. 18.12D). One of the chief characteristics of this rash is its lack of pattern. It is caused by the newborn's eosinophils reacting to the environment as the immune system matures. Histologically, erythema toxicum shows an abundance of eosinophils. Although it has been recognized and described for centuries, its etiology and pathogenesis remain unclear (Gloster, Gebauer, & Mistur, 2016a). It does not require any treatment and disappears in a few days.

Harlequin sign refers to the dilation of blood vessels on only one side of the body, giving the newborn the appearance of wearing a clown suit. It gives a distinct midline demarcation, which is described as pale on the nondependent side and red on the opposite, dependent side. It results from immature autoregulation of blood flow and is commonly seen in low-birth-weight

newborns when there is a positional change (Lomax, 2015). It is transient, lasting as long as 20 minutes, and no intervention is needed.

Nevus flammeus, also called a port-wine stain, commonly appears on the newborn's face or other body areas (see Fig. 18.12E). It is a capillary angioma located directly below the dermis. It is flat with sharp demarcations and is purple red. This skin lesion is made up of mature capillaries that are congested and dilated. It ranges in size from a few millimeters to large, occasionally involving as much as half the body surface. Although it does not grow in area or size, it is permanent and will not fade. Although they may occur anywhere on the body, the majority are located in the head and neck areas. Port-wine stains may be associated with structural malformations, bony or muscular overgrowth, and certain cancers. Recent studies have noted an association between port-wine birthmarks and childhood cancer, so newborns with these lesions should be monitored with periodic eye examinations, neurologic imaging, and extremity measurements. Lasers and intense pulsed light have been used to remove larger lesions with some success. The optimal timing of treatment is before 1 year of age (Giese & Richter, 2015).

Nevus vasculosus, also called a strawberry mark or strawberry hemangioma, is a benign capillary hemangioma in the dermal and subdermal layers. It is raised, rough, dark red, and sharply demarcated (see Fig. 18.12F). It is commonly found in the head region within a few weeks after birth and can increase in size or number. They are commonly found in about 10% of children. This type of hemangioma may be very subtle or even absent in the first few weeks of life, but they proliferate in the first few months of life. Commonly seen in premature infants weighing less than 1,500 g (El-Radhi, 2015), these hemangiomas tend to resolve by age 3 without any treatment.

The most important aspects of nursing management related to newborn skin variations include: adequate recognition of the lesions and knowledge of their natural history so that accurate information can be offered to the parents/significant other or partner. The majority of the skin lesions do not require any therapeutic intervention, but referral is necessary if there is: visual, airway or ear-canal obstruction, extensive growth, severe facial disfigurement, recurrent bleeding, infection, or ulceration, or excessive concern by the parents.

HEAD

Head size varies with age, gender, and ethnicity and has a general correlation with body size. Inspect a newborn's head from all angles. The head should

appear symmetric and round. As many as 90% of the congenital malformations present at birth are visible on the head and neck, so careful assessment is very important (Pfister & Ramel, 2014).

The newborn has two fontanels at the juncture of the cranial bones. The anterior fontanel is diamond shaped and closes by 18 to 24 months. Typically it measures 4 to 6 cm at the largest diameter (bone to bone). The posterior one is triangular, smaller than the anterior fontanel (usually fingertip size or 0.5 to 1 cm), and closes by 6 to 12 weeks. Palpate both fontanels, which should be soft, flat, and open. Then palpate the skull. It should feel somewhat smooth and fused, except at the area of the fontanels, over molding areas, and sutures. Also assess the size of the head and the anterior and posterior fontanels, and compare them with appropriate standards.

Variations in Head Size and Appearance. During inspection and palpation, be alert for common variations that may cause asymmetry. These include molding, caput succedaneum, and cephalhematoma.

Molding is the elongated shaping of the fetal head to accommodate passage through the birth canal (Fig. 18.13). It occurs with a vaginal birth from a vertex position in which elongation of the fetal head occurs with prominence of the occiput and overriding sagittal suture line. It typically resolves within a week after birth without intervention.

Caput succedaneum describes localized edema on the scalp that occurs from the pressure of the birth process. It is commonly observed after prolonged labor. Clinically, it appears as a poorly demarcated soft tissue swelling that crosses suture lines. Pitting edema and overlying petechiae and ecchymosis are noted (Fig. 18.14A). The swelling will gradually dissipate in about 3 days without any treatment. Newborns who were delivered via vacuum extraction usually have a caput in the area where the cup was used.

Cephalhematoma is a localized subperiosteal collection of blood of the skull which is always confined by one cranial bone. This condition is due to pressure on the head and disruption of the vessels during birth. It occurs after prolonged labor and use of obstetric interventions such as low forceps or vacuum extraction. The clinical features include a well-demarcated, often fluctuant swelling with no overlying skin discoloration. The swelling does not cross suture lines and is firmer to the touch than an edematous area (see Fig. 18.14B). Aspiration is not required for resolution and is likely to increase the risk of infection. Hyperbilirubinemia occurs following the breakdown of the red blood cells within the hematoma. This type of hyperbilirubinemia occurs later than

classic physiologic hyperbilirubinemia. Cephalhematoma usually appears on the second or third day after birth and disappears within weeks or months. Large cephalhematomas can lead to increased bilirubin levels and subsequent jaundice (Lomax, 2015).

Common Abnormalities in Head or Fontanel Size. Common abnormalities in head or fontanel size that may indicate a problem include:

- *Microcephaly*—a head circumference more than 2 standard deviations below average or less than 10% of normal parameters for gestational age, caused by failure of brain development. There is a reduced production of neurons leading to a reduction of brain volume and as a consequence of that a reduced skull size. Microcephaly is common, affecting more than 25,000 infants in the United States each year. Children with severe microcephaly, defined as more than 3 standard deviations below the mean for age and sex, are more likely to have imaging abnormalities and more severe developmental impairments than those with milder microcephaly. About 40% of children with microcephaly also have epilepsy, 20% have cerebral palsy, 50% have intellectual disability, and 20% to 50% have ophthalmologic and hearing disorders (Boom, 2015a). It can be familial, with autosomal dominant or recessive inheritance, and it may be associated with infections (cytomegalovirus), rubella, toxoplasmosis, and syndromes such as trisomy 13, 18, or 21 and fetal alcohol syndrome. Genetic counseling and clinical management through carrier detection/prenatal diagnosis in families can help reduce the incidence of these disorders (Alcantara & O'Driscoll, 2014).

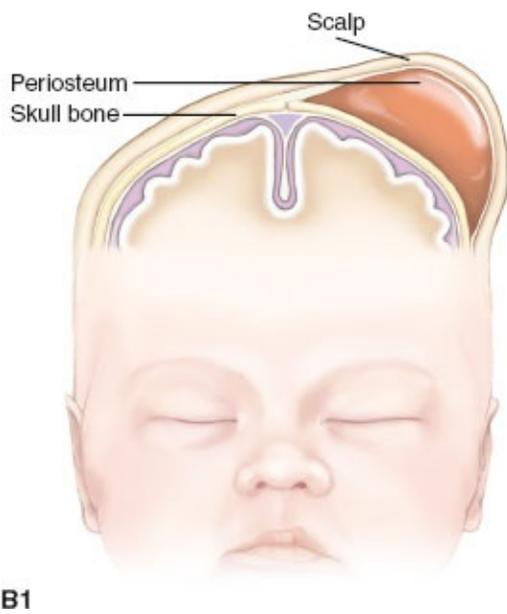
- *Macrocephaly*—a head circumference more than 90% of normal, typically related to hydrocephalus (Boom, 2015b). It is often familial (with autosomal dominant inheritance) and can be either an isolated anomaly or a manifestation of other anomalies, including hydrocephalus and skeletal disorders (achondroplasia).

- *Large fontanels*—more than 6 cm in the anterior diameter bone to bone or more than a 1-cm diameter in the posterior fontanel; possibly associated with malnutrition, hydrocephaly, congenital hypothyroidism, trisomies 13, 18, and 21, and various bone disorders such as osteogenesis imperfecta.

- *Small or closed fontanels*—smaller-than-normal anterior and posterior diameters or fontanels that are closed at birth. Craniosynostosis and abnormal brain development are associated with a small fontanel or early fontanel

closure associated with microcephaly (Sheth, Ranalli, & Aldana, 2014).

FACE

Observe the newborn's face for fullness and symmetry. The face should have full cheeks and should be symmetric when the baby is resting and crying. If forceps were used during birth, the newborn may have bruising and reddened areas over both cheeks and parietal bones secondary to the pressure of the forceps blades. Reassure the parents that this resolves without treatment, and point out improvement each day.


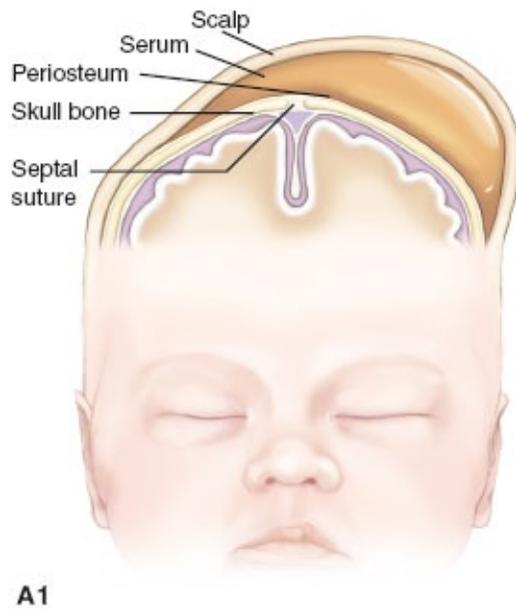


FIGURE 18.14 A1 and A2. Caput succedaneum involves the collection of serous fluid and often crosses the suture line. **(A2..** From Chung, *Visual diagnosis and treatment in pediatrics* (2nd ed.). Philadelphia: LWW.) **B1 and B2.** Cephalhematoma involves the collection of blood and does not cross the suture line. (Photos, except for (A2), from O'Doherty, N. (1979). *Atlas of the newborn*. Philadelphia: J B Lippincott, 1979:136, and 1979:117, 143, with permission.)

Problems with the face can also involve facial nerve paralysis caused by trauma from the use of forceps. Paralysis is usually apparent on the first or second day of life. Typically, the newborn will demonstrate asymmetry of the face with an inability to close the eye and move the lips on the affected side. Newborns with facial nerve paralysis have difficulty making a seal around the nipple, and consequently milk or formula drools from the paralyzed side of the mouth. Most facial nerve palsies resolve spontaneously within days, although full recovery may require weeks to months. Attempt to determine the cause from the newborn's history.

Nose. Inspect the nose for size, symmetry, position, and lesions. The newborn's nose is small and narrow. The nose should have a midline placement, patent nares, and an intact septum. The nostrils should be of equal size and should be patent. A slight mucous discharge may be present, but there should be no actual drainage. The newborn is a preferential nose breather and will use sneezing to clear the nose if needed. The newborn can smell after the nasal passages are cleared of amniotic fluid and mucus (Clark-Gambelunghe & Clark, 2015).

Mouth. Inspect the newborn's mouth, lips, and interior structures. The lips should be intact with symmetric movement and positioned in the midline; there should not be any lesions. Inspect the lips for pink color, moisture, and cracking. The lips should encircle the examiner's finger to form a vacuum. Variations involving the lip might include cleft upper lip (separation extending up to the nose) or thin upper lip associated with fetal alcohol syndrome.

Assess the inside of the mouth for alignment of the mandible, intact soft and hard palate, sucking pads inside the cheeks, a midline uvula, a free-moving tongue, and working gag, swallow, and sucking reflexes. The mucous membranes lining the oral cavity should be pink and moist, with minimal saliva present.

Normal variations might include Epstein's pearls (small, white epidermal cysts on the gums and hard palate that disappear in weeks), erupted natal teeth that may need to be removed to prevent aspiration (Fig. 18.15), and thrush (white plaque inside the mouth caused by exposure to *Candida albicans* during birth), which cannot be wiped away with a cotton-tipped applicator.

Eyes. Inspect the external eye structures, including the eyelids, lashes, conjunctiva, sclera, iris, and pupils, for position, color, size, and movement. There may be marked edema of the eyelids and subconjunctival hemorrhages

due to pressure during birth. The eyes should be clear and symmetrically placed. Test the blink reflex by bringing an object close to the eye; the newborn should respond quickly by blinking. Also test the newborn's pupillary reflex: pupils should be equal, round, and reactive to light bilaterally. Assess the newborn's gaze: he or she should be able to track objects to the midline. Movement may be uncoordinated during the first few weeks of life. Many newborns have transient strabismus (deviation or wandering of eyes independently) and searching nystagmus (involuntary repetitive eye movement), which is caused by immature muscular control. These are normal for the first 3 to 6 months of age.

FIGURE 18.15 A natal tooth in a 16-day-old neonate. Natal teeth can be present at birth and are usually considered benign. No treatment is needed if they don't interfere with feeding.

Examine the internal eye structures. A red reflex (luminous red appearance seen on the retina) should be seen bilaterally on retinoscopy. The red reflex normally shows no dullness or irregularities.

Chemical conjunctivitis commonly occurs within 24 hours of instillation of eye prophylaxis after birth. There is lid edema with sterile discharge from both eyes. Usually it resolves within 48 hours without treatment.

Ears. Inspect the ears for size, shape, skin condition, placement, amount of cartilage, and patency of the auditory canal. The ears should be soft and pliable and should recoil quickly and easily when folded and released. Ears should be aligned with the outer canthi of the eyes. Low-set ears and abnormally shaped ears are characteristic of many syndromes and genetic abnormalities, such as trisomy 13 or 18, and internal organ abnormalities involving the renal system. Findings of sinuses or preauricular skin tags should prompt further evaluation

for possible renal abnormalities since both systems develop at the same time.

An otoscopic examination is not typically done because the newborn's ear canals are filled with amniotic fluid and vernix caseosa, which would make visualization of the tympanic membrane difficult.

Newborn hearing screening is required by law in most states (discussed later in the chapter). Hearing loss is the most common birth defect in the United States: One in 1,000 newborns are profoundly deaf and 3 in 1,000 have some degree of hearing impairment (March of Dimes, 2015a). Delays in identification and intervention may affect the child's cognitive, verbal, behavioral, and emotional development. Screening at birth has reduced the age at which newborns with hearing loss are identified and has improved early intervention rates dramatically.

Available treatments include cochlear implantation, hearing augmentation, and follow-up by an audiologist, otolaryngologist, pediatrician, geneticist, and deaf education specialist (Nikolopoulos, 2015). Prior to universal newborn screening, children were usually older than 2 years before significant congenital hearing loss was detected; by this time it had already affected their speech and language skills (CDC, 2015b).

Causes of hearing loss can be conductive, sensorineural, or central. Risk factors for congenital hearing loss include cytomegalovirus infection and preterm birth necessitating a stay in the neonatal intensive care unit.

To assess for hearing ability generally, observe the newborn's response to noises and conversations. The newborn typically turns toward these noises and startles with loud ones.

NECK

Inspect the newborn's neck for movement and ability to support the head. The newborn's neck will appear almost nonexistent because it is so short. Creases are usually noted. The neck should move freely in all directions and should be capable of holding the head in a midline position. The newborn should have enough head control to be able to hold it up briefly without support. Report any deviations such as restricted neck movement or absence of head control.

Also inspect the clavicles (collarbone), which should be straight and intact. The clavicles are the bones mostly commonly broken in infants, especially large ones experiencing difficult births, in operative vaginal births, abnormal fetal positions, and in maternal obesity. In most cases, the fractured clavicle is asymptomatic, but edema, crepitus, and decreased or absent movement and pain

or tenderness on movement of the arm on the affected side may be noted. Major risk factors for clavicle fractures are typically vacuum births and large newborn birth weights (Ahn et al., 2015). If the newborn with clavicular fracture is in pain, the affected arm should be immobilized, with the arm abducted more than 60 degrees and the elbow flexed more than 90 degrees. In addition to immobilization, treatment involves minimizing pain overall.

CHEST

Inspect the newborn's chest for size, shape, and symmetry. The newborn's chest should be round, symmetric, and 2 to 3 cm smaller than the head circumference. The xiphoid process may be prominent at birth, but it usually becomes less apparent when adipose tissue accumulates. Nipples may be engorged and may secrete a white discharge. This discharge, which occurs in both boys and girls, is a result of exposure to high levels of maternal estrogen while in utero. This enlargement and milky discharge usually dissipates within a few weeks. Some newborns may have extra nipples, called supernumerary nipples. They are typically small, raised, pigmented areas vertical to the main nipple line, 5 to 6 cm below the normal nipple. Supernumerary nipples may be unilateral or bilateral, and they may include an areola, nipple, or both. They tend to be familial and do not contain glandular tissue. Supernumerary nipples are generally thought to be benign. Some studies have suggested an association with renal or urogenital anomalies, whereas other studies have failed to show this association. There is insufficient evidence to recommend imaging studies or removal in the absence of other clinical concerns or physical findings (Gloster, Gebauer, & Mistur, 2016b). Reassure parents that these extra small nipples are harmless.

The newborn chest is usually barrel shaped, with equal anteroposterior and lateral diameters, and symmetric. Auscultate the lungs bilaterally for equal breath sounds. Normal breath sounds should be heard, with little difference between inspiration and expiration. Fine crackles can be heard on inspiration soon after birth as a result of amniotic fluid being cleared from the lungs. Diminished breath sounds might indicate atelectasis or pneumonia (Weber & Kelley, 2014).

Listen to the heart when the newborn is quiet or sleeping. S1 and S2 heart sounds are accentuated at birth. The point of maximal impulse is a lateral to midclavicular line located at the fourth intercostal space. A displaced point of maximal impulse may indicate tension pneumothorax or cardiomegaly. Murmurs

are common during the first few hours as the foramen ovale is closing. Although cardiac murmurs in the neonatal period do not necessarily indicate heart disease, they should be evaluated if they persist (Fillipps & Bucciarelli, 2015).

ABDOMEN

Inspect the abdomen for shape and movement. Typically, the newborn's abdomen is protuberant but not distended. This contour is a result of the immaturity of the abdominal muscles. Abdominal movements are synchronous with respirations because newborns are, at times, abdominal breathers.

Auscultate bowel sounds in all four quadrants and then palpate the abdomen for consistency, masses, and tenderness. Perform auscultation and palpation systematically in a clockwise fashion until all four quadrants have been assessed. Palpate gently to feel the liver, the kidneys, and any masses. The liver is normally palpable 1 to 3 cm below the costal margin in the midclavicular line. The kidneys are 1 to 2 cm above and to both sides of the umbilicus. Normal findings would include bowel sounds in all four quadrants and no masses or tenderness on palpation. Absent or hyperactive bowel sounds might indicate an intestinal obstruction. Abdominal distention might indicate ascites, obstruction, infection, masses, or an enlarged abdominal organ. The newborn may also show signs of abdominal tenderness (Springer & Glasser, 2015). Imaging is a mainstay to diagnosis abdominal pathology and should be readily performed in a newborn with abdominal distention to determine the underlying etiology.

Inspect the umbilical cord area for the correct amount of blood vessels (two arteries and one vein). The umbilical vein is larger than the two umbilical arteries. Evidence of only a single umbilical artery is associated with renal and gastrointestinal anomalies. Also inspect the umbilical area for signs of bleeding, infection, inflammation, redness, swelling, purulent drainage or bleeding, erythema around the umbilicus, granuloma, or abnormal communication with the intra-abdominal organs. Umbilical infections can occur because of an embryologic remnant or poor hygiene. Traditionally, gram-positive organisms, such as *Staphylococcus aureus* and *Streptococcus pyogenes,* were most commonly identified, but gram-negative and polymicrobial infections are seen today. An umbilical cord infection (omphalitis) can spread to adjacent tissue, causing peritonitis, hepatic vein thrombosis and hepatic abscess. Immediate evaluation and referral is needed (Lomax, 2015).

GENITALIA

Male. Inspect the penis and scrotum in the male. In the circumcised male newborn, the glans should be smooth, with the meatus centered at the tip of the penis. It will appear reddened until it heals. For the uncircumcised male, the foreskin should cover the glans. Check the position of the urinary meatus: it should be in the midline at the glans' tip. If it is on the ventral surface of the penis, the condition is termed hypospadias; if it is on the dorsal surface of the penis, it is termed epispadias. In either case, circumcision should be avoided until further evaluation.

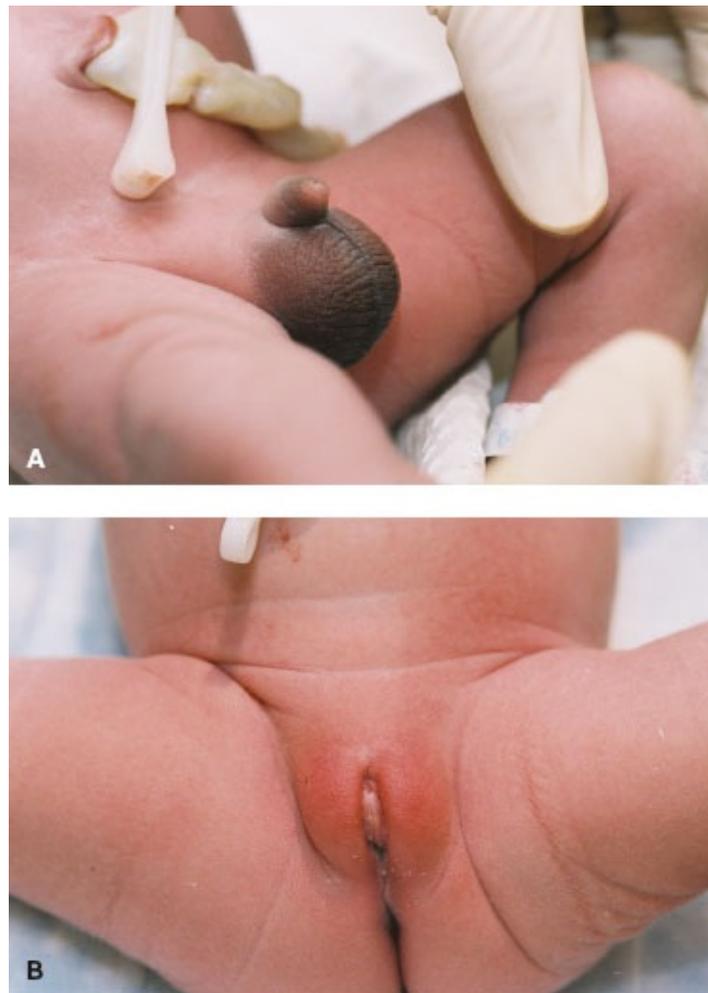
Inspect the scrotum for size, symmetry, color, presence of rugae, and location of testes. The scrotum usually appears relatively large with well-formed rugae and that should cover the scrotal sac. There should not be bulging, edema, or discoloration (Fig. 18.16A).


FIGURE 18.16 Newborn genitalia. **A.** Male genitalia. Note the darkened color of the scrotum. **B.** Female genitalia.

Palpate the scrotum for evidence of the testes, which should be in the scrotal sac. The testes should feel firm and smooth and should be of equal size on both sides of the scrotal sac in the term newborn. Undescended testes (cryptorchidism) might be palpated in the inguinal canal in preterm infants; they can be unilateral or bilateral. If the testes are not palpable within the scrotal sac, further investigation is needed.

Female. In the female newborn, inspect the external genitalia. The urethral meatus is located below the clitoris in the midline (Mutter & Prat, 2014). In contrast to the male genitalia, the female genitalia will be engorged: the labia majora and minora may both be edematous. The labia majora is large and covers the labia minora. The clitoris is large and the hymen is thick. These findings are due to the maternal hormones estrogen and progesterone (see Fig. 18.16B). A vaginal discharge composed of mucus mixed with blood may also be present during the first few weeks of life. This discharge, called **pseudomenstruation**, requires no treatment. Explain this phenomenon to the parents.

Variations in female newborns may include a labial bulge, which might indicate an inguinal hernia, ambiguous genitalia, a rectovaginal fistula with feces present in the vagina, and an imperforate hymen.

Male and Female. Inspect the anus in both male and female newborns for position and patency. Passage of meconium indicates patency. If meconium is not passed, a lubricated rectal thermometer can be inserted or a digital examination can be performed to determine patency. Abnormal findings would include anal fissures or fistulas and no meconium passed within 24 hours after birth.

EXTREMITIES AND BACK

Upper Extremities. Inspect the newborn's upper extremities for appearance and movement. Inspect the hands for shape, number, and position of fingers and presence of palmar creases. The newborn's arms and hands should be symmetric and should move through the range of motion without hesitation. Observe for spontaneous movement of the extremities. Each hand should have five digits. Note any extra digits (polydactyly) or fusing of two or more digits (syndactyly). Most newborns have three palmar creases on the hand. A single palmar crease, called a simian line, is frequently associated with Down syndrome.

A brachial plexus injury can occur during a difficult birth involving shoulder

dystocia. Erb palsy is an injury resulting from damage to the upper plexus, and palsies associated with the lower brachial plexus are termed Klumpke palsies. Factors associated with obstetric brachial plexus paralysis include large birth weight, breech delivery, labor anomalies, operative vaginal birth, and shoulder dystocia. Obstetric brachial plexus paralysis results from excessive lateral traction on the head away from the shoulder. This force on the brachial plexus can cause varying degrees of injury to the nerves. The affected arm hangs limp alongside the body, and the affected shoulder and arm are adducted, extended, and internally rotated with a pronated wrist. The Moro reflex is absent on the affected side in brachial palsy. Complete recovery may take 6 months or longer. Current research studies support endogenous labor forces as the etiology of this injury. Despite training in the management of shoulder dystocia and a rising institutional cesarean section rate, the incidence of brachial plexus injuries has remained unchanged compared with 10 years earlier (Tung & Moore, 2015).

Lower Extremities. Assess the lower extremities in the same manner. They should be of equal length, with symmetric skinfolds. Inspect the feet for clubfoot (a turning-inward position), which is secondary to intrauterine positioning. This may be positional or structural. Perform the Ortolani and Barlow maneuvers to identify congenital hip dislocation, commonly termed developmental dysplasia of the hip. Nursing Procedure 18.1 highlights the steps for performing these maneuvers. Table 18.3 summarizes the newborn assessment.

NEUROLOGIC STATUS

Assess the newborn's state of alertness, posture, muscle tone, and reflexes.

Newborn Alertness, Posture, and Muscle Tone. The newborn should be alert and not persistently lethargic. The normal posture is hips abducted and partially flexed, with knees flexed. Arms are adducted and flexed at the elbow. Fists are often clenched, with fingers covering the thumb.

Performing Ortolani and Barlow Maneuvers

Purpose: To Detect Congenital Developmental Dysplasia of the Hip

Ortolani Maneuver

1. Place the newborn in the supine position and flex the hips and knees to 90 degrees at the hip.
2. Grasp the inner aspect of the thighs and abduct the hips (usually to approximately 180 degrees) while applying upward pressure.

3. Listen for any sounds during the maneuver. There should be no "cluck" or "click" heard when the legs are abducted. Such a sound indicates the femoral head hitting the acetabulum as the head reenters the area. This suggests developmental hip dysplasia.

Barlow Maneuver

1. With the newborn still lying supine and grasping the inner aspect of the thighs (as just mentioned), adduct the thighs while applying outward and downward pressure to the thighs.
2. Feel for the femoral head slipping out of the acetabulum; also listen for a click.

Inspect the back. The spine should appear straight and flat and should be easily flexed when the baby is held in a prone position. Observe for the presence of a tuft of hair, a pilonidal dimple in the midline, a cyst, or a mass along the spine. These abnormal findings should be documented and reported to the primary health care provider.

TABLE 18.3 NEWBORN ASSESSMENT SUMMARY

Assessment	Usual Findings	Variations and Common Problems
Anthropometric measurements	Head circumference: 33–37 cm (13–14 in) Chest circumference: 30–33 cm (12–13 in) Weight: 2,500–4,000 g (5.5–8.5 lb) Length: 45–55 cm (19–21 in.)	SGA, LGA, preterm, post-term
Vital signs	Temperature: 97–99° F (36.5–37.5° C) Apical pulse: 110–160 bpm Respirations: 30–60 breaths/minute	
Skin	Normal: smooth, flexible, good skin turgor, well hydrated, warm	Jaundice, acrocyanosis, milia, Mongolian spots, stork bites
Head	Normal: varies with age, gender, and ethnicity	Microcephaly, macrocephaly, enlarged fontanels
Face	Normal: full cheeks, facial features symmetric	Facial nerve paralysis, nevus flammeus, nevus vasculosus
Nose	Normal: small, placement in the midline and narrow, ability to smell	Malformation or blockage
Mouth	Normal: aligned in midline, symmetric, intact soft and hard palate	Epstein's pearls, erupted precocious teeth, thrush
Neck	Normal: short, creased, moves freely, baby holds head in midline	Restricted movement, clavicular fractures
Eyes	Normal: clear and symmetrically placed on face; online with ears	Chemical conjunctivitis, subconjunctival hemorrhages
Ears	Normal: soft and pliable with quick recoil when folded and released	Low-set ears, hearing loss
Chest	Normal: round, symmetric, smaller than head	Nipple engorgement, whitish discharge
Abdomen	Normal: protuberant contour, soft, three vessels in umbilical cord	Distended, only two vessels in umbilical cord
Genitals	Normal male: smooth glans, meatus centered at tip of penis Normal female: swollen female genitals as a result of maternal estrogen	Edematous scrotum in males, vaginal discharge in females
Extremities and spine	Normal: extremities symmetric with free movement	Congenital hip dislocation; tuft or dimple on spine

Data from Davidson, M. R. (2014). *Fast facts for the neonatal nurse: A nursing orientation and care guide in a nutshell.* New York, NY: Springer Publishing Company; and Weber, J., & Kelley, J. (2014). *Health assessment in nursing* (5th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

To assess for muscle tone, support the newborn with one hand under the chest. Observe how the neck muscles hold the head. The neck extensors should be able to hold the head in line briefly. There should be only slight head lag when pulling the newborn from a supine position to a sitting one.

Newborn Reflexes. Assess the newborn's reflexes to evaluate neurologic function and development. Absent or abnormal reflexes in a newborn, persistence of a reflex past the age when the reflex is normally lost, or return of an infantile reflex in an older child or adult may indicate neurologic pathology (Table 18.4). Reflexes commonly assessed in the newborn include sucking,

Moro, stepping, tonic neck, rooting, Babinski, palmar grasp and plantar grasp reflexes. Spinal reflexes tested include truncal incurvation (Galant reflex) and anocutaneous reflex (anal wink).

The *sucking reflex* is elicited by gently stimulating the newborn's lips by touching them. The newborn will typically open the mouth and begin a sucking motion. Placing a gloved finger in the newborn's mouth will also elicit a sucking motion (Fig. 18.17A).

TABLE 18.4 NEWBORN REFLEXES: APPEARANCE AND DISAPPEARANCE

Reflex	Appearance	Disappearance
Blinking	Newborn	Persists into adulthood
Moro	Newborn	3–6 mo
Grasp	Newborn	3–4 mo
Stepping	Birth	1–2 mo
Tonic neck	Newborn	3–4 mo
Sneeze	Newborn	Persists into adulthood
Rooting	Birth	4–6 mo
Gag reflex	Newborn	Persists into adulthood
Cough reflex	Newborn	Persists into adulthood
Babinski sign	Newborn	12 mo

The *Moro reflex,* also called the embrace reflex, occurs when the neonate is startled. To elicit this reflex, place the newborn on his or her back. Support the upper body weight of the supine newborn by the arms, using a lifting motion, without lifting the newborn off the surface. Then release the arms suddenly. The newborn will throw the arms outward and flex the knees; the arms then return to the chest. The fingers also spread to form a C shape. The newborn initially appears startled and then relaxes to a normal resting position (see Fig. 18.17B).

Assess the *stepping reflex* by holding the newborn upright and inclined forward with the soles of the feet touching a flat surface. The baby should make

a stepping motion or walking, alternating flexion and extension with the soles of the feet (see Fig. 18.17C).

The *tonic neck reflex* resembles the stance of a fencer and is often called the fencing reflex. Test this reflex by having the newborn lie on the back. Turn the baby's head to one side. The arm toward which the baby is facing should extend straight away from the body with the hand partially open, whereas the arm on the side away from the face is flexed and the fist is clenched tightly. Reversing the direction to which the face is turned reverses the position (see Fig. 18.17D).

Elicit the *rooting reflex* by stroking the newborn's cheek. The newborn should turn toward the side that was stroked and should begin to make sucking movements (see Fig. 18.17E).

The *Babinski reflex* should be present at birth and disappears at approximately 1 year of age. It is elicited by stroking the lateral sole of the newborn's foot from the heel toward and across the ball of the foot. The toes should fan out. A diminished response indicates a neurologic problem and needs follow-up (see Fig. 18.17F).

The newborn exhibits two grasp reflexes: *palmar grasp* and *plantar grasp.* Elicit the palmar grasp reflex by placing a finger on the newborn's open palm. The baby's hand will close around the finger. Attempting to remove the finger causes the grip to tighten. Newborns have strong grasps and can almost be lifted from a flat surface if both hands are used. The grasp should be equal bilaterally (see Fig. 18.17G). The plantar grasp is similar to the palmar grasp. Place a finger just below the newborn's toes. The toes typically curl over the finger (see Fig. 18.17H).

FIGURE 18.17 Newborn reflexes. **A.** Sucking reflex. **B.** Moro reflex. **C.** Stepping reflex. **D.** Tonic neck reflex. **E.** Rooting reflex. **F.** Babinski reflex. **G.** Palmar grasp. **H.** Plantar grasp.

Blinking, sneezing, gagging, and *coughing* are all protective reflexes and are elicited when an object or light is brought close to the eye (blinking); something irritating is swallowed or a bulb syringe is used for suctioning (gagging and coughing); or an irritant is brought close to the nose (sneezing).

The *truncal incurvation reflex* (*Galant reflex*) is present at birth and disappears in a few days to 4 weeks (Fig. 18.18). With the newborn in a prone position or held in ventral suspension, apply firm pressure and run a finger down either side of the spine. This stroking will cause the pelvis to flex toward the stimulated side. This indicates T2–S1 innervation. Lack of response indicates a neurologic or spinal cord problem.

FIGURE 18.18 Trunk incurvation reflex. When the paravertebral area is stroked, the newborn flexes his or her trunk toward the direction of the stimulation. (Copyright Caroline Brown, RNC, MS, DEd.)

The *anocutaneous reflex* (*anal wink*) is elicited by stimulating the perianal skin close to the anus. The external sphincter will constrict (wink) immediately with stimulation. This indicates S4–S5 innervations (Marcdante & Kliegman, 2014).

Nursing Interventions

Developing confidence in caring for their newborn is challenging for most parents/significant others/partners. It takes time and patience, and a great deal of instruction provided by the nurse. "Showing and telling" parents about their newborn and all the procedures (e.g., feeding, bathing, changing, and handling) involved in daily care are key nursing interventions.

Providing General Newborn Care

Generally, newborn care involves bathing and hygiene, elimination and diaper area care, cord care, circumcision care, environmental safety measures, and prevention of infection. Nurses should teach these skills to parents and should serve as role models for appropriate and consistent interaction with newborns. Demonstrating respect for the newborn and family helps foster a positive atmosphere to promote the newborn's growth and development.

BATHING AND HYGIENE

Immediately after birth, drying the newborn and removing blood may minimize the risk of infection caused by hepatitis B, herpes virus, and HIV, but the specific benefits of this practice remain unclear. Until the newborn has been thoroughly bathed, standard precautions should be used when handling the newborn. Nurses need to follow their hospital policies regarding the timing and procedures for newborn bathing and hygiene.

Newborns are bathed primarily for aesthetic reasons, and bathing is postponed until thermal and cardiorespiratory stability is ensured. Traditional reasons why nurses bathe the newborn are so they can conduct a physical assessment, reduce the effect of hypothermia, and allow the mother to rest (Davidson, 2014). However, recent research suggests that nurses do not need to give the newborn an initial bath to reduce heat loss; rather, the parents could be given this opportunity, supported by nurses. A study found that the amount of heat loss was similar in newborns bathed by parents versus newborns who were bathed by nurses (Davidson, 2014).

Nursing Procedure 18.2 explains the steps for bathing the newborn. It is important for the nurse to wear gloves, because of potential exposure to maternal blood on the newborn, and perform the bath quickly, drying the baby thoroughly

to prevent heat loss by evaporation.

After bathing, place the newborn under the radiant warmer and wrap him or her securely in blankets to prevent chilling. Check the baby's temperature within an hour to make sure it is within normal limits. If it is low, place the newborn under a radiant heat source again.

After the initial bath, the newborn may not receive another full one during the stay in the birthing unit. The diaper area will be cleansed at each diaper change, and any milk spilled into the newborn's neck folds from breast-feeding or formula will be cleaned. Clear water and a mild soap are appropriate to cleanse the diaper area. The use of lotions, baby oil, and powders is not encouraged because oils and lotions can lead to skin irritation and can cause rashes. Powders should not be used because they can be inhaled, causing respiratory distress. If the parents want to use oils and lotions, have them apply a small amount onto their hand first, away from the newborn; this warms the lotion. Then the parents should apply the lotion or oil sparingly.

Encourage the parents to gather all items needed before starting the bath: a soft, clean washcloth; two cotton balls to clean the eyes; mild, unscented soap and shampoo; towels or blankets; a tub or basin with warm water; a clean diaper; and a change of clothes. Instruct parents that a bath two or three times weekly is sufficient for the first year; more frequent bathing may dry the skin. Parents should not fully immerse the newborn into water until the umbilical cord area is healed—up to 2 weeks after birth. Encourage parents to give the infant a sponge bath until the umbilical cord falls off and the navel area is healed completely. If the newborn has been circumcised, advise parents to wait until that area has also healed (usually 1 to 2 weeks). Until then, clean the penis with mild soap and water and apply a small amount of petroleum jelly to the tip to prevent the diaper from adhering to the penis. Instruct parents to apply the diaper loosely and place the newly circumcised male infant on his side or back to prevent pressure and irritation on the penis.

Other guidelines for bathing newborns are given in Teaching Guidelines 18.1.

Teaching Guidelines 18.1

BATHING A NEWBORN

- Select a warm room with a flat surface at a comfortable working height.
- Before the bath, gather all supplies needed so they will be within reach.
- Never leave the newborn alone or unattended at any time during the bath.
- Undress the newborn down to shirt and diaper.
- Always support the newborn's head and neck when moving or positioning him or her.
- Place a blanket or towel underneath the newborn for warmth and comfort.
- In this order, progressing from the cleanest to the dirtiest areas:
  - Wipe eyes with plain water, using either cotton balls or a washcloth. Wipe from the inner corner of the eyes to the outer with separate wipes.
  - Wash the rest of the face, including ears, with plain water.
  - Using baby shampoo, gently wash the hair and rinse with water.
  - Pay special attention to body creases, and dry thoroughly.
  - Wash extremities, trunk, and back. Wash, rinse, dry, cover.
  - Wash diaper area last, using soap and water, and dry; observe for rash.
- Put on a clean diaper and clean clothes after the bath.

ELIMINATION AND DIAPER AREA CARE

Newborn elimination patterns are highly individualized. Usually the urine is light amber in color. Soaking 6 to 12 diapers a day indicates adequate hydration. Stools can change in color, texture, and frequency without signaling a problem. Meconium is passed for the first 48 hours after birth; the stools appear thick, tarry, sticky, and dark green. Transitional stools (thin, brown to green, less sticky than meconium) typically appear by day 3 after initiation of feeding. The stool characteristics after transitional stool depend on whether the newborn is breast-fed or bottle-fed. Breast-fed newborns typically pass mustard-colored, soft stool with a seedy consistency; formula-fed newborns pass yellow to brown, soft stools with a pasty consistency. As long as the newborn seems content, is eating normally, and shows no signs of illness, minor changes in bowel movements should not be a concern.

The newborn needs to be checked frequently to see whether a diaper change is needed, especially after feeding. Adhere to standard precautions when providing diaper area care. Instruct parents to keep the top edge of the diaper folded down

below the umbilical cord area to prevent irritation and to allow air to help dry the cord. For a male infant, point the penis down to prevent urine from wetting the top of the diaper where the umbilicus is located.

Bathing the Newborn

It is important that the nurse wear gloves, because of potential exposure to maternal blood on the newborn, and performs the bath quickly, drying the baby thoroughly to prevent heat loss by evaporation. Keep the newborn covered to prevent heat loss during the bathing procedure.

1. Begin the newborn bath starting from the cleanest area (the eyes) and proceeding to the most soiled area (the diaper area) to prevent cross-contamination. Use plain warm water on the face and eyes, adding a mild soap (e.g., Dove) to cleanse the remainder of the body. Wash, rinse, and dry each area before proceeding to the next one.

2. Wash the hair using running water so that the scalp can be thoroughly rinsed. A mild shampoo or soap can be used. Wash both fontanel areas. Frequently, parents avoid these "soft spots" because they fear that they

will "hurt the baby's brain" if they rub too hard. Reassure parents that there is a strong membrane providing protection. Urge the parents to clean and rinse these areas well. If the anterior fontanel is not rinsed well after shampooing, cradle cap (dry flakes on the scalp) can develop. Avoid getting water in ears to prevent infection.

3. Make sure to cleanse all body creases, especially the neck folds to remove any milk that may have dripped into these areas.

4. Continue downward washing the trunk and extremities ending up with the diaper area last.

Meconium can be difficult to remove from the skin. Use plain water or special cleansing wipes if necessary to clean the area. Teach parents how to clean the diaper area properly and how to prevent skin irritation. Encourage them to avoid products such as powder and fragranced items, which could irritate the newborn's skin.

Discuss the pros and cons of using cloth diapers versus disposable diapers so that the parents can make informed decisions. Regardless of the type of diapers used, up to 10 diapers a day, or about 70 a week, will be needed.

Additional information about diapering might include:

• Before diapering, make sure all supplies are within reach, including clean diaper, cleaning agent or wipes, and ointment.

• Lay the newborn on a changing table and remove the dirty diaper.

• Use water and mild soap or wipes to gently wipe the genital area clean; wipe from front to back for girls to avoid urinary tract infections.

• Wash your hands thoroughly before and after changing diapers.

While performing diaper area care, parents should observe the area closely for irritation or rash. Tips for preventing or healing a diaper rash include:

• Change diapers frequently, especially after bowel movements.

• Apply a "barrier" cream, such as A&D ointment or Desitin, after cleaning with mild soap and water.

• Use dye- and fragrance-free detergents to wash cloth diapers.

• Avoid the use of plastic pants, because they tend to hold in moisture.

• Expose the newborn's bottom to air several times a day.

- Place the newborn's buttocks in warm water after he or she has had a diaper on all night.

 Take Note!

Advise parents that a rash that persists for more than 3 days may be fungal in origin and may require additional treatment. Encourage the parents to notify the health care provider.

CORD CARE

The umbilical cord begins drying within hours after birth and is shriveled and blackened by the second or third day. Within 7 to 10 days, it sloughs off and the umbilicus heals. During this transition, frequent assessments of the area are necessary to detect any bleeding or signs of infection. Cord bleeding is abnormal and may occur if the cord clamp is loosened. Any cord drainage is also abnormal and is generally caused by infection, which requires immediate treatment.

To protect the cord area during each diaper change, apply the appropriate agent (e.g., triple dye, alcohol, or an antimicrobial agent), according to facility policy, to the cord stump to prevent any ascending infections. Single-use agents for cleaning are recommended to prevent cross-contamination with other newborns. Expect to remove the cord clamp approximately 24 hours after birth by using a cord-cutting clamp. However, if the cord is still moist, keep the clamp in place and ensure a referral to home health care so that the home care nurse can remove it after discharge. Always adhere to agency policies regarding cord care; changes in policy may be necessary based on new research findings.

Many parents avoid contact with the cord site to make sure they don't "bother" it. Teach them how to care for the cord site when they go home to prevent complications (Teaching Guidelines 18.2).

 Teaching Guidelines 18.2

UMBILICAL CORD CARE

- Observe for bleeding, redness, drainage, or foul odor from the cord stump

and report it to your newborn's primary care provider immediately.

- Avoid tub baths until the cord has fallen off and the area has healed.
- Expose the cord stump to the air as much as possible throughout the day.
- Fold diapers below the level of the cord to prevent contamination of the site and to promote air-drying of the cord.
- Observe the cord stump, which will change color from yellow to brown to black. This is normal.
- Never pull the cord or attempt to loosen it; it will fall off naturally.

CIRCUMCISION AND CARE OF THE PENIS

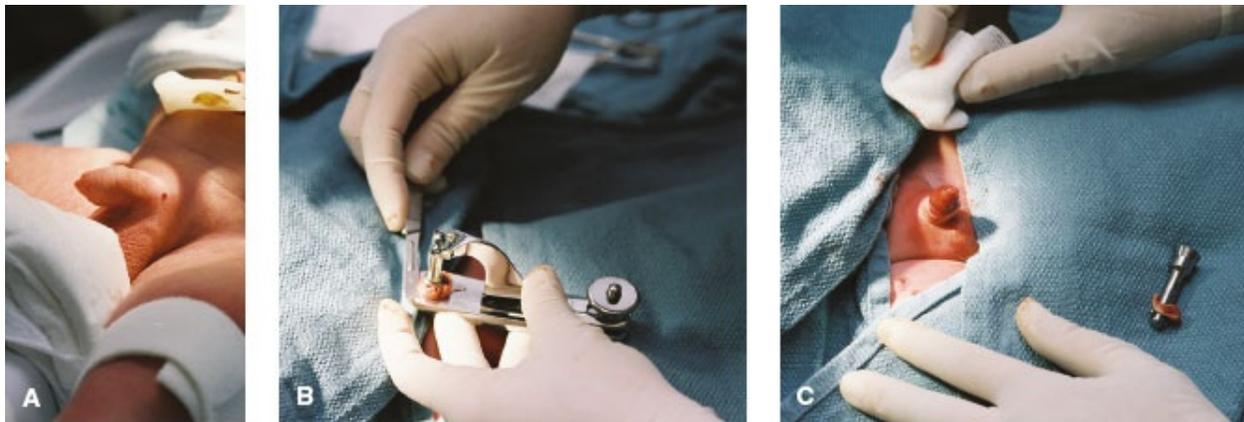
Circumcision is one of the oldest and most common surgical procedures performed worldwide, but remains controversial. It is performed for medical, religious, cultural, and social reasons. **Circumcision** is the surgical removal of all or part of the foreskin (prepuce) of the penis (Freedman & Hurwitz, 2015). This has been traditionally done for hygiene and medical reasons and is the oldest known religious rite. In the Jewish faith, circumcision is a ritual that is performed by a *mohel* (ordained circumciser) on the eighth day after birth if possible. The circumcision is followed by a *bris* (the Jewish religious ceremony), typically in the home, during which the newborn is named and symbolically enters the Jewish religious community.


FIGURE 18.19 Circumcision. **A.** Before the procedure. **B.** Clamp applied and foreskin removed. **C.** Appearance after circumcision.

Most other circumcisions are performed in the hospital before the newborn is

discharged as this is convenient for parents or taken to the doctor's outpatient office after discharge, is practical, and has a demonstrated record of safety. There are three commonly used methods of circumcision: the Gomco clamp, the Hollister Plastibell device, and the Mogen clamp. During the circumcision procedure, part of the foreskin is removed by clamping and cutting with a scalpel (Gomco or Mogen clamp) or by using a Plastibell. The Plastibell is fitted over the glans, and the excess foreskin is pulled over the plastic ring. A suture is tied around the rim to apply pressure to the blood vessels, creating hemostasis. The excess foreskin is cut away. The plastic rim remains in place until healing occurs. The plastic ring typically loosens and falls off in approximately 1 week. Petroleum jelly should be applied to the circumcised area after the procedure is done with the Gomco or Mogen clamp (Sinkey et al., 2015) (Fig. 18.19).

The debate over routine newborn circumcision continues in the United States. For many years, the purported benefits and harms of circumcision have been debated in the medical literature and society at large, with no clear consensus to date. Despite the controversy, circumcision is the most common surgical procedure performed on newborns, and almost two thirds (61%) of American male newborns are circumcised (CDC, 2015c).

Policy Statement by American Academy of Pediatrics. A policy statement by the AAP indicates that newborn circumcision has potential disadvantages and risks as well as medical benefits and advantages. Risks to the newborn include infection, hemorrhage, skin dehiscence, adhesions, urethral fistula, and pain. Benefits to the newborn include the following:

• Urinary tract infections are slightly less common in circumcised boys. However, rates are low in both circumcised and uncircumcised boys and are easily treated without long-term sequelae.

• Sexually transmitted infections are less common in circumcised males, but the risk is believed to be related more to behavioral factors than to circumcision status. However, circumcised males have a 50% lower risk of acquiring HIV infection, herpes simplex virus, human papillomavirus (HPV), genital ulcer disease, bacterial vaginosis, and trichomoniasis (Tobian, Kacker, & Quinn, 2014).

• There appears to be a slightly lower rate of penile cancer in circumcised males. However, penile cancer is rare and risk factors such as genital warts, infection with HPV, multiple sex partners, and cigarette smoking seem to play a much

larger role in causing penile cancer than circumcision status (Marcdante & Kliegman, 2014).

The new AAP recommendations state that if parents decide to circumcise their newborn, pain relief must be provided. Research has found that newborns circumcised without analgesia experience pain and stress, indicated by changes in heart rate, blood pressure, oxygen saturation, and cortisol levels (Morrison et al., 2014). Analgesic methods may include EMLA® cream (a topical mixture of local anesthetics, lidocaine and prilocaine), a dorsal penile nerve block with buffered lidocaine, acetaminophen, skin-to-skin contact, a sucrose pacifier, and swaddling (Cunningham et al., 2014).

The AAP (2015e) recommends that parents be given accurate and unbiased information about the risks and benefits of circumcision. As with other newborn procedures, research continues. Nurses must keep informed about current medical research to allow parents to make informed decisions. The absence of compelling medical evidence in favor of or against newborn circumcision makes informed consent of parents of paramount importance. The circumcision discussion involves cultural, religious, medical, and emotional considerations. Nurses may have difficulty remaining unbiased and unemotional as they present the facts to parents. Circumcision is a very personal decision for parents, and the nurse's major responsibility is to inform the parents of the risks and benefits of the procedure and to address concerns so that the parents can reach a fully informed decision.

Take Note!

The decision to circumcise the male newborn is often a social one, with the strongest factor being whether the newborn's father is himself circumcised (Mielke, 2014).

Preoperative circumcision preparation should include confirmation of the following:

• Infant is at least 12 hours old or older

• Infant has received standard vitamin K prophylaxis

• Infant has voided normally at least once since birth

- Infant has not eaten for at least an hour prior to the procedure
- Written parental consent has been obtained
- Correct identification of the infant brought to the procedure room

Immediately after circumcision, the tip of the penis is usually covered with petroleum-jelly–coated gauze to keep the wound from sticking to the diaper. Continued care of this site includes:

- Assess for bleeding every 30 minutes for at least 2 hours.
- Document the first voiding to evaluate for urinary obstruction or edema.
- Squeeze soapy water over the area daily and then rinse with warm water. Pat dry.
- Apply a small amount of petroleum jelly with every diaper change if the Plastibell was used; clean with mild soap and water if other techniques were used.
- Fasten the diaper loosely over the penis and avoiding placing the newborn on his abdomen to prevent friction.

If a Plastibell has been used, it will fall off by itself in about a week. Inform parents of this and advise them not to pull it off sooner. Also instruct the parents to check daily for any foul-smelling drainage, bleeding, or unusual swelling.

If the newborn is uncircumcised, wash the penis with mild soap and water after each diaper change and do not force the foreskin back; it will retract normally over time.

SAFETY

Newborns are completely dependent on those around them to ensure their safety. Their safety must be ensured while in the health care facility and after they are discharged. Parental education is key, especially as the newborn grows and develops and begins to respond to and explore his or her surroundings (Teaching Guidelines 18.3).

Teaching Guidelines 18.3

GENERAL NEWBORN SAFETY

- Have emergency telephone numbers readily available, such as those for emergency medical assistance and the poison control center.
- Keep small or sharp objects out of reach to prevent them from being aspirated.
- Put safety plugs in wall sockets within the child's reach to prevent electrocution.
- Do not leave the infant alone in any room without a portable intercom on.
- Always supervise the newborn in the tub: a newborn can drown in 2 in of water.
- Make sure the crib or changing table is sturdy, without any loose hardware, and is painted with lead-free paint.
- Avoid placing the crib or changing table near blinds or curtain cords.
- Provide a smoke-free environment for all infants.
- Place all infants on their backs to sleep to prevent sudden infant death syndrome.
- To prevent falls, do not leave the newborn alone on any elevated surface.
- Use sun shields on strollers and hats to avoid overexposing the newborn to the sun.
- To prevent infection, thoroughly wash your hands before preparing formula.
- Thoroughly investigate any infant care facility before using it.

Adapted from Centers for Disease Control and Prevention [CDC]. (2015d). *Infants and toddlers—safety in the home and community*. Retrieved from http://www.cdc.gov/parents/infants/safety.html

Environmental Safety. People who enter a health care facility for treatment expect to be safe there until they return home, but ensuring a safe environment can be a daunting challenge to a health care facility.

Consider this scenario: A woman dressed in nurse's clothing entered the hospital room of a new mother soon after she had given birth. This "nurse" told the mother that she needed to take her newborn to the nursery to have him weighed. Sometime later, a staff nurse making her routine rounds realized something was wrong when she saw that the newborn's bassinet in the mother's

room was empty and the mother was sound asleep in her bed. The staff nurse called security immediately because she suspected that a newborn abduction had taken place.

This is a typical abduction scenario that is repeated many times throughout the United States each year. In **infant abduction**, someone who is not a family member takes a child less than 1 year old (NCMEC, 2015). Infant abductions are traumatic for the parents, the community, and the health care facility. The facility may also face huge financial liability if a lawsuit is filed by the parents.

Abductions typically occur during the day and are usually carried out by women who are not criminally sophisticated. Many of these women experienced a pregnancy loss in the past; they are often emotionally immature and compulsive, with low self-esteem. Most female abductors can play the role of a hospital employee convincingly. Infants usually are abducted when taken for testing, during return to the nursery, when left unattended in the nursery, or while a mother was napping or showering (Joint Commission, 2015).

Health care agencies are challenged to prevent infant abduction by instituting sound security practices and systems (Joint Commission, 2015). Such measures include the following:

• All newborns must be transported in cribs and not carried.

• Nurses must respond immediately to any security alarm that sounds on the unit.

• Newborns must never be unattended at any time, especially in hallways.

• All staff must wear appropriate identification at all times.

• Encourage mothers to keep their baby/bassinet on their far side, away from the door.

• Personnel should be wary of visitors who do not seem to be visiting a specific mother.

• The electronic security system should be checked to make sure it works.

• Footprint the newborn, take a color photograph, and record the newborn's physical examination within 2 hours of birth.

• Discontinue publication of birth notices in local newspapers.

• Develop and implement a proactive infant abduction prevention plan.

• Ensure the proper functioning and placement of any electronic sensors used on newborns.

• Parents should be taught what infant abduction is; why infant security is

important; the schedule of nursery, feeding, and visiting hours; rules about visitor access; the facility's security policies and procedures; what parents can do to protect their infant in the hospital; which staff members are allowed to handle the newborn; and what a proper ID looks like.

Educating staff, educating mothers, and access control are the three key steps to preventing abductions from any health care facility. Providing a safe and secure environment is a shared responsibility of the facility, staff, and parents. Preventing abductions requires everyone to learn and follow the rules and policies.

Car Safety. Every state requires the use of car seats for infants and children, because motor vehicle accidents are still the leading cause of unintentional injury and death in children under age 5. National Highway Traffic Safety Administration statistics show that nearly one half of deaths and injuries in infants occurred because they were not properly restrained. Child safety seats, when installed and used properly, can prevent injuries and save lives (AAP, 2015f).

Despite evidence that the use of car seats can reduce the morbidity and mortality of motor vehicle crashes, parents who lack knowledge about them may underuse or misuse them (Hodges & Smith, 2014). Make sure that both parents understand the importance of safely transporting their newborn in a federally approved safety car seat every time the infant rides in a car. Do not release any newborn unless the parents have a car seat in place for their newborn's ride home (Fig. 18.20). If they cannot afford one, many community organizations will provide one for them. According to the AAP's policy statement on child passenger safety (AAP, 2015f), no one car seat is considered to be the "safest" or the "best," but rather consistent and proper use is the key to preventing injuries and deaths. Instruct parents in the following:

• Select a car seat that is appropriate for the child's size and weight.

• Caution caregivers against the placement of car seats on elevated or soft surfaces outside the car to prevent falling.

• Use the car seat correctly, every time the child is in the car.

• Use rear-facing car safety seats for most infants up to 2 years of age or until they reach the highest weight or height allowed by the manufacturer of their CSS.

• Make sure the harness (most seats have a three- to five-point harness) is in the slots at or below the shoulders.

FIGURE 18.20 Newborn in a properly secured car seat.

INFECTION PREVENTION

The nurse plays a major role in preventing infection in the newborn environment. Ways to control infection are as follows:

• Minimize exposure of newborns to organisms.
• Wash your hands before and after providing care, and insist that all personnel wash their hands before handling any newborn.
• Do not allow ill staff or visitors to visit or handle newborns.
• Avoid sharing any infant supplies with another infant
• Monitor the umbilical cord stump and circumcision site for signs of infection.
• Provide eye prophylaxis by instilling prescribed medication soon after birth.
• Educate parents about appropriate home measures that will prevent infections, such as practicing good hand hygiene before and after diaper changes, keeping the newborn well hydrated, avoiding taking the infant into crowds (which may expose him or her to colds and flu viruses), observing for early signs of infection (fever, vomiting, loss of appetite, lethargy, labored breathing, green watery stools, and drainage from umbilical cord site or eyes), and keeping pediatrician appointments for routine immunizations.

Promoting Sleep

Although many parents feel their newborns need them every minute of the day, babies actually need to sleep much of the day initially. Usually newborns sleep up to 15 hours daily. They sleep for 2 to 4 hours at a time but do not sleep through the night because their stomach capacity is too small to go long periods without nourishment.

![Take Note icon] *Take Note!*

All newborns develop their own sleep patterns and cycles, but it may take several months before the newborn sleeps through the night. Frequently, newborns have their day and night hours reversed and tend to sleep more during the daytime and less during the night.

Parents should place the newborn on his or her back to sleep. To prevent suffocation, all fluffy bedding, quilts, sheepskins, stuffed animals, and pillows should be removed from the crib. Parents should be informed that the practice of "co-sleeping" (sharing a bed) is not safe. For example, infants who sleep in adult beds are up to 40 times more likely to suffocate than those who sleep in cribs (AAP, 2015g). Suffocation can occur when the infant gets entangled in bedding or caught under pillows, or slips between the bed and the wall or the headboard and mattress. The parent may accidentally roll against or on top of the baby. The safest place for a newborn to sleep is in a crib, without any movable objects close by. Benefits versus risks of co-bedding, bed sharing, or co-sleeping include the following:

• *Benefits*—Promotes breast-feeding practices; increases bonding time between the infant and mother; promotes skin-to-skin contact; and increases maternal vigilance over infant.

• *Risks*—Increases risk for SIDS for infants younger than 4 months; risk of death if parent rolls over the infant; interrupts infant sleeping patterns; risk of asphyxia due to entrapment or airway obstruction; and unsafe design of adult beds for infants (Gaydos et al., 2014).

Teach parents to avoid other unsafe conditions, such as placing the newborn in the prone position, using a crib that does not meet federal safety guidelines, allowing window cords to hang loose and in proximity to the crib, placing blankets and pillows in the crib (can potentially smother infant), exposure to

tobacco smoke, alcohol, and illicit drugs or setting the room temperature too high (can cause overheating) (CDC, 2015d). Recommendations for safe infant sleeping practices are an important aspect of education for new parents. It is important for nurses to assess families' cultural beliefs and their prior practices to fully understand how to make recommendations in a culturally sensitive manner.

The *Safe to Sleep Campaign* (NICHD, 2014) recommends the following to reduce the risk of SIDS:

• Always place the baby on his or her back to sleep for all sleep times, including naps.

• Room share—keep baby's sleep area in the same room next to where you sleep.

• Use a firm sleep surface, free from soft objects, toys, blankets, and crib bumpers.

Enhancing Bonding

Encourage and enhance parent–newborn interaction by involving both parents with the baby and demonstrating appropriate nurturing behaviors:

• Say "hello" and introduce yourself to the newborn.

• Ask the parents' permission to care for and hold their newborn. This helps parents to realize that they are responsible for their child and reminds nurses of their role.

• Show parents the power of a soothing voice to calm the newborn (Fig. 18.21).

• Provide care to the newborn in the least stressful way.

• Demonstrate ways to gently wake up the newborn for better feeding.

• Tell parents what you are doing, why you are doing it, and how they can duplicate what you are doing at home.

• Offer the opportunity for parents to perform care while you observe them. Support their efforts to soothe the newborn throughout the care process.

• Help parents to interpret the communication cues the newborn uses.

• Point out the efforts the newborn is making to connect with the parents (e.g., alerting to the familiar voice, following the parents while they are speaking, quieting when held securely).

FIGURE 18.21 The father uses a soothing voice to calm the newborn.

One of the most pleasurable aspects of newborn care is being close to them. Bonding begins soon after birth when parents cradle their newborn and gently stroke him or her with their fingers. Provide parents with opportunities for "skin-to-skin" contact with the newborn, holding the baby against their own skin when feeding or cradling. Many newborns respond very positively to gentle massage. If necessary, recommend books and videos that cover the subject.

For newborns, crying is their only way to communicate that something is wrong. Try to find out the reason why: Is the diaper wet? Is the room too hot or too cold? Is the baby uncomfortable (e.g., diaper rash or tight clothing)? Suggest the following ways in which parents can soothe an upset newborn:

• Try feeding or burping to relieve air or stomach gas.

• Lightly rub the newborn's back and speak softly to him or her.

• Gently sway side to side, or rock back and forth in a rocking chair.

• Talk with the newborn while making eye contact.

• Take the newborn for a walk in a stroller or carriage to get fresh air.

• Change the baby's position from back to side or vice versa.

• Try singing, reciting poetry and nursery rhymes, or reading to the baby.

- Turn on a musical mobile above the newborn's head.
- Give more physical contact by walking, rocking, or patting the newborn.
- Swaddle the newborn to provide a sense of security and comfort. To do this:
  - Spread out a receiving blanket, with one corner folded slightly.
  - Lay the newborn face up with head at the folded corner.
  - Wrap the left corner over the baby's body and tuck it beneath the baby.
  - Bring the bottom corner over the baby's feet.
  - Wrap the right corner around the baby, leaving only the head exposed.
  - Arms can be released from the blanket to allow for self-comforting.

Assisting With Screening Tests

Newborn screening has been among the most successful public health programs of the 21st century. Approximately 4 million infants are screened annually in the United States (Adamkin, 2015). Screening newborns for problems is important because some potentially life-threatening metabolic diseases may not be obvious at birth. Newborn screening tests that are required in most states before discharge are used to check for certain genetic and inborn errors of metabolism and hearing. Early identification and initiation of treatment can prevent significant complications and can minimize the negative effects of untreated disease.

GENETIC AND INBORN ERRORS OF METABOLISM SCREENING

Although each state mandates which conditions must be tested, the most common screening tests are for PKU, hypothyroidism, galactosemia, and sickle cell disease (Table 18.5).

The trend toward early discharge of newborns can affect the timing of screening and the accuracy of some test results. For example, the newborn needs to ingest enough breast milk or formula to elevate phenylalanine levels for the screening test to identify PKU accurately, so newborn screening for PKU testing should not be performed before 24 hours of age.

Screening tests for genetic and inborn errors of metabolism require a few drops of blood taken from the newborn's heel (Fig. 18.22). These tests are usually performed shortly before discharge. Newborns that are discharged before 24 hours of age need to have repeat tests done within a week in an outpatient

facility.

Be aware of which conditions your state regularly screens for at birth to ensure that the parents are taught about the tests and the importance of early treatment. Also be familiar with the optimal time frame for screening and conditions that could affect the results. Ensure that a satisfactory specimen has been obtained at the appropriate time and that circumstances that could cause false results have been minimized. Send out specimens and completed forms within 24 hours of collection to the appropriate laboratory (Nagtalon-Ramos, 2014).

TABLE 18.5 SELECTED CONDITIONS SCREENED FOR IN THE NEWBORN

Condition	Description	Clinical Picture/ Effect If not Treated	Treatment	Timing of Screening
PKU	Autosomal recessive inherited deficiency in one of the enzymes necessary for the metabolism of phenylalanine to tyrosine—essential amino acids found in most foods	Irritability, vomiting of protein feedings, and a musty odor to the skin or body secretions of the newborn; if not treated, mental and motor retardation, seizures, microcephaly, and poor growth and development	Lifetime diet of foods low in phenylalanine (low protein) and monitoring of blood levels; special newborn formulas available: Phenex and Lofenalac	Universally screened for in the United States; testing is done 24–48 hours after protein feeding (PKU)
Congenital hypo- thyroidism	Deficiency of thyroid hormone necessary for normal brain growth, calorie metabolism, and development; may result from maternal hypothyroidism	Increased risk in newborns with birth weight <2,000 g or >4,500 g, and those of Hispanic and Asian ethnic groups; feeding problems, growth and breathing problems; if not treated, irreversible brain damage and intellectual disability before age 1	Lifelong thyroid replacement therapy	Testing (measures thyroxin [T_4] and TSH) is done between days 4 and 6 of life
Galactosemia	Absence of the enzyme needed for the conversion of the milk sugar galactose to glucose	Poor weight gain, vomiting, jaundice, mood changes, loss of eyesight, seizures, and intellectual disability; if untreated, galactose buildup causing permanent damage to the brain, eyes, and liver, and eventually death	Eliminate milk from diet; substitute soy milk	First test done on discharge from the hospital with a follow-up test within 1 mo
Sickle cell anemia	Recessively inherited abnormality in hemoglobin structure, most commonly found in African American newborns	Anemia developing shortly after birth; increased risk for infection, growth restriction, vaso-occlusive crisis	Maintenance of hydration and hemodilution, rest, electrolyte replacement, pain management, blood replacement, and antibiotics	Bloodspot obtained at same time of other newborn screening tests or prior to 3 months of age

HEARING SCREENING

Hearing loss is the most common birth disorder in the United States: approximately 3 to 5 newborns out of every 1,000 live births have some degree of hearing loss. Unlike a physical deformity, hearing loss is not clinically detectable at birth and thus remains difficult to assess (CDC, 2015b). Factors associated with an increased risk of hearing loss include the following:

• Family history of hereditary childhood sensory hearing loss

• Congenital infections such as cytomegalovirus, rubella, toxoplasmosis, or herpes

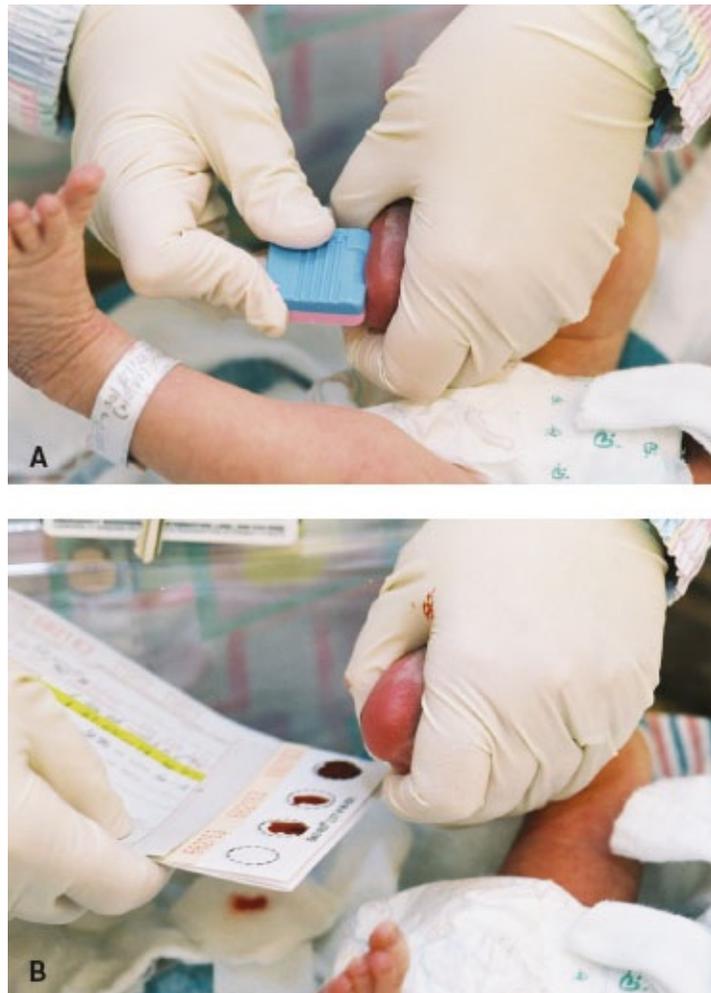
- Craniofacial anomalies involving the pinna or ear canal
- Low birth weight (less than 1,500 g)
- Postnatal infections such as bacterial meningitis
- Head trauma
- Hyperbilirubinemia requiring an exchange transfusion
- Exposure to ototoxic drugs, especially aminoglycosides
- Perinatal asphyxia (Nikolopoulos, 2015)


FIGURE 18.22 Screening for PKU. **A.** Performing a heel stick. **B.** Applying the blood specimen to the card for screening.

Delays in identification and intervention may affect the child's language development, academic performance, and cognitive development. Detection

before 3 months greatly improves outcomes. Because of this, auditory screening programs for all newborns are recommended by the AAP (2015d) and are mandated by law in over 30 states. Screening only infants with risk factors is not enough, because as many as 50% of infants born with hearing loss have no known risk factors (CDC, 2015b). Early identification and intervention can prevent severe psychosocial, educational, and language development delays.

The current goals of *Healthy People 2020* (USDHHS, 2010) are to screen all infants by 1 month of age, confirm hearing loss with an audiologic examination by 3 months of age, and treat with comprehensive early intervention services before 6 months of age (see the *Healthy People 2020* feature earlier in this chapter and Box 18.1 for screening methods). All newborns should be screened prior to discharge to ensure that any newborn with a hearing loss is not missed. Those with suspected hearing loss should be referred for follow-up assessment. In addition, nurses should ensure that testing is accurate to facilitate early diagnosis and intervention services and to optimize the newborn's developmental potential. The implementation of newborn hearing screenings has lowered the mean age of hearing loss identification and many deaf children are now diagnosed in the early age of months old.

BOX 18.1

NEWBORN HEARING SCREENING METHODS

Newborn hearing screening is the standard of care in hospitals nationwide. The primary purpose of newborn hearing screening is to identify newborns who are likely to have a hearing loss and who require further evaluation. A newborn's hearing can be screened in one of two ways: otoacoustic emission (OAE) or automated auditory brainstem response (ABR).

In OAE, an earphone is placed in the infant's ear canal and the sounds produced by the newborn's inner ear are measured in response to certain tones or clicks presented through the earphone. Preset parameters in the equipment decide whether the OAEs are sufficient for the newborn to pass or whether a referral is necessary for further evaluation.

In ABR, an earphone is placed in the ear canal or an earmuff is placed over the newborn's ear, and a soft, rapid tapping noise is presented. Electrodes placed around the newborn's head, neck, and shoulders record neural activity from the infant's brainstem in response to the tapping noises. The ABR tests how well the ear and the nerves leading to the brain work. Like OAEs, automated ABR screening is sensitive to more than mild degrees of hearing loss, but a "pass" does not guarantee normal hearing.

Common Concerns

During the newborn period of transition, certain conditions can develop that require intervention. These conditions, although not typically life threatening, can be a source of anxiety for the parents. Common concerns include transient

tachypnea of the newborn, physiologic jaundice, and hypoglycemia.

TRANSIENT TACHYPNEA OF THE NEWBORN

Transient tachypnea of the newborn appears soon after birth. It occurs when the fetal liquid in the lungs is removed slowly or incompletely. This can be due to the lack of thoracic squeezing that occurs during a cesarean birth or diminished respiratory effort if the mother received central nervous system depressant medication. Prolonged labor, macrosomia of the fetus, and maternal asthma also have been associated with this condition. A vaginal birth appears to be protective against transient tachypnea of the newborn (Cunningham et al., 2014).

Transient tachypnea is accompanied by retractions; expiratory grunting or cyanosis and is relieved by low-dose oxygen therapy. Mild or moderate respiratory distress typically is present at birth or within 6 hours of birth. Transient tachypnea of the newborn is generally a self-limited disorder without significant morbidity. Transient tachypnea of the newborn resolves over a 24-hour to 72-hour period.

Nursing interventions include providing supportive care: giving oxygen, ensuring warmth, observing respiratory status frequently, and allowing time for the pulmonary capillaries and the lymphatics to remove the remaining fluid. The clinical course is relatively benign, but any newborn respiratory issue can be very frightening to the parents. Provide a thorough explanation and reassure them that the condition will resolve over time.

PHYSIOLOGIC JAUNDICE

Physiologic jaundice is very common in newborns, with the majority demonstrating yellowish skin, mucous membranes, and sclera within the first 3 days of life. In any given year, approximately 65% of the newborns in the United States will experience clinical jaundice (King et al., 2015). Jaundice is the visible manifestation of hyperbilirubinemia. It typically results from the deposition of unconjugated bilirubin pigment in the skin and mucous membranes.

Physiologic jaundice can be best understood as an imbalance between the production and elimination of bilirubin, with a multitude of factors and conditions affecting each of these processes. When an imbalance results because of an increase in circulating bilirubin (or the bilirubin load) to significantly high levels, it may go on to cause acute neurologic sequelae (acute bilirubin encephalopathy). In most infants, an increase in bilirubin production (e.g., due to

hemolysis) is the primary cause of physiologic jaundice, and thus reducing bilirubin production is a rational approach for its management.

Factors that contribute to the development of physiologic jaundice in the newborn include an increased bilirubin load because of relative polycythemia, a shortened erythrocyte life span (80 days compared with the adult 120 days), and immature hepatic uptake and conjugation processes (Chu, 2014). Normally the liver removes bilirubin from the blood and changes it into a form that can be excreted. As the red blood cell breakdown continues at a fast pace, the newborn's liver cannot keep up with bilirubin removal. Thus, bilirubin accumulates in the blood, causing a yellowish discoloration on the skin.

AAP Guidelines for Prevention and Management of Hyperbilirubinemia in Newborns. The AAP has recently released guidelines for the prevention and management of hyperbilirubinemia in newborns:

• Promote and support successful breast-feeding practices to make sure the newborn is well hydrated and stooling frequently to promote elimination of bilirubin.

• Advise mothers to nurse their infants at least 8 to 12 times per day for the first several days.

• Avoid routine supplementation of nondehydrated breast-fed infants with water or dextrose water because that will not lower bilirubin levels.

• Ensure that all infants are routinely monitored for the development of jaundice and that nurseries have established protocols for the assessment of jaundice. Jaundice should be assessed whenever the infant's vital signs are measured but no less than every 8 to 12 hours.

• Before discharge, complete a systematic assessment for the risk of severe hyperbilirubinemia.

• Provide early and focused follow-up based on the risk assessment.

• When indicated, treat newborns with phototherapy or exchange transfusion to prevent acute bilirubin encephalopathy (AAP, 2015h).

In newborn infants, jaundice can be detected by blanching the skin with digital pressure on the bridge of the nose, sternum, or forehead, revealing the underlying color of the skin and subcutaneous tissue. If jaundice is present, the blanched area will appear yellow before the capillary refill. The assessment of jaundice must be performed in a well-lit room or, preferably, in daylight at a

window. Jaundice is usually seen first in the face and progresses caudally to the trunk and extremities (AAP, 2015h).

Measures that parents can take to reduce the risk of jaundice include exposing the newborn to natural sunlight for short periods of time throughout the day to help oxidize the bilirubin deposits on the skin, providing breast-feeding on demand to promote elimination of bilirubin through urine and stooling, and avoiding glucose water supplementation, which hinders elimination.

If or when the levels of unconjugated serum bilirubin increase and do not return to normal levels with increased hydration, phototherapy is used. The serum level of bilirubin at which phototherapy is initiated is a matter of clinical judgment by the physician, but it is often begun when bilirubin levels reach 12 to 15 mg/dL in the first 48 hours of life in a term newborn (Davidson, 2014). **Phototherapy** involves exposing the newborn to ultraviolet light, which converts unconjugated bilirubin into products that can be excreted through feces and urine. Phototherapy is the most common treatment for hyperbilirubinemia and has virtually eliminated the need for exchange transfusions in newborns now.

Take Note!

Exposure of newborns to sunlight represents the first documented use of phototherapy in the medical literature. Sister J. Ward, a charge nurse in Essex, England, recognized in 1956 that when jaundiced newborns were exposed to the sun they became less yellow. This observation changed the entire treatment of jaundice in newborns (Maisels, 2015).

Phototherapy reduces bilirubin levels in the blood by breaking down unconjugated bilirubin into colorless compounds. These compounds can then be excreted in the bile. Phototherapy aims to curtail the increase in bilirubin blood levels; thereby preventing kernicterus, a condition in which unconjugated bilirubin enters the brain. If not treated, kernicterus can lead to brain damage and death.

During the past several decades, phototherapy has generally been administered with either banks of fluorescent lights or spotlights. Factors that determine the dosage of phototherapy include spectrum of light emitted, irradiance of light source, design of light unit, surface area of newborn exposed

to the light, and distance of the newborn from the light source (McDermott, 2015). For phototherapy to be effective, the rays must penetrate as much of the skin as possible. Thus, the newborn must be naked and turned frequently to ensure maximum exposure of the skin. Several side effects of standard phototherapy have been identified: frequent loose stools, increased insensible water loss, transient rash, and potential retinal damage if the newborn's eyes are not covered sufficiently.

Recently, fiberoptic pads (Biliblanket or Bilivest) have been developed that can be wrapped around the newborn or on which the newborn can lie. The light is delivered from a tungsten–halogen bulb through a fiber-optic cable and is emitted from the sides and ends of the fibers inside a plastic pad (Plavskii, Tret'yakova, & Mostovnikova, 2014). These products work on the premise that phototherapy can be improved by delivering higher-intensity therapeutic light to decrease bilirubin levels. The pads do not produce appreciable heat like the banks of lights or spotlights do, so insensible water loss is not increased. Eye patches also are not needed; thus, parents can feed and hold their newborns continuously to promote bonding.

When caring for newborns receiving phototherapy for jaundice, nurses must do the following:

• Closely monitor body temperature and fluid and electrolyte balance.

• Document frequency, character, and consistency of stools.

• Monitor hydration status (weight, specific gravity of urine, and urine output).

• Turn frequently to increase the infant's skin exposure to phototherapy.

• Observe skin integrity (as a result of exposure to diarrhea and phototherapy lights).

• Provide eye protection to prevent corneal injury related to phototherapy exposure.

• Encourage parents to participate in their newborn's care to prevent parent–infant separation.

See Chapter 24 for a more detailed discussion of hyperbilirubinemia.

The home health nurse made a postpartum visit to Kelly to assess the situation. Kelly's son was slightly jaundiced when the home health nurse pressed gently over his sternum, but Kelly said he was nursing better

compared with the previous 2 days. What home suggestions can the nurse make to Kelly to reduce the jaundice? What specific education about physiologic jaundice is needed?

HYPOGLYCEMIA

During the first 24 to 48 hours of life, as normal newborns transition from intrauterine to extrauterine life, their plasma glucose levels are typically lower than later in life. Hypoglycemia affects as many as 40% of all full-term newborns. It is defined as a blood glucose level of less than 30 mg/dL or a plasma concentration of less than 40 mg/dL in the first 72 hours of life (Thornton et al., 2015). From a physiologic perspective, a newborn may be said to be hypoglycemic when glucose supply is inadequate to meet demand. In newborns, blood glucose levels fall to a low point during the first few hours of life because the source of maternal glucose is removed when the placenta is expelled. This period of transition is usually smooth, but certain newborns are at greater risk for hypoglycemia: infants of mothers who have diabetes, preterm newborns, and newborns with intrauterine growth restriction (IUGR), inadequate caloric intake, sepsis, asphyxia, hypothermia, polycythemia, glycogen storage disorders, and endocrine deficiencies (Adamkin, 2015).

Most newborns experience transient hypoglycemia and are asymptomatic. The symptoms, when present, are nonspecific and include jitteriness, lethargy, cyanosis, apnea, seizures, high-pitched or weak cry, hypothermia, and poor feeding. If hypoglycemia is prolonged or is left untreated, serious, long-term adverse neurologic sequelae such as learning disabilities and intellectual disabilities can occur (Stanley et al., 2015).

Treatment of hypoglycemia in the newborn includes administration of a rapid-acting source of glucose such as a sugar/water mixture or early formula-feeding. In acute, severe cases, intravenous administration of glucose may be required. Continuous monitoring of glucose levels is not only prudent but mandatory in high-risk newborns. Although there is no specific means of preventing hypoglycemia in newborns, it is wise and cautious to monitor for symptoms and intervene as soon as symptoms are noted. Subsequently, early diagnosis and appropriate intervention are essential for all newborns.

Nursing care of the hypoglycemic newborn includes monitoring for signs of hypoglycemia or identifying high-risk newborns prone to this disorder based on their perinatal history, physical examination, body measurements, and

gestational age. Glucose screening should be performed only on at-risk infants and those with clinical symptoms compatible with hypoglycemia (National Guideline Clearinghouse, 2015).

Prevent hypoglycemia in newborns at risk by initiating early feedings with breast milk or formula. If hypoglycemia persists despite feeding, notify the primary health care provider for orders such as intravenous therapy with dextrose solutions. Anticipate hypoglycemia in certain high-risk newborns and begin assessments immediately on nursery admission.

Promoting Nutrition

Several physiologic changes dictate the type and method of feeding throughout the newborn's first year. Some of these changes include the following:

- Stomach capacity is limited at birth. The emptying time is short (2 to 3 hours) and peristalsis is rapid. Therefore, small, frequent feedings are needed at first, with amounts progressively increasing with maturity.

- The immune system is immature at birth, so the baby is at a high risk for food allergies during the first 4 to 6 months of life. Introducing solid foods prior to this time increases the risk of developing food allergies.

- Pancreatic enzymes and bile to assist in digestion of fat and starch are in limited supply until about 3 to 6 months of age. Infants cannot digest cereal prior to this time.

- The kidneys are immature and unable to concentrate urine until about 4 to 6 weeks of age. Excess protein and mineral intake can place a strain on kidney function and can lead to dehydration. Infants need to consume more water per unit of body weight than adults do as a result of their high body weight from water.

- Immature muscular control at birth changes over time to assist in the feeding process by improving head and neck control, hand–eye coordination, swallowing, and ability to sit, grasp, and chew. At about 4 to 6 months, inborn reflexes disappear, head control develops, and the infant can sit to be fed, making spoon-feeding possible (Dudek, 2014)

NEWBORN NUTRITIONAL NEEDS

As newborns grow, their energy and nutrient requirements change to meet their body's changing needs. During infancy, energy, protein, vitamin, and mineral

requirements per pound of body weight are higher than at any other time of life. These high levels are needed to fuel the rapid growth and development during this stage of life. Generally, an infant's birth weight doubles in the first 4 to 6 months of life and triples within the first year (Walker, 2014).

A newborn's caloric needs range from 110 to 120 cal/kg body weight. Breast milk and formulas contain approximately 20 cal/oz, so the caloric needs of young infants can be met if several feedings are given throughout the day. Most term infants need a basic formula if the mother chooses not to breast-feed. These formulas are modeled after breast milk, which contains 20 cal/oz. There is no evidence to recommend one brand over the other since all of them are nutritionally interchangeable. All formulas are classified based on three parameters: caloric density, carbohydrate source, and protein composition (see Table 18.6).

Fluid requirements for the newborn and infant range from 100 to 150 mL/kg daily. This requirement can be met through breast- or bottle-feeding. Additional water supplementation is not necessary. Adequate carbohydrates, fats, protein, and vitamins are achieved through consumption of breast milk or formula. The AAP (2015i) recommends that bottle-fed infants be given iron supplementation, because iron levels are low in all types of formula milk. This can be achieved by giving iron-fortified formula from birth. The breast-fed infant draws on iron reserves for the first 6 months and then needs iron-rich foods or supplementation added at 6 months of age. The AAP (2015i) also has recommended that all infants (breast- and bottle-fed) receive a daily supplement of 400 IU of vitamin D starting within the first few days of life to prevent rickets and vitamin D deficiency. It is also recommended that fluoride supplementation be given to infants not receiving fluoridated water after the age of 6 months (AAP, 2015i). Recently, the AAP recommended that all pregnant and lactating women use iodized salt and take a supplement of 150 μg of iodine daily. An iodine deficiency can affect fetal and early childhood neurocognitive development (AAP, 2015j).

SUPPORTING THE CHOICE OF FEEDING METHOD

The benefits of breast-feeding are significant and well documented. Numerous health-related professional organizations promote breast-feeding because of the health benefits for both the mother and infant. Nurses should encourage and advocate breast-feeding for their clients and provide support for the family throughout their breast-feeding experiences. Parents typically decide about the

method of feeding well before the infant is born. Prenatal and childbirth classes present information about breast-feeding versus bottle-feeding and allow the parents to make up their minds about which method is best for them. Various factors can influence their decision, including socioeconomic status, culture, sexual objectification, fear of a negative community reaction, personal inconvenience, dietary restrictions, lack of social support, lack of self-efficacy, high frequency of violence, employment, level of education, lack of access to breast pumps, lack of time, free formula provided by government programs, range of care interventions provided during pregnancy, childbirth, and the early postpartum period, and especially partner support (Dunn et al., 2015). Nurses can provide evidence-based information to assist the couple in making their decision. Regardless of which method is chosen, the nurse needs to respect and support the couple's decision.

TABLE 18.6 COMPARISON OF BREAST MILK WITH SELECTED FORMULA COMPOSITION

Type	Brand Names	Calories per Ounce	Carbohydrate Source	Protein Source	Indications
Breast milk	None	20	Lactose	Human milk	Preferred for all infants
Term formula	Enfamil; Similac; Carnation Good Start	20	Lactose	Cow's milk	Appropriate for all term infants
Term formula with DHA and ARA	Enfamil Lipil; Good Start DHA and ARA; Similac Advance	20	Lactose	Cow's milk	Marketed to promote good vision and brain development; to make them more like breast milk.
Preterm formula	Enfamil 24 Premature; Preemie SMA 24	24	Lactose	Cow's milk	Usually given to preterm infants <34 weeks' gestation
Soy formula	Enfamil Prosobee; Good Start Soy	20	Corn based	Soy	For infants with galactosemia
Hypoallergenic formula	Similac Alimentum; Enfamil Nutramigen; Enfamil Pregestimil	20	Corn or sucrose	Extensively hydrolyzed	For infants with a milk protein allergy
Nonallergenic formula	Neocate; Nutramigen AA	20	Corn or sucrose	Amino acids	For infants with a milk protein allergy
Antireflux formula	Enfamil AR; Similac Sensitive RS	20	Lactose thickened with rice starch	Cow's milk	For infants with gastric reflux disorder

FEEDING THE NEWBORN

The newborn can be fed at any time during the transition period if assessments are normal and a desire is demonstrated. Before the newborn can be fed, determine his or her ability to suck and swallow. Clear any mucus in the nares or mouth with a bulb syringe before initiating feeding. Auscultate bowel sounds, check for abdominal distention, and inspect the anus for patency. If these parameters are within normal limits, newborn feeding may be started. Most newborns are on demand feeding schedules and are allowed to feed when they awaken. When they go home, mothers are encouraged to feed their newborns every 2 to 4 hours during the day and only when the newborn awakens during the night for the first few days after birth.

Parents often have many questions about feeding. Generally, newborns should be fed on demand whenever they seem hungry. Most newborns will give clues about their hunger status by crying, placing their fingers or fist in their mouth, rooting around, and sucking.

Newborns differ in their feeding needs and preferences, but most breast-fed ones need to be fed every 2 to 3 hours, nursing for 10 to 20 minutes on each breast. The length of feedings is up to the mother and newborn. Encourage the mother to respond to cues from her infant and not feed according to a standard or preset schedule.

Formula-fed newborns usually feed every 3 to 4 hours, finishing a bottle in 30 minutes or less. Daily formula intake for an infant should be 1.5 to 2 oz/lb of body weight, but growth is a better measure of health than the amount of formula consumed (Schlenker & Gilbert, 2015). If the newborn seems satisfied, wets 6 to 10 diapers daily, produces several stools a day, sleeps well, and is gaining weight regularly, then he or she is probably receiving sufficient breast milk or formula.

Newborns swallow air during feedings, which causes discomfort and fussiness. Parents can prevent this by burping them frequently throughout the feeding. Tips about burping include:

• Hold the newborn upright with his or her head on the parent's shoulder (Fig. 18.23A).

• Support the head and neck while the parent gently pats or rubs the newborn's back (Fig. 18.23B).

• Have the newborn sit on the parent's lap, while supporting the baby's chest and head. Gently rub the newborn's back with the other hand.

• Lay the newborn on the parent's lap with the baby's back facing up.

• Support the newborn's head in the crook of the parent's arm and gently pat or rub the back.

Take Note!

It is the upright position, not the strength of the patting or rubbing that allows the newborn to release air accumulated in the stomach.

FIGURE 18.23 The nurse demonstrates **(A)** holding the newborn upright over the shoulder and **(B)** sitting the newborn upright, supporting the neck and chin.

Stress to parents that feeding time is more than an opportunity to get nutrients into their newborn; it is also a time for closeness and sharing. Feedings are as much for the baby's emotional pleasure as his or her physical well-being. Encourage parents to maintain eye contact with the newborn during the feeding, hold him or her comfortably close to them, and talk softly during the feeding to promote closeness and security.

BREAST-FEEDING

There is consensus in the medical community that breast-feeding is optimal for all newborns. The AAP and the American Dietetic Association recommend breast-feeding exclusively for the first 6 months of life, continuing it in conjunction with other food at least until the newborn's first birthday. An estimated 75% of American mothers attempt to breast-feed, but just 13% are able to exclusively by 6 months (Busch, Logan, & Wilkinson, 2014). Box 18.2 highlights the advantages of breast-feeding for the mother and newborn. In addition, breast-feeding is associated with lower incidence of necrotizing enterocolitis and diarrhea during the early period of life and with lower incidence of inflammatory bowel diseases, type 2 diabetes, and obesity later in life (Martin, Fanaroff, & Welsh, 2014). Mothers should continue to breast-feed during mild illnesses such as colds or flu. However, in the United States mothers with HIV are advised not to breast-feed.

BOX 18.2

ADVANTAGES OF BREAST-FEEDING

Advantages for the Newborn

- Contributes to the development of a strong immune system
- Stimulates growth of positive bacteria in digestive tract
- Reduces incidence of stomach upset, diarrhea, and colic
- Begins the immunization process at birth by providing passive immunity
- Promotes optimal mother–infant bonding
- Reduces risk of newborn constipation
- Promotes greater developmental gains in preterm infants
- Provides easily tolerated and digestible formula that is sterile, at proper temperature, and readily available with no artificial colorings, flavorings, or preservatives
- Is less likely to result in overfeeding, leading to obesity
- Promotes better tooth and jaw development as a result of sucking hard
- Provides protection against food allergies
- Lowers health care costs due to fewer illnesses
- Is associated with avoidance of type 1 diabetes and heart disease

Advantages for the Mother

• Can facilitate postpartum weight loss by burning extra calories

• Stimulates uterine contractions to control bleeding

• Lowers risk for ovarian and endometrial cancers

• Facilitates bonding with newborn infant

• Lowers risk of type 2 diabetes

• Breast milk is free verses formula costs.

• Reduces risk of postpartum depression

• Promotes uterine involution as a result of release of oxytocin

• Lowers the risk of breast cancer and osteoporosis

• Affords some protection against conception, although it is not a reliable contraceptive method

Data from Schlenker, E., & Gilbert, J. A. (2015). *William's essentials of nutrition and diet therapy* (11th ed.). St. Louis, MO: Mosby Elsevier; Christopher, G. C., & Krell, J. K. (2014). Changing the breastfeeding conversation and our culture. *Breastfeeding Medicine,* 9(2), 53–55; and Walker, M. (2014). *Breastfeeding management for the clinician: Using the evidence* (3rd ed.). Burlington, MA: Jones & Bartlett Learning.

The composition of breast milk changes over time from colostrum to transitional milk, and finally to mature milk. Colostrum is a thick, yellowish substance secreted during the first few days after birth. It is high in protein, minerals, and fat-soluble vitamins. It is rich in immunoglobulins A, which help protect the newborn's gastrointestinal tract against infections. It is a natural laxative that helps rid the intestinal tract of meconium quickly (Gephart & Weller, 2014).

Transitional milk occurs between colostrum and mature milk and contains all the nutrients in colostrum, but it is thinner and less yellow than colostrum. This transitional milk is replaced by true or mature milk around day 10 after birth. Mature milk appears bluish and is not as thick as colostrum. It provides 20 cal/oz and contains the following:

- *Protein*—Although the content is lower than formula, it is ideal to support growth and development for the newborn. The majority of the protein is whey, which is easy to digest.
- *Fat*—Approximately 58% of total calories are fat, but they are easy to digest. Essential fatty acid content is high, as is the level of cholesterol, which helps develop enzyme systems capable of handling cholesterol later in life.
- *Carbohydrate*—Approximately 35% to 40% of total calories are in the form of lactose, which stimulates the growth of natural defense bacteria in the gastrointestinal system and promotes calcium absorption.
- *Water*—Water, the major nutrient in breast milk, makes up 85% to 95% of the total volume. Total milk volume varies with the age of the infant and demand.
- *Minerals*—Breast milk contains calcium, phosphorus, chlorine, potassium, and sodium, with trace amounts of iron, copper, and manganese. Iron absorption is about 50%, compared with about 4% for iron-fortified formulas.
- *Vitamins*—All vitamins are present in breast milk; vitamin D is the lowest in amount. Vitamin D supplementation is recommended by the AAP now.
- *Enzymes*—Lipase and amylase are found in breast milk to assist with digestion (Dudek, 2014).

Breast-Feeding Assistance. Breast-feeding can be initiated immediately after birth. If the newborn is healthy and stable, wipe the newborn from head to toe with a dry cloth and place him or her skin to skin on the mother's abdomen. Then cover the newborn and mother with another warmed blanket to hold in the warmth. Immediate mother–newborn contact takes advantage of the newborn's natural alertness after a vaginal birth and fosters bonding. This immediate contact also reduces maternal bleeding and stabilizes the newborn's temperature, blood glucose level, and respiratory rate (Khan et al., 2015).

Left alone on the mother's abdomen, a healthy newborn scoots upward, pushing with the feet, pulling with the arms, and bobbing the head until finding and latching on to the mother's nipple. A newborn's sense of smell is highly developed, which also helps in finding the nipple. As the newborn moves to the nipple, the mother produces high levels of oxytocin, which contracts the uterus, thereby minimizing bleeding. Oxytocin also causes the breasts to release colostrum when the newborn sucks on the nipple. Colostrum is rich in antibodies and thus provides the newborn with her "first immunization" against infection.

Keys to successful breast-feeding include:

- Initiating breast-feeding within the first hour of life if the newborn is stable
- Placing the newborn on the mother's chest/abdomen immediately after birth
- Following the newborn's feeding schedule—8 to 12 times in 24 hours
- Providing unrestricted periods of breast-feeding
- Offering no supplement unless medically indicated
- Having a lactation consultant observe a feeding session
- Avoiding artificial nipples and pacifiers except during a painful procedure
- Increasing fluid intake to encourage greater milk production (Evidence-Based Practice Box 18.1)
- Feeding from both breasts over each 24-hour period
- Watching for indicators of sufficient intake from infant:
  - Six to ten wet diapers daily
  - Waking up hungry 8 to 12 times in 24 hours
  - Acting content and falling asleep after feeding
- Keeping the newborn with the mother throughout the hospital stay
- The nurse or lactation consultant should be available to guide and support the breast-feeding mother while on the postpartum unit

EVIDENCE-BASED PRACTICE 18.1 PRIMARY CARE SETTING: A COMMUNITY PILOT PROJECT APPLYING THE TRI-CORE BREAST-FEEDING MODEL: BEYOND THE BASICS

STUDY

Ongoing evidence-based practice findings strongly indicate that the lifelong health and economic benefits of breast-feeding contributes greatly to the health status of the infant, the mother, the family, and the society at large. Promotional lactation interventions are needed in the community to initiate and foster breast-feeding efforts beyond the hospital after discharge. The purpose of this study was to develop a primary care breast-feeding support program, bridging the gap from hospital discharge into primary care to improve breast-feeding rates. The study incorporated the three core interventions of the Tri-Core model: (1) Improving lactation support; (2) enhancing maternal and staff lactation education; and (3) fostering maternal confidence in their ability to breast-feed.

Findings

The study population (N = 50) included middle- to low-income families that had recently given birth to a healthy full-term infant who desired to breast-feed within the early postpartum period. Outcomes were measured by the assessment of breast-feeding rates, durations, and reported maternal self-efficacy levels at 1 month, and a 2-month visit. Ongoing office support was provided with lactation visits and phone calls. Findings indicated significant gains in all three areas especially in overall breast-feeding rates when compared to previous rates, especially in rates of exclusive breast-feeding.

Help position the newborn so that latching-on is effective and is not painful for the mother. Placing pillows or a folded blanket under the mother's head may help, or rolling her to one side and tucking the newborn next to her. Assess both the mother and newborn during this initial session to determine needs for assistance and education. One tool used frequently in this assessment is the LATCH scoring tool (Abbas & Hasan, 2015). The LATCH scoring tool is a breast-feeding charting system that provides a systematic method for gathering information about individual breast-feeding sessions. The system assigns a numerical score of 0, 1, or 2 to five key components of breast-feeding. Each letter of the acronym LATCH denotes an area of assessment: "L" is for how well the infant latches onto the breast; "A" is for the amount of audible swallowing noted; "T" is for the mother's nipple type; "C" is for the mother's level of comfort; "H" is for the amount of help the mother needs to hold her infant to the breast. The system is visually represented in the same form as the Apgar scoring grid, and the numbers are handled in the same way. With the LATCH system, the nurse can assess maternal and infant variables, define areas of needed

intervention, and determine priorities in providing client care and teaching (Table 18.7). The higher the score, the lesser the nursing intervention needed by the mother and baby.

Breast-Feeding Positioning. The mother and infant must be in comfortable positions to ensure breast-feeding success. The four most common positions for breast-feeding are the football, cradle, across-the-lap, and side-lying holds. Each mother, on experimentation, can decide which positions feel most comfortable for her (Fig. 18.24).

• In the *football hold,* the mother holds the infant's back and shoulders in her palm and tucks the infant under her arm. Remind the mother to keep the infant's ear, shoulder, and hip in a straight line. The mother supports the breast with her hand and brings it to the infant's lips to latch on. She continues to support the breast until the infant begins to nurse. This position allows the mother to see the infant's mouth as she guides her infant to the nipple. This is a good choice for mothers who have had a cesarean birth because it avoids pressure on the incision.

• The *cradling position* is the one most commonly used. The mother holds the baby in the crook of her arm, with the infant facing the mother. The mother supports the breast with her opposite hand.

• In the *across-the-lap position,* the mother places a pillow across her lap, with the infant facing the mother. The mother supports the infant's back and shoulders with her palm and supports her breast from underneath. After the infant is in position, the infant is pulled forward to latch on.

• In the *side-lying position,* the mother lies on her side with a pillow supporting her back and another pillow supporting the newborn in the front. To start, the mother props herself up on an elbow and supports the newborn with that arm, while holding her breast with the opposite hand. Once nursing is started, the mother lies down in a comfortable position.

   To promote latching-on, instruct the mother to make a C or a V shape with her fingers. In the C hold, the mother places her thumb well above the areola and the other four fingers below the areola and under the breast. In the V hold, the mother places her index finger above the areola and her other three fingers below the areola and under the breast. Either method can be used as long as the mother's hand is well away from the nipple so the infant can latch on.

TABLE 18.7 THE LATCH SCORING TOOL

Parameters	0 Point	1 Point	2 Points
L: latch	Sleepy infant, no sustained latch achieved	Must hold nipple in infant's mouth to sustain latch and suck; must stimulate infant to continue to suck	Grasps nipple; tongue down; rhythmic sucking
A: audible swallowing	None	A few observed with stimulation	Spontaneous and intermittent both <24 hours old and afterward
T: type of nipple	Inverted (drawn inward into breast tissue)	Flat (not protruding)	Everted or protruding out after stimulation
C: comfort of nipple	Engorged, cracked bleeding; severe discomfort	Filling; reddened, small blisters or bruises; mild to moderate discomfort	Soft, nontender
H: hold (positioning)	Nurse must hold infant to breast	Minimal assistance; help with positioning, then mother takes over	No assistance needed by nurse

FIGURE 18.24 Breast-feeding positions.

Breast-Feeding Education. Breast-feeding is not an innate skill in human mothers. Almost all women have the potential to breast-feed successfully, but many fail because of inadequate knowledge. Nursing Care Plan 18.1 gives typical nursing diagnoses, outcomes, and interventions. For many mothers and newborns, breast-feeding goes smoothly from the start, but for others it is a struggle. Nurses can help throughout the experience by not being judgmental and by demonstrating techniques and offering encouragement and praise for success. Correct positioning will enhance good attachment and will ensure effective milk transfer. Nurses should emphasize that the key to successful breast-feeding is correct positioning and latching-on.

Teaching by nurses has been shown to have a significant effect on both the ability to breast-feed successfully and the duration of lactation (Dudek, 2014). During the first few breast-feeding sessions, mothers want to know how often they should be nursing, whether breast-feeding is going well, if the newborn is getting enough nourishment, and what problems may ensue and how to cope with them. Education for the breast-feeding mother is highlighted in Teaching Guidelines 18.4.

Take Note!

Remember that the supply of milk is equal to the demand—the more sucking, the more milk.

> *Remember Kelly, who was concerned about jaundice in her newborn son? At her son's 2-week well-baby checkup at the clinic, his bilirubin level came back within normal limits. Kelly still felt he was not getting enough to eat and stated that she might switch to formula-feeding her son. What information can the nurse present to promote and reinforce breast-feeding? Should the nurse make a referral to the lactation consultant?*

NURSING CARE PLAN 18.1

Overview of the Mother and Newborn Having Difficulty With Breast-Feeding

Baby boy James, weight 7 lb, 4 oz, was born a few hours ago. His mother, Jane, is a 19-year-old gravida 1, para 1[AQ8]. His Apgar scores were 9 points at both 1 and 5 minutes. Labor and birth were unremarkable, and James was admitted to the nursery for assessment. After stabilization, James was brought to his mother, who had said she wished to breast-feed. The postpartum nurse assisted the new mother with positioning and latching-on and left the room for a few minutes. On returning, the mother was upset, James was crying, and she stated she wanted a bottle of formula to feed him since she didn't have milk and her nipples hurt.

Assessment reveals a young, inexperienced mother placed in an uncomfortable situation with limited knowledge of breast-feeding. Anxiety from the mother transferred to James, resulting in crying. The mother, apprehensive about breast-feeding, needs additional help.

NURSING DIAGNOSIS: Ineffective breast-feeding related to pain and limited skill

Outcome Identification and Evaluation
The mother will demonstrate understanding of breast-feeding skills as evidenced by use of correct positioning and technique, and verbalization of appropriate information related to breast-feeding.

Interventions: *Providing Education*
• Instruct the mother on proper positioning for breast-feeding; suggest use of football hold, side-lying position, modified cradle, and across-the-lap position *to ensure comfort and to promote ease in breast-feeding.*
• Review breast anatomy and milk letdown reflex *to enhance mother's understanding of lactation.*
• Observe newborn's ability to suck and latch on to the nipple *to assess whether newborn has adequate ability.*
• Monitor sucking and newborn swallowing for several minutes *to ensure*

adequate latching on and to assess intake.
- Reinforce nipple care with water and exposure to air *to maintain nipple integrity.*

NURSING DIAGNOSIS: Anxiety related to breast-feeding ability and irritable, crying newborn

Outcome Identification and Evaluation
The mother will verbalize increased comfort with breast-feeding as evidenced by positive statements related to breast-feeding and verbalization of desire to continue to breast-feed newborn.

Interventions: *Reducing Anxiety*
- Ensure that the environment is calm and soothing without distractions *to promote maternal and newborn relaxation.*
- Show the mother correct latching-on technique *to promote breast-feeding.*
- Assist in calming newborn by holding and talking *to ensure that the newborn is relaxed prior to latching on.*
- Reassure the mother she can be successful at breast-feeding *to enhance her self-esteem and confidence.*
- Encourage frequent trials and attempts *to enhance confidence.*
- Encourage the mother to verbalize her anxiety/fears *to reduce anxiety.*

NURSING DIAGNOSIS: Pain related to breast-feeding and incorrect latching-on technique

Outcome Identification and Evaluation
The mother will experience a decrease in pain during breast-feeding as evidenced by statements of less nipple pain.

Interventions: *Reducing Pain*
- Suggest several alternate positions for breast-feeding *to increase comfort.*
- Demonstrate how to break suction before removing infant from breast *to minimize trauma to nipple.*
- Inspect nipple area *to promote early identification of trauma.*
- Reinforce correct latching-on technique *to prevent nipple trauma.*
- Administer pain medication if indicated *to relieve pain.*

• Instruct about nipple care between feedings *to maintain nipple integrity*.

 Teaching Guidelines 18.4

BREAST-FEEDING

• Set aside a quiet place where you can be relaxed and won't be disturbed. Relaxation promotes milk letdown.

• Sit in a comfortable chair or rocking chair or lie on a bed. Try to make each feeding calm, quiet, and leisurely. Avoid distractions.

• Listen to soothing music and sip a nutritious drink during feedings.

• Initially, nurse the newborn every few hours to stimulate milk production. Remember that the supply of milk is equal to the demand—the more sucking, the more milk.

• Watch for signals from the infant to indicate that he or she is hungry, such as:

  • Nuzzling against the mother's breasts

  • Demonstrating the rooting reflex by making sucking motions

  • Placing fist or hands in mouth to suck on

  • Crying and squirming

  • Smacking the lips

• Stimulate the rooting reflex by touching the newborn's cheek to initiate sucking.

• Look for signs indicating that the newborn has latched on correctly: wide-open mouth with the nipple and much of the areola in the mouth, lips rolled outward, and tongue over lower gum, visible jaw movement drawing milk out, rhythmic sucking with an audible swallowing (soft "ka" or "ah" sound indicates the infant is swallowing milk).

• Hold the newborn closely, facing the breast, with the newborn's ear, shoulder, and hip in direct alignment.

• Nurse the infant on demand, not on a rigid schedule. Feed every 2 to 3 hours within a 24-hour period for a total of 8 to 12 feedings.

- Alternate the breast you offer first; identify with a safety pin on bra.
- Vary your position for each feeding to empty breasts and reduce soreness.
- Look for signs that the newborn is getting enough milk:
  - At least six wet diapers and two to five loose yellow stools daily
  - Steady weight gain after the first week of age
  - Pale-yellow urine, not deep yellow or orange
  - Sleeping well, yet looks alert and healthy when awake
- Wake up the newborn if he or she has nursed less than 5 minutes by unwrapping him or her.
- Before removing the baby from the breast, break the infant's suction by inserting a finger.
- Burp the infant to release air when changing breasts and at the end of the breast-feeding session.
- Avoid supplemental formula feedings unless indicated for a medical reason. Do not take drugs or medications unless approved by the health care provider.
- Avoid drinking alcohol or caffeinated drinks because they pass through milk.
- Do not smoke while breast-feeding; it increases the risk of sudden infant death syndrome.
- Always wash your hands before expressing or handling milk to store.
- Wear nursing bras and clothes that are easy to undo.

Adapted from Dyson, L., McCormick, F. M., & Renfrew, M. J. (2014). Interventions for promoting the initiation of breastfeeding. *Sao Paula Medical Journal*, 132(1), 68–72; La Leche League. (2015a). *Lactation support and health care providers*. Retrieved from http://www.llli.org/resources/providers.html?m=0,2; and Walker, M. (2014). *Breastfeeding management for the clinician: Using the evidence* (3rd ed.). Sudbury, MA: Jones & Bartlett.

Breast Milk Storage and Expression. If the breast-feeding mother becomes separated from the newborn for any reason (e.g., work, travel, or illness), she needs instruction on how to express and store milk safely. Expressing milk can be done manually (hand compression of breast) or by using a breast pump.

Manual or handheld pumps are inexpensive and can be used by mothers who occasionally need an extra bottle if they are going out (Fig. 18.25A). Electric breast pumps are used for mothers who experience a lengthy separation from their infants and need to pump their breasts regularly, e.g., while at the work place (Fig. 18.25B).

To ensure the safety of expressed breast milk, instruct the mother as follows:

• Wash your hands before expressing milk or handling breast milk.

• Find a quiet, clean place to express milk if returned to workplace

• Use clean containers to store expressed milk.

• Use sealed and chilled milk within 24 hours.

• Discard any milk that has been refrigerated for more than 24 hours.

• Use any frozen expressed milk within 3 months.

• Do not use microwave ovens to warm chilled milk.

• Discard any used milk; never refreeze it.

• Store milk in quantities to be used for each feeding (2 to 4 oz).

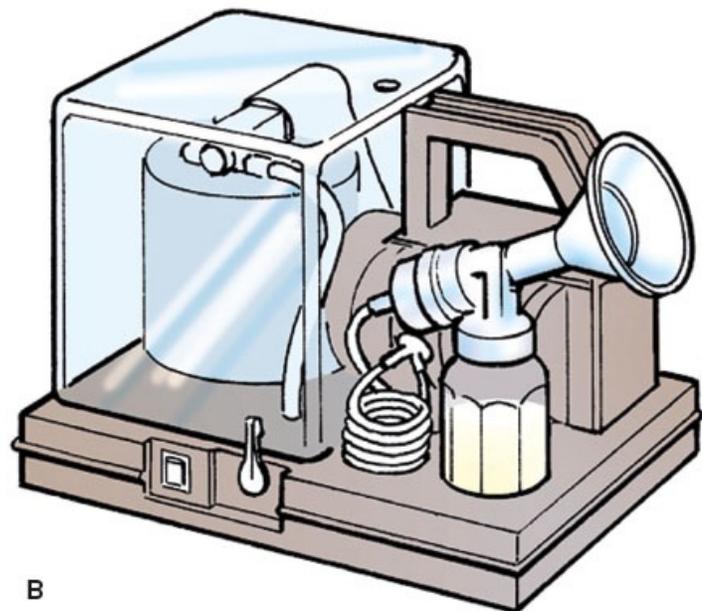
• Thaw milk in warm water before using (La Leche League, 2015b).


FIGURE 18.25 A. Hand-held breast pump. **B.** Electric breast pump. (Part B from Lippincott (2015).

Lippincott Nursing Procedures (7th ed.), Philadelphia, PA: Wolters Kluwer).

Common Breast-Feeding Concerns. Breast-feeding women may experience problems such as cracked nipples, engorgement (the painful overfilling of the breasts with milk), or mastitis (inflammation of the breast). Breast-feeding should not be painful for the mother. If she has sore, cracked nipples, the first step is to find the cause. Incorrect positioning or latching-on, removing the infant from the breast without first breaking the suction, or wearing a bra that is too tight can cause cracked or sore nipples. Cracked nipples can increase the risk of mastitis because a break in the skin may allow *Staphylococcus aureus* or other organisms to enter the body.

Sore nipples usually are caused by improper infant attachment, which traumatizes the tissue. The nurse should review techniques for proper positioning and latching-on. It is important to get this correct from the first feed to assist in the prevention of incorrect attachment and associated nipple trauma. Recommend the following to the mother:

• Use only warm water, not soap, to clean the nipples to prevent dryness.

• Express some milk before feeding to stimulate the milk ejection reflex.

• Avoid using breast pads with plastic liners, and change pads when they are wet.

• Wear a comfortable bra that is not too tight.

• Apply a few drops of breast milk to the nipples after feeding.

• Take systemic anti-inflammatory such as ibuprofen for discomfort.

• Rotate positions when feeding the infant to promote complete breast emptying.

• Leave the nursing bra flaps down after feeding to allow nipples to air-dry.

• Inspect the nipples daily for redness or cracks (Walker, 2014).

To ease nipple pain and trauma, reinforce appropriate latching-on techniques and remind the woman about the need to break the suction at the breast before removing the newborn from the breast. Additional measures may include applying cold compresses over the area and massaging breast milk onto the nipple after feeding.

Engorgement may occur as the milk comes in around day 3 or 4 after birth of the newborn. Explain to the mother that engorgement, though uncomfortable, is self-limited and will resolve as the newborn continues to nurse. The mother should continue to nurse during engorgement to avoid a plugged milk duct, which could lead to mastitis. Provide the following tips for relieving engorgement:

- Take warm to hot showers to encourage milk release.
- Express some milk manually before breast-feeding.
- Wear a supportive nursing bra 24 hours a day to provide support.
- Feed the newborn in a variety of positions—sitting up and then lying down.
- Massage the breasts from under the axillary area down toward the nipple.
- Increase the frequency of feedings.
- Apply warm compresses to the breasts prior to nursing.
- Stay relaxed while breast-feeding.
- Use a breast pump if nursing or manual expression is not effective.
- Remember that this condition is temporary and resolves quickly.

Mastitis, or inflammation of the breast, causes flu-like symptoms, chills, fever, and malaise. These symptoms may occur before the development of soreness, aching, swelling, and redness in the breast (usually the upper outer quadrant). This condition usually occurs in just one breast when a milk duct becomes blocked, causing inflammation, or through a cracked or damaged nipple, allowing bacteria to infect a portion of the breast. Treatment consists of rest, warm compresses, antibiotics, breast support, and continued breast-feeding (the infection will not pass into the breast milk). Explain to the mother that it is important to keep the milk flowing in the infected breast, whether it is through nursing or manual expression or with a breast pump.

FORMULA-FEEDING

Despite the general acknowledgment that breast-feeding is the most desirable means of feeding infants, many mothers choose formula-feeding and need education about this procedure. Formula-fed infants grow more rapidly than breast-fed infants not only in weight but also in length.

Formula-feeding requires more than just opening, pouring, and feeding. Parents need information about the types of formula available, preparation and storage of formula, equipment, feeding positions, and the amount to feed their newborn. The mother also needs to know how to prevent lactation (see Chapter 16 for more information).

Commercially prepared formulas are regulated by the Food and Drug Administration (FDA), which sets minimum and maximum levels of nutrients. Formulas are manufactured by numerous manufacturers in the United States.

Normal full-term infants usually receive conventional cow milk-based formula, but the health care provider makes this decision. If the infant shows signs of a reaction or lactose intolerance, a switch to another formula type is recommended.

The general recommendation is for all infants to receive iron-fortified formula until the age of 1 year. The latest generation of infant formulas includes some fortification with docosahexaenoic acid (DHA) and arachidonic acid (ARA), two natural components of breast milk. Many feel the FDA does not adequately regulate the use of fatty acid additives (DHA and ARA) to infant formula before they are marketed, and there is no systematic assessment after marketing is underway. Researchers are calling for more FDA regulation over additives in infant formulas (Kent, 2014). Commercial formulas come in three forms: powder, concentrate, and easy to feed or ready to use. All are similar in terms of nutritional content but differ in expense. Powdered formula is the least expensive, with concentrated formula the next most expensive. Both must be mixed with water before using. Ready-to-feed formula is the most expensive; it can be opened and poured into a bottle and fed directly to the infant.

Parents need information about the equipment needed for formula-feeding. Basic supplies are four to six 4-oz bottles, eight to ten 8-oz bottles, eight to ten nipple units, a bottle brush, and a nipple brush. A key area of instruction is assessing for flow of formula through the nipple and checking for any nipple damage. When the bottle is filled and turned upside down, the flow from the nipple should be approximately one drop per second. If the parents are using bottles with disposable bags, instruct them to make sure they have a tight-fitting nipple to prevent leaks. Frequent observation of the flow rate from the nipple and the condition of the nipple will prevent choking and aspiration associated with too fast a rate of delivery. Ask the parents to fill a bottle with formula and then turn it upside down and observe the rate at which the formula drips from the bottle. If it is too fast (more than one drop per second), then the nipple should be replaced.

Correct formula preparation is critical to the newborn's health and development. Mistakes in dilution may result if the parents do not understand how to prepare the formula or make measurement errors. The safety of the water supply should be considered. If well water is used, parents should sterilize the water by boiling it or should use bottled water. Many health care providers still recommend that all water used in formula preparation be brought to a rolling boil for 1 to 2 minutes and then cooled to room temperature before use.

Opened cans of ready-made or concentrated formula should be covered and refrigerated after being prepared for the day (24 hours). Instruct parents to discard any unused portions after 48 hours.

![Take Note icon] *Take Note!*

Any formula left in the bottle after feeding should also be discarded, because the infant's saliva has been mixed with it.

To warm refrigerated formula, advise the parents to place the bottle in a pan of hot water or an electric bottle warmer and test the temperature by letting a few drops fall on the inside of the wrist. If it is comfortably warm to the mother, it is the correct temperature.

Formula-Feeding Assistance. The process of feeding a newborn formula from a bottle should mirror breast-feeding as closely as possible. Although nutrition is important, so are the emotional and interactive components of feeding. Encourage parents to cuddle their newborn closely and position him or her so that the head is in a comfortable position, not too far back or turned, which makes swallowing difficult (Fig. 18.26). Also urge parents to communicate with their newborn during the feedings by talking and singing to him or her.

Although it may seem that bottle-feeding is not a difficult task, many new parents find it awkward. At first glance, holding an infant and a bottle appears simple enough, but both the position of the baby and the angle of the bottle must be correct.

Formula-Feeding Positions. Advise mothers to feed their newborns in a relaxed and quiet setting to create a sense of calm for themselves and the baby. Make sure that comfort is a priority for both mother and newborn. The mother can sit in a comfortable chair, using a pillow to support the arm in which she is holding the baby. The mother can cradle the newborn in a semi-upright position, supporting the newborn's head in the crook of her arm. Holding the newborn close during feeding provides stimulation and helps prevent choking. Holding the newborn's head raised slightly will help prevent formula from washing backward into the eustachian tubes in the ears, which can lead to an ear infection.

FIGURE 18.26 Father holding his newborn securely while feeding.

Formula-Feeding Education. Parents require teaching about the correct preparation and storage of formula as well as the techniques for feeding; refer to Teaching Guidelines 18.5

Teaching Guidelines 18.5

FORMULA-FEEDING

- Wash your hands with soap and water before preparing formula.
- Mix the formula and water amounts exactly as the label specifies.
- Always hold the newborn and bottle during feedings; never prop the bottle.
- Never freeze formula or warm it in the microwave.
- Place refrigerated formula in a pan of hot water for a few minutes to warm.
- Test the temperature of the formula by shaking a few drops on the wrist.
- Hold the bottle like a pencil, keeping it tipped to prevent air from entering. Position the bottle so that the nipple remains filled with milk.

- Burp the infant after every few ounces to allow air swallowed to escape.
- Move the nipple around in the infant's mouth to stimulate sucking.
- Always keep a bulb syringe close by to use if choking occurs.
- Avoid putting the infant to bed with a bottle to prevent "baby bottle tooth decay."
- Feed the newborn approximately every 3 to 4 hours.
- Use an iron-fortified formula for the first year.
- Prepare enough formula for the next 24 hours.
- Check nipples regularly and discard any that are sticky, cracked, or leaking.
- Store unmixed, open liquid formula in the refrigerator for up to 48 hours.
- Throw away any formula left in the bottle after each feeding.

Proper positioning makes bottle-feeding easier and more enjoyable for both the mother and newborn. As in breast-feeding, frequent burping is key. Advise the parents to hold the bottle so that formula fills the nipple, thus allowing less air to enter. Infants get fussy when they swallow air during feedings and need to be relieved of it every 2 to 3 oz.

Emphasize to parents that an electrolyte imbalance can occur in infants who are fed formula that has been incorrectly mixed. Mixing the formula with too *little* water (i.e., too thickly) can cause hypernatremia because the high concentration of sodium is too much for the baby's immature kidneys to handle. As a result, sodium is excreted along with water, leading to dehydration. Mixing the formula with too *much* water in an effort to save money can lead to failure to thrive, diminished nutrition, fluoride overdose, and lack of weight gain (Monahan, 2014).

WEANING AND INTRODUCTION OF SOLID FOODS

Weaning. Eventually, breast-feeding or formula-feeding comes to an end. Weaning involves the transition from breast to bottle, from breast or bottle to cup, or from liquids to solids. Weaning from breast-feeding to cup has several advantages over weaning to a bottle because it eliminates the step of weaning first to a bottle and then to a cup. Another advantage is that the bottle does not become a security object for the infant.

Weaning can be done because the mother is returning to work and cannot keep

breast-feeding, or because the infant is losing interest in breast-feeding and showing signs of independence. There is no "right" time to wean; it depends on the desires of the mother and infant. Weaning represents a significant change in the way the mother and infant interact, and each mother must decide for herself when she and her infant are ready to take that step. Either one can start the weaning process, but usually it occurs between 6 months and 1 year of age.

To begin weaning from the breast, instruct mothers to substitute breast-feeding with a cup or a bottle. Often the midday feeding is the easiest feeding to replace. A trainer cup with two handles and a snap-on lid with a spout is appropriate and minimizes spilling. Because weaning is a gradual process, it may take months. Instruct parents to proceed slowly and let the infant's willingness and interest guide them.

Weaning from the bottle to the cup also needs to be timed appropriately for mother and infant. Typically, the night bottle is the last to be given up, with cup drinking substituted throughout the day. Slowly diluting the formula with water over a week can help in this process; the final result is an all-water bottle. To prevent the baby from sucking on the bottle during the night, remove it from the crib after the infant falls asleep.

Introduction of Solid Foods. When infants double their birth weight and weigh at least 13 lb, it is time to consider introducing solid foods. Readiness cues include:

• Consumption of 32 oz of formula or breast milk daily (estimated)

• Ability to sit up with minimal support and turn head away to indicate fullness

• Reduction of protrusion reflex so cereal can be propelled to back of throat

• Demonstration of interest in food others around them are eating

• Ability to open mouth automatically when food approaches it

When introducing solid foods, certain principles apply:

• New foods should be introduced one at a time and a week apart so that if a problem develops, the responsible item can be identified.

• Infants should be allowed to set the pace regarding how much they wish to eat.

• New foods should not be introduced more frequently than every 3 to 5 days.

• Fruits are added after cereals; then vegetables and meats are introduced; eggs are introduced last.

- A relaxed, unhurried, calm atmosphere for meals is important.
- A variety of foods are provided to ensure a balanced diet.
- Infants should never be force-fed (Schlenker & Gilbert, 2015).

Nurses can promote good feeding practices by actively listening to new mothers, helping them clarify their feelings, and discussing solutions. A warm, sincere manner and tone of voice will put an anxious mother at ease. Giving accurate information, making suggestions, and presenting options will enable the mother to decide what is best for her and her infant. Nurses should be sensitive to the individual, family, and economic and cultural differences among mothers before offering suggestions for feeding practices that may not be appropriate.

Preparing for Discharge

Preparing the parents for discharge is an essential task for the nurse. Because of today's shorter hospital stays, the nurse must identify the major teaching topics that need to be covered. Nurses should assess the parents' baseline knowledge and learning needs and plan how to meet them. Using the following principles fosters a learner-centered approach:

- Make the environment conducive to learning. Encourage the parents to feel comfortable during this stressful time by using support and praise.
- Allow the parents to provide input about the content and the process of learning. What do they want and need to learn?
- Build the parents' self-esteem by confirming that their responses to the entire birthing process and aftercare are legitimate, and others have felt the same way.
- Ensure that what the parents learn is relevant to their day-to-day home situation.
- Encourage responsibility by reinforcing that their emotional and physical responses are within the normal range.
- Respect cultural beliefs and practices that are important to the family by taking into account their heritage and health beliefs regarding newborn care. Examples include placing a bellyband over the newborn's navel (Hispanics and African Americans), delaying naming the newborn (Asian Americans and Haitians), and delaying breast-feeding (Native Americans; they regard colostrum as "bad") (Bowers, 2015).

While in the hospital, women have ready access to support and hands-on instruction regarding feeding and newborn care. When the new mother is discharged, this close supervision and support by nurses should not end abruptly. Providing the new parents with the phone number of the mother–baby unit will help them through this stressful transitional period. Giving the new family information and offering backup support via the telephone will increase parenting success (see Evidence-Based Practice 18.1).

ENSURING FOLLOW-UP CARE

Most newborns are scheduled for their first health follow-up appointment within 2 to 4 days after discharge so they can have additional laboratory work done as part of the newborn screening series, especially if they were discharged within 48 hours. After this first visit, the typical schedule of health care visits is as follows: 2 to 4 weeks of age; 2, 4, and 6 months of age for checkups and vaccines; 9 months of age for a checkup; 12 months for a checkup and tuberculosis testing; 15 and 18 months for checkups and vaccines; and 2 years of age for a checkup. These appointments provide an opportunity for parents to ask questions and receive anticipatory guidance as their newborn grows and develops.

Consider This

I have always prided myself on being very organized and in control in most situations, but survival at home after childbirth wasn't one of them. I left the hospital 24 hours after giving birth to my son because my doctor said I could. The postpartum nurse encouraged me to stay longer, but wanting to be in control and sleeping in my own bed again won out. I thought my baby would be sleeping while I sent out birth announcements to my friends and family— wrong! What happened instead was my son didn't sleep as I imagined and my nipples became sore after breast-feeding every few hours. I was weary and tired and wanted to sleep, but I couldn't. Somehow I thought I would be getting a full night's sleep because I was up throughout the day, but that was a fantasy too. At 2 o'clock in the morning when you are up feeding your baby, you feel you are the only one in the world up at that time and feel very much

alone. My feelings of being organized and in control all the time have changed dramatically since I left the hospital. I have learned to yield to the important needs of my son and derive satisfaction from being able to bring comfort to him and to let go of my control.

Thoughts: It is interesting to see how a newborn changed this woman's need to organize and control her environment. What "tips of survival" could the nurse offer this woman to help in her transition to home with her newborn? How can friends and family help when women arrive home from the hospital with their newborns?

In addition to encouraging parents to keep follow-up appointments, advise parents to call their health care provider if they notice signs of illness in their newborn. They should know which over-the-counter medicines should be kept on hand. Review the following warning signs of illness with parents:

• Temperature of 101° F (38.3° C) or higher

• Forceful, persistent vomiting, not just spitting up

• Refusal to take feedings

• Two or more green, watery diarrheal stools

• Infrequent wet diapers and change in bowel movements from normal pattern

• Lethargy or excessive sleepiness

• Inconsolable crying and extreme fussiness

• Abdominal distention

• Difficult or labored breathing

Figure 1. Recommended immunization schedule for persons aged 0 through 18 years – United States, 2016.
(FOR THOSE WHO FALL BEHIND OR START LATE, SEE THE CATCH-UP SCHEDULE [FIGURE 2]).
These recommendations must be read with the footnotes that follow. For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the green bars in Figure 1. To determine minimum intervals between doses, see the catch-up schedule (Figure 2). School entry and adolescent vaccine age groups are shaded.

Vaccine	Birth	1 mo	2 mos	4 mos	6 mos	9 mos	12 mos	15 mos	18 mos	19–23 mos	2–3 yrs	4–6 yrs	7–10 yrs	11–12yrs	13–15yrs	16–18yrs
Hepatitis B (HepB)	1st dose	←— 2nd dose —→			←——————— 3rd dose ———————→											
Rotavirus (RV) RV1 (2-dose series); RV5 (3-dose series)			1st dose	2nd dose	See footnote 2											
Diphtheria, tetanus, & acellular pertussis (DTaP: <7 yrs)			1st dose	2nd dose	3rd dose			←—— 4th dose ——→				5th dose				
Haemophilus influenzae type b (Hib)			1st dose	2nd dose	See footnote 4		3rd or 4th dose, See footnote 4									
Pneumococcal conjugate (PCV13)			1st dose	2nd dose	3rd dose		←—— 4th dose ——→									
Inactivated poliovirus (IPV: <18yrs)			1st dose	2nd dose	←——————— 3rd dose ———————→							4th dose				
Influenza (IIV; LAIV)					Annual vaccination (IIV only) 1 or 2 doses							Annual vaccination (LAIV or IIV) 1 or 2 doses		Annual vaccination (LAIV or IIV) 1 dose only		
Measles, mumps, rubella (MMR)					See footnote 8		←—— 1st dose ——→					2nd dose				
Varicella (VAR)							←—— 1st dose ——→					2nd dose				
Hepatitis A (HepA)							←——— 2-dose series, See footnote 10 ———→									
Meningococcal (Hib-MenCY ≥6 weeks; MenACWY-D ≥9 mos; MenACWY-CRM ≥ 2 mos)					See footnote 11									1st dose		Booster
Tetanus, diphtheria, & acellular pertussis (Tdap: ≥7 yrs)														(Tdap)		
Human papillomavirus (2vHPV: females only; 4vHPV, 9vHPV: males and females)														(3-dose series)		
Meningococcal B														See footnote 11		
Pneumococcal polysaccharide (PPSV23)												See footnote 5				

Legend:

Range of recommended ages for all children	Range of recommended ages for catch-up immunization	Range of recommended ages for certain high-risk groups	Range of recommended ages for non-high-risk groups that may receive vaccine, subject to individual clinical decision making	No recommendation

This schedule includes recommendations in effect as of January 1, 2016. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Vaccination providers should consult the relevant Advisory Committee on Immunization Practices (ACIP) statement for detailed recommendations, available online at http://www.cdc.gov/vaccines/hcp/acip-recs/index.html. Clinically significant adverse events that follow vaccination should be reported to the Vaccine Adverse Event Reporting System (VAERS) online (http://www.vaers.hhs.gov) or by telephone (800-822-7967). Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for vaccination, is available from CDC online (http://www.cdc.gov/vaccines/recs/vac-admin/contraindications.htm) or by telephone (800-CDC-INFO [800-232-4636]).

This schedule is approved by the Advisory Committee on Immunization Practices (http://www.cdc.gov/vaccines/acip), the American Academy of Pediatrics (http://www.aap.org), the American Academy of Family Physicians (http://www.aafp.org), and the American College of Obstetricians and Gynecologists (http://www.acog.org).

NOTE: The above recommendations must be read along with the footnotes of this schedule.

FIGURE 18.27 Recommended childhood immunization schedule.

PROVIDING IMMUNIZATION INFORMATION

In the last century, vaccinations have been the most effective medical intervention to reduce mortality and morbidity caused by communicable diseases. It is believed that vaccines save at least two to three million lives annually worldwide (Delany, Rappuoli, & De Gregorio, 2014). Parents also need instructions about immunizations for their newborn. **Immunization** is the process of rendering an individual immune or of becoming immune to certain communicable diseases (Verklan & Walden, 2015). The purpose of the immune system is to identify unknown (nonself) substances in the body and develop a defense against these invaders. Disease prevention by immunization is a public health priority and is one of the leading health indicators as part of *Healthy People 2020*. Despite many advances in vaccine delivery, the goal of universal immunization has not been reached (Davidson, 2014). Nurses can help meet this national goal by educating new parents about the importance of disease

prevention through immunizations.

Immunity can be provided either passively or actively. Passive immunity is protection transferred via already formed antibodies from one person to another. Passive immunity includes transplacental passage of antibodies from a mother to her newborn, immunity passed through breast milk, and immunity from immunoglobulins. Passive immunity provides limited protection and decreases over a period of weeks or months (Chu & Englund, 2014). Active immunity is protection produced by an individual's own immune system. It can be obtained by having the actual disease or by receiving a vaccine that produces an immunologic response by that person's body. Active immunity may be lifelong either way; see Chapter 17.

Young infants and children are susceptible to various illnesses because their immune systems are not yet mature. Many of these illnesses can be prevented by following the recommended schedule of childhood immunizations. Figure 18.27 shows the *2015 Childhood Immunization Schedule*. Refer to *thePoint* website for information about how to view the latest CDC immunization schedule. The schedule for immunizations should be reviewed with parents, stressing the importance of continued follow-up health care to preserve their infant's health.

The newborn's first immunization (hepatitis B) is received in the hospital soon after birth. The first dose can also be given by age 2 months if the mother is HbsAg negative. If the mother is HbsAg positive, then the newborn should receive hepatitis B vaccine and hepatitis B immunoglobulin within 12 hours of birth (Cunningham et al., 2014).

Education for the parents should include the risks and benefits for each vaccine and possible adverse effects. Federal law requires a consent form to be signed before administering a vaccine. Parents have the right to refuse immunizations based on their religious beliefs and can sign a waiver noting their decision. When consent has been received, the nurse administering the vaccine must document the date and time it was given, name and manufacturer, lot number and expiration date of the vaccine given, site and route of administration, and the name and title of the nurse who administered the vaccine. Despite overwhelming evidence of vaccine safety, suspicion and misconception continues in small groups of hesitant or resistant parents/partners/significant others, often leading to outbreaks of vaccine-preventable infections. On the front lines of vaccinations, nurses can improve vaccination rates by developing trust with parents/partners/significant others and arming them with information based on sound evidence.

KEY CONCEPTS

- The period of transition from intrauterine to extrauterine life occurs during the first several hours after birth. It is a time of stabilization for the newborn's temperature, respiration, and cardiovascular dynamics.

- The newborn's bowel is sterile at birth. It usually takes about a week for the newborn to produce vitamin K in sufficient quantities to prevent VKDB.

- It is recommended that all newborns in the United States receive an installation of a prophylactic agent (erythromycin or tetracycline ophthalmic ointment) in their eyes within an hour or two of being born.

- Nursing measures to maintain newborns' body temperature include drying them immediately after birth to prevent heat loss through evaporation, wrapping them in prewarmed blankets, putting a hat on their head, and placing them under a temperature-controlled radiant warmer.

- The specific components of a typical newborn examination include a general survey of skin color, posture, state of alertness, head size, overall behavioral state, respiratory status, gender, and any obvious congenital anomalies.

- Gestational age assessment is pertinent because it allows the nurse to plot growth parameters and to anticipate potential problems related to prematurity/postmaturity and growth abnormalities such as SGA/LGA.

- After the newborn has passed the transitional period and stabilized, the nurse needs to complete ongoing assessments, vital signs, weight and measurements, cord care, hygiene measures, newborn screening tests, and various other tasks until the newborn is discharged home from the birthing unit.

- Important topics about which to educate parents include environmental safety, newborn characteristics, feeding and bathing, circumcision and cord care, sleep and elimination patterns of newborns, safe infant car seats, holding/positioning, and follow-up care.

- Newborn screening tests consist of hearing and certain genetic and inborn errors of metabolism tests required in most states for newborns before discharge from the birth facility.

- The AAP and the American Dietetic Association recommend breast-feeding exclusively for the first 6 months of life and that it continue along with other food at least until the first birthday.

- Parents who choose not to breast-feed need to know what types of formula are available, preparation and storage of formula, equipment, feeding positions, and how much to feed their infant.
- Common problems associated with the newborn include transient tachypnea, physiologic jaundice, and hypoglycemia.
- Transient tachypnea of the newborn appears soon after birth; is accompanied by retractions, expiratory grunting, or cyanosis; and is relieved by low-dose oxygen.
- Physiologic jaundice is a very common condition in newborns, with the majority demonstrating yellowish skin, mucous membranes, and sclera within the first 3 days of life. Newborns undergoing phototherapy in the treatment of jaundice require close monitoring of their body temperature and fluid and electrolyte balance; observation of skin integrity; eye protection; and parental participation in their care.
- The newborn with hypoglycemia requires close monitoring for signs and symptoms of hypoglycemia if present. In addition, newborns at high risk need to be identified based on their perinatal history, physical examination, body measurements, and gestational age.
- The schedule for immunizations should be reviewed with parents, stressing the importance of continual follow-up health care to preserve their infant's health.

CHAPTER **WORKSHEET**

MULTIPLE CHOICE QUESTIONS

1. At birth, a newborn's assessment reveals the following: heart rate of 140 bpm, loud crying, some flexion of extremities, crying when bulb syringe is introduced into the nares, and a pink body with blue extremities. The nurse would document the newborn's Apgar score as:

   a. 5 points

   b. 6 points

   c. 7 points

   d. 8 points

2. The nurse is explaining phototherapy to the parents of a newborn. The nurse would include which of the following as the purpose?

   a. Increase surfactant levels

   b. Stabilize the newborn's temperature

   c. Destroy Rh-negative antibodies

   d. Oxidize bilirubin on the skin

3. The nurse administers a single dose of vitamin K intramuscularly to a newborn after birth to promote:

a. Conjugation of bilirubin

b. Blood clotting

c. Foreman ovale closure

d. Digestion of complex proteins

4. A prophylactic agent is instilled in both eyes of all newborns to prevent which of the following conditions?

a. Gonorrhea and chlamydia

b. Thrush and enterobacter

c. Staphylococcus and syphilis

d. Hepatitis B and herpes

5. The AAP recommends that all newborns be placed on their backs to sleep to reduce the risk of:

a. Respiratory distress syndrome

b. Bottle mouth syndrome

c. Sudden infant death syndrome

d. GI regurgitation syndrome

6. Which one of the following immunizations is most commonly received by newborns before hospital discharge?

a. Pneumococcus

b. Varicella

c. Hepatitis A

d. Hepatitis B

7. Which condition would be missed if a newborn were screened before he had tolerated protein feedings for at least 48 hours?

a. Hypothyroidism

b. Cystic fibrosis

c. Phenylketonuria

d. Sickle cell disease

8. Which of the following findings in a newborn would the nurse document as abnormal when assessing the newborn head?

   a. Two soft spots palpated between the cranial bones

   b. A spongy area of edema outlined on the head

   c. Head circumference 32 cm, chest 34 cm

   d. Asymmetry of the head with overriding bones

9. Which of the following findings in a newborn would be considered normal?

   a. Passage of meconium within the first 24 hours

   b. Respiratory rate of 80 breaths/minute

   c. Yellow skin tones at 10 hours after birth

   d. Bleeding from the umbilicus area

CRITICAL THINKING EXERCISE

1. An African American mother who delivered her first baby, and is on the mother–baby unit, calls the nursery nurse into her room and expresses concern about how her daughter looks. The mother tells the nurse that her baby's head looks like a "banana" and is mushy to the touch, and she has "white spots" all over her nose. In addition, there appear to be "big bluish bruises" all over her baby's buttocks. She wants to know what is wrong with her baby and whether these problems will go away.

   a. How should the nurse respond to this mother's questions?

   b. What additional newborn instruction might be appropriate at this time?

   c. What reassurance can be given to this new mother regarding her daughter's appearance?

2. At approximately 12:30 am on a Friday, a woman enters a hospital through a busy emergency department. She is wearing a white uniform and a lab coat with a stethoscope around her neck. She identifies herself as a new nurse coming back to check on something she had left on the unit on an earlier shift. She enters a postpartum client's room containing the mother's newborn, pushes the open crib down a hallway, and escapes through an exit. The security cameras aren't working. The infant isn't discovered missing until the 2 am check by the nurse.

a. What impact does an infant abduction have on the family and the hospital?

b. What security measure was the weak link in the chain of security?

c. What can hospitals do to prevent infant abduction?

STUDY ACTIVITIES

1. Obtain a set of vital signs (temperature, pulse, and respiration) of a newborn on admission to the nursery. Repeat this procedure and compare changes in the values several hours later. Discuss what changes in the vital signs you would expect during this transitional period.

   The discussion of newborn changes noticed will vary from student to student, depending on the interview information obtained from the new mother.

2. Interview a new mother on the postpartum unit on her second day about the changes she has noticed in her newborn's appearance and behavior within the past 24 hours. Discuss your interview findings at postconference. This discussion will vary depending on questions asked during the bath demonstration as well as each individual mother's response to it.

3. Demonstrate a newborn bath to a new mother in her room, using the principle of bathing from the cleanest to the dirtiest body part. Discuss the questions asked by the mother and her reaction to the demonstration in postconference.

4. Go to the La Leche League web site (refer to thePoint website). Review the information it provides on breast-feeding. How helpful would it be to a new mother?

   The La Leche League website is filled with helpful information with pictures to assist new mothers with breast-feeding. Each student will have his or her own opinion about how helpful the website is and what educational level it addresses.

5. Debate the risks and benefits of neonatal circumcision within your nursing group at postconference. Did either side present a stronger position? What is your opinion, and why?

   The risks of neonatal circumcision include hemorrhage, infection,

adhesions, dehiscence, urethral fistula, meatal stenosis, and pain. The benefits of neonatal circumcision include prevention of penile cancer, decreased incidence of UTIs and STIs, and preservation of male body consistent with father and peers where the procedure is common. Students will express their own opinions about their thoughts based on their value systems and cultural backgrounds.

BRINGING IT ALL TOGETHER: CASE STUDY

Two days after having a difficult birth of her first child at 37 weeks' gestation, 25-year-old Molly and her partner took their son home from the hospital. That evening while she was breast-feeding him, Molly noticed that the whites of her son's eyes seemed slightly yellow, a condition that worsened noticeably by the next day. Molly called the *Healthy Start* Home Health nurse and requested a visit to evaluate her newborn.

ASSESSMENT

Upon examining the 3-day-old newborn, the nurse noted that there were a few areas of bruising on the newborn's head and a yellow hue on the infant's skin when she pressed on boney prominent areas. When questioning the mother about her breast-feeding, the mother stated that her son didn't seem all that interested at times, so she let him sleep instead.

Nursing Management of Pregnancy at Risk: Pregnancy-Related Complications

multiple gestation
oligohydramnios
placenta accreta
placenta previa
preeclampsia
premature rupture of membranes (PROM)
preterm premature rupture of membranes (PPROM)

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Compare and contrast a normal pregnancy to a high risk one. Determine the common factors that might place a pregnancy at high risk.

2. Detect the causes of vaginal bleeding during early and late pregnancy.

3. Outline nursing assessment and management for the pregnant woman experiencing vaginal bleeding.

4. Develop a plan of care for the woman experiencing preeclampsia, eclampsia, and HELLP syndrome.

5. Examine the pathophysiology of hydramnios and subsequent management.

6. Evaluate factors in a woman's prenatal history that place her at risk for premature rupture of membranes (PROMs).

7. Formulate a teaching plan for maintaining the health of pregnant women experiencing a high-risk pregnancy.

Helen, a 35-year-old G5 P4, presents to the labor and birth suite with severe abdominal pain. She reports that the pain began suddenly about an hour ago while she was resting. She has had two prior cesarean births and thus far has had an uneventful past 32 weeks. Helen appears distressed and is moaning. What additional assessments do you need to do to care for Helen? What might be your immediate nursing action?

Words of Wisdom

Detours and bumps along the road of life can be managed, but many cannot be

entirely cured.

INTRODUCTION

Most people view pregnancy as a natural process with a positive outcome—the birth of a healthy newborn. Unfortunately, conditions can occur that may result in negative outcomes for the fetus, mother, or both. A **high-risk pregnancy** is one in which a condition exists that jeopardizes the health of the mother, her fetus, or both. The condition may result from the pregnancy, or it may be a condition that was present before the woman became pregnant.

Approximately, one in four pregnant women is considered to be at high risk or diagnosed with complications (Nagtalon-Ramos, 2014). Women who are considered to be at high risk have a higher morbidity and mortality compared with mothers in the general population. The risk status of a woman and her fetus can change during the pregnancy, with a number of problems occurring during labor, birth, or afterward, even in women without any known previous antepartal risk. Examples of high-risk conditions include gestational diabetes and ectopic pregnancy. Many obstetric complications and conditions are life-threatening emergencies with high morbidity and mortality rates. It is essential that these be identified early to ensure the best possible outcome for the mother and infant. These conditions are specifically addressed in *Healthy People 2020* (U.S. Department of Health and Human Services, 2010). Early identification of the woman at risk is essential to ensure that appropriate interventions are instituted promptly, increasing the opportunity to change the course of events and provide a positive outcome.

The term *risk* may mean different things to different groups. For example, health care providers may focus on the disease processes and treatments to prevent complications. Nurses may focus on nursing care and on the psychosocial impact on the woman and her family. Insurance companies may concentrate on the economic issues related to the high-risk status. The woman's attention may be focused on her own needs and those of her family. Together, working as a collaborative team, the ultimate goal of care is to ensure the best possible outcome for the woman, her fetus, and her family.

HEALTHY PEOPLE 2020 • 19.1

Objective	Nursing Significance
MICH-6 Reduce maternal illness and complications due to pregnancy (complications during hospitalized labor and delivery).	Will reduce perinatal morbidity and mortality and optimize pregnancy outcomes.
MICH-9 Reduce preterm births.	Will help to preserve the health and well-being of the growing fetus if the pregnancy goes to term.

Healthy People objectives based on data from http://www.healthypeople.gov.

Risk assessment begins at the first antepartal visit and continues with each subsequent visit because factors may be identified in later visits that were not apparent during earlier visits. For example, as the nurse and client develop a trusting relationship, previously unidentified or unsuspected factors (such as drug abuse or intimate partner violence) may be revealed. Through education and support, the nurse can encourage the client to inform her health care provider of these concerns, and necessary interventions or referrals can be made.

Various factors must be considered when determining a woman's risk for adverse pregnancy outcomes, and a comprehensive approach to high-risk pregnancy is needed. For example, prenatal stress and distress have been shown to have significant consequences for the mother, child, and family. Pregnancy-specific stress such as depression, anxiety, and perceived stress may increase the risk for adverse birth outcomes and is associated with preterm births (Staneva et al., 2015). Risks are grouped into broad categories based on threats to health and pregnancy outcome. Current categories of risk are biophysical, psychosocial, sociodemographic, and environmental (Box 19.1) (Cunningham et al., 2014).

This chapter describes the major conditions directly related to pregnancy that can complicate a pregnancy, possibly affecting maternal and fetal outcomes. These include bleeding during pregnancy (spontaneous abortion, ectopic pregnancy, gestational trophoblastic disease, cervical insufficiency, placenta

previa, abruptio placentae, and placenta accreta), hyperemesis gravidarum, gestational hypertension, HELLP syndrome, gestational diabetes, blood incompatibility, amniotic fluid imbalances (polyhydramnios and oligohydramnios), multiple gestation, and premature rupture of membranes. Chapter 20 addresses preexisting conditions that can complicate a woman's pregnancy as well as populations that are considered to be at high risk.

BLEEDING DURING PREGNANCY

Bleeding at any time during pregnancy is potentially life threatening. Every minute of every day, a woman dies in pregnancy or childbirth. The biggest killer is obstetric hemorrhage, the successful treatment of which is a challenge for both the developed and developing worlds. The presence of an attendant at every birth and access to emergency obstetric care are strategic to reducing maternal morbidity and mortality (World Health Organization [WHO], 2015). Management of obstetric hemorrhage involves early recognition, assessment, and resuscitation. Various methods are available to try to stop the bleeding, ranging from pharmacologic methods to aid uterine contraction (e.g., oxytocin, ergometrine, and prostaglandins) to surgical methods to stem the bleeding (e.g., balloon tamponade, compression sutures, or arterial ligation). Bleeding can occur early or late in the pregnancy and may result from numerous conditions. Bleeding is experienced by approximately 20% of women during the first trimester of pregnancy (Knez, Day, & Jurkovic, 2014). Conditions commonly associated with early bleeding (first half of pregnancy) include spontaneous abortion, uterine fibroids, ectopic pregnancy, gestational trophoblastic disease, and cervical insufficiency. Conditions associated with late bleeding include placenta previa, abruptio placentae, and placenta accreta, which usually occur after the 20th week of gestation.

BOX 19.1

FACTORS PLACING A WOMAN AT RISK DURING PREGNANCY

Biophysical Factors

• Genetic conditions

• Chromosomal abnormalities

• Multiple pregnancy

• Defective genes

• Inherited disorders

• ABO incompatibility

• Large fetal size

• Medical and obstetric conditions

• Preterm labor and birth

• Cardiovascular disease

• Chronic hypertension

• Cervical insufficiency

• Placental abnormalities

• Infection

• Diabetes

• Maternal collagen diseases

• Thyroid disease

• Asthma

• Post-term pregnancy

• Hemoglobinopathies

• Nutritional status

• Inadequate dietary intake

• Food fads

• Excessive food intake

• Under- or overweight status

• Hematocrit value less than 33%

• Eating disorder

Psychosocial Factors

• Smoking

• Caffeine

• Alcohol and substance abuse

• Maternal obesity

• Inadequate support system

• Situational crisis

• History of violence

• Emotional distress

• Unsafe cultural practices

Sociodemographic Factors

• Poverty status

• Lack of prenatal care

• Age younger than 15 years or older than 35 years

• Parity—All first pregnancies and more than five pregnancies

• Marital status—Increased risk for unmarried women

• Accessibility to health care

• Ethnicity—Increased risk in non-White women

Environmental Factors

• Infections

• Radiation

• Pesticides

• Illicit drugs

• Industrial pollutants

• Second-hand cigarette smoke

• Personal stress

M., & Garite, T. (2014). *Obstetric intensive care manual* (4th ed.). New York, NY: McGraw-Hill Publishers; and Cunningham, F. G., Leveno, K. J., Bloom, S. L., Spong, C. Y., Dashe, J. S., Hoffman, B. L., Casey, B. M., & Sheffield, J. S. (2014). *Williams' obstetrics* (24th ed.). New York, NY: McGraw-Hill Education.

Spontaneous Abortion

Abortion is considered not only a major reproductive health matter, but also a health risk factor for women's well-being. Spontaneous abortion is the most common complication of early pregnancy (Tulandi & Al-Fozan, 2014). An **abortion** is the loss of an early pregnancy, usually before week 20 of gestation. Abortion can be spontaneous or induced. A spontaneous abortion refers to the loss of a fetus resulting from natural causes, that is, not elective or therapeutically induced by a procedure. A stillbirth is the loss of a fetus after the 20th week of development, whereas a miscarriage refers to a loss before the 20th week. Nonmedical people often use the term *miscarriage* to denote an abortion that has occurred spontaneously. A miscarriage can occur during early pregnancy, and many women who miscarry may not even be aware that they are pregnant. About 80% of spontaneous abortions occur within the first trimester. The terms *stillbirth* and *miscarriage* can sometimes be confusing. Both refer to the loss of an early pregnancy; however, stillbirth occurs later in pregnancy. Some stillbirths can occur right up to the time of labor and delivery. Stillbirths are much less common than miscarriages, occurring in only 1 out of every 160 pregnancies (March of Dimes, 2015a).

The overall rate for spontaneous abortion in the United States is reported to be 15% to 20% of recognized pregnancies in the United States. However, with the development of highly sensitive assays for human chorionic gonadotropin (hCG) levels that detect pregnancies prior to the expected next menses, the incidence of pregnancy loss increases significantly—to about 60% to 70% (King et al., 2015). The frequency of spontaneous abortion increases further with maternal age.

Pathophysiology

The causes of spontaneous abortion are varied and often unknown. The most common cause for first-trimester abortions is fetal genetic abnormalities, usually unrelated to the mother. Chromosomal abnormalities are more likely causes in the first trimester and maternal disease is more likely in the second trimester. Those occurring during the second trimester are more likely related to maternal conditions, such as cervical insufficiency, congenital, or acquired anomaly of the uterine cavity (uterine septum or fibroids), hypothyroidism, diabetes mellitus, chronic nephritis, use of crack cocaine, inherited and acquired thrombophilias,

lupus, polycystic ovary syndrome, severe hypertension, and acute infection such as rubella virus, cytomegalovirus, herpes simplex virus, bacterial vaginosis, and toxoplasmosis (Jones & Lopez, 2014).

Women experiencing a first-trimester abortion at home without a dilation and curettage (D&C) to resolve it require frequent monitoring of hCG levels to validate that all the conceptus tissues have been expelled. Women going through a second-trimester abortion are admitted to the hospital to have an augmented labor and delivery. Nursing care would focus on care of the laboring women with tremendous attention paid to providing emotional support to the woman and her family.

Nursing Assessment

When a pregnant woman calls and reports vaginal bleeding, she must be seen as soon as possible by a health care professional to ascertain the etiology. Varying degrees of vaginal bleeding, low back pain, abdominal cramping, and passage of products of conception tissue may be reported. Ask the woman about the color of the vaginal bleeding (bright red is significant) and the amount—for example, question her about the frequency with which she is changing her peripads (saturation of one peripad hourly is significant) and the passage of any clots or tissue. Instruct her to save any tissue or clots passed and bring them with her to the health care facility. Also, obtain a description of any other signs and symptoms the woman may be experiencing, along with a description of their severity and duration. It is important to remain calm and listen to the woman's description.

When the woman arrives at the health care facility, assess her vital signs and observe the amount, color, and characteristics of the bleeding. Ask her to rate her current pain level, using an appropriate pain assessment tool. Also, evaluate the amount and intensity of the woman's abdominal cramping or contractions, and assess the woman's level of understanding about what is happening to her. A thorough assessment helps in determining the type of spontaneous abortion, such as threatened abortion, inevitable abortion, incomplete abortion, complete abortion, missed abortion, and habitual abortion, that the woman may be experiencing (Table 19.1).

Nursing Management

Nursing management of the woman with a spontaneous abortion focuses on

providing continued monitoring and psychological support, for the family is experiencing acute loss and grief. An important component of this support is reassuring the woman that spontaneous abortions usually result from an abnormality and that her actions did not cause the abortion.

PROVIDING CONTINUED MONITORING

Continued monitoring and ongoing assessments are essential for the woman experiencing a spontaneous abortion. Monitor the amount of vaginal bleeding through pad counts and observe for passage of products of conception tissue. Assess the woman's pain and provide appropriate pain management to address the cramping discomfort.

Assist in preparing the woman for procedures and treatments such as surgery to evacuate the uterus or medications such as misoprostol or PGE2. If the woman is Rh negative and not sensitized, expect to administer RhoGAM within 72 hours after the abortion is complete. Drug Guide 19.1 gives more information about these medications.

PROVIDING SUPPORT

A woman's emotional reaction may vary depending on her desire for this pregnancy and her available support network. Provide both physical and emotional support. In addition, prepare the woman and her family for the assessment process and answer their questions.

Explaining some of the causes of spontaneous abortions can help the woman to understand what is happening and may allay her fears and guilt that she did something to cause the pregnancy loss. Most women experience an acute sense of loss and go through a grieving process with a spontaneous abortion. Providing sensitive listening, counseling, and anticipatory guidance to the woman and her family will allow them to verbalize their feelings and ask questions about future pregnancies.

The grieving period may last as long as two years after a pregnancy loss, with each person grieving in his or her own way. Encourage friends and family to be supportive but give the couple space and time to work through their loss. Referral to a community support group for parents who have experienced a miscarriage can be very helpful during this grief process.

TABLE 19.1 CATEGORIES OF ABORTION

Category	Assessment Findings	Diagnosis	Therapeutic Management
Threatened abortion	Vaginal bleeding (often slight) early in a pregnancy No cervical dilation or change in cervical consistency Mild abdominal cramping Closed cervical os No passage of fetal tissue	Vaginal ultrasound to confirm if sac is empty Declining maternal serum hCG and progesterone levels to provide additional information about viability of pregnancy	Conservative supportive treatment Possible reduction in activity in conjunction with nutritious diet and adequate hydration
Inevitable abortion	Vaginal bleeding (greater than that associated with threatened abortion) Rupture of membranes Cervical dilation Strong abdominal cramping Possible passage of products of conception	Ultrasound and hCG levels to indicate pregnancy loss	Vacuum curettage if products of conception are not passed, to reduce risk of excessive bleeding and infection Prostaglandin analogs such as misoprostol to empty uterus of retained tissue (only used if fragments are not completely passed)
Incomplete abortion (passage of some of the products of conception)	Intense abdominal cramping Heavy vaginal bleeding Cervical dilation	Ultrasound confirmation that products of conception still in uterus	Client stabilization Evacuation of uterus via D&C or prostaglandin analog
Complete abortion (passage of all products of conception)	History of vaginal bleeding and abdominal pain Passage of tissue with subsequent decrease in pain and significant decrease in vaginal bleeding	Ultrasound demonstrating an empty uterus	No medical or surgical intervention necessary Follow-up appointment to discuss family planning
Missed abortion (nonviable embryo retained in utero for at least 6 weeks)	Absent uterine contractions Irregular spotting Possible progression to inevitable abortion	Ultrasound to identify products of conception in uterus	Evacuation of uterus (if inevitable abortion does not occur): suction curettage during first trimester, dilation and evacuation during second trimester Induction of labor with intravaginal PGE2 suppository to empty uterus without surgical intervention
Habitual abortion	History of three or more consecutive spontaneous abortions Not carrying the pregnancy to viability or term	Validation via client's history	Identification and treatment of underlying cause (possible causes such as genetic or chromosomal abnormalities, reproductive tract abnormalities, chronic diseases or immunologic problems) Cervical cerclage in second trimester if incompetent cervix is the cause

Ectopic Pregnancy

An **ectopic pregnancy** is any pregnancy in which the fertilized ovum implants outside the uterine cavity. The term *ectopic* is derived from the Greek word *ektopos,* meaning "out of place," and refers to the implantation of a fertilized egg in a location outside of the uterine cavity, including the fallopian tubes, cervix, ovary, and the abdominal cavity. This abnormally implanted embryo grows and draws its blood supply from the site of abnormal implantation. As the embryo enlarges, it creates the potential for organ rupture because only the uterine cavity is designed to expand and accommodate fetal development. Ectopic pregnancy can lead to massive hemorrhage, infertility, or death.

DRUG GUIDE 19.1 MEDICATIONS RELATED TO ABORTIONS

Medication	Action/Indications	Nursing Implications
Misoprostol (Cytotec)	Stimulates uterine contractions to terminate a pregnancy; to evacuate the uterus after abortion to ensure passage of all the products of conception.	• Monitor for side effects such as diarrhea, abdominal pain, nausea, vomiting, and dyspepsia. • Assess vaginal bleeding and report any increased bleeding, pain, or fever. • Monitor for signs and symptoms of shock, such as tachycardia, hypotension, and anxiety.
Mifepristone (RU-486)	Acts as progesterone antagonist, allowing prostaglandins to stimulate uterine contractions; causes the endometrium to slough; may be followed by administration of misoprostol within 48 hours.	• Monitor for headache, vomiting, diarrhea, and heavy bleeding. • Anticipate administration of antiemetic prior to use to reduce nausea and vomiting. • Encourage client to use acetaminophen to reduce discomfort from cramping.
PGE2, dinoprostone (Cervidil, Prepidil Gel, Prostin E2)	Stimulates uterine contractions, causing expulsion of uterine contents; to expel uterine contents in fetal death or missed abortion during second trimester, or to efface and dilate the cervix in pregnancy at term.	• Bring gel to room temperature before administering. • Avoid contact with skin. • Use sterile technique to administer. • Keep client supine for 30 min after administering. • Document time of insertion and dosing intervals. • Remove insert with retrieval system after 12 hours or at the onset of labor. • Explain purpose and expected response to client.
Rh(D) immuno-globulin (Gamulin, HydroRho-D, Rho-GAM, MICRhoGAM)	Suppresses immune response of nonsensitized Rh-negative clients who are exposed to Rh-positive blood; to prevent isoimmunization in Rh-negative women exposed to Rh-positive blood after abortions, miscarriages, and pregnancies.	• Administer intramuscularly in deltoid area. • Give only MICRhoGAM for abortions and miscarriages <12 weeks unless fetus or father is Rh negative (unless client is Rh positive, Rh antibodies are present). • Educate woman that she will need this after subsequent deliveries if newborns are Rh positive; also check lab study results prior to administering the drug.

Adapted from King, T. L., Brucker, M. C., Kriebs, J. M., Fahey, J. O., Grgor, C. L., & Varney, H. (2015). *Varney's midwifery* (5th ed.). Burlington, MA: Jones & Bartlett Learning; and Skidmore-Roth, L. (2015). *Mosby's 2015 nursing drug reference* (28th ed.). Philadelphia, PA: Elsevier.

Ectopic pregnancies occur in 1 in every 50 pregnancies in the United States or roughly 2% of all pregnancies are diagnosed as ectopic; this rate has increased dramatically during the past 30 years (March of Dimes, 2015b). It is a major health concern for women of reproductive age and is the primary cause of death during the first trimester of pregnancy in the United States (Szypulski, 2015). The discovery of ectopic pregnancies prior to rupture has increased dramatically in the past few decades as a result of improved diagnostic techniques such as the development of sensitive and specific radioimmunoassays for hCG, high-resolution ultrasonography, and the widespread availability of laparoscopy (Desai et al., 2014).

With an ectopic pregnancy, rupture and hemorrhage may occur due to the growth of the embryo. A ruptured ectopic pregnancy is a medical emergency; therefore prediction of any tubal rupture before its occurrence is extremely

important. It is a potentially life-threatening condition and involves pregnancy loss. Even in the United States, women can and do still die from ectopic pregnancy, although early diagnosis has helped prevent that.

Pathophysiology

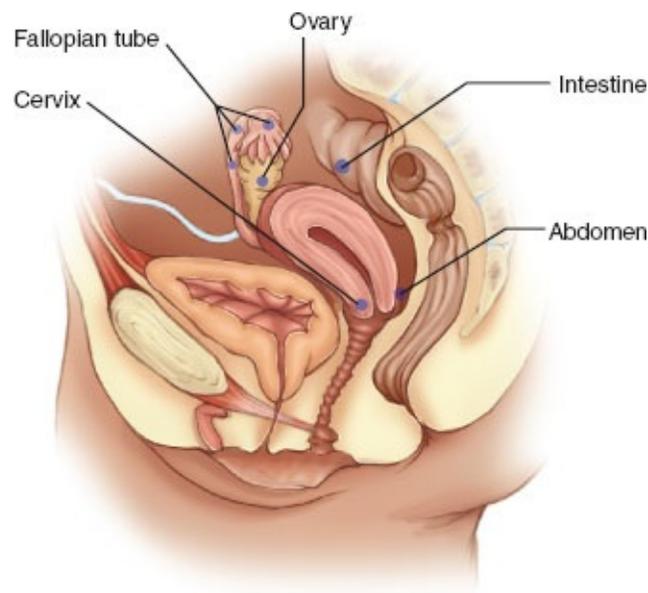
Normally, the fertilized ovum implants in the uterus. In ectopic pregnancy, the journey along the fallopian tube is arrested or altered in some way. With an ectopic pregnancy, the ovum implants outside the uterus. The most common site for implantation is the fallopian tubes, but some ova may implant in the ovary, the intestine, the cervix, or the abdominal cavity (Fig. 19.1) (Sepilian & Wood, 2015). None of these anatomic sites can accommodate placental attachment or a growing embryo.


FIGURE 19.1 Possible sites for implantation with an ectopic pregnancy.

Risk Factors

Ectopic pregnancies usually result from conditions that obstruct or slow the passage of the fertilized ovum through the fallopian tube to the uterus. This may be a physical blockage in the tube, or failure of the tubal epithelium to move the zygote (the cell formed after the egg is fertilized) down the tube into the uterus. In the general population, most cases are the result of tubal scarring secondary to pelvic inflammatory disease (PID). Organisms such as *Neisseria gonorrhea* and

Chlamydia trachomatis preferentially attack the fallopian tubes, producing silent infections. A recent study reported a twofold increased risk for ectopic pregnancy in women with a history of a chlamydia infection, secondary to tubal damage (Randall & LaMontagne, 2015). Other associated risk factors for ectopic pregnancy include previous tubal surgery, infertility, PID, previous pregnancy loss (induced or spontaneous, use of an intrauterine contraceptive system, previous ectopic pregnancy, uterine fibroids, sterilization, smoking (which alters tubal motility), history of multiple sexual partners, use of progestin-only oral contraceptives, douching, and exposure to diethylstilbestrol (DES) (Ardehali & Casikar, 2015).

Therapeutic Management

The diagnosis of ectopic pregnancy can be challenging because many women are asymptomatic before tubal rupture. The classic clinical triad of ectopic pregnancy includes abdominal pain, amenorrhea, and vaginal bleeding. Unfortunately, only about half of women present with all three symptoms.

Diagnostic procedures used for a suspected ectopic pregnancy include a urine pregnancy test to confirm the pregnancy, beta-hCG concentrations to exclude a false-negative urine test, and a transvaginal ultrasound to visualize the misplaced pregnancy (Bourne, 2015).

Historically, the treatment of ectopic pregnancy was limited to surgery. The therapeutic management of ectopic pregnancy depends on whether the tube is intact or has ruptured, creating a medical emergency. In the event of a surgical intervention, preservation of the affected fallopian tube is attempted (King et al., 2015).

MEDICAL INTERVENTION

With early diagnosis, most women with ectopic pregnancy could be treated with methotrexate. The overall success rate of medical treatment in properly selected women is nearly 90%. To be eligible for medical therapy, the client must be hemodynamically stable, with no signs of active bleeding in the peritoneal cavity, low beta-hCG levels (<5,000 mIU/mL) and the mass (which must measure less than 4 cm as determined by ultrasound) must be unruptured.

Contraindications to medical treatment include an unstable client, severe persistent abdominal pain, renal or liver disease, immunodeficiency, active pulmonary disease, peptic ulcer, suspected intrauterine pregnancy, and poor

client compliance (Tulandi, 2015). The potential advantages include avoidance of surgery, the preservation of tubal patency and function, and a lower cost.

The medical approach today for an unruptured tubal pregnancy most often consists of a single-dose IM injection of methotrexate (Rheumatrex; Trexall) with outpatient follow-up. Medical management with methotrexate, though not approved by the Food and Drug Administration for this purpose, has been endorsed by the American College of Obstetricians and Gynecologists. Prostaglandins, misoprostol, and actinomycin have also been used in the medical (nonsurgical) management of ectopic pregnancy, with a reported success rate of approximately 90%. Methotrexate is a folic acid antagonist that inhibits cell division in the developing embryo. It typically has been used as a chemotherapeutic agent in the treatment of leukemia, lymphomas, and carcinomas. It has been shown to produce results similar to that for surgical therapy in terms of high success rate, low complication rate, and good reproductive potential (Dalia et al., 2014). Adverse effects associated with methotrexate include nausea, vomiting, stomatitis, diarrhea, gastric upset, increased abdominal pain, and dizziness. Methotrexate for an ectopic pregnancy is ordered based on the client's body surface area. The administration of methotrexate should be limited to people who have had education and training in the handling and administration of hazardous drugs. In some facilities internal policies require that only nurses who have completed a chemotherapy certification and/or hazardous drug competency program can administer this product (Cohen et al., 2015).

Prior to receiving the single-dose intramuscular injection to treat unruptured pregnancies, the woman needs to be counseled on the risks, benefits, adverse effects, and the possibility of failure of medical therapy, which would result in tubal rupture, necessitating surgery (Tulandi, 2015). The woman is then instructed to return weekly for follow-up laboratory studies for the next several weeks until beta-hCG titers decrease. Beta-hCG level changes between days 0 and 4 after methotrexate therapy have clinical significance and predictive value. A decreasing beta-hCG level is highly predictive of treatment success (Agarwal & Odejinmi, 2014).

SURGICAL INTERVENTION

Surgical management for the unruptured fallopian tube might involve a linear salpingostomy to preserve the tube—an important consideration for the woman wanting to preserve her future fertility. It may also be considered when medical

treatment is considered unsuitable.

With a ruptured ectopic pregnancy, surgery is necessary as a result of possible uncontrolled hemorrhage. A laparotomy with a removal of the tube (salpingectomy) may be necessary. With earlier diagnosis and medical management, the focus has changed from preventing maternal death to facilitating rapid recovery and preserving fertility.

Regardless of the treatment approach (medical or surgical), the woman's beta-hCG level is monitored until it is undetectable to ensure that any residual trophoblastic tissue that forms the placenta is gone. Also, all Rh-negative unsensitized clients are given Rh immunoglobulin to prevent isoimmunization in future pregnancies.

Nursing Assessment

Nursing assessment focuses on determining the existence of an ectopic pregnancy and whether or not it has ruptured. A woman with a suspected ectopic pregnancy may have to undergo several diagnostic tests, some of which are invasive. Consider how she might feel during all of these tests, anticipate her questions, and offer her thorough explanations and reassurances.

HEALTH HISTORY AND PHYSICAL EXAMINATION

Assess the client thoroughly for signs and symptoms that may suggest an ectopic pregnancy. The onset of signs and symptoms varies, but they usually begin at about the seventh or eighth week of gestation. A missed menstrual period, adnexal fullness, and tenderness may indicate an unruptured tubal pregnancy. As the tube stretches, the pain increases. Pain may be unilateral, bilateral, or diffuse over the abdomen.

 Take Note!

The hallmark of ectopic pregnancy is abdominal pain with spotting within 6 to 8 weeks after a missed menstrual period. Although this is the classic triad, all three of these signs and symptoms occur in only about 50% of cases. Many women have symptoms typical of early pregnancy, such as breast tenderness, nausea, fatigue, shoulder pain, and low back pain.

In addition, review the client's history for possible contributing factors. These may include:

• Previous ectopic pregnancy

• History of sexually transmitted infections (STIs)

• Fallopian tube scarring from PID

• In utero exposure to DES

• Endometriosis

• Previous tubal or pelvic surgery

• Infertility and infertility treatments, including use of fertility drugs

• Uterine abnormalities such as fibroids

• Presence of intrauterine contraception

• Use of progestin-only mini pill (slows ovum transport)

• Postpartum or postabortion infection

• Altered estrogen and progesterone levels (interferes with tubal motility)

• Increasing age (older than 35 years)

• Cigarette smoking (Ardehali & Casikar, 2015).

If rupture or hemorrhage occurs before treatment begins, symptoms may worsen and include severe, sharp, and sudden pain in the lower abdomen as the tube tears open and the embryo is expelled into the pelvic cavity; feelings of faintness; referred pain to the shoulder area, indicating bleeding into the abdomen, caused by phrenic nerve irritation; hypotension; marked abdominal tenderness with distention; and hypovolemic shock (Cunningham et al., 2014).

LABORATORY AND DIAGNOSTIC TESTING

The use of transvaginal ultrasound to visualize the misplaced pregnancy and low levels of serum beta-hCG assist in diagnosing an ectopic pregnancy. The ultrasound determines whether the pregnancy is intrauterine, assesses the size of the uterus, and provides evidence of fetal viability. The visualization of an adnexal mass and the absence of an intrauterine gestational sac are diagnostic of ectopic pregnancy (Kao et al., 2014). In a normal intrauterine pregnancy, beta-hCG levels typically double every 2 to 4 days until peak values are reached 60 to 90 days after conception. Concentrations of hCG decrease after 10 to 11 weeks

and reach a plateau at low levels by 100 to 130 days (Ko & Cheung, 2014).). Therefore, low beta-hCG levels are suggestive of an ectopic pregnancy or impending abortion. Additional tests may be done to rule out other conditions such as spontaneous abortion, ruptured ovarian cyst, appendicitis, and salpingitis.

Nursing Management

Nursing management for the woman with an ectopic pregnancy focuses on preparing the woman for treatment, providing support, and providing education about preventive measures.

PREPARING THE WOMAN FOR TREATMENT

Administer analgesics as ordered to promote comfort and relieve discomfort from abdominal pain. Although the intensity of the pain can vary, women often report a great deal of pain. If the woman is treated medically, explain the medication that will be used and what she can expect. Also review signs and symptoms of possible adverse effects. If treatment will occur on an outpatient basis, outline the signs and symptoms of ectopic rupture (severe, sharp, stabbing, unilateral abdominal pain; vertigo/fainting; hypotension; and increased pulse) and advise the woman to seek medical help immediately if they occur.

If surgery is needed, close assessment and monitoring of the client's vital signs, bleeding (peritoneal or vaginal), and pain status are critical to identify hypovolemic shock, which may occur with tubal rupture. Prepare the client physiologically and psychologically for surgery or any procedure. Provide a clear explanation of the expected outcome. Astute vigilance and early referral will help reduce short- and long-term morbidity.

PROVIDING EMOTIONAL SUPPORT

The woman with an ectopic pregnancy requires support throughout diagnosis, treatment, and aftercare. A woman's psychological reaction to an ectopic pregnancy is unpredictable. However, it is important to recognize she has experienced a pregnancy loss in addition to undergoing treatment for a potentially life-threatening condition. The woman may find it difficult to comprehend what has happened to her because events occur so quickly. In the woman's mind, she had just started a pregnancy and now it has ended abruptly. Bleeding during any pregnancy is traumatic because of the uncertainty of the

outcome. Help her to make this experience more "real" by encouraging her and her family to express their feelings and concerns openly, and by validating that this is a loss of pregnancy and that it is okay to grieve over the loss. Although the woman may have physically recovered following an ectopic pregnancy, she may still experience significant emotional distress for a long time.

Provide emotional support, spiritual care, and information about community support groups (such as *Resolve through Sharing*) as the client grieves for the loss of her unborn child and comes to terms with the medical complications of the situation. Acknowledge the client's pregnancy and allow her to discuss her feelings about what the pregnancy means. Also, stress the need for follow-up blood testing for several weeks to monitor hCG titers until they return to zero, indicating resolution of the ectopic pregnancy. Ask about her feelings and concerns about her future fertility, and provide teaching about the need to use contraceptives for at least three menstrual cycles to allow her reproductive tract to heal and the tissue to be repaired. Include the woman's partner in this discussion to make sure both parties understand what has happened, what intervention is needed, and what the future holds regarding childbearing.

EDUCATING THE CLIENT

Preventing ectopic pregnancies through screening and client education is essential. Many can be prevented by avoiding conditions that might cause scarring of the fallopian tubes. In addition, a contributing factor to the development of ectopic pregnancy is a previous ectopic pregnancy. Therefore, educating the woman is crucial. Prevention education may include the following:

• Reduce risk factors such as sexual intercourse with multiple partners or intercourse without a condom.

• Avoid contracting STIs that lead to PID.

• Obtain early diagnosis and adequate treatment of STIs.

• If an intrauterine contraceptive system is chosen, descriptions of the signs of PID should be included to reduce the risk of repeat ascending infections, which can be responsible for tubal scarring.

• Avoid smoking during childbearing years since a correlation and increase in risk exists.

• Use condoms to decrease the risk of infections that cause tubal scarring.

• Seek prenatal care early to confirm the location of pregnancy.

Gestational Trophoblastic Disease

Gestational trophoblastic disease (GTD) comprises a spectrum of neoplastic disorders that originate in the placenta. There is abnormal hyperproliferation of trophoblastic cells that normally would develop into the placenta during pregnancy. GTDs encompass hydatidiform mole (complete and partial), invasive mole, gestational choriocarcinoma, placental-site trophoblastic tumor, and epithelioid trophoblastic tumor (Nguyen & Slim, 2014). Gestational tissue is present, but the pregnancy is not viable. The incidence is hard to determine due to uncommon diagnosis and inaccuracy of documentation of pregnancy loss, but it is thought to occur in about 1 in 1,000 pregnancies in the United States; in Asian countries, the rate is 1 of every 120 pregnancies American Cancer Society (ACS, 2015). The two most common types of GTD are hydatidiform mole (partial or complete) and choriocarcinoma.

Pathophysiology

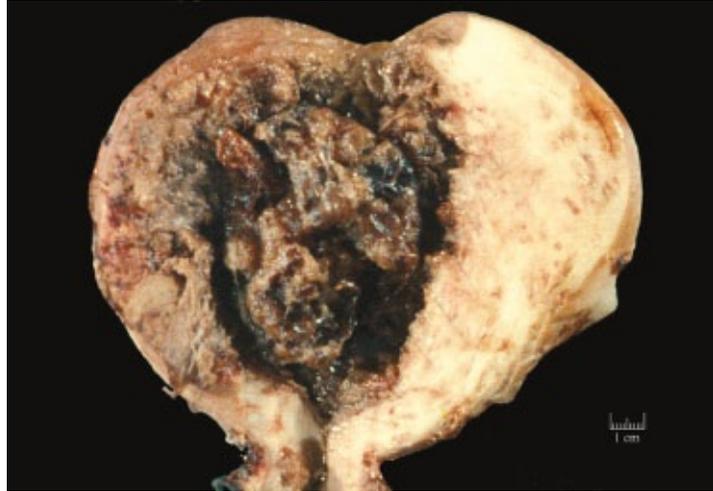
The pathogenesis is unique because the maternal tumor arises from gestational rather than maternal tissue. Hydatidiform mole is a benign neoplasm of the chorion in which the chorionic villi degenerate and become transparent vesicles containing clear, viscid fluid. Hydatidiform mole is classified as complete or partial, distinguished by differences in clinical presentation, pathology, genetics, and epidemiology (Strohl & Lurain, 2014). The complete mole contains no fetal tissue and develops from an "empty egg," which is fertilized by a normal sperm (the paternal chromosomes replicate, resulting in 46 all-paternal chromosomes) (Fig. 19.2). The embryo is not viable and dies. No circulation is established, and no embryonic tissue is found. The complete mole is associated with the development of choriocarcinoma. Surgery can totally remove most complete moles, but as many as one in five women will have some persistent molar tissue and require further treatment (ACS, 2015). Most women with a classic complete mole present with vaginal bleeding, anemia, excessively enlarged uterus, preeclampsia, and hyperemesis.


FIGURE 19.2 Complete hydatidiform mole as seen in a cutaway of a uterus. The chorionic villi degenerate and become filled with a viscid fluid, forming transparent vesicles. (From Reichert (2011). Diagnostic Gynecologic and Obstetric Pathology. Courtesy of Dr. Enrique Higa. Philadelphia, PA: LWW.)

The partial mole has a triploid karyotype (69 chromosomes), because two sperm have provided a double contribution by fertilizing the ovum. Women with a partial mole usually present with the clinical features of a missed or incomplete abortion, including vaginal bleeding and a small- or normal-size for date uterus (Dickson & Mullany, 2015).

The exact cause of molar pregnancy is unknown, but researchers are looking into a genetic basis. Other theories include an ovular defect, stress, or a nutritional deficiency (carotene). Although the etiology remains uncertain, at some point in the pregnancy trophoblastic cells that normally would form the placenta proliferate and the chorionic villi become edematous. The latter changes become the grape-like clusters that characterize the molar pregnancy (King et al., 2015). Studies have revealed some remarkable features about molar pregnancies, including:

• Ability to invade into the wall of the uterus

• Tendency to recur in subsequent pregnancies

• Possible development into choriocarcinoma, a virulent cancer with metastasis to other organs

• Influence of nutritional factors, such as protein deficiency

• Tendency to affect older women more often than younger women

Having a molar pregnancy (partial or complete) results in the loss of the

pregnancy and the possibility of developing choriocarcinoma, a chorionic malignancy from the trophoblastic tissue. Typically asymptomatic, the first symptoms of choriocarcinoma in 80% of cases are shortness of breath, indicative of metastasis to the lungs. Choriocarcinoma affects women of all ages and can occur during pregnancy, after childbirth, or even years remote from the antecedent pregnancy. The most frequent sites of metastases are the lungs, lower genital tract, brain, and liver. Choriocarcinoma is highly responsive to chemotherapy, with an overall remission rate greater than 90% (Hensley & Shviraga, 2014). Partial moles rarely transform into choriocarcinoma.

Therapeutic Management

Treatment consists of immediate evacuation of the uterine contents as soon as the diagnosis is made and long-term follow-up of the client to detect any remaining trophoblastic tissue that might become malignant. D&C is used to empty the uterus. The tissue obtained is sent to the laboratory for analysis to evaluate for choriocarcinoma. Serial levels of hCG are used to detect residual trophoblastic tissue for 1 year. If any tissue remains, hCG levels will not regress. In 80% of women with a benign hydatidiform mole, serum hCG titers steadily drop to normal within 8 to 12 weeks after evacuation of the molar pregnancy. In the other 20% of women with a malignant hydatidiform mole, serum hCG levels begin to rise (Berkowitz, Goldstein, & Horowitz, 2014).

As a result of the increased risk for cancer, the client is advised to receive extensive follow-up therapy for the next 12 months. The follow-up protocol may include:

• Baseline hCG level, chest radiograph, and pelvic ultrasound

• Quantitative hCG levels every week until undetectable for 3 consecutive weeks; then serial hCG levels monthly for 1 year

• Chest radiograph every 6 months to detect pulmonary metastasis

• Regular pelvic examinations to assess uterine and ovarian regression

• Systemic assessments for symptoms indicative of lung, brain, liver, or vaginal metastasis

• Strong recommendation to avoid pregnancy for 1 year because the pregnancy can interfere with the monitoring of hCG levels

• Use of a reliable contraceptive for at least 1 year (Cunningham et al., 2014)

Nursing Assessment

The nurse plays a crucial role in identifying and bringing this condition to the attention of the health care provider based on sound knowledge of the typical clinical manifestations and through astute antepartal assessments.

Clinical manifestations of GTD are very similar to those of spontaneous abortion at about 12 weeks of pregnancy. Assess the woman for potential clinical manifestations at each antepartal visit. Be alert for the following:

• Report of early signs of pregnancy, such as amenorrhea, breast tenderness, fatigue
• Brownish vaginal bleeding/spotting
• Anemia
• Inability to detect a fetal heart rate after 10 to 12 weeks' gestation
• Fetal parts not evident with palpation
• Bilateral ovarian enlargement caused by cysts and elevated levels of hCG
• Persistent, often severe, nausea and vomiting (due to high hCG levels)
• Fluid retention and swelling
• Uterine size larger than expected for pregnancy dates
• Extremely high hCG levels present; no single value considered diagnostic
• Early development of preeclampsia (usually not present until after 24 weeks)
• Absence of fetal heart rate or fetal activity
• Expulsion of grapelike vesicles (possible in some women)

The diagnosis is made by very high hCG levels and the characteristic appearance of the vesicular molar pattern in the uterus via transvaginal ultrasound.

Nursing Management

Nursing management of the woman with GTD focuses on preparing her for a D&C, providing emotional support to deal with the loss and potential risks, and educating her about the risk that cancer may develop after a molar pregnancy and the strict adherence needed with the follow-up program. The woman must understand the need for the continued follow-up care regimen to improve her chances of future pregnancies and to ensure her continued quality of life.

PREPARING THE CLIENT

Upon diagnosis, the client will need an immediate evacuation of the uterus. Perform preoperative care, preparing the client physically and psychologically for the procedure.

PROVIDING EMOTIONAL SUPPORT

To aid the client and her family in coping with the loss of the pregnancy and the possibility of a cancer diagnosis, use the following interventions:

• Listen to their concerns and fears.

• Allow them time to grieve for the pregnancy loss.

• Acknowledge their loss and sad feelings (say you are sorry for their loss).

• Encourage them to express their grief; allow them to cry.

• Provide them with as much factual information as possible to help them make sense of what is happening.

• Enlist support from additional family and friends as appropriate and with the client's permission.

EDUCATING THE CLIENT

After GTD is diagnosed, teach the client about the condition and appropriate interventions that may be necessary to save her life. Explain each phase of treatment accurately and provide support for the woman and her family as they go through the grieving process.

 Consider This

We had lived across the dorm hall from each other during nursing school but really did not get to know each other except for a casual hello in passing. When we graduated, Rose went to work in the emergency room and I worked in OB. We saw each other occasionally in the employee cafeteria, but a quick hello was all that we usually exchanged. I heard she married one of the paramedics who worked in the ER and was soon pregnant. I finally got to say more than hello when she was admitted to the OB unit bleeding during her

fourth month of pregnancy. Gestational trophoblastic disease was discovered instead of a normal pregnancy. I remember holding her in my arms as she wept. She was told she had a complete molar pregnancy after surgery, and she would need extensive follow-up for the next year. I lost track of her that summer as my life became busier. Around Thanksgiving time, I heard she had died from choriocarcinoma. I attended her funeral, finally, to get the time to say a final hello and good-bye, but this time with sadness and tears.

Thoughts: Rose was only 26 years old when she succumbed to this very virulent cancer. I think back and realize I missed knowing this brave young woman and wished that I had taken the time to say more than hello. Could her outcome have been different? Why wasn't it recognized earlier? Did she not follow up after her diagnosis? I can only speculate regarding the whom, what, and where. She lived a short but purposeful life, and hopefully continued research will change other women's outcomes in the future.

As with any facet of health care, be aware of the latest research and new therapies. Inform the client about her follow-up care, which will probably involve close clinical surveillance for approximately 1 year, and reinforce its importance in monitoring the client's condition. Tell the client that serial serum beta-hCG levels are used to detect residual trophoblastic tissue. Continued high or increasing hCG titers are abnormal and need further evaluation.

Inform the client about the possible use of chemotherapy, such as methotrexate, which may be started prophylactically. Strongly urge the client to use a reliable contraceptive to prevent pregnancy for 1 year, because a pregnancy would interfere with tracking the serial beta-hCG levels used to identify a potential malignancy. Stress the need for the client to cooperate and adhere to the plan of therapy throughout this yearlong follow-up period.

Cervical Insufficiency

Cervical insufficiency, also called premature dilation of the cervix, describes a weak, structurally defective cervix that spontaneously dilates in the absence of uterine contractions in the second trimester, or early third trimester, resulting in the loss of the pregnancy. Since this typically occurs in the fourth or fifth month of gestation before the point of fetal viability, the fetus dies unless the dilation can be arrested. The incidence of cervical insufficiency is less than 1% in the obstetrical population (AHRQ, 2015).

Pathophysiology

The exact mechanism contributing to cervical insufficiency is not known. The cervix may have less elastin, less collagen, and greater amounts of smooth muscle than the normal cervix, and thus results in loss of sphincter tone (Magowan, Owen, & Thomson, 2014). Several theories have been proposed that focus on damage to the cervix as a key component of hormonal factors, such as increased amounts of relaxin. When the pressure of the expanding uterine contents becomes greater than the ability of the cervical sphincter to remain closed, the cervix suddenly relaxes, allowing effacement and dilation to proceed. The cervical dilation is typically rapid, relatively painless, and accompanied by minimal bleeding (Norwitz & Conroy, 2015).

Cervical insufficiency is likely to be the clinical end point of many pathologic processes, such as congenital cervical hypoplasia, in utero DES exposure that caused cervical hypoplasia, or trauma to the cervix (conization, amputation, obstetric laceration, or forced cervical dilation [may occur during elective pregnancy termination]). Other conditions such as previous precipitous birth, a prolonged second stage of labor, increased amounts of relaxin and progesterone, or increased uterine volume (multiple gestation, hydramnios) are associated with cervical insufficiency (Berghella, 2014). However, the exact etiology of cervical insufficiency is not known.

Cervical length also has been associated with cervical insufficiency and, subsequently, preterm birth. Recent studies have examined the association between a short cervical length and the risk of preterm birth. Some have demonstrated a continuum of risk between a shorter cervix on ultrasound and a higher risk of preterm birth, leading to the hypothetical argument that women

with a short cervix on ultrasound might benefit from cervical cerclage (the sewing closed of the cervix). The American Congress of Obstetricians and Gynecologists (ACOG) does not recommend cerclage placement for women with a short cervix who do not have a history of preterm birth, as it has not been shown to be beneficial in this population (2014a).

Therapeutic Management

Cervical insufficiency may be treated in a variety of ways: bed rest; pelvic rest; avoidance of heavy lifting; progesterone supplementation in women at risk for preterm birth; placement of a cervical pessary (a round, silicone device at the mouth of the cervix) or surgically, via a cervical cerclage procedure in the second trimester. Cerclage was devised more than 50 years ago based on the hypothesis that for some women, weakness or malfunction of the cervix has a causative role in the pathway to preterm birth. It can either be performed transvaginally or transabdominally. Cervical cerclage involves using a heavy purse-string suture to secure and reinforce the internal os of the cervix (Fig. 19.3).

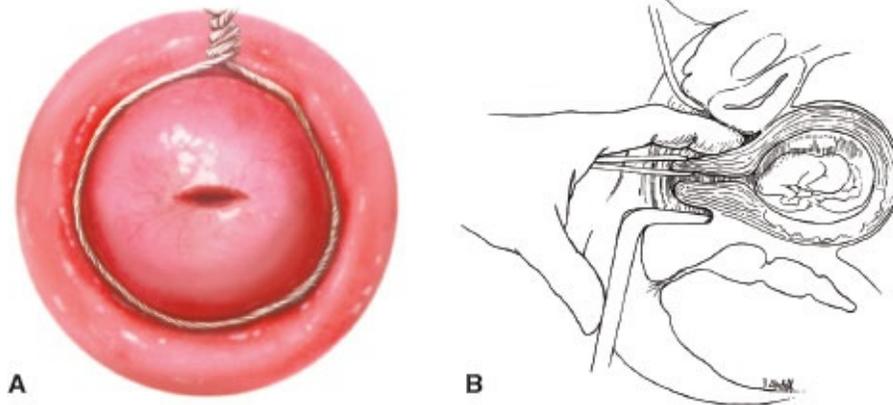
   According to the American College of Obstetricians and Gynecologists (ACOG) (2014a), if a short cervix is identified at or after 20 weeks and no infection (chorioamnionitis) is present, the decision to proceed with cerclage should be made with caution. ACOG recommends the following indications for cervical cerclage: history of second trimester pregnancy loss with painless dilatation; prior cerclage placement for cervical insufficiency; history of spontaneous preterm birth prior to 34 weeks' gestation; and painless cervical dilatation on physical examination in the second trimester (2014a). Complications associated with cerclage placement are suture displacement, rupture of membranes, and chorioamnionitis, and their incidence varies widely in relation to the timing and indications for the cerclage (Abu Hashim, Al-Inany, & Kilani, 2014). The optimal timing for cerclage removal is unclear, but ACOG (2014a) supports cerclage placement up to 28 weeks' gestation. A recent meta-analysis of randomized controlled trials concluded that either vaginal progesterone or cerclage are equally efficacious in the prevention of preterm birth in women with a short cervix in the mid trimester, singleton gestation, and previous preterm birth (Jena et al., 2015).


FIGURE 19.3 A. Cervical cerclage. **B.** Suturing the cervix for cervical insufficiency.

Nursing Assessment

RISK FACTORS

Nursing assessment focuses on obtaining a thorough history to determine any risk factors that might have a bearing on this pregnancy: previous cervical trauma, preterm labor, fetal loss in the second trimester, or previous surgeries, or procedures involving the cervix. History may reveal a previous loss of pregnancy around 20 weeks.

Also be alert for complaints of vaginal discharge or pelvic pressure. Commonly with cervical insufficiency the woman will report a pink-tinged vaginal discharge or an increase in low pelvic pressure, cramping to vaginal bleeding, and loss of amniotic fluid. Cervical dilation also occurs. If this continues, rupture of the membranes, release of amniotic fluid, and uterine contractions occur, subsequently resulting in delivery of the fetus, often before it is viable.

 Take Note!

The diagnosis of cervical insufficiency remains difficult in many circumstances. The cornerstone of diagnosis is a history of a pregnancy loss during the second or early third trimester associated with painless cervical dilation without evidence of uterine activity.

DIAGNOSTIC TESTS

Transvaginal Ultrasound. Transvaginal ultrasound typically is done between 16 and 24 weeks' gestation to determine cervical length, evaluate for shortening, and attempt to predict an early preterm birth. Cervical shortening occurs from the internal os outward and can be viewed on ultrasound as funneling. The amount of funneling can be determined by dividing funnel length by cervical length. The most common time at which a short cervix or funneling develops is 16 to 24 weeks, so ultrasound screening should be performed during this interval (Herrera & Lewis, 2014). A cervical length of less than 25 mm is abnormal between 16 and 24 weeks and may increase the risk of preterm labor. Among clients with a short cervix, provide education concerning the signs and symptoms of preterm labor, especially as the pregnancy approaches potential viability. Prenatal visits/contacts may be scheduled at more frequent intervals to increase client interaction with the care provider, especially between 20 and 34 weeks' gestation, which may decrease the rate of extremely early preterm births.

Expect the woman (particularly a woman with pelvic pressure, backache, or increased mucoid discharge) to undergo serial transvaginal ultrasound evaluations every few days to avoid missing rapid changes in cervical dilation or until the trend in cervical length can be characterized (Cunningham et al., 2014).

Home Uterine Activity Monitoring. For a woman at risk for preterm birth, home uterine activity monitoring can be used to screen for prelabor uterine contractility so that escalating contractility can be identified, allowing earlier intervention to prevent preterm birth. The home uterine activity monitor consists of a pressure sensor attached to a belt that is held against the abdomen and a recording/storage device that is carried on a belt or hung from the shoulder. Uterine activity is typically recorded by the woman for 1 hour twice daily, while she is performing routine activities. The stored data are transmitted via telephone to a perinatal nurse, and a receiving device prints out these data. The woman is contacted if there are any problems.

Although in theory identifying early contractions to initiate interventions to arrest the labor sounds reasonable, a recent Cochrane Review study found that uterine activity monitoring in asymptomatic high-risk women is inadequate for predicting preterm birth. There was no impact on maternal or perinatal outcomes or prediction of preterm births (Urquhart et al., 2015). This practice continues even though numerous randomized trials have found no relationship between monitoring and actual reduction of preterm labor. In more recent research findings, cervical length is predictive of preterm birth in all populations studied.

A cervical length of less than 25 mm warrants intervention to improve the health outcomes of pregnant women and their infants (Boots et al., 2014).

Nursing Management

Nursing management focuses on monitoring the woman very closely for signs of preterm labor: backache, increase in vaginal discharge, rupture of membranes, and uterine contractions. Provide emotional support and education to allay the couple's anxiety about the well-being of their fetus. Provide preoperative care and teaching as indicated if the woman will be undergoing cerclage. Teach the client and her family about the signs and symptoms of preterm labor and the need to report any changes immediately. Also reinforce the need for activity restrictions (if appropriate) and continued regular follow-up. Continuing surveillance throughout the pregnancy is important to promote a positive outcome for the family. The nurse can play a pivotal role in identifying preterm labor through risk assessment, physical examination, and client advocacy.

Placenta Previa

Placenta previa is a bleeding condition that occurs during the last two trimesters of pregnancy. In placenta previa (literally, "afterbirth first"), the placenta implants over the cervical os. It may cause serious morbidity and mortality to the fetus and mother. The risk of placenta previa in a first pregnancy is 1 in 400, but it rises to 1 in 160 after one cesarean section; 1 in 60 after two; 1 in 30 after three; and 1 in 10 after four cesarean sections and is associated with potentially serious consequences from hemorrhage, abruption (separation) of the placenta, or emergency cesarean birth (Joy & Temming, 2015). With the rising incidence of cesarean section operations combined with increasing maternal age and more infertility treatments, the number of cases of placenta previa is increasing dramatically. The cesarean section rate must be reduced to decrease maternal; morbidity and mortality. Comprehensive risk assessment, combined with advances in ultrasound, can provide earlier detection of this impaired placental implantation (Wiedaseck & Monchek, 2014).

Pathophysiology

The exact cause of placenta previa is unknown. It is initiated by implantation of the embryo in the lower uterus, perhaps due to uterine endometrial scarring or damage in the upper segment, which may incite placental growth in the unscarred lower uterine segment. Uteroplacental underperfusion may also be present, which may increase the surface area required for placental attachment and may cause the placenta to encroach on the lower uterine segment. With placental attachment and growth, the cervical os may become covered by the developing placenta. Placental vascularization is defective, allowing the placenta to attach directly to the myometrium (accreta), deeply attach to the myometrium (increta), or infiltrate the myometrium (percreta).

Placenta previa is generally classified according to the degree of coverage or proximity to the internal os, as follows (Fig. 19.4):

- Total placenta previa: the internal cervical os is completely covered by the placenta
- Partial placenta previa: the internal os is partially covered by the placenta
- Marginal placenta previa: the placenta is at the margin or edge of the internal os

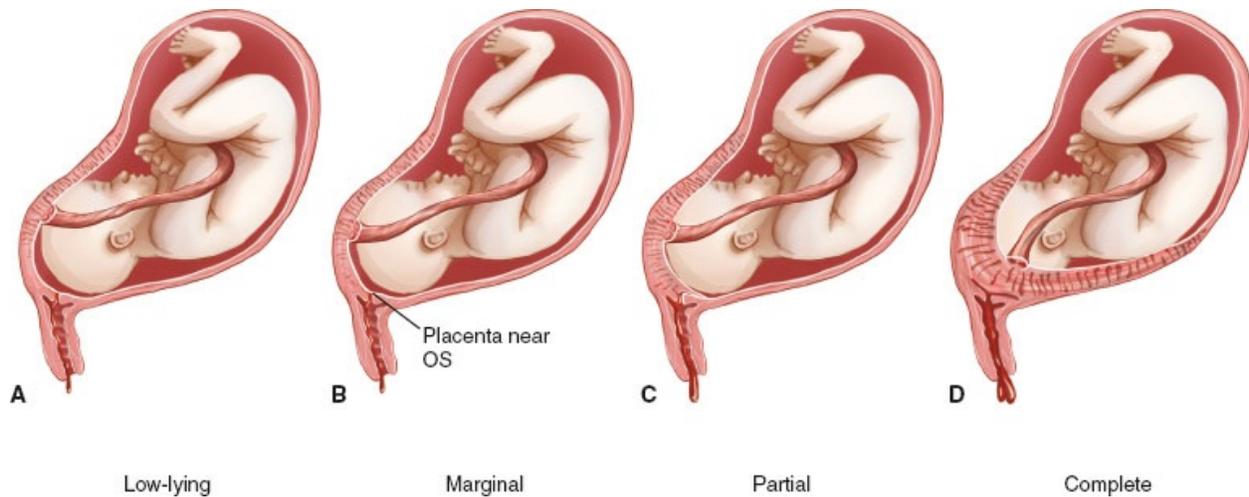
- Low-lying placenta previa: the placenta is implanted in the lower uterine segment and is near the internal os but does not reach it


FIGURE 19.4 Classification of placenta previa. **A.** Low-lying. **B.** Marginal. **C.** Partial. **D.** Complete.

Therapeutic Management

Therapeutic management depends on the extent of bleeding, the amount of placenta over the cervical os, whether the fetus is developed enough to survive outside the uterus, the position of the fetus, the mother's parity, and the presence or absence of labor (Cunningham et al., 2014). With the increase in the rate of previous cesarean sections, the frequency of placenta previa has increased. Most women continue to present in emergency departments, therefore the associated morbidity due to hemorrhage remains high. Efforts should be made to avoid primary cesarean section where possible. In addition, prenatal care and timely diagnosis of placenta previa on ultrasound can decrease the associated morbidity.

If the mother and fetus are both stable, therapeutic management may involve expectant ("wait-and-see" or watchful waiting) care. This care can be carried out at home or on an antepartal unit in the health care facility. If there is no active bleeding and the client has ready access to reliable transportation, can maintain bed rest at home, and can comprehend instructions, expectant care at home is appropriate. However, if the client requires continuous care and monitoring and cannot meet the home care requirements, the antepartal unit is the best environment.

Nursing Assessment

Nursing assessment involves a thorough history, including possible risk factors, and physical examination. Evaluate the client closely for these risk factors:

• Advancing maternal age (more than 35 years)

• Previous cesarean birth

• Multiparity

• Uterine insult or injury

• Cocaine use

• Prior placenta previa

• Infertility treatment

• Multiple gestations

• Previous induced surgical abortion

• Smoking

• Previous myomectomy to remove fibroids

• Short interval between pregnancies

• Hypertension or diabetes (Archibong & Ahmed, 2015).

HEALTH HISTORY AND PHYSICAL EXAMINATION

Ask the client if she has any problems associated with bleeding, now or in the recent past. The classical clinical presentation is painless, bright-red vaginal bleeding occurring during the second or third trimester. The initial bleeding usually is not profuse and it ceases spontaneously, only to recur again. The first episode of bleeding occurs (on average) at 27 to 32 weeks' gestation. The bleeding is thought to arise secondary to the thinning of the lower uterine segment in preparation for the onset of labor. When the bleeding occurs at the implantation site in the lower uterus, the uterus cannot contract adequately and stop the flow of blood from the open vessels. Typically with normal placental implantation in the upper uterus, minor disruptive placental attachment is not a problem, because there is a larger volume of myometrial tissue able to contract and constrict bleeding vessels.

Assess the client for uterine contractions, which may or may not occur with the bleeding. Palpate the uterus; typically it is soft and nontender on examination. Auscultate the fetal heart rate; it commonly is within normal parameters. Fetal distress is usually absent but may occur when cord problems arise, such as umbilical cord prolapse or cord compression, or when the client

has experienced blood loss to the extent that maternal shock or placental abruption has occurred (King et al., 2015).

LABORATORY AND DIAGNOSTIC TESTING

To validate the position of the placenta, a transvaginal ultrasound is done. In addition, MRI may be ordered when preparing for delivery because it allows identification of placenta accreta (placenta abnormally adherent to the myometrium), increta (placenta accreta with penetration of the myometrium), or percreta (placenta accreta with invasion of the myometrium to the peritoneal covering, causing rupture of the uterus) in addition to placenta previa. These placental abnormalities, although rare, carry a very high morbidity and mortality rate, possibly necessitating a hysterectomy at delivery.

Nursing Management

Whether the care setting is in the client's home or in the health care facility, the nurse focuses on monitoring the maternal–fetal status, including assessing for signs and symptoms of vaginal bleeding and fetal distress and providing support and education to the client and her family, including providing information about the diagnostic studies and procedures that are performed. For the majority of women, a cesarean birth will be planned. Nursing Care Plan 19.1 discusses the nursing process for the woman with placenta previa.

MONITORING MATERNAL–FETAL STATUS

Assess the degree of vaginal bleeding; inspect the perineal area for blood that may be pooled underneath the woman. Estimate and document the amount of bleeding. Perform a peripad count on an ongoing basis, making sure to report any changes in amount or frequency to the health care provider. If the woman is experiencing active bleeding, prepare for blood typing and cross-matching in the event a blood transfusion is needed.

 Take Note!

Avoid doing vaginal examinations in the woman with placenta previa because they may disrupt the placenta and cause hemorrhage.

NURSING CARE PLAN 19.1

Overview of the Woman with Placenta Previa

A 39-year-old G5, P4, multigravida client at 32 weeks' gestation, was admitted to the labor and birth suite with sudden vaginal bleeding. She had no further active bleeding and did not complain of any abdominal discomfort or tenderness. She did complain of occasional "tightening" in her stomach. Her abdomen palpated soft. Fetal heart rates were in the 140s with accelerations with movement. She was placed on bed rest with bathroom privileges. Ultrasound identified a low-lying placenta with a viable, normal-growth fetus. She was diagnosed with placenta previa and admitted for observation and surveillance of fetal well-being. Her history revealed two previous cesarean births, smoking half a pack of cigarettes per day, and endometritis infection after birth of her last newborn. Additional assessment findings included painless, bright-red vaginal bleeding with initial bleeding ceasing spontaneously; irregular, mild, and sporadic uterine contractions; fetal heart rate and maternal vital signs within normal range; fetus in transverse lie; anxiety related to the outcome of pregnancy; and expression of feelings of helplessness.

NURSING DIAGNOSIS: Risk for injury (fetal and maternal) related to threat to uteroplacental perfusion and hemorrhage

Outcome Identification and Evaluation
The client will maintain adequate tissue perfusion as evidenced by stable vital signs, decreased blood loss, few or no uterine contractions, normal fetal heart rate patterns and variability, and positive fetal movement.

Interventions: *Maintaining Adequate Tissue Perfusion*
• Establish intravenous access to allow for administration of fluids, blood, and medications as necessary.
• Obtain type and cross-match for at least two units blood products to ensure availability should bleeding continues.
• Obtain specimens as ordered for blood studies, such as CBC and clotting studies, to establish a baseline and use for future comparison.

- Monitor output to evaluate adequacy of renal perfusion.
- Administer intravenous fluid replacement therapy as ordered to maintain blood pressure and blood volume.
- Palpate for abdominal tenderness and rigidity to determine bleeding and evidence of uterine contractions.
- Institute bed rest to reduce oxygen demands.
- Assess for rupture of membranes to evaluate for possible onset of labor.
- Avoid vaginal examinations to prevent further bleeding episodes.
- Complete an Rh titer to identify the need for RhoGAM.
- Avoid nipple stimulation to prevent uterine contractions.
- Continuously monitor for contractions or PROM to allow for prompt intervention.
- Administer tocolytic agents as ordered to stall preterm labor.
- Monitor vital signs frequently to identify possible hypovolemia and infection.
- Assess frequently for active vaginal bleeding to minimize risk of hemorrhage.
- Continuously monitor fetal heart rate with electronic fetal monitor to evaluate fetal status.
- Assist with fetal surveillance tests as ordered to aid in determining fetal well-being.
- Observe for abnormal fetal heart rate patterns, such as loss of variability, decelerations, tachycardia, to identify fetal distress.
- Position client in side-lying position with wedge for support to maximize placental perfusion.
- Assess fetal movement to evaluate for possible fetal hypoxia.
- Teach woman to monitor fetal movement to evaluate well-being.
- Administer oxygen as ordered to increase oxygenation to mother and fetus.

NURSING DIAGNOSIS: Anxiety related to threat to self and fetus, unknown future.

Outcome Identification and Evaluation
The client will experience a decrease in anxiety as evidenced by verbal reports of less anxiety, use of effective coping measures, and calm demeanor.

> **Interventions:** *Minimizing Anxiety*
> • Provide factual information about diagnosis and treatment, and explain interventions and the rationale behind them *to provide client with understanding of her condition.*
> • Answer questions about health status honestly *to establish a trusting relationship.*
> • Speak calmly to client and family members *to minimize environmental stress.*
> • Encourage the use of past effective techniques for coping *to promote relaxation and feelings of control.*
> • Acknowledge and facilitate the woman's spiritual needs *to promote effective coping.*
> • Involve the woman and family in the decision-making process *to foster self-confidence and control over situation.*
> • Maintain a presence during stressful periods *to allay anxiety.*
> • Use the sense of touch if appropriate *to convey caring and concern.*
> • Encourage talking as a means *to release tension.*

Monitor maternal vital signs and uterine contractility frequently for changes. Have the client rate her level of pain using an appropriate pain rating scale. Assess fetal heart rates via Doppler or electronic monitoring to detect fetal distress. Monitor the woman's cardiopulmonary status, reporting any difficulties in respirations, changes in skin color, or complaints of difficulty in breathing. Have oxygen equipment readily available should fetal or maternal distress develop. Encourage the client to lie on her side to enhance placental perfusion.

If the woman has an intravenous (IV) line inserted, inspect the IV site frequently. Alternately, anticipate the insertion of an intermittent IV access device such as a saline lock, which can be used if quick access is needed for fluid restoration and infusion of blood products. Obtain laboratory tests as ordered, including complete blood count (CBC), coagulation studies, and Rh status if appropriate.

Administer pharmacologic agents as necessary. Give Rh immunoglobulin if the client is Rh negative at 28 weeks' gestation. Monitor tocolytic (anticontraction) medication if prevention of preterm labor is needed.

PROVIDING SUPPORT AND EDUCATION

Determine the woman's level of understanding about placenta previa and the associated procedures and treatment plan. Doing so is important to prevent confusion and gain her cooperation. Provide information about the condition and make sure that all information related is consistent with information from the primary care provider. Explain all assessments and treatment measures as needed.

Act as a client advocate in obtaining information for the family. Teach the woman how to perform and record daily fetal movement. This action serves two purposes: (1) It provides valuable information about the fetus and (2) it is an activity in which the client can participate, thereby fostering some feeling of control over the situation.

If the woman will require prolonged hospitalization or home bed rest, assess the physical and emotional impact that this may have on her. Evaluate her coping mechanisms to help determine how well she will be able to adjust and adhere to the treatment plan. Allow the client to verbalize her feelings and fears, and provide emotional support. Also, provide opportunities for distraction—educational videos, arts and crafts, computer games, reading books—and evaluate the client's response.

In addition to the emotional impact of prolonged bed rest, thoroughly assess the woman's skin to prevent skin breakdown and to help alleviate her discomfort secondary to limited physical activity. Instruct the woman in appropriate skin care measures. Encourage her to eat a balanced diet with adequate fluid intake to ensure adequate nutrition and hydration and prevent complications associated with urinary and bowel elimination secondary to bed rest.

Teach the client and family about any signs and symptoms that should be reported immediately. In addition, prepare the woman for the possibility of a cesarean birth. The woman must notify her health care provider about any bleeding episodes or backaches (may indicate preterm labor contractions) and must adhere to the prescribed bed rest regimen. To ensure adherence to the plan and a positive outcome, the client needs to be aware of and understand the rationales for the ongoing observations.

Abruptio Placentae

Abruptio placentae is the premature separation of a normally implanted placenta after the 20th week of gestation prior to birth, which leads to hemorrhage. It is a significant cause of third-trimester bleeding, with a high mortality rate. It occurs in about 1% of all pregnancies throughout the world, or approximately 1 in 100 pregnancies. There is a 10 to 20 times greater risk of reoccurrence in a subsequent pregnancy. It typically peaks between 24 and 26 weeks' gestation.

Maternal risks include obstetric hemorrhage, need for blood transfusions, emergency hysterectomy, disseminated intravascular coagulopathy (DIC), and renal failure. Maternal death is rare, but seven times higher than the overall maternal mortality rate. Perinatal consequences include low birth weight, preterm delivery, asphyxia, stillbirth, and perinatal death. In developed countries, approximately 10% of all preterm births and 10% to 20% of all perinatal deaths are caused by placental abruption (Mukherjee et al., 2014). The overall fetal mortality rate for placental abruption is up to 50%, depending on the extent of the abruption. Maternal mortality is approximately 6% in abruptio placentae and is related to cesarean birth and/or hemorrhage/coagulopathy (Jaju, Kulkarni, & Mundada, 2014).

Pathophysiology

The etiology of this condition is unknown; however, it has been proposed that abruption starts with degenerative changes in the small maternal blood vessels, resulting in blood clotting, degeneration of the decidua (uterine lining), and possible rupture of a vessel. Bleeding from the blood vessel forms a blood clot between the placenta and the uterine wall. The continued bleeding causes increased pressure behind the placenta and results in separation from the uterine wall (Moses, 2015a). Fetal blood supply is compromised and fetal distress develops in proportion to the degree of placental separation. This is caused by the insult of the abruption itself and by issues related to prematurity when early birth is required to alleviate maternal or fetal distress.

Abruptio placentae is classified according to the extent of separation and the amount of blood loss from the maternal circulation. Classifications include:

• Mild (grade 1): Minimal bleeding (less than 500 mL), marginal separation

(10% to 20%), tender uterus, no coagulopathy, no signs of shock, no fetal distress

• Moderate (grade 2): Moderate bleeding (1,000 to 1,500 mL), moderate separation (20% to 50%), continuous abdominal pain, mild shock, normal maternal blood pressure, maternal tachycardia

• Severe (grade 3): Absent to moderate bleeding (more than 1,500 mL), severe separation (more than 50%), profound shock, dark vaginal bleeding, agonizing abdominal pain, decreased maternal blood pressure, significant maternal tachycardia and development of DIC(Atkinson et al., 2015).

Abruptio placentae also may be classified as partial or complete, depending on the degree of separation. Alternately, it can be classified as concealed or apparent, by the type of bleeding (Fig. 19.5).

> *Remember Helen, the pregnant woman with severe abdominal pain? Electronic fetal monitoring revealed uterine hypertonicity with absent fetal heart sounds. Palpation of her abdomen revealed rigidity and extreme tenderness in all four quadrants. Her vital signs were as follows: temperature, afebrile; pulse, 94; respirations, 22; blood pressure, 130/90 mm Hg. What might you suspect as the cause of Helen's abdominal pain? What course of action would you anticipate for Helen?*

A Partial abruption, concealed hemorrhage

B Partial abruption, apparent hemorrhage

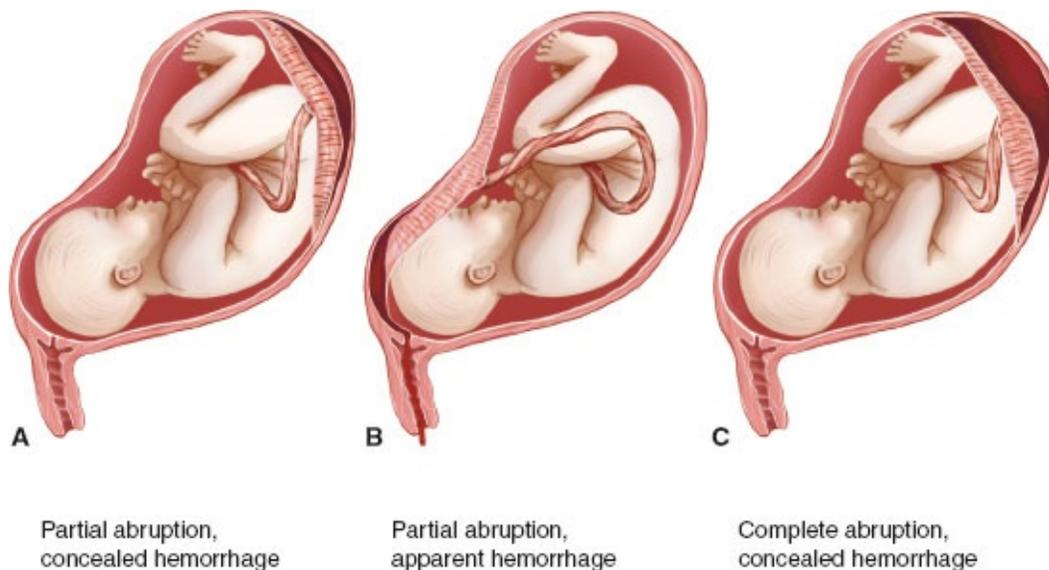
C Complete abruption, concealed hemorrhage


FIGURE 19.5 Classifications of abruptio placentae. **A.** Partial abruption with concealed hemorrhage. **B.**

Partial abruption with apparent hemorrhage. **C.** Complete abruption with concealed hemorrhage.

Therapeutic Management

Treatment of abruptio placentae is designed to assess, control, and restore the amount of blood lost; provide a positive outcome for both mother and newborn; and prevent coagulation disorders, such as DIC (Box 19.2). Emergency measures include starting two large-bore intravenous lines with normal saline or lactated Ringer's solution to combat hypovolemia, obtaining blood specimens for evaluating hemodynamic status values and for typing and cross-matching, and frequently monitoring fetal and maternal well-being. After the severity of abruption is determined and appropriate blood and fluid replacement is given, cesarean birth is done immediately if fetal distress is evident. If the fetus is not in distress close monitoring continues, with delivery planned at the earliest signs of fetal distress. Because of the possibility of fetal blood loss through the placenta, a neonatal intensive care team should be available during the birth process to assess and treat the newborn immediately for shock, blood loss, and hypoxia.

BOX 19.2

DISSEMINATED INTRAVASCULAR COAGULATION

DIC is a bleeding disorder characterized by an abnormal reduction in the elements involved in blood clotting resulting from their widespread intravascular clotting (Davis & Kessler, 2014).). This disorder can occur secondary to abruptio placentae, amniotic fluid embolism, endotoxin sepsis, retained dead fetus, posthemorrhagic shock, hydatidiform mole, and gynecologic malignancies.

The clinical and pathologic manifestations of DIC can be described as a loss of balance between the clot-forming activity of thrombin and the clot-lysing activity of plasmin. Therefore, too much thrombin tips the balance toward the prothrombic state and the client develops clots. Alternately, too much clot lysis (fibrinolysis) results from plasmin formation and the client hemorrhages. Small clots form throughout the body, and eventually the blood-clotting factors are used up, rendering them unavailable to form clots at sites of tissue injury. Clot-dissolving mechanisms are also increased, which results in bleeding (possibly severe).

DIC is usually associated with high mortality and morbidity rates. No single laboratory test is sensitive or specific enough to diagnose DIC definitively, but it can be diagnosed by using a combination of multiple clinical and laboratory tests that reflect the pathophysiology of the syndrome.

Laboratory studies that assist in the diagnosis include:

• Decreased fibrinogen and platelets

• Prolonged PT and aPTT

• Positive D-dimer tests and fibrin (split) degradation products (objective evidence of the simultaneous formation of thrombin and plasmin) (ARUP Laboratories, 2016)

Adapted from Davis, S. J., & Kessler, C. M. (2014). Disseminated intravascular coagulation: Diagnosis and management. In *Hemostasis and thrombosis: Practical guidelines in clinical management* (pp. 151–168). Hoboken, NJ: Wiley Blackwell; and Kobayashi, T. (2014). Obstetrical disseminated intravascular coagulation score. *Journal of Obstetrics and Gynecology Research*, 40(6), 1500–1506.

If the woman develops DIC, treatment focuses on determining the underlying cause of DIC and correcting it. Replacement therapy of the coagulation factors is achieved by transfusion of fresh-frozen plasma along with cryoprecipitate to maintain the circulating volume and provide oxygen to the cells of the body. Anticoagulant therapy (low-molecular-weight heparin), packed red cells, platelet concentrates, antithrombin concentrates, and nonclotting protein-containing volume expanders, such as plasma protein fraction or albumin, are also used to combat this serious condition. The use of blood products must be dictated by the clinical picture and not simply to normalize laboratory test results (Holt, 2015). Prompt identification and early intervention are essential for a woman with acute DIC associated with abruptio placentae to treat DIC and possibly save her life.

Nursing Assessment

Abruptio placentae is a medical emergency. The nurse plays a critical role in assessing the pregnant woman presenting with abdominal pain and/or experiencing vaginal bleeding, especially in a concealed hemorrhage, in which the extent of bleeding is not recognized. Rapid assessment is essential to ensure prompt, effective interventions to prevent maternal and fetal morbidity and mortality. Comparison Chart 19.1 compares placenta previa with abruptio placentae.

HEALTH HISTORY AND PHYSICAL EXAMINATION

Abruptio placentae produces a wide range of clinical effects, depending on the extent of placental separation and the amount of maternal blood loss. Begin the health history by assessing the woman for risk factors that may predispose her to abruptio placentae, such as advanced maternal age (over 35 years old), poor nutrition, multiple gestation, excessive intrauterine pressure caused by polyhydramnios, chronic hypertension, cigarette smoking, severe trauma (e.g., auto accident, intimate partner violence), history of abruption in a previous pregnancy, placental abnormalities, cocaine or methamphetamine abuse, thrombophilia, alcohol ingestion, and multiparity (Deering, 2015). In addition, be alert for other notable risk factors, such as male fetal gender, chorioamnionitis, prolonged premature ruptured membranes (more than 24 hours), oligohydramnios, preeclampsia, and low socioeconomic status (Nagtalon-Ramos, 2014).

COMPARISON CHART 19.1 PLACENTA PREVIA VERSUS ABRUPTIO PLACENTAE

Manifestation	Placenta Previa	Abruptio Placentae
Onset	Insidious	Sudden
Type of bleeding	Always visible; slight, then more profuse	Can be concealed or visible
Blood description	Bright red	Dark
Discomfort/pain	None (painless)	Constant; uterine tenderness on palpation
Uterine tone	Soft and relaxed	Firm to rigid
Fetal heart rate	Usually in normal range	Fetal distress or absent
Fetal presentation	May be breech or transverse lie; engagement is absent	No relationship

Assess the woman for bleeding. As the placenta separates from the uterus, hemorrhage ensues. It can be apparent, appearing as vaginal bleeding, or it can be concealed. Vaginal bleeding is present in 80% of women diagnosed with abruptio placentae and may be significant enough to jeopardize both maternal and fetal health within a short time frame. The remaining 20% of abruptions are associated with a concealed hemorrhage and the absence of vaginal bleeding. Monitor the woman's level of consciousness, noting any signs or symptoms that may suggest shock.

Take Note!

Vital signs can be within normal range, even with significant blood loss, because a pregnant woman can lose up to 40% of her total blood volume without showing signs of shock (Schultz & McConachie, 2015).

Assess the woman for complaints of pain, including the type, onset, and location. Ask if she has had any contractions. Palpate the abdomen, noting any contractions, uterine tenderness, tenseness, or rigidity. Ask if she has noticed any changes in fetal movement and activity. Decreased fetal movement may be the presenting complaint, resulting from fetal jeopardy or fetal death (Cunningham et al., 2014). Assess fetal heart rate and continue to monitor it electronically.

Classic manifestations of abruptio placentae include painful, dark-red vaginal bleeding (port-wine color) because the bleeding comes from the clot that was formed behind the placenta; "knife-like" abdominal pain; uterine tenderness; contractions; and decreased fetal movement. Rapid assessment is essential to ensure prompt, effective interventions to prevent maternal and fetal morbidity and mortality.

LABORATORY AND DIAGNOSTIC TESTING

Laboratory and diagnostic tests may be helpful in diagnosing the condition and guiding management. These studies may include:

- *CBC:* Determines the current hemodynamic status; however, it is not reliable for estimating acute blood loss.

- *Fibrinogen levels:* Typically are increased in pregnancy (hyperfibrinogenemia); thus, a moderate dip in fibrinogen levels might suggest DIC and, if profuse bleeding occurs, the clotting cascade might be compromised.

- *Prothrombin time (PT)/activated partial thromboplastin time (aPTT):* Determines the client's coagulation status, especially if surgery is planned.

- *Type and cross-match:* Determines blood type if a transfusion is needed

- *Nonstress test:* Demonstrates findings of fetal jeopardy manifested by late decelerations or bradycardia.

- *Biophysical profile:* Aids in evaluating clients with chronic abruption; a low score (less than 6 points) suggests possible fetal compromise (Creasy et al., 2014).

Ultrasound is not useful for making a definitive diagnosis because the clot is sonographically visible in less than 50% of the cases. A CT scan is a more reliable method for evaluation of placental abruption (Hosein, Abdel-Kariem, & Shriki, 2014).

Nursing Management

Nursing management of the woman with abruptio placentae warrants immediate care to provide the best outcome for both mother and fetus.

ENSURING ADEQUATE TISSUE PERFUSION

When the woman arrives at the facility, place her on strict bed rest and in a left lateral position to prevent pressure on the vena cava. This position provides uninterrupted perfusion to the fetus. Expect to administer oxygen therapy via nasal cannula to ensure adequate tissue perfusion. Monitor oxygen saturation levels via pulse oximetry to evaluate the effectiveness of interventions.

Obtain maternal vital signs frequently, as often as every 15 minutes as indicated, depending on the woman's status and amount of blood loss. Observe for changes in vital signs suggesting hypovolemic shock and report them immediately. Also expect to insert an indwelling urinary (Foley) catheter to assess hourly urine output and initiate an intravenous infusion for fluid replacement using a large-bore catheter.

Assess fundal height for changes. An increase in size would indicate bleeding. Monitor the amount and characteristics of any vaginal bleeding as frequently as every 15 to 30 minutes. Be alert for signs and symptoms of DIC, such as bleeding gums, tachycardia, oozing from the intravenous insertion site, and petechiae, and administer blood products as ordered if DIC occurs.

Institute continuous electronic fetal monitoring. Assess uterine contractions and report any increased uterine tenseness or rigidity. Also observe the tracing for tetanic uterine contractions or changes in fetal heart rate patterns suggesting that the fetus has been compromised.

PROVIDING SUPPORT AND EDUCATION

A woman diagnosed with abruptio placentae may be filled with a sense of heightened anxiety and apprehension for her own health as well as for the health of her fetus. Communicate empathy and understanding of the client's experience, and provide emotional support throughout this frightening time. Remain with the woman and her partner, acknowledge their emotions and fears, and address their spiritual and cultural needs. Answer their questions about the status of their fetus openly and honestly, being sure to explain indicators of fetal well-being. Provide information about the various diagnostic tests, treatments, and procedures that may be done, including the possible need for a cesarean birth. Depending on the client's status, extent of bleeding, and length of gestation, the fetus may not survive. If the fetus does survive, he or she most likely will require neonatal intensive care. Assist the client and family to deal with the loss or with the birth of a newborn in the neonatal intensive care unit.

Although abruptio placentae is not a preventable condition, client education is

important to help reduce the risk for a recurrence of this condition. Encourage the woman to avoid drinking, smoking, or using drugs during pregnancy. Urge her to seek early and continuous prenatal care and to receive prompt health care if any signs and symptoms occur in future pregnancies.

> *Think back to Helen, the pregnant woman described at the beginning of the chapter. She was diagnosed with abruptio placentae and was prepared for an emergency cesarean birth. On exploration, there was almost a 75% abruption, with approximately 800 mL of concealed blood between the uterus and the placenta. In addition, she lost an additional 500 mL during surgery. What in Helen's history may have placed her at increased risk for abruption? What assessments and interventions would be essential during her postpartum recovery secondary to her large blood loss? What psychosocial interventions would be necessary due to her fetal loss?*

Placenta Accreta

Placenta accreta is a potentially life-threatening obstetrical hemorrhagic condition that requires a multidisciplinary approach to management. The incidence of placenta accreta has increased and seems to parallel the increasing cesarean birth rate or intrauterine procedures. Placenta accreta is a condition in which the placenta attaches itself too deeply into the wall of the uterus but does not penetrate the uterine muscle. It is further subcategorized as *placenta increta*, when the placenta invades the myometrium, and *placenta percreta*, when it has extended through the myometrium and uterine serosa and adjacent tissue. A common risk of placenta accreta during the birthing process is the possibility of hemorrhaging during manual attempts to detach the placenta. According to the March of Dimes (2015c), 1 in 530 births results in this condition. The specific cause of placenta accreta is unknown, but it can be related to placenta previa, advanced maternal age, smoking, and previous cesarean births. According to the literature, a cesarean birth increases the possibility of a future placenta accreta; the more cesarean births that are done, the greater the incidence.

According to ACOG (2014b), postpartum hemorrhage is a complication associated with placenta accreta. Ninety percent of accretas have postpartum hemorrhage, and 50% of these will result in a hysterectomy (ACOG, 2014b). Women at highest risk of emergency hysterectomy are those who are multiparous, had a cesarean birth in either a previous or the present pregnancy, or had abnormal placentation. The essential management issues are early detection and immediate and appropriate intervention. If a placenta accreta diagnosis is made, the client should be counseled that a cesarean section and possible hysterectomy may be necessary interventions (Creasy et al., 2014).

Placenta accreta is typically diagnosed after birth when the placenta fails to normally separate from the uterine wall. A prenatal screening diagnosis via ultrasound and magnetic resonance imaging (MRI) would decrease maternal and fetal morbidities and mortalities. A profuse hemorrhage may result because the uterus cannot contract to close off the open blood vessels. Management will depend on the severity of the bleeding and frequently necessitates a prompt hysterectomy (Humphrey, 2015). Nurses need to be prepared to assist in this emergency situation as dictated by the health care provider.

HYPEREMESIS GRAVIDARUM

Hyperemesis gravidarum is a severe form of nausea and vomiting of pregnancy associated with significant costs and psychosocial impacts. At least 70% to 85% of women experience nausea and vomiting during their pregnancy (Castillo & Phillippi, 2015). The term *morning sickness* is often used to describe this condition when symptoms are relatively mild. Studies have shown that nausea and vomiting of pregnancy is associated with improved fetal outcomes, such as lower rates of miscarriage (Ayyavoo et al., 2014). Such symptoms usually disappear after the first trimester. This mild form mostly affects the quality of life of the woman and her family, whereas the severe form—**hyperemesis gravidarum**—results in dehydration, weight loss, electrolyte imbalance, and the need for hospitalization (Taylor, 2014).

Unlike morning sickness, hyperemesis gravidarum is a complication of pregnancy characterized by persistent, uncontrollable nausea and vomiting that begins in the first trimester and causes dehydration, ketosis, and weight loss of more than 5% of prepregnancy body weight. Risk factors for hyperemesis include previous pregnancy complicated by hyperemesis, molar pregnancies, history of helicobacter pylori infection, multiple gestation, prepregnancy history of genitourinary disorders, clinical hyperthyroid disorders, and prepregnancy psychiatric diagnosis (King et al., 2015).

Hyperemesis (uncontrollable vomiting) is estimated to occur in approximately 2% of pregnant women. The prevalence increases in molar pregnancies and multiple gestations. The peak incidence is at 8 to 12 weeks of pregnancy, and symptoms usually resolve by week 20 (Maltepe et al., 2015).

 Take Note!

Every pregnant woman needs to be instructed to report any episodes of severe nausea and vomiting or episodes that extend beyond the first trimester.

Pathophysiology

Although the exact cause of nausea and vomiting is unknown, its effects—decreased placental blood flow, decreased maternal blood flow, and acidosis—can threaten the health of the mother and fetus. Dehydration can also lead to preterm labor (Smith et al., 2016). Numerous theories abound, but few studies have produced scientific evidence to identify the etiology of this condition. It is likely that multiple factors contribute to it.

Elevated levels of hCG are present in all pregnant women during early pregnancy, usually declining after 12 weeks. This corresponds to the usual duration of morning sickness. In hyperemesis gravidarum, the hCG levels are often higher and extend beyond the first trimester. Symptoms exacerbate the disease. Decreased fluid intake and prolonged vomiting cause dehydration; dehydration increases the serum concentration of hCG, which in turn exacerbates the nausea and vomiting—a vicious cycle. A few other theories that have been proposed to explain its etiology include:

• *Endocrine theory*—High levels of hCG and estrogen during pregnancy.

• *Metabolic theory*—Vitamin B_6 deficiency.

• *Genetic factors* that may predispose the woman to this condition.

• *Psychological theory*—psychological stress increases the symptoms.

Therapeutic Management

Hyperemesis gravidarum is a diagnosis of exclusion. Careful consideration of other conditions must be assessed when a client experiences nausea and vomiting for the first time after 9 weeks' gestation.

Conservative management in the home is the first line of treatment for the woman with hyperemesis gravidarum. This usually focuses on dietary and lifestyle changes. If conservative management fails to alleviate the client's symptoms and nausea and vomiting continue, hospitalization is necessary to reverse the effects of severe nausea and vomiting.

On admission to the hospital, blood tests are ordered to assess the severity of the client's dehydration, electrolyte imbalance, ketosis, and malnutrition. Parenteral fluids and drugs are ordered to rehydrate the woman and reduce the symptoms. The first choice for fluid replacement is generally normal saline, which aids in preventing hyponatremia, with vitamins (pyridoxine [B_6]) and electrolytes added. Oral food and fluids are withheld for the first 24 to 36 hours to allow the gastrointestinal tract to rest. Antiemetics may be administered rectally or intravenously to control the nausea and vomiting initially because the woman is considered NPO (not able to ingest anything by mouth). Once her condition stabilizes and she is allowed oral intake, medications may be administered orally.

If the client does not improve after several days of bed rest, "gut rest," intravenous fluids, and antiemetics, total parenteral nutrition or feeding through a percutaneous endoscopic gastrostomy tube is instituted to prevent malnutrition. Administering antiemetics intravenously or intramuscularly is typically the second pillar of treatment for hyperemesis gravidarum. Finding a drug that works for any given client is largely a matter of trial and error. If one drug is ineffective, another class of drugs with a different mechanism of action may help. Promethazine (Phenergan) and prochlorperazine (Compazine) are among the older preparations usually tried first. If they fail to relieve symptoms, newer drugs such as ondansetron (Zofran) may be tried. Most drugs are given intravenously or intramuscularly. There is no evidence that any antiemetic class is superior to another with respect to effectiveness (King et al., 2015) (Drug Guide 19.2).

Few women receive complete relief of symptoms from any one therapy. Complementary and alternative medicine therapies appeal to many women as

supplements to traditional ones. Some popular therapies include acupressure, massage, therapeutic touch, ginger, and the wearing of Sea-Bands to prevent nausea and vomiting. Recent research has reported a positive effect of using acupressure (provided by Sea-Bands) over the *nei guan* acupoint on the wrist to control nausea and vomiting associated with pregnancy (Matthews et al., 2014).

Concept Mastery Alert

Priority Interventions in Hyperemesis Gravidarum

Hyperemesis gravidarum is nausea and vomiting in early pregnancy that prevents the woman from ingesting adequate nutrition. IV fluids may be required for rehydration, but the priority is to stop all intake of food and fluid for a period of time until vomiting has stopped.

Nursing Assessment

Nursing assessment of the woman with hyperemesis gravidarum requires a thorough history and physical examination to identify signs and symptoms associated with this disorder. The client is extremely uncomfortable. She may experience many hours of lost work productivity and sleep, and hyperemesis may damage family relationships. If hyperemesis progresses untreated, it may cause neurologic disturbances, renal damage, dehydration, ketosis, alkalosis from loss of hydrochloric acid, hypokalemia, retinal hemorrhage, or death (Peled et al., 2014). Laboratory and diagnostic tests aid in determining the severity of the disorder.

DRUG GUIDE 19.2 MEDICATIONS USED FOR HYPEREMESIS GRAVIDARUM

Medication	Action/Indications	Nursing Implications
Promethazine (Phenergan)	Diminishes vestibular stimulation and acts on the chemoreceptor trigger zone (CTZ) Symptomatic relief of nausea and vomiting, and motion sickness.	Be alert for urinary retention, dizziness, hypotension, and involuntary movements. Institute safety measures to prevent injury secondary to sedative effects. Offer hard candy and frequent rinsing of mouth for dryness.
Prochlorperazine (Compazine)	Acts centrally to inhibit dopamine receptors in the CTZ and peripherally to block vagus nerve stimulation in the gastrointestinal tract. Controls severe nausea and vomiting.	Be alert for abnormal movements and for neuroleptic malignant syndrome such as seizures, hyper/hypotension, tachycardia, and dyspnea. Assess mental status, intake/output. Caution client not to drive as a result of drowsiness or dizziness. Advise to change position slowly to minimize effects of orthostatic hypotension.
Ondansetron (Zofran)	Blocks serotonin release, which stimulates the vagal afferent nerves, thus stimulating the vomiting reflex	Monitor for possible side effects such as diarrhea, constipation, abdominal pain, headache, dizziness, drowsiness, and fatigue. Monitor liver function studies as ordered.

Adapted from King, T. L., Brucker, M. C., Kriebs, J. M., Fahey, J. O., Grgor, C. L., & Varney, H. (2015). *Varney's midwifery* (5th ed.). Burlington, MA: Jones & Bartlett Learning; and Ogunyemi, D. A., Fong, A., & Herrero, T. C. (2015). Hyperemesis gravidarum. *eMedicine*. Retrieved from http://emedicine.medscape.com/article/254751-overview

Health History and Physical Examination

Begin the history by asking the client about the onset, duration, and course of her nausea and vomiting. Ask her about any medications or treatments she used and how effective they were in relieving her nausea and vomiting. Obtain a diet history from the client, including a dietary recall for the past week. Note the client's knowledge of nutrition and need for appropriate nutritional intake. Be alert for patterns that may contribute to or trigger her distress. Also ask about any complaints of ptyalism (excessive salivation), anorexia, indigestion, and abdominal pain or distention. Ask if she has noticed any blood or mucus in her stool.

Review the client's history for possible risk factors, such as young age, nausea and vomiting with previous pregnancy, history of intolerance of oral contraceptives, nulliparity, trophoblastic disease, multiple gestation, emotional or psychological stress, gastroesophageal reflux disease, primigravida status, obesity, hyperthyroidism, and *Helicobacter pylori* seropositivity (Ogunyemi, Fong, & Herrero, 2015). Weigh the client and compare this weight with her weight before she began experiencing symptoms and to her prepregnancy weight to estimate the degree of loss. With hyperemesis, weight loss usually exceeds 5% of body mass.

Inspect the mucous membranes for dryness and check skin turgor for evidence of fluid loss and dehydration. Assess blood pressure for changes, such as hypotension, that may suggest a fluid volume deficit. Also note any complaints of weakness, fatigue, activity intolerance, dizziness, or sleep disturbances.

Assess the client's perception of the situation. Note any evidence of depression, anxiety, irritability, mood changes, and decreased ability to concentrate, which can add to her emotional distress. Much of the psychological distress is self-limiting in this condition and probably in the causal pathway (Tan et al., 2014). Determine the woman's support systems that are available for help.

Laboratory and Diagnostic Testing

The results of laboratory and diagnostic tests may provide clues to the severity or etiology of the disorder. These may include:

• *Liver enzymes:* To rule out hepatitis, pancreatitis, and cholestasis; elevations of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are

usually present.

- *CBC:* Elevated levels of red blood cells and hematocrit, indicating dehydration.
- *Urine ketones:* Positive when the body breaks down fat to provide energy in the absence of adequate intake.
- *TSH and T4* to rule out thyroid disease.
- *Blood urea nitrogen:* Increased in the presence of salt and water depletion
- *Urine specific gravity*—greater than 1.025, possibly indicating concentrated urine linked to inadequate fluid intake or excessive fluid loss; ketonuria.
- *Serum electrolytes:* Decreased levels of potassium, sodium, and chloride resulting from excessive vomiting and loss of hydrochloric acid in stomach.
- *Ultrasound:* Evaluation for molar pregnancy or multiple gestation (Cunningham et al., 2014).

Nursing Management

Nursing management for the client with hyperemesis gravidarum focuses on promoting comfort by controlling the client's nausea and vomiting and promoting adequate nutrition. In addition, the nurse plays a major role in supporting and educating the client and her family.

Promoting Comfort and Nutrition

During the initial period, expect to withhold all oral food and fluids, maintaining NPO status to allow the gastrointestinal tract to rest. In addition, administer prescribed antiemetics to relieve the nausea and vomiting and intravenous fluids to replace fluid losses. Monitor the rate of infusion to prevent overload and assess the intravenous insertion site to prevent infiltration or infection. Also administer electrolyte replacement therapy as ordered to correct any imbalances, and periodically check serum electrolyte levels to evaluate the effectiveness of therapy.

Provide physical comfort measures such as hygiene measures and oral care. Pay special attention to the environment, making sure to keep the area free of pungent odors. As the client's nausea and vomiting subside, gradually introduce oral fluids and foods in small amounts. Monitor intake and output and assess the client's tolerance to the increase in intake.

Providing Support and Education

Women with hyperemesis gravidarum commonly are fatigued physically and emotionally. Many are exhausted, frustrated, and anxious. Offer reassurance that all interventions are directed toward promoting positive pregnancy outcomes for both the woman and her fetus. Providing information about the expected plan of care may help to alleviate the client's anxiety. Listen to her concerns and feelings, answering all questions honestly. Educate the woman and her family about the condition and its treatment options (Teaching Guidelines 19.1). Teach the client about therapeutic lifestyle changes, such as avoiding stressors and fatigue that may trigger nausea and vomiting. Offer ongoing support and encouragement and promote active participation in care decisions, thereby empowering the client and her family. Attempting to provide the client with a sense of control may help her overcome the feeling that she has lost control. If

necessary, refer the client to a spiritual advisor or counseling. Also suggest possible local or national support groups that the client may contact for additional information. Arrange for possible home care follow-up for the client and reinforce discharge instructions to promote understanding. Timely counseling, balanced nutrition, pharmacotherapy, and emotional support are associated with favorable outcomes for the woman with this condition. Collaborate with community resources to ensure continuity of care.

Teaching Guidelines 19.1

TEACHING TO MINIMIZE NAUSEA AND VOMITING

• Avoid noxious stimuli—such as strong flavors, perfumes, or strong odors such as frying bacon—that might trigger nausea and vomiting.

• Avoid tight waistbands to minimize pressure on abdomen.

• Eat small, frequent meals throughout the day—six small meals.

• Separate fluids from solids by consuming fluids in between meals.

• Avoid lying down or reclining for at least 2 hours after eating.

• Use high-protein supplement drinks.

• Avoid foods high in fat.

• Increase your intake of carbonated beverages.

• Increase your exposure to fresh air to improve symptoms.

• Eat when you are hungry, regardless of normal mealtimes.

• Drink herbal teas containing peppermint or ginger.

• Avoid fatigue and learn how to manage stress in life.

• Schedule daily rest periods to avoid becoming overtired.

• Eat foods that settle the stomach, such as dry crackers, toast, or soda.

HYPERTENSIVE DISORDERS OF PREGNANCY

Hypertension remains the most commonly encountered medical condition in pregnant women, complicating up to 15% of all pregnancies. It results in frequent hospital admissions, maternal morbidity and mortality, and preterm births with concomitant neonatal morbidity and mortality. Hypertensive disorders of pregnancy comprise a spectrum of severity ranging from a mild elevation of blood pressure to severe preeclampsia and hemolysis. Recent data show that hypertensive disorders of pregnancy are associated with long-term cardiovascular risks in women (Miller & Carpenter, 2015).

Hypertensive disorders of pregnancy include chronic hypertension, gestational hypertension, preeclampsia, eclampsia, and chronic hypertension with superimposed preeclampsia. Preeclampsia complicates about 3% to 5% of pregnancies. All hypertensive disorders, which affect up to 15% of pregnancies, are on the rise. Hypertensive disorders are associated with higher rates of maternal, fetal, and infant mortality and with severe morbidity, especially in cases of severe preeclampsia, eclampsia, and HELLP syndrome (ACOG, 2014c).

ACOG (2010c) and the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy (2002) have identified a classification system for hypertensive disorders. Hypertension may be a preexisting condition (chronic hypertension) or it may present for the first time during pregnancy (gestational hypertension). Both chronic hypertension and preeclampsia can be subclassified as either mild or severe. For chronic hypertension, subclassification is dependent on systolic and diastolic values. For preeclampsia, subclassification is dependent on the severity of end organ involvement (Foley, Strong, & Garite, 2014). Regardless of its onset or subclassification, hypertension jeopardizes the well-being of the mother as well as the fetus.

The classification of hypertensive disorders in pregnancy currently consists of five categories:

1. *Chronic hypertension*: Hypertension that exists prior to pregnancy or that develops before 20 weeks' gestation.

2. *Gestational hypertension*: Blood pressure elevation (140/90 mm Hg) identified after 20 weeks' gestation without proteinuria. Blood pressure returns to normal by 12 weeks' postpartum.

3. *Preeclampsia*: most common hypertensive disorder of pregnancy, which develops with proteinuria after 20 weeks' gestation. It is a multisystem disease process, which is classified as mild or severe, depending on the severity of the organ dysfunction.

4. *Eclampsia*: Onset of seizure activity in a woman with preeclampsia

5. *Chronic hypertension with superimposed preeclampsia*: Occurs in approximately 20% of pregnant women with increased maternal and fetal morbidity rates (King et al., 2015).

Population-based data indicate that approximately 1% of pregnancies are complicated by chronic hypertension, 5% to 6% by gestational hypertension (without proteinuria), and 3% to 5% by preeclampsia (Carson & Gibson, 2015). Worldwide, 50,000 to 60,000 women die from preeclampsia each year, corresponding to 12% of all maternal deaths (Clausen & Bergholt, 2014).

Chronic Hypertension

Chronic hypertension is defined as blood pressure exceeding 140/90 mm Hg before pregnancy or before 20 weeks' gestation. When hypertension is first identified during a woman's pregnancy and she is less than 20 weeks' gestation, blood pressure elevations usually represent chronic hypertension. Chronic hypertension occurs in about 20% of women of childbearing age, with the prevalence varying according to age, race, and body mass index (BMI). As our nation's obesity rate rises, more women will start pregnancies with elevated blood pressures. About 25% of women with chronic hypertension develop preeclampsia during pregnancy (Clausen & Bergholt, 2014). Women with chronic hypertension in pregnancy should be monitored for the development of worsening hypertension and/or the development of superimposed preeclampsia.

Women with mild chronic hypertension often do not require antihypertensive therapy during most of pregnancy. Pharmacologic treatment of mild hypertension does not reduce the likelihood of developing preeclampsia later in gestation and increases the likelihood of intrauterine growth restriction. If maternal blood pressure exceeds 160/100 mm Hg, however, drug treatment is recommended (Magee et al., 2015). Nurses can play a large role in educating their hypertensive clients to help them understand potential complications and how simple changes in their lifestyles might be helpful in influencing the pregnancy outcome positively.

Gestational Hypertension

The gestational hypertension category is used in women with nonproteinuric hypertension of pregnancy, in which the pathophysiologic disturbances of the preeclampsia syndrome do not develop before giving birth. Gestational hypertension is a temporary diagnosis for hypertensive pregnant women who do not meet the criteria for preeclampsia (both hypertension and possibly proteinuria) or chronic hypertension (hypertension first detected before the 20th week of pregnancy).

Gestational hypertension is characterized by hypertension (>140/90) without proteinuria after 20 weeks' gestation resolving by 12 weeks' postpartum (Magowan, Owen, & Thomson, 2014). Previously, gestational hypertension was known as pregnancy-induced hypertension or toxemia of pregnancy, but these terms are no longer used. Gestational hypertension is defined as systolic blood pressure > 140 mm Hg and/or diastolic > 90 mm Hg on at least two occasions at least 4 to 6 hours apart after the 20th week of gestation, in women known to be normotensive prior to this time and prior to pregnancy (King et al., 2015). Gestational hypertension can be differentiated from chronic hypertension, which appears before the 20th week of gestation; or hypertension before the current pregnancy, which continues after the woman gives birth.

A recent study found that progesterone supplementation during the first trimester significantly reduced the incidence of gestational hypertension and fetal distress in primigravida women. This supplementation might be a future therapy with addition studies to validate it (Zainul et al., 2014).

Preeclampsia and Eclampsia

Normal physiologic adaptations to pregnancy are altered in the woman who develops preeclampsia. **Preeclampsia** can be described as a multisystem, vasopressive disorder that targets the cardiovascular, hepatic, renal, and central nervous systems (CNSs). Preeclampsia can be classified as mild or severe with a potential progression to eclampsia. Each is associated with specific criteria. Comparison Chart 19.2 highlights these classifications.

Pathophysiology

Preeclampsia remains an enigma. The condition can be devastating to both the mother and fetus, yet the etiology still remains a mystery to medical science despite decades of research. Many theories exist, but none has truly explained the widespread pathologic changes that result in pulmonary edema, oliguria, seizures, thrombocytopenia, and abnormal liver enzymes (Cunningham et al., 2014). Despite the results of several research studies, the use of aspirin or supplementation with calcium, magnesium, zinc, or antioxidant therapy (vitamin C and E), salt restriction, diuretic therapy, or fish oils has not proved to prevent this destructive condition.

Preeclampsia is a two-stage event; .the underlying mechanisms involved are vasospasm and hypoperfusion. In the first stage, the key feature is widespread vasospasm. In addition, endothelial injury occurs, leading to platelet adherence, fibrin deposition, and the presence of schistocytes (fragment of an erythrocyte). The second stage of preeclampsia is the woman's response to abnormal placentation, when symptoms appear, i.e., hypertension, proteinuria, and edema due to hypoperfusion.

The first stage of generalized vasospasm results in elevation of blood pressure and reduced blood flow to the brain, liver, kidneys, placenta, and lungs. Decreased liver perfusion leads to impaired liver function and subcapsular hemorrhage. This is demonstrated by epigastric pain and elevated liver enzymes in the maternal serum. Decreased brain perfusion leads to small cerebral hemorrhages and symptoms of arterial vasospasm such as headaches, visual disturbances, blurred vision, and hyperactive deep tendon reflexes (DTRs). A thromboxane/prostacyclin imbalance leads to increased thromboxane (potent vasoconstrictor and stimulator of platelet aggregation) and decreased

prostacyclin (potent vasodilator and inhibitor of platelet aggregation), which contribute to the hypertensive state. Decreased kidney perfusion reduces the glomerular filtration rate, resulting in decreased urine output and increased serum levels of sodium, BUN, uric acid, and creatinine, further increasing extracellular fluid and edema. Increased capillary permeability in the kidneys allows albumin to escape, which reduces plasma colloid osmotic pressure and moves more fluid into extracellular spaces; this leads to pulmonary edema and generalized edema. Poor placental perfusion resulting from prolonged vasoconstriction helps to contribute to intrauterine growth restriction, premature separation of the placenta (abruptio placentae), persistent fetal hypoxia, and acidosis. In addition, hemoconcentration (resulting from decreased intravascular volume) causes increased blood viscosity and elevated hematocrit (ACOG, 2014c).

COMPARISON CHART 19.2 PREECLAMPSIA VERSUS ECLAMPSIA

	Mild Preeclampsia	Severe Preeclampsia	Eclampsia
Blood pressure	>140/90 mm Hg after 20 weeks' gestation	>160/110 mm Hg	>160/110 mm Hg
Proteinuria	300 mg/24 hours or greater than 1+ protein on a random dipstick urine sample	>500 mg/24 hours; greater than 3+ on random dipstick urine sample	Marked proteinuria
Seizures/coma	No	No	Yes
Hyperreflexia	No	Yes	Yes
Other signs and symptoms	Mild facial or hand edema Weight gain	Headache Oliguria Blurred vision, scotomata (blind spots) Pulmonary edema Thrombocytopenia (platelet count <100,000 platelets/mm^3) Cerebral disturbances Epigastric or RUQ pain HELLP	Severe headache Generalized edema RUQ or epigastric pain Visual disturbances Cerebral hemorrhage Renal failure HELLP

Therapeutic Management

Management of the woman with preeclampsia varies depending on the severity

of her condition and its effects on the fetus. Typically the woman is managed conservatively if she is experiencing mild symptoms. However, if the condition progresses, management becomes more aggressive. The "cure" for preeclampsia/eclampsia is always delivery of the placenta. The resolution following expulsion of the placenta supports theories related to the placental influence on the disease (Dekker, 2014). According to recent studies, prevention of preeclampsia should be considered with daily low-dose aspirin from 12 weeks' gestation and onward to women identified at high risk for it. While women with chronic hypertension or a personal history of preeclampsia should receive aspirin during pregnancy, further research should be ongoing to predict preeclampsia in low risk women (Bujold, 2015).

MANAGEMENT FOR MILD PREECLAMPSIA

Conservative strategies for mild preeclampsia are used if the woman exhibits no signs of renal or hepatic dysfunction or coagulopathy. A woman with mild elevations in blood pressure may be placed on bed rest at home. She is encouraged to rest as much as possible in the lateral recumbent position to improve uteroplacental blood flow, reduce her blood pressure, and promote diuresis. In addition, antepartal visits and diagnostic testing—such as CBC, clotting studies, liver enzymes, and platelet levels—increase in frequency. The woman will be asked to monitor her blood pressure daily (every 4 to 6 hours while awake) and report any increased readings; she will also measure the amount of protein found in urine using a dipstick and will weigh herself for any weight gain. She also should take daily fetal movement counts, and if there is any decrease in movement, she needs to be evaluated by her health care provider that day. A balanced, nutritional diet with no sodium restriction is advised. In addition, she is encouraged to drink six to eight 8-oz glasses of water daily. If home management fails to reduce the blood pressure, admission to the hospital is warranted and the treatment strategy is individualized based on the severity of the condition and the gestational age at the time of diagnosis.

During the hospitalization, the woman with mild preeclampsia is monitored closely for signs and symptoms of severe preeclampsia or impending eclampsia (e.g., persistent headache, hyperreflexia). Blood pressure measurements are frequently recorded along with daily weights to detect excessive weight gain resulting from edema. Fetal surveillance is instituted in the form of daily fetal movement counts, nonstress testing, and serial ultrasounds to evaluate fetal growth and amniotic fluid volume to confirm fetal well-being. Expectant

management (watchful waiting) usually continues until the pregnancy reaches term, fetal lung maturity is documented, or complications develop that warrant immediate birth. Women with mild preeclampsia are at greatest risk for postpartum hypertension (King et al., 2015).

Prevention of disease progression is the focus of treatment during labor. Blood pressure is monitored frequently and a quiet environment is important to minimize the risk of stimulation and to promote rest. Intravenous magnesium sulfate is infused to prevent any seizure activity, along with antihypertensives if blood pressure values begin to rise. Calcium gluconate is kept at the bedside in case the magnesium level becomes toxic. Continued close monitoring of neurologic status is warranted to detect any signs or symptoms of hypoxemia, impending seizure activity, or increased intracranial pressure. An indwelling urinary (Foley) catheter usually is inserted to allow for accurate measurement of urine output.

MANAGEMENT FOR SEVERE PREECLAMPSIA

Severe preeclampsia may develop suddenly and bring with it high blood pressure of more than 160/110 mm Hg, proteinuria of more than 5 g in 24 hours, oliguria of less than 400 mL in 24 hours, cerebral and visual symptoms, and rapid weight gain. This clinical picture signals severe preeclampsia, and immediate hospitalization is needed.

Treatment is highly individualized and based on disease severity and fetal age. Birth of the infant is the only cure, because preeclampsia depends on the presence of trophoblastic tissue. Therefore, the exact age of the fetus is assessed to determine viability.

Severe preeclampsia is treated aggressively because hypertension poses a serious threat to mother and fetus. The goal of care is to stabilize the mother–fetus dyad and prepare for birth. Therapy focuses on controlling hypertension, preventing seizures, preventing long-term morbidity, and preventing maternal, fetal, or newborn death (Foo et al., 2015). Intense maternal and fetal surveillance starts when the mother enters the hospital and continues throughout her stay.

The woman in labor with severe preeclampsia typically receives oxytocin to stimulate uterine contractions and magnesium sulfate to prevent seizure activity. Oxytocin and magnesium sulfate can be given simultaneously via infusion pumps to ensure both are administered at the prescribed rate. Magnesium sulfate is given intravenously via an infusion pump. A loading dose of 4 to 6 g is given over 5 minutes. Then, a maintenance dose of 2 g/hr is given.

The client is evaluated closely for magnesium toxicity. If at all possible, a vaginal delivery is preferable to a cesarean birth for better maternal outcomes and less risk associated with a surgical birth. PGE2 gel may be used to ripen the cervix. A cesarean birth may be performed if the client is seriously ill. A pediatrician/neonatologist or neonatal nurse practitioner should be available in the birthing room to care for the newborn. A newborn whose mother received high doses of magnesium sulfate needs to be monitored for respiratory depression, hypocalcemia, and hypotonia. Decreased fetal heart rate variability may occur but, in general, magnesium sulfate does not pose a risk to the fetus. The newborn may exhibit respiratory depression, loss of reflexes, muscle weakness, and neurologic depression (Martin, Fanaroff, & Walsh, 2014).

MANAGEMENT OF ECLAMPSIA

In the woman who develops an eclamptic seizure, the convulsive activity begins with facial twitching, followed by generalized muscle rigidity. The woman's face initially may become distorted, with protrusion of the eyes, and foaming at the mouth may occur. Respirations cease for the duration of the seizure, resulting from muscle spasms, thus compromising fetal oxygenation. Seizure complications can include tongue biting, head trauma, broken bones, and aspiration. Coma usually follows the seizure activity, with respiration resuming. Eclamptic seizures are life-threatening emergencies and require immediate treatment to decrease maternal morbidity and mortality.

As with any seizure, the initial management is to clear the airway and administer adequate oxygen. Positioning the woman on her left side and protecting her from injury during the seizure are the key. Suction equipment must be readily available to remove secretions from her mouth after the seizure is over. Intravenous fluids are administered after the seizure at a rate to replace urine output and additional insensible losses. Fetal heart rate is monitored closely. Magnesium sulfate is administered intravenously to prevent further seizures. Serum magnesium levels, respiratory rate, reflexes, and urine output in women receiving magnesium sulfate are closely monitored to avoid magnesium toxicity and prevent cardiac arrest. Calcium gluconate (1 g intravenously) is typically ordered to counteract magnesium toxicity. Hypertension is controlled with antihypertensive medications. After the woman's seizures are controlled, her stability is assessed. If she is found stable, birth via induction or cesarean birth is performed (Amorim et al., 2015). If the woman's condition remains stable, she will be transferred to the postpartum unit for care. If she becomes

unstable after giving birth, she may be transferred to the critical care unit for closer observation.

Nursing Assessment

Preventing complications related to preeclampsia requires the use of assessment, advocacy, and counseling skills. Assessment begins with the accurate measurement of the client's blood pressure at each encounter. In addition, nurses need to assess for subjective complaints that may indicate progression of the disease—visual changes, severe headaches, unusual bleeding or bruising, or epigastric pain (Nagtalon-Ramos, 2014). The significant signs of preeclampsia—proteinuria and hypertension—occur without the woman's awareness. Unfortunately, by the time symptoms are noticed, gestational hypertension can be severe.

Take Note!

The absolute blood pressure (value that validates elevation) of 140/90 mm Hg should be obtained on two occasions 4 to 6 hours apart to be diagnostic of preeclampsia. Proteinuria is defined as 300 mg or more of urinary protein per 24 hours or more than 1+ protein by chemical reagent strip or dipstick of at least two random urine samples collected at least 4 to 6 hours apart with no evidence of urinary tract infection (ACOG, 2014c).

HEALTH HISTORY AND PHYSICAL EXAMINATION

Take a thorough history during the first antepartal visit to identify whether the woman is at risk for preeclampsia. Risk factors include:

• Primigravida status

• Chromosomal abnormalities

• Structural congenital anomalies

• Multiple gestation

• History of preeclampsia in a previous pregnancy

• Excessive placental tissue, as is seen in women with GTD

• Chronic stress

- Use of ovulation drugs
- Family history of preeclampsia (mother or sister)
- Lower socioeconomic status
- History of diabetes, hypertension, or renal disease
- Poor nutrition
- Lower socioeconomic status
- African–American ethnicity
- Age extremes (younger than 20 or older than 35)
- Obesity (Ross, 2015).

In addition, complete a nutritional assessment that includes the woman's usual intake of protein, calcium, daily calories, and fluids.

Women at risk for preeclampsia require more frequent prenatal visits throughout their pregnancy, and they require teaching about problems so that they can report them promptly.

Blood pressure must be measured carefully and consistently. Obtain all measurements with the woman in the same position (blood pressure is highest in the sitting position and lowest in the side-lying position) and by using the same technique (automated vs. manual). This standardization in position and technique will yield the most accurate readings (Norwitz, 2015).

Obtain the client's weight (noting gain since last visit), and assess for amount and location of edema. Asking questions such as "Do your rings still fit on your fingers?" or "Is your face puffy when you get up in the morning?" will help to determine whether fluid retention is present or if the woman's status has changed since her last visit.

Take Note!

Although edema is not a cardinal sign of preeclampsia, weight should be monitored frequently to identify sudden gains in a short time span. Current research relies less on the classic triad of symptoms (hypertension, proteinuria, and edema or weight gain) and more on decreased organ perfusion, endothelial dysfunction (capillary leaking and proteinuria), and elevated blood pressure as key indicators (Carson & Gibson, 2015).

If edema is present, assess the distribution, degree, and pitting. Document your findings and identify whether the edema is dependent or pitting. Dependent edema is present on the lower half of the body if the client is ambulatory, where hydrostatic pressure is greatest. It is usually observed in the feet and ankles or in the sacral area if the client is on bed rest. Pitting edema is edema that leaves a small depression or pit after finger pressure is applied to a swollen area (Carson & Gibson, 2014). Record the depth of pitting demonstrated when pressure is applied. Although subjective, the following is used to record relative degrees:

• 1+ pitting edema = 2-mm depression into skin; disappears rapidly

• 2+ pitting edema = 4-mm skin depression; disappears in 10 to 15 seconds

• 3+ pitting edema = 6-mm depression into skin; lasts more than 1 minute

• 4+ pitting edema = 8-mm depression into skin; lasts 2 to 3 minutes

At every antepartal visit, assess the fetal heart rate with a Doppler device. Also check a clean-catch urine specimen for protein using a dipstick.

LABORATORY AND DIAGNOSTIC TESTING

Various laboratory tests may be performed to evaluate the woman's status. Typically these include a CBC, serum electrolytes, BUN, creatinine, and hepatic enzyme levels. Urine specimens are checked for protein; if levels are 1 to 2+ or greater, a 24-hour urine collection is completed.

Nursing Management

Nursing management of the woman with preeclampsia focuses on close monitoring of blood pressure and ongoing assessment for evidence of disease progression. Throughout the client's pregnancy, fetal surveillance is essential.

INTERVENING FOR PREECLAMPSIA

The woman with mild preeclampsia requires frequent monitoring to detect changes because preeclampsia can progress rapidly. Instruct all women in the signs and symptoms of preeclampsia and urge them to contact their health care professional for immediate evaluation should any occur.

Typically, women with mild preeclampsia can be managed at home if they have a good understanding of the disease process, blood pressure and vital signs are stable, there are no abnormal laboratory test results, and if good fetal

movement is demonstrated (Teaching Guidelines 19.2). The home care nurse makes frequent visits and follow-up phone calls to assess the woman's condition, to assist with scheduling periodic evaluations of the fetus (such as nonstress tests), and to evaluate any changes that might suggest a worsening of the woman's condition.

Teaching Guidelines 19.2

TEACHING FOR THE WOMAN WITH MILD PREECLAMPSIA

• Rest in a quiet environment to prevent cerebral disturbances.

• Drink 8 to 10 glasses of water daily.

• Consume a balanced, high-protein diet including high-fiber foods.

• Obtain intermittent bed rest to improve circulation to the heart and uterus.

• Limit your physical activity to promote urination and subsequent decrease in blood pressure.

• Enlist the aid of your family so that you can obtain appropriate rest time.

• Perform self-monitoring as instructed, including:

  • Taking your own blood pressure twice daily

  • Checking and recording weight daily

  • Performing urine dipstick twice daily

  • Recording the number of fetal kicks daily

• Contact the home health nurse if any of the following occurs:

  • Increase in blood pressure

  • Protein present in urine

  • Gain of more than 1 lb in 1 week

  • Burning or frequency when urinating

  • Decrease in fetal activity or movement

  • Headache (forehead or posterior neck region)

- Dizziness or visual disturbances
- Increase in swelling in hands, feet, legs, and face
- Stomach pain, excessive heartburn, or epigastric pain
- Decreased or infrequent urination
- Contractions or low back pain
- Easy or excessive bruising
- Sudden onset of abdominal pain
- Nausea and vomiting

Early detection and management of mild preeclampsia is associated with the greatest success in reducing progression of this condition. As long as the client carries out the guidelines of care as outlined by the health care provider and remains stable, home care can continue to maintain the pregnancy until the fetus is mature. If disease progression occurs, hospitalization is required.

INTERVENING FOR SEVERE PREECLAMPSIA

The woman with severe preeclampsia requires hospitalization. Maintain the client on complete bed rest in the left lateral lying position. Ensure that the room is dark and quiet to reduce stimulation. Give sedatives as ordered to encourage quiet bed rest. The client is at risk for seizures if the condition progresses. Therefore, institute and maintain seizure precautions, such as padding the side rails and having oxygen, suction equipment, and call light readily available to protect the client from injury.

Take Note!

Preeclampsia increases the risk of placental abruption, preterm birth, intrauterine growth restriction, and fetal distress during childbirth. Always be prepared if you see symptoms of preeclampsia!

Closely monitor the client's blood pressure. Administer antihypertensives as ordered to reduce blood pressure (Drug Guide 19.3). Assess the client's vision and level of consciousness. Report any changes and any complaints of headache

or visual disturbances. Offer a high-protein diet with 8 to 10 glasses of water daily. Monitor the client's intake and output every hour and administer fluid and electrolyte replacements as ordered. Assess the woman for signs and symptoms of pulmonary edema, such as crackles and wheezing heard on auscultation, dyspnea, decreased oxygen saturation levels, cough, neck vein distention, anxiety, and restlessness. The treatment of acute pulmonary edema is symptomatic and includes the administration of vasodilating agents and of diuretics. The development of acute pulmonary edema in women with hypertension during pregnancy is associated with high levels of intravenous fluid administration (Pauli & Repke, 2015).

To achieve a safe outcome for the fetus, prepare the woman for possible testing to evaluate fetal status as preeclampsia progresses. Testing may include the nonstress test, serial ultrasounds to track fetal growth, amniocentesis to determine fetal lung maturity, Doppler velocimetry to screen for fetal compromise, and biophysical profile to evaluate ongoing fetal well-being (Mattson & Smith, 2016).

Other laboratory tests may be performed to monitor the disease process and to determine if it is progressing into HELLP syndrome. These include liver enzymes such as lactic dehydrogenase (LDH), ALT, and AST; chemistry panel, such as creatinine, BUN, uric acid, and glucose; CBC, including platelet count; coagulation studies, such as PT, PTT, fibrinogen, and bleeding time; and a 24-hour urine collection for protein and creatinine clearance.

DRUG GUIDE 19.3 MEDICATIONS USED WITH PREECLAMPSIA AND ECLAMPSIA

Medication	Action/Indications	Nursing Implications
Magnesium sulfate	Blockage of neuromuscular transmission, vasodilation Prevention and treatment of eclamptic seizures	Loading dose of 4 to 6 g by IV in 100 mL of fluid administered over 15 to 20 minutes, followed by a maintenance dose of 2 g as a continuous intravenous infusion. Monitor serum magnesium levels closely. Assess DTRs and check for ankle clonus. Have calcium gluconate readily available in case of toxicity. Monitor for signs and symptoms of toxicity, such as flushing, sweating, hypotension, and cardiac and central nervous system depression.
Hydralazine hydrochloride (Apresoline)	Vascular smooth muscle relaxant, thus improving perfusion to renal, uterine, and cerebral areas Reduction in blood pressure	Administer 5 to 10 mg by slow intravenous bolus every 20 minutes as needed. Use parenteral form immediately after opening ampule. Withdraw drug slowly to prevent possible rebound hypertension. Monitor for adverse effects such as palpitations, headache, tachycardia, anorexia, nausea, vomiting, and diarrhea.
Labetalol hydrochloride (Normodyne)	Alpha-1 and beta blocker Reduction in blood pressure	Be aware that drug lowers blood pressure without decreasing maternal heart rate or cardiac output. Administer IV dose of 20 to 40 mg every 15 minutes as needed and then administer intravenous V infusion of 2 mg/min until desired blood pressure value achieved. Monitor for possible adverse effects such as gastric pain, flatulence, constipation, dizziness, vertigo, and fatigue.
Nifedipine (Procardia)	Calcium channel blocker/dilation of coronary arteries, arterioles, and peripheral arterioles Reduction in blood pressure, stoppage of preterm labor	Administer 10 to 20 mg orally for three doses and then every 4 to 8 hours. Monitor for possible adverse effects such as dizziness, peripheral edema, angina, diarrhea, nasal congestions, cough.
Sodium nitroprusside	Rapid vasodilation (arterial and venous) Severe hypertension requiring rapid reduction in blood pressure	Administer via continuous IV infusion with dose titrated according to blood pressure levels. Wrap intravenous infusion solution in foil or opaque material to protect from light. Monitor for possible adverse effects, such as apprehension, restlessness, retrosternal pressure, palpitations, diaphoresis, abdominal pain.
Furosemide (Lasix)	Diuretic action, inhibiting the reabsorption of sodium and chloride from the ascending loop of Henle Pulmonary edema (used only if condition is present)	Administer via slow IV bolus at a dose of 10 to 40 mg over 1 to 2 minutes. Monitor urine output hourly. Assess for possible adverse effects such as dizziness, vertigo, orthostatic hypotension, anorexia, vomiting, electrolyte imbalances, muscle cramps, and muscle spasms.

Adapted from King, T. L., Brucker, M. C., Kriebs, J. M., Fahey, J. O., Grgor, C. L., & Varney, H. (2015). *Varney's midwifery* (5th ed.). Burlington, MA: Jones & Bartlett Learning; and Skidmore-Roth, L. (2015). *Mosby's 2015 nursing drug reference* (28th ed.). Philadelphia, PA: Elsevier Health Science.

Administer parenteral magnesium sulfate as ordered to prevent seizures. Assess DTRs to evaluate the effectiveness of therapy. Clients with preeclampsia commonly present with hyperreflexia. Severe preeclampsia causes changes in the cortex, which disrupts the equilibrium of impulses between the cerebral cortex and the spinal cord. Brisk reflexes (hyperreflexia) are the result of an irritable cortex and indicate CNS involvement (Marik, 2015). Diminished or absent reflexes occur when the client develops magnesium toxicity. Because magnesium is a potent neuromuscular blockade, the afferent and efferent nerve pathways do not relay messages properly and hyporeflexia develops. Common sites used to assess DTRs are biceps reflex, triceps reflex, patellar reflex, Achilles reflex, and plantar reflex. Nursing Procedure 19.1 highlights the steps for assessing the patellar reflex.

The National Institute of Neurological Disorders and Stroke, a division of the National Institutes of Health, published a scale in the early 1990s that, although subjective, is used widely today. It grades reflexes from 0 to 4+. Grades 2+ and 3+ are considered normal, whereas grades 0 and 4 may indicate pathology (Table 19.2). Because these are subjective assessments, to improve communication of reflex results, condensed descriptor categories such as absent, average, brisk, or clonus should be used rather than numeric codes (Magowan, Owen, & Thomson, 2014).

Clonus is the presence of rhythmic involuntary contractions, most often at the foot or ankle. Sustained clonus confirms CNS involvement. Nursing Procedure 19.2 highlights the steps when testing for ankle clonus.

With magnesium sulfate administration, the client is at risk for magnesium toxicity. Closely assess the client for signs of toxicity, which include a respiratory rate of less than 12 breaths per minute, absence of DTRs, and a decrease in urinary output (<30 mL/hr). Also monitor serum magnesium levels. Although exact levels may vary among agencies, serum magnesium levels ranging from 4 to 7 mEq/L are considered therapeutic, whereas levels more than 8 mEq/dL are generally considered toxic. As levels increase, the woman is at risk for severe problems:

• 10 mEq/L: Possible loss of DTRs

• 15 mEq/L: Possible respiratory depression

• 25 mEq/L: Possible cardiac arrest (Skidmore-Roth, 2015).

If signs and symptoms of magnesium toxicity develop, expect to administer

calcium gluconate as the antidote.

Throughout the client's stay, closely monitor her for signs and symptoms of labor. Perform continuous electronic fetal monitoring to assess fetal well-being. Note trends in baseline rate and presence or absence of accelerations or decelerations. Also observe for signs of fetal distress and report them immediately. Administer glucocorticoid treatment as ordered to enhance fetal lung maturity and prepare for labor induction if the mother's condition warrants.

NURSING PROCEDURE 19.1

Assessing the Patellar Reflex

Purpose: To Evaluate for Nervous System Irritability Related to Preeclampsia

1. Place the woman in the supine position (or sitting upright with the legs dangling freely over the side of the bed or examination table).
2. If lying supine, have the woman flex her knee slightly.
3. Place a hand under the knee to support the leg and locate the patellar tendon. It should be midline just below the knee cap.
4. Using a reflex hammer or the side of your hand, strike the area of the patellar tendon firmly and quickly.
5. Note the movement of the leg and foot. A patellar reflex occurs when the leg and foot move (documented as 2+).
6. Repeat the procedure on the opposite leg.

Keep the client and family informed of the woman's condition and educate them about the course of treatment. Provide emotional support for the client and family. Severe preeclampsia is very frightening for the client and her family, and most expectant mothers are very anxious about their own health as well as that of the fetus. To allay anxiety, use light touch to comfort and reassure her that the necessary actions are being taken. Actively listening to her concerns and fears and communicating them to the health care provider are important to keep open the lines of communication. Offering praise for small accomplishments can provide positive reinforcement for effective behaviors.

TABLE 19.2 GRADING DEEP TENDON REFLEXES

Description of Finding	Grade
Reflex absent, none elicited	0
Hypoactive response, sluggish	1
Reflex in lower half of normal range	2
Reflex in upper half of normal range	3
Hyperactive, brisk, clonus present	4

Adapted from King, T. L., Brucker, M. C., Kriebs, J. M., Fahey, J. O., Grgor, C. L., & Varney, H. (2015). *Varney's midwifery.* (5th ed.), Burlington, MA: Jones & Bartlett Learning; Nagtalon-Ramos, J. (2014). *Maternal-newborn nursing care: Best evidence-based practices.* Philadelphia, PA: F. A. Davis Company.

INTERVENING FOR ECLAMPSIA

The onset of seizure activity identifies **eclampsia**. Typically, eclamptic seizures are generalized and start with facial twitching. The body then becomes rigid, in a state of tonic muscular contraction. The clonic phase of the seizure involves alternating contraction and relaxation of all body muscles. Respirations stop during seizure activity and resume shortly after it ends. Client safety is the primary concern during eclamptic seizures. If possible, turn the client to her side and remain with her. Make sure that the side rails are up and padded. Dim the lights and keep the room quiet.

Document the time and sequence of events as soon as possible. After the seizure activity has ceased, suction the nasopharynx as necessary and administer oxygen. Continue the magnesium sulfate infusion to prevent further seizures. Ensure continuous electronic fetal monitoring, evaluating fetal status for changes. Also assess the client for uterine contractions. After the client is stabilized, prepare her for the birthing process as soon as possible to reduce the risk of perinatal mortality.

PROVIDING FOLLOW-UP CARE

After delivery of the newborn, continue to monitor the client for signs and symptoms of preeclampsia/eclampsia for at least 48 hours. Expect to continue to administer magnesium sulfate infusion for 24 hours to prevent seizure activity, and monitor serum magnesium levels for toxicity.

NURSING PROCEDURE 19.2

Testing for Ankle Clonus

Purpose: To Evaluate for Nervous System Irritability Related to Preeclampsia

1. Place the woman in the supine position.

2. Have the client slightly bend her knee and place a hand under the knee to support it.

3. Dorsiflex the foot briskly and then quickly release it.

4. Watch for the foot to rebound smoothly against your hand. If the movement is smooth without any rapid contractions of the ankle or calf muscle, then clonus is not present; if the movement is jerky and rapid, clonus is present.

5. Repeat on the opposite side.

Assess vital signs at least every 4 hours, along with routine postpartum assessments: fundus, lochia, breasts, bladder, bowels, and the woman's emotional state. Monitor urine output closely. Diuresis is a positive sign that, along with a decrease in proteinuria, signals resolution of the disease.

HELLP SYNDROME

HELLP syndrome is an acronym for hemolysis, elevated liver enzymes, and low platelet count. It is a variant of the preeclampsia/eclampsia syndrome that occurs in 10% to 20% of clients whose conditions are labeled as severe. Women with HELLP syndrome are at increased risk for complications such as cerebral hemorrhage, retinal detachment, hematoma/liver rupture, acute renal failure, disseminated intravascular coagulation (DIC), placental abruption, and maternal death (Vigil-De Gracia, 2015). It is a life-threatening obstetric complication considered by many to be a severe form of preeclampsia involving hemolysis, thrombocytopenia, and liver dysfunction.

Both HELLP and preeclampsia occur during the later stages of pregnancy, and sometimes after childbirth. HELLP syndrome is a clinically progressive condition. Early diagnosis is critical to prevent liver distention, rupture, and hemorrhage and the onset of DIC. If the condition presents prenatally, morbidity and mortality can affect both mother and baby.

HELLP syndrome occurs in up to 20% of pregnant women diagnosed with severe preeclampsia. It is unique, as it is a laboratory-value specific diagnosis. Women with HELLP usually have fewer signs of abnormalities consistent with the metabolic syndrome and a lower prevalence of thrombophilia as compared with preeclampsia women without HELLP (Sibai, 2015). Although it has been reported as early as 17 weeks' gestation, most of the time it is diagnosed between 22 and 36 weeks' gestation (Cunningham et al., 2014). It can present prior to the presence of an elevated blood pressure. HELLP syndrome leads to an increased maternal risk for developing liver hematoma or rupture, stroke, cardiac arrest, seizure, pulmonary edema, DIC, subendocardial hemorrhage, adult respiratory distress syndrome, renal damage, sepsis, hypoxic encephalopathy, and maternal, or fetal death (Moses, 2015b). The recognition of HELLP syndrome and an aggressive multidisciplinary approach and prompt transfer of these women to obstetric centers with expertise in this field are required for the improvement of maternal–fetal prognosis.

Pathophysiology

The hemolysis that occurs is termed microangiopathic hemolytic anemia. This cascade of events is thought to happen when red blood cells become fragmented as they pass through small, damaged blood vessels. Elevated liver enzymes are the result of reduced blood flow to the liver secondary to obstruction from fibrin deposits. At the same time, endothelial damage and fibrin deposition in the liver may lead to liver impairment and can result in hemorrhagic necrosis, indicated by right upper quadrant tenderness, nausea, and vomiting. Hyperbilirubinemia and jaundice result from liver impairment. Low platelets result from vascular damage, the result of vasospasm, and platelets aggregate at sites of damage, resulting in thrombocytopenia in multiple sites (Khan & Meirowitz, 2015).

Therapeutic Management

The treatment for HELLP syndrome is based on the severity of the disease, the gestational age of the fetus, and the condition of the mother and fetus. The mainstay of treatment is lowering of high blood pressure with rapid-acting antihypertensive agents, prevention of convulsions or further seizures with magnesium sulfate, and use of steroids for fetal lung maturity if necessary, followed by the birth of the infant and placenta (Foley, Strong, & Garite, 2014). The client should be admitted or transferred to a tertiary center with a neonatal intensive care unit. Additional treatment includes correction of the coagulopathies that accompany HELLP syndrome. After this syndrome is diagnosed and the woman's condition is stable, birth of the infant is indicated.

Magnesium sulfate is used prophylactically to prevent seizures. Antihypertensives such as hydralazine or labetalol are given to control blood pressure. Blood component therapy—such as fresh-frozen plasma, packed red blood cells, or platelets—is transfused to address the microangiopathic hemolytic anemia. Birth may be delayed up to 96 hours so that betamethasone or dexamethasone can be given to stimulate lung maturation in the preterm fetus.

Nursing Assessment

Nursing assessment of the woman with HELLP is similar to that for the woman with severe preeclampsia. Be alert for complaints of nausea (with or without vomiting), malaise, epigastric or right upper quadrant pain, and demonstrable edema. Perform systematic assessments frequently, as indicated by the woman's condition and response to therapy.

A diagnosis of HELLP syndrome is made based on laboratory test results, including:

• Low hematocrit that is not explained by any blood loss

• Elevated LDH (liver impairment)

• Elevated AST (liver impairment)

• Elevated ALT (liver impairment)

• Elevated BUN

• Elevated bilirubin level

• Elevated uric acid and creatinine levels (renal involvement)

• Low platelet count (less than 100,000 cells/mm^3)

Nursing Management

Nursing management of the woman diagnosed with HELLP syndrome is the same as that for the woman with severe preeclampsia. If possible, the woman with HELLP syndrome should be transferred to a tertiary care center once she has been assessed and stabilized. Closely monitor the client for changes and provide ongoing support throughout this experience.

GESTATIONAL DIABETES

Gestational diabetes is a condition involving glucose intolerance that occurs during pregnancy. It is discussed in greater detail in Chapter 20.

BLOOD INCOMPATIBILITY

Blood incompatibility most commonly involves one of two issues: blood type or the Rh factor. *Blood type incompatibility*, also known as ABO incompatibility, arises when a mother with blood type O becomes pregnant with a fetus with a different blood type (type A, B, or AB). The mother's serum contains naturally occurring anti-A and anti-B, which can cross the placenta and hemolyze fetal red blood cells. It is usually less severe than Rh incompatibility. One reason is that fetal red blood cells express less of the ABO blood group antigens compared with adult levels. In addition, in contrast to the Rh antigens, the ABO blood group antigens are expressed by a variety of fetal (and adult) tissues, reducing the chances of anti-A and anti-B binding their target antigens on the fetal red blood cells. ABO incompatibility rarely causes significant hemolysis, and prenatal treatment is not warranted.

Rh isoimmunization occurs when a pregnant woman's immune system creates antibodies against fetal Rh blood factors. Although the mother will exhibit no symptoms of Rh incompatibility, Rh antibodies adversely affect fetal health. Rh antibodies can cause fetal heart problems, breathing difficulties, jaundice, and a form of anemia known as hemolytic disease of the newborn. Rh sensitization occurs in approximately 1 in 1,000 births to Rh-negative women (March of Dimes, 2015d). Today RH isoimmunization in pregnant women and hemolytic disease of the newborn are rarely seen, primarily because women who are Rh negative are given anti-D immune globulin prophylaxis (RhoGAM) in the third trimester of pregnancy and after childbirth if the newborn is Rh positive.

Pathophysiology

ABO Incompatibility

Hemolysis associated with ABO incompatibility is limited to type O mothers with fetuses who have type A or B blood. In mothers with type A and B blood, naturally occurring antibodies are of the IgM class, which do not cross the placenta, whereas in type O mothers, the antibodies are predominantly IgG in nature. Because A and B antigens are widely expressed in a variety of tissues besides red blood cells, only a small portion of the antibodies crossing the placenta is available to bind to fetal red cells. In addition, fetal red cells appear to have less surface expression of A or B antigen, resulting in few reactive sites —hence the low incidence of significant hemolysis in affected neonates.

With ABO incompatibility, usually the mother is blood type O, with anti-A and anti-B antibodies in her serum; the infant is blood type A, B, or AB. The incompatibility arises as a result of the interaction of antibodies present in maternal serum and the antigen sites on the fetal red cells.

Rh Incompatibility

Rh incompatibility is a condition that develops when a woman with Rh-negative blood type is exposed to Rh-positive blood cells and subsequently develops circulating titers of Rh antibodies. Individuals with Rh-positive blood type have the D antigen present on their red cells, whereas individuals with an Rh-negative blood type do not. The presence or absence of the Rh antigen on the RBC membrane is genetically controlled.

In the United States, about 15% of the White population, 5% to 8% of the African American and Hispanic populations, and 1% to 2% of the Asian and Native American populations are Rh negative. The vast majority (85%) of individuals is considered Rh positive (March of Dimes, 2015d).

Rh incompatibility most commonly arises with exposure of an Rh-negative mother to Rh-positive fetal blood during pregnancy or birth, during which time erythrocytes from the fetal circulation leak into the maternal circulation. Isoimmunization can also occur during an amniocentesis, ectopic pregnancy, placenta previa, placenta abruption, in utero fetal death, spontaneous abortion, or abdominal/pelvic trauma. After a significant exposure, alloimmunization or

sensitization occurs. As a result, maternal antibodies are produced against the foreign Rh antigen.

Theoretically, fetal blood and maternal blood do not mix during pregnancy. In reality, however, small placental accidents (transplacental bleeds secondary to minor separation), abortions, ectopic pregnancy, abdominal trauma, trophoblastic disease, amniocentesis, placenta previa, and abruptio placentae allow fetal blood to enter the maternal circulation and initiate the production of antibodies to destroy Rh-positive blood. The amount of fetal blood necessary to produce Rh incompatibility varies. In one study, less than 1 mL of Rh-positive blood was shown to result in sensitization of women who are Rh negative (Salem & Singer, 2015).

Once sensitized, it takes approximately a month for Rh antibodies in the maternal circulation to cross over into the fetal circulation. In 90% of cases, sensitization occurs during delivery (Cunningham et al., 2014). Thus, most firstborn infants with Rh-positive blood type are not affected because the short period from first exposure of Rh-positive fetal erythrocytes to the birth of the infant is insufficient to produce a significant maternal IgG antibody response.

The risk and severity of alloimmune response increase with each subsequent pregnancy involving a fetus with Rh-positive blood. A second pregnancy with an Rh-positive fetus often produces a mildly anemic infant, whereas succeeding pregnancies produce infants with more serious hemolytic anemia.

Nursing Assessment

At the first prenatal visit, determine the woman's blood type and Rh status. Also obtain a thorough health history, noting any reports of previous events involving hemorrhage to delineate the risk for prior sensitization. When the client's history reveals an Rh-negative mother who may be pregnant with an Rh-positive fetus, prepare the client for an antibody screen (indirect Coombs test) to determine whether she has developed isoimmunity to the Rh antigen. This test detects unexpected circulating antibodies in a woman's serum that could be harmful to the fetus (Davidson, 2014).

Nursing Management

If the indirect Coombs test is negative (meaning no antibodies are present), then the woman is a candidate for RhoGAM. If the test is positive, RhoGAM is of no value because isoimmunization has occurred. In this case, the fetus is carefully monitored for hemolytic disease.

The incidence of isoimmunization has declined dramatically as a result of prenatal and postnatal RhoGAM administration after any event in which blood transfer may occur. The standard dose is 300 mcg, which is effective for 15 mL of fetal blood cells. Rh immunoglobulin helps to destroy any fetal cells in the maternal circulation before sensitization occurs, thus inhibiting maternal antibody production. This provides temporary passive immunity, thereby preventing maternal sensitization.

The current recommendation is for every Rh-negative nonimmunized woman to receive RhoGAM at some point between 28 and 32 weeks' gestation and again within 72 hours after giving birth. Other indications for RhoGAM include:
• Ectopic pregnancy
• Chorionic villus sampling
• Amniocentesis
• Prenatal hemorrhage
• Molar pregnancy
• Maternal trauma
• Percutaneous umbilical sampling
• Therapeutic or spontaneous abortion
• Fetal death
• Fetal surgery (King et al., 2015).

Despite the availability of RhoGAM and laboratory tests to identify women and newborns at risk, isoimmunization remains a serious clinical reality that continues to contribute to perinatal and neonatal mortality. Nurses, as client advocates, are in a unique position to make sure test results are brought to the health care provider's attention so appropriate interventions can be initiated. In addition, nurses must stay abreast of current literature and research regarding isoimmunization and its management. Stress to all women that early prenatal

care can help identify and prevent this condition. Because Rh incompatibility is preventable with the use of RhoGAM, prevention remains the best treatment. Nurses can make a tremendous impact to ensure positive outcomes for the greatest possible number of pregnancies through education.

AMNIOTIC FLUID IMBALANCES

Amniotic fluid develops from several maternal and fetal structures, including the amnion, chorion, maternal blood, fetal lungs, gastrointestinal tract, kidneys, and skin. Any alteration in one or more of the various sources will alter the amount of amniotic fluid. Polyhydramnios and oligohydramnios are two imbalances associated with amniotic fluid.

Polyhydramnios

Polyhydramnios, also called hydramnios, is a condition in which there is too much amniotic fluid (more than 2,000 mL) surrounding the fetus between 32 and 36 weeks. It occurs in approximately 2% of all pregnancies and is associated with fetal anomalies of development such as upper gastrointestinal obstruction or atresias, neural tube defects, and anterior abdominal-wall defects, together with impaired swallowing in fetuses with chromosomal anomalies, such as trisomy 13 and 18 (Carter & Boyd, 2015). Approximately 18% of all women with diabetes will develop polyhydramnios during their pregnancy. There is an increase in cesarean births for fetal labor intolerance, low 5-min Apgar scores, increased neonatal birth weight, congenital anomalies, and newborn intensive care unit admissions for women with too much amniotic fluid at term (Moore, 2015). Overall, it is associated with poorer fetal outcomes because of the increased incidence of preterm births, fetal malpresentation, and cord prolapse.

There are several causes of polyhydramnios. Generally, too much fluid is being produced, there is a problem with the fluid being taken up, or both. It can be associated with maternal disease and fetal anomalies, but it can also be idiopathic (of unknown cause) in nature.

Therapeutic Management

Treatment may include close monitoring and frequent follow-up visits with the health care provider if the polyhydramnios is mild to moderate. In severe cases in which the woman is in pain and experiencing shortness of breath, an amniocentesis or artificial rupture of the membranes is done to reduce the fluid and the pressure. Removal of fluid by amniocentesis is only transiently effective. A noninvasive treatment may involve the use of a prostaglandin synthesis inhibitor (indomethacin) to decrease amniotic fluid volume by decreasing fetal urinary output, but this may cause premature closure of the fetal ductus arteriosus (King et al., 2015).

Nursing Assessment

Begin the assessment with a thorough history, being alert to risk factors such as maternal diabetes or multiple gestations. Review the maternal history for information about possible fetal anomalies including fetal esophageal or

intestinal atresia, neural tube defects, chromosomal deviations, fetal hydrops, CNS or cardiovascular anomalies, and hydrocephaly.

Determine the gestational age of the fetus and measure the woman's fundal height. With polyhydramnios, there is a discrepancy between fundal height and gestational age, or a rapid growth of the uterus is noted. Assess the woman for complaints of discomfort in her abdomen, such as being severely stretched and tight. Also note any reports of uterine contractions, which may result from overstretching of the uterus. Assess for shortness of breath resulting from pressure on her diaphragm and inspect her lower extremities for edema, which results from increased pressure on the vena cava. Palpate the abdomen and obtain fetal heart rate. Often the fetal parts and heart rate are difficult to obtain because of the excess fluid present.

Prepare the woman for possible diagnostic testing to evaluate for the presence of possible fetal anomalies. An ultrasound usually is done to measure the pockets of amniotic fluid to estimate the total volume. In some cases, ultrasound also is helpful in finding the etiology of polyhydramnios, such as multiple pregnancy or a fetal structural anomaly.

Nursing Management

Nursing management of the woman with polyhydramnios focuses on ongoing assessment and monitoring for symptoms of abdominal pain, dyspnea, uterine contractions, and edema of the lower extremities. Explain to the woman and her family that this condition can cause her uterus to become overdistended and may lead to preterm labor and preterm rupture of membranes. Outline the signs and symptoms of both conditions and instruct the woman to contact her health care provider if they occur. If a therapeutic amniocentesis is performed, assist the health care provider and monitor maternal and fetal status throughout for any changes.

Oligohydramnios

Oligohydramnios is a decreased amount of amniotic fluid (less than 500 mL) between 32 and 36 weeks' gestation. It occurs in approximately 4% of all pregnancies. Oligohydramnios may result from any condition that prevents the fetus from making urine or blocks it from going into the amniotic sac. Oligohydramnios occurs in about four out of every 100 pregnancies. It is most common in the last trimester of pregnancy, but it can develop at any time in the pregnancy. About one out of eight women whose pregnancies last 2 weeks past the due date develops oligohydramnios. This happens as amniotic fluid levels naturally decline. This condition puts the fetus at an increased risk of perinatal morbidity and mortality (March of Dimes, 2015e). Reduction in amniotic fluid reduces the ability of the fetus to move freely without risk of cord compression, which increases the risk for fetal death and intrapartal hypoxia.

Therapeutic Management

The woman with oligohydramnios can be managed on an outpatient basis with serial ultrasounds and fetal surveillance through nonstress testing and biophysical profiles. As long as fetal well-being is demonstrated with frequent testing, no intervention is necessary. If fetal well-being is compromised, however, birth is planned along with amnioinfusion (the transvaginal infusion of crystalloid fluid to compensate for the lost amniotic fluid). The fluid is introduced into the uterus through an intrauterine pressure catheter. The infusion is administered in a controlled fashion to prevent overdistention of the uterus. Amnioinfusion is thought to improve abnormal fetal heart rate patterns, decrease cesarean births, and possibly minimize the risk of neonatal meconium aspiration syndrome, but more studies need to be done to validate this (Carter & Boyd, 2015).

Nursing Assessment

Review the maternal history for factors associated with oligohydramnios, including:

• Uteroplacental insufficiency

• Premature rupture of membranes prior to labor onset

- Hypertension of pregnancy
- Maternal diabetes
- Intrauterine growth restriction
- Post-term pregnancy
- Fetal renal agenesis
- Polycystic kidneys
- Urinary tract obstructions

Assess the client for complaints of fluid leaking from the vagina. Leaking of amniotic fluid from the vagina occurs with rupture of the amniotic sac. Leaking in conjunction with a uterus that is small for expected dates of gestation also suggests oligohydramnios. Unfortunately, the woman may not present with any symptoms. Typically, the reduced volume of amniotic fluid is identified on ultrasound.

Nursing Management

Nursing management of the woman with oligohydramnios involves continuous monitoring of fetal well-being during nonstress testing or during labor and birth by identifying category II and III patterns on the fetal monitor. Variable decelerations indicating cord compression are common. Changing the woman's position might be therapeutic in altering this fetal heart rate pattern. After the birth, evaluate the newborn for signs of postmaturity, congenital anomalies, and respiratory difficulty.

Assist with amnioinfusion as indicated and continue to assess the woman's vital signs and contraction status and the fetal heart rate throughout the procedure. Provide comfort measures such as changing the bed linens and the woman's bed clothes frequently because of the constant leakage of fluid from the vagina. Also provide frequent perineal care during the infusion.

MULTIPLE GESTATION

Multiple gestation is defined as a pregnancy with two or more fetuses.. This includes twins, triplets, and higher-order multiples such as quadruplets. In the past two decades, the number of multiple gestations in the United States has jumped dramatically because of the widespread use of fertility drugs, older age of women having babies, and the development of assisted reproductive technologies to treat infertility. About one third of live births from assisted reproductive technology result in more than one infant, and twins represent 85% of those multiple-birth children (De Sutter, 2015).

In the United States, the overall prevalence of twins is approximately 12 per 1,000, and two thirds are dizygotic (derived from two separate ova [March of Dimes, 2015f]). The increasing number of multiple gestations is a concern because women who are expecting more than one infant are at high risk for preterm labor, polyhydramnios, hyperemesis gravidarum, anemia, preeclampsia, and antepartum hemorrhage. Fetal/newborn risks or complications include prematurity, respiratory distress syndrome, birth asphyxia/perinatal depression, congenital anomalies (CNS, cardiovascular, and gastrointestinal defects), twin-to-twin transfusion syndrome (transfusion of blood from one twin [i.e., donor] to the other twin [i.e., recipient]), intrauterine growth restriction, and becoming conjoined twins (Martin, Fanaroff, & Walsh, 2014).

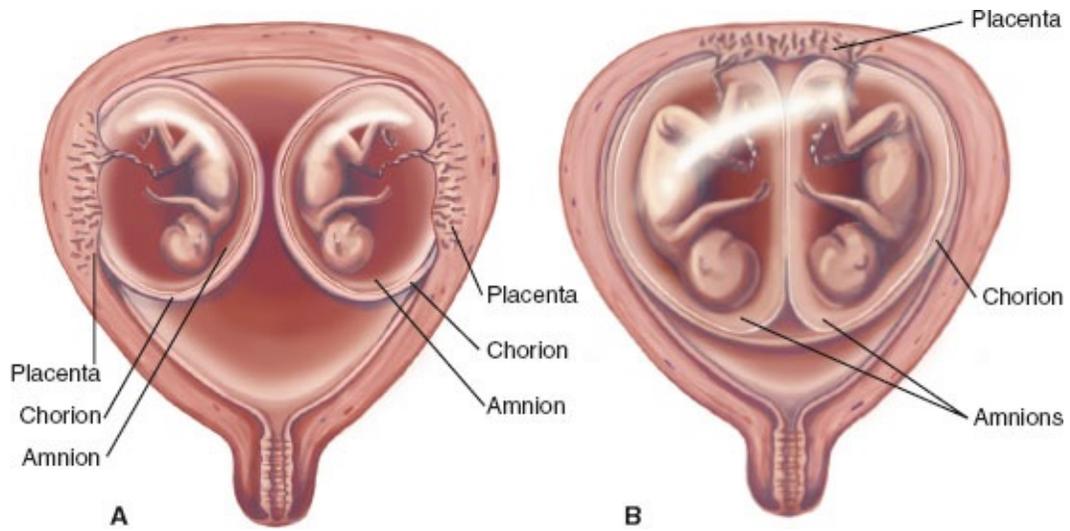
The two types of twins are monozygotic and dizygotic (Fig. 19.6). Monozygotic twins develop when a single, fertilized ovum splits during the first 2 weeks after conception. Monozygotic twins also are called identical twins. Two sperm fertilizing two ova produce dizygotic twins, which are called fraternal twins. Separate amnions, chorions, and placentas are formed in dizygotic twins. Triplets can be monozygotic, dizygotic, or trizygotic.


FIGURE 19.6 Multiple gestation with twins. **A.** Dizygotic twins, where each fetus has its own placenta, amnion, and chorion. **B.** Monozygotic twins, where the fetuses share one placenta, two amnions, and one chorion.

Therapeutic Management

When a multiple gestation is confirmed, the woman is followed with serial ultrasounds to assess fetal growth patterns and development. Biophysical profiles along with nonstress tests are ordered to determine fetal well-being. Many women are hospitalized in late pregnancy to prevent preterm labor and receive closer surveillance. During the intrapartum period the woman is closely monitored, with a perinatal team available to assist after birth. Operative delivery is frequently needed due to fetal malpresentation.

Nursing Assessment

Obtain a health history and perform a physical examination. Be alert for complaints of fatigue and severe nausea and vomiting. Assess the woman's abdomen and fundal height. Typically with a multiple gestation the uterus is larger than expected based on the estimated date of birth. Laboratory test results may reveal anemia. Prepare the woman for ultrasound, which typically confirms the diagnosis of a multiple gestation.

Nursing Management

During the prenatal period, provide education and support for the woman regarding nutrition, increased rest periods, and close observation for pregnancy complications such as anemia, excessive weight gain, proteinuria, edema, vaginal bleeding, and hypertension. Instruct the woman to be alert for and report immediately any signs and symptoms of preterm labor: contractions, uterine cramping, low back ache, increase in vaginal discharge, loss of mucus plug, pelvic pain, and pressure.

With the onset of labor, expect to monitor fetal heart rates continuously. Prepare the woman for an ultrasound to assess the presentation of each fetus to determine the best delivery approach. Ensure that extra nursing staff and the perinatal team are available for any birth or newborn complications.

After the babies are born, closely assess the woman for hemorrhage by frequently assessing uterine involution. Palpate the uterine fundus and monitor the amount and characteristics of lochia.

Throughout the entire pregnancy, birth, and hospital stay, inform and support the woman and her family. Encourage them to ask questions and verbalize any fears and concerns.

PREMATURE RUPTURE OF MEMBRANES

Premature rupture of membranes (**PROMs**) is the rupture of the bag of waters before the onset of true labor. There are a number of associated conditions and complications, such as infection, prolapsed cord, abruptio placentae, and preterm labor. High-risk factors associated with preterm PROM include low socioeconomic status, multiple gestation, low BMI, tobacco use, history of preterm labor, placenta previa, abruptio placentae, urinary tract infection, vaginal bleeding at any time in pregnancy, cerclage, and amniocentesis (Jazayeri, 2015).

If prolonged (greater than 24 hours), the woman's risk for infection (chorioamnionitis, endometritis, sepsis, and neonatal infections) increases and continues to increase the longer the time since the bag of waters ruptured. The time interval from rupture of membranes to the onset of regular contractions is termed the latent period.

Women with PROM present with leakage of fluid, vaginal discharge, vaginal bleeding, and pelvic pressure, but they are not having contractions. PROM is diagnosed by speculum vaginal examination of the cervix and vaginal cavity. Pooling of fluid in the vagina or leakage of fluid from the cervix, ferning of the dried fluid under microscopic examination, and alkalinity of the fluid as determined by nitrazine paper (ph indicator) confirm the diagnosis.

The terminology of PROM can be confusing. PROM is rupture of the membranes prior to the onset of labor and is used appropriately when referring to a woman who is beyond 37 weeks' gestation, has presented with spontaneous rupture of the membranes, and is not in labor. A related term is **preterm premature rupture of membranes** (**PPROM**), which is defined as rupture of membranes prior to the onset of labor in a woman who is *less* than 37 weeks' gestation. Perinatal risks associated with PPROM may stem from immaturity, including respiratory distress syndrome, intraventricular hemorrhage, patent ductus arteriosus, and necrotizing enterocolitis. Eighty-five percent of neonatal morbidity and mortality is a result of prematurity. PPROM is associated with 30% to 40% of preterm deliveries and is the leading identifiable cause of preterm delivery. PPROM complicates 3% of all pregnancies and occurs in approximately 150,000 pregnancies yearly in the United States (Jazayeri, 2015).

The exact cause of PROM is not known, but may be associated with vaginal

bleeding, placental abruption, microbial invasion of the amniotic cavity, and defective placentation. In many cases, PROM occurs spontaneously. Increasing evidence associates abnormalities in vaginal flora during pregnancy with preterm labor and birth with potential neonatal sequelae due to prematurity and poor perinatal outcome (Gilbert, 2014). A recent study found that women with previous PPROM are at increased risk for recurrence, and a short interval between pregnancies is associated with increased risk (Gibbins et al., 2014).

Therapeutic Management

Treatment of PROM typically depends on the gestational age. Under no circumstances is an unsterile digital cervical examination done until the woman enters active labor, to minimize infection exposure. If the fetal lungs are mature, induction of labor is initiated. PROM is not a lone indicator for surgical birth. If the fetal lungs are immature, expectant management is carried out with adequate hydration, reduced physical activity, pelvic rest, and close observation for possible infection, such as with frequent monitoring of vital signs and laboratory test results (e.g., the white blood cell count). Corticosteroids may be given to enhance fetal lung maturity if lungs are immature, although this remains controversial. Recent studies have shown clear benefits of antibiotics to decrease neonatal morbidity associated with PPROM (Mattson & Smith, 2016).

Nursing Assessment

Nursing assessment focuses on obtaining a complete health history and performing a physical examination to determine maternal and fetal status. An accurate assessment of the gestational age and knowledge of the maternal, fetal, and neonatal risks are essential to appropriate evaluation, counseling, and management of women with PROM and PPROM. Nurses need to be aware that the risk of infection increases with the duration of PPROM.

Health History and Physical Examination

Review the maternal history for risk factors such as infection, increased uterine size (polyhydramnios, macrosomia, multiple gestation), uterine and fetal anomalies, lower socioeconomic status, STIs, cervical insufficiency, vaginal bleeding, and cigarette smoking during pregnancy. Ask about any history or current symptoms of urinary tract infection (frequency, urgency, dysuria, or flank pain) or pelvic or vaginal infection (pain or vaginal discharge).

Assess for signs and symptoms of labor, such as cramping, pelvic pressure, or back pain. Also assess her vital signs, noting any signs indicative of infection such as fever and elevated white blood cell count (more than 18,000 cells/mm^3) (Nagtalon-Ramos, 2014).

Institute continuous electronic fetal heart rate monitoring to evaluate fetal well-being. Conduct a vaginal examination to ascertain the cervical status in PROM. If PPROM exists, a sterile speculum examination (where the examiner inspects the cervix but does not palpate it) is done rather than a digital cervical examination because it may diminish latency (period of time from rupture of membranes to birth) and increase newborn morbidity (Cunningham et al., 2014).

Observe the characteristics of the amniotic fluid. Note any evidence of meconium, or a foul odor. When meconium is present in the amniotic fluid, it typically indicates fetal distress related to hypoxia. Meconium stains the fluid yellow to greenish brown, depending on the amount present. A foul odor of amniotic fluid indicates infection. Also observe the amount of fluid. A decreased amount of amniotic fluid reduces the cushioning effect, thereby making cord compression a possibility. Some research shows that restoring the volume of lost amniotic fluid will help to reduce the risk of infection and reduce cord compression. See Evidence-Based Practice 19.1. Key assessments are

summarized in Box 19.3.

EVIDENCE-BASED PRACTICE 19.1 A LOW-DOSE ASPIRIN FOR PREVENTING PREECLAMPSIA AND ITS COMPLICATIONS: A META-ANALYSIS

STUDY

Preeclampsia is a major cause of perinatal mortality and morbidity worldwide. The etiology of it remains unclear, but it is thought that the condition arises because of abnormal trophoblastic invasion of uterine vessels or endothelial cell activation and dysfunction. Low-dose aspirin is thought to prevent preeclampsia in high-risk pregnancy, but it is not universally used because of safety concerns. The World Health Organization (WHO) and the US Preventive Services Task Force (USPSTF) both recommend using low-dose aspirin in women at high risk for preeclampsia. A systematic review and meta-analysis were analyzed using 29 studies involving 21,403 women.

Findings

The meta-analysis showed that low-dose aspirin significantly reduced the incidence of preeclampsia. Risk of preeclampsia was reduced when initiated before 16 weeks gestation. Prophylactic low-dose aspirin, especially initiated before 16 weeks' gestation, is effective at preventing preeclampsia, preterm birth, and fetal growth restriction in high-risk pregnancies.

Nursing Implications

Based on the study's results, nurses can be involved in prenatal assessments of the high-risk mother to identify them early so that prophylactic low-dose aspirin can be prescribed if deemed appropriate by the health care provider. The nurse can provide instruction and rationales for the use and timing of this therapy to the clients. Two major professional health organizations have recommended this therapy to prevent preeclampsia, so nurses can view this therapy as an evidence-based intervention to promote better outcomes for mothers and their infants.

Adapted from Xu, T. T., Zhou, F., Deng, C. Y., Huang, G. Q., Li, J. K., & Wang, X. D. (2015). Low-dose aspirin for preventing preeclampsia and its complications: A meta-analysis. *The Journal of Clinical Hypertension*. 17(7), 567–573.

BOX 19.3

KEY ASSESSMENTS WITH PREMATURE RUPTURE OF MEMBRANES

For the woman with PROM, the following assessments are essential:

• Determining the date, time, and duration of membrane rupture by client interview.

• Ascertaining gestational age of the fetus based on date of mother's last menstrual period, fundal height, and ultrasound dating.

• Questioning the woman about possible history of or recent UTI or vaginal infection that might have contributed to PROM.

• Assessing for any associated labor symptoms, such as back pain or pelvic pressure.

• Assisting with or performing diagnostic tests to validate leakage of fluid, such as Nitrazine test, "ferning" on slide, and ultrasound. Contamination of Nitrazine tape with lubricant or insufficient fluid will render the assessment unreliable.

• Continually assessing for signs of infection including:

  • Elevation of maternal temperature and pulse rate

  • Abdominal/uterine tenderness

  • Fetal tachycardia more than 160 bpm

  • Elevated white blood cell count and C-reactive protein

  • Cloudy, foul-smelling amniotic fluid

Adapted from Nagtalon-Ramos, J. (2014). *Maternal-newborn nursing care: Best evidence-based practices.* Philadelphia, PA: F. A. Davis Company; Cunningham, F. G., Leveno, K. J., Bloom, S. L., Spong, C. Y., Dashe, J. S., Hoffman, B. L., et al. (2014). *Williams' obstetrics* (24th ed.). New York, NY: McGraw-Hill Education; and Magowan, B. A., Owen, P., & Thomson, A. (2014). *Clinical obstetrics & gynecology* (3rd ed.). St. Louis, MO: Saunders Elsevier.

Laboratory and Diagnostic Testing

To diagnose PROM or PPROM, several procedures may be used: the nitrazine test, fern test, or ultrasound. After the insertion of a sterile speculum, a sample of the fluid in the vaginal area is obtained. With a nitrazine test, the pH of the fluid is tested; amniotic fluid is more basic (7.0) than normal vaginal secretions (4.5). Nitrazine paper turns blue in the presence of amniotic fluid. However, false-positive results can occur if blood, urine, semen, or antiseptic chemicals are also present; all will increase the pH.

For the fern test, a sample of vaginal fluid is place on a slide to be viewed directly under a microscope. Amniotic fluid will develop a fern-like pattern when it dries because of sodium chloride crystallization. If both of these tests are inconclusive, a transvaginal ultrasound can also be used to determine whether membranes have ruptured by demonstrating a decreased amount of amniotic fluid (oligohydramnios) in the uterus (Jazayeri, 2015).

Other laboratory and diagnostic tests that may be used include:

• Urinalysis and urine culture for UTI or asymptomatic bacteriuria

• Cervical test or culture for chlamydia or gonorrhea

• Vaginal culture for bacterial vaginosis and trichomoniasis

• Vaginal introital/rectal culture for group B streptococcus

Nursing Management

Nursing management for the woman with PROM or PPROM focuses on preventing infection and identifying uterine contractions. The risk for infection is great because of the break in the amniotic fluid membrane and its proximity to vaginal bacteria. Therefore, monitor maternal vital signs closely. Be alert for a temperature elevation or an increase in pulse, which could indicate infection. Also monitor the fetal heart rate continuously, reporting any fetal tachycardia (which could indicate a maternal infection) or variable decelerations (suggesting cord compression). If variable decelerations are present, anticipate amnioinfusion based on agency policy. Evaluate the results of laboratory tests such as a CBC. An elevation in white blood cells would suggest infection. Administer antibiotics if ordered.

Encourage the woman and her partner to verbalize their feelings and concerns. Educate them about the purpose of the protective membranes and the implications of early rupture. Keep them informed about planned interventions, including potential complications and required therapy. As appropriate, prepare the woman for induction or augmentation of labor as appropriate if she is near term.

If labor does not start within 48 hours, the woman with PPROM may be discharged home on expectant management, which may include:

• Antibiotics if cervicovaginal cultures are positive

• Activity restrictions

• Education about signs and symptoms of infection and when to call with problems or concerns (Teaching Guidelines 19.3)

• Frequent fetal testing for well-being

• Ultrasound every 3 to 4 weeks to assess amniotic fluid levels

• Possible corticosteroid treatment depending on gestational age

• Daily kick counts to assess fetal well-being

Teaching Guidelines 19.3

TEACHING FOR THE WOMAN WITH PPROM

- Monitor your baby's activity by performing fetal kick counts daily.
- Check your temperature daily and report any temperature increases to your health care provider.
- Watch for signs related to the beginning of labor. Report any tightening of the abdomen or contractions.
- Avoid any touching or manipulating of your breasts, which could stimulate labor.
- Do not insert anything into your vagina or vaginal area—no tampons, avoid vaginal intercourse
- Do not swim in pools or in the ocean or sit in a hot tub or Jacuzzi.
- Take showers for daily hygiene needs; avoid sitting in a tub bath.
- Maintain any specific activity restrictions as recommended.
- Wash your hands thoroughly after using the bathroom and make sure to wipe from front to back each time.
- Keep your perineal area clean and dry.
- Take your antibiotics as directed if your health care provider has prescribed them.
- Call your health care provider with changes in your condition, including fever, uterine tenderness, feeling like your heart is racing, and foul-smelling vaginal discharge.

KEY CONCEPTS

- Identifying risk factors early on and throughout the pregnancy is important to ensure the best outcome for every pregnancy. Risk assessment should start with the first prenatal visit and continue with subsequent visits.
- The three most common causes of hemorrhage early in pregnancy (first half of pregnancy) are spontaneous abortion, ectopic pregnancy, and GTD.
- Ectopic pregnancies occur in about 1 in 50 pregnancies and have increased dramatically during the past few decades.
- Having a molar pregnancy results in the loss of the pregnancy and the

possibility of developing choriocarcinoma, a chronic malignancy from the trophoblastic tissue.

- The classic clinical picture presentation for placenta previa is painless, bright-red vaginal bleeding occurring during the third trimester.

- Treatment of abruptio placentae is designed to assess, control, and restore the amount of blood lost; to provide a positive outcome for both mother and infant; and to prevent coagulation disorders.

- DIC can be described in simplest terms as a loss of balance between the clot-forming activity of thrombin and the clot-lysing activity of plasmin.

- Hyperemesis gravidarum is a complication of pregnancy characterized by persistent, uncontrollable nausea and vomiting before the 20th week of gestation.

- Gestational hypertension is the leading cause of maternal death in the United States and the most common complication reported during pregnancy.

- HELLP is an acronym for hemolysis, elevated liver enzymes, and low platelets.

- Rh incompatibility is a condition that develops when a woman of Rh-negative blood type is exposed to Rh-positive fetal blood cells and subsequently develops circulating titers of Rh antibodies.

- Polyhydramnios occurs in approximately 3% to 4% of all pregnancies and is associated with fetal anomalies of development.

- Nursing care related to the woman with oligohydramnios involves continuous monitoring of fetal well-being during nonstress testing or during labor and birth by identifying category II and III patterns on the fetal monitor.

- The increasing number of multiple gestations is a concern because women who are expecting more than one infant are at high risk for preterm labor, hydramnios, hyperemesis gravidarum, anemia, preeclampsia, and antepartum hemorrhage.

- Nursing care related to PROM centers on infection prevention and identification of preterm labor contractions.

- Monitoring maternal vital signs for changes and the fetal hearth rate once PPROM occurs is essential to increasing the changes of a good outcome.

- It is essential that nurses educate all pregnant women how to detect the early signs of PROM and what action is needed if it happens.

CHAPTER **WORKSHEET**

MULTIPLE CHOICE QUESTIONS

1. Which of the following women should receive RhoGAM postpartum?
    a. Nonsensitized Rh-negative mother with an Rh-negative newborn
    b. Nonsensitized Rh-negative mother with an Rh-positive newborn
    c. Sensitized Rh-negative mother with an Rh-positive newborn
    d. Sensitized Rh-negative mother with an Rh-negative newborn

2. A woman is suspected of having abruptio placentae. Which of the following
    would the nurse expect to assess as a classic symptom?
    a. Painless, bright-red bleeding
    b. "Knife-like" abdominal pain
    c. Excessive nausea and vomiting
    d. Hypertension and headache

3. RhoGAM is given to Rh-negative women to prevent maternal sensitization. In addition to pregnancy, Rh-negative women would also receive this medication after which of the following?

    a. Therapeutic or spontaneous abortion

    b. Head injury from a car accident

    c. Blood transfusion after a hemorrhage

    d. Unsuccessful artificial insemination procedure

4. After teaching a woman about hyperemesis gravidarum and how it differs from the typical nausea and vomiting of pregnancy, which statement by the woman indicates that the teaching was successful?

    a. "I can expect the nausea to last through my second trimester."

    b. "I should drink fluids with my meals instead of in between them."

    c. "I need to avoid strong odors, perfumes, or flavors."

    d. "I should lie down after I eat for about 2 hours."

5. A pregnant woman, approximately 12 weeks' gestation, comes to the emergency department after calling her health care provider's office and reporting moderate vaginal bleeding. Assessment reveals cervical dilation and moderately strong abdominal cramps. She reports that she has passed some tissue with the bleeding. The nurse interprets these findings to suggest which of the following?

    a. Threatened abortion

    b. Inevitable abortion

    c. Incomplete abortion

    d. Missed abortion

6. When administering magnesium sulfate to a client with preeclampsia, the nurse explains to her that this drug is given to:

    a. Reduce blood pressure

    b. Increase the progress of labor

    c. Prevent seizures

    d. Lower blood glucose levels

7. A woman is being discharged after receiving treatment for a hydatidiform molar pregnancy. The nurse should include which of the following in her discharge teaching?

    a. Do not become pregnant for at least a year; use contraceptives to prevent it

    b. Have the client's blood pressure checked weekly in the clinic

    c. RhoGAM must be given within the next month to her at the clinic

    d. An amniocentesis can detect a recurrence of this disorder in the future

CRITICAL THINKING EXERCISE

1. A 16-year-old primigravida, presents to the maternity clinic complaining of continual nausea and vomiting for the past 3 days. She states that she is approximately 15 weeks pregnant and has been unable to hold anything down or take any fluids in without throwing up for the past 3 days. She reports she is dizzy and weak. On examination, Suzanne appears pale and anxious. Her mucous membranes are dry, skin turgor is poor, and her lips are dry and cracked.

    a. What is your impression of this condition?

    b. What risk factors does Suzanne have?

    c. What intervention is appropriate for this woman?

2. An obese 39-year-old primigravida of African–American descent who is diagnosed with gestational hypertension. Her history reveals that her sister developed preeclampsia during her pregnancy. When describing her diet to the nurse, this client mentions that she tends to eat a lot of fast food.

    a. What risk factors does this client have that increase her risk for gestational hypertension?

    b. When assessing this client, what assessment findings would lead the nurse to suspect that this client has developed severe preeclampsia?

STUDY ACTIVITIES

1. Ask a community health maternity nurse how the signs and symptoms of gestational hypertension (including preeclampsia and eclampsia) are taught, and how effective efforts have been to reduce the incidence in the area.

2. Find a website designed to help parents who have suffered a pregnancy loss secondary to a spontaneous abortion. What is its audience level? Is the information up to date?

3. A pregnancy in which the blastocyst implants outside the uterus is a/an _____ pregnancy.

4. The most serious complication of hydatidiform mole is the development of _____ afterward.

5. Discuss various activities a woman with a multiple gestation could engage in to help pass the time when ordered to be on bed rest at home for 2 months.

BRINGING IT ALL TOGETHER: CASE STUDY

A 21-year-old woman presented to the local Public Health maternity clinic with a chief complaint of intermittent vaginal bleeding, abdominal cramping, and nausea. She stated her last menstrual period was 8 weeks ago and she had done a home pregnancy test prior to coming here, which was positive. She was taking no medications and had no known drug allergies. She did admit that she was a half-pack a day smoker, but had been trying to quit.

ASSESSMENT

The nurse started to take her history which revealed that this client had been taking oral contraceptives until approximately 3 months ago when her copayment went up and she did not get her prescription filled because they did not have the money. She also reported that she had a dilation and curettage (D & C) for dysfunctional bleeding about a year ago because she did not respond to medications. Her sexual history revealed that she had five sexual partners in the past with inconsistent use of condoms with those partners. She had tested positive for gonorrhea and chlamydia and was treated for that about 6 months ago. Her retest was negative. Her vital signs were within normal range and the remainder of her physical examination was unremarkable.

Nursing Management of the Pregnancy at Risk: Selected Health Conditions and Vulnerable Populations

KEY TERMS

acquired immunodeficiency syndrome (AIDS)
adolescence
anemia
fetal alcohol spectrum disorder (FASD)
gestational diabetes mellitus
glycosylated hemoglobin (HbA1C) level
human immunodeficiency virus (HIV)

impaired fasting glucose
impaired glucose tolerance
multiple sclerosis (MS)
neonatal abstinence syndrome (NAS)
perinatal drug abuse
pica
pregestational diabetes
rheumatoid arthritis (RA)
systemic lupus erythematosus (SLE)
teratogen
type 1 diabetes
type 2 diabetes

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Select at least two conditions present before pregnancy that can have a negative effect on a pregnancy.
2. Examine how a condition present before pregnancy can affect the woman physiologically and psychologically when she becomes pregnant.
3. Evaluate the nursing assessment and management for a pregnant woman with diabetes from that of a pregnant woman without diabetes.
4. Explore how congenital and acquired heart conditions can affect a woman's pregnancy.
5. Design the nursing assessment and management of a pregnant woman with cardiovascular disorders and respiratory conditions.
6. Differentiate among the types of anemia affecting pregnant women in terms of prevention and management.
7. Relate the nursing care needed for the pregnant woman with an autoimmune disorder.
8. Compare the most common infections that can jeopardize a pregnancy, and propose possible preventive strategies.
9. Develop a plan of care for the pregnant woman who is HIV positive.
10. Outline the nurse's role in the prevention and management of adolescent pregnancy.
11. Determine the impact of pregnancy on a woman over the age of 35.
12. Analyze the effects of substance abuse during pregnancy.

> ***Rose,*** *a thin 16-year-old appearing very pregnant, came into the clinic wheezing and having difficulty catching her breath. She had missed several previous prenatal visits but arrived at the clinic today in distress. Rose has a history of asthma since she was 5 years old. How might Rose's current condition affect her pregnancy? Is this picture typical of the pregnant woman with asthma?*

Words of Wisdom

As the sun sets each day, nurses should make sure they have done something for others, and should try to be understanding even under the most difficult of conditions.

INTRODUCTION

Pregnancy and childbirth are exciting yet complex facets within the continuum of women's health. Pregnancy is a special time in most women's lives, but the 9-month waiting period can be very anxiety-producing if it is complicated by a medical condition which might complicate the pregnancy and jeopardize the fetal outcome. Ideally the pregnant woman is free of any conditions that can affect a pregnancy, but in reality many women enter pregnancy with a multitude of health-related or psychosocial issues that can have a negative impact on the outcome. Currently, because of the obesity epidemic in the nation and women postponing their pregnancies until later in their lives, nurses will increasingly see more women with medical conditions that affect their pregnancies.

Many pregnant women express the wish "I hope my baby is born healthy." Nurses can play a major role in helping this become a reality by educating women before they become pregnant. Conditions such as diabetes, cardiac and respiratory disorders, anemia, autoimmune disorders, and specific infections frequently can be controlled through close prenatal management so that their impact on pregnancy is minimized. Nurses can provide pregnancy prevention strategies when counseling teenagers. Meeting the developmental needs of pregnant adolescents is a challenge. Finally, lifestyle choices can place many women at risk during pregnancy, and nurses need to remain nonjudgmental when working with these special populations. Lifestyle choices such as use of alcohol, nicotine, and illicit substances during pregnancy are addressed in a *Healthy People 2020* goal.

HEALTHY PEOPLE 2020 • *20.1*

Objective	Nursing Significance
Increase abstinence from alcohol, cigarettes, and illicit drugs among pregnant women	Will help to focus attention on measures for reducing substance exposure and use, thereby minimizing the effects of these substances on the fetus and newborn
Increase in reported abstinence in the past month from substances by pregnant women	
Alcohol from a baseline of 89.4% to 98.3%	
Binge drinking from a baseline of 95% to 100%	
Cigarette smoking from a baseline of 89.6% to 98.6%	
Illicit drugs from a baseline of 94.9% to 100%	

Healthy People objectives based on data from http://www.healthypeople.gov.

Chapter 19 described pregnancy-related conditions that place the woman at risk. This chapter addresses common conditions that can have a negative impact on the pregnancy and special populations at risk, outlining appropriate nursing assessment and management for each condition or situation. The unique skills of nurses, in conjunction with the other members of the health care team, can increase the potential for a positive outcome in many high-risk pregnancies.

DIABETES MELLITUS

Diabetes mellitus is a chronic disease characterized by a relative lack of insulin or absence of the hormone that is necessary for glucose metabolism. The chronic hyperglycemia of diabetes is associated with long-term damage, dysfunction, and failure of the eyes, kidneys, nerves, heart, and blood vessels. The prevalence of diabetes in the United States is increasing at an alarming rate, already reaching epidemic proportions. Contributing factors to these increasing rates are more sedentary lifestyles, dietary changes, continued immigration by high-risk populations, and the growing epidemic of childhood and adolescent obesity. Currently, an estimated 20% of people over the age of 20 have undiagnosed prediabetes. This group of people is the pool from which childbearing women are drawn. Current estimates project that by 2025, one in three adults in the United States will have diabetes mellitus (Knox, Delaney, & Winterstein, 2014). The Institute for Alternative Futures estimates that the number of Americans living with diabetes (diagnosed and undiagnosed) will increase 64% by 2025. The resulting medical and societal cost of diabetes will be approximately $515 billion (Institute for Alternative Futures, 2015).

Diabetes commonly is classified based on disease etiology (American Diabetes Association [ADA], 2015a). These groups include:

- *Type 1 diabetes*: Absolute insulin deficiency (due to an autoimmune process); usually appears before the age of 30 years; approximately 5% % of those diagnosed have type 1 diabetes.

- *Type 2 diabetes*: Insulin resistance or deficiency (related to obesity, sedentary lifestyle); diagnosed primarily in adults older than 30 years of age but now being seen in children; the most common type of diabetes. It is more common in African Americans, Latinos, Native Americans, and Asian Americans/Pacific Islanders, as well as older adults.

- *Impaired fasting glucose* and *impaired glucose tolerance*: characterized by hyperglycemia at a level lower than what qualifies as a diagnosis of diabetes (fasting blood glucose level between 100 and 125 mg/dL; blood glucose level between 140 and 199 mg/dL after a 2-hour glucose tolerance test, respectively); symptoms of diabetes are absent; newborns are at risk for being large for gestational age (LGA).

- *Gestational diabetes mellitus***:** Glucose intolerance with its onset during pregnancy usually around the 24th week or first detected in pregnancy. The prevalence of gestational diabetes has been increasing in the United States and is as high as up to 10% in the United States.

  During pregnancy, diabetes typically is categorized into two groups: **pregestational diabetes** (alteration in carbohydrate metabolism identified before conception), which includes women with type 1 or type 2 disease and gestational diabetes, which develops during pregnancy.

  The International Association of Diabetes and Pregnancy Study Group has issued recommendations for diagnosing and classifying hyperglycemia in pregnancy (see Table 20.1).

  Gestational diabetes is associated with either neonatal complications such as macrosomia, hypoglycemia, and birth trauma or maternal complications such as preeclampsia and cesarean birth. All women of childbearing age with diabetes should be counseled about the importance of strict glycemic control prior to conception. Observational studies show an increase risk of anencephaly, microcephaly, and congenital heart disease, which increases directly with elevations in their A1C (Lapolla & Dalfra, 2015).

  Before the discovery of insulin in 1922, most women with diabetes were infertile or experienced spontaneous abortion (March of Dimes, 2015a). During the past several decades, great strides have been made in improving the outcomes of pregnancy in women with diabetes, but this chronic metabolic disorder remains a high-risk condition during pregnancy. A favorable outcome requires commitment on the woman's part to adhere to frequent prenatal visits, dietary restrictions, self-monitoring of blood glucose levels, frequent laboratory tests, intensive fetal surveillance, and perhaps hospitalization.

Pathophysiology

Diabetes is a complex and progressive disease that has major societal and economic impact. It is a multifactorial disease, the pathophysiology of which involves not only the pancreas but also the liver, skeletal muscle, adipose tissue, gastrointestinal tract, brain, and kidney. Reduced sensitivity to insulin in the liver, muscle, and adipose tissue, and a progressive decline in pancreatic beta cell function leads to impaired insulin secretion, eventually resulting in hyperglycemia, the hallmark of diabetes (Cornell, 2015). Current understanding of the pathophysiology of gestational diabetes includes two key components. These are the existence of pancreatic beta cell dysfunction prior to pregnancy and the unmasking of this problem by the development of insulin resistance during pregnancy, which requires enhanced insulin production to maintain normal blood glucose ranges.

Normal pregnancy is characterized by increasing peripheral resistance to insulin and a compensatory increase in insulin secretion. Therefore, pregnancy might be viewed as a stress test for the glucose homeostasis mechanisms. That is, women who have some degree of chronic insulin resistance and compensatory increased insulin production resulting in beta-cell dysfunction before pregnancy may be unable to mount a sufficiently robust beta-cell response to pregnancy-mediated insulin resistance. Pregnancy is accompanied by insulin resistance, mediated by placental secretion of diabetogenic hormones. These and other metabolic changes that occur during pregnancy ensure that the fetus has an ample supply of nutrients.

TABLE 20.1 RECOMMENDATIONS FOR DIAGNOSING AND CLASSIFYING HYPERGLYCEMIA IN PREGNANCY

When	Diagnosis	Test	Cutoff for Diagnosis
First prenatal visit	Overt (pregestational) diabetes or high risk history—physical inactivity, first-degree relative with diabetes, hypertension, high risk race/ethnicity, obesity, polycystic ovarian syndrome, hypercholesterolemia, previous large infant >9 lb; and smoker.	Fasting HbA1C Random	126 mg/dL <7% 200 mg/dL
24–28 weeks	Gestational diabetes	Fasting 75 g OGTT–1 hr 75 g OGTT–2 hr	92 mg/dL 180 mg/dL 153 mg/dL

OGTT, oral glucose tolerance test.

Retrieved from http://care.diabetesjournals.org/content/early/2012/01/23/dc11-1643; ACOG. (2014a). ACOG guidelines at a glance: Gestational Diabetes Mellitus. *Contemporary OB/GYN*. Retrieved from http://contemporaryobgyn. modernmedicine.com/contemporary-obgyn/news/acog-guidelines-glance-gestational-diabetes-mellitus?page=full; and Roglie, G., & Colagiuri, S. (2014). Gestational diabetes mellitus: Squaring the circle. *Diabetes Care, 37*(6), 143–144.

With diabetes, there is a deficiency of or resistance to insulin. This alteration interferes with the body's ability to obtain essential nutrients for fuel and storage. If a pregnant woman has pregestational diabetes or develops gestational diabetes, the profound metabolic alterations that occur during pregnancy and that are necessary to support the growth and development of the fetus are greatly affected.

Maternal metabolism is directed toward supplying adequate nutrition for the fetus. In pregnancy, placental hormones cause insulin resistance at a level that tends to parallel the growth of the fetoplacental unit. As the placenta grows, more placental hormones are secreted. Human placental lactogen (hPL) and growth hormone (somatotropin) increase in direct correlation with the growth of placental tissue, rising throughout the last 20 weeks of pregnancy and causing insulin resistance. Subsequently, insulin secretion increases to overcome the resistance of these two hormones. In the pregnant woman without diabetes, the pancreas can respond to the demands for increased insulin production to maintain normal glucose levels throughout the pregnancy (Toledano, Hadar, & Hod, 2015). However, the woman with glucose intolerance or diabetes during pregnancy cannot cope with changes in metabolism resulting from insufficient insulin to meet the needs during gestation.

Over the course of pregnancy, insulin resistance does change. It peaks in the last trimester to provide more nutrients to the fetus. The insulin resistance typically results in postprandial hyperglycemia, although some women also have an elevated fasting blood glucose level (Aktas et al., 2014). With this increased demand on the pancreas in late pregnancy, women with diabetes or glucose intolerance cannot accommodate the increased insulin demand; glucose levels

rise as a result of insulin deficiency, leading to hyperglycemia. Subsequently, the mother and her fetus can experience major problems, as shown in Table 20.2.

Screening

Currently, there are inconsistent standards around the world for how women are tested for gestational diabetes, as well cut-off values to diagnose it. The American College of Obstetricians and Gynecologists (ACOG) and ADA currently recommend a risk analysis of all pregnant women at their first prenatal visit and additional screening of all high-risk pregnant women again at 24 to 28 weeks, or earlier if risk factors are present. If the initial screening risk assessment is low, additional screening may not be necessary. Pregnant women who fulfill all of the following criteria need not be screened at their first prenatal visit:

TABLE 20.2 DIABETES AND PREGNANCY: EFFECTS ON THE MOTHER AND FETUS

Effects on the Mother	Effects on the Fetus/Neonate
• Hydramnios due to fetal diuresis caused by hyperglycemia • Gestational hypertension of unknown etiology • Ketoacidosis due to uncontrolled hyperglycemia • Preterm labor secondary to premature membrane rupture • Stillbirth in pregnancies complicated by ketoacidosis and poor glucose control • Hypoglycemia as glucose is diverted to the fetus (occurring in first trimester) • Urinary tract infections resulting from excess glucose in the urine (glucosuria), which promotes bacterial growth • Chronic monilial vaginitis due to glucosuria, which promotes growth of yeast • Difficult labor, cesarean birth, postpartum hemorrhage secondary to an overdistended uterus to accommodate a macrosomic infant	• Cord prolapse secondary to polyhydramnios and abnormal fetal presentation • Congenital anomaly due to hyperglycemia in the first trimester (cardiac problems, neural tube defects, skeletal deformities, and genitourinary problems) • Macrosomia resulting from hyperinsulinemia stimulated by fetal hyperglycemia • Birth trauma due to increased size of fetus, which complicates the birthing process (shoulder dystocia) • Preterm birth secondary to polyhydramnios and an aging placenta, which places the fetus in jeopardy if the pregnancy continues • Fetal asphyxia secondary to fetal hyperglycemia and hyperinsulinemia • Intrauterine growth restriction secondary to maternal vascular impairment and decreased placental perfusion, which restricts growth • Perinatal death due to poor placental perfusion and hypoxia • Respiratory distress syndrome resulting from poor surfactant production secondary to hyperinsulinemia inhibiting the production of phospholipids, which make up surfactant • Polycythemia due to excessive red blood cell (RBC) production in response to hypoxia • Hyperbilirubinemia due to excessive RBC breakdown from hypoxia and an immature liver unable to break down bilirubin • Neonatal hypoglycemia resulting from ongoing hyperinsulinemia after the placenta is removed • Subsequent childhood obesity and carbohydrate intolerance

Adapted from Cunningham, F. G., Leveno, K. J., Bloom, S. L., Spong, C., & Dashe, J. (2014). *Williams' obstetrics* (24th ed.). New York, NY: McGraw-Hill Professional Publishing; Moore, T. R. (2015). Diabetes mellitus and pregnancy. *eMedicine*. Retrieved from http://emedicine.medscape.com/article/127547 and March of Dimes (2015a). *Gestational diabetes*. Retrieved from http://www.marchofdimes.com/pregnancy/gestational-diabetes.aspx

• No history of glucose intolerance

• Less than 25 years old

• Normal body weight

• No family history (first-degree relative) of diabetes

• No history of poor obstetric outcome

• Not from an ethnic/racial group with a high prevalence of diabetes (ADA, 2015b)

If the initial risk assessment is high, rescreening should take place between 24 and 28 weeks. A woman with abnormal early results may have had diabetes before the pregnancy, and her fetus is at great risk for congenital anomalies. An elevated glycosylated hemoglobin supports the likelihood of gestational diabetes. Combining the use of HbA1c and plasma glucose measurements for the diagnosis of diabetes offers the benefits of each test and reduces the risk of systematic bias inherent in HbA1c testing alone (Petry, 2014).

There is little consensus regarding the appropriate screening method. Typically, screening is based on a 75-g 1-hour glucose challenge test, usually performed between 24 and 28 weeks of gestation (McIntyre, Dyer, & Metzger, 2015). A 75-g oral glucose load is given, without regard to the timing or content of the last meal. Blood glucose is measured 1 hour later; a level above 140 mg/dL is abnormal. If the result is abnormal, a 3-hour glucose tolerance test is done. Normal values are:

• Fasting blood glucose level: Less than 92 mg/dL

• At 1 hour: Less than 180 mg/dL

• At 2 hours: Less than 153 mg/dL

• At 3 hours: Less than 140 mg/dL

A diagnosis of gestational diabetes can be made only after an abnormal result is obtained on the glucose tolerance test. One or more abnormal values confirm a diagnosis of gestational diabetes (Farrar et al., 2015). A newer, more controlled screening (HbA1C) has been adopted by ADA and ACOG because of mounting evidence that diagnosing and treating even mild gestational diabetes reduces morbidity for both mother and infant (ADA, 2015c). If adopted universally, the new guidelines are expected to have immediate, widespread clinical implications.

Therapeutic Management

Care for the Woman with Pregestational Diabetes

Pregestational diabetes is a significant public health problem that increases the risk for structural birth defects affecting both maternal and neonatal pregnancy outcomes. Women who have pregestational diabetes (the alteration in carbohydrate metabolism is identified before conception) need comprehensive prenatal care. Achieving good metabolic control during the period prior to conception is essential to reducing congenital malformations that can occur in pregnancies complicated by diabetes. The primary goals of care are to maintain glycemic control and minimize the risks of the disease on the fetus. Key aspects of treatment include nutritional management, exercise, insulin regimens, and close maternal and fetal surveillance (Fig. 20.1).

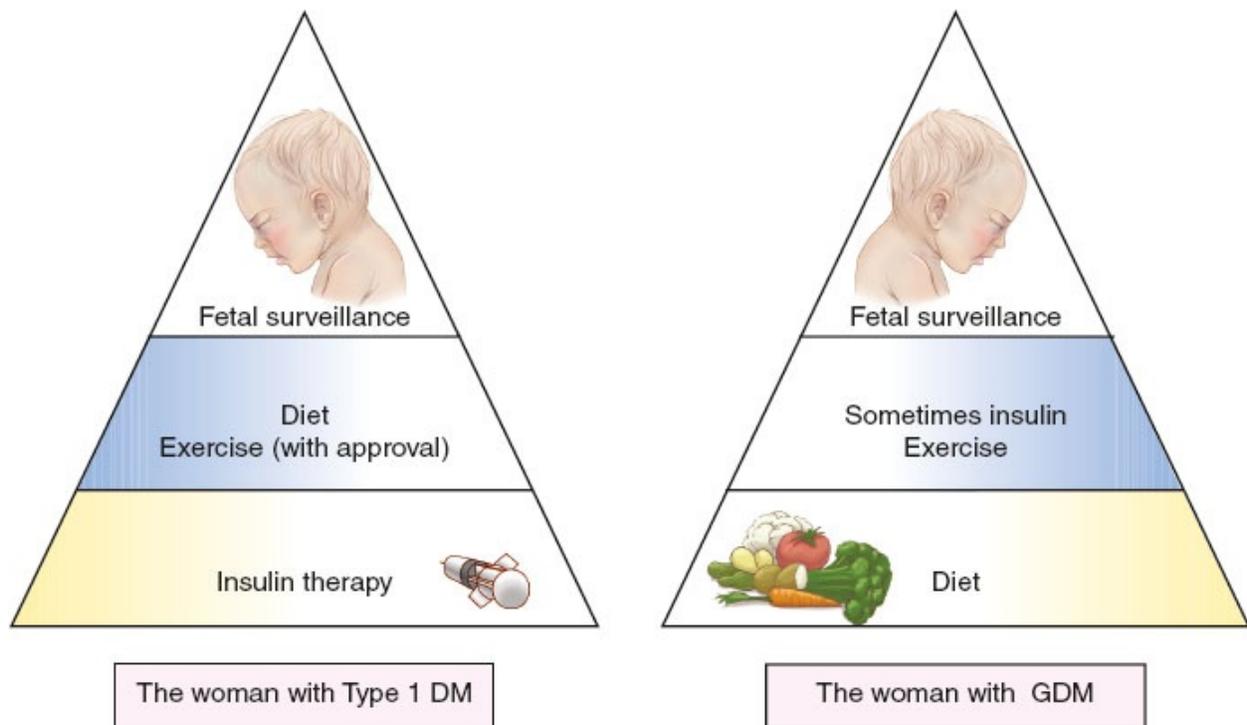
Preconception counseling is essential for the woman with pregestational diabetes (the alteration in carbohydrate metabolism that is identified before conception) to ensure that her disease state is stable. The problem is that as many as half of all pregnancies in the United States are unplanned. Thus women with chronic medical conditions such as diabetes might not have the opportunity to take steps to optimize management of their diabetes before becoming pregnant. When preconception care is possible, women with pregestational diabetes should be taught how to improve their metabolic control prior to conception to reduce the risk of birth defects. Nurses caring for women of reproductive age can contribute to preconception care by helping to counsel someone who is prediabetic to avoid progression to diabetes and its attendant risks during pregnancy. The goals of preconception care are to:


FIGURE 20.1 Treatment overview for diabetes in pregnancy. For women with pregestational type 1 DM, the foundation of glycemic management is insulin therapy along with dietary management, exercise, and fetal surveillance. For the woman who develops gestational diabetes, dietary modification is generally the foundation of treatment. Some women may require insulin along with dietary modifications, whereas others will not require insulin therapy, and others do not. Exercise and fetal surveillance are also important facets of care.

- integrate the woman into the management of her diabetes;
- achieve the lowest glycosylated hemoglobin A1C test results without excessive hypoglycemia;
- ensure effective contraception until stable glycemia is achieved;
- identify and evaluate long-term diabetic complications such as retinopathy, nephropathy, neuropathy, cardiovascular disease (CVD), and hypertension (Gabbay-Benziv et al., 2015).

Excellent control of blood glucose, as evidenced by normal fasting blood glucose levels and a **glycosylated hemoglobin (HbA1C) level** (a measurement of the average glucose levels during the past 100 to 120 days), is crucial to achieve the best pregnancy outcome. A glycosylated hemoglobin level of less than 7% indicates good control; a value of more than 8% indicates poor control

and warrants intervention. A pregestional diabetic pregnant woman has up to a nine-fold increase in birth defects, compared with the rate seen in nondiabetic pregnancies if she does not have glycemic control (Mitanchez et al., 2015).

Preconception counseling is also important in helping to reduce the risk of congenital malformation. The most common malformations associated with diabetes occur in the renal, cardiac, skeletal, and central nervous systems. Since these defects occur by the eighth week of gestation, preconception counseling is critical. The rate of congenital anomalies in women with pregestational diabetes can be reduced if excellent glycemic control is achieved at the time of conception (Simeone et al., 2015). This information needs to be stressed with all women with diabetes who are contemplating a pregnancy. In addition, the woman with pregestational diabetes needs to be evaluated for complications of diabetes. This evaluation should be part of baseline screening and continuing assessment during pregnancy.

Care During Pregnancy for the Woman with Gestational Diabetes

Lifestyle modification, nutritional changes, and encouragement of physical activities forms the primary mode of therapy for diabetes during pregnancy. Therapeutic management for the woman with gestational diabetes mellitus (defined as glucose intolerance with its onset during pregnancy or first detected during pregnancy) focuses on tight glucose control. The ADA (2015b) recommends maintaining a fasting blood glucose level below 92 mg/dL, with postprandial levels below 180 mg/dL at 1-hour and 2-hour postprandial levels below 153 mg/dL. In comparison, for pregnant women without diabetes, near-normal glucose values include a fasting value between 60 and 90 mg/dL, a 1-hour postprandial value of 100 to 120 mg/dL, and a 2-hour postprandial value of 60 to 120 mg/dL. Such tight control has been advocated because it is associated with a reduction in macrosomia. In addition, maternal prepregnancy weight and weight gain during pregnancy appear to be significant and independent risk factors for macrosomia in women with gestational diabetes also (Grandy et al. 2015).

Nutritional management focuses on maintaining balanced glucose levels and providing enough energy and nutrients for the pregnant woman, while avoiding ketosis, and minimizing the risk of hypoglycemia in women treated with insulin. Nutrition therapy is the cornerstone of therapy for women with gestational diabetes. Women should receive ethically appropriate nutritional advice on how

to change their dietary habits from a dietitian. The diet counseling must be in keeping with their present cultural dietary patterns and not radically different to become adopted and followed. If rice is a staple of a Chinese client's diet, then it must be incorporated into the diet counseling plan and not eliminated (He et al., 2015). A low-glycemic index diet is considered safe and has positive effects on the glycemic control and pregnancy outcomes for both healthy women, those with type 2 diabetes and gestational diabetes. A moderately low carbohydrate diet with a carbohydrate content of 40% of the calories results in good glycemic control for most (Roskjaer et al., 2014). Eating for two during pregnancy for a woman who has diabetes means eating not volume for two, but rather quality and timing to support both mother and fetus. Women who receive dietary instruction and follow it have been shown to have a better pregnancy outcome than those who do not receive dietary advice (Ma et al., 2015).

PHARMACOLOGIC THERAPY FOR GESTATIONAL DIABETES

For the woman with gestational diabetes, nutritional management and exercise may be all that is necessary. Pharmacologic therapy is considered if nutrition and exercise fail to maintain target glucose levels. Blood glucose levels in the woman can be controlled by nutritional therapy and exercise, but in uncontrolled cases, where target glycemic levels cannot be reached, insulin is also required. Insulin, which does not cross the placenta, historically has been the medication of choice for treating hyperglycemia in pregnancy. Insulin is calculated based on the woman's weight. Combining intermediate and short-acting insulin yields the best result for most women. Two insulin doses are given daily with two thirds of the total insulin in the morning to cover energy needs of the active day and one third at night.

Oral Medications for Management of Gestational Diabetes. Women tend to manage oral medications better than insulin, so the standard of care may be moving toward the oral route (King et al., 2015). Recent studies have examined the use of oral hypoglycemic medications in pregnancy with much success. Several studies have used glyburide (DiaBeta) with promising results. Many health care providers are using glyburide and metformin as an alternative to insulin therapy because they do not cross the placenta and therefore do not cause fetal/neonatal hypoglycemia. Some oral hypoglycemic medications are considered safe and may be used if nutrition and exercise are not adequate alone. Maternal and newborn outcomes are similar to those seen in women who are

treated with insulin. Oral hypoglycemic agents, however, must be further investigated to determine their safety with confidence and provide better treatment options for diabetes in pregnancy. Currently, there is a growing acceptance of glyburide (glibenclamide) use as a primary therapy for gestational diabetes Glyburide and metformin (Glucophage) have also been found to be safe, effective, and economical for the treatment of gestational diabetes, although neither drug has been approved by the FDA for use in pregnancy. Insulin, however, still has an important role to play in gestational diabetes (Buschur, Brown, & Wyckoff, 2015).) Gestational diabetes offers a window of opportunity, which needs to be seized, for prevention of diabetes in future life (Nagtalon-Ramos, 2014).

The ADA (2015c) recommends that women diagnosed with gestational diabetes by a 3-hour glucose tolerance test receive nutritional counseling from a registered dietitian. The ADA also recommends insulin therapy or oral diabetic medications if diet is unsuccessful in achieving a fasting glucose level below 92 mg/dL, a 1-hour postprandial level below 180 mg/dL, or 2-hour postprandial level below 153 mg/dL (ADA, 2015c).

The ACOG (2014a) recommends the use of diet or insulin or oral diabetic medications to achieve a 1-hour postprandial blood glucose level of 130 mg/dL. Randomized studies show that glyburide and insulin are equally effective in achieving glycemic control. Glycemic control—regardless of whether it involves diet, insulin, or oral agents—leads to fewer cases of shoulder dystocia, hyperbilirubinemia requiring phototherapy, nerve palsy, bone fracture, LGA status, and fetal macrosomia (ACOG, 2014a).

Exercise is another important component of comprehensive prenatal care for the pregnant woman with glucose intolerance. Regular exercise helps maintain glucose control by increasing the uptake of glucose into the cells and decreasing central obesity, hypertension, and dyslipidemia, which will ultimately decrease the woman's insulin requirements (Jordan et al., 2014). Regular physical activity has been proven to result in marked benefits for mother and fetus. Maternal benefits include improved cardiovascular function, limited pregnancy weight gain, decreased musculoskeletal discomfort, reduced incidence of muscle cramps and lower limb edema, mood stability, and reduction of gestational diabetes mellitus and gestational hypertension. Fetal benefits include decreased fat mass, improved stress tolerance, and advanced neurobehavioral maturation. Research also suggests the role of physical activity in prevention of gestational diabetes (Bain, Crane et al., 2015).

Insulin for Management of Gestational Diabetes. Insulin remains the medication of choice for glycemic control if oral medications, diet, or exercise fail to yield results in pregnant and lactating women with any type of diabetes (Moore, 2015). Generally, insulin doses are reduced in the first trimester to prevent hypoglycemia resulting from increased insulin sensitivity as well as from nausea and vomiting. Newer short-acting insulins such as lispro (Humalog) and aspart (NovoLog), which do not cross the placenta, may help reduce postprandial hyperglycemia, episodes of hypoglycemia between meals. Target fasting glucose values of 60 to 90 mg/dL and 1-hour postprandial values less than 120 mg/dL are necessary to provide good glycemic control and good pregnancy outcomes (Moore, 2015). Changes in diet and activity level add to the need for changes in insulin dosages throughout pregnancy.

Insulin regimens vary, and controversy remains over the best strategy for insulin delivery in pregnancy. Many health care providers use a split-dose therapy (two thirds of the daily dose in the morning and the remaining one third in the evening). Others advocate the use of an insulin pump to deliver a continuous subcutaneous insulin infusion. Regardless of which protocol is used, frequent blood glucose measurements are necessary, and the insulin dosage is adjusted on the basis of daily glucose levels. Insulin therapy or oral hypoglycemic agents, in addition to diet and exercise are main elements of achieving glycemic control. See Evidence-Based Practice 20.1.

Close maternal and fetal surveillance is also essential. Frequent laboratory tests are done during pregnancy to monitor the woman's status and glucose control. Fetal surveillance via diagnostic testing aids in evaluating fetal well-being and assisting in determining the best time for birth.

Care During and After Labor for the Woman with Gestational Diabetes

For the laboring woman with diabetes, intravenous saline or lactated Ringer's is given and blood glucose levels are monitored every 1 to 2 hours. Glucose levels are maintained below 110 mg/dL throughout labor to reduce the likelihood of neonatal hypoglycemia. If necessary, an infusion of regular insulin may be given to maintain this level (King et al., 2015). If the woman was receiving insulin during her pregnancy, adjustments in dosage may be necessary after birth since glucose diversion across the placenta to supply the growing fetus is no longer present and insulin resistance is now removed. Frequently, the woman with

gestational diabetes can remain controlled through diet and weight management; the woman with type 1 diabetes usually returns to prepregnant levels of insulin administration (Kim, 2014).

EVIDENCE-BASED PRACTICE 20.1 PREVENTION OF GESTATIONAL DIABETES IN PREGNANT WOMEN WITH RISK FACTORS FOR GESTATIONAL DIABETES: A SYSTEMATIC REVIEW AND META-ANALYSIS OF RANDOMIZED TRIALS

STUDY

Gestational diabetes mellitus (GDM) is defined as the diabetes diagnosed during pregnancy that is not clearly overt diabetes. According to this definition, glycemic levels meeting the thresholds of overt diabetes are considered to have pre-existing diabetes and the rest are given diagnosis of GDM. The objective of the systematic review was to identify any intervention that could be used for primary prevention of gestational diabetes in women with risk factors for it.

A systematic review and meta-analysis was conducted by including randomized controlled trials comparing any form of therapeutic intervention in comparison to usual antenatal care. A literature search was conducted using electronic databases together with a hand search of relevant journals and conference proceedings.

Findings

A total of 2,422 women from 14 randomized trials were included which compared diet, exercise, lifestyle changes, and metformin with standard care in women with risk factors for gestational diabetes. Dietary intervention was associated with statistically significant lower incidence of gestational diabetes and gestational hypertension compared to standard of care. There was no statistically significant difference in the incidence of gestational diabetes with exercise, lifestyle changes or metformin used compared to standard care.

Nursing Implications

Based on these findings, nurses can encourage healthy dietary changes as a primary prevention strategy to prevent gestational diabetes for high-risk women since this intervention was shown to be a statistically significant intervention over standard care. Instructing them on health dietary habits either preconceptually or at the first prenatal visit may help prevent gestational diabetes and turn the tide for better pregnancy outcomes for both the mother and the infant.

Adapted from Madhuvrata, P., Govinden, G., Bustani, R., Song, S., & Farrell, T. A. (2015). Prevention of gestational diabetes in pregnant women with risk factors for gestational diabetes: A systematic review and meta-analysis of randomized trials. *Obstetric Medicine: The Medicine of Pregnancy*, 8(2), 68–85.

After giving birth, the overt glycemic abnormalities of gestational diabetes usually resolve. This phenomenon suggests that the diabetes is transient and that the consequences of gestational diabetes end with the birth of the infant. However, for the woman, childbirth is not the end of the story. The diagnosis of gestational diabetes heralds future health risks. Knowledge of this "failed" stress test conveys new information about her future risk for type 2 diabetes, which warrants further screening and prevention efforts during the postpartum period and beyond.

Nursing Assessment

Nursing assessment begins at the first prenatal visit. A thorough history and physical examination in conjunction with specific laboratory and diagnostic testing aids in developing an individualized plan of care for the woman with diabetes.

Health History and Physical Examination

For the woman with pregestational diabetes, obtain a thorough history of the preexisting diabetic condition. Ask about her duration of disease, management of glucose levels (insulin injections, insulin pump, or oral hypoglycemic agents), dietary adjustments, presence of vascular complications and current vascular status, current insulin regimen, and technique used for glucose testing. Review any information that she may have received as part of her preconception counseling and measures that were implemented during this time.

Be knowledgeable about the woman's nutritional requirements and assess the adequacy and pattern of her dietary intake. Assess her blood glucose self-monitoring in terms of technique, frequency, and her ability to adjust the insulin dose based on the changing patterns. Ask about the frequency of episodes of hypoglycemia or hyperglycemia to ascertain the woman's ability to recognize and treat them. Continue to assess her for signs and symptoms of hypo- and hyperglycemia.

During antepartum visits, assess the client's knowledge about her disease, including the signs and symptoms of hypoglycemia, hyperglycemia, and diabetic ketoacidosis, insulin administration techniques, and the impact of pregnancy on her chronic condition. If possible have the woman demonstrate her technique for blood glucose monitoring and insulin administration if appropriate. It is essential that the nurse keeps in mind that there is a huge learning curve for women with diabetes concerning the need for dietary changes, frequency of blood glucose monitoring, exercise, and insulin or oral medication administration. Suddenly, the woman is expected to make rapid changes in her life, which can be overwhelming. The nurse can help facilitate these changes by exercising patience and understanding and reinforcing all verbal instructions with written material. Frequent encouragement is also needed to assist the woman in her lifestyle changes. Although the client may have had diabetes for some time, do

not assume that she has a firm knowledge base about her disease process or management of it (Fig. 20.2).

FIGURE 20.2 The nurse is demonstrating the technique for self-blood glucose monitoring with a pregnant client who has diabetes.

Assess the woman's risk for gestational diabetes at the first prenatal visit. The clinical presentation of diabetes mellitus in pregnancy may be quite varied, but the classical triad of the symptoms of polydipsia, polyphagia, and polyuria may not be reported by most women during pregnancy. Instead, the women may present with previous history of medical complications of diabetes (chronic hypertension/chronic renal disease) and obesity. All of these conditions can influence pregnancy outcome. The ADA (2015a) recommends assessing all women for risk factors and then determining the need for additional testing in the high-risk group only. Factors that place a woman at high risk include:

• Previous infant with congenital anomaly (skeletal, renal, central nervous system, cardiac)

• History of gestational diabetes or polyhydramnios in a previous pregnancy

• Family history of diabetes

• Medications: corticosteroids or antipsychotics

• Age 35 years or older

• Polycystic ovarian syndrome

- Multiple pregnancy (twins, triplets)
- Previous infant weighing more than 9 lb (4,000 g)
- Previous unexplained fetal demise or neonatal death
- Maternal obesity (body mass index [BMI] >30)
- Hypertension before pregnancy or in early pregnancy
- Hispanic, Native American, Pacific Islander, or African– American ethnicity
- Recurrent monilia infections that do not respond to treatment
- Signs and symptoms of glucose intolerance (polyuria, polyphagia, polydipsia, fatigue)
- Presence of glycosuria or proteinuria (Gupta, 2015).

Women with clinical characteristics consistent with a high risk for gestational diabetes should undergo glucose testing as soon as feasible.

Provide close ongoing assessment throughout the antepartal period. Women with gestational diabetes mellitus (GDM) are at increased risk for preeclampsia and glucose control–related complications such as hypoglycemia, hyperglycemia, and ketoacidosis. Gestational diabetes of any severity increases the risk of fetal macrosomia, as noted earlier. It is also associated with an increased frequency of maternal hypertensive disorders and operative births. This may be the result of fetal growth disorders (ADA, 2015a). Even though gestational diabetes is diagnosed during pregnancy, the woman may have had glucose intolerance before the pregnancy. Therefore, monitor the woman closely for signs and symptoms of possible complications.

Also assess the woman's psychosocial adaptation to her condition. This assessment is critical to gain her cooperation for a change in regimen or the addition of a new regimen throughout pregnancy. Identify her support systems and note any financial constraints, because she will need intense monitoring and frequent fetal surveillance.

Laboratory and Diagnostic Testing

The results of laboratory and diagnostic tests provide valuable information about maternal and fetal well-being. Women with pregestational diabetes and those discovered to have gestational diabetes require ongoing maternal and fetal surveillance to promote the best outcome.

SURVEILLANCE

Maternal surveillance may include the following:

• Urine check for protein (may indicate the need for further evaluation for preeclampsia) and for nitrates and leukocyte esterase (may indicate a urinary tract infection).

• Urine check for ketones (may indicate the need for evaluation of eating habits).

• Kidney function evaluation every trimester for creatinine clearance and protein levels.

• Eye examination in the first trimester to evaluate the retina for vascular changes.

• HbA1c every 4 to 6 weeks to monitor glucose trends (Jordan et al., 2014).

Fetal surveillance may include ultrasound to provide information about fetal growth, activity, and amniotic fluid volume and to validate gestational age. Alpha-fetoprotein levels may be obtained to detect congenital anomalies such as an open neural tube or ventral wall defects of omphalocele or gastroschisis, and a fetal echocardiogram may be necessary to rule out cardiac anomalies. A biophysical profile helps to monitor fetal well-being and uteroplacental profusion, and nonstress tests commonly are performed weekly after 28 weeks of gestation to evaluate fetal well-being. As the pregnancy progresses, an amniocentesis may be done to determine the lecithin/sphingomyelin (L/S) ratio and the presence of phosphatidyl glycerol (PG) to evaluate whether the fetal lung is mature enough for birth (Moore, 2015).

Nursing Management

The ideal outcome of every pregnancy is a healthy newborn and mother. Nurses can be pivotal in realizing this positive outcome for women with pregestational or gestational diabetes by implementing measures to minimize risks and complications. Since the woman with diabetes is considered to be at high risk, antepartal visits occur more frequently (every 2 weeks up to 28 weeks and then twice a week until birth), providing the nurse with numerous opportunities for ongoing assessment, education, and counseling (Nursing Care Plan 20.1).

Promoting Optimal Glucose Control

At each visit, review the mother's blood glucose levels, including any laboratory tests and self-monitoring results. Reinforce with the woman the need to perform blood glucose monitoring (usually four times a day: before meals and at bedtime) and to keep a record of the results. If appropriate, obtain a fingerstick blood glucose level to evaluate the accuracy of self-monitoring results. Also assess the woman's techniques for monitoring blood glucose levels and for administering insulin if ordered, and offer support and guidance. If the woman is receiving insulin therapy, assist with any changes needed if glucose levels are not controlled. Obtain a urine specimen and check for glucose, protein, and ketones. Ask the woman if she has had any episodes of hypoglycemia and what she did to alleviate them. Discuss dietary measures related to blood glucose control (Fig. 20.3). In addition, recommend the following:

• Avoid weight loss and dieting during pregnancy.

• Ensure that food intake is adequate to prevent ketone formation and promote weight gain.

• Eat three meals a day plus three snacks to promote glycemic control:
  • 40% of calories from good-quality complex carbohydrates
  • 35% of calories from protein sources
  • 25% of calories from unsaturated fats.
  • Small frequent feedings throughout the day are recommended.
  • Bedtime snacks are recommended for all women.
  • Include protein and fat at each meal (National Diabetes Information Clearing

House, 2015).

Take Note!

Nutrient requirements and recommendations for weight gain for the pregnant woman with diabetes are the same as those for the pregnant nondiabetic woman.

If necessary, arrange for consultation with a dietitian or nutritionist to individualize the dietary plan. Also encourage the women to participate in an exercise program that includes at least three sessions which last at least 30 minutes daily. Exercise may lessen the need for insulin or dosage adjustments.

When caring for the laboring woman with pregestational or gestational diabetes, adjust the intravenous flow rate and the rate of supplemental regular insulin based on the blood glucose levels as ordered. Monitor blood glucose levels every 1 to 2 hours or more frequently if necessary. Keep a syringe with 50% dextrose solution Retrieved from the bedside to treat profound hypoglycemia. Monitor fetal heart rate patterns throughout labor to detect category II and III patterns. Assess maternal vital signs every hour, in addition to assessing the woman's urinary output with an indwelling catheter. If a cesarean birth is scheduled, monitor the woman's blood glucose levels hourly and administer short-acting insulin or glucose based on the blood glucose levels as ordered.

After birth, monitor blood glucose levels every 2 to 4 hours for the first 48 hours to determine the woman's insulin need and continue intravenous fluid administration as ordered. Encourage breast-feeding to assist in maintaining good glucose control. For the woman with pregestational diabetes and type 1 or 2 diabetes, expect insulin needs to decrease rapidly after birth: they may be reduced by half of the antepartum dose as meals are started (King et al., 2015). Some women may return to their prepregnancy insulin dosage. In addition, the nurse must monitor the infant of the diabetic mother for common problems see in them which includes macrosomia, respiratory distress syndrome, hypoglycemia, polycythemia, hypocalcemia, hyperbilirubinemia, and a variety of congenital anomalies (Green, 2016). Frequently, admission to the neonatal intensive care unit (NICU) for close observational and glucose control is needed.

NURSING CARE PLAN 20.1

Overview of the Pregnant Woman with Type 1 Diabetes

Donna, a 30-year-old woman with type 1 diabetes, presents to the maternity clinic for preconception care. She has had diabetes for 8 years and takes insulin twice daily by injection. She does blood glucose self-monitoring four times daily. She reports that her disease is fairly well controlled, but "I'm worried about how my diabetes will affect a pregnancy and my baby. Will I need to make changes in my routine? Will my baby be normal?" She reports that she recently had a foot infection and needed to go to the emergency department because it led to an episode of ketoacidosis. She states that her last glycosylated hemoglobin A1c test results were abnormal.

NURSING DIAGNOSIS: Ineffective health maintenance: Maternal related to deficient knowledge regarding care in diabetic condition in pregnancy as evidenced by questions about effect on pregnancy, possible changes in regimen, and pregnancy outcome

Outcome Identification and Evaluation
The client will demonstrate increased knowledge of type 1 diabetes and effects on pregnancy as evidenced by proper techniques for blood glucose monitoring and insulin administration, ability to modify insulin doses and dietary intake to achieve control, and verbalization of need for glycemic control prior to pregnancy, with blood glucose levels remaining within normal range.

Interventions: *Providing Client Teaching*
• Assess client's knowledge of diabetes and pregnancy to establish a baseline from which to develop an individualized teaching plan.
• Review the underlying problems associated with diabetes and how pregnancy affects glucose control to provide client with a firm knowledge base for decision making.
• Review signs and symptoms of hypoglycemia and hyperglycemia and prevention and management measures to ensure client can deal with them should they occur.

- Provide written materials describing diabetes and care needed for control to provide opportunity for client's review and promote retention of learning.
- Observe client administering insulin and self-glucose testing for technique and offer suggestions for improvement if needed to ensure adequate self-care ability.
- Discuss proper foot care to prevent future infections.
- Teach home treatment for symptomatic hypoglycemia to minimize risk to client and fetus.
- Outline acute and chronic diabetic complications to reinforce the importance of glucose control.
- Discuss use of contraceptives until blood glucose levels can be optimized before conception occurs to promote best possible health status before conception.
- Explain the rationale for good glucose control and the importance of achieving excellent glycemic control before pregnancy to promote a positive pregnancy outcome.
- Review self-care practices (blood glucose monitoring and frequency of testing; insulin administration; adjustment of insulin dosages based on blood glucose levels) to foster independence in self-care and feelings of control over the situation.
- Refer client for dietary counseling to ensure optimal diet for glycemic control.
- Outline obstetric management and fetal surveillance needed for pregnancy to provide client with information on what to expect.
- Discuss strategies for maintaining optimal glycemic control during pregnancy to minimize risks to client and fetus.

NURSING DIAGNOSIS: Anxiety related to threat to self and fetus as evidenced by questions about her condition's effect on the baby and baby being normal

Outcome Identification and Evaluation
The client will openly express her feelings related to her diabetes and pregnancy as evidenced by statements of feeling better about her preexisting condition and pregnancy outlook, and statements of understanding related to future childbearing by linking good glucose control with positive outcomes

for both her and offspring.

Interventions: *Minimizing Anxiety*
- Review the need for a physical examination to evaluate for any effects of diabetes on the client's health status.
- Explain the rationale for assessing client's blood pressure, vision, and peripheral pulses at each visit to provide information related to possible effects of diabetes on health status.
- Identify any alterations in present diabetic condition that need intervention to aid in minimizing risks that may increase client's anxiety level.
- Review potential effects of diabetes on pregnancy to promote client understanding of risks and ways to control or minimize them.
- Encourage active participation in decision making and planning pregnancy to promote feelings of control over the situation and foster self-confidence.
- Discuss feelings about future childbearing and managing pregnancy to help reduce anxiety related to uncertainties.
- Encourage client to ask questions or voice concerns to help decrease anxiety related to the unknown.
- Emphasize the use of frequent and continued surveillance of client and fetal status during pregnancy to reduce the risk of complications and aid in alleviating anxieties related to the unknown.
- Provide positive reinforcement for healthy behaviors and actions to foster continued use and enhancement of self-esteem.

FIGURE 20.3 The pregnant client with diabetes eating a nutritious meal to ensure adequate glucose control.

The therapy plan after childbirth is individualized. If recommended dietary modifications are carried out along with weight loss, the woman with gestational diabetes may return to her normal glucose levels. This is also true for the woman with pregestational diabetes, except that she will return to her prepregnancy insulin administration levels. This provides the nurse with a wonderful opportunity to reinforce healthy lifestyle interventions on the postpartum unit. Nurses can also become involved with community-based education to continue to offer their expertise.

Preventing Complications

Assess the woman closely for signs and symptoms of complications at each visit. Anticipate possible complications and plan appropriate interventions or referrals. Check the woman's blood pressure for changes and evaluate for proteinuria when obtaining a urine specimen. These might suggest the development of preeclampsia. Measure fundal height and review gestational age. Note any discrepancies between fundal height and gestational age or a sudden increase in uterine growth. These may suggest polyhydramnios.

Encourage the woman to perform daily fetal movement counts to monitor

fetal well-being. Tell her specifically when she should notify her health care provider. Also prepare the woman for the need for frequent laboratory and diagnostic testing to evaluate fetal status. Assist with serial ultrasounds to monitor fetal growth and with nonstress tests and biophysical profiles to assess fetal well-being.

Consider This

Scott and I had been busy all day setting up the new crib in our nursery, and we finally sat down to rest. I was due any day, and we had been putting this off until we had a long weekend to complete the task. I was excited to think about all the frilly pinks that decorated her room. I was sure that my new daughter would love it as much as I loved her already. A few days later I barely noticed any fetal movement, but I thought that she must be as tired as I was by this point.

That night I went into labor and kept looking at the worried faces of the nurses and the midwife in attendance. I had been diagnosed with gestational diabetes a few months ago and had tried to follow the instructions regarding diet and exercise, but old habits are hard to change when you are 38 years old. I was finally told after a short time in the labor unit that they couldn't pick up a fetal heartbeat and an ultrasound was to be done—still no heartbeat was detected. Scott and I were finally told that our daughter was a stillborn. All I could think about was that she would never get to see all the pink colors in the nursery.

Providing Client Education and Counseling

The pregnant woman with diabetes requires counseling and education about the need for strict glucose monitoring, diet and exercise, and signs and symptoms of complications. Encourage the client and her family to make any lifestyle changes needed to optimize the pregnancy outcome. Providing dietary education, weight control measures, and lifestyle advice that extends beyond pregnancy may lower the risk that the woman will have gestational diabetes in subsequent pregnancies as well as type 2 diabetes (Hashemi-Beni et al., 2015). At each visit stress the

importance of performing blood glucose screening and documenting the results. With proper instruction, the client and her family will be able to cope with all the changes in her body during pregnancy (Teaching Guidelines 20.1).

Teaching Guidelines 20.1

TEACHING FOR THE PREGNANT WOMAN WITH DIABETES

• Be sure to keep your appointments for frequent prenatal visits and tests for fetal well-being.

• Perform blood glucose self-monitoring as directed, usually before each meal and at bedtime. Keep a record of your results and call your health care provider with any levels outside the established range. Bring your results to each prenatal visit.

• Perform daily "fetal kick counts." Document them and report any decrease in activity.

• Drink eight to ten 8-oz glasses of water each day to prevent bladder infections and maintain hydration.

• Wear proper, well-fitted footwear when walking to prevent injury.

• Engage in a regular exercise program such as walking to aid in glucose control, but avoid exercising in temperature extremes.

• Consider breast-feeding your infant to lower your blood glucose levels.

• If you are taking insulin:

  • Administer the correct dose of insulin at the correct time every day.

  • Eat breakfast within 30 minutes after injecting regular insulin to prevent a reaction.

  • Plan meals at a fixed time and snacks to prevent extremes in glucose levels.

• Avoid simple sugars (cake, candy, cookies), which raise blood glucose levels.

• Know the signs and symptoms of hypoglycemia and treatment needed:

- Sweating, tremors, cold, clammy skin, headache
- Feeling hungry, blurred vision, disorientation, irritability
- Treatment: Drink 8 oz of milk and eat two crackers or take two glucose tablets
- Carry "glucose boosters" (such as Life Savers) to treat hypoglycemia.
- Know the signs and symptoms of hyperglycemia and treatment needed:
  - Dry mouth, frequent urination, excessive thirst, rapid breathing
  - Feeling tired, flushed, hot skin, headache, drowsiness
  - Treatment: Notify health care provider, because hospitalization may be needed
- Wear a diabetic identification bracelet at all times.
- Wash your hands frequently to prevent infections.
- Report any signs and symptoms of illness, infection, and dehydration to your health care provider, because these can affect blood glucose control.

Review discussions about the timing of birth and the rationale. Counsel the client about the possibility of cesarean birth for an LGA infant, or inform the woman who will be giving birth vaginally about the possible need for augmentation with oxytocin (Pitocin).

Take Note!

In the woman with well-controlled diabetes, birth is typically not induced before term unless complications arise, such as preeclampsia or fetal compromise. An early delivery date might be set for the woman with poorly controlled diabetes or a large size fetus who is having complications.

Instruct the client about the benefits of breast-feeding related to blood glucose control. Breast-feeding helps to normalize blood glucose levels. Therefore, encourage the woman to breast-feed her newborn. Also teach the woman receiving insulin for her diabetes that her insulin needs after birth will drastically decrease. Inform her that she will need a repeat glucose challenge test at a postpartum visit (ADA, 2015d).

For the woman with gestational diabetes, the focus is on lifestyle education. Women with gestational diabetes have a greater than 50% increased risk of developing type 2 diabetes (ADA, 2015d). Inform the woman that screening most likely will be done at the postpartum follow-up appointment in 6 weeks. Women with normal results at that visit typically are screened every 3 years thereafter (ADA, 2015d).). Teach her how to maintain an optimal weight to reduce her risk of developing diabetes. If necessary, refer the woman to a dietitian to help outline a balanced nutritious diet.

CARDIOVASCULAR DISORDERS

Despite an increase in awareness of a wide range of health concerns, the myth still exists that CVD is a man's disease and women do not need to be concerned about it. Every minute, an American woman dies of CVD and more than one in three women is living with a cardiovascular disorder, including nearly half of all African–American women and 34% of white women (American Heart Association [AHA], 2015). CVD is the leading cause of death for men and women in the United States and is more deadly than all forms of cancer. It kills nearly 500,000 women each year. Despite the prominent reduction in cardiovascular mortality among men, the rate has not declined for women. CVD has killed more women than men since 1984 (AHA, 2015). In addition to being the number-one killer of women, at the time of diagnosis women have both a poorer overall prognosis and a higher risk of death than men diagnosed with heart disease. Women represent 53% of deaths from CVD than the next three causes of death combined, including all forms of cancer (Worel & Hayman, 2015). In both men and women risk factors such as hypertension, high blood cholesterol level, smoking, lack of physical activity, and obesity increase the probability of developing CVD. Menopause, gestational diabetes, oral contraceptive use, and bilateral oophorectomy in premenopausal women also affect the risk of CVD in women (Chomistek, Chiuve, & Eliassen, 2015).

More women die of heart disease, stroke, and other CVDs than men, yet many women do not realize they are at risk. These diseases kill more women each year than the next three causes of death combined, including all types of cancer (AHA, 2015). Approximately 3% of pregnant women have cardiac disease, which is responsible for 10% to 25% of maternal deaths (Cunningham et al., 2014). The prevalence of cardiac disease is increasing as a result of lifestyle patterns, including cigarette smoking, diabetes, and stress. As women are delaying childbearing, the incidence of cardiac disease in pregnancy will continue to increase. The cardiovascular adaptations during pregnancy are well tolerated by the normal heart, but may unveil undiagnosed underlying heart disease, or tip the hemodynamic balance and lead to decompensation in those with existing heart disease (Harvey, Coffman, & Miller, 2015).

Rheumatic heart disease used to represent the majority of cardiac conditions during pregnancy, but congenital heart disease now constitutes nearly half of all

cases of heart disease encountered during pregnancy. Classic symptoms of heart disease mimic common symptoms of late pregnancy, such as palpitations, shortness of breath with exertion, and occasional chest pain. Few women with heart disease die during pregnancy, but they are at risk for other complications, such as heart failure, arrhythmias, and stroke. Their offspring are also at risk of complications, such as premature birth, low birth weight for gestational age, respiratory distress syndrome, intraventricular hemorrhage, and death (Gilstrap & Wood, 2014).

Congenital and Acquired Heart Disease

Congenital heart disease often involves structural defects that are present at birth but may not be discovered at that time (Table 20.3). Until recently, women with congenital heart disease did not live long enough to bear children. Today, due to new surgical techniques to correct these defects, many of these women can complete a successful pregnancy at relatively low risk when appropriate counseling and optimal care are provided. Increasing numbers of women with complex congenital heart disease are reaching childbearing age. Complications such as growth restriction, preterm and premature birth, and fetal and neonatal mortality are more common among children of women with congenital heart disease. The risk of complications is determined by the severity of the cardiac lesion, the presence of cyanosis, the maternal functional class, and the use of anticoagulation therapy (Choreño-Machain, Barrios, & Reta, 2015).

TABLE 20.3 SELECTED HEART CONDITIONS AFFECTING PREGNANCY

Condition	Description	Management
Congenital		
Tetralogy of Fallot	Congenital defect involving four structural anomalies: obstruction to pulmonary flow; ventricular septal defect (abnormal opening between the right and left ventricles); dextroposition of the aorta (aortic opening overriding the septum and receiving blood from both ventricles); and right ventricular hypertrophy (increase in volume of the myocardium of the right ventricle).	Hospitalization and bed rest possible after the 20th week with hemodynamic monitoring via a pulmonary artery catheter to monitor volume status Oxygen therapy may be necessary during labor and birth.
Atrial septal defect (ASD)	Congenital heart defect involving a communication or opening between the atria with left-to-right shunting due to greater left-sided pressure. Arrhythmias present in some women.	Treatment with atrioventricular nodal blocking agents, and at times with electrical cardioversion.
Ventricular septal defect (VSD)	Congenital heart defect involving an opening in the ventricular septum, permitting blood flow from the left to the right ventricle. Complications include arrhythmias, heart failure, and pulmonary hypertension.	Rest with limited activity if symptomatic.
Patent ductus arteriosus	Abnormal persistence of an open lumen in the ductus arteriosus between the aorta and the pulmonary artery after birth; results in increased pulmonary blood flow and redistribution of flow to other organs.	Surgical ligation of the open ductus during infancy; subsequent problems minimal after surgical correction.

Acquired		
Mitral valve prolapse	Very common in the general population, occurring most often in younger women. Leaflets of the mitral valve prolapse into the left atrium during ventricular contraction. The most common cause of mitral valve regurgitation if present during pregnancy. Usually improvements in mitral valve function due to increased blood volume and decreased systemic vascular resistance of pregnancy; most women are able to tolerate pregnancy well.	Most women are asymptomatic; diagnosis is made incidentally. Occasional palpations, chest pain, or arrhythmias in some women, possibly requiring beta-blockers. Usually no special precautions are necessary during pregnancy.
Mitral valve stenosis	Most common chronic rheumatic valvular lesion in pregnancy. Causes obstruction of blood flow from the atria to the ventricle, thereby decreasing ventricular filling and causing a fixed cardiac output. Resultant pulmonary edema, pulmonary hypertension, and right ventricular failure. Most pregnant women with this condition can be managed medically.	General symptomatic improvement with medical management involving diuretics, beta blockers, and anticoagulant therapy. Activity restriction, reduction in sodium, and potentially bed rest if condition severe.
Aortic stenosis	Narrowing of the opening of the aortic valve, leading to an obstruction to left ventricular ejection Women with mild disease can tolerate hypervolemia of pregnancy; with progressive narrowing of the opening, cardiac output becomes fixed. Diagnosis can be confirmed with echocardiography. Most women can be managed with medical therapy, bed rest, and close monitoring.	Diagnosis confirmed with echocardiography Pharmacologic treatment with beta blockers and/or antiarrhythmic agents to reduce risk of heart failure and/or dysrhythmias. Bed rest/limited activity and close monitoring.

| Peripartum cardiomyopathy | Rare congestive cardiomyopathy that may arise during pregnancy. Multiparity, age, multiple fetuses, hypertension, an infectious agent, autoimmune disease, or cocaine use may contribute to its presence.
Development of heart failure in the last month of pregnancy or within 5 months of giving birth without any preexisting heart disease or any identifiable cause. | Preload reduction with diuretic therapy
Afterload reduction with vasodilators.
Improvement in contractility with inotropic agents.
Nonpharmacologic approaches include salt restriction and daily exercise such as walking or biking.
The question of whether another pregnancy should be attempted is controversial due to the high risk of repeat complications. |
| Myocardial infarction (MI) | Rare during pregnancy but incidence is expected to increase as older women are becoming pregnant and the risk factors for coronary artery disease become more prevalent.
Factors contributing to MI include family history, stress, smoking, age, obesity, multiple fetuses, hypercholesterolemia, and cocaine use.
Increased plasma volume and cardiac output during pregnancy increase the cardiac workload as well as the myocardial oxygen demands; imbalance in supply and demand may contribute to myocardial ischemia. | Usual treatment modalities for any acute MI along with consideration for the fetus
Anticoagulant therapy, rest, and lifestyle changes to preserve the health of both parties. |

Women with certain congenital conditions should avoid pregnancy. These include uncorrected tetralogy of Fallot or transposition of the great arteries, and

Eisenmenger's syndrome, a defect with both cyanosis and pulmonary hypertension (Brickner, 2014).

Acquired heart diseases are conditions affecting the heart and its associated blood vessels that develop during a person's lifetime, in contrast with congenital heart diseases, which are present at birth. Acquired heart diseases include coronary artery disease, coronary heart disease, rheumatic heart disease, diseases of the pulmonary vessels and the aorta, diseases of the tissues of the heart, and diseases of the heart valves. The incidence of rheumatic heart disease has declined dramatically in the past several decades because of prompt identification of streptococcal throat infections and treatment with antibiotics. When the heart is involved, valvular lesions, such as mitral stenosis, prolapse, or aortic stenosis, are common (see Table 20.3).

Many women are postponing childbearing until their 30s and 40s. With advancing maternal age, underlying medical conditions such as hypertension, diabetes, and hypercholesterolemia contributing to ischemic heart disease become more common and increase the incidence of acquired heart disease complicating pregnancy. Coronary artery disease and myocardial infarction may result.

A woman's ability to function during the pregnancy is often more important than the actual diagnosis of the cardiac condition. The following is a functional classification system developed by the Criteria Committee of the New York Heart Association (1994) based on past and present disability and physical signs. It provides a simple way of classifying the extent of heart failure by placing people in one of four categories based on how much they are limited during physical activity, normal breathing, and varying degrees of shortness of breath and/or chest pain:

- *Class I:* Asymptomatic with no limitation of physical activity; no objective evidence of cardiac disease. Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or chest pain.

- *Class II:* Symptomatic (dyspnea, chest pain) with increased activity resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain. Minimal CVD present.

- *Class III:* Symptomatic (fatigue, palpitations) with normal activity resulting in marked limitation of physical activity. They are comfortable at rest. Less than ordinary activity causes fatigue, palpitation, dyspnea, or anginal pain.

Moderately severe CVD present.

- *Class IV*: Symptomatic at rest or with any physical activity resulting in inability to carry on any physical activity without discomfort. Symptoms of heart failure or the anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased. Severe CVD present.

The classification may change as the pregnancy progresses and the woman's body must cope with the increasing stress on the cardiovascular system resulting from the numerous physiologic changes taking place. Typically, a woman with class I or II cardiac disease can go through a pregnancy without major complications. A woman with class III disease usually has to maintain bed rest during pregnancy. A woman with class IV disease typically should be advised to avoid pregnancy (Grewal, Silversides, & Coleman, 2014). Women with cardiac disease may benefit from preconception counseling so that they know the risks before deciding to become pregnant.

Maternal mortality varies directly with the functional class at pregnancy onset. ACOG has adopted a three-tiered classification according to the risk of death during pregnancy (Box 20.1).

Pathophysiology

Numerous hemodynamic changes occur in all pregnant women. These normal physiologic changes can overstress the woman's cardiovascular system, increasing her risk for problems. Increased cardiac workload and greater myocardial oxygen demand during pregnancy place the woman's cardiovascular system at high risk for morbidity and mortality.

Pregnancy causes cardiac output to rise as early as the first trimester, reaching peak values at 20 to 24 weeks, and continues to increase until it plateaus between 28 and 34 weeks of gestation. This rise in cardiac output is due to a 30% to 50% increase in blood volume (stroke volume) and a 30% increase in heart rate. A normal resting heart rate for any pregnant woman can be on average 20 beats per minute above her normal values.

Take Note!

Uterine blood flow increases by at least 1 liter per minute, requiring the body to produce more blood during pregnancy. This results in a 25% increase in red

blood cells, a 50% expansion of plasma volume during pregnancy, and an overall hemodilution. In addition, the increase in total red blood cellular volume includes an increase in clotting factors and platelets, defining the hypercoagulable state of pregnancy (Swan, 2014). These changes start as early as the second month of gestation.

BOX 20.1

CLASSIFICATION OF MATERNAL MORTALITY RISK

Group I (minimal risk) has a mortality rate of 1% and comprises women with:
• Patent ductus arteriosus
• Tetralogy of Fallot, corrected
• Atrial septal defect
• Ventricular septal defect
• Mitral stenosis, class I and II

Group II (moderate risk) has a mortality rate of 5% to 15% and comprises women with:
• Tetralogy of Fallot, uncorrected
• Mitral stenosis with atrial fibrillation
• Aortic stenosis, class III and IV
• Aortic coarctation without valvular involvement
• Artificial valve replacement

Group III (major risk) has a 25% to 50% mortality rate and comprises women with:
• Pulmonary hypertension
• Complicated aortic coarctation
• Previous myocardial infarction

Retrieved from https://www.goredforwomen.org/about-heart-disease/facts_about_heart_disease_in_women-sub-category/statistics-at-a-glance/; Alonso-Gonzalez, R., & Swan, L. (2014). Treating cardiac disease in pregnancy. *Women's Health*, 10(1), 79–90; and Mohamad, T. N., Fakhri, H. A., Bernal, J. M., Thatai, D., & Peterson, E. (2014). Cardiovascular disease and pregnancy. *eMedicine*. Retrieved from http://emedicine.medscape.com/article/162004-overview

Similarly, cardiac output increases steadily during pregnancy by 30% to 50% over prepregnancy levels. Stroke volume increases 20% to 30% from prepregnant levels, and the maternal heart rate increases by 10 to 20 beats per minute (bpm). The increase is due to both the expansion in blood volume and the augmentation of stroke volume and heart rate. Other hemodynamic changes associated with pregnancy include a decrease in both the systemic vascular resistance and pulmonary vascular resistance, thereby lowering the systolic and diastolic blood pressure. In addition, the hypercoagulability associated with pregnancy might increase the risk of arterial thrombosis and embolization. These normal physiologic changes are important for a successful adaptation to pregnancy but create unique physiologic challenges for the woman with cardiac disease (Comparison Chart 20.1).

Therapeutic Management

Ideally, a woman with a history of congenital or acquired heart disease should consult her health care provider and undergo a risk assessment before becoming pregnant. This risk assessment must consider the woman's functional capacity, exercise tolerance, degree of cyanosis, medication needs, and history of arrhythmias. Data needed for risk assessment can be acquired from a thorough cardiovascular history and examination, a 12-lead electrocardiogram (ECG), and evaluation of oxygen saturation levels by pulse oximetry. The impact of heart disease on a woman's childbearing potential needs to be clearly explained, and providing information on how pregnancy may affect her and the fetus is important. This allows women to make an informed choice about whether they wish to accept the risks associated with pregnancy. When possible, any surgical procedures, such as valve replacement, should be done before pregnancy to improve fetal and maternal outcomes (Sliwa et al., 2015).

COMPARISON CHART 20.1 CARDIOVASCULAR CHANGES: PREPREGNANCY VERSUS PREGNANCY

Measurement	Prepregnancy	Pregnancy
Heart rate	72 (±10 bpm)	+10–20%
Cardiac output	4.3 (±0.9 L/min)	+30–50%
Blood volume	5 L	+20–50%
Stroke volume	73.3 (±9 mL)	+30%
Systemic vascular resistance	1,530 (±520 dyne/cm/sec)	−20%
Oxygen consumption	250 mL/min	+20–30%

If the woman presents for care after she has become pregnant, prenatal counseling focuses on the impact of the hemodynamic changes of pregnancy, the signs and symptoms of cardiac compromise, and dietary and lifestyle changes needed. More frequent prenatal visits (every 2 weeks until the last month and then weekly) are usually needed to ensure the health and safety of the mother and fetus.

Nursing Assessment

Frequent and thorough assessments are crucial during the antepartum period to ensure early detection of and prompt intervention for problems. Assess the woman's vital signs, noting any changes. Auscultate the apical heart rate and heart sounds, being especially alert for abnormalities, including irregularities in rhythm or murmurs. Check the client's weight and compare with baseline and weights obtained on previous visits. Report any weight gain outside recommended parameters. Inspect the extremities for edema and note any pitting.

Question the woman about fetal activity, and ask if she has noticed any changes. Report any changes such as a decrease in fetal movements. Ask the woman about any symptoms of preterm labor, such as low back pain, uterine

contractions, and increased pelvic pressure and vaginal discharge, and report them immediately. Assess the fetal heart rate and review serial ultrasound results to monitor fetal growth.

Assess the client's lifestyle and her ability to cope with the changes of pregnancy and its effect on her cardiac status and ability to function. Evaluate the client's understanding of her condition and what restrictions and lifestyle changes may be needed to provide the best outcome for her and her fetus. A healthy infant and mother at the end of pregnancy is the ultimate goal. As the client's pregnancy advances, expect her functional class to be revised based on her level of disability. Suggest realistic modifications.

The nurse plays a major role in recognizing the signs and symptoms of cardiac decompensation. Decompensation refers to the heart's inability to maintain adequate circulation. As a result, tissue perfusion in the mother and the fetus is impaired. Common complaints of normal pregnancy, such as dyspnea, fatigue, palpitations, orthpnea, and pedal edema, mimic symptoms of worsening cardiac disease and create challenges when trying to evaluate pregnant women with cardiac disease. The pregnant woman is most vulnerable for this complication from 28 to 32 weeks of gestation and in the first 48 hours postpartum (Gandhi & Martin, 2015). Assess the woman for the following signs and symptoms:

• Shortness of breath on exertion, dyspnea

• Cyanosis of lips and nail beds

• Swelling of face, hands, and feet

• Jugular vein engorgement

• Rapid respirations

• Abnormal heartbeats, reports of heart racing or palpitations

• Chest pain with effort or emotion

• Syncope with exertion

• Increasing fatigue

• Moist, frequent cough

Take Note!

Assessing the pregnant woman with heart disease for cardiac decompensation is vital because the mother's hemodynamic status determines the health of the

fetus.

Nursing Management

Nursing management of the pregnant woman with heart disease focuses on assisting with measures to stabilize the mother's hemodynamic status, because a decrease in maternal blood pressure or volume will cause blood to be shunted away from the uterus, thus reducing placental perfusion. Pregnant women with cardiac disease also need assistance in reducing risks that would lead to complications or further cardiac compromise; therefore, education and counseling are critical. Collaboration between the cardiologist, obstetrician, perinatologist, and nurse is needed to promote the best possible outcome.

Drug therapy may be indicated for the pregnant woman with a cardiac disorder. Possible drugs include diuretics, such as Lasix, to prevent heart failure; digitalis to increase contractility and decrease heart rates; antiarrhythmic agents (lidocaine); beta blockers (labetalol); calcium channel blockers (nifedipine) to treat hypertension; and anticoagulants (low-molecular-weight heparin). Warfarin (Coumadin) is not recommended because it crosses the placenta and may have teratogenic effects. It has been associated with spontaneous abortion, multiple birth defects, fetal growth restriction, and stillbirth (Lichtin & Philipson, 2014).

The FDA has changed their drug risk categories as of 6/30/15. They are no longer using categories A, B, C, D, and X. The new rule requires removal of the previous letter pregnancy categories. The package inserts will now include three separate categories that provide information in a narrative format. The goal of the new labeling is to provide information about the drug to the consumer. They now use specific subheadings under each of the three categories: Pregnancy; Lactation; and Females and Males of Reproductive Potential. For specific changes under each category, please access the following FDA web site: http://www.fda.gov/Drugs/DevelopmentApprovalProcess/DevelopmentResources

Encourage the woman to continue taking her cardiac medications as prescribed. Review the indications, actions, and potential side effects of the medications. Reinforce the importance of frequent antepartal visits and close medical supervision throughout the pregnancy.

Discuss the need to conserve energy. Help the client to prioritize household chores and child care to allow rest periods. Encourage the client to rest in the side-lying position, which enhances placental perfusion.

Encourage the client to eat nutritious foods and consume a high-fiber diet to

prevent straining and constipation. Discuss limiting sodium intake if indicated to reduce fluid retention. Contact a dietitian to assist the woman in planning nutritionally appropriate meals.

Assist the woman in preparing for diagnostic tests to evaluate fetal well-being. Describe the tests that may be done, such as ECG and echocardiogram, and explain the need for serial nonstress testing, usually beginning at approximately 32 weeks of gestation. Instruct the woman in how to monitor fetal activity and movements. Urge her to do this daily and report any changes in activity immediately.

Although the morbidity and mortality rates of pregnant women with cardiac disease have decreased greatly, hemodynamic changes during pregnancy (increased heart rate, stroke volume, cardiac output, and blood volume) have a profound effect, which may increase cardiac work and might exceed the functional capacity of the diseased heart. These changes may result in pulmonary hypertension, pulmonary edema, heart failure, or maternal death (Alonso-Gonzalez, & Swan, 2014). Explain the signs and symptoms of these complications and review the sign and symptoms of cardiac decompensation, encouraging the woman to notify her health care provider if any occur.

Provide support and encouragement throughout the antepartal period. Assess the support systems available to the client and her family, and encourage her to use them. If necessary, assist with referrals to community services for additional support.

During labor, anticipate the need for invasive hemodynamic monitoring, and make sure the woman has been prepared for this beforehand. Monitor her fluid volume carefully to prevent overload. Anticipate the use of epidural anesthesia if a vaginal birth is planned. After birth, assess the client for fluid overload as peripheral fluids mobilize. This fluid shift from the periphery to the central circulation taxes the heart, and signs of heart failure such as cough, progressive dyspnea, edema, palpitations, and crackles in the lung bases may ensue before postpartum diuresis begins. Because hemodynamics do not return to baseline for several days after childbirth, women at intermediate or high risk require monitoring for at least 48 hours postpartum (Cunningham et al., 2014).

Pregnancy offers a unique window through which women at risk of future CVD may be identified. Nurses have the opportunity to implement health monitoring, lifestyle modifications, and other needed interventions to reduce the burden of future CVD in all of their pregnant clients. Dispelling the myths surrounding CVD in women verses men (it is a man's disease only) would be

huge in promoting awareness.

Hypertension in Pregnancy

ACOG has recently published revised guidelines for management of hypertension in pregnancy. They have outlined four categories to describe hypertension in pregnancy: preeclampsia–eclampsia, chronic hypertension, chronic hypertension with superimposed preeclampsia, and gestational hypertension. "Mild" is no longer used to categorize the severity of preeclampsia. The woman has it or not, with or without severe features (thrombocytopenia, renal insufficiency, impaired liver function, pulmonary edema, visual, or cerebral changes). Proteinuria is no longer required to diagnose preeclampsia now. ACOG recommends women with preeclampsia without severe features should give birth at 37 0/7 weeks; women with preeclampsia with severe features give birth at 34 0/7 weeks (ACOG, 2013).

Chronic Hypertension

Entering pregnancy with chronic hypertension is increasingly common. It is an important risk factor for pregnancy complications, including for the fetus or newborn, poor fetal growth, preterm birth, low birth weight, admission to the NICU and death, and for the mother, superimposed preeclampsia/eclampsia, acute renal failure, pulmonary edema, surgical birth, placental abruption, stoke, postpartum cardiomyopathy, and mortality (Solomon & Greene, 2015). Chronic hypertension exists when the woman has high blood pressure before pregnancy or before the 20th week of gestation, or when hypertension persists for more than 12 weeks postpartum. The *Eighth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure* (Joint National Committee [JNC 8], 2014) previously classified blood pressure that remained unchanged as follows:

• *Normal:* Systolic less than 120 mm Hg, diastolic less than 80 mm Hg.

• *Prehypertension*: Systolic 120 to 139 mm Hg, diastolic 80 to 89 mm Hg.

• *Mild hypertension:* Systolic 140 to 159 mm Hg, diastolic 90 to 99 mm Hg.

• *Severe hypertension*: Systolic 160 mm Hg or higher, diastolic 100 mm Hg or higher (James et al., 2014).

   Chronic hypertension occurs in up to 22% of women of childbearing age, with the prevalence varying according to age, race, and BMI. It complicates at least 5% of pregnancies, with one in four women developing preeclampsia during pregnancy (Sibai, 2015). Chronic hypertension is typically seen in older, obese women with glucose intolerance. The most common complication is preeclampsia, which is seen in approximately 25% of women who enter the pregnancy with hypertension. Worldwide, about 60,000 women die from preeclampsia each year, corresponding to 12% of all maternal deaths (Raio, Bolla, & Baumann, 2015). (See Chapter 19 for more information about preeclampsia.)

Therapeutic Management

Preconception counseling is important in fostering positive outcomes. Typically, it involves lifestyle changes such as diet, exercise, weight loss, and smoking

cessation. Treatment for women with chronic hypertension focuses on maintaining normal blood pressure, preventing superimposed preeclampsia/eclampsia, and ensuring normal fetal development.

Once the woman is pregnant, antihypertensive agents are typically reserved for severe hypertension >160 mm Hg systolic and >100 mm Hg diastolic. Methyldopa (Aldomet) is commonly prescribed because of its safety record during pregnancy. This slow-acting antihypertensive agent helps to improve uterine perfusion. Other antihypertensive agents that can be used include labetalol (Trandate), atenolol (Tenormin), and nifedipine (Procardia) (Foo et al., 2015).

The U.S. Preventive Services Task Force [USPTF] (2015) recommends daily low-dose aspirin (81 mg/day) after 12 weeks of pregnancy in women, with chronic hypertension and other risk factors, who are at high risk for preeclampsia to reduce its occurrence.

Lifestyle changes are needed and should continue throughout gestation. The woman with chronic hypertension will be seen more frequently (every 2 weeks until 28 weeks and then weekly until birth) to monitor her blood pressure and to assess for any signs of preeclampsia. At approximately 24 weeks of gestation, the woman will be instructed to document fetal movement. At this same time, serial ultrasounds will be ordered to monitor fetal growth and amniotic fluid volume. Additional tests will be included if the client's status changes.

Nursing Assessment

Nursing assessment of the woman with chronic hypertension involves a thorough history and physical examination. Review the woman's history closely for risk factors. The pathogenesis of hypertension is multifactorial and includes many modifiable risk factors such as smoking, obesity, caffeine intake, excessive alcohol intake, excessive salt intake, and use of nonsteroidal anti-inflammatory drugs (NSAIDs). Also be alert for nonmodifiable risk factors such as increasing age and African–American race (Miller & Carpenter, 2015). Ask if the woman has received any preconception counseling and what measures have been used to prevent or control hypertension.

Assess the woman's vital signs, in particular her blood pressure. Evaluate her blood pressure in all three positions (sitting, lying, and standing) and note any major differences in the readings. Assess her for orthostatic hypertension when she changes her position from sitting to standing. Document your findings.

Ask the woman if she monitors her blood pressure at home; if so, inquire about the typical readings. Ask the woman if she uses any medications for blood pressure control, including the drug, dosage, and frequency of administration, as well as any side effects. Ask the woman about lifestyle modifications that she has used to address any modifiable risk factors, and their effectiveness.

Hypertension during pregnancy decreases uteroplac-ental perfusion. Therefore, fetal well-being must be assessed and closely monitored. Anticipate serial ultrasounds to assess fetal growth and amniotic fluid volume. Question the woman about fetal movement and evaluate her report of daily "kick counts." Assess fetal heart rate at every visit.

Nursing Management

Preconception counseling is the ideal time to discuss lifestyle changes to prevent or control hypertension. One area to cover during this visit would be the Dietary Approaches to Stop Hypertension (DASH) diet, which contains an adequate intake of potassium, magnesium, and calcium. Sodium is usually limited to 2.4 g. Suggest aerobic exercise as tolerated. Encourage smoking cessation and avoidance of alcohol. If the woman is overweight, encourage her to lose weight before becoming pregnant, not during the pregnancy (Killion, 2015). Stressing the positive benefits of a healthy lifestyle might help motivate the woman to make the necessary modifications and change unhealthy habits.

Assist the woman in scheduling appointments for antepartum visits every 2 weeks until 28 weeks of gestation and then weekly. Prepare the woman for frequent fetal assessments. Explaining the rationale for the need to monitor fetal growth is important to gain the woman's cooperation. Carefully monitor the woman for signs and symptoms of abruptio placenta (abdominal pain, rigid abdomen, vaginal bleeding), as well as superimposed preeclampsia (elevation in blood pressure, weight gain, edema, proteinuria). Alerting the woman to these risks can mean early identification and prompt intervention.

Stress the importance of daily periods of rest (1 hour) in the left lateral recumbent position to maximize placental perfusion. Encourage women with chronic hypertension to use home blood pressure monitoring devices. Urge the woman to report any elevations. As necessary, instruct the woman and her family how to take and record a daily blood pressure, and reinforce the need for her to take her medications as prescribed to control her blood pressure and to ensure the well-being of her unborn child. Praising her for her efforts at each

prenatal visit may motivate her to continue the regimen throughout her pregnancy.

The close monitoring of the woman with chronic hypertension continues during labor and birth and during the postpartum period to prevent or identify the onset of preeclampsia. Accurate and frequent blood pressure readings and careful administration of antihypertensive medications, if prescribed, are essential components of care. Stressing the need for continued medical supervision after childbirth is vital to motivate the woman to maintain or initiate lifestyle changes and dietary habits and stay compliant with her medication regimen.

RESPIRATORY CONDITIONS

During pregnancy, the respiratory system is affected by hormonal changes, mechanical changes, and prior respiratory conditions. These changes can cause a woman with a history of compromised respiration to decompensate during pregnancy. Although upper respiratory infections are typically self-limiting, chronic respiratory conditions, such as asthma or tuberculosis (TB), can have a negative effect on the growing fetus when alterations in oxygenation occur in the mother. The outcome of pregnancy in a woman with a respiratory condition depends on the severity of the oxygen alteration as well as the degree and duration of hypoxia on the fetus.

Asthma

Worldwide, the prevalence of asthma among pregnant women is on the rise; pregnancy leads to a worsening of asthma for many women (Nagtalon-Ramos, 2014). Asthma affects approximately up to 13% of pregnancies globally, ranging between 200,000 and 376,000 women annually in the United States. It affects over 20 million Americans and is one of the most common and potentially serious medical conditions to complicate pregnancy (Jordan et al., 2014). Maternal asthma is associated with an increased risk of infant death, preeclampsia, intrauterine growth restriction (IUGR), preterm birth, and low birth weight. These risks are linked to the severity of asthma: more severe asthma increases the risk (National Asthma Education and Prevention Program [NAEPP], 2015).

Remember Rose, the pregnant teenager with asthma in acute distress described at the beginning of the chapter? What therapies might be offered to control her symptoms? Should she be treated differently than someone who is not pregnant? Why or why not?

Pathophysiology

Asthma is an allergic-type inflammatory response of the respiratory tract to various stimuli such as allergens (pollen and animal dander), irritants (cigarette smoke and chemicals), stress, infections (colds or flu), and physical exertion. It is also known as reactive airway disease because the bronchioles constrict in response to these stimuli. Asthma is characterized by paroxysmal or persistent symptoms of bronchoconstriction including breathlessness, wheezing, chest tightness, cough, and sputum production. In addition to bronchoconstriction, inflammation of the airways produces thick mucus that further limits the movement of air and makes breathing difficult.

The normal physiologic changes of pregnancy affect the respiratory system. Although the respiratory rate does not change, hyperventilation increases at term by 48% due to high progesterone levels. Diaphragmatic elevation and a decrease in functional lung residual capacity occur late in pregnancy, which may reduce the woman's ability to inspire deeply to take in more oxygen. Oxygen

consumption and the metabolic rate both increase, placing additional stress on the woman's respiratory system (American Academy of Allergy, Asthma, & Immunology [AAAAI], 2015).

Both the woman and her fetus are at risk if asthma is not well managed during pregnancy. When a pregnant woman has trouble breathing, her fetus also has trouble getting the oxygen it needs for adequate growth and development. Severe persistent asthma has been linked to the development of maternal hypertension, low birth weight, preterm birth, preeclampsia, placenta previa, uterine hemorrhage, and oligohydramnios. Women whose asthma is poorly controlled during pregnancy are at increased risk of preterm birth, low birth weight, and stillbirth (Vanders & Murphy, 2015).

The severity of the condition improves in one third of pregnant women, remains unchanged in one third, and worsens in one third (Cunningham et al., 2014). However, the effect of pregnancy on asthma is unpredictable. The greatest increase in asthma attacks usually occurs between 24 and 36 weeks of gestation; flare-ups are rare during the last 4 weeks of pregnancy and during labor (AAAAI, 2015).

Therapeutic Management

Asthma should be treated as aggressively in pregnant women as in nonpregnant women because the benefits of averting an asthma attack outweigh the risks of medications. The ultimate goal of asthma therapy is to prevent hypoxic episodes to preserve continuous fetal oxygenation; improved maternal and perinatal outcomes are achieved with optimal control of asthma. One third of women with asthma develop worsening of control during pregnancy; therefore, close monitoring and reevaluation are essential. Four important aspects of asthma treatment ensure optimal control: close monitoring, education of clients, avoidance of asthma triggers, and pharmacologic therapy.

Many women with asthma have positive skin tests to allergens, the most common being animal dander, dust mites, cockroach antigens, pollens, and molds. There are nonimmune triggers as well, including strong odors, tobacco smoke, air pollutants, and drugs such as aspirin and beta-blockers. For exercise-triggered asthma, the use of a bronchodilator 5 to 60 minutes before exercise may reduce symptoms. Avoidance of these allergens and triggers can significantly reduce the need for medication and the occurrence of exacerbations during and after pregnancy. All women should be strongly encouraged to stop

smoking, but especially those with asthma because they are at increased risk for worsening chronic and acute asthma sequelae.

Allergy injections may benefit those with allergies and asthma, called allergic asthma. Also called immunotherapy, allergy shots do not "cure" asthma in the manner in which an injection of, say, antibiotics might cure an infection. Instead, allergy shots work a bit more like a vaccine. Allergy injections for asthma actually contain a very small amount of an allergen (substance causing allergy). Over time, the dosage is increased. Exposure to progressive amounts of the allergen is likely to help the body develop a tolerance to it. If the allergen buildup is effective, the allergic reaction will become much less severe. Allergy injections can reduce the symptoms of allergies and prevent the development of asthma.

Medical therapy includes a stepwise approach in an attempt to use the least amount of medication necessary to control a woman's asthma and keep her severity in the mild range. Goals of therapy include having normal or near-normal pulmonary function and minimal or no chronic symptoms, exacerbations, or limitations on activities. The final goal is to minimize the adverse effects of treatment. Inhaled corticosteroids are preferred for the management of all levels of persistent asthma in pregnancy. Corticosteroids are the most effective treatment for the airway inflammation of asthma and reduce the hyper-responsiveness of airways to allergens and triggers.

NAEPP (2015) recommends three specific drugs to be used during pregnancy to control asthma:

• Budesonide (inhaled corticosteroid)

• Albuterol (short-acting $beta_2$ agonist)

• Salmeterol (long-acting $beta_2$ agonist)

Oral corticosteroids are not recommended for the long-term treatment of asthma during pregnancy, but they can be used to treat severe asthma attacks during pregnancy (AAAAI, 2015). In addition, two prostaglandins (hemabate and misoprostol [Cytotec]) used for treating postpartum hemorrhage and cervical ripening are contraindicated for clients with asthma due to the risk of bronchial spasm and bronchoconstriction (King et al., 2015).

Nursing Assessment

Obtain a thorough history of the disease, including the woman's usual therapy

and control measures. Question the woman about asthma triggers and strategies used to reduce exposure to them (Box 20.2). Review the client's medication therapy regimen.

Auscultate the lungs and assess respiratory and heart rates. Include the rate, rhythm, and depth of respirations; skin color; blood pressure and pulse rate; and signs of fatigue. Clients with an acute asthma attack often present with wheezing, chest tightness, tachypnea, nonproductive coughing, shortness of breath, and dyspnea. Lung auscultation findings might include diffuse wheezes and rhonchi, bronchovesicular sounds, and a more prominent expiratory phase of respiration compared to the inspiratory phase (Kelly, Massoumi, & Lazarus, 2015). If the pregnancy is far enough along, the fetal heart rate is measured and routine prenatal assessments (weight, blood pressure, fundal height, urine for protein) are completed.

Laboratory studies usually include a complete blood count with differential (to assess the degree of nonspecific inflammation and identify anemia) and pulmonary function tests (to assess the severity of an attack and to provide a baseline to evaluate the client's response to treatment).

Nursing Management

Nursing management focuses on client education about the condition and the skills necessary to manage it: self-monitoring, correct use of inhalers, identifying

and limiting exposure to asthma triggers, and following a long-term plan for managing asthma and for promptly handling signs and symptoms of worsening asthma. Client education fosters adherence to the treatment regimen, thereby promoting an optimal environment for fetal growth and development.

Client education should begin at the first prenatal visit. The importance of optimal asthma control and the risks of poor control for the woman and her fetus should be discussed early in pregnancy. Clients should be taught signs and symptoms, and which should be of concern, as well as who to contact in emergent situations. Women should be observed using their inhalers and correct use reinforced. Frank discussion about the importance of continuing asthma medications and the possible severe consequences for the woman and her fetus with discontinuation is vital.

Ensure that the woman understands drug actions and interactions, the uses and potential abuses of asthma medications, and the signs and symptoms that require medical evaluation. Reviewing potential perinatal complications with the woman is helpful in motivating her to adhere to the prescribed regimen. At each antepartum visit, reassess the efficacy of the treatment plan to determine whether adjustments are needed.

Taking control of asthma in pregnancy is the responsibility of the client along with her health care team. Providing the client with the knowledge and tools to monitor her condition, control triggers and her environment (Teaching Guidelines 20.2), and use medications to prevent acute exacerbations assist the client in taking control. Facilitating a partnership with the woman will improve perinatal outcomes.

 Teaching Guidelines 20.2

TEACHING TO CONTROL ASTHMA LINKED TO ENVIRONMENTAL TRIGGERS

- Remove any carpeting in the house, especially the bedroom, to reduce dust mites.
- Use allergen-proof encasing on the mattress, box spring, and pillows.
- Wash all bedding in hot water.

- Remove dust collectors in house, such as stuffed animals, books, knickknacks.
- Avoid pets in the house to reduce exposure to pet dander.
- Keep humidity <50% to reduce dust mites
- Use a high-efficiency particulate air-filtering system in the bedroom.
- Do not smoke, and avoid places where you can be exposed to passive cigarette smoke from others.
- Dust and vacuum frequently using vacuum with a high-efficiency HEPA air filter
- Avoid use of wood stove heaters within the house
- Stay indoors and use air conditioning when the pollen or mold count is high or air quality is poor.
- Wear a covering over your nose and mouth when going outside in the cold weather.
- Avoid exposure to persons with colds, flu, or viruses.

When teaching the pregnant woman with asthma, cover the following topics:
- Signs and symptoms of asthma progression and exacerbation
- Importance and safety of medication to the fetus and to herself
- Warning signs that indicate the need to contact the health care provider
- Potential harm to the fetus and to herself by under treatment or delay in seeking help
- Prevention and avoidance of known triggers
- Home use of metered-dose inhalers
- Adverse effects of medications

Nurses should instruct and strongly urge women to remain on asthma medications during pregnancy because one third of clients have worsening of their asthma, including those women with mild asthma. There are proven negative effects from exacerbations and poor control on pregnancy outcome, whereas there are clear benefits of good control. Client education about the importance of good asthma control is essential for improving pregnancy outcomes.

During labor, monitor the client's oxygenation saturation by pulse oximetry and provide pain management through epidural analgesia to reduce stress, which may trigger an acute attack. Continuously monitor the fetus for distress during labor and assess fetal heart rate patterns for hypoxia. Assess the newborn for signs and symptoms of hypoxia.

> **Rose,** *the pregnant teenager described earlier, is concerned about passing her asthma on to her baby. What should the nurse discuss with her? What questions should the nurse ask to help in identifying triggers in Rose's environment to prevent future asthma attacks?*

 Take Note!

Successful asthma management can reduce adverse perinatal outcomes: preeclampsia, preterm birth, and low birth weight.

Tuberculosis

TB is known as the great masquerader and manifestation of the disease can be vague and widespread. It is a disease that has been around for years but never seems to go away completely. TB is curable and preventable. Globally, TB is second only to HIV/AIDS as a cause of illness and death in adults, accounting for over 9 million cases of active disease and 2 million deaths each year. Someone in the world is newly infected with TB every second. Overall, one third of the world's population is currently infected with TB (World Health Organization [WHO], 2015b).

Although it is not prevalent in the United States, a resurgence was noted starting in the mid-1980s secondary to the AIDS epidemic and immigration. Left undiagnosed and untreated, each person with active TB will infect on average between 10 and 15 people each year (WHO, 2015b). The link between poverty and TB is strong. With the large numbers of immigrants coming to the United States, all nurses must be skilled in screening for and managing this condition.

In many cultures the social consequences associated with the diagnosis of TB fall most heavily on women. Difficulties finding a marriage partner and divorce or abandonment among those already married are significant consequences for women from Pakistan, Vietnam, and India. Fear of social consequences can translate into delayed or absent health-seeking behavior. In pregnancy, TB that is treated early and adequately has outcomes equivalent to those in nonpregnant women. By contrast, studies have reported an increase in obstetrical mortality with increased incidence of spontaneous abortion, preterm labor, and preeclampsia in cases where TB was diagnosed late (Bates et al., 2015).

A person becomes infected by inhaling the infectious organism *Mycobacterium tuberculosis,* which is carried on droplet nuclei and spread by airborne transmission. The lung is the major site of involvement, but the lymph glands, meninges, bones, joints, and kidneys can become infected. Women can remain asymptomatic for long periods of time as the organism lies dormant. Pregnant women with untreated TB are more likely to have an underweight infant, an infant with a low Apgar score, and perinatal death (Mehta et al., 2015). The newborn is at risk of postnatally acquired TB if the mother still has active TB at the time of birth. Therefore, prenatal diagnosis and effective treatment of the mother are essential.

Therapeutic Management

The WHO recommends that the treatment of TB in pregnant women should be the same as that in nonpregnant women and the rest of the general population. The only exception is that streptomycin should be avoided in pregnancy because it is ototoxic to the fetus.

Medications are the cornerstone of treatment to prevent infection from progressing. The FDA developed pregnancy categories that rank the risk of teratogenic effects of drugs to be used in drug labeling (see the list earlier in the chapter in the discussion of heart disease). The safety of the first-line drugs for the management of active TB in pregnancy has been established, and therapy improves both maternal and neonatal outcomes.

Pregnant women should start treatment as soon as TB is suspected. The preferred initial treatment regimen is INH, rifampin, and ethambutol daily for 2 months, followed by INH and rifampin daily, or twice weekly for 7 months. Women taking INH should also be taking pyridoxine (vitamin B6) supplementation (CDC, 2015b).

Nursing Assessment

Review the woman's history for risk factors such as immunocompromised status, recent immigration status, homelessness or overcrowded living conditions, and injectable drug use. Women emigrating from developing countries such as Latin America, Asia, the Indian subcontinent, Eastern Europe, Russia, China, Mexico, Haiti, and Africa with high rates of TB also are at risk.

At antepartum visits, be alert for clinical manifestations of TB, including fatigue, fever or night sweats, nonproductive cough, weakness, slow weight loss, anemia, hemoptysis, fatigue, and anorexia (Herchline & Amorosa, 2015). If TB is suspected or the woman is at risk for developing TB, anticipate screening with purified protein derivative (PPD) administered by intradermal injection. If the client has been exposed to TB, a reddened induration will appear within 72 hours. If the test is positive, anticipate a follow-up chest X-ray with lead shielding over the abdomen, as well as sputum cultures to confirm the diagnosis.

Nursing Management

Adherence to the multidrug therapy is critical to protect the woman and her fetus from progression of TB. Provide education about the disease process, the mode

of transmission, prevention, potential complications, and the importance of adhering to the treatment regimen.

Stressing the importance of health promotion activities throughout the pregnancy is important. Some suggestions might include avoiding crowded living conditions, avoiding sick people, maintaining adequate hydration, eating a nutritious, well-balanced diet, keeping all prenatal appointments to evaluate fetal growth and well-being, and getting plenty of fresh air outside. Determining the woman's understanding of her condition and treatment plan is important for adherence. A language interpreter may be needed to validate and reinforce her understanding if she does not speak English.

Breast-feeding is not contraindicated during the time the mother is on the medication regimen and should in fact be encouraged. If the mother is untreated for TB at the time of childbirth they should not breastfeed or be in direct contact with their newborn until at least 2 weeks after starting antituberculin medications. Untreated mothers can be encouraged to pump their milk to feed their newborns until they can breastfeed directly (American Academy of Pediatrics [AAP, 2015]). Nurses should consult their hospital policies regarding mothers with tuberculosis for guidance. Management of the newborn of a mother with TB involves preventing transmission by teaching the parents not to cough, sneeze, or talk directly into the newborn's face. Nurses need to stay current about new therapies and screening techniques to treat this centuries-old disease.

HEMATOLOGIC CONDITIONS

Anemia, a reduction in red blood cell volume, is measured by hematocrit (Hct) or a decrease in the concentration of hemoglobin (Hgb) in the peripheral blood. This results in reduced capacity of the blood to carry oxygen to the vital organs of the mother and fetus. Anemia is a sign of an underlying problem but does not indicate its origin.

Iron-Deficiency Anemia

Iron deficiency is the most common pathologic cause of anemia in pregnancy. Increased risk during pregnancy is due to increased maternal iron needs and demands from the growing fetus, increased erythrocyte mas; and, in the third trimester, expanded maternal blood volume (Cantor et al., 2015). Anemia affects one fourth of the world's population, and iron deficiency is the predominate cause. Iron-deficiency anemia mainly reflects poor nutrition, principally attributed to poor economic status worldwide. A recent study supports that and found that iron-deficiency anemia is strongly associated with low socioeconomic status, which affects women's knowledge and health-seeking behaviors. The study concludes that empowering women in terms of education and economic status is the key factor in combating anemia in pregnancy to prevent the vicious cycle of associated problems (Friedman et al., 2015).

Iron-deficiency anemia accounts for 75% to 95% of the cases of anemia in pregnant women (affecting one in four pregnancies), and is usually related to an iron-deficient diet, gastrointestinal issues affecting absorption, or a short pregnancy interval (Jimenez et al., 2015). A woman who is pregnant often has insufficient iron stores to meet the demands of pregnancy.

The clinical consequences of iron-deficiency anemia include preterm delivery, perinatal mortality, and postpartum depression. Fetal and neonatal consequences include low birth weight and poor mental and psychomotor performance (Subramaniam & Girish, 2015). With significant maternal iron depletion, the fetus will attempt to store iron, but at a cost to the mother. Anemia at term increases the perinatal risk for both the mother and newborn. The risks of hemorrhage (impaired platelet function) and infection during and after birth also are increased. Clinical symptoms of iron-deficiency anemia include fatigue, diminished quality of life, impaired cognitive function, increased risk for thromboembolic events, headache, restless legs syndrome, and **pica** (consuming nonfood substances) eating behaviors (Camaschella, 2015).

Therapeutic Management

The goals of treatment for iron-deficiency anemia in pregnancy are to eliminate symptoms, correct the deficiency, and replenish iron stores. The Centers for Disease Control and Prevention (CDC), Health and Medicine Division (HMD),

and ACOG recommend routine iron supplementation for all pregnant women starting at a low dose of 30 mg/day beginning at the first prenatal visit (Moses, 2015). Attempting to meet maternal iron requirements solely through diet in the face of diminished iron stores is difficult.

Nursing Assessment

Review the mother's history for factors that may contribute to the development of iron-deficiency anemia, including poor nutrition, hemolysis, pica (consuming nonfood substances), multiple gestation, limited intervals between pregnancies, and blood loss. Assess the woman's dietary intake as well as the quantity and timing of ingestion of substances that interfere with iron absorption, such as tea, coffee, chocolate, and high-fiber foods. Ask the woman if she has fatigue, weakness, malaise, anorexia, or increased susceptibility to infection, such as frequent colds. Inspect the skin and mucous membranes, noting any pallor. Obtain vital signs and report any tachycardia.

Prepare the woman for laboratory testing. Laboratory tests usually reveal low Hgb (<11 g/dL), low Hct (<35%), low serum iron (<30 mcg/dL), microcytic and hypochromic cells, and low serum ferritin (<100 mg/dL).

Take Note!

Hemoglobin and hematocrit decrease normally during pregnancy in response to an increase in blood plasma in comparison to red blood cells. This hemodilution can lead to physiologic anemia of pregnancy, which does not indicate a decrease in oxygen-carrying capacity or true anemia.

Nursing Management

Nursing management of the woman with iron-deficiency anemia focuses on encouraging adherence to drug therapy and providing dietary instruction about the intake of iron-rich foods. Although iron constitutes a minimal percentage of the body's total weight, it has several major roles: it assists in the transport of oxygen and carbon dioxide throughout the body, it aids in the production of red blood cells, and it plays a role in the body's immune response.

Stress the importance of taking the prenatal vitamin and iron supplement consistently. Encourage the woman to take the iron supplement with vitamin C-

containing fluids such as orange juice, which will promote absorption, rather than milk, which can inhibit iron absorption. Taking iron on an empty stomach improves its absorption, but many women cannot tolerate the gastrointestinal discomfort it causes. In such cases, advise the woman to take it with meals. Instruct the woman about adverse effects, which are predominantly gastrointestinal and include gastric discomfort, nausea, vomiting, anorexia, diarrhea, metallic taste, and constipation. Suggest that the woman take the iron supplement with meals and increase her intake of fiber and fluids to help overcome the most common side effects.

Provide dietary counseling. Recommend foods high in iron, such as dried fruits, whole grains, green leafy vegetables, meats, peanut butter, and iron-fortified cereals (Dudek, 2014). Anticipate the need for a referral to a dietitian. Teaching Guidelines 20.3 highlights instructions for the pregnant woman with iron-deficiency anemia.

Teaching Guidelines 20.3

TEACHING FOR THE WOMAN WITH IRON-DEFICIENCY ANEMIA

- Take your prenatal vitamin daily; if you miss a dose, take it as soon as you remember.
- For best absorption, take iron supplements between meals.
- Awareness of the side effects of iron supplementation
- Avoid taking iron supplements with coffee, tea, chocolate, and high-fiber food.
- Eat foods rich in iron, such as:
  - Meats, green leafy vegetables, legumes, dried fruits, whole grains
  - Peanut butter, bean dip, whole-wheat fortified breads and cereals
- For best iron absorption from foods, consume the food along with a food high in vitamin C.
- Increase your exercise, fluids, and high-fiber foods to reduce constipation.
- Plan frequent rest periods during the day.

Thalassemia

Thalassemia is a group of hereditary anemias in which synthesis of one or both chains of the hemoglobin molecule (alpha and beta) is defective. Inheritance is autosomal recessive. A low Hgb and a microcytic, hypochromic anemia results. The prevalence and severity of thalassemia depend on the woman's racial background: persons of Mediterranean, Asian, Italian, or Greek heritage and African Americans are most frequently affected. Beta-thalassemia is the most common form found in the United States (March of Dimes, 2015b).

Thalassemia occurs in two forms: alpha-thalassemia and beta-thalassemia. Alpha-thalassemia (minor), the heterozygous form, results from the inheritance of one abnormal gene from either parent, placing the offspring in a carrier trait state. These women have little or no hematologic disease and are clinically asymptomatic (silent carrier state). Beta-thalassemia (major) is the form involving inheritance of the gene from both parents. Beta-thalassemia major can be very severe. Genetic counseling might be necessary when decisions about childbearing are being made.

Thalassemia minor has little effect on pregnancy, although the woman will have mild, persistent anemia. This anemia does not respond to iron therapy, and iron supplements should not be prescribed. Several recent studies suggest that pregnancy appears safe for a woman with well-treated beta thalassemia major who does not have heart disease (Rigby, 2015).

Management of thalassemia during pregnancy depends on the severity of the disease. Apart from the routine prenatal visit schedule, thalassemic pregnant women need additional care which includes regular and periodic evaluation of cardiac function by a cardiologist to prevent fluid overload; and frequent hemoglobin and ferritin levels should be monitored to avoid iron overload. Identification and screening are important to plan care. The woman's ethnic background, medical history, and blood studies are analyzed. If the woman is determined to be a carrier, screening of the father of the child is indicated. Knowledge of the carrier state of each parent provides the genetic counselor with knowledge about the risk that the fetus will be a carrier or will have the disease (Karimi, Cohan, & Parand, 2015). Mild anemia may be present, and instructions to rest and avoid infections are helpful. Nurses should provide supportive care and expectant management throughout the pregnancy.

Sickle Cell Anemia

Sickle cell anemia is an autosomal recessive inherited condition that results from a defective hemoglobin molecule (hemoglobin S). It is found most commonly in African Americans, Southeast Asians, and Middle Eastern populations. Sickle cell disease affects millions of people across the globe. In the United States, approximately 90,000, to 100,000 people have the disease, and 2 million have the sickle cell trait. Sickle cell disease occurs once in every 500 African–American births, and once in 36,000 Hispanic–American births. One in 12 African Americans has the sickle cell trait (CDC, 2015c).

Women with sickle cell disease can have more adverse maternal outcomes such as preeclampsia, eclampsia, preterm labor, placental abruption, intrauterine growth restriction, low birth weight, and maternal mortalities (Costa, Viana, & Aguiar, 2015). The gene offers protection against malaria, but can be a cause of chronic pain and early death. Life expectancy is shortened as a consequence of renal damage, cardiac damage, and infection (March of Dimes, 2015c). People with only one gene for the trait (heterozygous) will have sickle cell trait without obvious symptoms of the disease and with little effect on the pregnancy.

Pathophysiology

In the human body, the hemoglobin molecule serves as the oxygen-carrying component of the red blood cells. Most people have several types of circulating hemoglobin (HbA and HbA2) that make up the majority of their circulatory system. In sickle cell disease, the abnormal hemoglobin S (HbS) replaces HbA and HbA2. This abnormal hemoglobin (HbS) becomes "sickle" shaped as a result of any stress or trauma such as infection, fever, acidosis, dehydration, physical exertion, excessive cold exposure, or hypoxia. The sickle shape of the hemoglobin causes clumping together, which blocks the microvasculature. Significant anemia usually results.

Sickle cell anemia during pregnancy is associated with more severe anemia and frequent vaso-occlusive crises, with increased maternal and perinatal morbidity and mortality. In pregnant women with sickle cell anemia, complications can occur at any time during gestation, labor and birth, or postpartum. This is believed to be secondary to hormonal modifications, hypercoagulable state, and increased susceptibility to infection. Microvascular

sickling in the placental circulation is associated with miscarriages, placental abruption, preeclampsia, preterm labor, intrauterine growth restriction, fetal distress, and low birth weight (Vichinsky, 2015).

Therapeutic Management

Ideally, women with hemoglobinopathies are screened before conception and are made aware of the risks of sickle cell anemia to themselves and to the fetus. A blood hemoglobin electrophoresis (lab study used for both DNA and RNA analysis) is done for all women from high-risk ancestry at their first prenatal visit to determine the types and percentages of hemoglobin present. This information should help them in making reproductive decisions.

Treatment depends on the health status of the woman. The effect of sickle cell disease on pregnancy depends on which manifestations the woman is experiencing. For example, sickle cell anemia combined with the increased blood volume in pregnancy increases the risks for heart failure should fluid overload occur in therapy for the anemia (Cunningham et al., 2014).

Early and continuous prenatal care is needed to safeguard the fetus/infant from potential complications during the antepartum, intrapartum, and postpartum periods. Toward this end, prenatal visits for the first and second trimester should be scheduled more frequently. During pregnancy, only supportive therapy is used: blood transfusions for severe anemia, analgesics for pain, and antibiotics for infection.

Nursing Assessment

Assess the woman for signs and symptoms of sickle cell anemia. Ask the woman if she has anorexia, dyspnea, or malaise. Inspect the color of the skin and mucous membranes, noting any pallor. Be alert for indicators of sickle cell crisis, including severe abdominal pain, muscle spasms, leg pains, joint pain, fever, stiff neck, nausea and vomiting, and seizures (Jordan et al., 2014).

Nursing Management

Clients require emotional support, education, and follow-up care to deal with this chronic condition, which can have a great impact on the woman and her family. Monitor vital signs, fetal heart rate, weight gain, and fetal growth. Assess hydration status at each visit and urge the client to drink 8 to 10 glasses of fluid

daily to prevent dehydration. Teach the client about the need to avoid infections (including meticulous hand hygiene), cigarette smoking, alcohol consumption, and temperature extremes.

Assist the woman in scheduling frequent fetal well-being assessments, such as biophysical profiles, nonstress tests, and contraction stress tests, and monitor laboratory test results for changes. Throughout the antepartal period, be alert for early signs and symptoms of crisis.

During labor, encourage rest and provide pain management. Oxygen supplementation is typically used throughout labor, along with intravenous fluids to maintain hydration. The fetal heart rate is monitored closely. After giving birth, the woman is fitted with antiembolism stockings to prevent blood clot formation. Before discharge from the facility after birth of the newborn, discuss family planning options.

The ability to predict the clinical course of sickle cell anemia during pregnancy is difficult. Outcomes have improved for pregnant women with the disease, and currently the majority can achieve a successful live birth. However, pregnancy is associated with an increased incidence of morbidity and mortality. Optimal management during pregnancy should be directed at preventing pain crises, chronic organ damage, and early mortality using a multidisciplinary team approach and prompt, effective, and safe relief of acute pain episodes. Although these measures do not remove the risk of maternal and fetal complications, they are thought to minimize them, promoting a successful pregnancy outcome. As part of the obstetric health care team, the nurse provides nursing interventions for the labor and postpartum client aimed at pain management, maternal/fetal safety, and client education. The overall objective is a healthy outcome for the childbearing family. The nurse has a vital role in making this happen.

AUTOIMMUNE DISORDERS

Autoimmune disorders are a group of more than 80 distinct diseases that emerge when the immune system launches an immune response against its own cells and tissues. Two distinct types of autoimmune disease occur:

1. Localized disorders target specific organs such as the thyroid gland in Hashimoto's thyroiditis and Graves' disease.

2. Systemic disorders affect multiple organs. For example, in systemic lupus erythematosus (SLE), the immune system can target the lungs, hearts, joints, kidneys, brain, and red blood cells.

Autoimmune disorders may cause mild insidious symptoms that come and go or debilitating conditions with high mortality.

Women suffer from autoimmune disease more than men. According to the CDC (2015d), autoimmune diseases affect approximately 8% of the population, 78% of whom are women. Autoimmune diseases are the third most common category of disease in the United States after cancer and heart disease; they affect approximately 5% to 8% of the population or 14 to 22 million people (CDC, 2015d). Previously, the general advice to women with autoimmune diseases, especially SLE, multiple sclerosis, or rheumatoid syndromes, was to avoid pregnancy because there was a high risk of maternal and fetal morbidity and mortality. However, it is now clear that these risks can be reduced in general by avoiding pregnancy when the diseases are active and continuing appropriate medication to reduce the chances of disease flare during pregnancy.

Systemic Lupus Erythematosus

Lupus disease, also known as **systemic lupus erythematosus (SLE)**, is diagnosed based on laboratory values, symptoms, and signs, SLE is a chronic, relapsing autoimmune disease of the connective tissues that can affect various organs, such as the skin, joints, kidneys, and serosal membranes. Lupus disease is of unknown etiology, but it is thought to be a failure of the regulatory mechanisms of the autoimmune system. It is usually managed with anti-inflammatory and antirheumatic medications. Several triggers that cause the disease to activate include estrogen; cigarette smoking; infections, especially Epstein–Barr virus; physical or psychologic stress; exposure to ultraviolet light; and pregnancy. Lupus symptoms may include swollen joints, extreme fatigue, oral ulcers, skin rashes, and sensitivity to sunlight (Mohindra & Marwah, 2015). Lupus is a complex disorder characterized by periods of relative inactivity and periods of disease exacerbation (flare-ups). To be diagnosed with SLE a woman must have at least four out of 11 positive American College of Rheumatology Criteria which include red rash on face, photosensitivity, oral ulcers, arthritis, serositis, renal disease, seizures, fatigue, weight changes, anemia, and a positive antinuclear antibody test (Wasserman & Clowse, 2014).

The overall incidence of lupus in the United States is 150 per 100,000 people. The peak onset occurs between ages 15 and 45 with over 80% of the cases being diagnosed in women who are in their childbearing years. SLE is more common among those of African American, Afro–Caribbean, Asian, Native American, and Hispanic descent (Schur & Hahn, 2015).

Pathophysiology

The autoimmune responses in SLE prevent the body from recognizing "self" from "nonself," thus allowing antibodies to be formed that attack the body's own cells and proteins. This activity causes suppression of the body's normal immunity and damage to the body tissue. The autoimmune response may initially involve one organ or several. The most common organs/organ systems involved are the cardiovascular, integumentary, musculoskeletal, nervous systems, kidneys, and lungs. In pregnancy, inflammation of the connective tissue of the deciduas can result in placental implantation problems and poor functioning (Bartels & Muller, 2015).

Women with SLE are at increased risk for adverse pregnancy outcomes and cardiovascular disease. A pregnancy with lupus is prone to complications, including flares of disease activity during pregnancy or in the postpartum period, preeclampsia, pregnancy loss, miscarriage, stillbirth, fetal growth restriction, and preterm birth. Active lupus nephritis poses the greatest risk. The recognition of a lupus flare during pregnancy may be difficult because the signs and symptoms may mimic those of normal pregnancy (Singh & Chowdhary, 2015).

Therapeutic Management

The focus of therapy is to control disease flare-ups, suppress symptoms, and prevent organ damage. Treatment decisions are based on severity of the condition and organ involvement. Treatment of SLE in pregnancy is generally limited to NSAIDs (e.g., ibuprofen [Advil]), prednisone (Deltasone), and an antimalarial agent, hydroxychloroquine (Plaquenil). During pregnancy in the woman with SLE, the goal is to keep drug therapy to a minimum (King et al., 2015).

Nursing Assessment

The time at which the nurse comes in contact with the woman in her childbearing life cycle will determine the focus of the assessment. If the woman is considering pregnancy, it is recommended that she postpone conception until the disease has been stable or in remission for 6 months. Active disease at time of conception and history of renal disease increase the likelihood of a poor pregnancy outcome (Cunningham et al., 2014). In particular, if pregnancy is planned during periods of inactive or stable disease, the result often is giving birth to healthy full-term babies without increased risks of pregnancy complications. Nonetheless, pregnancies in most autoimmune diseases are still classified as high risk because of the potential for major complications. Preconception counseling should include the medical and obstetric risks of spontaneous abortion, stillbirth, fetal death, fetal growth restriction, preeclampsia, preterm labor, and neonatal death and the need for more frequent visits for monitoring her condition (Hadar, Ashwal, & Hod, 2014).

If the woman is already pregnant when the nurse encounters her, the nurse needs to assess for the following:

• Duration and presence of SLE signs and symptoms (fatigue, fever, malaise, polyarthritis, skin rashes, and multiorgan involvement)

- Evidence of anemia, thrombocytopenia, and thrombophilias
- Underlying renal disease (check the urine for protein and specific gravity)
- Signs of flare-ups
- Abnormalities in laboratory tests
- Signs of infection (check at each prenatal visit especially urinary tract infections and upper respiratory infections since prednisone can mask signs of infection and lower resistance)
- Fetal well-being and growth (check using ultrasound, fundal height measurements, nonstress tests, and biophysical profiles)

Nursing Management

The nurse should discuss with the woman the importance of having good control over her SLE condition throughout the pregnancy. Discussions should focus on the effects of SLE during the pregnancy and possible risk for exacerbations. Emphasize the importance of frequent prenatal visits to detect early preeclampsia, preterm labor, or infections. Instruction should cover the implications and potential side effects of all drug therapies prescribed. Teach energy conservation techniques to prevent fatigue, signs and symptoms to report (extreme fatigue, edema, confusion, abdominal pain, weight loss, leg pain, anorexia), and the need for frequent and close monitoring for fetal well-being.

After childbirth, a discussion of birth control and the effects of the various methods on the disease is essential. Referral to self-help groups and local and national SLE organizations is important for further education of the woman and her family.

SLE can greatly complicate a pregnancy if close supervision is not maintained. The keys to a successful outcome for the mother and her infant include an accurate assessment of the disease and of the various systems involved, and vigilance during the pregnancy for disease progression, effects on the fetus, and development of complications. Nursing care should be directed at early detection of problematic signs and symptoms, education of the mother and family, careful evaluation of the fetal status, and providing support to assist the mother in strengthening her coping strategies.

Multiple Sclerosis

Multiple sclerosis (MS) is a chronic inflammatory, demyelinating autoimmune disorder of the central nervous system. The Multiple Sclerosis Association of America [MSAA] (2015) estimates that approximately 400,000 people in the United States have MS. It is more commonly seen in women than in men, and the mean age of onset is 30 years. Globally, approximately 2.5 million are affected. There is no cure for the disease, and the disease usually becomes a chronic condition (2015).

In the early, inflammatory course of MS, autoreactive T cells cross the blood–brain barrier, attacking myelin proteins and leading to inflammation and demyelination. As the inflammatory process continues, repeated injury results of the myelin membrane with progressive neurodegeneration. The pathologic hallmark of MS can be described as multicentric, multiphasic central nervous system inflammation with resultant demyelination (Armon et al. 2015).

Uncomplicated MS does not have adverse effects on fertility, labor, or birth. Rates of spontaneous abortion, congenital anomalies, and fetal mortality are no higher among women with MS when compared with women in the general population (Vukusic & Marignier, 2015). There is no indication that women with MS require different care or management during the labor and birth process. Pregnant women with MS tend to have fewer relapses during gestation with a subsequent increase in disease activity in the first 3 months postpartum. Breast-feeding does not seem to have an influence on severity or frequency of exacerbations or the health of mothers, and has been shown to decrease MS relapse rates during the first 6 months postpartum (Walker, 2014). Breast-feeding should be encouraged as long as the woman is not being treated with disease-modifying agents.

The clinical presentation of MS can be similar to common pregnancy-related symptoms, especially fatigue, weakness, constipation, urinary frequency, balance problems, back pain, and visual changes. The similarity of the symptoms makes it difficult to attribute any symptoms that may develop during an established pregnancy to the disease process. These symptoms should be assessed carefully to assess MS exacerbations (Novotna & Ehler, 2014).

The focus of therapy for MS is to prevent clinical relapse and postpone neurodegeneration and the subsequent disability. Current medications include anti-inflammatories, immunosuppressants, immunomodulators/biologic agents,

and a variety of complementary and alternative therapies such as vitamin/mineral supplementation, homeopathy, botanical products, and antioxidants. The complementary or alternative therapies have not been proven to reduce relapse rates or disease progression, but many MS sufferers turn to them (King et al., 2015). Most medications used in MS treatment are not FDA-approved during pregnancy, but many have been used and have not shown to have adverse effects.

Nursing care is similar to that outlined previously under SLE. The need for support at this life-changing time is crucial. Continuity of care, access to information tailored to their needs, when requested by the woman or her family, and having a point of contact are all important aspects of nursing care.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is characterized by joint inflammation and progressive disability and is one of the most common chronic autoimmune disorders. It predominates in women, commonly affecting women of childbearing age and may complicate pregnancy. RA primarily affects synovial joints and tissues of the hands and feet, but any joint can be involved. Over time, bone and cartilage are damaged by the chronic inflammation process, resulting in joint deformity and loss of function. Progression of the disease and ensuing disability is unpredictable.

Rheumatoid arthritis affects approximately 1.3 million adults in the United States. It is present in nearly all geographic areas and affects all ethnic groups. The disease typically presents between 30 and 50 years of age and affects twice as many women as men (American College of Rheumatology, 2015). The course of RA during pregnancy is usually benign. In about three fourths of pregnancies, the symptoms of the disease lessen. In these cases, most women experience relief in the first trimester that continues throughout the pregnancy. For many women with RA, pregnancy can provide a reprieve from long-term joint pain and inflammation, but others will not experience remission and will continue to need medication. RA does not adversely affect pregnancy outcome. With occasional exceptions, RA returns after the third to fourth month postpartum (Strangfeld et al., 2015).

Individuals with RA typically present with pain, swelling, and tenderness in joints; decreased mobility; and stiffness after periods of inactivity. Treatment of RA focuses on reducing joint inflammation, managing pain, and preventing joint destruction. The categories of medications used to accomplish this are NSAIDs, glucocorticoids, hydroxychloroquine, methotrexate, immunomodulators/biologic agents, and complementary alternative therapies such as physical therapy, exercise, acupuncture, and joint splinting for pain relief. During pregnancy, medications are limited to hydroxychloroquine, glucocorticoids, and NSAIDs. Methotrexate is a, is contraindicated during pregnancy (King et al., 2015). Careful preconception counseling and risk assessment is important in women with rheumatoid arthritis. Antibody status and all medications need to be reviewed before pregnancy. Maintaining low disease activity before and during pregnancy is essential for optimal outcomes.

Nursing care should address the teratogenicity (the ability to cause birth

defects) and adverse effects of some of the medications used to treat rheumatoid arthritis. Women with RA must be monitored closely following childbirth because most are likely to have arthritis flare-ups during the postpartum period. The general nursing care is similar to that outlined for the low-risk pregnant woman. Nurses caring for women with any disability (physical or cognitive) in general need to provide level-appropriate education on all reproductive health issues and improved access to health care. The woman's specific disability, her resources, and her approach to pregnancy and childbirth all help shape her experience. The nurse can play a role in making her experience a positive, memorable time in her life. Care for the woman with a disability should be well planned and coordinated by ensuring all documentation of the woman's needs and concerns is readily available to all personnel involved in her care. All members of the health care team should be involved in the plan of care and kept up to date of any changes. It is essential that the nurse facilitate care to ensure continuity of care throughout the woman's pregnancy and childbirth experience (Ostensen, 2014).

INFECTIONS

A wide variety of infections can affect the progression of pregnancy, possibly having a negative impact on the outcome. The effect of the infection depends on the timing and severity of the infection and the body systems involved. Common viral infections include cytomegalovirus, rubella, herpes simplex, hepatitis B, varicella, parvovirus B19, and several sexually transmitted infections (STIs; Table 20.4). Toxoplasmosis and group B streptococcus are common nonviral infections. Only the most common infections will be discussed here.

Cytomegalovirus

Human cytomegalovirus (CMV) infects greater than 50% of the human population. Humans are the only known hosts of CMV, which is transmitted via body fluids. Worldwide, the birth prevalence is estimated at seven per 1000 births with the highest rates seen in developing countries. It is typically asymptomatic in most individuals. CMV is the most common congenital and perinatal viral infection in the world (Fig. 20.4). CMV is the leading cause of congenital infection, with morbidity and mortality at birth and sequelae. Each year approximately 1% to 7% of pregnant women acquire a primary CMV infection (Kovacs & Briggs, 2015). Of these, about 30% to 40% transmit the infection to their fetuses. The risk of serious fetal injury is greatest when maternal infection develops in the first trimester or early in the second trimester. Between 10% and 15% of congenitally infected infants are acutely symptomatic at birth and most of the survivors have serious long-term complications (March of Dimes, 2015d). It is a leading cause of hearing loss and intellectual disability in the United States. As a result of its substantial disease burden, congenital CMV is associated with an estimated $1 billion to $2 billion in direct economic costs each year. However, there has been limited progress in developing interventions to prevent or treat CMV infection (Bialas, Swamy, & Permar, 2015). Pregnant women acquire active disease primarily from sexual contact, blood transfusions, kissing, and contact with children in daycare centers. It can also be spread through vertical transmission from mother to child in utero (causing congenital CMV), during birth, or through breast-feeding. The virus can be found in virtually all body fluids. Prevalence rates in women in the United States range from 50% to 85% (CDC, 2015e). In the United States, approximately 1 in 60 people undergo seroconversion each year. Although prevalent in the United States population, CMV is not easily transmitted from host to recipient. The incidence of primary CMV infection in pregnant women in the United States ranges from 1% to 4% (CDC, 2015e).). CMV infection during pregnancy may result in abortion, stillbirth, low birth weight, IUGR, microcephaly, deafness, blindness, intellectual disability, jaundice, or congenital or neonatal infection. The first or primary infection, if it occurs during pregnancy, is the most dangerous to the fetus: the fetus has a 30% to 40% chance of being infected.

There are three time periods during which mother-to-child transmission can

occur: in utero, during birth, and after birth. However, permanent disability only occurs in association with in utero infection. Such disability can result from maternal infection during any point in the pregnancy, but more severe disabilities are usually associated with maternal infection during the first trimester.

Most women are asymptomatic and do not know that they have been exposed to CMV. Symptoms of CMV in the fetus and newborn, known as CMV inclusion disease, include hepatomegaly, thrombocytopenia, IUGR, jaundice, microcephaly, hearing loss, chorioretinitis, and intellectual disability. Newborns that are asymptomatic at birth may go on to develop late neurodevelopmental sequelae, with sensorineural hearing loss being the most common condition (Silasi et al., 2015). Prenatal screening for CMV infection is not routinely performed. Unfortunately, a preventive vaccine remains elusive. Since there is no therapy to prevent or treat CMV infections, nurses are responsible for educating and supporting childbearing-age women at risk for CMV infection. Stressing the importance of good hand hygiene and the use of sound hygiene practices can help to reduce transmission of the virus. A few specific hygiene guidelines for pregnant women include the following:

• Wash hands frequently with soap and water and wear gloves, especially after diaper changes, feeding, wiping nose or drool, and handling children's toys.

• Do not share cups, plates, utensils, food, or toothbrushes.

• Do not share towels or washcloths.

• Do not put a child's pacifier in your mouth.

• Clean toys, countertops, and other surfaces that come in contact with children's urine or saliva.

• Practice safe sex, including limiting sexual partners and use condoms consistently.

TABLE 20.4 SEXUALLY TRANSMITTED INFECTIONS AFFECTING PREGNANCY

Infection/Organism	Effect on Pregnancy and Fetus/Newborn	Implications
Syphilis (*Treponema pallidum*)	Maternal infection increases risk of premature labor and birth. Newborn may be born with congenital syphilis—jaundice, rhinitis, anemia, IUGR, and CNS involvement.	All pregnant women should be screened for this STI and treated with benzathine penicillin G 2.4 million units IM to prevent placental transmission.
Gonorrhea (*Neisseria gonorrhea*)	Majority of women are asymptomatic. It causes ophthalmia neonatorum in the newborn from birth through infected birth canal.	All pregnant women should be screened at first prenatal visit, with repeat screening in the third trimester. All newborns receive mandatory eye prophylaxis with tetracycline or erythromycin within the first hour of life. Mother is treated with ceftriaxone (Rocephin) 125 mg IM in single dose before going home.
Chlamydia (*Chlamydia trachomatis*)	Majority of women are asymptomatic. Infection is associated with infertility and ectopic pregnancy, spontaneous abortions, preterm labor, premature rupture of membranes, low birth weight, stillbirth, and neonatal mortality. Infection is transmitted to newborn through vaginal birth. Neonate may develop conjunctivitis or pneumonia.	All pregnant women should be screened at first prenatal visit and treated with erythromycin.
Human papillomavirus (HPV)	Infection causes warts in the anogenital area, known as condylomata acuminata. These warts may grow large enough to block a vaginal birth. Fetal exposure to HPV during birth is associated with laryngeal papillomas.	Warts are treated with trichloroacetic acid, liquid nitrogen, or laser therapy under colposcopy. Two HPV vaccines have been FDA approved (Gardasil and Cervarix) against the viral types most likely to cause cervical cancer (types 16 and 18) and genital warts (types 6 and 11) has been licensed in the United States for girls and women 9 to 26 years old. The vaccines are 95% to 100% effective. The vaccines are now recommended for young boys also.
Trichomonas (*Trichomonas vaginalis*)	Infection produces itching and burning, dysuria, strawberry patches on cervix, and vaginal discharge. Infection is associated with premature rupture of membranes and preterm birth.	Treatment is with a single 2-g dose of metronidazole (Flagyl).

Rubella

Rubella, commonly called German measles, is spread by droplets or through direct contact with a contaminated object. The risk of a pregnant woman transmitting this virus through the placenta to her fetus increases with earlier exposure to the virus. When infection occurs within the first month after conception, 50% of fetuses show signs of infection; in the second month following conception, 25% of fetuses will be infected; and in the third month, 10% of fetuses will be affected. Congenital rubella can manifest with a diverse range of symptoms in the newborn, including congenital cataracts, glaucoma, cardiac defects, microcephaly, as well as hearing and intellectual disabilities (Jyoti, Shirke, & Matalia, 2015).

FIGURE 20.4 Clinical appearance of infant with congenital CMV with stigmata of disease, including petechial rash, microcephaly, jaundice, and abnormal posture of upper extremities secondary to CNS damage.

Preconception care has been defined as a set of interventions designed to identify and modify risks to a woman's health or pregnancy outcome through prevention and management. This care should be provided any time any health care provider sees a reproductive age woman. Personal and family history, physical exam, laboratory screening, reproductive plan, nutrition, supplements, weight, exercise, vaccinations, and injury prevention should be reviewed in all women. Folic acid 400 mcg per day, as well as proper diet and exercise, should be encouraged. Women should receive the influenza vaccine if planning

pregnancy during flu season; the rubella and varicella vaccines if there is no evidence of immunity to these viruses; and tetanus/diphtheria/pertussis if lacking adult vaccination (Lambert et al., 2015).

Education for primary prevention is the key. Ideally, all women have been vaccinated and have adequate immunity against rubella. However, all women are still screened at their first prenatal visit to determine their status. A rubella antibody titer of 1:8 or greater proves evidence of immunity. Women who are not immune should be vaccinated during the immediate postpartum period so that they will be immune before becoming pregnant again (Agent, 2015). Nurses need to check the rubella immune status of all new mothers and should make sure all mothers with a titer of less than 1:8 are immunized prior to discharge after birth of the newborn.

Herpes Simplex Virus

Genital herpes is an STI caused by the herpes simplex virus (HSV) type 1 or type 2. Both types can cause genital infections, although in recent years HSV-1 has become the predominant cause of genital herpes. Approximately 45 million people are infected with genital herpes in the United States, and 1.5 million new cases are diagnosed annually, including 1,500 newborns. Untreated neonatal HSV infection is associated with a mortality rate of 60%, and survivors experience considerable disability (Ural, 2015). Despite strategies designed to prevent perinatal transmission, the number of cases of newborn HSV infection continues to rise, mirroring the rising prevalence of genital herpes infection in women of childbearing age (Fig. 20.5) (James & Kimberlin, 2015).

FIGURE 20.5 Newborn with disseminated herpes simplex virus infection. Note the healing ulcerations on the abdomen of the infant. From Sweet RL, Gibbs RS. (2009). *Infectious diseases of the female genital tract* (5th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

HSV is a DNA virus with two subtypes: HSV-1 and HSV-2. HSV-1 infections were traditionally associated with oral lesions (fever blisters), whereas HSV-2 infections occurred in the genital region. Currently, either type can be found in either location, but HSV-1 is predominately causing genital herpes now (Ural, 2015).

Infection occurs by direct contact of the skin or mucous membranes with an active lesion through such activities as kissing, sexual (vaginal, oral, anal) contact, or routine skin-to-skin contact. HSV is associated with infections of the

genital tract that when acquired during pregnancy can result in severe systemic symptoms in the mother and significant morbidity and mortality in the newborn. In addition, it may cause spontaneous abortion, birth anomalies, IUGR, or preterm labor. A 60% mortality rate may occur if the neonatal exposure is with an active primary infection (Silasi et al., 2015). Once the virus enters the body, it never leaves.

Infants born to mothers with a primary HSV infection have a 30% to 50% risk of acquiring the infection via perinatal transmission near or during birth. Recurrent genital HSV infections carry a 1% to 3% risk of neonatal infection if the recurrence occurs around the time of vaginal birth (March of Dimes, 2015e). About one in four pregnant women is infected with genital herpes, although most do not know it. Fortunately, only a small number pass the infection on to their newborns (March of Dimes, 2015e).

The greatest risk of transmission is when the mother develops a primary infection near term and it is not recognized. Most neonatal infections are acquired at or around the time of birth through either ascending infection after ruptured membranes or contact with the virus at the time of birth. The method and timing of birth in a woman with genital herpes are controversial. The CDC (2015f) recommends that in the absence of active lesions, a vaginal birth is acceptable, but if the woman has active herpetic lesions near or at term, a cesarean birth might be planned. All invasive procedures that might cause a break in the infant's skin should be avoided, such as artificial rupture of membranes, fetal scalp electrode, or forceps and vacuum extraction (Jordan et al., 2014).

Management for the woman with genital herpes during pregnancy involves caring for her as well as reducing the risk of newborn herpes. Some health care providers start the mother on prophylactic antiviral medications to prevent an active outbreak at the time of childbirth. No therapy can eradicate HSV, and this chronic infection is noted for its frequent asymptomatic viral shedding. Because the majority of newborn herpes cases result from perinatal transmission of the virus during vaginal birth, and because transmission can result in severe neurologic impairment or death, treatment of the mother with an antiviral agent such as acyclovir (Zovirax) must be started as soon as the culture comes back positive. Since the introduction of acyclovir, newer second-generation antivirals have been introduced (e.g., valacyclovir [Valtrex] and famciclovir [Famvir]) and are available (King et al., 2015). Use of condoms and antiviral mediations assist in preventing transmission. Evidence does not support routine HSV serologic

screening among asymptomatic pregnant women currently (Workowski & Bolan, 2015), U, so nurses need to remain knowledgeable about current practice to provide accurate and sensitive care to all women. Despite the surge in vaccine research, there is unfortunately no readily available or preventative or therapeutic vaccine for HSV to date.

Hepatitis B Virus

Hepatitis B virus (HBV) is one of the most prevalent chronic diseases in the world. It is a serious global public health problem in Asia, Africa, Southern Europe, and Latin America especially. It has infected approximately 2 billion people worldwide, of whom more than 350 million are chronically infected. Life-threatening liver disease (cirrhosis, liver failure, and hepatocellular carcinoma) occurs in as many as 40% of people with hepatitis B. HBV infection causes about 5,000 deaths annually in the United States (Contag & Arrabal, 2015). HBV can be transmitted through contaminated blood, illicit drug use, and sexual contact. The virus is 100 times more infectious than HIV and, unlike HIV, it can live outside the body in dried blood for more than a week (Salman et al., 2015).

Sexual transmission accounts for most adult HBV infections in the United States. Acutely infected women develop hepatitis with anorexia, nausea, vomiting, fever, abdominal pain, and jaundice. In women with acute hepatitis B, vertical transmission occurs in approximately 10% of newborns when infection occurs in the first trimester and in 80% to 90% of newborns when acute infection occurs in the third trimester. Without intervention, 40% of infants born to women who are positive for hepatitis B will have chronic hepatitis B by 6 months of age (CDC, 2015g). In addition, hepatitis B infection during pregnancy is associated with an increased risk of preterm birth, fetal distress during labor, meconium peritonitis, low birth weight, and neonatal death. Newborns infected with HBV are likely to become chronic carriers of the virus, becoming reservoirs for continued infection in the population (CDC, 2015g). The fetus is at particular risk during birth because of the possible contact with contaminated blood at this time.

The CDC (2015g) recommends that all pregnant women should be tested for hepatitis B surface antigen (HBsAg) regardless of previous HBV vaccine or screening. Infants born to HBsAg-positive mothers should receive single-antigen HBV vaccine and hepatitis B immunoglobulin (HBIG) within 12 hours after birth. Completion of the vaccine schedule is recommended by HBV vaccination at 1 and 6 months (CDC, 2015g). There is a growing body of literature supporting the safety and efficacy of antiviral therapies administered in the third trimester of pregnancy to the reduce the vertical transmission of the HBV from the mother to the fetus, but to date there has not been any formal

recommendations (Lamberth et al., 2015).

Nursing Assessment

Review the woman's history for factors placing her at high risk:
• History of STIs household contacts with HBV-infected persons
• Employment as a health care provider
• Abuse of intravenous drugs
• Prostitution
• Foreign born
• Multiple sexual partners
• Chinese, Southeast Asian, or African heritage
• Sexual partners who are HBV-infected (CDC, 2015g)

At the first prenatal visit, all pregnant women should be screened for HbsAg via blood studies, even if they were previously vaccinated or tested. Expect to repeat this screening later in pregnancy for women in high-risk groups (Park & Pan, 2014).

Nursing Management

If a woman tests positive for HBV, expect to administer HBV immune globulin (HBIG, Hep-B-Gammagee). The newborn will also receive HBV vaccine (Recombivax-HB, Engerix-B) within 12 hours of birth. The second and third doses of the vaccine are given at 1 and 6 months of age (CDC, 2015g). The CDC recommends routine vaccination of all newborns.

Women who are HbsAg negative may be vaccinated safely during pregnancy. No current research supports the use of surgical births to reduce vertical transmission of HBV. Breast-feeding by mothers with chronic HBV infection does not increase the risk of viral transmission to their newborns, nor is it a contraindication to breast-feeding, unless the woman is taking antiviral medication and has bleeding nipples. Women with bleeding nipples should abstain from breast-feeding until they are healed (Jhaveri, 2015).

Client education related to prevention of HBV is essential. Teach the woman about safer sex practices, good hand hygiene techniques, and the use of standard precautions (Teaching Guidelines 20.4). Protection can be afforded with the

highly effective hepatitis B vaccine.

Teaching Guidelines 20.4

TEACHING TO PREVENT HEPATITIS B VIRUS PROGRESSION

• Abstain from alcohol and potentially hepatotoxic medications.

• Avoid intravenous drug exposure or sharing of needles.

• Encourage all household contacts and sexual partners to be vaccinated.

• Receive immediate treatment for any STI.

• Know that your newborn will receive the hepatitis B vaccine soon after birth.

• Use good hand hygiene techniques at all times.

• Avoid contact with blood or body fluids.

• Use barrier methods such as condoms during sexual intercourse.

• Avoid sharing any personal items, such as razors, toothbrushes, or eating utensils.

• Inform all health care providers of your HBV status.

Permanent remission of the disease even with treatment rarely occurs. Therefore, therapy is directed at long-term suppression of viral replication and prevention of end-stage liver disease. Urge the woman to consume a high-protein diet and avoid fatigue. A healthy lifestyle can help delay disease progression. Initiate an open discussion about the modes of transmission and use of condoms to prevent spread.

Varicella Zoster Virus

Varicella zoster virus (VZV), is one of the eight herpes family viruses. It is the virus that causes both varicella (chickenpox) and herpes zoster (shingles). Primary VZV leads to varicella (chicken pox) and establishes latency in dorsal root ganglia. Reactivation of VZV causes herpes zoster, commonly called shingles. Herpes zoster can occur once immune response against the virus wanes, usually with advancing age.

Pregnant women are at risk for developing varicella when they come in close contact with children who have active infection. Varicella occurs year round, but there is a higher incidence during winter and spring months. Maternal varicella can be transmitted to the fetus through the placenta, leading to congenital varicella syndrome, if the mother is infected during the first half of pregnancy, via an ascending infection during birth, or by direct contact with infectious lesions, leading to infection after birth. Varicella occurs in approximately 1/1,000 pregnancies (Charlier et al., 2014).

Congenital varicella syndrome can occur in newborns of mothers infected during early pregnancy. The vertical transmission rate is estimated to be between 2% and 10%. It is characterized by low birth weight, skin lesions in a dermatomal distribution, spontaneous abortion, chorioretinitis, cataracts, fetal growth restriction, delayed milestones, cutaneous scarring, limb hypoplasia, microcephaly, ocular abnormalities, intellectual disability, and early death (Swamy & Heine, 2015).

Preconception counseling is important for preventing this condition. A major component of counseling involves determining the woman's varicella immunity. Vaccination is the cornerstone of prevention. The vaccine is administered if needed. Varicella vaccine is a live attenuated viral vaccine. It should be administered to all adolescents and adults 13 years of age and older who do not have evidence of varicella immunity (King et al., 2015). Provide education to women who work in occupations that increase the risk of exposure to the virus, such as daycare workers, teachers of young children, and staff caring for children in institutional settings.

Varicella during pregnancy can be associated with severe illnesses for both the mother and her newborn. If contracted in the first half of pregnancy, some pregnant women are at risk for developing varicella pneumonia, which may put them at risk of life-threatening ventilatory compromise and death. Risk of

varicella pneumonia appears to increase during pregnancy (Zhang, Patenaude, & Abenhaim, 2014). If the mother develops varicella rashes close to her due date, generalized neonatal varicella leading to death in about 20% of cases can be expected (Jordan et al. 2014).

Parvovirus B19

Parvovirus B19 infection, often referred to as Fifth disease, occurs worldwide and is extremely common. Most infected persons are asymptomatic. The incidence of acute B19 infection in pregnancy is about 3%. Approximately 30% to 50% of pregnant women are not immune, and vertical transmission is common following maternal infection in pregnancy. Fetal infection may be associated with a normal outcome, but fetal death may also occur without ultrasound evidence of infectious sequelae (Desai & Brustman, 2014). Parvovirus B19 is a common, self-limiting, benign childhood virus that causes erythema infectiosum, also known as Fifth disease (referring to its fifth place in a list of common childhood infections). Approximately 65% of women of reproductive age have developed immunity to parvovirus B19. Infection with parvovirus B19 affects one in 400 pregnant women, but the majority has no adverse pregnancy outcome. Those that do may experience spontaneous abortion and severe fetal anemia. There is no treatment for the pregnant woman with parvovirus B19 infection (Malee, 2015).

Pathophysiology

The infection is spread transplacentally, by the oropharyngeal route in casual contact, and through infected blood. Infection of the fetus occurs through transplacental passage of the virus. Acute infection in pregnancy can cause B19 infection in the fetus, leading to nonimmune fetal hydrops (a serious abnormal accumulation of fluid in two or more fetal compartments, including ascites, pleural effusion, pericardial effusion, and skin edema), secondary to severe anemia or fetal loss, depending on the gestational age at the time of infection. The risk to the fetus is greatest when the woman is exposed and infected within the first 20 weeks of gestation. In addition to hydrops, other fetal effects of parvovirus include spontaneous abortion, congenital anomalies (central nervous system, craniofacial, and eye), and long-term effects such as hepatic insufficiency, myocarditis, and learning disabilities (Edwards, 2014). Fetal infection with B19V is also associated with intrauterine fetal death, nonimmune hydrops fetalis, thrombocytopenia, myocarditis, and neurologic manifestations. Fetal infection can also remain clinically unrecognized (Suliman & Seopela, 2015).

Therapeutic Management

Generally, a diagnosis of parvovirus is based on clinical symptoms and serologic antibody testing for parvovirus immunoglobulin G (IgG) and parvovirus immunoglobulin M (IgM). Parvovirus B19 infection is followed by lifelong immunity, which is shown by positive serum B19 IgG. Pregnant women who have been exposed to or who develop symptoms of parvovirus B19 require assessment to determine whether they are susceptible to infection (nonimmune). If the woman is immune, she can be reassured that she will not develop infection and that the virus will not adversely affect her pregnancy. If she is nonimmune, then referral to a perinatologist is recommended and counseling regarding the risks of fetal transmission, fetal loss, and hydrops is necessary. Knowledge of how best to manage this infection during pregnancy lags behind our understanding of the potential adverse consequences.

Intrauterine B19 infection is a cause of fetal anemia, hydrops, and demise, and perhaps also of congenital anomalies. The best strategy for surveillance of the infected pregnant woman is serial ultrasounds for detection of hydropic changes and fetal anemia, and treatment for severe fetal anemia. Serial ultrasounds are advocated because the rates of fetal death and complications peak 4 to 6 weeks after exposure, but they can occur as late as 3 months following onset of symptoms. The infected newborn is assessed for any anomaly and followed for up to 6 years to identify any sequelae (Smith, 2015).

Nursing Assessment

Review the mother's history for any risk factors. Schoolteachers, daycare workers, and women living with school-aged children are at highest risk for being seropositive for parvovirus B19, especially if a recent outbreak has occurred in those settings. Also assess the woman for specific signs and symptoms. The characteristic rash starts on the face with a "slapped-cheeks" appearance and is followed by a generalized maculopapular rash. Fever, arthralgia, and generalized malaise are usually present in the mother. Prepare the mother for antibody testing.

Nursing Management

Prevention is the best strategy. Stress the need for hand hygiene after handling children; cleaning toys and surfaces that children have been in contact with; and

avoiding the sharing of food and drinks. Screening for parvovirus B19 during early pregnancy may help in early diagnosis, but the cost effectiveness of a national screening program has not been accepted to date. The nurse can provide information regarding risk factors and potential complications if exposed and support the parent's decision.

Group B Streptococcus

Group B streptococcus (GBS) is a naturally occurring bacterium found in approximately 50% of healthy adults. Women who test positive for the GBS bacteria are considered carriers. Carrier status is transient and does not indicate illness. Approximately 25% of pregnant women carry GBS in the rectum or vagina, thus introducing the risk of colonization of the fetus during birth. GBS affects about 1 in every 2,000 newborns in the United States (March of Dimes, 2015f). Approximately 1 out of every 100 to 200 newborns born to mothers who carry GBS will develop signs and symptoms of GBS disease. Although GBS is rarely serious in adults, it can be life threatening to newborns. GBS is the most common cause of sepsis and meningitis in newborns and is a frequent cause of newborn pneumonia (Puopolo, Madoff, & Baker, 2015). Newborns with early-onset (within a week after birth) GBS infections may have pneumonia or sepsis, whereas late-onset (after the first week) infections often manifest with meningitis (CDC, 2015i).

Genital tract colonization poses the most serious threat to the newborn because of exposure during birth and to the mother because of ascending infection after the membranes rupture. GBS colonization in the mother is thought to cause chorioamnionitis, endometritis, and postpartum wound infection.

Therapeutic Management

Antibiotic therapy usually is effective in treating women with GBS infections of the urinary tract or uterus, or chorioamnionitis without any sequelae. According to the CDC guidelines, all pregnant women should be screened for GBS at 35 to 37 weeks of gestation and treated (2015i). Vaginal and rectal specimens are cultured for the presence of the bacterium. Both pregnant women and women during labor who have positive cultures are treated with a penicillin-based anti-infective agent.

Penicillin G is the treatment of choice for GBS infection because of its narrow spectrum. Alternative antibiotics can be prescribed for clients with a penicillin allergy. The drug is usually administered intravenously at least 4 hours before birth so that it can reach adequate levels in the serum and amniotic fluid to reduce the risk of newborn colonization. Close monitoring is required during the

administration of intravenous antibiotics because severe allergic reactions can occur rapidly.

Nursing Assessment

Review the woman's prenatal history, and ask about any previous infection. Determine if the woman's membranes have ruptured and the time of rupture. Rupture of amniotic membranes more than 18 hours increases the risk for infection. Monitor the mother's vital signs, reporting any maternal fever greater than 100.4° F (38° C). Assess the woman for other risk factors for perinatal transmission of GBS, including previous colonization with GBS, low socioeconomic status, African–American race, age less than 20 years, positive colonization at 35 to 37 weeks of gestation, GBS in urine sample, previous birth of GBS-positive newborn, preterm birth, and use of invasive obstetric procedures (March of Dimes, 2015f). Document this information to help prevent vertical transmission to the newborn.

Many women with GBS infection are asymptomatic, but they may have urinary tract infections, uterine infections, and chorioamnionitis.

Nursing Management

Nurses play major roles as educators and advocates for all women and newborns to reduce the incidence of GBS infections. Ensure that pregnant women between 35 and 37 weeks of gestation are screened for GBS infection during a prenatal visit. Record the results and notify the birth attendant if the woman has tested positive for GBS. During labor, be prepared to administer intravenous antibiotics to all women who are GBS positive.

Toxoplasmosis

Toxoplasmosis is a relatively widespread parasitic infection caused by a one-celled organism, *Toxoplasma gondii*. It is found all over the world, and can affect any warm-blooded animal, including humans, although the primary host is the cat. When a pregnant woman is exposed to this protozoan, the infection can pose serious risks to her fetus through transplacental transfer from the mother to the fetus. Between 1 in 1,000 and 8,000 newborns are born infected with toxoplasmosis in the United States (Hokelek, 2015). Cats are the definitive hosts of this parasite and shed it in their feces. It is transferred by hand to mouth after touching cat feces while changing the cat litter box or through gardening in contaminated soil. Consuming undercooked infected meat, such as pork, lamb, or venison drinking contaminated water, and eating unwashed fruits and vegetables can also transmit this organism.

A pregnant woman that contracts toxoplasmosis for the first time has an approximately 40% chance of passing the infection to her fetus. Toxoplasmosis acquired during pregnancy means high risk of damage for the fetus (March of Dimes, 2015g). Although the woman typically remains asymptomatic, transmission to her fetus can occur throughout pregnancy. A fetus that contracts congenital toxoplasmosis typically has a low birth weight, enlarged liver and spleen, chorioretinitis, jaundice, IUGR, hydrocephalus, microcephaly, neurologic damage, and anemia. Severity varies with gestational age; usually, the earlier the infection, the more severe the effects (Silasi et al., 2015).

Treatment of the woman during pregnancy to reduce the risk of congenital infection is a combination of pyrimethamine and sulfadiazine. Treatment with sulfonamides during pregnancy has been shown to reduce the risk of congenital infection.

Although there is much to learn about the best approach to the identification and treatment of toxoplasmosis, it is known that early treatment leads to the best neurodevelopmental outcomes in infants. Prevention is the key to managing this infection. Nurses play a key role in educating the woman about measures to prevent toxoplasmosis (Teaching Guidelines 20.5).

TEACHING TO PREVENT TOXOPLASMOSIS

• Avoid eating raw or undercooked meat, especially lamb or pork. Cook all meat to an internal temperature of 160° F (71° C) throughout.

• Clean cutting boards, work surfaces, and utensils with hot soapy water after contact with raw meat or unwashed fruits and vegetables.

• Peel or thoroughly wash all raw fruits and vegetables before eating them.

• Wash hands thoroughly with warm water and soap after handling raw meat.

• Avoid feeding the cat raw or undercooked meats.

• Avoid emptying or cleaning the cat's litter box. Have someone else do it daily.

• Keep outdoor sandboxes covered to prevent cat feces contamination

• Keep the cat indoors to prevent it from hunting and eating birds or rodents.

• Avoid uncooked eggs and unpasteurized milk.

• Wear gardening gloves when in contact with outdoor soil.

• Avoid contact with children's sandboxes, because cats can use them as litter boxes.

Women Who Are HIV Positive

The **human immunodeficiency virus (HIV)** infection is a chronic infection causes by the retrovirus HIV infection of T cells that express CD4 receptors causing immunodeficiency. Once the CD4-positive cell count falls below a certain level, HIV infection causes increased susceptibility to infections, cancers, and neurologic damage (Hardy, Esposti, & Nee, 2015). HIV is transmitted by blood and body fluids. The number of people contracting HIV infection annually is estimated at nearly 50 million, including approximately 20 million women of childbearing age and 2.5 million children, most of whom acquired HIV from mother-to-child transmission. According to the most recent incidence estimates, more than one million people in the United States are living with HIV infection, and almost one in six are unaware of their infection (CDC, 2015j).

Despite the revolutionary strides that have been made in treatment and detection and recent clinical advances and cautious optimism associated with combination therapies and vaccines, the number of individuals who are HIV-positive continues to climb worldwide. Intensive efforts notwithstanding, no real "cure" can be seen on the horizon. To achieve a durable end to the HIV pandemic, a vaccine remains essential in the fight against this virus (Fauci, Folkers, & Marston, 2014). Also, despite dramatic reductions in perinatal transmission of HIV in the United States, barriers to prevention still exist and perinatal HIV infections continue.

Historically, HIV/AIDS was associated with the male homosexual community and intravenous drug users, but currently the prevalence of HIV/AIDS is now increasing more rapidly among women than men. Women account for one in four people living with HIV in the United States, and are the fastest growing segment of persons becoming infected with HIV; transmission in women occurs most frequently from sexual contact (84%) and from intravenous drug use (15%) (CDC, 2015k). Most women, a large number of whom are mothers, have acquired the disease through heterosexual contact. The risk of acquiring HIV through heterosexual contact is greater for women due to exposure to the higher viral concentration in semen. In addition, sexual intercourse may cause breaks in the vaginal lining, increasing the chances that the virus will enter the woman's body. Fifty percent of all HIV/AIDS cases worldwide occur in women. AIDS is the third leading cause of death among all U.S. women aged 25 to 44 years and the leading cause of death among African–American women in this age group.

At some point in their lifetimes, an estimated 1 in 32 African–American women will be diagnosed with HIV infection (CDC, 2015k).

Pathophysiology

The three recognized modes of HIV transmission are unprotected sexual intercourse with an infected partner, contact with infected blood or blood products, and perinatal transmission.

Take Note!

HIV is not transmitted by doorknobs, faucets, toilets, dirty dishes, mosquitoes, wet towels, coughing or sneezing, shaking hands, or being hugged or by any other indirect method.

The virus attacks the T4 cells, decreases the CD4 cell count, and disables the immune system. The HIV condition can progress to a severe immunosuppressed state termed **acquired immunodeficiency syndrome (AIDS)**. AIDS is a progressive, debilitating disease that suppresses cellular immunity, predisposing the infected person to opportunistic infections and malignancies. The CDC defines AIDS as an HIV-infected person with a specific opportunistic infection or a CD4 count of less than 200. Eventually, death occurs. The time from infection with HIV to development of AIDS is a median of 11 years but varies depending on whether the client is taking current antiretroviral therapy (ART) (Maartens, Celum, & Lewin, 2014). Research indicates that pregnancy does not accelerate the progression of HIV to AIDS or death (Calvert & Ronsmans, 2015).

TABLE 20.5 STAGES OF HIV INFECTION OUTLINED BY THE CDC

Stages	Description	Clinical Picture
I	Acute infection	Early stage with pervasive viral production. Flu-like symptoms 2–4 weeks after exposure. Signs and symptoms: weight loss, low-grade fever, fatigue, sore throat, night sweats, and myalgia. Ability to spread HIV is highest during this stage because large amounts of HIV are being produced in the body and the CD4 count drops.
II	Asymptomatic infection or clinical latency	Viral replication continues within lymphatics, but slows down Usually free of symptoms; lymphadenopathy.
III	Persistent generalized lymphadenopathy	Possibly remaining in this stage for years; AIDS develops in most within 7–10 years. Opportunistic infections occur.
IV	End-stage disease (AIDS)	Severe immune deficiency; very vulnerable to infections. High viral load and low CD4 counts. Signs and symptoms: bacterial, viral, or fungal opportunistic infections, fever, wasting syndrome, fatigue, neoplasms, and cognitive changes.

Adapted from Centers of Disease Control and Prevention [CDC]. (2015s). *About HIV/AIDS.* Retrieved from http://www.cdc.gov/hiv/basics/whatishiv.html

Once infected with HIV, the woman develops antibodies that can be detected with the enzyme-linked immunosorbent assay (ELISA) and confirmed with the Western blot test. Antibodies develop within 6 to 12 weeks after exposure, although this latent period is much longer in some women. Table 20.5 highlights the four stages of HIV infection according to the CDC (2015l).

Impact of HIV on Pregnancy

When a woman who is infected with HIV becomes pregnant, the risks to herself, her fetus, and the newborn are great. The risks are compounded by problems such as drug abuse, lack of access to prenatal care, poverty, poor nutrition, and high-risk behaviors such as unsafe sex practices and multiple sex partners, which can predispose the woman to additional STIs such as herpes, syphilis, or human papillomavirus (HPV). Additional risk factors to assess for include women who exchange sex for money or drugs or have sex partners who do; a woman whose past or present sex partners were HIV infected; and women who had a blood transfusion between 1978 and 1985. Early identification of maternal HIV seropositivity allows early antiretroviral treatment to prevent mother-to-child transmission, allows a provider to avoid obstetric practices that may increase the risk for transmission, and allows an opportunity to counsel the mother against breast-feeding (also known to increase the risk for transmission) (U.S. Preventive Services Task Force [USPSTF], 2014). Subsequently, pregnant women who are HIV-positive are at risk for preterm delivery, fetal growth restriction, premature rupture of membranes, intrapartal or postpartum

hemorrhage, postpartum infection, poor wound healing, and genitourinary tract infections (CDC, 2015m).

Perinatal transmission of HIV (from the mother to the fetus or child) also can occur. However, such cases have decreased in the past several years in the United States, primarily due to the use of antiretroviral therapy in pregnant women infected with HIV. This has not been the case in poor countries without similar resources. The Joint United Nations programs on HIV/AIDS (UNAIDS) estimate that over 2000 new infections due to mother-to-child transmission occur daily. This number is expected to increase rapidly as the prevalence rises in Southeast Asia (Rakhmanina & van den Anker, 2014). Perinatal transmission rates are as high as 35% when there is no intervention (ART) and below 1% when antiretroviral treatment and appropriate care are available African–American and Hispanic women make up 82% of HIV/AIDS cases among women and according to CDC data (2015j), the majority of prenatally infected children were African American or Hispanic. Lack of timely HIV testing during pregnancy is a major contributor to this outcome. Interventions are needed that will address knowledge barriers to HIV testing among African–American and Hispanic women. Research has found that women who have information about methods to prevent perinatal HIV transmission and the importance of testing for the baby's or mother's health are more likely to be HIV tested. Media campaigns addressing the benefits of HIV testing may be a significant intervention. Media campaigns are not only successful in promoting HIV testing but, in populations with high HIV prevalence, they also are cost effective (International AIDS Society, 2015).

With perinatal transmission, approximately half of children manifest AIDS within the first year of life, and about 80% have clinical symptoms of the disease within 3 to 5 years (Rivera & Frye, 2014). Breast-feeding is a major contributing factor for mother-to-child transmission, and the infected mother must be informed about this (March of Dimes, 2015i). The U.S. Public Health Service recommends that women who are HIV positive should avoid breast-feeding to prevent HIV transmission to the newborn. Given the devastating effects of HIV infection on children, preventing its transmission is critical (NIH, 2014).

In addition to perinatal transmission, the fetus and newborn also are at risk for prematurity, IUGR, low birth weight, and infection. Prompt treatment with antiretroviral medications for the infant with an HIV infection may slow the progression of the disease.

Therapeutic Management

Women who are seropositive for HIV require counseling about the risk of perinatal transmission and the potential for obstetric complications. The risk of perinatal transmission directly correlates with the viral load (Drake et al., 2014). A discussion of the options on continuing the pregnancy, medication therapy, risks, perinatal outcomes, and treatment is warranted. Women who elect to continue with the pregnancy should be treated with ART regardless of their CD4 count or viral load. Interventions to reduce HIV transmission include antiretroviral therapy to the mother and the newborn, consideration of elective cesarean section in women with elevated plasma viral load, and the avoidance of breastfeeding. With these interventions, the risk of HIV transmission is now less than 1% (Giles, 2015).

Drug therapy is the mainstay of treatment for pregnant women infected with HIV. The standard treatment is oral antiretroviral drugs given twice daily until giving birth, intravenous administration during labor, and oral zidovudine (AZT) for the newborn within 6 to 12 hours of birth (Vogler, 2014). The goal of therapy is to reduce the viral load as much as possible, which reduces the risk of transmission to the fetus.

Decisions about the birthing method to be used are made on an individual basis based on several factors involving the woman's health. Some reports suggest that cesarean birth may reduce the risk of HIV infection (King et al., 2015). Efforts to reduce instrumentation, such as avoiding the use of an episiotomy, fetal scalp electrodes, and fetal scalp sampling, will reduce the newborn's exposure to body fluids.

With appropriate therapies, the prognosis for pregnant women with HIV infection has improved significantly. In addition, the newborns of women with HIV infection who have received treatment usually do not become infected. Unfortunately, therapy is complicated and medications are expensive. Moreover, the medications are associated with numerous adverse effects and possible toxic reactions. These therapies offer a dual purpose: reduce the likelihood of mother-to-infant transmission and provide optimal suppression of the viral load in the mother. The core goal of all medical therapy is to bring the client's viral load to an undetectable level, thus minimizing the risk of transmission to the fetus and newborn.

Nursing Assessment

Nursing assessment begins with a thorough history and physical examination. In addition, the woman is offered screening for HIV antibodies. Screening and effective intervention for women who are HIV positive are essential components of prenatal services, which also include education, counseling, testing, treatment, and continued care.

HEALTH HISTORY AND PHYSICAL EXAMINATION

Review the woman's history for risk factors, such as unsafe sex practices, multiple sex partners, and injectable drug use. Also have the woman complete a risk assessment survey. In addition, question the woman about any flu-like symptoms such as a low-grade fever, fatigue, sore throat, night sweats, diarrhea, cough, skin lesions, or muscle pain. Numerous factors influence perinatal transmission. Factors that increase risk of perinatal transmission include high maternal viral load; maternal immune depletion (low CD4 T cell counts); maternal genital tract infections; nutritional deficiencies; drug abuse; cigarette smoking; unprotected sexual intercourse; other opportunistic and coexisting infections (TB, malaria); prolonged ruptured membranes; and breast-feeding. Nurses need to take a thorough history to identify risk factors present.

Perform a complete physical examination. Obtain the woman's weight and determine if she has lost weight recently. Assess for signs and symptoms of STIs, such as vulvovaginal candidiasis, bacterial vaginosis, HSV, chancroid, CMV, or chlamydia because of the increased risk for STIs.

Take Note!

Women who request an HIV test despite reporting no individual risk factors should be considered at risk, since many are not likely to disclose their high-risk behaviors.

LABORATORY AND DIAGNOSTIC TESTING

The USPSTF (2014) recommends that all pregnant women be offered HIV antibody testing, regardless of their risk of infection, and that testing be done during the initial prenatal evaluation. Testing is essential because treatments are available that can reduce the likelihood of perinatal transmission and maintain the health of the woman.

Screening only women who are identified as high risk based on their histories is inadequate due to the prolonged latency period that can exist after exposure. Also, research indicating that treatment with antiretroviral agents could reduce vertical transmission from the infected mother to the newborn has dramatically increased the importance of HIV antibody screening in pregnancy.

Offer all women who are pregnant or planning a pregnancy HIV testing using ELISA. Prepare the woman with a reactive screening test for an additional test, such as the Western blot or an immunofluorescence assay. The Western blot is the confirmatory diagnostic test. A positive antibody test confirmed by a supplemental test indicates that the woman has been infected with HIV and can pass it on to others. HIV antibodies are detectable in at least 95% of women within 3 months after infection (Rayment, Asboe, & Sullivan, 2014).

In addition to the usual screening tests done in normal pregnancy, additional testing for STIs may be necessary. Women infected with HIV have high rates of STIs, especially HPV, vulvovaginal candidiasis, bacterial vaginosis, syphilis, HSV, chancroid, CMV, gonorrhea, chlamydia, and hepatitis B (March of Dimes, 2015i).

Nursing Management

Women infected with HIV should have comprehensive prenatal care, which starts with pretest and post-test counseling. In pretest counseling, the client completes a risk assessment survey and the nurse explains the meaning of positive versus negative test results, obtains informed consent for HIV testing, and educates the woman on how to prevent HIV infection by changing lifestyle behaviors if needed. Post-test counseling includes informing the client of the test results, reviewing the meaning of the results again, and reinforcing safer sex guidelines. All pretest and post-test counseling should be documented in the client's chart.

EDUCATING THE CLIENT

Pregnant clients are dealing with many issues at their first prenatal visit. The confirmation of pregnancy may be accompanied by feelings of joy, anxiety,

depression, or other emotions. Simultaneously, the client is given many pamphlets and receives advice and counseling about many important health issues (e.g., nutrition, prenatal development, appointment schedules). This health teaching may be done while the woman feels excited, tired, and anxious. To expect women to understand detailed explanations of a complex disease entity (HIV/AIDS) too may be unrealistic. Determine the client's readiness for this discussion. Identify the client's individual needs for teaching, emotional support, and physical care. Nurses need to approach education and counseling of HIV-positive pregnant women in a caring, sensitive manner. Address the following information:

• Infection control issues at home

• Safer sex precautions

• Stages of the HIV disease process and treatment for each stage

• Symptoms of opportunistic infections

• Preventive drug therapies for her unborn infant

• Avoidance of breast-feeding

• Referrals to community support, counseling, and financial aid

• Client's support system and potential caretaker

• Importance of continual prenatal care

• Need for a well-balanced diet

• Measures to reduce exposure to infections

Be knowledgeable about HIV infection and how HIV is transmitted and share this knowledge with all women. Nurses also can work to influence legislators, public health officials, and the entire health establishment toward policies to address the HIV epidemic. Research toward treatment and cure is tremendously important, but the major key to prevention of the spread of the virus is education. Nurses play a major role in this education.

SUPPORTING THE CLIENT

Be aware of the psychosocial sequelae of HIV/AIDS. A diagnosis of HIV can put a woman into an emotional tailspin, during which she is worried about her own health and that of her unborn infant. She may experience grief, fear, or anxiety about the future of her children. Along with the medications that are so

important to her health maintenance, address the woman's mental health needs, family dynamics, capacity to work, and social concerns and provide appropriate support and guidance.

A stigma against both mothers and newborns who are HIV-exposed or infected persists as a challenge on many maternity care units. As nurses work to address this preventable disease, they should do so in a respectful conscientious manner. Beyond basic nursing care, nurses should strive to provide respectful care for all mothers and their newborns together. To accomplish this, be aware of your personal beliefs and attitudes toward women who are HIV positive or have AIDS. Incorporate this awareness in your actions as you help the woman face the reality of the diagnosis and treatment options. Empathy, understanding, caring, and assistance are key to helping the client and her family.

PREPARING FOR LABOR, BIRTH, AND AFTERWARD

Current evidence suggests that cesarean birth performed before the onset of labor and before the rupture of membranes significantly reduces the rate of perinatal transmission. ACOG recommends that HIV-positive women be offered elective cesarean birth to reduce the rate of transmission beyond that which may be achieved through ART. They further suggest that operative births be performed at 38 weeks of gestation and that amniocentesis be avoided to prevent contamination of the amniotic fluid with maternal blood. Decisions concerning the method of delivery should be based on the woman's viral load, the duration of ruptured membranes, the progress of labor, and other pertinent clinical factors (USPSTF, 2014).

Prepare the woman physically and emotionally for the possibility of cesarean birth and assist as necessary. Ensure that she understands the rationale for the surgical birth.

After the birth of the newborn, the motivation for taking antiretroviral medications may be lower, thus affecting the woman's adherence to therapy. Encourage the woman to continue therapy for her own sake as well as that of the newborn. Nurses can make a difference in helping women to adhere to their complex drug regimens.

Reinforce family planning methods during this time, incorporating a realistic view of her disease status. It is clear that hormonal contraceptives are not protective against HIV infection and that dual protection with condoms should be the goal for women using hormonal contraception (U.S. Agency for International Development [USAID] 2014). Advise the woman that breast-

feeding is not recommended. Instruct the woman who is HIV positive in self-care measures, including the proper method for disposing of perineal pads to reduce the risk of exposing others to infected body fluids. Finally, teach her the signs and symptoms of infection in newborns and infants, encouraging her to report any to the health care provider.

The evolution of HIV infection into a chronic disease has implications across all clinical care settings. Every nurse should be knowledgeable about the prevention, testing, treatment, and chronicity of the disease in order to provide high-quality care to people with or at risk for HIV. Breakthroughs in the prevention of HIV important to public health include male circumcision, antiretrovirals to prevent mother-to-child transmission, ART in HIV+ people to prevent transmission, and antiretrovirals for pre-exposure prophylaxis. Nurses, therefore, need to have an understanding of the changing epidemiology of the disease, the most recent testing recommendations, developments in screening technology, the implications of aging with HIV infection, and the nursing implications of this ongoing epidemic.

Take Note!

When providing direct care, **ALWAYS** follow standard precautions.

VULNERABLE POPULATIONS

Every year there are an estimated 208 million pregnancies worldwide, with about 6.6 million of them in the United States (Alan Guttmacher Institute, 2015b). Each pregnancy runs the risk of an adverse outcome for the mother and the baby, but risks are dramatically increased for certain vulnerable populations: adolescents, women over the age of 35, women who are obese, and women who abuse substances. Although risks cannot be totally eliminated once pregnancy has begun, they can be reduced through appropriate and timely interventions.

Every woman's experience with pregnancy is unique and personal. The circumstances each one faces and what pregnancy means to her involve emotions and experiences that belong solely to her. Many women in these special population groups go through this experience in confusion and isolation, feeling desperately in need of help but not knowing where to go. Although all pregnant women experience these emotions to a certain extent, they are heightened in women who have numerous psychosocial issues. Pregnancy is a stressful time. Pregnant women face wide-ranging changes in their lives, relationships, and bodies as they move toward parenthood. These changes can be challenging for a woman without any additional stresses but are even more so in the face of age extremes, illness, or substance abuse.

Skilled nursing interventions are essential to promote the best outcome for the client and her baby. Timely support and appropriate interventions during the perinatal period can have long-standing implications for the mother and her newborn, ultimately with the goal of stability and integration of the family as a unit.

Pregnant Adolescent

Adolescence lasts from the onset of puberty to the cessation of physical growth, roughly from 11 to 19 years of age. Adolescents vacillate between being children and being adults. They need to adjust to the physiologic changes their bodies are undergoing and establish a sexual identity during this time. They search for personal identity and desire freedom and independence of thought and action. However, they continue to have a strong dependence on their parents (Crockett & Crouter, 2014).

Adolescent pregnancy has emerged as one of the most significant social problems facing our society. The latest estimates show that approximately one million teens become pregnant each year in the United States (Alan Guttmacher Institute, 2015a; CDC, 2015a). Among these approximately half will give birth, slightly over one-third will opt for abortions, and the remaining 14% will have miscarriages or stillbirths. Despite being an advanced and relatively affluent nation, teens in the United States have higher rates of pregnancy and childbearing than any other industrialized country (Sedgh et al., 2015). It is estimated that 11% of births worldwide are to adolescents 15 to 19 years old (Ganchimeg et al., 2014). In addition, about half of all teen pregnancies occur within 6 months of first having sexual intercourse. About one in four teen mothers under age 18 have a second baby within 2 years after the birth of their first baby. Most of these girls are unmarried, and many are not ready for the emotional, psychological, and financial responsibilities of parenthood. Teens are least likely of all maternal age groups to get early and regular prenatal care (March of Dimes, 2015j). Adolescent pregnancy is further complicated by the adolescent's lack of financial resources: the income of teen mothers is half that of women who have given birth in their 20s (March of Dimes, 2015j).

Although the incidence of teenage pregnancy has steadily declined since the early 1990s, it continues to be higher in the United States than in any other industrialized country (Alan Guttmacher Institute, 2015a). Even this reduced incidence represents what is considered an unacceptably high level of pregnancy in an age group that is most likely to suffer the social consequences of early pregnancy. Although teen birth rates in the United States have declined, they remain high, especially among African–American and Hispanic teens and in southern states. The highest rate of unintended teenage pregnancies occurs in Hispanics and African Americans.

Currently, fewer high school students are having sexual intercourse, and more sexually active students are using some method of contraception. However, many teens who have had sexual intercourse have not spoken with their parents about sex, and use of contraceptives remains rare (Centers for Disease Control and Prevention [CDC] 2015a). Subsequently, adolescent pregnancy is considered a major health problem and is addressed in *Healthy People 2020* (see Healthy People 2020 20.1).

Impact of Pregnancy in Adolescence

The impact of adolescent pregnancy is evident in maternal and perinatal morbidity and mortality. Nonetheless, in addition to the age involved in precocious pregnancy, it also reflects previous conditions such as malnutrition, communicable diseases, and deficiencies in the health care given to pregnant adolescents. The most important impact lies in the psychosocial area: it contributes to a loss of self-esteem, societal discrimination, a destruction of life projects, and the maintenance of the circle of poverty (WHO, 2015a).

HEALTHY PEOPLE 2020 • 20.2

Objective	Nursing Significance
FP-8 Reduce pregnancy rates among adolescent females by 10% by 2020.	Will help to foster a continued decline in adolescent pregnancy rates by focusing on interventions related to pregnancy prevention, including safe sex practices and teaching about the complications associated with adolescent pregnancy.
FP-9 Increase the proportion of adolescents ages 17 years and under who have never had sexual intercourse by 10% by 2020.	
FP-10 Increase the proportion of sexually active persons ages 15 to 19 years who use condoms to both effectively prevent pregnancy and provide barrier protection against disease by 10% by 2020.	
FP-11 Increase the proportion of sexually active persons ages 15 to 19 years who use condoms and hormonal or intrauterine contraception to both effectively prevent pregnancy and provide barrier protection against disease by 10% by 2020.	
FP-12 Increase the proportion of adolescents who received formal instruction on reproductive health topics before they were 18 years old by 10% by 2020.	
FP-13 Increase the proportion of adolescents who talked to a parent or guardian about reproductive health topics before they were 18 years old by 10% by 2020.	
HIV-8 Reduce the number of perinatally acquired HIV and AIDS cases by 10% by 2020.	Education for the pregnant mothers about the need and rationale for antiretroviral drug therapy to prevent vertical transmission of HIV to their fetus will help reduce this incidence.
MICH-11 Increase abstinence from alcohol, cigarettes, and illicit drugs among pregnant women by 10% by 2020. **MICH-25** Reduce the occurrence of fetal alcohol syndrome (FAS) by 10% by 2020.	Education and support offered to pregnant women regarding the hazards of alcohol, cigarettes, and illicit drugs will reduce the abuse of these substances to enhance the perinatal outcomes.
NWS-22 Reduce iron deficiency among pregnant females.	Providing nutritional instruction on iron-rich foods will help reduce the incidence of iron deficiency anemia during pregnancy.

Healthy People objectives based on data from http://www.healthypeople.gov.

Adolescents are a unique group with special needs related to their stage of development. Adolescent pregnancy can be an emotionally charged situation, laden with ethical dilemmas and decisions. Topics such as abstinence, safer sex, abortion, and the decision to have a child are sensitive issues.

Adolescent pregnancy is an area when a nurse's moral convictions may influence the care that he or she provides to clients. Nurses need to examine their own beliefs about teen sexuality to identify personal assumptions. Putting aside one's moral convictions may be difficult, but it is necessary when working with pregnant adolescents. To be effective, health care providers must be able to communicate with adolescents in a manner they can understand and respect them as individuals.

The idea of it taking "a village to raise a child," as suggested by former First Lady Hillary Clinton in 1996, is perhaps even more valid than previously

thought regarding teen pregnancy. The evidence suggests that it's not enough to teach teens to "just say no," nor is it enough to give them information about contraceptive methods; teens need to be connected to their parents, their peers, and their community (Whitworth & Cockerill, 2014). Nurses should feel that there is always hope and the chance of positive outcomes; nurses see that every day, often in the faces of their youngest clients. Nurses have to believe in that and work toward '*connecting*' with their teen clients. Nurses are on the front line of health care, and are often the first to interact and build rapport with teenagers. Teens that engage in risky sexual behavior may seek out nurses first. Nurse's scope of practice includes providing education and a source of comfort and support to all ages. It is therefore imperative for all nurses to be able to provide age appropriate information about sexual health. In providing this care, the quality of life and outcome of both mother and her infant can be improved.

Developmental Issues

An adolescent must accomplish certain developmental tasks to advance to the next stage of maturity. These developmental tasks include:

• Seeking economic and social stability

• Adjusting to sexually maturing bodies and feelings

• Developing a personal value system

• Building meaningful relationships with others (Fig. 20.6)

• Becoming comfortable with their changing bodies

• Working to become independent from their parents

• Learning to verbalize conceptually (CDC, 2015n)

Adolescents have special needs when working to accomplish their developmental tasks and making a smooth transition to young adulthood. One of the biggest areas of need is sexual health. Adolescents commonly lack the information, skills, and services necessary to make informed choices related to their sexual and reproductive health. Developmentally, adolescents are trying to figure out who they are and how they fit into society. As adolescents mature, their parents become less influential and peers become more influential. Peer pressure can lead adolescents to participate in sexual activity, as can the typical adolescent's belief that "it won't happen to me" (Box 20.3). As a result, unplanned pregnancies occur. Work on the developmental tasks of adolescence,

especially identity, can be interrupted as the adolescent attempts to integrate the tasks of pregnancy, bonding, and preparing to care for another with the tasks of developing self-identity and independence. A pregnant adolescent must try to meet her own needs along with those of her fetus. The process of learning how to separate from the parents while learning how to bond and attach to a newborn brings conflict and stress. A pregnancy can exacerbate an adolescent's feeling of loss of control and helplessness (American Academy of Pediatrics, 2014).

FIGURE 20.6 Adolescent girls sharing time together.

POSSIBLE FACTORS CONTRIBUTING TO ADOLESCENT PREGNANCY

• Early menarche

• Peer pressure to become sexually active

• Sexual or other abuse as a child

• Lack of accurate contraceptive information

• Fear of telling parents about sexual activity

• Feelings of invulnerability

• Poverty (85% of births occur in poor families)

• Culture or ethnicity (high incidence in Hispanic and African-American girls)

• Unprotected sex

• Low self-esteem and inability to negotiate

• Lack of appropriate role models

• Strong need for someone to love

• Drug use, truancy from school, or other behavioral problems

• Wish to escape a bad home situation

• Early dating without supervision

Health and Social Issues

Adolescent pregnancy has a negative impact in terms of both health and social consequences. For example, 7 out of 10 adolescents will drop out of school.

More than 75% will receive public assistance within 5 years of having their first child. In addition, children of adolescent mothers are at greater risk of preterm birth, low birth weight, child abuse, neglect, poverty, and death. The younger the adolescent is at the time of the first pregnancy, the more likely it is that she will have another pregnancy during her teens (March of Dimes, 2015j). Adolescent pregnancy also places them at high risk for obstetric complications such as preterm labor and births; low-birth-weight infants; STIs; poor maternal weight gain, preeclampsia, iron-deficiency anemia, poor eating habits, and inadequate nutrition and postpartum depression (Rajoriya & Kalra, 2015).

The psychosocial risks associated with early childbearing often have an even greater impact on mothers, families, and society than the obstetric or medical risks (Northridge & Coupey, 2015). Pregnant adolescents experience higher rates of domestic violence and substance abuse. Those experiencing abuse are more likely to abuse substances, receive inadequate prenatal care, and have lower pregnancy weight compared with those who are not (Jeha et al., 2015). Moreover, substance abuse (cigarettes, alcohol, or illicit drugs) can contribute to low birth weight, fetal growth restriction, preterm births, newborn addiction, and sepsis (March of Dimes, 2015j).

Although early childbearing (12 to 19 years of age) occurs in all socioeconomic groups, it is more prevalent among poor women and those from minority backgrounds, who face more obstetric and newborn risks than their more affluent counterparts (March of Dimes, 2015j). Poverty often contributes to delayed prenatal care and medical complications related to poor nutrition, such as anemia.

The financial burden of adolescent pregnancy is high and costs taxpayers an estimated $11 billion annually in the United States (Alan Guttmacher Institute, 2015b). Much of the expense stems from Medicaid, food stamps, state health department maternity clinics, the federal Aid to Families with Dependent Children program, and direct payments to health care providers. However, this amount does not address the costs to society in terms of the loss of human resources and the far-reaching intergenerational effects of adolescent parenting. For some adolescents, pregnancy may be seen as a hopeless situation: a grim story of poverty and lost dreams, of being trapped in a life that was never wanted. Health-related behaviors, such as smoking, diet, sexual behavior, and help-seeking behaviors, which are developed during adolescence often, endure into later life (Fedorowicz et al., 2014). The consequences associated with an adolescent's less-than-optimal health status at this age due to pregnancy can

ultimately affect her long-term health and that of her children. However, some adolescents can create a happy, stable life for themselves and their children by facing their challenges and working hard to beat the odds.

> *Recall Rose, the pregnant teenager with asthma. What issues would be important for the nurse to discuss with her related to her pregnancy, her asthma, and her age?*

Nursing Assessment

Assessment of the pregnant adolescent is the same as that for any pregnant woman. However, when dealing with pregnant teens, the nurse also needs to ask:
• How does the girl see herself in the future?
• Are realistic role models available to her?
• How much does she know about child development?
• What financial resources are available to her?
• Does she work? Does she go to school?
• What emotional support is available to her?
• Can she resolve conflicts and manage anger?
• What does she know about health and nutrition for herself and her child?
• Will she need help dealing with the challenges of the new parenting role?
• Does she need information about community resources?

Having an honest regard for adolescents requires getting to know them and being able to appreciate the important aspects of their life. Doing so forms a basis for the nurse's clinical judgment and promotes care that takes into account the concerns and practical circumstances of the teen and her family. Skillful practice includes knowing how and when to advise a teen and when to listen and refrain from giving advice. Giving advice can be misinterpreted as "preaching," and the adolescent will probably ignore the information. The nurse must be perceptive, flexible, and sensitive and must work to establish a therapeutic relationship.

Nursing Management

For adolescents, as for all women, pregnancy can be a physically, emotionally, and socially stressful time. The pregnancy is often both the result of and cause of social problems and stressors that can be overwhelming to them. Nurses must support adolescents during the transition from childhood into adulthood, which is complicated by their emergence into motherhood. Assist the adolescent in identifying family and friends who want to be involved and provide support throughout the pregnancy.

Help the adolescent identify the options for this pregnancy, such as abortion, self-parenting of the child, temporary foster care for the baby or herself, or placement of the child for adoption. Explore with the adolescent if the pregnancy was planned or unintended. Becoming aware of why she decided to have a child is necessary to help with the development of the adolescent and her ability to parent. Identify barriers to seeking prenatal care, such as lack of transportation, too many problems at home, financial concerns, the long wait for an appointment, and lack of sensitivity on the part of the health care system. Encourage the girl to set goals and work toward them. Assist her in returning to school and furthering her education. As appropriate, initiate a referral for career or job counseling.

Stress that the girl's physical well-being is important for both her and her developing fetus, which depends on her for its own health-related needs. Assist with arrangements for care, including stress management and self-care. Having a healthy newborn eases the transition to motherhood somewhat, rather than having to deal with the added stress of caring for an unhealthy baby (Rajoriya & Kalra, 2015). Monitor weight gain, sleep and rest patterns, and nutritional status to promote positive outcomes for both mother and child. Stress the importance of attending prenatal education classes. Provide appropriate teaching based on the adolescent's developmental level and emphasize the importance of continued prenatal and follow-up care. Monitor maternal and fetal well-being throughout pregnancy and labor (Fig. 20.7).

FIGURE 20.7 A pregnant adolescent receiving care during labor.

Nurses can also play a major role in preventing adolescent pregnancies, perhaps by volunteering to talk to teen groups. Teaching Guidelines 20.6 highlights the key areas for teaching adolescents about pregnancy prevention.

Teaching Guidelines 20.6

TOPICS FOR TEACHING ADOLESCENTS TO PREVENT PREGNANCY

• High-risk behaviors that lead to pregnancy.

• Involvement in programs such as Free Teens, Teen Advisors, or Postponing Sexual Involvement.

• Planning and goal setting to visualize their futures in terms of career, college, travel, and education.

• Choice of abstinence or taking a step back to become a "second-time virgin."

• Discussions about sexuality with a wiser adult—someone they respect can help put things in perspective.

• Protection against STIs and pregnancy if they choose to remain sexually active.

• Critical observation and review of peers and friends to make sure they are

creating the right atmosphere for friendship.

- Empowerment to make choices that will shape their life for years to come, including getting control of their own lives now.

- Appropriate use of recreational time, such as sports, drama, volunteer work, music, jobs, church activities, and school clubs.

Tackling many issues surrounding adolescent pregnancy is difficult. Making connections with clients is crucial regardless of how complex their situation is. The future challenges nurses to find solutions to teenage pregnancies. Nurses must take proactive positions while working with adolescents, parents, schools, and communities to reduce the problems associated with early childbearing.

Nurses who provide care to adolescents have an opportunity to discuss future pregnancies and to use health care visits to teach about preconception health. Teaching adolescents who both express a desire for pregnancy and those who do not express such a desire is an important part of comprehensive nursing care. Teens require thorough teaching about health care risks such as smoking cessation, body weight control, interpersonal violence, and the need for folic acid. Adolescents should be the prime recipients of preconception education at every health care visit.

Teen childbearing is associated with adverse consequences for mothers and their children and imposes high public sector costs. Prevention of teen pregnancy requires evidence-based sex education, support for parents in talking with their children about pregnancy prevention and other aspects of sexual and reproductive health, and ready access to effective and affordable contraception for teens who are sexually active (CDC, 2015o).

The Advanced Maternal Age Woman

It is estimated that by the year 2025 about 25% of mothers will begin their childbearing period at an "advanced age." Advanced age is a risk factor for female infertility, pregnancy loss, fetal anomalies, stillbirth, and obstetric complications (Sauer, 2015). A few decades ago, a woman having a baby after the age of 35 probably was giving birth to the last of several children, but today she may be having her first. With advances in technology and the tendency of women to seek career advancement prior to childbearing, the dramatic increase in women having first pregnancies after the age of 35 will likely continue.

Impact of Pregnancy on the Advanced Maternal Age Woman

Whether childbearing is delayed by choice or by chance, women starting a family at age 35 or older are not doing so without risk. Women in this age group may already have chronic health conditions that can put the pregnancy at risk. In addition, numerous studies have shown that increasing maternal age is a risk factor for infertility and spontaneous abortions, gestational diabetes, chronic hypertension, postpartum hemorrhage, preeclampsia, preterm labor and birth, multiple pregnancy, genetic disorders and chromosomal abnormalities, placenta previa, fetal growth restriction, low Apgar scores, and surgical births (Schimmel et al., 2015). However, even though increased age implies increased complications, most women today, who become pregnant after age 34, have healthy pregnancies and healthy newborns. Today, one in five women in the United States has her first child after age 34 (March of Dimes, 2015m).

Nursing Assessment

Nursing assessment of the pregnant woman over age 34 is the same as that for any pregnant woman. For a woman of this age, a preconception visit is important to identify chronic health problems that might affect the pregnancy and also to address lifestyle issues that may take time to modify. Encourage the advanced maternal aged woman to plan for the pregnancy by seeing her health care provider before getting pregnant to discuss preexisting medical conditions, medications, and lifestyle choices. Assess the woman for risk factors such as cigarette smoking, poor nutrition, overweight or underweight, alcohol use, or illicit drug use.

A preconception visit also provides the opportunity to educate the woman about risk factors and provide information on how to modify her lifestyle habits to improve the pregnancy outcome. Assist the woman with lifestyle changes so that she can begin pregnancy in an optimal state of health. For example, if the woman is overweight, educate her about weight loss so that she can start the pregnancy at a healthy weight. If the woman smokes, encourage smoking cessation to reduce the effects of nicotine on herself and her fetus.

Prepare the woman for laboratory and diagnostic testing to establish a baseline for future comparisons. The risk of having a baby with Down syndrome increases with age, especially over age 34. Amniocentesis is routinely offered to all older women to allow the early detection of numerous chromosomal abnormalities, including Down syndrome. Additionally, a quadruple blood test screen (alpha fetoprotein [AFP], human chorionic gonadotropin [hCG], unconjugated estriol [UE], and inhibin A [placental hormone]) drawn between 15 and 20 weeks of pregnancy can be helpful in screening for Down syndrome and neural tube defects.

Nursing Management

During routine prenatal visits, the nurse can play a key role in promoting a healthy pregnancy. Consider social, genetic, and environmental factors that are unique to the advanced maternal aged pregnant women and prepare to address these factors when providing care. In a study by Mills& Lavender (2014), compared with the younger women, older women had statistically similar rates of gestational hypertension, gestational diabetes, preterm premature rupture of membranes/preterm labor, and abnormal placentation. Cesarean birth was higher in older women versus younger ones. Neonatal outcomes of gestational age and birth weight were excellent and similar between groups. Despite the increase risks, there are potential psychologic and social advantages to delaying childbirth and absolute numbers of complications are small.

Assess the woman's knowledge about risk factors and measures to reduce them. Educate her about measures to promote a positive outcome. Encourage her to get early and regular prenatal care. Advise her to eat a variety of nutritious foods, especially fortified cereals, enriched grain products, and fresh fruits and vegetables, and drink at least six to eight glasses of water daily and to take the prescribed vitamin containing 400 mcg of folic acid daily. Also stress the need for her to avoid alcohol intake during pregnancy, avoid exposure to second-hand

smoke, and take no drugs unless they are prescribed. Provide continued surveillance of the mother and fetus throughout the pregnancy.

The Obese Pregnant Woman

Obese pregnant women are a particularly vulnerable group because their disability (obesity) is highly visible. In the United States, nearly 36% of adults are obese, including one out of three women (CDC, 2015p). Excess weight and obesity have gained attention as serious health care threats globally. Obesity during pregnancy is defined as a Body Mass Index (BMI) of 30 kg/m² or more calculated using the height and weight measured at the first prenatal visit. Compared to normal weight women, overweight and obese women tend to gain excessive weight in pregnancy and are high risk for maternal and birth outcomes. Excessive gestational weight gain is strongly associated with postpartum weight retention which increases the risk of additional weight gains in subsequent pregnancies (Chang et al., 2015). Obesity contributes to social, psychological, and economic problems throughout a woman's lifetime. Negative attitudes and discrimination by society can have negative consequences for the woman's quality of life. The number of women who are overweight or obese during pregnancy has also increased. During pregnancy, excess weight increases both obstetric and neonatal risks, including:

• Gestational diabetes

• Hypertension

• Thromboembolism

• Preeclampsia

• Preterm labor and birth

• Congenital anomalies

• Childhood and adolescent obesity

• Fetal macrosomia (birth weight. >4,000 g)

• Difficulty fighting postpartum infections

• Depression

• Tendency to remain overweight/obesity between pregnancies

• Prolongation of pregnancy/increased likelihood of post-term infant

• Increased risk of stillbirth

• Higher rate of cesarean births

• Increased risk of maternal mortality

• High risk for postpartum hemorrhage (ACOG, 2014b)

Negative or judgmental attitudes toward overweight or obese individuals can be encountered within the health care community and its providers, including nurses. Nurses can find it difficult to discuss weight issues during prenatal visits with obese women (Knight-Agarwal et al., 2014). Preconception assessment and counseling are needed for obese women and should include specific information about maternal and fetal risks of obesity in pregnancy, as well as encouragement to undertake a weight-reduction program including diet, exercise and behavior modification, enable achievement of a healthy weight prior to conception.

Obese pregnant women require individualized nursing care. Extra time may be needed to promote healthful practices, which should include dealing with issues of weight, diet, and exercise. Specialist dietary interventions and evidence-based guidelines for working with childbearing women must be seen as a public health priority by all nurses. This care must be done with honesty and respect for all of the woman's needs. There is an opportunity for health promotion aimed at disseminating information about the risks of obesity in pregnancy to overweight and obese women of childbearing age.

The Pregnant Woman and Substance Abuse

Substance abuse in pregnancy is a significant public health crisis causing increased morbidity in tow individuals, the mother, and the fetus. The epidemic of substance abuse continues to pose a significant challenge to all nations. Although there is a tendency to simply associate drug abuse with poverty, the problem affects every social stratum, gender, and race; and pregnant women are no exception. **Perinatal drug abuse** is the use of alcohol and other drugs by pregnant women. The incidence of substance abuse during pregnancy is highly variable because most pregnant women are reluctant to reveal the extent of their use. The National Institute on Drug Abuse (NIDA) (2015a) estimates that 7% or more of the women in the United States have used illicit drugs while pregnant. These include cocaine, marijuana, heroin, and psychotherapeutic drugs that were not prescribed by a health care provider. More than 20% used alcohol and 19% smoked cigarettes during their pregnancy (2015a).

Impact of Substance Abuse on Pregnancy

Substance use can be viewed along a continuum between social recreational drug use and addiction. Substance abuse is very prevalent remains and continues to remain undetected and underdiagnosed in many pregnant women. Substance abuse rarely starts during pregnancy. More often, women enter pregnancy already abusing or dependent on drugs.

Prenatal education and counseling is essential to successfully impacting this high-risk population. The positive overall impact of adequate prenatal care on birth outcomes is well documented. For pregnant substance users, the receipt of adequate prenatal care is especially critical. Several studies have reported that increasing the adequacy of prenatal care utilization in pregnant substance users reduces risks for prematurity, low birth weight, and perinatal mortality. However, many pregnant women who are substance users do not seek prenatal care for fear of being reported to Child Protective Services (SAMHSA, 2015).

The use of drugs, legal or not, increases the risk of medical complications in the mother and poor birth outcomes in the newborn. The placenta acts as an active transport mechanism, not as a barrier, and substances pass from a mother to her fetus through the placenta. Thus, along with the mother, the fetus experiences substance use, abuse, and addiction. Additionally, fetal vulnerability

to drugs is much greater because the fetus has not developed the enzymatic system needed to metabolize drugs (Doulatram, Raj, & Govindaraj, 2015).

EFFECTS OF ADDICTION

Addiction is a multifaceted process that is affected by environmental, psychological, family, and physical factors. Women who use drugs, alcohol, or tobacco come from all socioeconomic backgrounds, cultures, and lifestyles. Factors associated with substance abuse during a pregnancy may include low self-esteem, inadequate support systems, low self-expectations, high levels of anxiety, socioeconomic barriers, involvement in abusive relationships, chaotic familial and social systems, and a history of psychiatric illness or depression. Women often become substance abusers to relieve their anxieties, previous physical, sexual, and emotional traumas in their life, depression, and feelings of worthlessness (Slater, 2015).

Societal attitudes regarding women and substance abuse may prohibit them from admitting the problem and seeking treatment. Society sanctions women for failing to live up to expectations of how a pregnant woman "should" behave, thereby possibly driving them further away from the treatment they so desperately need. For many reasons, pregnant women who abuse substances feel unwelcome in prenatal clinics or medical settings. Often they seek prenatal care late or not at all. They may fear being shamed or reported to legal or child protection authorities. A nonjudgmental atmosphere and unbiased teaching to all pregnant women regardless of their lifestyle is crucial. A caring, concerned manner is critical to help these women feel safe and respond honestly to assessment questions.

Pregnancy can be a motivator for some who want to try treatment. The goal of therapy is to help the client deal with pregnancy by developing a trusting relationship. Providing a full spectrum of medical, social, and emotional care is needed.

EFFECTS OF COMMONLY ABUSED SUBSTANCES

Substance abuse in pregnancy has increased during the past three decades in the United States, resulting in approximately 250,000 infants being born yearly with prenatal exposure to illicit substances (CDC, 2015q). Routine screening and education of women of childbearing age remain the most important ways to reduce addiction in pregnancy.

Substance abuse during pregnancy, particularly in the first trimester, has a

negative effect on the health of the mother and the growth and development of the fetus. The fetus experiences the same systemic effects as the mother, but often more severely. The fetus cannot metabolize drugs as efficiently as the expectant mother and will experience the effects long after the drugs have left the women's system. Substance abuse during pregnancy is associated with preterm labor, abortion, IUGR, abruptio placenta, depressed Apgar scores, third trimester bleeding, meconium staining at birth, fetal demise, low birth weight, neurobehavioral abnormalities, and long-term childhood developmental consequences (WHO, 2015c). Table 20.6 summarizes the effects of selected drugs during pregnancy. *Healthy People 2020* (see Healthy People 2020 20.2) also addresses goals for perinatal substance abuse.

TABLE 20.6 EFFECTS OF SELECTED DRUGS ON PREGNANCY

Substance	Effect on Pregnancy
Alcohol	Spontaneous abortion, inadequate weight gain, IUGR, fetal alcohol spectrum disorder, the leading cause of intellectual disability
Caffeine	Vasoconstriction and mild diuresis in mother; fetal stimulation, but teratogenic effects not documented via research
Nicotine	Vasoconstriction, reduced uteroplacental blood flow, decreased birth weight, abortion, prematurity, abruptio placentae, fetal demise
Cocaine	Vasoconstriction, gestational hypertension, abruptio placentae, abortion, "snow baby syndrome," CNS defects, IUGR
Marijuana	Anemia, inadequate weight gain, "amotivational syndrome," hyperactive startle reflex, newborn tremors, prematurity, IUGR

Opiates and Narcotics	Maternal and fetal withdrawal, abruptio placentae, preterm labor, premature rupture of membranes, perinatal asphyxia, newborn sepsis and death, intellectual impairment, malnutrition
Sedatives	CNS depression, newborn withdrawal, maternal seizures in labor, newborn abstinence syndrome, delayed lung maturity

Alcohol. Alcohol abuse is a major public health issue in the United States. Alcohol is a teratogen, a substance known to be toxic to human development. The true rate of prenatal alcohol consumption is unknown. It is recognized that fetal alcohol spectrum disorder (FASD) is entirely preventable through alcohol abstinence, but worldwide approximately 30% of pregnant women consume alcohol during pregnancy (Vall et al., 2015). Theoretically, no mother would give a glass of wine, beer, or hard liquor to her newborn, but when she drinks, her embryo or fetus is exposed to the same blood alcohol concentration as she is.

The teratogenic effects of heavy maternal drinking have been recognized since 1973, when fetal alcohol syndrome was first described. Fetal alcohol syndrome is now a classification under the broader term of **fetal alcohol spectrum disorder (FASD)**; this disorder includes the full range of birth defects, such as structural anomalies and behavioral and neurocognitive disabilities caused by prenatal exposure to alcohol (Vaux & Chambers, 2015). FASD affects 1 in 100 infants each year, more than autism, Down syndrome, cerebral palsy, cystic fibrosis, spina bifida, and sudden infant death syndrome (SIDS) combined (National Organization on Fetal Alcohol Syndrome [NOFAS], 2015). Each year in the United States, up to 50,000 infants are born with FASD. It is the leading cause of nongenetic intellectual disability in the United States, possibly exceeding even Down syndrome, which is currently approaching 1 in 500 live

births. Alcohol consumption during pregnancy results in brain, craniofacial, and heart defects, neurotoxicity, and immune systems dysfunction.

Characteristics of FASD include craniofacial dysmorphia (thin upper lip, small head circumference, and small eyes), IUGR, microcephaly, and congenital anomalies such as limb abnormalities and cardiac defects. Long-term sequelae include postnatal growth restriction, attention deficits, delayed reaction time, and poor scholastic performance (NOFAS, 2015).). The complex neurobehavioral problems typically manifest themselves insidiously. Children with prenatal alcohol exposure struggle with cognitive, academic, social, emotional, and behavioral challenges. These challenges reduce the child's ability to learn and function successfully in many structured environments (Mohammadzadeh & Farhat, 2014). Common cognitive and behavioral problems are listed in Box 20.4, and Figure 20.8 illustrates the characteristic facial features. See Chapter 24 for a more detailed discussion of the newborn with FASD.

The preferred action taken to prevent alcohol consumption during pregnancy is abstinence. However, the detection, diagnosis, and treatment of FASD remain major public health needs in this country and throughout the world. Not every woman who drinks during pregnancy will give birth to an affected child. Based on the best research available, the following is known about alcohol consumption during pregnancy:

• Intake increases the risk of alcohol-related birth defects, including growth deficiencies, facial abnormalities, central nervous system impairment, behavioral disorders, and intellectual development.

• No amount of alcohol consumption is considered safe during pregnancy.

• Damage to the fetus can occur at any stage of pregnancy, even before a woman knows she is pregnant.

• Cognitive defects and behavioral problems resulting from prenatal exposure are lifelong.

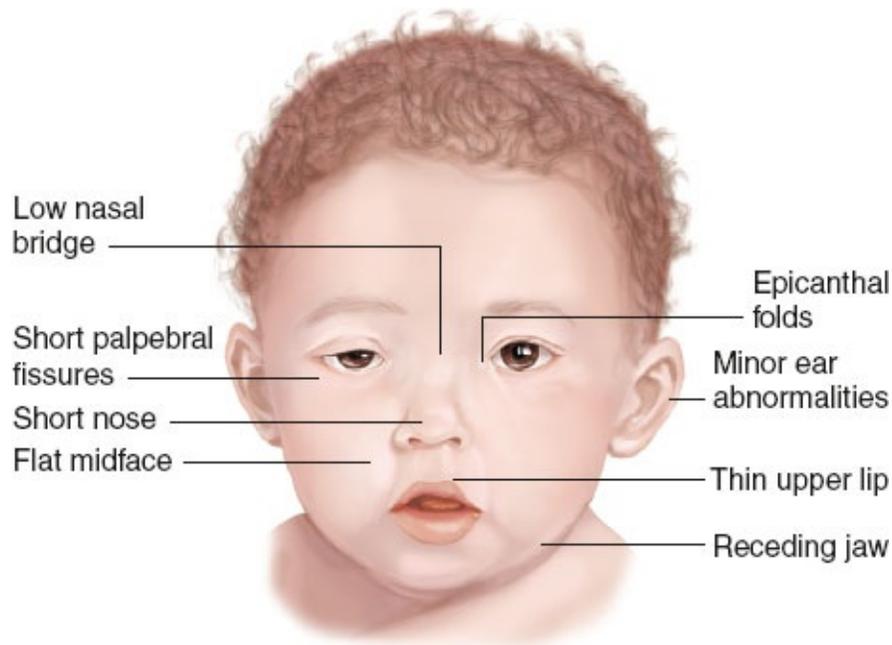
• Alcohol-related birth defects are completely preventable (ACOG, 2014c).


FIGURE 20.8 Typical facial characteristics of a newborn with FASD.

Risk factors for giving birth to an alcohol-affected newborn include maternal age, socioeconomic status, ethnicity, genetic factors, poor nutrition, depression, family disorganization, unplanned pregnancy, and late prenatal care (ACOG, 2014d). Identification of risk factors strongly associated with alcohol-related birth outcomes could help identify high-risk pregnancies requiring intervention.

One of the biggest challenges in determining the true prevalence of FASD is how to recognize the syndrome, which depends in part on the age and physical features of the person being assessed. Difficulty identifying alcohol abuse results from the client's denial of alcohol use, unwillingness to report alcohol consumption, underreporting, and limited ability to recollect the frequency, quantity, and type of alcohol consumed. This makes it difficult to identify women who are drinking during pregnancy, institute preventive measures, or refer them for treatment.

Women who drink excessively while pregnant are at high risk for giving birth to children with birth defects. To prevent these defects, women should stop drinking during all phases of a pregnancy. Unfortunately, many women continue to drink during their pregnancy despite warnings from professionals.

Currently, it is not known whether there is a minimal amount of alcohol safe to drink during pregnancy; an occasional glass of wine might be harmless or might not be. Therefore, eliminating alcohol consumption during pregnancy is

the ultimate goal to prevent FASD. Most women know they should not drink during pregnancy, but the window of vulnerability—i.e., the time lag between conception and the discovery of pregnancy—may put substantial numbers of children at risk. Additionally, traditional alcohol-screening questionnaires, such as the Michigan Alcoholism Screening Test (MAST) and the CAGE Questionnaire, are not sensitive enough to detect low levels of alcohol consumption among women.

Several challenges remain in preventing birth defects due to alcohol consumption:

• Ways to improve clinical recognition of high-risk women who drink alcohol.

• Ways to intervene more effectively to modify drinking behaviors.

• In utero approaches to prevent or minimize fetal injury.

• Strategies to address the neurodevelopmental problems of children affected by maternal alcohol ingestion.

Sedatives. Sedatives relax the central nervous system and are used medically for inducing relaxation and sleep, relieving tension, and treating seizures. Sedatives easily cross the placenta and can cause birth defects and behavioral problems. Infants born to mothers who abuse sedatives during pregnancy may be physically dependent on the drugs themselves and are more prone to respiratory problems, feeding difficulties, disturbed sleep, sweating, irritability, and fever (Alexander et al., 2014).

Nicotine. Cigarette smoking during pregnancy is the biggest preventable cause of death and illness in women and infants and is associated with numerous obstetric, fetal, and developmental complications, as well as an increased risk of adverse health consequences in the adult offspring. Nicotine replacement therapy has been developed as a pharmacotherapy for smoking cessation and is considered to be a safer alternative for women to smoking during pregnancy. The safety of nicotine replacement therapy (transdermal patches and bupropion) use during pregnancy has been evaluated in a limited number of short-term human trials, but there is currently no information on the long-term effects of developmental nicotine exposure in humans (Dhalwani, Szatkowski et al., 2015).

Nicotine is found in cigarettes, and is another substance that is harmful to the pregnant women and her fetus. Nicotine, which causes vasoconstriction, transfers across the placenta and reduces blood flow to the fetus, contributing to

fetal hypoxia. When compared with alcohol, marijuana, and other illicit drug use, tobacco use is less likely to decline as the pregnancy progresses (Velez & Jansson, 2015). Smoking is associated with adverse pregnancy outcomes. However, these adverse outcomes can be avoided if the woman stops smoking before becoming pregnant.

Smoking increases the risk of spontaneous abortion, tubal ectopic pregnancy, preterm labor and birth, fetal growth restriction, stillbirth, premature rupture of membranes, low fetal iron stores, maternal hypertension, placenta previa, and abruptio placentae. The perinatal death rate among infants of smoking mothers is 20% to 35% higher than that of nonsmoking mothers (Varner et al., 2014). Perinatal and childhood risks associated with mothers smoking during their pregnancies include increased risk of cleft lip and palate, clubfoot, asthma, middle ear infections, SIDS, reduced head circumference, altered brainstem development, and cerebral palsy (Cunningham et al., 2014).

Smoking has also been considered an important risk factor for low birth weight, SIDS, and cognitive deficits, especially in language, reading, and vocabulary, as well as poorer performances on tests of reasoning and memory. Researchers have also reported behavior problems, such as increased activity, inattention, impulsivity, opposition, and aggression (Skoglund et al., 2014). Women who smoke during the pregnancy often continue to smoke after giving birth, and thus the infant will be exposed to nicotine after birth. This environmental or passive exposure affects the child's development and increases the risk of childhood respiratory disorders.

Caffeine. Caffeine is a widely used and accepted pharmacologically active substance. The socially sanctioned nature of caffeinated beverages promotes caffeine's popularity and at the same time obscures the fact that as a drug it can definitely be abused. The effect of caffeine intake during pregnancy on fetal growth and development is still unclear. A recent study found that caffeine intake of no more than 300 mg/day during pregnancy does not affect pregnancy duration and the condition of the newborn (Procter & Campbell, 2014). Caffeine, a stimulant of the central nervous system, is present in varying amounts in such common products as coffee, tea, colas, and chocolate. It is also in cold remedies and analgesics. Birth defects have not been linked to caffeine consumption, but maternal coffee consumption decreases iron absorption and may increase the risk of anemia during pregnancy.

Moderate caffeine consumption (less than 300 mg/day) does not appear to be

a major contributing factor in miscarriage or preterm birth. The relationship of caffeine to growth restriction remains undetermined. A final conclusion cannot be made at this time as to whether there is a correlation between high caffeine intake and miscarriage due to lack of sufficient studies (Calhoun, & Lewis, 2016).

Energy drinks represent a new class of caffeinated beverages that are marketed to improve energy, athletic performance, concentration, endurance, and weight loss, although the claims have not been supported by rigorous scientific evidence (Higgins, Yarlagadda, & Yang, 2015). All energy drinks surpass the FDA official soft drink concentration of caffeine limit, typically two to four times the amount seen in one serving of soda or tea. Adverse effects of energy drinks can occur in healthy people, however pregnant women would be considered in an at risk group and should avoid excessive caffeine intake which has been linked to adverse reproductive outcomes, such as low birth weight. Consumption of energy drinks is associated with increased demand of the heart causing hypertension, tachycardia, dysrhythmias, coronary artery spasm, and sudden cardiac death (James, 2015). Given the rise in emergency room visits for complications of energy drink consumption, nurses should advise their pregnant clients to refrain from drinking them.

Marijuana. Marijuana is the most commonly used illicit drug in America, with over 90 million people having tried it at least once. Its estimated prevalence in pregnant women is about 10–15%. It is often called pot, reefer, herb, widow, hash, grass, weed, Mary Jane, or MJ (NIDA, 2015c). Marijuana is a preparation of the leaves and flowering tops of *Cannabis sativa,* the hemp plant, which contains a number of pharmacologically active agents. Tetrahydrocannabinol (THC) is the most active ingredient of marijuana. With heavy smoking, THC narrows the bronchi and bronchioles and produces inflammation of the mucous membranes. Smoking marijuana causes tachycardia and a reduction in blood pressure, resulting in orthostatic hypotension. Although the federal government considers marijuana a Schedule I substance (having no medicinal uses and high risk for abuse), a few states have legalized it for adult recreational use, and many states have passed laws allowing its use as a treatment for medical conditions (pain, nausea and vomiting, HIV/AIDS, cancer).

The effects of marijuana smoking on pregnancy are not yet fully understood because there are very few studies on its long-term effects on child development. One can speculate that the effects of marijuana on the immature nervous system

may be subtle and not detected until more complex functions are required, usually in a formal educational setting. There is some evidence that marijuana increases the risk of spontaneous abortion and preterm delivery (Desai, Mark, & Terplan, 2014). Although marijuana is not considered teratogenic, many newborns display altered responses to visual stimuli, increased tremulousness, and a high-pitched cry, which might indicate insults against the central nervous system (Volkow et al., 2014). A strong correlation exists between the use of marijuana and the use of alcohol and cigarettes.

Opiates and Narcotics. Opiates and narcotics include opium, heroin (known as horse, junk, smack, downtown), morphine, codeine, hydromorphone (Dilaudid; little D), oxycodone (Percodan, perkies), meperidine (Demerol, demise), and methadone (meth, dollies). Opiates can be inhaled, injected, snorted, ingested, or used subcutaneously. These drugs are central nervous system depressants that soothe and lull. They may be used medically for pain, but all have a high potential for abuse. Most cause an intense addiction in both mother and newborn.

Narcotic dependence is particularly problematic in pregnant women. It leads to medical, nutritional, and social neglect by the woman due to the long-term risks of physical dependence, malnutrition, compromised immunity, hepatitis, and fatal overdose (Alexander et al., 2014). Taking opiates or narcotics during pregnancy places the woman at increased risk for preterm labor, fetal growth restriction, abruptio placenta, perinatal mortality, preterm rupture of membranes, and preeclampsia (Prasad, 2014).

Heroin is the most common illicitly used opioid. It is derived from the seeds of the poppy plant and can be sniffed, smoked, or injected. It crosses the placenta via simple diffusion within 1 hour of maternal consumption (ACOG, 2014e). Use of heroin during pregnancy is believed to affect the developing brain of the fetus and may cause behavioral abnormalities in childhood. Risks of perinatal opiate exposure are not limited to the fetus. Maternal opiate overdose deaths have increased dramatically, which translates to 18 women dying per day, and for every woman who dies, 30 are being treated in emergency departments for abuse (Alexander et al., 2014).

The most common harmful effect of heroin and other narcotics on newborns is withdrawal, or **neonatal abstinence syndrome (NAS)** (see Chapter 24). This collection of symptoms may include irritability, hypertonicity, jitteriness, fever, excessive and often high-pitched cry, vomiting, diarrhea, feeding disturbances,

respiratory distress, disturbed sleeping, excessive sneezing and yawning, nasal stuffiness, diaphoresis, fever, poor sucking, tremors, and seizures (Slater, 2015).

Withdrawal from opiates during pregnancy is extremely dangerous for the fetus, so a prescribed oral methadone maintenance program combined with psychotherapy is recommended for the pregnant woman. This closely supervised treatment program reduces withdrawal symptoms in the newborn, reduces drug cravings, and blocks the euphoric effects of narcotic drugs in order to reduce illicit drug use. Management of opioid addiction in pregnancy includes maintenance therapy with methadone or buprenorphine in addition to traditional prenatal care and psychosocial treatment of substance abuse, such as self-help, 12-step groups, individual and group substance abuse counseling, and psychotherapy. Maintenance therapy drugs provide a steady state of opiate levels, thus reducing the risk of withdrawal to the fetus and exposure to HIV and other STIs because the mother is no longer injecting drugs. However, maintenance therapy drugs have the same withdrawal consequences for women and newborns as heroin does (McKeever et al., 2014).

Methamphetamines. Methamphetamine use is now more common than cocaine use in pregnancy, and its use by women of childbearing age is increasing in the United States. This highly addictive stimulant is commonly known as speed, meth, or chalk. In its smoked form, it is often referred to as ice, crystal, crank, and glass. Smoking or injecting the drug quickly delivers it to the brain for an immediate, intense euphoria. Because the pleasure also fades quickly, users often take repeated doses, in a "binge and crash" pattern. It is a white, odorless, bitter-tasting powder that was developed from its parent drug, amphetamine, and was used originally in nasal decongestants and bronchial inhalers. The maternal effects include increased energy and alertness, an intense rush, decreased appetite, tachycardia, and tachypnea. Chronic use can lead to psychosis, including paranoia, hallucinations, memory loss, and aggressive or violent behavior. Signs of methamphetamine use include track marks from intravenous injection, malnutrition, severe dental decay (meth mouth), and skin abscesses from skin picking (ACOG, 2014f). Few studies have been done on the effects of methamphetamine abuse during pregnancy, but the few done indicate an increased risk for preterm births, low birth weight, placental abruption, fetal growth restriction, and congenital anomalies (NIDA, 2015d). These findings are hard to interpret, however, due to small sample size and polydrug use of the participants.

Cocaine. Cocaine use is second only to marijuana use in women who abuse drugs during pregnancy. The incidence of cocaine exposure in utero is approximately 1 to 10 per 1,000 live births (Brandt et al., 2014). There is evidence that cocaine affects infant development both directly, via in utero exposure, and indirectly via alterations in maternal care after birth.

Cocaine is a psychoactive drug derived from the leaves of the coca plant, which grows in the Andes Mountains of Peru, Ecuador, and Bolivia. The freebase form, called "crack" because of the cracking or popping noise made in its preparation, is less expensive, easily made, and smokable. Cocaine is a powerful vasoconstrictor. When sniffed into the mucous membranes of the nose, it produces an intense "rush" that some have compared to an orgasmic experience. Smoked crack is absorbed rapidly by the pulmonary vasculature and reaches the brain's circulation in 6 to 8 seconds (NIDA, 2015b).

Cocaine use produces vasoconstriction, dilates pupils, increases body temperature, tachycardia, and hypertension in both the mother and the fetus (Kahn, Mikhael, & Vadivelu, 2015). Uteroplacental insufficiency may result from reduced blood flow and placental perfusion. Chronic use can result in low birth weight, the most common effect of cocaine use in pregnancy (NIDA, 2015b).

Studies suggest that perinatal cocaine use increases the risk of preterm labor, abortion, abruptio placentae, fetal growth restriction, intrauterine fetal distress and demise, seizures, withdrawal, and cerebral infarcts. Cocaine may increase the risk of uterine rupture and congenital anomalies (NIDA, 2015b). Fetal anomalies associated with cocaine use in early pregnancy involve neurologic problems such as neural tube defects and microcephaly; cardiovascular anomalies such as congenital heart defects; genitourinary conditions such as prune belly syndrome, hydronephrosis, and ambiguous genitalia; and gastrointestinal system problems such as necrotizing enterocolitis (Connery, 2014). Some infants exposed to cocaine in utero show increased irritability and are difficult to calm and soothe to sleep.

Nonmedical Use of Prescription Drugs. In addition to alcohol and illicit drug use, a new worldwide trend has emerged and may soon exceed illicit drug use. That is, the nonmedical use of prescription drugs found in many home medicine cabinets. Prescription drug abuse has reached epidemic levels in the United States. Estimates of prescription drug abuse rates during pregnancy range from 5% to 20%. Common drugs of choice include analgesics, stimulants, sedatives,

and tranquilizers. A frequent belief among abusers is that prescribed medications are less dangerous than street drugs and using a friend's medication is safe. Unfortunately, unintentional poisoning deaths occur frequently. In addition, the development of a counterfeit market has developed utilizing the Internet, thereby creating a global counterfeit drug market (McHugh, Nielsen, & Weiss, 2015).

Early detection through a comprehensive evaluation is essential to improve overall treatment outcomes. New research supports screening all pregnant women for substance abuse. A major role of the nurse is to focus on prevention by educating all women about the dangers associated with misuse of prescription medications. Community education is vital to manage risks to prevent problems from developing.

Nursing Assessment

Complete a thorough history and physical examination to evaluate a client for substance use and abuse. Substance abuse screening in pregnancy is done to detect the use of any substance known or suspected to exert a deleterious effect on the client or her fetus. Routinely ask about substance abuse with all women of childbearing age, inform them of the risks involved, and advise them against continuing. Screening questionnaires are helpful in identifying potential users, may reduce the stigma of asking clients about substance abuse, and may result in a more accurate and consistent evaluation. The questions in Box 20.5 may be helpful in assessing a client who is at risk for substance abuse during pregnancy. Using "accepting" terminology may encourage the woman to give honest answers without fear of reproach.

A woman who claims to have taken no drugs while pregnant may be unaware that substances such as hair dye, diet cola, paint, or over-the-counter medications for colds or headaches are still considered drugs. Thus, it is very difficult to get a true picture of the real use of drugs by pregnant women.

Many drugs are considered to have a teratogenic effect on growing fetuses. A **teratogen** is any environmental substance that can cause physical defects in the developing embryo and fetus. Pregnant women with substance abuse commonly present with polysubstance abuse, which is likely to be more damaging than the use of any single substance. Thus, it is inherently difficult to ascribe a specific perinatal effect to any one substance (McKeever, Spaeth-Brayton, & Sheerin, 2014).

A urine toxicology screen may also be helpful in determining drug use,

although a urine screen identifies only recent or heavy use of drugs. The length of time a drug is present in urine is as follows:

• Cocaine: 24 to 48 hours in an adult, 72 to 96 hours in an infant.

• Heroin: 24 hours in an adult, 24 to 48 hours in an infant.

• Marijuana: 1 week to 1 month in an adult, up to a month or longer in an infant.

• Methadone: up to 10 days in an infant (Wang, 2015).

Nursing Management

If the woman's drug screen is positive, use this as an opportunity to discuss prenatal exposure to substances that may be harmful. The discussion may lead the nurse to refer the client for a diagnostic assessment or identify an intervention such as counseling that may be helpful. Being nonjudgmental is a key to success; a client is more apt to trust and reveal patterns of abuse if the nurse does not judge her and her lifestyle choices.

A positive drug screen in a newborn warrants an investigation by the state protection agency. In the interim, institute measures to reduce stress and stimuli to promote the newborn's comfort (see Chapter 24 for a more in-depth discussion).

Be proactive, supportive, and accepting when caring for the client. Assure women with substance abuse problems that sharing information of a confidential nature with health care providers will not render them liable to criminal prosecution. Provide counseling and education, emphasizing the following:

• Effects of substance exposure on the fetus

• Interventions to improve mother–child attachment and improve parenting

• Psychosocial support if treatment is needed to reduce substance abuse

• Referral to outreach programs to improve access to treatment facilities

• Hazardous legal substances to avoid during pregnancy

• Follow-up of children born to substance-dependent mothers

• Dietary counseling to improve the pregnancy outcome for both mother and child

• Drug screening to identify all drugs a client is using

• More frequent prenatal visits to monitor fetal well-being

• Maternal and fetal benefits of remaining drug free

• Cultural sensitivity

• Coping skills, support systems, and vocational assistance

There is nothing categorically different about addiction in pregnancy compared with addiction in general. Pregnant women who use drugs are women who use drugs, get pregnant, and cannot stop using drugs. The fact that they are condemned in society leads to their further marginalization, which does nothing to improve their lives or the lives of their children.

Substance abuse is a complex problem that requires sensitivity to each woman's unique situation and contributing factors. Be sure to address individual psychological and sociocultural factors to help the woman regain control of her life. Nurses must be aware of these women's unique needs and the related legal and ethical ramifications surrounding pregnancy. Treatment must combine different approaches and provide ongoing support for women learning to live drug free. Developing personal strengths, such as communication skills, assertiveness, and self-confidence, will help the woman to resist drug use. Encourage the use of appropriate coping skills. Enhancing self-esteem also helps provide a foundation to avoid drugs. Through therapeutic communication, nursing interventions, clinical assessment, and building trusting relationships, nurses can have a significant impact in managing clients with substance abuse.

KEY CONCEPTS

- Preconception counseling for the woman with diabetes is helpful in promoting blood glucose control to prevent congenital anomalies.

- The classification system for diabetes is based on disease etiology and not pharmacology management; the classification includes type 1 diabetes, type 2 diabetes, gestational diabetes, and impaired fasting glucose and impaired glucose tolerance.

- A functional classification for heart disease during pregnancy is based on past and present disability: class I, asymptomatic with no limitation of physical activity; class II, symptomatic (dyspnea, chest pain) with increased activity; class III, symptomatic (fatigue, palpitation) with normal activity; and class IV, symptomatic at rest or with any physical activity.

- Chronic hypertension exists when the woman has a blood pressure of 140/90 mm Hg or higher before pregnancy or before the 20th week of gestation or when hypertension persists for more than 12 weeks' postpartum.

- Successful management of asthma in pregnancy involves elimination of environmental triggers, drug therapy, and client education.

- Ideally, women with hematologic conditions are screened before conception and are made aware of the risks to themselves and to a pregnancy.

- A wide variety of infections, such as cytomegalovirus, rubella, herpes simplex, hepatitis B, varicella, parvovirus B19, and many sexually transmitted infections can affect a pregnancy, having a negative impact on its outcome.

- The prevalence of HIV/AIDS is increasing more rapidly among women than men: half of all the HIV/AIDS cases worldwide now occur in women. There are only three recognized modes of HIV transmission: unprotected sexual intercourse with an infected partner, contact with infected blood or blood products, and perinatal transmission. Breast-feeding is a major contributing factor in mother-to-child transmission of HIV.

- Cases of perinatal AIDS have decreased in the past several years in the United States, primarily because of the use of zidovudine (ZDV) therapy in pregnant women with HIV. The U.S. Preventive Services Task Force recommends that all pregnant women should be offered HIV antibody testing regardless of their risk of infection, and that testing should be done during the initial prenatal evaluation.

- The younger an adolescent is at the time of her first pregnancy, the more likely it is that she will have another pregnancy during her teens. About 1 million teenagers between the ages of 15 and 19 become pregnant each year; about half give birth and keep their infants.

- The nurse's role in caring for the pregnant adolescent is to assist her in identifying the options for this pregnancy, including abortion, self-parenting of the child, temporary foster care for the baby or herself, or placement for adoption.

- Pregnant women with substance abuse problems commonly abuse several substances, making it difficult to ascribe a specific perinatal effect to any one substance. Societal attitudes regarding pregnant women and substance abuse may prohibit them from admitting the problem and seeking treatment.

- Substance abuse during pregnancy is associated with preterm labor, abortion, low birth weight, central nervous system and fetal anomalies, and long-term childhood developmental consequences.

- Fetal alcohol spectrum disorder is a lifelong yet completely preventable set of

physical, mental, and neurobehavioral birth defects; it is the leading cause of intellectual disability in the United States.

○ Nursing management for the woman with substance abuse focuses on screening and preventing substance abuse to reduce the high incidence of obstetric and medical complications as well as the morbidity and mortality among passively addicted newborns.

CHAPTER **WORKSHEET**

MULTIPLE CHOICE QUESTIONS

1. Which of the following would the nurse include when teaching a pregnant woman about the pathophysiologic mechanisms associated with gestational diabetes?

   a. Pregnancy fosters the development of carbohydrate cravings.

   b. There is progressive resistance to the effects of insulin.

   c. Hypoinsulinemia develops early in the first trimester.

   d. Glucose levels decrease to accommodate fetal growth.

2. When providing prenatal education to a pregnant woman with asthma, which of the following would be important for the nurse to do?

   a. Explain that she should avoid steroids during her pregnancy.

   b. Demonstrate how to assess her blood glucose levels.

   c. Teach correct administration of subcutaneous bronchodilators.

   d. Ensure she seeks treatment for any acute exacerbation.

3. Which of the following conditions would most likely cause a pregnant woman with type 1 diabetes the greatest difficulty during her pregnancy?

   a. Placenta previa

   b. Hyperemesis gravidarum

   c. Abruptio placentae

d. Rh incompatibility

4. Women who drink alcohol during pregnancy:

    a. Often produce more alcohol dehydrogenase.

    b. Usually become intoxicated faster than before.

    c. Can give birth to an infant with fetal alcohol spectrum disorder.

    d. Gain fewer pounds throughout the gestation.

5. When explaining to a pregnant woman about HIV infection and transmission, which of the following would the nurse include?

    a. It primarily occurs when there is a large viral load in the blood.

    b. HIV is most commonly transmitted via sexual contact.

    c. It affects the majority of infants of mothers with HIV infection.

    d. Nurses are most frequently affected due to needle sticks.

6. Women who are obese have a greater risk of developing which of the following during pregnancy?

    a. Type 1 diabetes

    b. Hypotension

    c. Low birth weight infant

    d. Gestational hypertension

7. Maintenance on methadone or buprenorphine is the most common medical treatment for which of the following drug addictions?

    a. Alcohol

    b. Nicotine

    c. Opiates

    d. Marijuana

CRITICAL THINKING EXERCISE

1. A client at 26 weeks of gestation came to the clinic to follow up on her previous 1-hour glucose screening. Her results had come back outside the accepted screening range, and a 3-hour glucose tolerance test (GTT) had been

ordered. It resulted in three abnormal values, confirming a diagnosis of gestational diabetes. As the nurse in the prenatal clinic you are seeing her for the first time.

a. What additional information will you need to provide care for her?

b. What education will she need to address this new diagnosis?

c. How will you evaluate the effectiveness of your interventions?

2. A 14-year-old girl comes to the public health clinic with her mother. The mother tells you that her daughter has been "out messing around and has gotten herself pregnant." The girl is crying quietly in the corner and avoids eye contact with you. The mother reports that her daughter "must be following in my footsteps" because she became pregnant when she was only 15 years old. The client's mother goes back out into the waiting room and leaves the client with you.

a. What is your first approach with the client to gain her trust?

b. List the client's educational needs during this pregnancy.

c. What prevention strategies are needed to prevent a second pregnancy?

3. A 27-year-old G3P2, is admitted to the labor and birth suite because of preterm rupture of membranes at an estimated 35 weeks of gestation. She has received no prenatal care and reports this was an unplanned pregnancy. Linda appears distracted and very thin. She reports that her two previous children have been in foster care since birth because the child welfare authorities "didn't think I was an adequate mother." She denies any recent use of alcohol or drugs, but you smell alcohol on her breath. She has a spontaneous vaginal birth a few hours later, producing a 4-lb baby boy with Apgar scores of 8 at 1 minute and 9 at 5 minutes.

a. What aspects of this woman's history may lead the nurse to suspect that this infant may be at risk for fetal alcohol spectrum disorder?

b. What additional screening or laboratory tests might validate your suspicion?

c. What physical and neurodevelopmental deficits might present later in life if the infant has fetal alcohol spectrum disorder?

STUDY ACTIVITIES

1. In the maternity clinic or hospital setting, interview a pregnant woman with a preexisting medical condition (e.g., diabetes, asthma, sickle cell anemia) and find out how this condition affects her life and this pregnancy, especially her lifestyle choices.

2. You have a close friend who has a problem with alcohol but denies it. She now admits to you that she thinks she is pregnant because she missed her period. What specific information and advice should you give her concerning alcohol use during pregnancy?

3. Should marijuana be legalized in the United States? What impact might your view (pro or con) have on pregnant women and their offspring?

4. Outline a discussion you might have with an HIV-positive pregnant woman who doesn't see the need to take antiretroviral agents to prevent perinatal transmission.

5. The nurse is preparing a teaching session about breast-feeding for a group of pregnant women who have various infections listed below. The nurse would include women with which of the following conditions? Select all that apply.
   a. Hepatitis B
   b. Parvovirus B19
   c. Herpesvirus type 2
   d. HIV-positive status
   e. Cytomegalovirus
   f. Varicella-zoster virus

BRINGING IT ALL TOGETHER: CASE STUDY

Linda is an 18 year old, very thin client who has been abusing alcohol since the age of 12. She lived in foster care for much of her life and is recently on her own with a part-time job. She reports she had experienced both emotional and sexual abuse during her childhood. At 16, she was introduced to crack cocaine. So many of her friends and relatives were using, that it was impossible for her to see any other lifestyle or want to seek help for her addiction. She states she wanted to start a new life and get clean when she found out she was pregnant, but

admitted she ended up partying and using drugs for the past 4 months of this pregnancy. She presents today for her first prenatal visit. She claims that she is ready to commit to a positive change.

ASSESSMENT

Based on Linda's history, she is very vulnerable because of her young age, underweight, abusive history, substance abuse, and lack of a supportive network to assist her in making a "positive change" in her life. Although she states she is ready to "get clean" and get off drugs, she has been unable to move toward that goal on her own previously. At this stage of her pregnancy, her vital signs and fetal heart rates were within normal limits, her weight is below standard limits for her height and lab tests were normal except for low hemoglobin indicating iron deficient anemia.

Go to thePoint to find questions to consider about this case.

vaginal birth after cesarean (VBAC)

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Propose at least five risk factors associated with dystocia.
2. Differentiate the four major abnormalities or problems associated with dysfunctional labor patterns, giving examples of each problem.
3. Examine the nursing management for the woman with dysfunctional labor experiencing a problem with the powers, passenger, passageway, or psyche.
4. Devise a plan of care for the woman experiencing preterm labor.
5. Relate the nursing assessment and management of the woman experiencing a prolonged pregnancy.
6. Assess four obstetric emergencies that can complicate labor and birth, including appropriate management for each.
7. Compare and contrast the nursing management for the woman undergoing labor induction or augmentation, forceps- and vacuum-assisted birth.
8. Summarize the plan of care for a woman who is to undergo a cesarean birth.
9. Evaluate the key areas to be addressed when caring for a woman that undergoes a vaginal birth after cesarean (VBAC).

__Jennifer,__ a 29-year-old G1P0, is at 41 weeks of gestation. Her health care provider has recommended that she come in for induction. She is very anxious about doing this since she has heard "horror stories" about the "hard painful contractions" that can result. What can the nurse do to calm her fears?

Words of Wisdom

In the face of a crisis or a potentially bad outcome, add a mixture of warmth and serenity to your technical abilities.

INTRODUCTION

Most women describe pregnancy as an exciting time in their lives, but the development of an unexpected problem can suddenly change this description dramatically. Consider the woman who has had a problem-free pregnancy and then suddenly develops a condition during labor, changing a routine situation into a possible crisis. Many complications occur with little or no warning and present challenges for the perinatal health care team as well as the family. The nurse plays a major role in identifying the problem quickly and coordinating immediate intervention, ultimately achieving a positive outcome.

National health goals address maternal and newborn outcomes involving complications of labor and birth and cesarean birth (U.S. Department of Health and Human Services, 2010). These goals are highlighted in *Healthy People 2020*.

This chapter will address several conditions occurring during labor and birth that may increase the risk of an adverse outcome for the mother and fetus. It also describes birth-related procedures that may be necessary for the woman who develops a condition that increases her risk or that may be needed to reduce the woman's risk for developing a condition, thus promoting optimal maternal and fetal outcomes. Nursing management of the woman and her family focuses on professional support and compassionate care.

DYSTOCIA

Dystocia, defined as abnormal or difficult labor, can be influenced by a vast number of maternal and fetal factors. Dystocia is said to exist when the progress of labor deviates from normal; it is characterized by a slow and abnormal progression of labor. It occurs in approximately 8% to 11% of all labors and is the leading indicator for primary cesarean birth in the United States (Joy, Lyon, & Scott, 2015). It is of concern because of its fatiguing factor for both mother and fetus and frequently requires medical or surgical interventions, which increases risk.

HEALTHY PEOPLE 2020 • 21.1

Objective	Nursing Significance
MICH-9 Reduce preterm births	• Will help to focus attention on the need for close antepartum surveillance and identification of risks factors for preterm labor/births and provide appropriate interventions to reduce it.
MICH-7 Reduce cesarean births among low-risk (full-term, singleton, vertex presentation) women	• Will help to reduce the number of surgical births with accompanying risk factors and costs by appropriate labor management, continual labor support, and practice patterns, while helping to ensure positive maternal and newborn outcomes.

Healthy People objectives based on data from
http://www.healthypeople.gov.

To characterize a labor as abnormal, a basic understanding of normal labor is essential. Normal labor starts with regular uterine contractions that are strong enough to result in cervical effacement and dilation. Early in labor, uterine contractions are irregular and cervical effacement and dilation occurs gradually. When cervical dilation reaches 5 to 6 cm and uterine contractions become more powerful, the active phase of labor begins. It is usually during the active phase that dystocia becomes apparent. Because dystocia cannot be predicted or diagnosed with certainty, the term "failure to progress" is often used. This term includes lack of progressive cervical dilation, lack of descent of the fetal head, or both. An adequate trial of labor is needed to declare with confidence that dystocia or "failure to progress" exists.

Early identification of and prompt interventions for dystocia are essential to minimize risk to the woman and fetus. According to the American College of Obstetricians and Gynecologists [ACOG] (2014a) factors associated with an increased risk for dystocia include epidural analgesia, excessive analgesia, multiple pregnancy, hydramnios, maternal exhaustion, ineffective maternal pushing technique, occiput posterior position, longer first stage of labor, nulliparity, short maternal stature (less than 5 ft tall), fetal birth weight (more than 8.8 lb), shoulder dystocia, abnormal fetal presentation or position (breech), fetal anomalies (hydrocephalus), maternal age older than 34 years, high caffeine intake, overweight, gestational age more than 41 weeks, chorioamnionitis, ineffective uterine contractions, and high fetal station at complete cervical dilation.

One in three women who gives birth in the United States today does so by a cesarean birth. The most common indications for primary cesarean births include, in order of frequency, labor dystocia, abnormal fetal heart rate tracing, fetal malpresentation, multiple gestations, and suspected macrosomia. It is time to revisit the definition of labor dystocia because recent studies show that contemporary labor progresses at a rate substantially slower than what was historically taught. Labors today are often longer which may in part be due to higher body mass index (BMI), higher rates of labor induction, and the significant increase in the use of epidural anesthesia (ACOG, 2014a).

Admitting women too early to the hospital while still in the early latent phase of labor may increase the diagnosis of dystocia and increase the risk of augmentation of labor and epidural analgesia. These two interventions may cascade into a surgical birth. Adequate hydration, rest, emotional and physical support, and, if needed, pharmacologic sedation can be encouraged as

alternatives to early hospital admission. Patience should be the critical factor here.

Dystocia can result from problems or abnormalities involving the expulsive forces (known as the "powers"); presentation, position, and fetal development (the "passenger"); the maternal bony pelvis or birth canal (the "passageway"); and maternal stress (the "psyche"). Table 21.1 summarizes the diagnosis, therapeutic management, and nursing management of the common problems associated with dystocia.

Problems with the Powers

When the expulsive forces of the uterus become dysfunctional, the uterus may either never fully relax (hypertonic contractions), placing the fetus in jeopardy, or relax too much (hypotonic contractions), causing ineffective contractions. Still another dysfunction can occur when the uterus contracts so frequently and with such intensity that a very rapid birth will take place (precipitate labor).

Hypertonic uterine dysfunction occurs when the uterus never fully relaxes between contractions. Subsequently, contractions are ineffectual, erratic, and poorly coordinated because they involve only a portion of the uterus and because more than one uterine pacemaker is sending signals for contraction. Women in this situation experience a prolonged latent phase, stay at 2 to 3 cm, and do not dilate as they should. Placental perfusion becomes compromised, thereby reducing oxygen to the fetus. These hypertonic contractions exhaust the mother, who is experiencing frequent, intense, and painful contractions with little progression. This dysfunctional pattern occurs in early labor and affects nulliparous women more than multiparous women (Hinshaw & Kenyon, 2015).

Hypotonic uterine dysfunction occurs during active labor (dilation more than 5 to 6 cm) when contractions become poor in quality and lack sufficient intensity to dilate and efface the cervix. Factors associated with this abnormal labor pattern include overstretching of the uterus, a large fetus, multiple fetuses, hydramnios, multiple parity, bowel or bladder distention preventing descent, and excessive use of analgesia. Clinical manifestations of hypotonic uterine dysfunction include weak contractions that become milder, a uterine fundus that can be easily indented with fingertip pressure at the peak of each contraction, and contractions that become more infrequent and briefer (King et al., 2015). The major risk with this complication is hemorrhage after giving birth because the uterus cannot contract effectively to compress blood vessels.

Labor refers to uterine contractions resulting in progressive dilation and effacement of the cervix, and accompanied by descent and expulsion of the fetus. *Abnormal labor, dystocia,* and *failure to progress* are imprecise terms that have been used to describe a difficult labor pattern that deviates from that observed in the majority of women who have spontaneous vaginal deliveries. A better classification is to characterize labor abnormalities as protraction disorders (i.e., slower than normal progress) or arrest disorders (i.e., complete cessation of progress).

The term **protracted disorders** refers to a series of events including protracted active phase dilation (slower than normal rate of cervical dilation) and protracted descent (delayed descent of the fetal head in the active phase). A laboring woman with a slower than normal rate of cervical dilation is said to have a protraction labor pattern disorder. A slow progress may be the result of cephalopelvic disproportion. Most women, however, benefit greatly from adequate hydration and some nutrition, emotional reassurance, and position changes—these women may go on and give birth vaginally.

Arrest disorders include secondary arrest of dilation (no progress in cervical dilation in >2 hours), arrest of descent (fetal head does not descend for more than 1 hour in primip and more that 0.5 hour in multip), and failure of descent (no descent). About 20% of labors involve either protracted or arrest disorders (Ehsanipoor & Satin, 2016).

Precipitate labor is a labor that is completed in less than 3 hours from the start of contractions to birth. Not only can labor be too slow, but it can be abnormally rapid. The prevailing opinion has been that too rapid a labor can result in maternal injury and place the fetus at risk for traumatic or asphyxia insults (Suzuki, 2015). Women experiencing precipitate labor typically have soft perineal tissues that stretch readily, permitting the fetus to pass through the pelvis quickly, or abnormally strong uterine contractions. Maternal complications are rare if the maternal pelvis is adequate and the soft tissues yield to a fast fetal descent. However, if the fetus delivers too fast, it does not allow the cervix to dilate and efface, which leads to cervical lacerations and the potential for uterine rupture. Potential fetal complications may include head trauma, such as intracranial hemorrhage or nerve damage, and hypoxia due to the rapid progression of labor (Cunningham et al., 2014).

Precipitate labor is an anxiety-producing situation and frequently very painful with little rest between contractions. Continuous monitoring, frequent updates on her labor progress, pain management, and reassurance about her condition can assist in reducing the mother's anxious state of mind. Management includes readiness of the health care team for this rapid birth.

Problems with the Passenger

Any presentation other than occiput anterior (head down and anterior facing) or a slight variation of the fetal position or size increases the probability of dystocia. These variations can affect the contractions or fetal descent through the maternal pelvis. Common problems involving the fetus include occiput posterior position, breech presentation, multifetal pregnancy, excessive size (macrosomia) as it relates to cephalopelvic disproportion, and structural anomalies.

TABLE 21.1 Diagnosis and Management of Common Problems Associated with Dystocia

	Description	Diagnosis	Therapeutic Management	Nursing Management
Problems with the Powers				
Hypertonic uterine dysfunction	Occurring in the latent phase of the first stage of labor (cervical dilation of <4 cm); uncoordinated. Force of contraction typically in the midsection of uterus at the junction of the active upper and passive lower segments of the uterus rather than in the fundus. Loss of downward pressure to push the presenting part against the cervix. Woman commonly becomes discouraged due to lack of progress; also has increased pain secondary to uterine anoxia.	Characteristic hypertonicity of the contractions and the lack of labor progress	Therapeutic rest with the use of sedatives to promote relaxation and stop the abnormal activity of the uterus. Identification and intervention of any contributing factors. Ruling out abruptio placentae (also associated with high resting tone and persistent pain). Onset of a normal labor pattern occurs in many women after a 4- to 6-h rest period.	Institute bed rest and sedation to promote relaxation and reduce pain. Assist with measures to rule out fetopelvic disproportion and fetal malpresentation. Evaluate fetal tolerance to labor pattern, such as monitoring of FHR patterns. Assess for signs of maternal infection. Promote adequate hydration through IV therapy. Provide pain management via epidural or IV analgesics. Assist with amniotomy to augment labor. Explain to woman and family about dysfunctional pattern. Plan for operative birth if normal labor pattern is not achieved.
Hypotonic uterine dysfunction	Often termed secondary uterine inertia because the labor begins normally and then the frequency and intensity of contractions decrease. Possible contributing factors: overdistended uterus with multifetal pregnancy or large single fetus, too much pain medicine given too early in labor, fetal malposition, and regional anesthesia.	Evaluation of the woman's labor to confirm that she is having hypotonic active labor rather than a long latent phase. Evaluation of maternal pelvis and fetal presentation and position to ensure that they are not contributing to the prolonged labor without noticeable progress.	Identification of possible cause of inefficient uterine action (a malpositioned fetus, a too small maternal pelvis, overdistention of the uterus with fluid or a macrosomic fetus). Rupture of amniotic sac (amniotomy) if all causes ruled out. Possible augmentation with oxytocin (Pitocin) to stimulate effective uterine contractions. Cesarean birth if amniotomy and augmentation ineffective.	Administer oxytocin as ordered once fetopelvic disproportion is ruled out. Assist with amniotomy if membranes are intact. Provide continuous electronic fetal monitoring. Monitor vital signs, contractions, and cervix continually. Assess for signs of maternal and fetal infection. Explain to woman and family about dysfunctional pattern. Plan for surgical birth if normal labor pattern is not achieved or fetal distress occurs.
Precipitate labor	Abrupt onset of higher-intensity contractions occurring in a shorter period of time instead of the more gradual increase in frequency, duration, and intensity that typifies most spontaneous labors.	Identification based on the rapidity of progress through the stages of labor	Vaginal delivery if maternal pelvis is adequate.	Closely monitor woman with previous history. Anticipate use of scheduled induction to control labor rate. Administer pharmacologic agents, such as tocolytics, to slow labor. Stay in constant attendance to monitor progress.

	Description	Diagnosis	Therapeutic Management	Nursing Management
Problems with the Passenger				
Persistent occiput posterior position	Engagement of fetal head in the left or right occipito-transverse position with the occiput rotating posteriorly rather than into the more favorable occiput anterior position (fetus born facing upward instead of the normal downward position). Labor usually much longer and more uncomfortable (causing increased back pain during labor) if fetus remains in this position. Possible extensive caput succedaneum and molding from the sustained occiput posterior position.	Leopold maneuvers and vaginal examination to determine position of fetal head in conjunction with the mother's complaints of severe back pain (back of fetal head pressing on mother's sacrum and coccyx).	Labor to proceed, preparing the woman for a long labor (spontaneous resolution possible). Comfort measures and maternal positioning to help promote fetal head rotation.	Assess for complaints of intense back pain in first stage of labor. Anticipate possible use of forceps to rotate to anterior position at birth or manual rotation to anterior position at end of second stage. Assess for prolonged second stage of labor with arrest of descent (common with this malposition). Encourage maternal position changes to promote fetal head rotation: hands and knees and rocking pelvis back and forth; side-lying position; side lunges during contractions; sitting, kneeling, or standing while leaning forward; squatting position to give birth and enlarge pelvic outlet. Prepare for possible cesarean birth if rotation is not achieved. Administer agents as ordered for pain relief (effective pain relief crucial to help the woman to tolerate the back discomfort). Apply low back counter pressure during contractions to ease the discomfort. Use other helpful measures to attempt to rotate the fetal head, including lateral abdominal stroking in the direction that the fetal head should rotate; assisting the client into a hands-and-knees position (all fours); and squatting, pelvic rocking, stair climbing, assuming a side-lying position toward the side that the fetus should rotate, and side lunges. Provide measures to reduce anxiety. Continuously reinforce the woman's progress. Teach woman about measures to facilitate fetal head rotation.

Face and brow presentation	Face presentation with complete extension of the fetal head. Brow presentation: fetal head between full extension and full flexion so that the largest fetal skull diameter presents to the pelvis.	Diagnosis only once labor is well established via vaginal examination; palpation of facial features as the presenting part rather than the fetal head.	Vaginal birth possible with face presentation with an adequate maternal pelvis and fetal head rotation; cesarean birth if head rotates backward. Cesarean birth for brow presentation unless head flexes.	Assist with evaluating for fetopelvic disproportion. Anticipate cesarean birth if vertex position is not achieved. Explain fetal malposition to the woman and her partner. Provide close observation for any signs of fetal hypoxia, as evidenced by late decelerations on the fetal monitor.
Breech presentation	Fetal buttocks, or breech, presenting first rather than the head. 1. Frank breech: buttock as the presenting part, with hips flexed and legs and knees extended upward 2. Complete breech (or full breech): buttock as presenting part, with hips flexed and knees flexed in a "cannonball" position 3. Footling or incomplete breech: One or two feet as the presenting part, with one or both hips extended	Vaginal examination to determine breech presentation. Ideally, ultrasound to confirm a clinically suspected presentation and to identify any fetal anomalies.	The optimal method of birth is controversial: cesarean birth by some providers unless the fetus is small and the mother has a large pelvis; vaginal birth by others with each occurrence treated individually and labor monitored very closely. Regardless of the birth method selected, the risk for trauma is high. Breech vaginal births are not recommended by ACOG and come with a higher risk to the mother and infant than a planned surgical birth. Vaginal delivery: fetus allowed to spontaneously deliver up to the umbilicus; then maneuvers to assist in the delivery of the remainder of the body, arms, and head; fetal membranes left intact as long as possible to act as a dilating wedge and to prevent cord prolapse; anesthesiologist and pediatrician present. Cesarean birth; use of external cephalic version to reduce the chance of breech presentation at birth; attempted after the 35th week of gestation but before the start of labor (some fetuses spontaneously turn to a cephalic presentation on their own toward term, and some will return to the breech presentation if external cephalic version is attempted too early; variable success rates, with risk for fractured bones, ruptured viscera, abruptio placentae, fetomaternal hemorrhage, and umbilical cord entanglement. Tocolytic drugs to relax the uterus, as well as other methods, to facilitate external cephalic version at term. Individual evaluation of each woman for all factors before any interventions is initiated.	Assess for associated conditions such as placenta previa, hydramnios, fetal anomalies, and multifetal pregnancy. Arrange for ultrasound to confirm fetal presentation. Assist with external cephalic version possible after 36 weeks and administer tocolytics to assist with external cephalic version. Anticipate trial labor for 4 to 6 hours to evaluate progress if version is unsuccessful. Plan for cesarean birth if no progress is seen or fetal distress occurs. After external cephalic version, administer RhoGAM to the Rh-negative woman to prevent a sensitization reaction if trauma has occurred and the potential for mixing of blood exists.

	Description	Diagnosis	Therapeutic Management	Nursing Management
Shoulder dystocia	Delivery of fetal head with neck not appearing; retraction of chin against the perineum; shoulders remaining wedged behind the mother's pubic bone, causing a difficult birth with potential for injury to both mother and baby. If shoulders still above the brim at this stage, no advancement. Newborn's chest trapped within the vaginal vault; chest unable to expand with respiration (although nose and mouth are outside). Risk of umbilical cord compression between the fetal body and the maternal pelvis.	Emergency, often unexpected complication. Diagnosis made when newborn's head delivers without delivery of neck and remaining body structures. Primary risk factors, including suspected infant macrosomia (weight > 4500 g), maternal diabetes mellitus, excessive maternal weight gain, abnormal maternal pelvic anatomy, maternal obesity, postdated pregnancy, short stature, a history of previous shoulder dystocia, and use of epidural analgesia.	If anticipated, preparatory tasks instituted: alerting of key personnel; education of woman and family regarding steps to be taken in the event of a difficult birth; emptying of woman's bladder to allow additional room for possible maneuvers needed for the birth. McRobert's maneuver. Suprapubic pressure (not fundal) (see Fig. 21.1). Combination of maneuvers effective in more than 50% of cases of shoulder dystocia. Newborn resuscitation team readily available.	Intervene immediately due to cord compression. Perform McRobert's maneuver and application of suprapubic pressure. Assist with positioning the woman in squatting position, hands-and-knees position, or lateral recumbent position for birth to free shoulder. Anticipate cesarean birth if no success in dislodging shoulders. Clear room of unnecessary clutter to make room for additional personnel and equipment. After the birth, assess newborn for crepitus, deformity, Erb's palsy, or bruising, which might suggest neurologic damage or a fracture.
Multiple pregnancy	More than one fetus, leading to uterine overdistention and possibly resulting in hypotonic contractions and abnormal presentations of the fetuses. Fetal hypoxia during labor a significant threat due to placenta providing oxygen and nutrients to more than one fetus.	Nearly all multiples are now diagnosed early by ultrasound. Most women go into labor before 37 weeks.	Admission to facility with specialized care unit if a woman goes into labor. Spontaneous progression of labor if woman has no complicating factors and first fetus is in longitudinal lie. Separate monitoring of each FHR during labor and birth. After birth of first fetus, clamping of cord and lie of the second twin assessed. Possible external cephalic version necessary to assist in providing a longitudinal lie. Second and subsequent fetuses at greater risk for birth-related complications, such as umbilical cord prolapse, malpresentation, and abruptio placentae. Cesarean birth if risk factors high.	Assess for hypotonic labor pattern due to overdistention. Evaluate for fetal presentation, maternal pelvic size, and gestational age to determine mode of delivery. Ensure presence of neonatal team for birth of multiples. Anticipate need for cesarean birth, which is common in multifetal pregnancy.

Excessive fetal size and abnormalities	Macrosomia leading to fetopelvic disproportion (fetus unable to fit through the maternal pelvis to be born vaginally). Reduced contraction strength due to overdistention by large fetus leading to a prolonged labor and the potential for birth injury and trauma. Fetal abnormalities possibly interfering with fetal descent, leading to prolonged labor and difficult birth.	A diagnosis of fetal macrosomia can be confirmed by measuring the birth weight after birth. Suspicion of macrosomia based on the findings of an ultrasound examination before onset of labor (if suspected due to conditions such as maternal diabetes or obesity, estimation of fetal weight via ultrasound). Leopold's maneuvers to estimate fetal weight and position on admission to labor and birth unit.	Scheduled cesarean birth if diagnosis is made before the onset of labor to reduce the risk of injury to both the newborn and the mother. If identified by Leopold's maneuvers, possible trial of labor to evaluate progress; however, providers usually opt to proceed with a cesarean birth in a primigravida with a macrosomic fetus.	Assess for inability of fetus to descend. Anticipate need for vacuum and forceps-assisted births (common). Plan for cesarean birth if maternal parameters are inadequate to give birth to large fetus.
Problems with the Passageway	Contraction of one or more of the three planes of the pelvis. Poorer prognosis for vaginal birth in women with android and platypelloid types of pelvis. Contracted pelvis involving reduction in one or more of the pelvic diameters interfering with progress of labor: inlet, midpelvis, and outlet contracture. Obstruction in the birth canal, such as placenta previa that partially or completely obstructs the internal os of the cervix, fibroids in the lower uterine segment, a full bladder or rectum, an edematous cervix caused by premature bearing-down efforts, and human papillomavirus (HPV) warts.	Shortest A-P diameter <10 cm or greatest transverse diameter <12 cm. (Approximation of A-P diameter via measurement of diagonal conjugate, which in the contracted pelvis is <11.5 cm.) X-ray pelvimetry to determine the smallest A-P diameter through which the fetal head must pass. Interischial tuberous diameter of <8 cm possibly compromising outlet contracture (outlet and midpelvic contractures frequently occur together).	Focus on allowing natural forces of labor contractions to push the largest diameter (biparietal) of the fetal head beyond the obstruction or narrow passage. Possible forceps and vacuum extraction to assist navigation through this passageway.	Assess for poor contractions, slow dilation, prolonged labor. Evaluate bowel and bladder status to reduce soft tissue obstruction and allow increased pelvic space. Anticipate trial of labor; if no labor progression after an adequate trial, plan for cesarean birth.

	Description	Diagnosis	Therapeutic Management	Nursing Management
Problems with the Psyche	Release of stress-related hormones (catecholamines, cortisol, epinephrine, beta-endorphin), which act on smooth muscle (uterus) and reduce uterine contractility. Excessive release of catecholamines and other stress-related hormones not therapeutic. Release also results in decreased uteroplacental perfusion and increased risk for poor newborn adjustment.	Ruling out of other possible causes of dystocia	Treatment dependent on woman's responses such as anxiety, fear, anger, frustration, or denial (highly variable due to woman's understanding of the condition itself, past experiences, previous coping mechanisms, and the amount of family and nursing support received). Appropriate medical or surgical interventions depending on the underlying condition.	Provide comfortable environment—dim lighting, music. Encourage partner to participate. Provide pain management to reduce anxiety and stress. Ensure continuous presence of staff to allay anxiety. Provide frequent updates concerning fetal status and progress. Provide ongoing encouragement to minimize the woman's stress and help her to cope with labor and to promote a positive, timely outcome. Assist in relaxation and comfort measures to help her body work more effectively with the forces of labor. Engage the woman in conversation about her emotional well-being; offer anticipatory guidance and reassurance to increase her self-esteem and ability to cope, decrease frustration, and encourage cooperation.

Persistent occiput posterior is the most common malposition, occurring in

about 15% of laboring women. The reasons for this malposition are often unclear. This position presents slightly larger diameters to the maternal pelvis, thus slowing fetal descent. A fetal head that is poorly flexed may be responsible. In addition, poor uterine contractions may not push the fetal head down into the pelvic floor to the extent that the fetal occiput sinks into it rather than being pushed to rotate in an anterior direction.

Face and brow presentations are rare and are associated with fetal abnormalities (anencephaly), pelvic contractures, high parity, placenta previa, hydramnios, low birth weight, or a large fetus (World Health Organization [WHO], 2014a).

By 35 to 36 weeks of gestation, the majority of fetuses will spontaneously settle into the vertex presentation (head down, toward the birth canal). In about 3% to 4% of cases, however, the fetus will remain in a breech presentation with the buttocks or feet presenting. There is less risk to the fetus and mother when the head is down at the time of birth. This presentation frequently is associated with multifetal or multiple pregnancies, grand multiparity (more than five births), pregnancy over age 35 (advanced maternal age), placenta previa, hydramnios, preterm births, uterine malformations or fibroids, a scarred uterus, a female infant, and fetal anomalies such as hydrocephaly (Sharshiner & Silver, 2015). In a persistent breech presentation, an increased frequency of prolapsed cord, placenta previa, low birth weight from preterm birth, fetal or uterine anomalies, and perinatal morbidity and mortality from a difficult birth may occur (Cunningham et al., 2014). A breech presentation may be an indicator for subtle fetal abnormalities, as apparently healthy breech infants have on average poorer long-term neurodevelopmental scores than cephalic infants (Hofmeyr, 2015). Perinatal mortality is increased two- to fourfold with a breech presentation, regardless of the mode of delivery.

External cephalic version refers to a procedure in which the fetus is rotated from the breech to the cephalic presentation by manipulation through the mother's abdominal wall at or near term. Several national organizations (ACOG, WHO, AFP), recommend that this maneuver be offered to women between 36 and 38 weeks of gestation. It is performed only in a hospital setting under direct ultrasound guidance and continuous fetal monitoring. External cephalic version is successful in approximately 50% of cases. Women with a breech presentation today are often advised to have a surgical birth with no attempt to rotate the fetal position (Hofmeyr, Kulier, & West, 2015).

Shoulder dystocia is defined as the obstruction of fetal descent and birth by

the axis of the fetal shoulders after the fetal head has been delivered. The incidence of shoulder dystocia is increasing due to increasing birth weight, with reports of it in up to 2% of vaginal births. It is an obstetric emergency that requires a coordinated team response, as there is no reliable way to predict it, and thus decrease the rate at which adverse outcomes occur (Gherman, 2015). It is one of the most anxiety-provoking emergencies encountered in labor. Failure of the shoulders to deliver spontaneously places both the woman and the fetus at risk for injury. Postpartum hemorrhage, secondary to uterine atony, vaginal lacerations, anal tears, and uterine rupture are major complications to the mother. Transient Erb's or Duchenne's brachial plexus palsies and clavicular or humeral fractures are the most common fetal injuries encountered with shoulder dystocia. The occurrence of neonatal brachial plexus palsy in the United States is 1.5 per 1,000 live births, with about one-third suffering permanent upper extremity functional insufficiencies (Mehlman, 2015). Newborns experiencing shoulder dystocia typically have greater shoulder-to-head and chest-to-head disproportions compared with those delivered without dystocia (Cunningham et al., 2014). Prompt recognition and appropriate management, such as with McRobert's maneuver or suprapubic pressure, can reduce the severity of injuries to the mother and newborn (Fig. 21.1).

Take Note!

Prompt recognition and appropriate management of shoulder dystocia can reduce the severity of injuries to the mother and infant. Immediately assess the infant for signs of trauma such as a fractured clavicle, Erb's palsy, or neonatal asphyxia. Assess the mother for excessive vaginal bleeding and blood in the urine from bladder trauma.

Multiple or multifetal gestation refers to twins, triplets, or more infants within a single pregnancy (Box 21.1). The incidence is increasing, primarily as a result of infertility treatment (both ovarian stimulation and in vitro fertilization) and an increased number of women giving birth at older ages. The incidence of twins, triples, and higher order multiple gestations have now reached approximately 3% of all pregnancies (March of Dimes, 2015a). The incidence of twins is approximately 1 in 30 conceptions, with about two thirds of them due to the fertilization of two ova (dizygotic or fraternal) and about one-third occurring

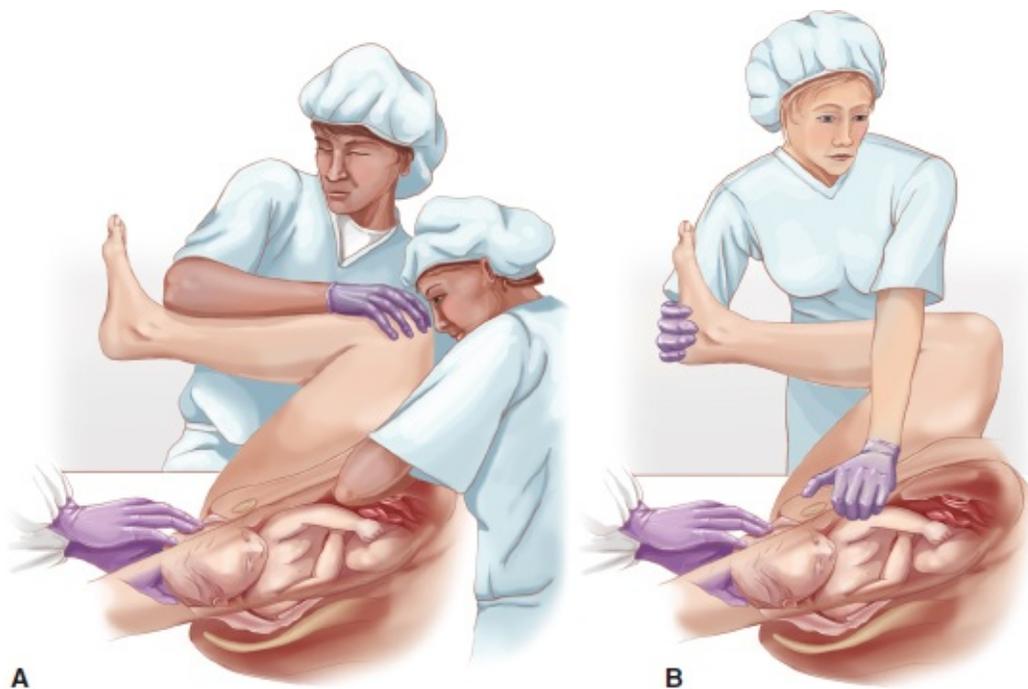
from the splitting of one fertilized ovum (monozygotic or identical twins). One in approximately 8,100 pregnancies results in triplets (March of Dimes, 2015a). The most common maternal complication is postpartum hemorrhage resulting from uterine atony. Compared with singletons (one fetus), the risk of perinatal morbidity and mortality is markedly increased in multiple gestations. Based on recent level 1 evidence from a randomized-controlled study, it was found that there was no difference in newborn outcomes between a planned surgical birth versus a planned vaginal birth for twins between 32 to 39 weeks of gestation. As long as the presenting twin is vertex, a vaginal birth should be considered (Bibbo & Robinson, 2015).


FIGURE 21.1 Maneuvers to relieve shoulder dystocia. **A.** McRobert's maneuver. The mother's thighs are flexed and abducted as much as possible to straighten the pelvic curve. **B.** Suprapubic pressure. Light pressure is applied just above the pubic bone, pushing the fetal anterior shoulder downward to displace it from above the mother's symphysis pubis. The newborn's head is depressed toward the mother's anus while light suprapubic pressure is applied.

Excessive fetal size and abnormalities can also contribute to labor and birth dysfunctions. **Macrosomia**, in which a newborn weighs 4,000 to 4,500 g (8.13 to 9.15 lb) or more at birth, complicates approximately 10% of all pregnancies. It is the result of a change in body composition in the neonate with an increase in both percentage of fat and fat mass. Macrosomia is associated with later life

obesity, diabetes, and cardiovascular disease (Jazayeri, 2015). Fetal abnormalities may include hydrocephalus, ascites, or a large mass on the neck or head. Complications associated with dystocia related to excessive fetal size and anomalies include an increased risk for postpartum hemorrhage, shoulder dystocia, low Apgar scores, dysfunctional labor, fetopelvic disproportion, soft tissue laceration during vaginal birth, fetal injuries or fractures, and perinatal asphyxia (Hobbins, 2015a).

As the name implies, a multiple gestation or a multifetal pregnancy involves more than one fetus. These fetuses can result from fertilization of a single ovum or multiple ova. Monozygotic (identical) twins develop from one single ovum that divides into equal halves during early cleavage phase. Monozygotic twins are genetically identical; always the same gender, and look very similar in appearance. The number of amnions and chorions depends on the timing of division (cleavage). One fertilized ovum splitting into two separate individuals is termed *natural clones*. This type of twinning occurs in approximately 1 of 250 live births (March of Dimes, 2015a).

Twin pregnancies that are multiple-ova conceptions (dizygotic twins) result from two ova fertilized by two sperms. They are referred to as fraternal twins. Genetically, dizygotic twins are as alike (or unlike) as any other pair or siblings. There are separate amnions and chorions although the chorions and placentas may be fused. The incidence of dizygotic twinning is approximately 1 in 500 Asians, 1 in 125 Whites, and as high as 1 in 20 in African populations (March of Dimes, 2015a). Fraternal twins account for two-thirds of all twins and there is a tendency to repeat within families. Currently the incidence of fraternal twins is increasing secondary to advancing maternal age when pregnancy occurs and an increase in use of fertility drugs and procedures being done.

Multiple births other than twins can be of the identical type, the fraternal type, or combinations of the two. Triplets can occur from the division of one zygote into two, with one dividing again, producing identical triplets, or they can come from two zygotes, one dividing into a set of identical twins, and the second zygote developing as a single fraternal sibling, or from three separate zygotes. Triplets are said to occur once in 7,000 births and quadruplets once in 660,000 births (March of Dimes, 2015a). In recent years, fertility drugs used to induce ovulation have resulted in a greater frequency of quadruplets, quintuplets, sextuplets, and even octuplets.

Problems with the Passageway

Problems with the passageway (pelvis and birth canal) are related to a contraction of one or more of the three planes of the maternal pelvis: inlet, midpelvis, and outlet. The female pelvis can be classified into four types based on the shape of the pelvic inlet, which is bounded anteriorly by the posterior border of the symphysis pubis, posteriorly by the sacral promontory, and laterally by the linea terminalis. The four basic types are: gynecoid, anthropoid, android, and platypelloid (see Chapter 12 for additional information). Contraction of the midpelvis is more common than inlet contraction and typically causes an arrest of fetal descent. Obstructions in the maternal birth canal, such as swelling of the soft maternal tissue and cervix, termed soft tissue dystocia, also can hamper fetal descent and impede labor progression outside the maternal bony pelvis.

Problems with the Psyche

Many women experience an array of emotions during labor, which may include fear, anxiety, helplessness, isolation, and weariness. These emotions can lead to psychological stress, which indirectly can cause dystocia. Hormones released in response to anxiety can cause dystocia. Intense anxiety stimulates the sympathetic nervous system, which releases catecholamines that can lead to myometrial dysfunction. Norepinephrine and epinephrine then lead to uncoordinated or increased uterine activity (Cheng & Caughey, 2015).

Nursing Assessment

Begin the assessment by reviewing the client's history to look for risk factors for dystocia which may include maternal short stature, obesity, hydramnios, uterine abnormalities, fetal malpresentation, cephalopelvic disproportion, over stimulation with oxytocin, maternal exhaustion, ineffective pushing, excessive size fetus, poor maternal positioning in labor, and maternal anxiety and fear (Green, 2016). Include in the assessment the mother's frame of mind to identify fear, anxiety, stress, lack of support, and pain, which can interfere with uterine contractions and impede labor progress. Helping the woman to relax will promote normal labor progress.

Assess the woman's vital signs. Note any elevation in temperature (might suggest an infection) or changes in heart rate or blood pressure (might signal hypovolemia). Evaluate the uterine contractions for frequency and intensity. Question the woman about any changes in her contraction pattern, such as a decrease or increase in frequency or intensity, and report these. Assess fetal heart rate (FHR) and pattern, reporting any abnormal patterns immediately.

Assess fetal position via *Leopold's maneuvers* (see Chapter 14 for more information) to identify any deviations in presentation or position, and report any deviations. Assist with or perform a vaginal examination to determine cervical dilation, effacement, and engagement of the fetal presenting part. Evaluate for evidence of membrane rupture. Report any malodorous fluid.

Nursing Management

Nursing management of the woman with dystocia, regardless of the etiology, requires patience. The nurse should provide physical and emotional support to the client and her family. The final outcome of any labor depends on the size and shape of the maternal pelvis, the quality of the uterine contractions, and the size, presentation, and position of the fetus. Thus, dystocia is diagnosed after labor has progressed for a time, not at the beginning of labor.

PROMOTING THE PROGRESS OF LABOR

The nurse plays a major role in determining the progress of labor. Continue to assess the woman, frequently monitoring cervical dilation and effacement, uterine contractions, and fetal descent, and document that all assessed

parameters are progressing. Evaluate progress in active labor by using the simple rule of 1 cm per hour for cervical dilation. When the woman's membranes rupture, if they have not already ruptured, observe for visible cord prolapse.

Take Note!

If a dysfunctional labor occurs, contractions will slow or fail to advance in frequency, duration, or intensity; the cervix will fail to respond to uterine contractions by dilating and effacing; and the fetus will fail to descend.

Throughout labor, assess the woman's fluid balance status. Check skin turgor and mucous membranes. Monitor intake and output. Also monitor the client's bladder for distention at least every 2 hours and encourage her to empty her bladder often. In addition, monitor her bowel status. A full bladder or rectum can impede descent.

Continue to monitor fetal well-being. If the fetus is in the breech position, be especially observant for visible cord prolapse and note any variable decelerations in heart rate. If either occurs, report it immediately.

Be prepared to administer a labor stimulant such as oxytocin (Pitocin) if ordered to treat hypotonic labor contractions. Anticipate the need to assist with manipulations if shoulder dystocia is diagnosed. Prepare the woman and her family for the possibility of a cesarean birth if labor does not progress.

PROVIDING PHYSICAL AND EMOTIONAL COMFORT

Employ physical comfort measures to promote relaxation and reduce stress. Offer blankets for warmth and a backrub, if the client wishes, to reduce muscle tension. Provide an environment conducive to rest so the woman can conserve her energy. Lower the lights and reduce external noise by closing the hallway door. Offer a warm shower to promote relaxation (if not contraindicated). Use pillows to support the woman in a comfortable position, changing her position every 30 minutes to reduce tension and to enhance uterine activity and efficiency. Offer her fluids/food as appropriate to moisten her mouth and replenish her energy (Fig. 21.2).

FIGURE 21.2 The nurse applies a cool, moist washcloth to the client's forehead and offers her ice chips to combat thirst and provide comfort to the woman experiencing dystocia.

Assist with providing counter pressure along with backrubs if the fetus is in the occiput posterior position. Encourage the woman to assume different positions to promote fetal rotation. Upright positions are helpful in facilitating fetal rotation and descent. Also encourage the woman to visualize the descent and birth of the fetus.

Assess the woman's level of pain and degree of distress. Administer analgesics as ordered or according to the facility's protocol. Evaluate the mother's level of fatigue throughout labor, such as verbal expressions of feeling exhausted, inability to cope in early labor, or inability to rest or calm down between contractions. Praise the woman and her partner for their efforts. Provide empathetic listening to increase the client's coping ability, and remain with the client to demonstrate caring.

PROMOTING EMPOWERMENT

Educate the client and family about dysfunctional labor and its causes and therapies. Explain therapeutic interventions that may be needed to assist with the labor process. Encourage the client and her partner to participate in decision making about interventions.

Assist the woman and partner in expressing their fears and anxieties. Provide encouragement to help them to maintain control. Support the client and her partner in their coping efforts. Keep the woman and her partner informed of progress and advocate for them.

ALTERNATIVE/NONTRADITIONAL FAMILIES

There is a growing awareness of nontraditional families in the world. If one considers family forms cross-nationally, a variety of configurations exists. This awareness requires nurses to shift away from heterosexist thinking in caring for the childbearing family. Nurses must be adequately educated about lesbian-gay-bisexual-transgender-queer (LGBTQ) health issues to be empathetic and conscious of the needs of this population. With increasing numbers of LGBTQ couples getting married, and availability of alternative methods of conception, these couples are coming in contact with nurses through the birthing process. LGBTQ couples may face making complex childbearing decisions, navigating a health care system designed for heterosexual couples and confronting barriers such as insurance issues, non-accepting negative attitudes by health care workers, and uncertain legal rights (Holley & Pasch, 2015).

LGBTQ individuals are not a homogeneous group and they are shaped by a range of factors including race, sexual orientation, ethnicity, socioeconomic status, and age. This community has been previously marginalized in society. Nurses caring for LGBTQ clients need to allow them to have their own identity, values, and beliefs. Every client should be treated with the kindness, with an individualized approach, and be an advocate for their needs. Nurses need to consider the following when they are caring for the childbearing LGBTQ family by using appropriate language/identification and cultural representation by asking how they wish to be identified; and by personalizing their care that includes all intersecting aspects of their identity (Westwood et al., 2015).

PRETERM LABOR

Preterm labor is defined as the occurrence of regular uterine contractions accompanied by cervical effacement and dilation before the end of the 37th week of gestation. If not halted, it leads to preterm birth. Preterm births remain one of the biggest contributors to perinatal morbidity and mortality in the world. According to the March of Dimes (2015b), about 12% of births (one in eight infants) in the United States are premature.

Preterm birth is one of the most common obstetric complications, and its sequelae have a profound effect on the survival and health of the newborn. The rate of preterm births in the United States has increased 35% in the past 20 years. Preterm births account for 75% of neurodevelopmental disorders and other serious morbidities, as well as behavioral and social problems. They account for 85% of all perinatal morbidity and mortality. In addition, up to $30 billion is spent on maternal and infant care related to prematurity annually (March of Dimes, 2015b). Infants born prematurely also are at risk for serious sequelae such as respiratory distress syndrome, infections, congenital heart defects, thermoregulation problems that can lead to acidosis and weight loss, intraventricular hemorrhage, jaundice, hypoglycemia, feeding difficulties resulting from diminished stomach capacity and an underdeveloped suck reflex, and neurologic disorders related to hypoxia and trauma at birth. Many will face the prospect of numerous lifelong disabilities, such as cerebral palsy, intellectual impairment, vision defects, and hearing loss. A recent study's findings indicated that a single course of corticosteroids prenatally improved most neonate's neurodevelopmental outcomes if given before 34 weeks of gestation (Sotiriadis et al., 2015). Although great strides have been made in neonatal intensive care, prematurity remains the leading cause of death within the first month of life and is the second leading cause of all infant deaths (March of Dimes, 2015b). The exact cause of preterm labor is not known. Currently, prevention is the goal.

Therapeutic Management

Predicting the risk of preterm labor is valuable only if there is an available intervention that is likely to improve the situation. According to ACOG, many factors must be considered before selecting an intervention. Many factors influence the decision to intervene when women present with symptoms of preterm labor, including the probability of progressive labor, gestational age, and the risks of treatment. ACOG (2014b) recommends the following as guidelines:

• There are no clear first-line **tocolytic** drugs (drugs that promote uterine relaxation by interfering with uterine contractions) to manage preterm labor, and the results of research on their efficacy are mixed. Clinical circumstances and the health care provider's preference should dictate treatment.

• Antibiotics do not appear to prolong gestation and should be reserved for group B streptococcal prophylaxis in women in whom birth is imminent.

• Tocolytic drugs may prolong pregnancy for 2 to 7 days; during this time, steroids can be given to improve fetal lung maturity and the woman can be transported to a tertiary care center.

• A single course of corticosteroids is recommended for all pregnant women between 24 and 34 weeks of gestation who are at risk of preterm birth within 7 days. Prenatal corticosteroids significantly reduce the incidence and severity of neonatal respiratory distress syndrome.

With these recommendations, health care providers continue to prescribe pharmacologic treatment for preterm labor at home and in the hospital setting. This treatment often includes oral or intravenous tocolytics and varying degrees of activity restriction (Fig. 21.3). Antibiotics may also be prescribed to treat presumed or confirmed infections. Steroids may be given to enhance fetal lung maturity between 24 and 34 weeks of gestation.

FIGURE 21.3 The mother with preterm labor resting in bed at home.

Tocolytic Therapy

The decision to stop preterm labor is individualized based on risk factors, extent of cervical dilation, membrane status, fetal gestational age, and presence or absence of infection. Tocolytic therapy is most likely ordered if preterm labor occurs before the 34th week of gestation in an attempt to delay birth and thereby to reduce the severity of respiratory distress syndrome and other complications associated with prematurity. Tocolytic therapy does not typically prevent preterm birth, but it may delay it. It is contraindicated for abruptio placentae, acute fetal distress or death, eclampsia or severe preeclampsia, active vaginal bleeding, dilation of more than 6 cm, chorioamnionitis, and maternal hemodynamic instability (Locatelli, Consonni, & Ghidini, 2015).

Medications commonly used for tocolysis include magnesium sulfate (which reduces the muscle's ability to contract), indomethacin (Indocin, a prostaglandin synthetase inhibitor), atosiban (Tractocile, Antocin, an oxytocin receptor antagonist), and nifedipine (Procardia, a calcium channel blocker) (see Evidence-Based Practice 21.1). These drugs are used "off label," which means that they are effective for this purpose but have not been officially tested and developed for this purpose by the U.S. Food and Drug administration (FDA) (Haas et al., 2014). In a recent Cochrane review study, calcium channel blockers were found to be better in preventing preterm labor when compared to beta-mimetics (Flenady et al., 2014). All of these medications have serious side effects, and the woman needs close supervision when they are being administered (Drug Guide 21.1).

EVIDENCE-BASED PRACTICE 21.1 BED REST IN SINGLETON PREGNANCIES FOR PREVENTING PRETERM BIRTH

STUDY

Preterm birth, defined a birth occurring prior to 37 weeks of gestation occurs in up to 10% of all pregnancies worldwide. Although there are many different therapies available for preventing preterm birth, very few are proven to be effective and recommended for clinical use. One therapy, bed rest, has been traditionally been recommended for preventing preterm birth as a first step in treatment. This therapy is based on the observation that hard work and hard physical activity during pregnancy could be associated with preterm birth, and with the idea that bed rest could reduce uterine activity. Bed rest does have adverse effects such as increasing the incidence of venous thrombosis, muscle atrophy, and cardiovascular deconditioning. The purpose of this study was to evaluate the effect of bed rest in the hospital or at home for preventing preterm birth.

Findings

Randomized, cluster-randomized, and quasi-randomized control studies were sought. Two studies met the inclusion criteria with 1266 women participating. There was no evidence found to support or refute the use of bed rest at home or in the hospital to prevent preterm birth. Due to the potential adverse effects that bed rest can have on women, it is suggested that health care providers discuss this intervention thoroughly with their clients. Additional research is needed.

Nursing Implications

Although the study did not reveal results that were statistically significant, nurses need to be aware of the potential benefits and limitations associated with bed rest employed to delay a preterm birth so that they can provide women and their families with the most appropriate information about options to prolonged pregnancy. Potential benefits and harms should be discussed with women facing an increased risk of preterm birth. Nurses can integrate information from this study in their teaching about the risks associated with preterm labor and births. They can also use this information to help answer couple's questions about interventions currently used and their effectiveness as well as provide anticipatory guidance about the procedure. Doing so fosters empowerment of the woman and her family, promoting optimal informed decision making.

DRUG GUIDE 21.1 MEDICATIONS USED WITH PRETERM LABOR

Drug	Action/Indication	Nursing Implications
Magnesium sulfate	Relaxes uterine muscles to stop irritability and contractions, to arrest uterine contractions for preterm labor (off-label use). Has been used in seizure prophylaxis and treatment of seizures in preeclamptic and eclamptic clients for almost 100 years	Administer IV with a loading dose of 4–6 g over 15–30 min initially, and then maintain infusion at 1–4 g/hr. Assess vital signs and deep tendon reflexes (DTRs) hourly; report any hypotension or depressed or absent DTRs. Monitor level of consciousness; report any headache, blurred vision, dizziness, or altered level of consciousness. Perform continuous electronic fetal monitoring; report any decreased FHR variability, hypotonia, or respiratory depression. Monitor intake and output hourly; report any decrease in output (<30 mL/hr). Assess respiratory rate; report respiratory rate <12 breaths/min; auscultate lung sounds for evidence of pulmonary edema. Monitor for common maternal side effects, including flushing, nausea and vomiting, dry mouth, lethargy, blurred vision, and headache. Assess for nausea, vomiting, transient hypotension, lethargy. Assess for signs and symptoms of magnesium toxicity, such as decreased level of consciousness, depressed respirations and DTRs, slurred speech, weakness, and respiratory and/or cardiac arrest. Have calcium gluconate readily available at the bedside to reverse magnesium toxicity.

Drug	Action/Indication	Nursing Implications
Indomethacin (Indocin)	Inhibits prostaglandins, which stimulate contractions; inhibits uterine activity to arrest pre-term labor	Continuously assess vital signs, uterine activity, and FHR. Administer oral form with food to reduce GI irritation. Do not give to women with peptic ulcer disease. Schedule ultrasound to assess amniotic fluid volume and function of ductus arteriosus before initiating therapy; monitor for signs of maternal hemorrhage. Be alert for maternal adverse effects such as nausea and vomiting, heartburn, rash, prolonged bleeding time, oligohydramnios, and hypertension. Monitor for neonatal adverse effects, including constriction of ductus arteriosus, premature ductus closure, necrotizing entero-colitis, oligohydramnios, and pulmonary hypertension. Contraindicated in >32 weeks of gestations, fetal growth restric-tion, history of asthma, urticaria, or allergic type reactions to aspirin or NSAIDS.
Nifedipine (Procardia)	Blocks calcium movement into muscle cells, inhibits uterine activity to arrest preterm labor	Use caution if giving this drug with magnesium sulfate because of increased risk for hypotension. Monitor blood pressure hourly if giving with magnesium sulfate; report a pulse rate >110 bpm. Monitor for fetal effects such as decreased uteroplacental blood flow manifested by fetal bradycardia, which can lead to fetal hypoxia. Monitor for adverse effects, such as flushing of the skin, head-ache, transient tachycardia, palpitations, postural hypertension, peripheral edema, and transient fetal tachycardia. Contraindicated in women with cardiovascular disease or hemo-dynamic instability.
Betamethasone (Celestone)	Promotes fetal lung maturity by stimulating surfactant produc-tion; prevents or reduces risk of respiratory distress syn-drome and intraventricular hemorrhage in the preterm neonate less than 34 weeks of gestation	Administer two doses intramuscularly 24 h apart. Monitor for maternal infection or pulmonary edema. Educate parents about potential benefits of drug to preterm infant. Assess maternal lung sounds and monitor for signs of infection.

Corticosteroids

Corticosteroids given to the mother in preterm labor can help prevent or reduce the frequency and severity of respiratory distress syndrome in premature infants delivered between 24 and 34 weeks of gestation. The beneficial effects of corticosteroids on fetal lung maturation have been reported within 48 hours of initial administration. A recent Cochrane review found that corticosteroids repeatedly administered to the woman in preterm labor provided short-term benefits to the preterm infant of less respiratory distress and fewer serious health

problems in the first few weeks after birth. They supported the use of repeat dose(s) of prenatal corticosteroids for women still at risk of preterm birth 7 days or more after an initial course. These benefits were associated with a small reduction in size at birth. The current available evidence reassuringly shows no significant harm in early childhood, although no benefit. Further research is needed on the long-term benefits and risks for the woman and baby. Individual client data meta-analysis may clarify how to maximize benefit and minimize harm (Cabbad et al., 2015). These drugs require at least 24 hours to become effective, so timely administration is crucial.

Nursing Assessment

The preterm birth rate cannot be reduced until there are ways to predict the risk for preterm birth. Because the etiology is often multifactorial, an individualized approach is needed.

Health History and Physical Examination

The signs of preterm labor are subtle and may be overlooked by the client as well as the health care provider. Obtain a thorough health history and be alert for risk factors associated with preterm labor and birth (Box 21.2).

BOX 21.2

RISK FACTORS ASSOCIATED WITH PRETERM LABOR AND BIRTH

- African-American race (double the risk)
- Maternal age extremes (<16 years and> 40 years old)
- Low socioeconomic status
- Alcohol or other drug use, especially cocaine
- Poor maternal nutrition
- Maternal periodontal disease
- Cigarette smoking
- Low level of education
- History of prior preterm birth (triples the risk)
- Uterine abnormalities, such as fibroids
- Low pregnancy weight for height
- Preexisting diabetes or hypertension
- Multiple pregnancy
- Premature rupture of membranes
- Late or no prenatal care
- Short cervical length
- Sexually transmitted infections: gonorrhea, *Chlamydia*, trichomoniasis
- Bacterial vaginosis (50% increased risk)
- Chorioamnionitis
- Hydramnios
- Gestational hypertension
- Cervical insufficiency
- Short interpregnancy interval (<1 year between births)
- Placental problems, such as placenta previa and abruption placenta
- Maternal anemia

• Urinary tract infection

• Domestic violence

• Stress, acute and chronic

Adapted from March of Dimes. (2015b). *Preterm labor and birth: A serious pregnancy complication.*
Retrieved from http://www.marchofdimes.com/pregnancy/preterm_indepth.html

Frequently, women are unaware that uterine contractions, effacement, and dilation are occurring, thus making early intervention ineffective in arresting preterm labor and preventing the birth of a premature newborn. Ask the woman about any complaints, being alert for the subtle symptoms of preterm labor, which may include:

• Change or increase in vaginal discharge with mucous, water, or blood in it

• Pelvic pressure (pushing-down sensation)

• Low, dull backache

• Menstrual-like cramps

• Urinary tract infection symptoms

• Feeling of pelvic pressure or fullness

• Gastrointestinal upset: nausea, vomiting, and diarrhea

• General sense of discomfort or unease

• Heaviness or aching in the thighs

• Uterine contractions, with or without pain

• More than six contractions per hour

• Intestinal cramping, with or without diarrhea (Jordan et al., 2014).

Assess the pattern of the contractions: the contractions must be persistent, such that four contractions occur every 20 minutes or 8 contractions occur in 1 hour. Evaluate cervical dilation and effacement: cervical effacement is 80% or greater and cervical dilation is greater than 1 cm (ACOG, 2014b). On examination, engagement of the fetal presenting part will be noted.

Laboratory and Diagnostic Testing

Commonly used diagnostic testing for preterm labor risk assessment includes a

complete blood count to detect infection, which may be a contributing factor to preterm labor; urinalysis to detect bacteria and nitrites, which are indicative of a urinary tract infection; and an amniotic fluid analysis to determine fetal lung maturity and the presence of subclinical chorioamnionitis.

Other tests that may be used for preterm labor prediction include fetal fibronectin testing and cervical length evaluation by transvaginal ultrasound., Fetal fibronectin and cervical length examinations have a high negative predictive value and are thus better at predicting which pregnant women are unlikely to have a preterm birth as opposed to predicting those who will (van Baaren et al., 2015).

FETAL FIBRONECTIN

Fetal fibronectin, a glycoprotein produced by the chorion, is found at the junction of the chorion and decidua (fetal membranes and uterus). It acts as biologic glue, attaching the fetal sac to the uterine lining. It normally is present in cervicovaginal secretions up to 22 weeks of pregnancy and again at the end of the last trimester (1 to 3 weeks before labor). It usually cannot be detected between 24 and 34 weeks of pregnancy (5½ to 8½ months) unless there has been a disruption between the chorion and deciduas. It is present in cervicovaginal fluid prior to delivery, regardless of gestational age.

The test is a useful marker for impending membrane rupture within 7 to 14 days if the level increases to >0.05 mcg/mL. The accuracy of fetal fibronectin is decreased in the presence of lubricants, blood, recent intercourse, or cervical manipulation within the previous 24 hours. Conversely, a negative fetal fibronectin test is a strong predictor that preterm labor in the next 2 weeks is unlikely (Abbott et al., 2015).

A sterile applicator is used to collect a cervicovaginal sample during an examination by speculum. The result is either positive (fetal fibronectin is present) or negative (fetal fibronectin is not present). Interpretation of fetal fibronectin results must always be viewed in conjunction with the clinical findings; it is not used as a lone indicator for predicting preterm labor. The primary importance of cervicovaginal fetal fibronectin lies in the high negative predictive values of the test for reducing preterm birth risk. Fibronectin testing can be a useful tool in the triaging of women symptomatic for preterm labor.

CERVICAL LENGTH MEASUREMENT

Transvaginal ultrasound of the cervix has been used as a tool to predict preterm

labor in high-risk pregnancies and to differentiate between true and false preterm labor. Three parameters are evaluated during the transvaginal ultrasound: cervical length and width, funnel width and length, and percentage of funneling. Measurement of the closed portion of the cervix visualized during the transvaginal ultrasound is the single most reliable parameter for prediction of preterm delivery in high-risk women (van Baaren et al., 2014).

Cervical length varies during pregnancy and can be measured fairly reliably after 16 weeks of gestation using an ultrasound probe inserted in the vagina. A cervical length of 3 cm or more indicates that delivery within 14 days is unlikely. Women with a short cervical length of 2.5 cm during the mid-trimester have a substantially greater risk of preterm birth prior to 35 weeks of gestation. As with fetal fibronectin testing, negative results can be reassuring and prevent unnecessary interventions (Souka et al., 2015).

Nursing Management

Nurses play a key role in reducing preterm labor and births to improve pregnancy outcomes for both mothers and their infants. Early detection of preterm labor is currently the best strategy to improve outcomes. Because of the numerous factors associated with preterm labor, it is challenging to identify and address all of them, especially when women experiencing contractions are frequently falsely reassured and not assessed thoroughly to determine the cause. This delay impedes initiation of interventions to reduce infant death and morbidity.

Preterm birth prevention programs for women at high risk have used self-monitoring of symptoms and patterns, weekly cervical examinations, clinical markers, telephone monitoring, home visiting, alone or in combination, with disappointing results. Preterm labor is currently thought to be a chronic, long-term multifactorial process with a genetic component. A recent study found a multiple pregnancy, prior preterm birth, low socioeconomic status, maternal medical disorders, and maternal infections were statistically significant risk factors for predicting spontaneous preterm labor (Patel, Pitre, & Bhooker, 2015). Despite technologic and pharmacologic advances in the identification and treatment of preterm labor, the incidence remains high and is growing in the United States.

Supportive nursing care is needed for the woman in preterm labor whether the contractions are stopped with tocolytic therapy or not. Nursing tasks include monitoring vital signs, measuring intake and output, encouraging bed rest on the woman's left side to enhance placental perfusion, monitoring the fetal heart rate via an external monitor continuously, limiting vaginal examinations to prevent an ascending infection, and monitoring the mother and fetus closely for any adverse effects from the tocolytic agents. Offering the couple ongoing explanations will help prepare them for the birth.

Administering Tocolytic Therapy

Tocolysis is the use of drugs to inhibit uterine contractions. The primary goals of tocolytic therapy are to arrest labor and delay birth long enough to initiate prophylactic corticosteroid therapy when indicated for stimulation of fetal lung maturity and to arrange for maternal-fetal transport to a perinatal tertiary care

hospital. A firm diagnosis of preterm labor is necessary before treatment is considered. Diagnosis requires the presence of both uterine contractions and cervical change (or an initial cervical examination of more than 2 cm and/or more than 80% effacement in a nulliparous client). A cause for preterm labor should always be sought.

Absolute contraindications to administering tocolytic agents to stop labor include intrauterine infection, active hemorrhage, fetal distress, fetus before viability, fetal abnormality incompatible with life, fetal growth restriction severe preeclampsia, heart disease, prolonged premature rupture of the membranes (PPROM), and intrauterine demise (Callahan, 2016). Bed rest and hydration are commonly recommended, but without proven efficacy.

Prevention of preterm labor remains an elusive goal. Presently, women at high risk for preterm labor are offered progesterone therapy at the start of their second trimester. Although progesterone therapy is recommended by ACOG, it has not been FDA approved for this purpose and has mixed results (Iams, 2015).

Magnesium sulfate may be ordered. This agent acts as a physiologic calcium antagonist and a general inhibitor of neurotransmission. Expect to administer it intravenously. Monitor the woman for nausea, vomiting, headache, weakness, hypotension, and cardiopulmonary arrest. Frequent monitoring of maternal respiratory effort and deep tendon reflexes is essential for early recognition of overdose. Because magnesium is exclusively excreted by the kidneys, adequate renal function is essential for safe administration. Assess the fetus for decreased FHR variability, drowsiness, and hypotonia. Magnesium has a wide margin of safety, but is not any more effective in delaying preterm birth as any other tocolytic agent. However, if administered prenatally, it is effective in helping women who develop preeclampsia and helping to protect fetal brains (Nakazawa et al., 2015).

Calcium channel blockers promote uterine relaxation by decreasing the influx of calcium ions into myometrium cells to inhibit contractions. Although calcium channel blockers may be prescribed to manage preterm labor, available literature provides little evidence that they have better efficacy in treating preterm labor than any other tocolytic agent. The perfect tocolytic drug that is 100% efficacious and 100% safe does not exist yet (van den Bosch, Ruys, & Roos-Hesselink, 2015). Administer calcium channel blockers (nifedipine) orally or sublingually every 4 to 8 hours as ordered. Monitor the woman for hypotension, reflex tachycardia, headache, nausea, and facial flushing.

Prostaglandin synthetase inhibitor (indomethacin [Indocin]) reduces

prostaglandin synthesis from decidual macrophages. It readily crosses the placenta and can cause oligohydramnios due to a decrease in fetal renal blood flow if used for more than 48 hours. During treatment, urine output, maternal temperature, and amniotic fluid index (AFI) should be evaluated periodically. The initial recommended dose is 50 to 100 mg orally or per rectum followed by 25 to 50 mg every 6 hours for 8 doses. Indomethacin therapy is not recommended for gestations of 32 weeks or greater (Ross, 2015).

Educating the Client

Ensure that every pregnant woman receives basic education about preterm labor, including information about harmful lifestyles, the signs of genitourinary infections and preterm labor, and the appropriate response to these symptoms. Teach the client how to palpate for and time uterine contractions. Provide written materials to support this education at a level and in a language appropriate for the client. Also educate clients about the importance of prenatal care, risk reduction, and recognizing the signs and symptoms of preterm labor. Teaching Guidelines 21.1 highlights important instructions related to preventing preterm labor.

Teaching Guidelines 21.1

TEACHING TO PREVENT PRETERM LABOR

• Avoid traveling for long distances in cars, trains, planes, or buses.

• Avoid lifting heavy objects, such as laundry, groceries, or a young child.

• Avoid performing hard, physical work, such as yard work, moving of furniture, or construction.

• Mild to moderate levels of exercise are permitted such as walking daily.

• Achieve an appropriate prepregnancy weight.

• Achieve adequate iron stores through balanced nutrition.

• Wait at least 18 months between pregnancies.

• Visit a dentist in early pregnancy to evaluate and treat periodontal disease.

• Enroll in a smoking cessation program if you are unable to quit on your

own.

- Curtail sexual activity until after 37 weeks if experiencing preterm labor symptoms.

- Consume a well-balanced nutritional diet to gain appropriate weight.

- Avoid the use of substances such as marijuana, cocaine, and heroin.

- Identify factors and areas of stress in your life, and use stress management techniques to reduce them.

- If you are experiencing intimate partner violence, seek resources to modify the situation.

Recognize the signs and symptoms of preterm labor and notify your birth attendant if any occur:

- Uterine contractions, cramping, or low back pain

- Feeling of pelvic pressure or fullness

- Increase in vaginal discharge

- Nausea, vomiting, and diarrhea

- Leaking of fluid from vagina

If you are experiencing any of these signs or symptoms, do the following:

- Stop what you are doing and rest for 1 hour.

- Empty your bladder.

- Lie down on your side.

- Drink two to three glasses of water.

- Feel your abdomen and make note of the hardness of the contraction. Call your health care provider and describe the contraction as

  - Mild if it feels like the tip of the nose

  - Moderate if it feels like the tip of the chin

  - Strong if it feels like your forehead

Adapted from Jordan, R. G., Engstrom, J. L., Marfell, J. A., & Farley, C. L. (2014). *Prenatal and postnatal care: A woman-centered approach*. Ames, Iowa: John Wiley & Sons, Inc.; and Ross, M. G. (2015). Preterm labor. *eMedicine*. Retrieved from http://emedicine.medscape.com/article/260998-overview#aw2aab6b7

Explaining to the couple what is happening in terms of labor progress, the treatment regimen, and the status of the fetus is important to reduce the anxiety associated with the risk of giving birth to a preterm infant. Educate them about the importance of promotion of fetal lung maturity with corticosteroids. Include supportive family members in all education. Allow time for the woman and her family to express their concerns about the possible outcome for the infant and the possible side effects of the tocolytic therapy. Encourage them to vent any feelings, fears, and anger they may experience. Provide the woman and her family with an honest appraisal of the situation and plan of treatment throughout her care.

Providing Psychological Support

Preterm labor and birth present multifactorial challenges for everyone involved. If the woman's activities are restricted, additional stresses may be placed on the family, contributing to the crisis. Assess the stress levels of the client and family, and make appropriate referrals. Emphasize the need for more frequent supervision and office visits, and encourage clients to talk to their health care provider for reassurance.

Every case of spontaneous preterm labor is unique. Care must take into account the clinical circumstances, and the full and informed consent of the woman and her partner is needed. Half of all women who ultimately give birth prematurely have no identifiable risk factors. Nurses should be sensitive to any complaint and should provide appropriate assessment, information, and follow-up. Sensitivity to the subtle differences between normal pregnancy sensations and the prodromal symptoms of preterm labor is a key factor in ensuring timely care. Offer validation and clarification of the woman's symptoms.

If tocolytic therapy is not successful in stopping uterine contractions, support the couple through this stressful period to prepare them for the birth. Keep them informed of all progress and changes; for example, continuously monitor maternal and fetal vital signs, especially the maternal temperature to detect signs of early infection. Offer one-on-one contact and be available throughout this difficult and anxiety-producing period.

POST-TERM PREGNANCY

A term pregnancy usually lasts 38 to 42 weeks. A post-term or prolonged pregnancy is one that continues past the end of the 42nd week of gestation, or 294 days from the first day of the last menstrual period. A **post-term or prolonged pregnancy** is defined as a pregnancy that extends to 42 0/7 weeks and beyond. Within the United States, about 7% of singleton pregnancies extend beyond 41 weeks (Walker & Gan, 2015). Incorrect dates account for the majority of these cases: many women have irregular menses and thus cannot identify the date of their last menstrual period accurately.

> *Recall Jennifer described at the beginning of the chapter, who was at 41 weeks of gestation. What information would be most important to determine on admission to the facility? What interventions might the nurse anticipate when she arrives?*

The exact etiology of a post-term or prolonged pregnancy is unknown because the mechanism for the initiation of labor is not completely understood. Theories suggest there may be a deficiency of estrogen and continued secretion of progesterone that prohibits the uterus from contracting, but no evidence has validated this. A woman who has one prolonged pregnancy is at greater risk for another in subsequent pregnancies.

Post-term pregnancies may adversely affect both the mother and fetus or newborn. Maternal risk is related to the large size of the fetus at birth, which increases the chances that a cesarean birth will be needed. Other issues might include dystocia, birth trauma, postpartum hemorrhage, and infection. Mechanical or artificial interventions such as forceps or vacuum-assisted birth and labor induction with oxytocin may be necessary. In addition, maternal exhaustion and feelings of despair over this prolonged gestation can add to the woman's anxiety level and reduce her coping ability. Women often blame themselves for prolonging the pregnancy, and a woman's negative feelings about herself can bring about strained relationships with the people closest to her.

Fetal risks associated with a post-term pregnancy include macrosomia, shoulder dystocia, brachial plexus injuries, low Apgar scores, postmaturity

syndrome (loss of subcutaneous fat and muscle and meconium staining), and cephalopelvic disproportion. All of these conditions predispose this fetus to birth trauma or a surgical birth. The perinatal mortality rate at more than 42 weeks of gestation is twice that at term and increases sixfold and higher at 43 weeks of gestation and beyond. Uteroplacental insufficiency, meconium aspiration, and intrauterine infection contribute to the increased rate of perinatal deaths (Callahan, 2016). As the placenta ages, its perfusion decreases and it becomes less efficient at delivering oxygen and nutrients to the fetus. Amniotic fluid volume also begins to decline after 38 weeks of gestation, possibly leading to oligohydramnios, subsequently resulting in fetal hypoxia and an increased risk of cord compression because the cushioning effect offered by adequate fluid is no longer present. Hypoxia and oligohydramnios predispose the fetus to aspiration of meconium, which is released by the fetus in response to a hypoxic insult (Caughey & Butler, 2015). All of these issues can compromise fetal well-being and lead to fetal distress.

Nursing Assessment

Obtain a thorough history to determine the estimated date of birth. Many women are unsure of the date of their last menstrual period, so the date given may be unreliable. Despite numerous methods used to date pregnancies, many are still misdated. Accurate gestational dating via ultrasound is essential.

When expectant management is chosen versus labor induction for the post-term pregnancy, the nurse should anticipate that assessments for a post-term pregnancy will typically include daily fetal movement counts done by the woman, nonstress tests with amniotic fluid assessments as part of the biophysical profile done twice weekly, and weekly cervical examinations to evaluate for ripening. Induction can be deferred until 42 weeks if the fetal surveillance is reassuring. In addition, assess the following:

• Client's understanding of the various fetal well-being tests

• Client's stress and anxiety concerning her lateness

• Client's coping ability and support network

Nursing Management

Once the dates have been established and post-term status is confirmed, monitoring fetal well-being becomes critical. When determining the plan of care for a woman with a prolonged pregnancy, the first decision is whether to deliver the baby or wait. If the decision is to wait, then fetal surveillance is the key. If the decision is to have the woman give birth, labor induction is initiated. Both decisions remain controversial, and there is no clear answer about which option is more appropriate. Therefore, the plan must be individualized.

> *Think back to Jennifer, who is scheduled for labor induction. What ongoing nursing assessments would be important when providing care for her?*

Providing Support

The intense surveillance is time consuming and intrusive, adding to the anxiety and worry already being experienced by the woman about her overdue status. Be alert to the woman's anxiety and allow her to discuss her feelings. Provide reassurance about the expected time range for birth and the well-being of the fetus based on the assessment tests. Validating the woman's stressful state due to the post-term pregnancy provides an opportunity for her to verbalize her feelings openly.

Educating the Woman and Her Partner

Teach the woman and her partner about the testing required and the reasons for each test. Also describe the methods that may be used for cervical ripening if indicated. Explain about the possibility of induction if the woman's labor is not spontaneous or if a dysfunctional labor pattern occurs. Also prepare the woman for the possibility of a surgical delivery if fetal distress occurs.

Providing Care During the Intrapartum Period

During the intrapartum period, continuously assess and monitor FHR to identify potential fetal distress early (e.g., late or variable decelerations) so that interventions can be initiated. Also monitor the woman's hydration status to

ensure maximal placental perfusion. When the membranes rupture, assess amniotic fluid characteristics (color, amount, and odor) to identify previous fetal hypoxia and prepare for prevention of meconium aspiration. Report meconium-stained amniotic fluid immediately when the woman's membranes rupture. Anticipate the need for amnioinfusion to minimize the risk of meconium aspiration by diluting the meconium in the amniotic fluid expelled by the hypoxic fetus. In addition, monitor the woman's labor pattern closely because dysfunctional patterns are common (Soni, Vaishnav, & Gohil, 2015). Encourage the woman to verbalize her feelings and concerns, and answer all her questions. Provide support, presence, information, and encouragement throughout this time.

WOMEN REQUIRING LABOR INDUCTION AND AUGMENTATION

Ideally, all pregnancies go to term, with labor beginning spontaneously. However, many women need help to initiate or sustain the labor process. **Labor induction** involves the stimulation of uterine contractions by medical or surgical means before the onset of spontaneous labor. The labor induction rate is at an all-time high in the United States. The widespread use of artificial induction of labor for convenience has contributed to the recent increase in the number of cesarean births. Evidence is compelling that elective induction of labor significantly increases the risk of cesarean birth, instrumented delivery, use of epidural analgesia, and neonatal intensive care unit admission, especially for nulliparous women (Caughey, 2014a).

Labor induction is not an isolated event: it brings about a cascade of other interventions that may or may not produce a favorable outcome. Labor induction also involves intravenous therapy, bed rest, continuous electronic fetal monitoring, significant discomfort from stimulating uterine contractions, epidural analgesia/anesthesia, and a prolonged stay on the labor and birth unit (Vogel et al., 2014). Labor augmentation (stimulating the uterus, typically with oxytocin) enhances ineffective contractions after labor has begun. Continuous electronic FHR monitoring is necessary.

The World Health Organization ([WHO], 2014b) has put forth recommendations regarding labor induction which includes:

• Labor induction should be performed only for a clear medical indication

• Women being induced should not be left unattended

• Labor induction should only be performed after CPD has been ruled out

• Labor induction should be applied to women with abnormal fetal presentations

• Close monitoring is needed of the fetal heart rate and uterine contraction pattern

There are multiple medical and obstetric reasons for inducing labor, the most common being prolonged gestation. Other indications for inductions include PPROM, gestational hypertension, cardiac disease, renal disease, chorioamnionitis, dystocia, intrauterine fetal demise, isoimmunization, and

diabetes (Jordan et al., 2014). Contraindications to labor induction include complete placenta previa, abruptio placentae, transverse fetal lie, prolapsed umbilical cord, a prior classic uterine incision that entered the uterine cavity, pelvic structure abnormality, previous myomectomy, vaginal bleeding with unknown cause, invasive cervical cancer, active genital herpes infection, and abnormal FHR patterns (Cunningham et al., 2014). In general, labor induction is indicated when the benefits of birth outweigh the risks to the mother or fetus for continuing the pregnancy. However, the balance between risk and benefit remains controversial.

Take Note!

Before labor induction is started, fetal maturity (dating, ultrasound, amniotic fluid studies) and cervical readiness (vaginal examination, Bishop scoring; see Table 21.2) must be assessed. Both need to be favorable for a successful induction.

Therapeutic Management

The decision to induce labor is based on a thorough evaluation of maternal and fetal status. Typically, this includes an ultrasound to evaluate fetal size, position, and gestational age and to locate the placenta; engaged presenting fetal part; pelvimetry to rule out fetopelvic disproportion; a nonstress test to evaluate fetal well-being; a phosphatidylglycerol (PG) level to assess fetal lung maturity; confirmation of Category I fetal heart rate pattern; complete blood count and urinalysis to rule out infection; and a vaginal examination to evaluate the cervix for inducibility (Kriebs, 2015). Accurate dating of the pregnancy also is essential before cervical ripening and induction are initiated to prevent a preterm birth.

TABLE 21.2 BISHOP SCORING SYSTEM

Score	Dilation (cm)	Effacement (%)	Station	Cervical Consistency	Position of Cervix
0	Closed	0–30	−3	Firm	Posterior
1	1–2	40–50	−2	Medium	Midposition
2	3–4	60–70	−1 or 0	Soft	Anterior
3	5–6	80	+1 or +2	Very soft	Anterior

Modified from International Childbirth Education Association [ICEA]. (2014). *ICEA position paper: Induction.* Retrieved from http://www.icea.org/sites/default/files/Induction%20PP-FINAL.pdf

Cervical Ripening

Cervical ripening is a process by which the cervix softens via the breakdown of collagen fibrils. It is the first step in the process of cervical effacement and dilation so that, on average, the cervix is approximately 50% effaced and 2 cm dilated at the onset of labor, although wide differences do exist. There has been increasing awareness that if the cervix is unfavorable or unripe, a successful vaginal birth is unlikely. Cervical ripeness is an important variable when labor induction is being considered. A ripe cervix is shortened, centered (anterior), softened, and partially dilated. An unripe cervix is long, closed, posterior, and firm. Cervical ripening usually begins prior to the onset of labor contractions and is necessary for cervical dilation and the passage of the fetus.

Various scoring systems to assess cervical ripeness have been introduced, but the Bishop score is most commonly used today. The Bishop score helps identify

women who would be most likely to achieve a successful induction (Table 21.2). The duration of labor is inversely correlated with the Bishop score: a score over 8 indicates a successful vaginal birth. Bishop scores of less than 6 usually indicate that a cervical ripening method should be used prior to induction (Goldberg, 2015). Medical induction of labor has two components: cervical ripening and induction of contractions. When induction of labor is indicated, cervical readiness for labor is evaluated by pelvic exam and determination of a Bishop score is documented.

COMPLEMENTARY AND ALTERNATIVE MEDICINE METHODS

Nonpharmacologic methods for cervical ripening are less frequently used today, but nurses need to be aware of them and question clients about their use. Methods may include herbal agents such as evening primrose oil, black haw, black and blue cohosh, and red raspberry leaves. In addition, castor oil, hot baths, and enemas are used for cervical ripening and labor induction. The risks and benefits of these agents are unknown. None have been evaluated scientifically, and thus, none can be recommended regarding their efficacy or safety.

Another nonpharmacologic method suggested for labor induction is sexual intercourse along with breast stimulation. This promotes the release of oxytocin, which stimulates uterine contractions. In addition, human semen is a biologic source of prostaglandins used for cervical ripening. According to a Cochrane review, sexual intercourse with breast stimulation would appear beneficial, but safety issues have not been fully evaluated, nor can this activity be standardized. It appears to shorten the latent phase of labor (King et al., 2015). Therefore, its use as a method for labor induction is not validated by research.

MECHANICAL METHODS

Mechanical methods are used to open the cervix and stimulate the progression of labor. All share a similar mechanism of action: application of local pressure stimulates the release of prostaglandins to ripen the cervix. Potential advantages of mechanical methods, compared with pharmacologic methods, may include simplicity or preservation of the cervical tissue or structure, lower cost, and fewer side effects. The risks associated with these methods include infection, bleeding, membrane rupture, and placental disruption (Sciscone, 2014). For example, an indwelling (Foley) catheter (e.g., 26 French) can be inserted into the endocervical canal to ripen and dilate the cervix. The catheter is placed in the

uterus, and the balloon is filled. Direct pressure is then applied to the lower segment of the uterus and the cervix. This direct pressure causes stress in the lower uterine segment and probably the local production of prostaglandins. The risks, benefits, and expected side effects should be explained to the woman prior to the insertion of the balloon catheter (Fuks et al., 2015).

Hygroscopic dilators absorb endocervical and local tissue fluids; as they enlarge, they expand the endocervix and provide controlled mechanical pressure. The products available include natural osmotic dilators (laminaria, a type of dried seaweed) and synthetic dilators containing magnesium sulfate (Lamicel, Dilapan). Hygroscopic dilators are advantageous because they can be inserted on an outpatient basis and no fetal monitoring is needed. As many dilators are inserted in the cervix as will fit, and they expand over 12 to 24 hours as they absorb water. Absorption of water leads to expansion of the dilators and opening of the cervix. They are a reliable alternative when prostaglandins are contraindicated or unavailable (Goldberg, 2015).

Recently there has been a reduction in the use of hygroscopic and osmotic dilators for the induction of labor in favor of pharmacologic agents. The increased risk of maternal and fetal infections with hygroscopic and osmotic dilators when compared with that associated with the use of other pharmacologic agents and the ease of pharmacologic administration may be reasons for the decline. Placement of dilators also requires additional training and may be associated with rupture of membranes, vaginal bleeding, and client discomfort or pain (Drunecky et al., 2015).

Recent systematic review of randomized trials that compared cervical ripening with mechanical methods versus alternative pharmacologic agents or placebo demonstrated that maternal infection was increased in clients who underwent cervical ripening with mechanical methods. Thus, mechanical methods for cervical ripening have fallen into disfavor and are used infrequently today when compared with pharmacologic or surgical methods for induction (McCarthy & Kenny, 2014).

SURGICAL METHODS

Surgical methods used to ripen the cervix and induce labor include stripping of the membranes and performing an amniotomy. Stripping of the membranes is accomplished by inserting a finger through the internal cervical os and moving it in a circular direction. This motion causes the membranes to detach. Manual separation of the amniotic membranes from the cervix is thought to induce

cervical ripening and the onset of labor (Afzal, Asif, & Miraj, 2015). However, there is no strong evidence at this time that membrane stripping significantly shortens the duration of pregnancy.

An amniotomy involves inserting a cervical hook (Amniohook) through the cervical os to deliberately rupture the membranes. This promotes pressure of the presenting part on the cervix and stimulates an increase in the activity of prostaglandins locally. Risks associated with these procedures include umbilical cord prolapse or compression, maternal or neonatal infection, FHR deceleration, bleeding, and client discomfort (King et al., 2015).

When either of these techniques is used, amniotic fluid characteristics (such as whether it is clear or bloody, or meconium is present) and the FHR pattern must be monitored closely.

PHARMACOLOGIC METHODS

The use of pharmacologic agents has revolutionized cervical ripening. The use of prostaglandins to attain cervical ripening has been found to be highly effective in producing cervical changes independent of uterine contractions (Grobman, 2015). In some cases, women will go into labor and require no additional stimulants for induction. Induction of labor with prostaglandins offers the advantage of promoting both cervical ripening and uterine contractility. A drawback of prostaglandins is their ability to induce excessive uterine contractions, which can increase maternal and perinatal morbidity (Callahan, 2016). Prostaglandin analogs commonly used for cervical ripening include dinoprostone gel (Prepidil), dinoprostone inserts (Cervidil), and misoprostol (Cytotec). Misoprostol (Cytotec), a synthetic PGE1 analog, is a gastric cytoprotective agent used in the treatment and prevention of peptic ulcers. It can be administered intravaginally or orally to ripen the cervix or induce labor. It is available in 100-mcg or 200-mcg tablets, but doses of 25 to 50 mcg are typically used. It is important to note that only dinoprostone is approved by the FDA for use as a cervical ripening agent, although ACOG acknowledges the apparent safety and effectiveness of misoprostol for this purpose (King et al., 2015). A major adverse effect of the obstetric use of Cytotec is hyperstimulation of the uterus, which may progress to uterine tetany with marked impairment of uteroplacental blood flow, uterine rupture (requiring surgical repair, hysterectomy, and/or salpingo-oophorectomy), or amniotic fluid embolism (Ahmed et al., 2015; Drug Guide 21.2). Furthermore, it is contraindicated for women with prior uterine scars and therefore should not be used for cervical

ripening in women attempting a vaginal birth after cesarean.

DRUG GUIDE 21.2 DRUGS USED FOR CERVICAL RIPENING AND LABOR INDUCTION

Drug	Action/Indication	Nursing Implications
Dinoprostone (Cervidil insert; Prepidil gel)	Directly softens and dilates the cervix/to ripen cervix and induce labor FDA approved for cervical ripening	Provide emotional support. Administer pain medications as needed. Frequently assess degree of effacement and dilation. Monitor uterine contractions for frequency, duration, and strength. Assess maternal vital signs and FHR pattern frequently. Monitor woman for possible adverse effects such as headache, nausea and vomiting, and diarrhea.
Misoprostol (Cytotec)	Ripens cervix/to induce labor	Instruct client about purpose and possible adverse effects of medication. Ensure informed consent is signed per hospital policy. Assess vital signs and FHR patterns frequently. Monitor client's reaction to drug. Initiate oxytocin for labor induction at least 4 hours after last dose was administered. Monitor for possible adverse effects such as nausea and vomiting, diarrhea, uterine hyperstimulation, and category II FHR patterns.
Oxytocin (Pitocin)	Acts on uterine myofibrils to contract/to initiate or reinforce labor	Administer as an IV infusion via pump, increasing dose based on protocol until adequate labor progress is achieved. Assess baseline vital signs and FHR and then frequently after initiating oxytocin infusion. Determine frequency, duration, and strength of contractions frequently. Notify health care provider of any uterine hypertonicity or abnormal FHR patterns. Maintain careful I&O, being alert for water intoxication. Keep client informed of labor progress. Monitor for possible adverse effects such as hyperstimulation of the uterus, impaired uterine blood flow leading to fetal hypoxia, rapid labor leading to cervical lacerations or uterine rupture, water intoxication (if oxytocin is given in electrolyte-free solution or at a rate exceeding 20 mU/min), and hypotension.

Methods of cervical ripening and labor induction: Pharmacologic. *Clinical Obstetrics and Gynecology, 57*(2), 377–390.

Oxytocin

Oxytocin is a potent endogenous uterotonic agent used for both artificial induction and augmentation of labor. It is produced naturally by the posterior

pituitary gland and stimulates contractions of the uterus. For women with low Bishop scores, cervical ripening is typically initiated before oxytocin is used. Once the cervix is ripe, oxytocin is the most popular pharmacologic agent used for inducing or augmenting labor.

Frequently, a woman with an unfavorable cervix is admitted the evening before induction to ripen her cervix with one of the prostaglandin agents. Then induction begins with oxytocin the next morning if she has not already gone into labor. Doing so markedly enhances the success of induction.

Response to oxytocin varies widely: some women are very sensitive to even small amounts. The most common adverse effect of oxytocin is uterine hyperstimulation, leading to fetal compromise and impaired oxygenation (King, et al., 2015). The response of the uterus to the drug is closely monitored throughout labor so that the oxytocin infusion can be titrated appropriately. In addition, oxytocin has an antidiuretic effect, resulting in decreased urine flow that may lead to water intoxication. Symptoms to watch for include headache and vomiting.

Oxytocin is administered via an intravenous infusion pump piggybacked into the main intravenous line at the port most proximal to the insertion site. Typically, 10 units of oxytocin are added to 1 L of isotonic solution. The dose is titrated according to protocol to achieve stable contractions every 2 to 3 minutes lasting 40 to 60 seconds. Recent studies suggest that a more conservative oxytocin protocol with lower doses reduces the number of neonatal intensive care unit admissions and lower cesarean sections (Lewis et al., 2014; Manjula et al., 2015).

The uterus should relax between contractions. If the resting uterine tone remains above 20 mm Hg, uteroplacental insufficiency and fetal hypoxia can result. This underscores the importance of continuous FHR monitoring. Unfortunately, neither the optimal oxytocin administration regimen nor the maximum oxytocin dose has been established or agreed upon through research or expert opinion. Nurses assisting with labor inductions need to become familiar with their hospital protocols concerning dosage, infusion rates, and frequency of change.

Oxytocin has many advantages: it is potent and easy to titrate, it has a short half-life (1 to 5 minutes), and it is generally well tolerated. Induction using oxytocin has side effects (water intoxication, hypotension, and uterine hypertonicity), but because the drug does not cross the placental barrier, no direct fetal problems have been observed (Arrowsmith & Wray, 2014) (Fig.

FIGURE 21.4 The nurse monitors an intravenous infusion of oxytocin being administered to a woman in labor who is being induced.

Remember Jennifer, the young woman described at the beginning of the chapter? After her cervix is ripened, an oxytocin infusion is started and her progress is slow. What encouragement can the nurse offer? After a few hours, her contractions begin to increase in intensity and frequency. What typical pain management measures can the nurse implement, and how would the nurse evaluate the effectiveness of these measures?

Nursing Assessment

Nursing assessment of the woman who is undergoing labor induction or augmentation involves a thorough history and physical examination. Review the woman's history for relative indications for induction or augmentation, such as diabetes, hypertension, post-term status, dysfunctional labor pattern, prolonged ruptured membranes, and maternal or fetal infection, and for contraindications such as placenta previa, over distended uterus, active genital herpes, fetopelvic disproportion, fetal malposition, or severe fetal distress.

Assist with determining the gestational age of the fetus to prevent a preterm birth. Assess fetal well-being to validate the client's and fetus's ability to withstand labor contractions. Evaluate the woman's cervical status, including cervical dilation and effacement, and station via vaginal examination as appropriate before cervical ripening or induction is started. Determine the Bishop score to determine the probable success of induction.

 Take Note!

Nurses working with women in labor play an important role acting as the eyes and ears for the birth attendant because they remain at the client's bedside throughout the entire experience. Close, frequent assessment and follow-up interventions are essential to ensure the safety of the mother and her unborn child during cervical ripening and labor induction or augmentation.

Nursing Management

Explain to the woman and her partner about the induction or augmentation procedure clearly, using simple terms (Teaching Guidelines 21.2). Ensure that an informed consent has been signed after the client and her partner have received complete information about the procedure, including its advantages, disadvantages, and potential risks. Ensure that the Bishop score has been determined before proceeding. Nursing Care Plan 21.1 presents an overview of the nursing care for a woman undergoing labor induction.

Teaching Guidelines 21.2

TEACHING IN PREPARATION FOR LABOR INDUCTION

- Your health care provider may recommend that you have your labor induced. This may be necessary for a variety of reasons, such as elevated blood pressure, a medical condition, prolonged pregnancy over 41 weeks, or problems with fetal heart rate patterns or fetal growth.

- Your health care provider may use one or more methods to induce labor, such as stripping the membranes, breaking the amniotic sac to release the fluid, administering medication close to or in the cervix to soften it, or administering a medication called oxytocin (Pitocin) to stimulate contractions.

- Labor induction is associated with some risks and disadvantages, such as overactivity of the uterus; nausea, vomiting, or diarrhea; and changes in fetal heart rate.

- Prior to inducing your labor, your health care provider may perform a procedure to ripen your cervix to help ensure a successful induction.

- Medication may be placed around your cervix the day before you are scheduled to be induced.

- During the induction, your contractions may feel stronger than normal. However, the length of your labor may be reduced with induction.

- Medications for pain relief and comfort measures will be readily available.
- Health care staff will be present throughout labor.

Administering Oxytocin

If not already done, prepare the oxytocin infusion by diluting 10 units of oxytocin in 1,000 mL of lactated Ringer's solution or ordered isotonic solution. Use an infusion pump on a secondary line connected to the primary infusion. Start the oxytocin infusion in mU/min or milliliters per hour as ordered. Each hospital has its own standards/protocols for oxytocin infusion and dilution. The nurse needs to follow that procedure when administering this medication. Maintain the rate once the desired contraction frequency has been reached. To ensure adequate maternal and fetal surveillance during induction or augmentation, the nurse-to-client ratio should not exceed 1:2 (Mattson & Smith, 2016).

During induction or augmentation, monitoring of the maternal and fetal status is essential. Apply an external electronic fetal monitor or assist with placement of an internal device. Obtain the mother's vital signs and the FHR every 15 minutes during the first stage. Evaluate the contractions (frequency, duration, and intensity) and resting tone, and adjust the oxytocin infusion rate accordingly. Monitor the FHR, including baseline rate, baseline variability, and decelerations, to determine whether the oxytocin rate needs adjustment. Discontinue the oxytocin and notify the birth attendant if uterine hyperstimulation or a category II or III FHR pattern occurs. Perform or assist with periodic vaginal examinations to determine cervical dilation and fetal descent: cervical dilation of 1 cm per hour typically indicates satisfactory progress. Continue to monitor the FHR continuously and document it every 15 minutes during the active phase of labor and every 5 minutes during the second stage. Assist with pushing efforts during the second stage. Measure and record the intake and output to prevent excess fluid volume. Encourage the client to empty her bladder every 2 hours to prevent soft tissue obstruction.

Providing Pain Relief and Support

Assess the woman's level of pain. Ask her frequently to rate her pain and provide pain management as needed. Offer position changes and other nonpharmacologic measures. Note her reaction to any medication given, and

document its effect. Monitor her need for comfort measures as contractions increase.

Throughout induction and augmentation, frequently reassure the woman and her partner about the fetal status and labor progress. Provide them with frequent updates on the condition of the woman and the fetus. Assess the woman's ability to cope with stronger contractions, and follow protocols of the hospital about how frequent pain assessments are performed for each phase and stage of labor (Nagtalon-Ramos, 2014). Provide support and encouragement as indicated.

After a very long day, Jennifer gives birth to a healthy baby boy with Apgar scores of 9 at 1 minute and 10 at 5 minutes. When transferring her to the postpartum unit, what information is essential to include for the accepting nurse? What specific nursing information should be given to the nursery nurse regarding the laboring experience? With such a lengthy labor, what assessments might the postpartum nurse need to focus on for the first few hours after birth?

NURSING CARE PLAN 21.1

Overview of the Women Undergoing Labor Induction

Rose, a 29-year-old primipara, is admitted to the labor and birth suite at 40 weeks of gestation for induction of labor. Assessment reveals that her cervix is ripe and 80% effaced, and dilated to 2 cm. Rose says, "I'm a bit nervous about being induced. I've never been through labor before and I'm afraid that I'll have a lot of pain from the medicine used to start the contractions." She consents to being induced but wants reassurance that this procedure won't harm the baby. Upon examination, the fetus is engaged and in a cephalic presentation, with the vertex as the presenting part. Her partner is at her side. Induction is initiated with oxytocin. Rose reports that contractions have started and are beginning to get stronger.

NURSING DIAGNOSIS: Anxiety related to induction of labor and associated medical interventions needed as evidenced by statements about being nervous, not having gone through labor before, fear of pain, and potential harm to fetus.

Outcome Identification and Evaluation
The client will experience decrease in anxiety as evidenced by ability to verbalize understanding of procedures involved and use of positive coping skills to reduce anxious state.

Interventions: *Minimizing Anxiety*
• Provide a clear explanation of the labor induction process *to provide client and partner with a knowledge base.*
• Maintain continuous physical presence *to provide physical and emotional support and demonstrate concern for maternal and fetal well-being.*
• Explain each procedure before carrying it out and answer questions *to promote understanding of procedure and rationale for use and decrease fear of the unknown.*
• Review with client measures used in the past to deal with stressful situations *to determine effectiveness;* encourage use of past effective coping strategies *to aid in controlling anxiety.*

- Instruct client's partner in helpful measures to assist client in coping and encourage their use *to foster joint participation in the process and feelings of being in control and to provide support to the client.*
- Offer frequent reassurance of fetal status and labor progress *to help alleviate client's concerns and foster continued participation in the labor process.*

NURSING DIAGNOSIS: Risk for injury (maternal or fetal) related to induction procedure risk factors: hypertonic uterine contractions, potential preterm birth as evidenced by client's concerns about fetal well-being and possible adverse effects of oxytocin administration.

Outcome Identification and Evaluation
The client will remain free of complications associated with induction as evidenced by progression of labor as expected, delivery of healthy newborn, and absence of signs and symptoms of maternal and fetal adverse effects.

Interventions: *Promoting Maternal and Fetal Safety*
- Follow agency's protocol for medication use and infusion rate *to ensure accurate, safe drug administration.*
- Set up oxytocin IV infusion to piggyback into the primary IV infusion line *to allow for prompt discontinuation should adverse effects occur.*
- Use an infusion pump *to deliver accurate dose as ordered.*
- Gradually increase oxytocin dose in increments based on assessment findings and protocol *to promote effective uterine contractions.*
- Maintain oxytocin rate once desired frequency of contractions has been reached *to ensure continued progress in labor.*
- Accurately monitor contractions for frequency, duration, and intensity and resting tone *to prevent development of hypertonic contractions.*
- Maintain a nurse-to-client ratio of 1:2 *to ensure maternal and fetal safety.*
- Monitor FHR via electronic fetal monitoring during induction and continuously observe the FHR response to titrated medication rate *to ensure fetal well-being and identify adverse effects immediately.*
- Obtain maternal vital signs every 1 to 2 hours or as indicated by agency's protocol, reporting any deviations, *to promote maternal well-being and allow for prompt detection of problems.*
- Communicate with birth attendant frequently concerning progress *to ensure continuity of care.*

- Discontinue oxytocin infusion if tetanic contractions (>90 seconds), uterine hyperstimulation (<2 minutes apart), elevated uterine resting tone, or a distressed FHR pattern occurs *to minimize risk of drug's adverse effects.*
- Provide client with frequent reassurance of maternal and fetal status *to minimize anxiety.*

NURSING DIAGNOSIS: Pain related to uterine contractions as evidenced by client's statements about contractions increasing in intensity and expected effect of oxytocin administration

Outcome Identification and Evaluation
The client will report a decrease in pain as evidenced by statements of increased comfort and pain rating of 3 or less on numeric pain rating scale.

Interventions: *Promoting Maternal and Fetal Safety*
- Explain to the client that she will experience discomfort sooner than with naturally occurring labor *to promote client's awareness of events and prepare client for the experience.*
- Frequently assess client's pain using a pain rating scale *to quantify client's level of pain and evaluate effectiveness of pain relief measures.*
- Provide comfort measures, such as hygiene, backrubs, music, and distraction, and encourage the use of breathing and relaxation techniques *to help promote relaxation.*
- Provide support for her partner *to aid in alleviating stress and concerns.*
- Employ nonpharmacologic methods, such as position changes, birthing ball, hydrotherapy, visual imagery, and effleurage, *to help in managing pain and foster feelings of control over situation.*
- Administer pharmacologic agents such as analgesia or anesthesia as appropriate and as ordered *to control pain.*
- Continuously reassess client's pain level *to evaluate effectiveness of pain management techniques used.*

VAGINAL BIRTH AFTER CESAREAN

Vaginal birth after cesarean (VBAC) describes a woman who gives birth vaginally after having at least one previous cesarean birth. Despite evidence that some women who have had a cesarean birth are candidates for vaginal birth, most women who have had a cesarean birth once undergo another for subsequent pregnancies.

A multidisciplinary guideline group representing family medicine, epidemiology, obstetrics, and midwifery developed recommendations based on high-quality systematic evidence-based, peer-reviewed research, that individual assessment of risks and benefits be discussed with the pregnant woman with a history of one or more prior cesarean births who are deciding between a planned VBAC or a repeat cesarean birth. A planned VBAC is an appropriate option for most women with a history of prior cesarean birth (King et al., 2015).

Contraindications to VBAC include a prior classic uterine incision, prior transfundal uterine surgery (myomectomy), uterine scar other than low-transverse cesarean scar, contracted pelvis, and inadequate staff or facility if an emergency cesarean birth in the event of uterine rupture is required (Caughey, 2014b). Most women go through a trial of labor to see how they progress, but this must be performed in an environment capable of handling the emergency of uterine rupture. The use of cervical ripening agents increases the risk of uterine rupture and thus is contraindicated in VBAC clients. The woman considering induction of labor after a previous cesarean birth needs to be informed of the risks versus benefits with an induction than with spontaneous labor (Scott, 2015).

Women are the primary decision makers about the choice of birth method, but they need education about VBAC during their prenatal course. Management is similar for any women experiencing labor, but certain areas require special focus:

- *Consent:* Fully informed consent is essential for the woman who wants to have a trial of labor after cesarean birth. The client must be advised about the risks as well as the benefits. She must understand the ramifications of uterine rupture, even though the risk is small.

- *Documentation:* Record keeping is an important component of safe client care. If and when an emergency occurs, it is imperative to take care of the client, but

also to keep track of the plan of care, interventions and their timing, and the client's response. Events and activities can be written right on the fetal monitoring tracing to correlate with the change in fetal status.

• *Surveillance:* A distressed fetal monitor tracing in a woman undergoing a trial of labor after a cesarean birth should alert the nurse to the possibility of uterine rupture. Terminal bradycardia must be considered an emergency situation, and the nurse should prepare the team for an emergency delivery.

• *Readiness for emergency:* According to ACOG (2010), criteria for a safe trial of labor for a woman who has had a previous cesarean birth, the physician, anesthesia provider, and operating room team must be immediately available. Anything less would place the women and fetus at risk.

Women and their health care providers are advised to consider VBAC in the context of potential risk, available resources, and the health care system. The ACOG (2010) guidelines state that VBACs are safe and appropriate for most women, but emphasize the need for thorough counseling, shared decision making, and client autonomy. Nurses must act as advocates, giving input on the appropriate selection of women who wish to undergo VBAC. Nurses also need to become experts at reading fetal monitoring tracings to identify fetal distress and set in motion an emergency birth. Including all of these nursing strategies will make VBAC safer for all.

INTRAUTERINE FETAL DEMISE

Pregnancy and childbirth are associated with hopes, expectations, joy, and happiness for the future. When an unborn life suddenly ends with fetal loss, the family members are profoundly affected. Intrauterine fetal demise (IUFD) is fetal death that occurs after 20 weeks of gestation but before birth. The cause of IUFD is often unknown. The sudden loss of an expected child is tragic and the family's grief can be very intense: it can last for years and can cause extreme psychological stress and emotional problems (Sousou & Smart, 2015). The family's anticipation of a joyous birth is supplanted by despair, confusion, and loss. To women and their families who have gone through this harrowing experience, culturally appropriate and sensitive care is crucial. Particularly for the mother, fetal death in the last trimester of pregnancy, when she feels very close to the fetus due to its frequent movement in the uterus, must be similar to losing a part of her body.

Fetal demise can be due to an extensive range of risk factors and possible causes, such as post-term pregnancy, renal disease, substance abuse, infection, hypertension, advanced maternal age, multiple gestation, Rh disease, uterine rupture, diabetes, congenital anomalies, obesity, smoking, cord accident, abruption, blunt trauma, premature rupture of membranes, or hemorrhage—or it may go unexplained (Hugin & Sultani, 2015). Trauma in pregnancy remains one of the major contributors to maternal and fetal morbidity and mortality. Potential complications include maternal injury or death, shock, internal hemorrhage, intrauterine fetal demise, direct fetal injury, abruptio placentae, and uterine rupture. The leading causes of obstetric trauma are motor vehicle accidents, falls, assaults, and gunshots, and ensuing injuries are classified as blunt abdominal trauma, pelvic fractures, or penetrating trauma. In view of the significant impact of trauma on the pregnant woman and her fetus, preventive strategies are paramount (Kilpatrick, 2014).

Early pregnancy loss may be through a spontaneous abortion (miscarriage), an induced abortion (therapeutic abortion), or a ruptured ectopic pregnancy. A wide spectrum of feelings may be expressed, from relief to sadness and despair. A fetal death can occur at any gestational age, and typically there is little or no warning other than reduced fetal movement. The effects of childbearing loss may affect women and their families for a lifetime. The need to reflect, share,

and regain strength is universal for all families dealing with loss. Grief, the typical response to the loss of a valued object, is not an intellectual response. Rather, it is personally experienced as a deep emotion of sadness and sorrow. Feelings such as helplessness, disbelief, unreality, and powerlessness are common. Emotional recovery from the pain of perinatal loss occurs with time, but it varies with each couple.

The moment that fetal death is diagnosed can frequently be described very clearly and in detail by most women. In many cases, the death was sudden, and women have no chance to prepare for the impending grief. Once IUFD is confirmed, most women choose to immediately undergo induction of labor. Approximately 90% of women will go into spontaneous labor within two weeks of fetal death (Green, 2016). With the death of a fetus or neonate, a couple's dreams and hopes for their expected child suddenly dissolve. To women who have experienced a sudden fetal death, the following processes may take place: experiencing a quiet birth without the infant, eclipsed by emptiness, anger, anxiety, loneliness, and sorrow; living without their infant, making it very difficult to see others with young infants; and experiencing differences with their partner over the loss (Callister, 2014). The process of grieving a death is not completed within a specific time frame, and for some, it is never complete. In general, the grief accompanying the loss of a fetus proceeds in the following order:

1. Accepting the reality of the loss

2. Getting over suffering from the loss

3. Adapting to the new environment without the deceased

4. Emotionally relocating the deceased and getting on with life (Grunebaum & Chervenak, 2014)

The period following a fetal death is extremely difficult for the family. For many women, emotional healing takes much longer than physical healing. The feelings of loss can be intense. The grief response in some women may be so great that their relationships become strained, and healing can become hampered unless appropriate interventions and support are provided.

Fetal death also affects the health care staff. Despite the trauma that the loss of a fetus causes, some staff members avoid dealing with the bereaved family, never talking about or acknowledging their grief. This seems to imply that not discussing the problem will allow the grief to dissolve and vanish. As a result, the family's needs go unrecognized. Failing to keep the lines of communication

open with a bereaved client and her family closes off some of the channels to recovery and healing that may be desperately needed. Subsequently, the bereaved family members may feel isolated.

Nursing Assessment

A woman experiencing an IUFD is likely to seek care when she notices that the fetus is not moving or when she experiences contractions, loss of fluid, or vaginal bleeding. History and physical examination frequently are of limited value in the diagnosis of fetal death, since many times the only history tends to be recent absence of fetal movement and no fetal heart beat heard. An inability to obtain fetal heart sounds on examination suggests fetal demise, but an ultrasound is necessary to confirm the absence of fetal cardiac activity. Once fetal demise is confirmed, induction of labor or expectant management is offered to the woman.

Nursing Management

IUFD is associated with posttraumatic stress disorder (PTSD) and anxiety in a subsequent pregnancy (Robinson, 2014). The nurse can play a major role in assisting the grieving family. Nurses who can deal honestly with their own feelings regarding loss will be better able to help others cope with theirs. By working with couples who have suffered a significant loss, the nurse can grow personally and professionally and gain a deeper perspective about life. With skillful intervention, the bereaved family may be better prepared to resolve their grief and move forward.

To assist families in the grieving process, include the following measures:

• Provide accurate, understandable information to the family.

• Acknowledge that the woman's feeling of loss is legitimate.

• Reassure mother that there was likely nothing that she could have done to prevent it.

• Be knowledgeable about the grief process and comfortable in sharing another's grief.

• Utilize active listening to provide needed encouragement to the family members to open up to their feelings.

• Create a warm, receptive, accepting, and caring environment conducive to dialogue.

• Dispel guilt by saying that nothing the woman did caused the fetal death.

• Acknowledge their grief by saying that their feeling sad is appropriate.

• Recognize that each family member may express their grief differently.

• Provide reassurance about successful future pregnancies.

• Encourage discussion of the loss and venting of feelings of grief and guilt.

• Provide the family with baby mementos and pictures to validate the reality of death.

• Allow unlimited time with the stillborn infant after birth to validate the death; provide time for the family members to be together and grieve; offer the family the opportunity to see, touch, and hold the infant.

• Use appropriate touch, such as holding a hand or touching a shoulder.

- Inform the chaplain or the religious leader of the family's denomination about the death and request his or her presence.
- Assist the parents with the funeral arrangements or disposition of the body.
- Provide the parents with brochures offering advice about how to talk to other siblings about the loss.
- Refer the family to the support group SHARE Pregnancy and Infant Loss Support, Inc., which is designed for those who have lost an infant through abortion, miscarriage, fetal death, stillbirth, or other tragic circumstances.
- Make community referrals to promote a continuum of care after discharge.

Openness to talking with couples about their loss and grief is the basis for support provided by nurses, which can have a positive influence on the long-term adjustment of couples and families coping with perinatal loss. A sensitive nurse who is comfortable talking about loss and is able to assist couples in navigating the process of grief provides a starting point for preparation for future pregnancy. Couples need to talk about their loss, its meaning, and the emotions that accompany it while the nurse listens. Nurses play a significant role in linking women and men to appropriate professional support. As couples move through their grief and begin to consider another pregnancy, sensitive nursing care may mediate the understandable anxiety and concern that accompany this process. Nurses are a vital part of the interdisciplinary health care team caring for families with IUFD, who continue to require timely and sensitive care throughout the grieving process.

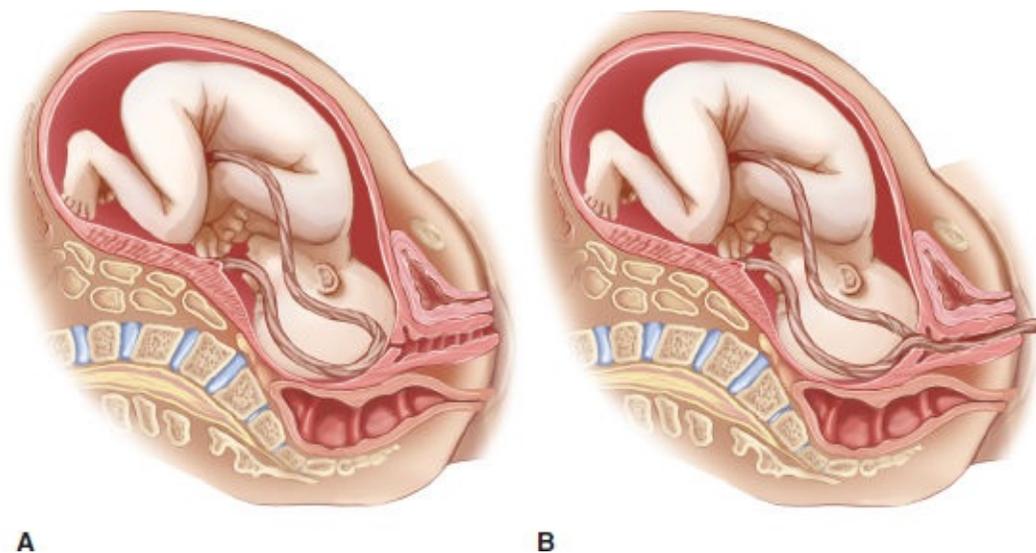

FIGURE 21.5 Prolapsed cord. **A.** Prolapse within the uterus. **B.** Prolapse with the cord visible at the vulva.

WOMEN EXPERIENCING AN OBSTETRIC EMERGENCY

Obstetric emergencies are challenging to all labor and birth personnel because of the increased risk of adverse outcomes for the mother and fetus. Quick clinical judgment and good critical decision making will increase the odds of a positive outcome for both mother and fetus. This section discusses a few of these emergencies: umbilical cord prolapse, placenta previa, placental abruption, uterine rupture, and amniotic fluid embolism.

Umbilical Cord Prolapse

Umbilical cord prolapse is a rare obstetrical emergency that occurs when the cord precedes the fetus out. An **umbilical cord prolapse** is the protrusion of the umbilical cord alongside (occult) or ahead of the presenting part of the fetus (Fig. 21.5). This condition occurs in 1 out of every 300 births and requires prompt recognition and intervention for a positive outcome (March of Dimes, 2015c). Cord prolapse occurs in 3% of deliveries when the fetus is in the vertex position and in 3.7% of deliveries when the fetus is in the breech position. The risk is increased further when the presenting part does not fill the lower uterine segment, as is the case with incomplete breech presentations (5% to 10%), premature infants, and multiparous women (Bush, Eddleman, & Belogolovkin, 2015). With a 50% perinatal mortality rate, it is one of the most catastrophic events in the intrapartum period (Beall & Ross, 2014).

Pathophysiology

Prolapse usually leads to total or partial occlusion of the cord. Since this is the fetus's only lifeline, fetal perfusion deteriorates rapidly. Complete occlusion renders the fetus helpless and oxygen deprived. The fetus will die if the cord compression is not relieved.

Nursing Assessment

Prevention is the key to managing cord prolapse by identifying clients at risk for this condition. Carefully assess each client to help predict her risk status. Be aware that cord prolapse is more common in pregnancies involving malpresentation, growth restriction, prematurity, ruptured membranes with a fetus at a high station, hydramnios, grandmultiparity, and multiple gestation (Cunningham et al., 2014). Continuously assess the client and fetus to detect changes and to evaluate the effectiveness of any interventions performed.

Take Note!

When the presenting part does not fully occupy the pelvic inlet, prolapse is more likely to occur.

Nursing Management

Prompt recognition of a prolapsed cord is essential to reduce the risk of fetal hypoxia resulting from prolonged cord compression. Often the first sign of cord prolapse is a sudden fetal bradycardia or recurrent variable decelerations that become progressively more severe. Call for help immediately and do not leave the woman. Inform the woman of what is happening and what options may be discussed by her health care provider. When membranes are artificially ruptured, assist with verifying that the presenting part is well applied to the cervix and engaged into the pelvis. If pressure or compression of the cord occurs, assist with measures to relieve the compression. Typically, the examiner places a sterile gloved hand into the vagina and holds the presenting part off the umbilical cord until delivery. Changing the woman's position to a modified Sims, Trendelenburg, or knee–chest position also helps relieve cord pressure. Do not attempt to replace the cord in the uterus. Monitor fetal heart rate, maintain bed rest, and administer oxygen if ordered. Provide emotional support and explanations as to what is going on to allay the woman's fears and anxiety. If the mother's cervix is not fully dilated, prepare the woman for an emergency cesarean birth to save the fetus's life if that is the intervention planned for by her health care provider.

Placenta Previa

Placenta previa is placental implantation in the lower uterine segment over or near the internal os of the cervix, typically during the second or third trimester of pregnancy. With uterine segment formation and cervical dilation, placental implantation over or near the cervical os, instead of along the uterine wall, inevitably results in spontaneous placental separation—and subsequent hemorrhage. This position can create a barrier for the fetus from the uterus during the birthing process. As the cervix begins to thin and dilate (open up) in preparation for labor, blood vessels that connect the placenta to the uterus may tear and cause bleeding. It is the most common cause of bleeding in the second half of pregnancy and should be suspected in any woman beyond 24 weeks of gestation presenting with vaginal bleeding; ultrasonography (e.g., transvaginal) is used to diagnose it. During labor and birth, bleeding can be severe, which can place the mother and fetus at risk. Reported incidence is approximately 1 in 200 births (March of Dimes, 2015d).

There is a direct relationship between the number of previous cesarean births and the risk of placenta previa, probably due to uterine scarring. The degree of occlusion of the internal cervical os may depend on the degree of cervical dilation, so what may appear to be a low-lying or marginal placenta previa prior to the onset of labor can progress to become more serious as the cervix effaces and opens up (King et al., 2015).

The incidence of maternal mortality is less than 1%, but common morbidities include septicemia, renal failure, hemorrhage and hypovolemic shock, invasive placenta (accrete, increta, and percreta), and postpartum anemia. Risk factors for placenta previa include previous cesarean section, advanced maternal age > 34, multiparity, multiple gestation, prior placenta previa, and cigarette smoking. The risk for perinatal mortality is less than 10%, but common neonatal morbidities include stillbirth, prematurity, malpresentation, fetal growth restriction, and fetal anemia (Joy & Finneran, 2015).

Maternal signs and symptoms of placenta previa include sudden, painless bleeding (that may be heavy enough to be considered hemorrhaging), anemia, pallor, hypoxia, low blood pressure, tachycardia, soft and nontender uterus, and rapid, weak pulse. Bleeding may be episodic, with spontaneous initiation and cessation; in some cases, it is asymptomatic because there is intrauterine bleeding only without external signs.

Management of placenta previa varies by type and gestational age, and frequent medical surveillance may be sufficient in marginal cases; prompt treatment with bed rest, close monitoring, and control/replacement of blood loss greatly reduces risk for maternal and fetal complications and death. Vaginal delivery is possible when bleeding is minimal, placenta previa is marginal, or labor is rapid. Pregnancy termination, early birth by cesarean section, or a hysterectomy may be necessary in order to control severe bleeding, especially for clients with complete placenta previa. The overall maternal prognosis is good if hemorrhage is controlled and sepsis or other complications are prevented. Fetal prognosis is directly related to the amount of blood loss. The United States perinatal mortality rate associated with placental previa is 2% to 3%, and the maternal mortality rate is 0.03%. Risk for placenta previa recurrence in subsequent pregnancies is 4% to 8% (Lal & Hibbard, 2015).

Nursing management within the acute care setting includes the following: monitor maternal vital signs, intake and output, vaginal bleeding, and physiologic status for signs of hemorrhage, shock, or infection; closely monitor fetal heart tones for distress (e.g., bradycardia, tachycardia, baseline changes); and treat fetal distress, as ordered. Administer prescribed intravenous fluids, packed red blood cells platelets, and frozen plasma for transfusion, if ordered; Rho(D) immune globulin, if the client is Rh negative; intravenous-augmented oxytocin (Pitocin) to induce labor, if needed; and in cases of preterm labor, tocolytics (e.g., magnesium sulfate) to inhibit uterine contractions and corticosteroids (e.g., betamethasone) to enhance fetal lung maturity. Follow facility pre- and postsurgical protocols if woman becomes a surgical candidate (e.g., for cesarean section); reinforce pre- and postsurgical education and ensure completion of facility's informed consent documents; closely monitor postsurgically for bleeding, infection, and other complications; assess client's anxiety level and coping ability; and provide emotional support and reassurance.

Frequently there is expectant management for the woman after her first placenta previa bleed if it isn't severe and fetus well-being is validated. After she is assessed, she is released to go home. It is common for women to experience an initial bleeding episode, which then subsides. These women are monitored at home and instructed to report any additional bleeding episodes and come in to be evaluated (King et al., 2015).

Placental Abruption

Placental abruption refers to premature separation of a normally implanted placenta from the maternal myometrium. Placental abruption occurs in about 1% of all pregnancies throughout the world and is associated with significant perinatal mortality and morbidity (March of Dimes, 2015e). Risk factors include preeclampsia, gestational hypertension, seizure activity, advanced maternal age >34, uterine rupture, trauma, smoking, cocaine use, coagulation defects, chorioamnionitis, premature rupture of membranes, hydramnios, uterine trauma, external cephalic version for breech presentation, previous history of abruption, domestic violence, and placental pathology. These conditions may force blood into the underlayer of the placenta and cause it to detach (Deering, 2015).

Management of placental abruption depends on the gestational age, the extent of the hemorrhage, and maternal–fetal oxygenation perfusion/reserve status (see Chapter 19 for additional information on abruptio placentae). Treatment is based on the circumstances. Typically once the diagnosis is established, the focus is on maintaining the cardiovascular status of the mother and developing a plan to deliver the fetus quickly. A cesarean birth may take place quickly if the fetus is still alive with only a partial abruption. A vaginal birth may take place if there is fetal demise secondary to a complete abruption.

Uterine Rupture

Uterine rupture in pregnancy is a rare and often catastrophic complication with a high incidence of fetal and maternal morbidity. Uterine rupture is a catastrophic tearing of the uterus at the site of a previous scar into the abdominal cavity. Its onset is often marked only by sudden fetal bradycardia, and treatment requires rapid surgery for good outcomes. From the time of diagnosis to delivery, only 10 to 30 minutes are available before clinically significant fetal morbidity occurs. Fetal morbidity occurs secondary to catastrophic hemorrhage, fetal anoxia, or both.

Nursing Assessment

Review the mother's history for risk conditions such as uterine scars, prior cesarean births, prior rupture, trauma, prior invasive molar pregnancy, history of placenta percreta or increta, congenital uterine anomalies, multiparity, previous uterine myomectomy, malpresentation, labor induction with excessive uterine stimulation, and crack cocaine use (Nahum & Pham, 2015). Reviewing a client's history for risk factors might prove to be lifesaving for both mother and fetus.

Generally, the first and most reliable symptom of uterine rupture is sudden fetal distress. Other signs may include acute and continuous abdominal pain with or without an epidural, vaginal bleeding, hematuria, irregular abdominal wall contour, loss of station in the fetal presenting part, and hypovolemic shock in the woman, fetus, or both (Scott, 2015).

Timely management of uterine rupture depends on prompt detection. Because many women desire a trial of labor after a previous cesarean birth, the nurse must be familiar with the signs and symptoms of uterine rupture. It is difficult to prevent uterine rupture or to predict which women will experience rupture, so constant preparedness is necessary. Screening all women with previous uterine surgical scars is important, and continuous electronic fetal monitoring should be used during labor because this may provide the only indication of an impending rupture.

Nursing Management

Because the presenting signs may be nonspecific, the initial management will be the same as that for any other cause of acute fetal distress. Urgent delivery by

cesarean birth is usually indicated. Monitor maternal vital signs and observe for hypotension and tachycardia, which might indicate hypovolemic shock. Assist in preparing for an emergency cesarean birth by alerting the operating room staff, anesthesia provider, and neonatal team. Insert an indwelling urinary (Foley) catheter if one is not in place already. Inform the woman of the seriousness of this event and remind her that the health care staff will be working quickly to ensure her health and that of her fetus. Remain calm and provide reassurance that everything is being done to ensure a safe outcome for both.

The life-threatening nature of uterine rupture is underscored by the fact that the maternal circulatory system delivers approximately 500 mL of blood to the term uterus every minute (Cunningham et al., 2014). Maternal death is a real possibility without rapid intervention. Newborn outcome after rupture depends largely on the speed with which surgical rescue is carried out. As in any case of acute obstetric emergency, preparation and timely mobilization of all necessary personnel is essential to optimizing outcome.

Take Note!

When excessive bleeding occurs during the childbirth process and it persists or signs such as bruising or petechiae appear, disseminated intravascular coagulation (DIC) should be suspected.

Amniotic Fluid Embolism

Amniotic fluid embolism (AFE) is an unforeseeable, life-threatening complication of childbirth. Amniotic fluid embolism remains an enigmatic, but devastating obstetric condition associated with significant maternal and newborn morbidity and mortality. It is a rare and often fatal event characterized by the sudden onset of hypotension, hypoxia, and coagulopathy. Amniotic fluid containing particles of debris (e.g., hair, skin, vernix, or meconium) enters the maternal circulation and obstructs the pulmonary vessels, causing respiratory distress and circulatory collapse (Sadera & Vasudevan, 2015). Prediction and diagnosis of the event are nearly impossible. However, timely recognition and response is critical in saving a woman's life. Although estimates vary, amniotic fluid embolism, also referred to as anaphylactoid syndrome of pregnancy, occurs in from 1 in 15,000 births, with a reported mortality rate reaching 60% despite technological advances in critical care life support (Moore, 2015).

Pathophysiology

The pathophysiology appears to involve an abnormal maternal response to fetal tissue exposure associated with breaches of the maternal-fetal physiologic barrier during the postpartum period. Normally, amniotic fluid does not enter the maternal circulation because it is contained within the uterus, sealed off by the amniotic sac. An embolus occurs when the barrier between the maternal circulation and the amniotic fluid is broken and amniotic fluid enters the maternal venous system via the endocervical veins, the placental site (if the placenta is separated), or a site of uterine trauma. This condition has a high mortality rate: as many as 50% of women die within the first hour after the onset of symptoms, and about 85% of survivors have permanent hypoxia-induced neurologic damage (Sadera & Vasudevan, 2015).

Although medical science has supplied many answers to questions about this condition, health care providers remain largely unable to predict or prevent an amniotic fluid embolism or to decrease its mortality rate.

Nursing Assessment

Predisposing factors associated with amniotic fluid embolism include placental abruption, uterine over distention, fetal demise, uterine trauma, oxytocin-

stimulated labor, amnioinfusion, multiparity, advanced maternal age, and ruptured membranes. However, many women present without any of the risk factors.

Nurses must stay a step ahead and be prepared at all times in this obstetric emergency. A team response is essential because every person will be needed. No test can diagnose an amniotic fluid embolism. Therefore, the nurse's assessment skills are critical. Immediate recognition and diagnosis of this condition are essential to improve maternal and fetal outcomes. Until recently, the diagnosis could be made only after an autopsy of the mother revealed squamous cells, lanugo hair, or other fetal and amniotic material in the pulmonary arterial vasculature (Baldisseri, 2014).

The clinical appearance is varied, but most women report difficulty breathing. Other symptoms include hypotension, cyanosis, hypoxemia, uterine atony, seizures, tachycardia, coagulation failure, disseminated intravascular coagulation (DIC), pulmonary edema, seizures, uterine atony with subsequent hemorrhage, adult respiratory distress syndrome, and cardiac arrest (Viswanathan, Venkateswaran, & Daniel, 2014).

 Take Note!

Amniotic fluid embolism should be suspected in any pregnant women with an acute onset of dyspnea, hypotension, and DIC. By knowing how to intervene, the nurse can promote a better chance of survival for both the mother and her newborn. Most women are transferred to the intensive care unit.

Nursing Management

Upon recognizing the signs and symptoms of this life-threatening diagnosis, institute supportive measures: oxygenation (resuscitation and 100% oxygen), circulation (intravenous fluids, inotropic agents to maintain cardiac output and blood pressure), control of hemorrhage and coagulopathy (oxytocic agents to control uterine atony and bleeding), seizure precautions, and administration of steroids to control the inflammatory response. Monitor vital signs, pulse oximetry, skin color, and temperature and observe for clinical signs of coagulopathy (vaginal bleeding, bleeding from intravenous site, bleeding from gums) (Moses, 2015).

Care is largely supportive and aimed at maintaining oxygenation and hemodynamic function and correcting coagulopathy. There is no specific therapy that is lifesaving once this condition starts. Adequate oxygenation is necessary, with endotracheal intubation and mechanical ventilation for most women. Vasopressors are used to maintain hemodynamic stability. Management of DIC may involve replacement with packed red blood cells or fresh-frozen plasma as necessary. Oxytocin infusions and prostaglandin analogs can be used to address uterine atony.

Explain to the client and family what is happening and what therapies are being instituted. The woman is usually transferred to a critical care unit for intensive observation and care. Assist the family to express their feelings and provide support as needed. Inform and reassure the woman and family as much as possible during this crisis.

WOMEN REQUIRING BIRTH-RELATED PROCEDURES

Many women can give birth without the need for any operative obstetric interventions. Most do not anticipate the need for any medical intervention. However, in some situations interventions are necessary to safeguard the health of the mother and fetus. The most common birth-related procedures are amnioinfusion, forceps-assisted or vacuum-assisted birth, cesarean birth, episiotomy (see Chapter 14), and vaginal birth following a previous cesarean birth (see section earlier in this chapter). Nurses play a major role in helping couples to cope with any unanticipated procedures by offering thorough explanations of the procedure, its anticipated benefits and risks, and any other options available.

Amnioinfusion

Amnioinfusion is a technique in which a volume of warmed, sterile, normal saline or Ringer's lactate solution is introduced into the uterus transcervically through an intrauterine pressure catheter to increase the volume of fluid when oligohydramnios is present. It is a procedure used during labor. It is used to change the relationship of the uterus, placenta, cord, and fetus to improve placental and fetal oxygenation. Instilling an isotonic glucose-free solution into the uterus helps to cushion the umbilical cord to prevent compression or dilute thick meconium. Studies support the use of this procedure a safe and effective in resolving FHR decelerations (Hofmeyr, Eke, & Lawrie, 2014).

This procedure is commonly indicated for severe variable decelerations due to cord compression, oligohydramnios due to placental insufficiency, postmaturity or rupture of membranes, preterm labor with premature rupture of membranes, and thick meconium fluid. However, it does not prevent meconium aspiration syndrome (Hofmeyr, Xu, & Eke, 2014). Contraindications to amnioinfusion include vaginal bleeding of unknown origin, umbilical cord prolapse, amnionitis, uterine hypertonicity, and severe fetal distress (Fong et al., 2014).

There is no standard protocol for amnioinfusion; nurses should follow their own institution protocols. After obtaining informed consent, a vaginal examination is performed to evaluate for cord prolapse, establish dilation, and confirm presentation. Next, 250 to 500 mL of warmed normal saline or lactated Ringer's solution is administered using an infusion pump over 20 to 30 minutes. Overdistention of the uterus is a risk, so the amount of fluid infused must be monitored closely. Amnioinfusion should reach therapeutic result or increase the amniotic fluid volume in approximately 30 minutes (Mattson & Smith, 2016).

When caring for the woman who is receiving an amnioinfusion, include the following:

• Explain the need for the procedure, what it involves, and how it may solve the problem.

• Inform the mother that she will need to remain on bed rest during the procedure.

• Assess the mother's vital signs and associated discomfort level.

• Maintain intake and output records.

• Assess the duration and intensity of uterine contractions frequently to identify

overdistention or increased uterine tone.

- Assess for fluid leakage by evaluating the chuck or pad under the woman to determine that it is not being retained in the uterus, which could lead to increased uterine pressure.

- Monitor the FHR pattern to determine whether the amnioinfusion is improving the fetal status.

- Prepare the mother for a possible cesarean birth if the FHR does not improve after the amnioinfusion.

Forceps- or Vacuum-Assisted Birth

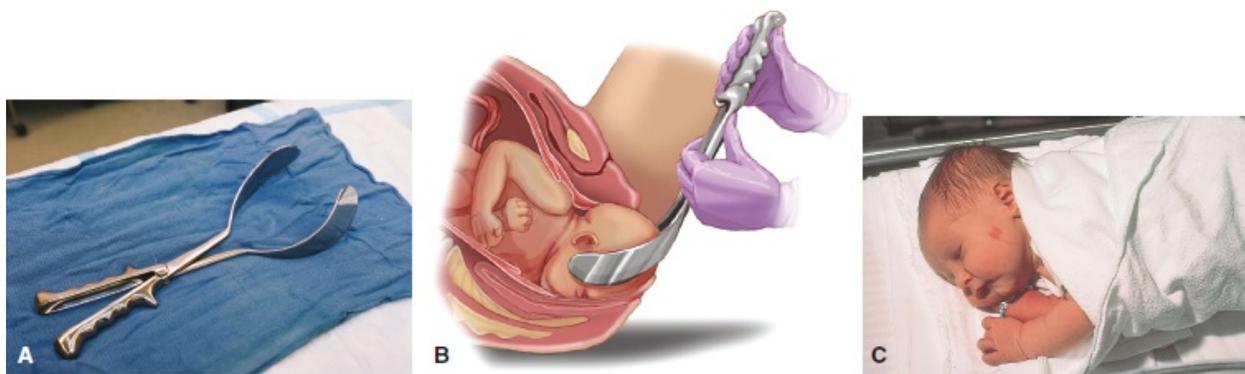
Forceps or a vacuum extractor may be used to apply traction to the fetal head or to provide a method of rotating the fetal head during birth. **Forceps** are stainless-steel instruments, similar to tongs, with rounded edges that fit around the fetus's head. Some forceps have open blades and some have solid blades. Outlet forceps are used when the fetal head is crowning and low forceps are used when the fetal head is at a +2 station or lower but not yet crowning. The forceps are applied to the sides of the fetal head. The type of forceps used is determined by the birth attendant. All forceps have a locking mechanism that prevents the blades from compressing the fetal skull. Use of forceps has declined in popularity recently because many obstetricians are not trained to use them in their residency since they are rarely used in obstetrical practice today (Fig. 21.6).


FIGURE 21.6 Forceps delivery (uncommon). **A.** Example of forceps. **B.** Forceps being applied to the fetus. **C.** Forceps marks are commonly found in newborns delivered by forceps. Such marks are transient and disappear in a day or two.

A **vacuum extractor** is a cup-shaped instrument attached to a suction pump used for extraction of the fetal head (Fig. 21.7). The suction cup is placed against the occiput of the fetal head. The pump is used to create negative pressure (suction) of approximately 50 to 60 mm Hg. The birth attendant then applies traction until the fetal head emerges from the vagina.

The indications for the use of either method are similar and include a prolonged second stage of labor, a distressed FHR pattern, failure of the presenting part to fully rotate and descend in the pelvis, limited sensation and inability to push effectively due to the effects of regional anesthesia, presumed

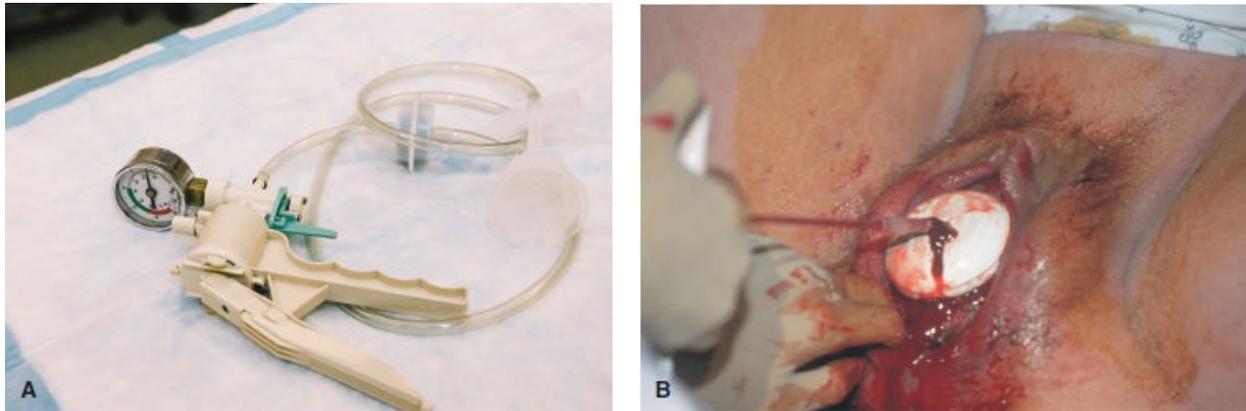
fetal jeopardy or fetal distress, maternal heart disease, acute pulmonary edema, intrapartum infection, maternal fatigue, or infection. There is a clear trend to choose vacuum extraction over forceps to assist delivery, but the evidence supporting that trend is unconvincing. Recent literature confirms some advantages for forceps (e.g., a lower failure rate) and some disadvantages for vacuum extraction (e.g., increased neonatal injury), depending on the clinical circumstances (O'Grady & St. Andre, 2015).


FIGURE 21.7 Vacuum extractor for delivery. **A.** Example of a vacuum extractor. **B.** Vacuum extractor applied to the fetal head to assist in delivery.
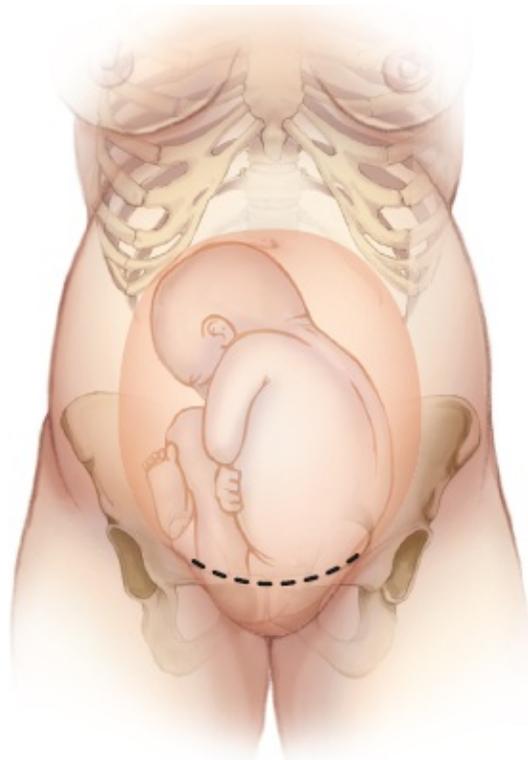

FIGURE 21.8 Low transverse incision for cesarean birth.

The use of forceps or a vacuum extractor poses the risk of tissue trauma to the mother and the newborn. Maternal trauma may include lacerations of the cervix, vagina, or perineum; hematoma; extension of the episiotomy incision into the anus; hemorrhage; and infection. Potential newborn trauma includes ecchymoses, facial and scalp lacerations, facial nerve injury, cephalhematoma, and caput succedaneum (Cunningham et al., 2014). For forceps or a vacuum extractor to be applied, the following criteria need to be met: membranes ruptured, cervix completely dilated, fetus vertex and engaged, and an adequate maternal pelvis size.

Prevention is the key to reducing the use of these techniques. Preventive measures include frequently changing the client's position, encouraging ambulation if permitted, frequently reminding the client to empty her bladder to allow maximum space for birth, and providing adequate hydration throughout labor. Additional measures include assessing maternal vital signs, the contraction pattern, the fetal status, and the maternal response to the procedure. Provide a thorough explanation of the procedure and the rationale for its use. Reassure the mother that any marks or swelling on the newborn's head or face will disappear without treatment within 2 to 3 days. Alert the postpartum nursing staff about the use of the technique so that they can observe for any bleeding or infection related to genital lacerations.

Cesarean Birth

A **cesarean birth** is the surgical birth of the fetus through an incision in the abdomen and uterine wall (Fig. 21.8) and is the most commonly performed surgery in the United States (Green, 2016).

High cesarean birth rates are an international concern. The cesarean birth rate in the United States is on the rise at an alarming rate. Today, approximately 33% or one in three births occurs this way. This is the 14th consecutive year the cesarean birth rate has risen, despite a number of medical organizations, including the WHO and ACOG, urging medical care providers to work on lowering the cesarean birth rate (Centers for Disease Control and Prevention, 2015). Cesarean births may result from maternal, fetal, or placental factors that interfere with a vaginal birth. Several factors may explain this increased incidence of cesarean deliveries: the use of electronic fetal monitoring, which identifies fetal distress early; the reduced number of forceps-assisted births; older maternal age and reduced parity; increasing maternal obesity, with more nulliparous women having infants; convenience to the client and doctor; and an increase in malpractice suits. The leading indications for cesarean births are previous cesarean birth, breech presentation, dystocia, and fetal distress. Once a woman has experienced a primary cesarean birth, she has a 90% chance of having another one in a subsequent pregnancy (Joy & Contag, 2015).

Cesarean birth is a major surgical procedure with increased risks compared with a vaginal birth. The client is at risk for complications such as infection, hemorrhage, aspiration, pulmonary embolism, urinary tract trauma, thrombophlebitis, paralytic ileus, and atelectasis. Fetal injury and transient tachypnea of the newborn also may occur (Cunningham et al., 2014).

Spinal, epidural, or general anesthesia is used for cesarean births. Epidural anesthesia is most commonly used because it is associated with less risk and most women wish to be awake and aware of the birth experience.

Nursing Assessment

Review the woman's history for indications associated with cesarean birth and complete a physical examination. Any condition that prevents the safe passage of the fetus through the birth canal or that seriously compromises maternal or fetal well-being may be an indication for a cesarean birth. Controversy exists for

the option of elective cesarean birth on maternal request. The Agency for Healthcare Research and Quality (AHRQ) has published a report on personal maternal request for a surgical birth, and although there is no high-quality medical evidence to support this, it is recognized that women have the right to be actively involved in choosing the route of her childbirth (Norwitz, 2015). The pregnant woman requesting a surgical birth must be made aware of the associated risks and benefits for the current and any subsequent pregnancies is reasonable. The clinician's role should be to provide the best evidence-based counseling possible to the woman and to respect her autonomy and decision-making capabilities when considering route of birth.

Examples of specific indications include active genital herpes, fetal macrosomia, fetopelvic disproportion, prolapsed umbilical cord, placental abnormality (placenta previa or abruptio placentae), previous classic uterine incision or scar, gestational hypertension, diabetes, positive human immunodeficiency virus (HIV) status, and dystocia. Fetal indications include malpresentation (nonvertex presentation), congenital anomalies (fetal neural tube defects, hydrocephalus, abdominal wall defects), and fetal distress (Joy & Contag, 2015).

Nursing Management

Once the decision has been made to proceed with a cesarean birth, assess the woman's knowledge of the procedure and necessary preparation. Assist with obtaining diagnostic tests as ordered. These tests are usually ordered to ensure the well-being of both parties and may include a complete blood count; urinalysis to rule out infection; blood type and cross-match so that blood is available for transfusion if needed; an ultrasound to determine fetal position and placental location; and an amniocentesis to determine fetal lung maturity if needed.

Although the nurse's role in a cesarean birth can be very technical and skill oriented at times, the focus must remain on the woman, not the equipment surrounding the bed. Care should be centered on the family, not the surgery. Provide education and minimize separation of the mother, father, and newborn. Remember that the client is anxious and concerned about her welfare as well as that of her child. Use touch, eye contact, therapeutic communication, and genuine caring to provide couples with a positive birth experience, regardless of the type of delivery.

PROVIDING PREOPERATIVE CARE

Client preparation varies depending on whether the cesarean birth is planned or unplanned. The major difference is the time allotted for preparation and teaching. In an unplanned cesarean birth, institute measures quickly to ensure the best outcomes for the mother and fetus. Ensure that the woman has signed an informed consent, and allow for discussion of fears and expectations. Provide essential teaching and explanations to reduce the woman's fears and anxieties.

Ascertain the client's and family's understandings of the surgical procedure. Reinforce the reasons for surgery given by the surgeon. Outline the procedure and expectations of the surgical experience. Ensure that all diagnostic tests ordered have been completed, and evaluate the results. Explain to the woman and her family about what to expect postoperatively. Reassure the woman that pain management will be provided throughout the procedure and afterward. Encourage the woman to report any pain. Ask the woman about the time she last had anything to eat or drink. Document the time and what was consumed. Throughout the preparations, assess maternal and fetal status frequently.

Provide preoperative teaching to reduce the risk of postoperative complications. Demonstrate the use of the incentive spirometer and deep-breathing and leg exercises. Instruct the woman on how to splint her incision.

Complete the preoperative procedures, which may include:

• Preparing the surgical site as ordered

• Starting an intravenous infusion for fluid replacement therapy as ordered

• Inserting an indwelling (Foley) catheter and informing the client about how long it will remain in place (usually 24 hours)

• Administering any preoperative medications as ordered; documenting the time administered and the client's reaction

Maintain a calm, confident manner in all interactions with the client and family. Help transport the client and her partner to the operative area.

PROVIDING POSTOPERATIVE CARE

Postoperative care for the mother who has had a cesarean delivery is similar to that for one who has had a vaginal birth, with a few additional measures. Assess vital signs and lochia flow every 15 minutes for the first hour, then every 30 minutes for the next hour, and then every 4 hours if stable. Assist with perineal care and instruct the client in the same. Inspect the abdominal dressing and

document description, including any evidence of drainage. Assess uterine tone to determine fundal firmness. Check the patency of the intravenous line, making sure the infusion is flowing at the correct rate. Inspect the infusion site frequently for redness.

Assess the woman's level of consciousness if sedative drugs were administered. Institute safety precautions until the woman is fully alert and responsive. If a regional anesthetic was used, monitor for the return of sensation to the legs.

Assess for evidence of abdominal distention and auscultate bowel sounds. Assist with early ambulation to prevent respiratory and cardiovascular problems and to promote peristalsis. Monitor intake and output at least every 4 hours initially and then every 8 hours as indicated.

Encourage the woman to cough, perform deep-breathing exercises, and use the incentive spirometer every 2 hours. Enhance comfort and general well-being. Administer analgesics as ordered and provide comfort measures, such as splinting the incision and pillows for positioning. Assist the client to move in bed and turn side to side to improve circulation. Also encourage the woman to ambulate to promote venous return from the extremities. Prevent/minimize postoperative complications.

Encourage early touching and holding of the newborn to promote bonding. Promote family unity and bonding. Assist with breast-feeding initiation and offer continued support. Suggest alternate positioning techniques to reduce incisional discomfort while breast-feeding. (See Chapter 18 for breast-feeding positions.)

Review with the couple their perception of the surgical birth experience. Allow them to verbalize their feelings and assist them in positive coping measures. Promote a positive emotional response to the birth experience and parenting role. Prior to discharge, teach the woman about the need for adequate rest, activity restrictions such as lifting, and signs and symptoms of infection. Provide information about postpartum care at home upon discharge.

KEY CONCEPTS

- Risk factors for dystocia include epidural analgesia, occiput posterior position, longer first stage of labor, nulliparity, short maternal stature (<5 ft tall), high birth weight, maternal age older than 35 years, gestational age more than 41 weeks, chorioamnionitis, pelvic contractions, macrosomia, and high station at complete cervical dilation.

- Dystocia may result from problems in the powers, passenger, passageway, or psyche.

- Problems involving the powers that lead to dystocia include hypertonic uterine dysfunction, hypotonic uterine dysfunction, and precipitate labor.

- Management of hypertonic labor pattern involves therapeutic rest with the use of sedatives to promote relaxation and stop the abnormal activity of the uterus.

- Any presentation other than occiput or a slight variation of the fetal position or size increases the probability of dystocia.

- Multiple pregnancy may result in dysfunctional labor due to uterine overdistention, which may lead to hypotonic dystocia and abnormal presentations of the fetuses.

- During labor, evaluation of fetal descent, cervical effacement and dilation, and characteristics of uterine contractions are paramount to determine progress or lack thereof.

- Antepartum assessment for a post-term pregnancy typically includes daily fetal movement counts done by the woman, nonstress tests done twice weekly, amniotic fluid assessments as part of the biophysical profile, and weekly cervical examinations to check for ripening for induction.

- Once the cervix is ripe, oxytocin is the most popular pharmacologic agent used for inducing or augmenting labor.

- Generally, the first and most reliable symptom of uterine rupture is fetal distress.

- Amniotic fluid embolism is a rare but often fatal event characterized by the sudden onset of hypotension, hypoxia, and coagulopathy.

- Cesarean births have steadily risen in the United States; today, approximately one in three births occurs this way. Cesarean birth is a major surgical procedure and has increased risks over vaginal birth.

CHAPTER **WORKSHEET**

MULTIPLE CHOICE QUESTIONS

1. When reviewing the medical record of a client, the nurse notes that the woman has a condition in which the fetus cannot physically pass through the maternal pelvis. The nurse interprets this as:

   a. Cervical insufficiency

   b. Contracted pelvis

   c. Maternal disproportion

   d. Fetopelvic disproportion

2. The nurse would anticipate a cesarean birth for a client who has which active infection present at the onset of labor?

   a. Hepatitis

   b. Herpes simplex virus

   c. Toxoplasmosis

   d. Human papillomavirus

3. After a vaginal examination, the nurse determines that the client's fetus is in an occiput posterior position. The nurse would anticipate that the client will have:

   a. Intense back pain

   b. Frequent leg cramps

   c. Nausea and vomiting

   d. A precipitous birth

4. When assessing the following women, which would the nurse identify as being at the greatest risk for preterm labor?

a. Woman who had twins in a previous pregnancy

b. Client living in a large city close to the subway

c. Woman working full time as a computer programmer

d. Client with a history of a previous preterm birth

5. The rationale for using a prostaglandin gel for a client prior to the induction of labor is to:

a. Stimulate uterine contractions

b. Numb cervical pain receptors

c. Prevent cervical lacerations

d. Soften and efface the cervix

6. A client who was in active labor and whose cervix had dilated to 4 cm experiences a weakening in the intensity and frequency of her contractions and exhibits no further progress in labor. The nurse interprets this as a sign of:

a. Hypertonic labor

b. Precipitate labor

c. Hypotonic labor

d. Dysfunctional labor

7. The nurse is developing a plan of care for a woman experiencing dystocia. Which of the following nursing interventions would be the nurse's high priority?

a. Changing the woman's position frequently

b. Providing comfort measures to the woman

c. Monitoring the fetal heart rate patterns

d. Keeping the couple informed of the labor progress

8. The nurse is caring for a woman experiencing hypertonic uterine dystocia. The woman's contractions are erratic in their frequency, duration, and of high intensity. The priority nursing intervention would be to:

a. Encourage ambulation every 30 minutes

b. Provide pain relief measures

c. Monitor the Pitocin infusion rate closely

d. Prepare the woman for an amniotomy

CRITICAL THINKING EXERCISE

1. A 26-year-old multipara, is admitted to the labor and birth suite in active labor. After a few hours, the nurse notices a change in her contraction pattern—poor contraction intensity and no progression of cervical dilatation beyond 5 cm. The client keeps asking about her labor progress and appears anxious about "how long this labor is taking."

   a. Based on the nurse's findings, what might you suspect is going on?

   b. How can the nurse address the client's anxiety?

   c. What are the appropriate interventions to change this labor pattern?

2. The woman activates her call light and states, "I feel increased wetness down below."

   a. What might be occurring?

   b. How will the nurse confirm the suspicions?

   c. What interventions are appropriate for this finding?

STUDY ACTIVITIES

1. Visit the SHARE Pregnancy and Infant Loss Support, Inc., website at the Point and assess its helpfulness to parents.

2. Outline the fetal and maternal risks associated with a prolonged pregnancy.

3. An abnormal or difficult labor describes _____.

BRINGING IT ALL TOGETHER: CASE STUDY

Tegan is a nulliparous woman who is now at 41 3/7 weeks of gestation with a male fetus. She presents for a routine prenatal visit. Fetal well-bring is reassuring at this point with FHR 144, active fetal movement, no complaints voiced except

for fatigue and a mild backache when she stands for long periods of time. She expresses concern that she has not yet gone into labor.

ASSESSMENT

The mean duration of pregnancy is 40 weeks (280 days) dated from the first day of the last normal menstrual period. Post-term pregnancy is defined as a gestational age of >42 weeks (>292 days) dated from the last menstrual period. Approximately 10% of low risk pregnancies continue beyond the 42nd week gestation. Her fetal well-being assessment is within normal limits.

Go to thePoint **to find questions to consider about this case.**

22

Nursing Management of the Postpartum Woman at Risk

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Examine the major conditions that place the postpartum woman at risk.
2. Analyze the risk factors, assessment, preventive measures, and nursing management of common postpartum complications.
3. Differentiate the causes of postpartum hemorrhage based on the underlying pathophysiologic mechanisms.
4. Outline the nurse's role in assessing and managing the care of a woman with a thromboembolic condition.
5. Characterize the nursing management of a woman who develops a postpartum infection.
6. Compare and contrast at least two affective disorders that can occur in women after birth, describing specific therapeutic management for each.

Joan gave birth about an hour ago to her fifth baby boy, who weighed 10 pounds, and she is resting in bed when the nurse comes in to assess her. She tells the nurse that she feels like there is "something really wet" between her legs. She also feels a bit light-headed. What would the nurse suspect is happening? What findings would support the nurse's suspicion? What should the nurse do first?

Words of Wisdom

Nurses should remain vigilant and observant throughout the childbirth experience all the way through discharge of the childbearing family.

INTRODUCTION

The postpartum period is the culmination of the childbearing experience. Numerous adaptations and adjustments must be made to assimilate the newborn into the established family unit. It is a time designed for maternal recovery, family attachment, and new role development. Typically, recovery from childbirth progresses normally both physiologically and psychologically. Just like everything else in life, a woman's body faces significant changes in the weeks and months following childbirth. It is a time filled with many changes and wide-ranging emotions, and the new mother commonly experiences a great sense of accomplishment. However, the woman can experience deviations from the norm, developing a postpartum condition that places her at risk. These high-risk conditions or complications can become life threatening. *Healthy People 2020* addresses these risks in two national health goals that were retained from the 2010 document.

This chapter addresses the nursing management of the most common conditions that place the postpartum woman at risk: hemorrhage, thromboembolic disease, infections, and postpartum affective disorders.

POSTPARTUM HEMORRHAGE

Postpartum hemorrhage (PPH) is a potentially life-threatening complication that can occur after both vaginal and cesarean births. It is the leading cause of maternal death in both developed and developing countries, accounting for about 35% of all maternal deaths. Every year about 14 million women globally suffer from PPH or approximately one in twenty births Agency for Healthcare Research and Quality [AHRQ], 2015). A hemorrhage occurs in 5% of all births and is responsible for a major part of maternal mortality. The majority of these deaths occur within 4 hours of childbirth, which indicates that they are a consequence of the third stage of labor management (Crowe & Faulkner, 2014; Ekin et al., 2015).

HEALTHY PEOPLE 2020 • 22.1

Objective	Nursing Significance
BDBS-15 Increase the proportion of women with von Willebrand disease (vWD) who are timely and accurately diagnosed by 10% by 2020.	• Will help foster the need for early identification of problems and prompt intervention to reduce the potential negative outcomes of pregnancy and birth.
MHMD-4 Reduce the proportion of persons who experience major depressive episode by 10% by 2020.	• Will help to contribute to lower rates of rehospitalization, morbidity, and mortality by focusing on thorough assessments in the postpartum period. • Will help to minimize the devastating effects of complications during the postpartum period and the woman's ability to care for her newborn.

Healthy People objectives based on data from http://www.healthypeople.gov.

PPH is defined as a blood loss greater than 500 mL after vaginal birth or more than 1,000 mL after a cesarean birth. However, this definition is arbitrary, because estimates of blood loss at birth are subjective and generally inaccurate. Moreover, average blood loss from birth frequently exceeds 500 or 1,000 mL, and symptoms of hemorrhage or shock from blood loss may be hidden by normal plasma volume increases that occur during pregnancy. Morbidity from PPH can be severe, with sequelae including organ failure, shock, edema, thrombosis, acute respiratory distress, sepsis, anemia, intensive care admissions, and prolonged hospitalization (AHRQ, 2015). A major obstetric hemorrhage is defined as a blood loss of more than 1,500 to 2,500 mL or bleeding that required more than 5 units of transfused blood (Pavord & Maybury, 2015). Hemorrhage is the most common reason postpartum women are admitted to intensive care units

and it is the most preventable cause of maternal death. Timely, accurate identification and initiation of appropriate interventions would improve outcomes (Clapp, 2015). Blood loss that occurs within 24 hours of birth is termed *primary (immediate or early) postpartum hemorrhage;* blood loss that occurs 24 hours to 12 weeks after birth is termed *delayed (late) postpartum hemorrhage.* A more objective definition of PPH would be any amount of bleeding that places the mother in hemodynamic jeopardy.

Pathophysiology

Excessive bleeding can occur at any time between the separation of the placenta and its expulsion or removal. The most common cause of PPH is **uterine atony**, failure of the uterus to contract and retract after birth. The uterus must remain contracted after birth to control bleeding from the placental site. Uterine atony is responsible for 80% of primary or immediate PPH, while obstetric lacerations, uterine inversion, and rupture compromise about 20% of all primary or early PPHs (Kamel & Mastrogiannis, 2015). Any factor that causes the uterus to relax after birth will cause bleeding—even a full bladder that displaces the uterus.

During the third stage of labor the muscles of the uterus contract downward, causing constriction of the blood vessels that pass through the uterine wall to the placental surface and stopping the flow of blood. This action also causes the placenta to separate from the uterine wall. The absence of uterine contractions may result in excessive blood loss. Uterotonic medications promote uterine contractions to prevent atony and speed delivery of the placenta.

Over the course of pregnancy, maternal blood volume increases as much as 50% (from 4 to 6 L). The plasma volume increases twice as much in comparison to the total red blood cell volume. As a result, hemoglobin and hematocrit fall. The increase in blood volume meets the perfusion demands of the low-resistance uteroplacental unit and provides a reserve for the blood loss that occurs at delivery (Cunningham et al., 2014). Given this increase, the typical signs of hemorrhage (e.g., falling blood pressure, increasing pulse rate, and decreasing urinary output) do not appear until as much as 1,800 to 2,100 mL of blood has been lost. Current evidence on postpartum volume replacement suggests packed red blood cells, fresh frozen plasma, platelets, and recombinant factor VIIa be used for volume replacement (Nagtalon-Ramos, 2014). Clinical manifestations of shock resulting from blood loss are seen in Table 22.1.

In addition, accurate determination of actual blood loss is difficult because of blood pooling inside the uterus, on peripads, mattresses, and the floor. Because no universal clinical standard exists, nurses must remain vigilant, assessing for risk factors and checking clients carefully before the birth attendant leaves the birthing area.

Other causes of PPH include lacerations of the genital tract, episiotomy, retained placental fragments, uterine inversion, coagulation disorders, large for gestational age newborn, failure to progress during the second stage of labor,

placenta accreta, induction or augmentation of labor with oxytocin, surgical birth, and hematomas of the vulva, vagina, or subperitoneal areas (Moses, 2015). A helpful way to remember the causes of postpartum hemorrhage is by using the 4 Ts:

TABLE 22.1 CLINICAL MANIFESTATIONS OF SHOCK DUE TO BLOOD LOSS

Degree of Shock	Blood Loss	Signs and Symptoms
Mild	20%	Diaphoresis, increased capillary refilling, cool extremities, maternal anxiety
Moderate	20–40%	Tachycardia, postural hypotension, oliguria
Severe	>40%	Hypotension, agitation/confusion, hemodynamic instability

1. **T**one: uterine atony, distended bladder

2. **T**issue: retained placenta and clots; uterine subinvolution

3. **T**rauma: lacerations, hematoma, inversion, rupture

4. **T**hrombin: coagulopathy (pre-existing or acquired)

Tone

Altered uterine muscle tone most commonly results from overdistention of the uterus. Overdistention can be caused by multiple gestation, fetal macrosomia, hydramnios, fetal abnormality, placenta previa, precipitous birth, or retained

placental fragments. Other causes might include prolonged or rapid, forceful labor, especially if stimulated by oxytocin; bacterial toxins (e.g., chorioamnionitis, endomyometritis, septicemia); use of anesthesia, especially halothane; and magnesium sulfate used in the treatment of preeclampsia (Jordan et al., 2014). Overdistention of the uterus is a major risk factor for uterine atony, the most common cause of early postpartum hemorrhage, which can lead to hypovolemic shock. A distended bladder can also displace the uterus from the midline to either side, which impedes its ability to contract to reduce bleeding.

Tissue

Uterine contraction and retraction lead to detachment and expulsion of the placenta after birth. Classic signs of placental separation include a small gush of blood with lengthening of the umbilical cord and a slight rise of the uterus in the pelvis. Complete detachment and expulsion of the placenta permit continued contraction and optimal occlusion of blood vessels. Failure of complete placental separation and expulsion leads to retained fragments, which occupy space and prevent the uterus from contracting fully to clamp down on blood vessels; this can lead to hemorrhage. Clots can also occupy space, which inhibits uterine contractions.

   After the placenta has been expelled, a thorough inspection is necessary to confirm its intactness; tears or fragments left inside may indicate an accessory lobe or placenta accreta (an uncommon condition in which the chorionic villi adhere to the myometrium, causing the placenta to adhere abnormally to the uterus and not separate and deliver spontaneously). Profuse hemorrhage results because the uterus cannot contract fully.

SUBINVOLUTION OF THE UTERUS

Subinvolution refers to incomplete involution of the uterus or failure to return to its normal size and condition after birth. Typically, subinvolution occurs when the myometrial fibers of the uterus do not contract effectively and causes relaxation. Complications of subinvolution include hemorrhage, pelvic peritonitis, salpingitis, and abscess formation (King et al., 2015). Causes of subinvolution include retained placental fragments, distended bladder, excessive maternal activity prohibiting proper recovery, uterine myoma, and infection. All of these conditions contribute to delayed postpartum bleeding. The clinical picture includes a postpartum fundal height that is higher than expected, with a

boggy uterus; the lochia fails to change colors from red to serosa to alba within a few weeks. This condition is usually identified at the woman's postpartum examination 4 to 6 weeks after birth with a bimanual vaginal examination or ultrasound. Treatment is directed toward stimulating the uterus to expel fragments with a uterine stimulant, and antibiotics are given to prevent infection.

Trauma

Damage to the genital tract may occur spontaneously or through the manipulations used during birth. Lacerations and hematomas resulting from birth trauma can cause significant blood loss. Hematomas can present as pain or as a change in vital signs disproportionate to the amount of blood loss. Most often, hematoma formation is associated with episiotomy, instrumental birth, or nulliparity. Many hematomas can be prevented with gentle, controlled birth, and appropriate inspection and repair of lacerations or episiotomy (Jordan et al., 2014). Uterine inversion happens when the top of the uterus collapses into the inner cavity due to excessive fundal pressure or pulling on the umbilical cord when the placenta is still firmly attached to the fundus after the infant has been born. Treatment for uterine inversion includes giving uterine relaxants and immediate manual replacement by the health care provider. Additionally, uterine rupture can occur and cause damage to the genital tract and is more common in women with previous cesarean incisions or those who have undergone any procedure resulting in disruption of the uterine wall, including myomectomy, perforation of the uterus during a dilation and curettage, biopsy, or intrauterine system insertion. Classically, its signs and symptoms combine pain, fetal heart rate abnormalities, and vaginal bleeding. Uterine rupture is a catastrophic complication that requires a rapid diagnosis and intervention, but initial clinical manifestations may be nonspecific (Nahum & Pham, 2015).

Trauma can also occur after prolonged or vigorous labor, especially if the uterus has been stimulated with oxytocin or prostaglandins. Trauma can also occur after extrauterine or intrauterine manipulation of the fetus.

Cervical lacerations commonly occur during a forceps delivery or in mothers who have not been able to resist bearing down before the cervix is fully dilated. Vaginal sidewall lacerations are associated with operative vaginal births but may occur spontaneously, especially if the fetal hand presents with the head. Lacerations can arise during manipulations to resolve shoulder dystocia. Lacerations should always be suspected in the face of a contracted uterus with

bright-red blood continuing to trickle out of the vagina.

Thrombin

Thrombosis (formation of a blood clot) helps to prevent PPH immediately after birth by providing hemostasis. Fibrin deposits and clots in supplying vessels play a significant role in the hours and days after birth. Disorders that interfere with the clot formation can lead to postpartum hemorrhage. Medication used to prevent hemorrhage by stimulating uterine contractions may delay the appearance of coagulation disorders. Coagulopathies should be suspected when postpartum bleeding persists without any identifiable cause (Agency for Healthcare Research and Quality [AHRQ], 2015).

Disorders of coagulation are relatively uncommon as a sole cause of PPH. Coagulation disturbances should be suspected in women with a family history of such abnormalities and women with a history of menorrhagia. Clinical circumstances may also suggest coagulation defect as a cause of PPH. Diagnosis of a coagulation disorder often requires a high index of suspicion and should not be overlooked in the evaluation of obstetric hemorrhage (Yiadom & Carusi, 2015).

Ideally, the client's coagulation status is determined during pregnancy. However, if she received no prenatal care, coagulation studies should be ordered immediately to determine her status. Abnormal results typically include decreased platelet and fibrinogen levels, increased prothrombin time, partial thromboplastin time, and fibrin degradation products, and a prolonged bleeding time (Cunningham et al., 2014). Selected conditions associated with coagulopathies in the postpartum client include idiopathic thrombocytopenic purpura, von Willebrand disease, and disseminated intravascular coagulation (DIC).

IDIOPATHIC THROMBO PURPURA

Idiopathic thrombocytopenia purpura (ITP) is an autoimmune disorder of increased platelet destruction caused by autoantibodies, which can increase a woman's risk of hemorrhaging. There is a decrease in the number of circulating platelets in the absence of toxic exposure or a disease associated with a low platelet count. It is most common in young women during childbearing age and may be associated with maternal and fetal complications. The incidence of ITP in adults is approximately 66 cases per 1,000,000 per year (Silverman, 2015).

Glucocorticoids and immune globulin are the mainstays of medical therapy (Kessler & Sandler, 2015).

VON WILLEBRAND DISEASE

von Willebrand disease is a congenital bleeding disorder that is inherited as an autosomal dominant trait. It is characterized by a prolonged bleeding time, a deficiency of von Willebrand factor, and impairment of platelet adhesion Centers for Disease Control and Prevention [CDC], 2015a). It is the most common hereditary bleeding disorder, affecting approximately 1% of the general population (National Hemophilia Foundation, 2015). Although vWD is thought to affect men and women equally, it is diagnosed more frequently in women because of menorrhagia, and it is more common among white women than African-American women American College of Obstetrics and Gynecologists [ACOG], 2014a). Most cases remain undiagnosed due to lack of awareness, difficulty in diagnosis, a tendency to attribute bleeding to other causes, and variable symptoms.

The most common symptoms of vWD include bleeding gums, easy bruising, menorrhagia, blood in urine and stools, nosebleeds and hematomas. Prolonged bleeding from trivial wounds, oral cavity bleeding, and excessive menstrual bleeding are common. Gastrointestinal bleeding is rare. During pregnancy, the von Willebrand factor level increases in most women; thus, labor and birth usually proceed normally. However, all women should be monitored for excessive bleeding, particularly during the first week postpartum (Pollak, 2015).

DISSEMINATED INTRAVASCULAR COAGULATION

DIC is a life-threatening, acquired coagulopathy in which the clotting system is abnormally activated, resulting in widespread clot formation in the small vessels throughout the body, which leads to the depletion of platelets and coagulation factors. This is why DIC is also known as consumption coagulopathy.

DIC is not itself a specific illness; rather it is always a secondary diagnosis that occurs as a complication of abruptio placentae, amniotic fluid embolism, intrauterine fetal death with prolonged retention of the fetus, acute fatty liver of pregnancy, severe preeclampsia, HELLP syndrome (hemolysis, i.e., the breakdown of red blood cells, elevated liver enzymes, and low platelet count), septicemia, and postpartum hemorrhage. Clinical features include petechiae, ecchymoses, bleeding gums, fever, hypotension, acidosis, hematomas, tachycardia, proteinuria, uncontrolled bleeding during birth, and acute renal

failure (Levi & Schmaier, 2015).Treatment goals are to maintain tissue perfusion through aggressive administration of fluid therapy, oxygen, heparin, and blood products. The most important treatment concept in DIC is that it is a secondary manifestation of an underlying disorder. The most important therapeutic maneuver is treating the initiating disorder, DIC will disappear, and the coagulation status will normalize Without this, supportive measures ultimately fail (Erez, Mastrolia, & Thachil, 2015).

Therapeutic Management

Prompt diagnosis and understanding of the underlying triggers of this complication is essential for a favorable outcome. Team work and prompt treatment are essential for the successful management of women with DIC. Therapeutic management focuses on the underlying cause of the hemorrhage. For example, uterine massage is used to treat uterine atony. If retained placental fragments are the cause, the fragments are usually manually separated and removed and a uterine stimulant is given to promote the uterus to expel fragments. Antibiotics are administered to prevent infection. Lacerations are sutured or repaired. Glucocorticoids and intravenous immunoglobulin, intravenous anti-RhoD, and platelet transfusions may be given for ITP. Perinatal management of ITP should also include maintenance of maternal platelet count and regular monitoring of fetal growth along with prediction and prevention of fetal passive immune thrombocytopenia (Silverman, 2015).

The mainstays of therapy for vWD are desmopressin and plasma concentrates that contain von Willebrand factor. Delayed postpartum hemorrhage may occur, despite adequate prophylaxis. Frequent monitoring and continued prophylaxis and/or treatment are recommended for at least 2 weeks after childbirth (Pollak, 2015).

Nursing Assessment

Most women will not have identifiable risk factors. Nonetheless, primary prevention of a PPH begins with an assessment of identifiable risk factors. Pregnancy and childbirth involve significant health risks, even for women with no pre-existing health problems. In the United States, where most births occur in hospitals and where resources are likely to be available as compared with developing countries, PPH still continues to be among the top causes of maternal deaths. Retrospective studies of these events suggest that some cases are preventable. As with many other sources of perinatal harm, delays in recognition, diagnosis, and treatment, problems with hierarchy and communication, and lack of knowledge, policies, and protocols were often cited as contributing factors (Shields et al., 2015).

The period after the birth and the first hours postpartum are crucial times for the prevention, assessment, and management of bleeding. Compared with other maternal risks such as infection, bleeding can rapidly become life threatening, and nurses, along with other health care providers, need to identify this condition quickly and intervene appropriately.

Begin by reviewing the mother's history, including labor and birth history, for risk factors associated with PPH (Table 22.2). The incidence of PPH has been rising, though the mortality has come down, suggesting improvement in the management of this condition. Although specific risk factors have been identified, PPH is often unanticipated and still occurs in approximately 5% of all births and increasing (Ekin et al., 2015).

TABLE 22.2 Factors Placing A Woman at Risk for Postpartum Hemorrhage

Clinical Risk Factors	Associated Clinical Conditions
Tone (abnormalities of uterine contractions)	
Overdistention of uterus	Polyhydramnios Multifetal gestation Macrosomia
Uterine muscle exhaustion	Rapid labor Prolonged labor Oxytocin use
Uterine infection	Maternal fever Prolonged rupture of membranes
Tissue (retained in uterus)	
Products of conception	Incomplete placenta at birth
Retained blood clots	Atonic uterus
Trauma (of the genital tract)	
Lacerations anywhere	Precipitate birth or operative birth
Laceration extensions	Malposition of fetus Previous uterine surgery
Uterine inversion	Forceful pulling when placenta isn't separated yet; traction on the cord when uterus isn't contracted
Thrombin (coagulation abnormalities)	
Pre-existing conditions	Hereditary inheritance Hemophilia von Willebrand's disease History of previous PPH Acquired in pregnancy Idiopathic thrombocytopenia purpura Bruising, elevated blood pressure Disseminated intravascular coagulation

Adapted from Centers for Disease Control and Prevention [CDC]. (2015a). *Facts about von Willebrand Disease*. Retrieved from http://www.cdc.gov/ncbddd/vwd/facts.html; King, T. L., Brucker, M. C., Kriebs, J. M., Fahey, J. O., Gegor, C. L., & Varney, H. (2015). *Varney's midwifery* (5th ed.) Burlington, MA: Jones & Bartlett Learning; and Mattson, S., & Smith, J. E. (2015). *Core curriculum for maternal-newborn nursing* (5th ed.), St. Louis, MO: Saunders Elsevier.

Since the most common cause of immediate severe PPH is uterine atony (failure of the uterus to contract properly after birth), assess uterine tone after birth by palpating the fundus for firmness and location. A soft, boggy fundus indicates uterine atony.

Take Note!

A soft, boggy uterus that deviates from the midline suggests that a full bladder is interfering with uterine involution. If the uterus is not in correct position (midline), it will not be able to contract to control bleeding.

Assess the amount of bleeding. Visual estimation is the most frequently practiced method of determining blood loss during childbirth in the United States, and the results are usually included in the documentation of events pertaining to the birth. This method is used despite repeated studies showing its inaccuracy and underestimation. Weighing or counting peri pads or using a Signaling a Postpartum Hemorrhage Emergency mat would provide a more accurate estimate of blood loss. The mat was constructed so that each square on the mat would absorb up to 50 mL of blood. Blood loss is then calculated by multiplying the number of blood-saturated squares by 50 mL (Wilcox et al., 2015). In any method used, nurses should consult their hospital protocols and follow them. If bleeding continues even though there are no lacerations, suspect retained placental fragments. The uterus remains large with painless, dark-red bleeding mixed with clots. This cause of hemorrhage can be prevented by carefully inspecting the placenta for intactness.

If trauma is suspected, attempt to identify the source and document it. Typically, the uterus will be firm with a steady stream or trickle of unclotted bright-red blood noted in the perineum. Most deaths from PPH are not due to gross bleeding, but rather to inadequate management of slow, steady blood loss (Clapp, 2015).

Assess for hematoma which may require surgical treatment. The uterus would be firm, with bright-red bleeding. Observe for a localized bluish bulging area just under the skin surface in the perineal area (Fig. 22.1). Often the woman will report severe perineal or pelvic pain and will have difficulty voiding. In addition, she may exhibit hypotension, tachycardia, and anemia. Frequently, the health care provider will incise the skin bulge to evacuate the hematoma of trapped blood. A pressure dressing is applied to this area to prevent further bleeding (Green, 2016).

Inspect the skin and mucous membranes for gingival bleeding or petechiae and ecchymoses. Check venipuncture sites for oozing or prolonged bleeding. These findings might suggest a coagulopathy as a cause of PPH. Also assess the amount of lochia, which would be much greater than usual. Urinary output would be diminished, with signs of acute renal failure. Vital signs would show an increased pulse rate and a decreased level of consciousness. However, signs of shock do not appear until hemorrhage is far advanced due to the increased fluid and blood volume of pregnancy.

FIGURE 22.1 Perineal hematoma. Note the bulging swollen mass.

Nursing Management

When excessive bleeding is encountered, initial management steps are aimed at improving uterine tone with immediate fundal massage, intravenous fluid resuscitation, and administration of uterotonic medications. If these methods fail to control bleeding, additional resources are mobilized and more aggressive interventions such as bimanual compression, internal uterine packing, and/or balloon tamponade techniques are employed by the health care provider. Other potential causes of bleeding should be thoroughly explored, and laboratory tests such as a complete blood count, type and cross-match, and coagulations studies should be obtained immediately. Transfusion of blood products should be instituted without hesitation once estimates of bleeding reach 1,500 mL (Nagtalon-Ramos, 2014).

Concept Mastery Alert

Priority Intervention for Uterine Atony

Before initiating fundal massage, the nurse must first place a hand over the symphysis pubis to anchor the uterus and prevent possible uterine inversion.

Clearly, in all cases of unexpected hemorrhage, the interventions discussed as follows must be performed without delay. Postpartum hemorrhage is best managed by using a stepwise progressive approach. Manual message and pharmacologic therapies are first-line treatments. If the bleeding continues, second-line interventions might include the use of intrauterine balloon (or gauze) tamponade and uterine compression sutures. If these second-line therapies still don't stop the bleeding, women may need to undergo radiologic embolization, pelvic devascularization, or hysterectomy. Peripartum hysterectomy remains the last-resort lifesaving measure and carries with it a higher mortality rate compared with nonobstetric hysterectomy. It is a most demanding obstetric surgery performed under very trying circumstances of life-threatening hemorrhage (Van de Velde, Diez, & Varon, 2015). Moreover, high-volume transfusions are often required, and there are significant postsurgical morbidity

risks such as renal failure, hepatic failure, respiratory distress syndrome, coagulopathies, septicemia, tissue hypoxia, and pituitary necrosis (Sheehan syndrome) (Rong, Yuna, & Yan, 2014). Postpartum hemorrhage outcomes can be improved by thorough preparation, anticipating the risks of PPH, and coordinating consultants for interventional procedures if warranted.

PPH is a serious complication of pregnancy that is often unanticipated. Even with prompt aggressive management, postpartum bleeding can quickly evolve into a life-threatening event. Perinatal nurses are often the first to observe significant postpartum bleeding and their prompt initial response and continued assessments are pivotal in the anticipation and coordination of necessary interventions. Multidisciplinary team support is critical because obstetric caregivers need a full array of medical and surgical strategies to manage intractable bleeding. Because all postpartum women are at risk for hemorrhage, nurses need to possess the knowledge and skills to practice active management of the third stage of labor to prevent hemorrhage and to recognize, assess, and respond rapidly to excessive blood loss in their clients.

Massage the Uterus

Massage the uterus if uterine atony is noted. The uterine muscles are sensitive to touch; massage stimulates the muscle fibers to contract. Massage the boggy uterus to stimulate contractions and expression of any accumulated blood clots while supporting the lower uterine segment. As blood pools in the vagina, stasis of blood causes clots to form. These clots need to be expelled as pressure is placed on the fundus. Note, however, that overly forceful massage can tire the uterine muscles, resulting in further uterine atony and increased pain. See Nursing Procedure 22.1 for the steps in massaging the fundus.

Administer a Uterotonic Drug

Administer a uterotonic drug if repeated fundal massage and expression of clots fail; medication is probably needed to contract the uterus in order to control bleeding from the placental site. The injection of a uterotonic drug immediately after birth is an important intervention used to prevent PPH. Oxytocin (Pitocin); a synthetic analog of prostaglandin E1, misoprostol (Cytotec) or dinoprostone (Prostin E2); methylergonovine maleate (Methergine); and a derivative of prostaglandin (PGF2α), carboprost (Hemabate), are drugs used to manage postpartum hemorrhage (Drug Guide 22.1). However, misoprostol is not

approved by the U.S. Food and Drug Administration (FDA) for this purpose. The choice of which uterotonic drug to use for management of bleeding depends on the judgment of the health care provider, the availability of drugs, and the risks and benefits of the drug.

All nurses need to be aware of the contraindications of administering each of the medications used to control postpartum hemorrhage as follows:

• *Pitocin*–never give undiluted as a bolus injection intravenously

NURSING PROCEDURE 22.1

Massaging the Fundus

Purpose: To Promote Uterine Contraction

1. After explaining the procedure to the woman, place one gloved hand on the area above the symphysis pubis (this helps to support the lower uterine segment).

2. Place the other gloved hand (usually the dominant hand) on the fundus.

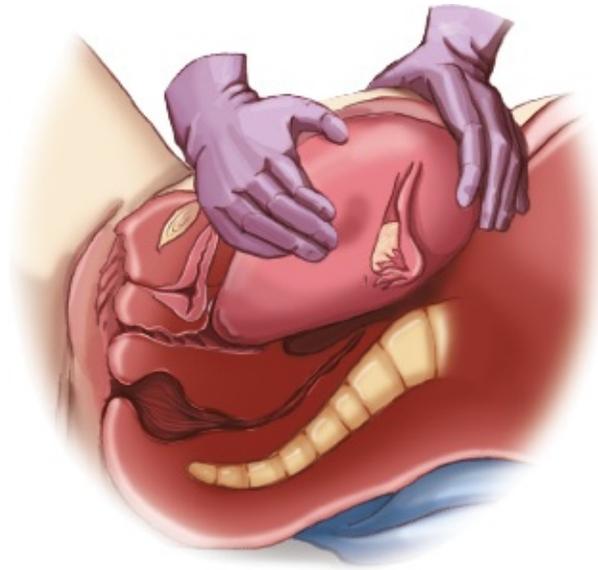
3. With the hand on the fundus, gently massage the fundus in a circular manner. Be careful not to over massage the fundus, which could lead to muscle fatigue and uterine relaxation.

4. Assess for uterine firmness (uterine tissue responds quickly to touch).

5. If firm, apply gentle yet firm pressure in a downward motion toward the vagina to express any clots that may have accumulated.

6. Do not attempt to express clots until the fundus is firm because the application of firm pressure on an uncontracted uterus could cause uterine inversion, leading to massive hemorrhage.

7. Assist the woman with perineal care and applying a new perineal pad.

8. Remove gloves and wash hands.


🌺 DRUG GUIDE 22.1 DRUGS USED TO CONTROL POSTPARTUM HEMORRHAGE

Drug	Action/Indication	Nursing Implications
Oxytocin (Pitocin) First-line therapy	Stimulates the uterus to contract/ to contract the uterus to control bleeding from the placental site 20–40 units in a liter IV or 10 units IM	Assess fundus for evidence of contraction and compare amount of bleeding every 15 min or according to orders. Monitor vital signs every 15 min. Monitor uterine tone to prevent hyperstimulation. Reassure client about the need for uterine contraction and administer analgesics for comfort. Offer explanation to client and family about what is happening and the purpose of the medication. Provide nonpharmacologic comfort measures to assist with pain management. Set up the IV infusion to be piggybacked into a primary IV line. This ensures that the medication can be discontinued readily if hyperstimulation or adverse effects occur while maintaining the IV site and primary infusion.
Misoprostol (Cytotec)	Stimulates the uterus to contract/ to reduce bleeding; a prostaglandin analog 800 mcg per rectum, one dose (range, 400–1,000 mcg)	Contraindications: Never give undiluted as a bolus injection IV. As above. Not FDA approved for this indication, but a very effective drug therapy for acute postpartum hemorrhage Contraindications: allergy, active CVD, pulmonary or hepatic disease; use with caution in women with asthma
Dinoprostone (Prostin E2)	20 mg vaginal or rectal suppository May be repeated every two hours	Monitor blood pressure frequently since hypotension is a frequent side effect along with vomiting and diarrhea, nausea, temperature elevation
Methylergonovine maleate (Methergine)	Stimulates the uterus/to prevent and treat postpartum hemorrhage due to atony or subinvolution 0.2 mg IM injection May be repeated in 5 min Thereafter every 2–4 h	Assess baseline bleeding, uterine tone, and vital signs every 15 min or according to protocol. Offer explanation to client and family about what is happening and the purpose of the medication. Monitor for possible adverse effects, such as hypertension, seizures, uterine cramping, nausea, vomiting, and palpitations. Report any complaints of chest pain promptly. Contraindications: Hypertension
Prostaglandin (PGF2α), Carboprost, (Hemabate)	Stimulates uterine contractions/ to treat postpartum hemorrhage due to uterine atony when not controlled by other methods 0.25 mg IM injection May be repeated every 15–90 min up to 8 doses Stimulates uterine contractions to reduce bleeding when not controlled by the first-line therapy of oxytocin	Assess vital signs, uterine contractions, client's comfort level, and bleeding status as per protocol. Offer explanation to client and family about what is happening and the purpose of the medication. Monitor for possible adverse effects, such as fever, chills, headache, nausea, vomiting, diarrhea, flushing, and bronchospasm. Contraindications: asthma or active cardiovascular disease Same as above Contraindications: active cardiac, pulmonary, renal, or hepatic disease

Adapted from Callahan, T. L. (2016). *Tarascon's OB/GYN pocketbook*. Burlington, MA: Jones & Bartlett Learning.; Bohlmann, M., & Rath, W. (2014). Medical prevention and treatment of postpartum hemorrhage: a comparison of different guidelines. *Archives of Gynecology & Obstetrics, 289*(3), 555–567.; and Skidmore-Roth, L. (2015). *Mosby's 2015 nursing drug reference* (28th ed.). St. Louis, MO: Mosby Elsevier.

- *Cytotec*–allergy, active cardiovascular disease, pulmonary or hepatic disease
- *Prostin E2*–active cardiac, pulmonary, renal, or hepatic disease
- *Methergine*–if the woman is hypertensive, do not administer

• *Hemabate*–contraindicated with asthma due to risk of bronchial spasm

> *Remember Joan, the woman described at the beginning of the chapter? The nurse assesses her and finds that her uterus is boggy. What would the nurse do next? What additional nursing measures might be used if Joan's fundus remains boggy? When should the health care provider be notified?*

Maintain the Primary Intravenous Infusion

Maintain the primary intravenous infusion and be prepared to start a second infusion at another site if blood transfusions are necessary. Draw blood for type and cross-match and send it to the laboratory. Administer oxytocics as ordered, correlating and titrating the infusion rate to assessment findings of uterine firmness and lochia. Assess for visible vaginal bleeding, and count or weigh perineal pads.

Take Note!

Postpartum hemorrhage outcomes can be improved by thorough preparation, anticipating the risks factors of PPH in every woman admitted, and coordinating consultants for interventional procedures if warranted.

Check Vital Signs

Check vital signs every 15 to 30 minutes, depending on the acuity of the mother's health status. Monitor her complete blood count to identify any deficit or assess the adequacy of replacement. Assess the woman's level of consciousness to determine changes that may result from inadequate cerebral perfusion.

A Foley catheter is typically in place to keep the bladder empty to avoid displacement of her uterus. A fundus above the umbilicus and deviated laterally indicates a full bladder and interferes with uterine contractions to slow the bleeding.

Prepare the Woman for Removal of Retained Placental Fragments

Prepare the woman for removal of retained placental fragments. These fragments usually are manually separated and removed by the health care provider. Be sure that the health care provider remains long enough after birth to assess the bleeding status of the woman and determine the etiology. Assist the health care provider with suturing any lacerations immediately to control hemorrhage and repair the tissue.

Nurses should anticipate and prepare the woman for transfer to the operating room for surgical intervention if tamponade techniques fail to achieve hemostasis. The blood bank should be notified that additional transfusions may be required and the woman's condition closely monitored for signs of hypovolemic shock.

Continually Assess the Woman for Signs and Symptoms of Hemorrhagic Shock

Continually assess the woman for signs and symptoms of hemorrhagic shock, a condition in which inadequate perfusion of organs results in insufficient availability of oxygen to satisfy the metabolic needs of the tissues (Green, 2016). Hemorrhagic shock is the most common form of shock encountered in obstetric practice. Subsequently, a catabolic state develops, leading to inflammation, endothelial dysfunction, and disruption of normal metabolic processes in vital organs. Once these events become established, the process of shock is often irreversible, even if volume and red blood cell deficits are corrected. The main goals of treatment of hemorrhagic shock include fluid resuscitation, correction of the imbalance between oxygen delivery and consumption, and treating DIC (Tanczos, Nemeth, & Molnar, 2015).

A postpartum hemorrhage is a traumatic experience because medical complications are unexpected during what is anticipated as a joyful time. Assess the anxiety level of the woman; the woman going into hypovolemic shock is highly anxious and may lose consciousness. The woman's significant others experience a high level of anxiety as well and need a great deal of support.

Monitor the woman's blood pressure, pulse, capillary refill, mental status, and urinary output. These assessments allow estimation of the severity of blood loss and help direct treatment. If the woman develops hemorrhagic shock, interventions focus on controlling the source of blood loss; restoring adequate oxygen-carrying capacity; and maintaining adequate tissue perfusion. Successful treatment depends on efficient collaboration among all health care team

members to meet the woman's specific needs.

For the woman with ITP, expect to administer glucocorticoids, intravenous immunoglobulin, intravenous anti-RhoD, and platelet transfusions. Prepare the woman for a splenectomy if the bleeding tissues do not respond to medical management. Be alert for women with abnormal bleeding tendencies, ensuring that they receive proper diagnosis and treatment. Teach them how to prevent severe hemorrhage by learning how to feel for and massage their fundus when boggy, assisting the nurse to keep track of the number of and amount of bleeding on perineal pads, and avoiding any medications with antiplatelet activity such as aspirin, antihistamines, or nonsteroidal anti-inflammatory drugs (NSAIDs).

Institute Emergency Measures If DIC Develops

If the woman develops DIC, institute emergency measures to control bleeding and impending shock and prepare to transfer her to the intensive care unit. Identification of the underlying condition and elimination of the causative factor are essential to correct the coagulation problem. Be ready to replace fluid volume, administer blood component therapy, and optimize the mother's oxygenation and perfusion status to ensure adequate cardiac output and end-organ perfusion. Continually reassess the woman's coagulation status via laboratory studies.

Monitor vital signs closely, being alert for changes that signal an increase in bleeding or impending shock. Observe for early signs of ecchymosis, including spontaneous bleeding from gums or nose, petechiae, excessive bleeding from the cesarean incision site or intravenous site, hematuria, and blood in the stool. Late signs include progressive changes in vital signs, skin color, and reduction of urinary output. Collectively, these findings correlate with decreased blood volume, decreased organ and peripheral tissue perfusion, and clots in the microcirculation (Levi & Schmaier, 2015).

Take Note!

Always remember the five causes of postpartum hemorrhage and the appropriate intervention for each: (1) uterine atony—massage and oxytocics; (2) retained placental tissue—evacuation and oxytocics; (3) lacerations or hematoma—surgical repair; (4) thrombin (bleeding disorders)—blood products; and (5) uterine inversion caused by too much cord traction—gentle replacement of

uterus and oxytocics.

Institute measures to avoid tissue trauma or injury, such as giving injections and drawing blood. Also provide emotional support to the client and her family throughout this critical time by being readily available and providing explanations and reassurance.

Preventing Postpartum Hemorrhage

Avoid an episiotomy unless an emergency birth is necessary and the perineum is a limiting factor. It is important to have the continuous intrapartum presence of an experienced labor and birth nurse. Provide active management of the third stage of labor, including administration of a uterotonic medication after birth of anterior shoulder, controlled and gentle cord traction to deliver the placenta, and uterine massage after the placenta is out. Authors of a Cochrane review concluded that active management of the third stage of labor is associated with reduced blood loss, reduced risk of PPH, and a reduced prolonged third stage of labor (Mousa et al., 2014).

Frequent staff education and PPH drills will help keep skills up to date. Nurses must identify and correct anemia and screen for coagulopathies before labor and birth. After birth, it is important to inspect the placenta (once it is delivered) for completeness. Assess woman for lower genital tract lacerations immediately after birth and reevaluate the woman's vital signs and vaginal flow after childbirth. Finally, it is important to be aware of the mother's beliefs about blood transfusions. Recently a workgroup representing all major women's health professional organizations developed an obstetric hemorrhage safety bundle for practice to improve PPH outcomes. Some of their selected readiness action domains include:

• Having a hemorrhage cart with supplies and instruction cards on every OB unit

• Having immediate access to medications used to treat a massive hemorrhage

• Establishing a response team within the hospital that can be called

• Developing emergency-release transfusion protocols in the blood bank

• Educating all staff on protocols and holding unit-based drills frequently (Main et al., 2015).

In summary, careful monitoring of the mother's vital signs, laboratory tests (in

particular, coagulation testing) and immediate diagnosis of the cause of PPH are important key factors to reduce maternal morbidity and mortality. Nurses must always be prepared to identify signs and symptoms of PPH, recognize maternal compromise and deal with hemorrhage promptly. By identifying hemorrhage promptly and providing swift interventions, maternal mortality and morbidity can be reduced.

An intravenous oxytocin infusion is started for Joan. What assessments will need to be done frequently to make sure Joan is not losing too much blood? What discharge instructions need to be reinforced with Joan?

VENOUS THROMBOEMBOLIC CONDITIONS

Venous thromboembolism is one of the leading causes of maternal mortality and morbidity with an annual incidence of one per 1,000 pregnancies, a ten times higher risk than the nonpregnant population (Testa et al., 2015). A thrombosis (blood clot within a blood vessel) can cause an inflammation of the blood vessel lining (thrombophlebitis), which in turn can lead to a thromboembolism (obstruction of a blood vessel by a blood clot carried by the circulation from the site of origin). Thrombi can involve the superficial or deep veins in the legs or pelvis. Superficial venous thrombosis usually involves the saphenous venous system and is confined to the lower leg. Superficial thrombophlebitis may be caused by the use of the lithotomy position during birth. Deep venous thrombosis (DVT) can involve deep veins from the foot to the calf, to the thighs, or pelvis. In both locations, thrombi can dislodge and migrate to the lungs, causing a pulmonary embolism (PE).

DVT is a common condition that can have serious complications. Deep venous thrombi have a high probability of propagating and leading to pulmonary emboli, which may cause chest pain, breathlessness, and sudden death. Thus, an accurate and timely diagnosis of DVT is imperative. Although DVT is often clinically silent, it may present with a number of signs, including calf pain, edema, and venous distention.

The three most common venous thromboembolic conditions occurring during the postpartum period are superficial venous thrombosis, DVT, and PE. Although venous thromboembolic disorders occur in less than 1% of all postpartum women, pulmonary embolus can be fatal if a clot obstructs the lung circulation; thus, early identification and treatment are paramount. Risk for postpartum venous thromboembolism is highest during the first three weeks after childbirth. Women with obstetric complications are at highest risk for this, and this risk remains elevated throughout the first twelve weeks postpartum (Tepper et al., 2014).

Pathophysiology

Thrombus (blood clot) formation typically results from venous stasis, injury to the innermost layer of the blood vessel, and hypercoagulation. Venous stasis and hypercoagulation are both common in the postpartum period.

If a clot dislodges and travels to the pulmonary circulation, PE can occur. PE is a potentially fatal condition that occurs when the pulmonary artery is blocked by a blood clot that has traveled from another vein into the lungs, causing an obstruction and infarction. When the clot is large enough to block one or more of the pulmonary vessels that supply the lungs, it can result in sudden death. Approximately 600,000 PEs occur yearly in the United States, resulting in 60,000 to 100,000 deaths (CDC, 2015b). Only 25% of all clients with PE are actually diagnosed, indicating that thousands of PEs go undetected. Many deaths due to PE are unrecognized and the diagnosis is often made at autopsy. PE is the leading cause of pregnancy-related death in the United States, occurring in 2 out of 100,000 live births. It most commonly occurs up to 3 weeks postpartum and following a surgical birth (Conti, et al., 2014). A national review of severe obstetric complications found a significant increase in the rate of PE associated with the increasing rate of cesarean births. Adequate treatment of thrombotic events in pregnancy is important to prevent progression of thrombosis to the development of pulmonary embolism (Sucker & Zotz, 2015).

Nursing Assessment

Assess the woman closely for risk factors and signs and symptoms of thrombophlebitis. Look for risk factors in the woman's history such as use of oral contraceptives before the pregnancy, smoking, employment that necessitates prolonged standing, history of thrombosis, thrombophlebitis, or endometritis, or evidence of current varicosities. Also look for other factors that can increase a woman's risk, such as prolonged bed rest, diabetes, obesity, cesarean birth, progesterone-induced distensibility of the veins of the lower legs during pregnancy, severe anemia, varicose veins, advanced maternal age (older than 34 years), and multiparity. The likelihood of thrombophlebitis is increased through most of pregnancy and for approximately 12 weeks after childbirth. This is partly due to increased platelet stickiness and partly due to reduced fibrinolytic activity (Guimicheva, Czuprynska, & Arya, 2015).

Ask the woman if she has pain or tenderness in the lower extremities. Suspect superficial venous thrombosis in a woman with varicose veins who reports tenderness and discomfort over the site of the thrombosis, most commonly in the calf area. The area appears reddened along the vein and is warm to the touch. The woman will report increased pain in the affected leg when she ambulates and bears weight.

Manifestations of DVT are often absent and diffuse. If present, they are caused by an inflammatory process and obstruction of venous return. Calf swelling, erythema, warmth, tenderness, and pedal edema may be noted. A positive Homans' sign (pain in the upper calf upon dorsiflexion) is not a definitive diagnostic sign as it is insensitive and nonspecific and is no longer recommended as an indicator of DVT. That is because calf pain can also be caused by a strained muscle, contusion, clients with herniated intervertebral discs, calf muscle spasm, neurogenic leg pain, ruptured Baker's cyst, and cellulitis (Heffline & Schmidt, 2014).

Be alert for signs and symptoms of pulmonary embolism, including unexplained sudden onset of shortness of breath and severe chest pain. The woman may be apprehensive and diaphoretic. Additional manifestations may include tachypnea, tachycardia, hypotension, syncope, distention of the jugular vein, decreased oxygen saturation (shown by pulse oximetry), cardiac arrhythmias, hemoptysis, and a sudden change in mental status as a result of hypoxemia (Quellette, Harrington, & Kamangar, 2015). Prepare the woman for a

lung scan to confirm the diagnosis.

Nursing Management

Nursing management focuses on preventing thrombotic conditions, promoting adequate circulation if thrombosis occurs, and educating the client about preventive measures, anticoagulant therapy, and danger signs.

Preventing Thrombotic Conditions

Prevention of thrombotic conditions is an essential aspect of nursing management and can be achieved with the routine use of simple measures:

• Developing public awareness about risk factors, symptoms, and preventive measures

• Preventing venous stasis by encouraging activity that causes leg muscles to contract and promotes venous return (leg exercises and walking)

• Dorsi/plantar flexion of feet with prolonged sitting to promote venous return

• Using intermittent sequential compression devices to produce passive leg muscle contractions until the woman is ambulatory

• Elevating the woman's legs above her heart level to promote venous return

• Stopping smoking to reduce or prevent vascular vasoconstriction

• Applying compression stockings and removing them daily for inspection of legs

• Using postoperative deep-breathing exercises to improve venous return by relieving the negative thoracic pressure on leg veins

• Reducing hypercoagulability with the use of aspirin or anticoagulation therapy

• Preventing venous pooling by avoiding pillows under knees, not crossing legs for long periods, and not leaving legs up in stirrups for long periods

• Padding stirrups to reduce pressure against the popliteal angle

• Avoiding sitting or standing in one position for prolonged periods

• Avoiding trauma to legs to prevent injury to the vein wall

• Increasing fluid intake to prevent dehydration

• Avoiding the use of oral contraceptives

  In women at risk, early ambulation is the easiest and most cost-effective

method. Use of compression stockings decreases distal calf vein thrombosis by decreasing venous stasis and augmenting venous return (Wells, Forgie, & Rodger, 2014). Women who are at a high risk for thromboembolic disease based on risk factors or a previous history of DVT or PE may be placed on prophylactic anticoagulation therapy during pregnancy. A low-molecular-weight heparin such as enoxaparin (Lovenox) can be given or rivaroxaban (Xarelto), apixaban (Eliquis), or dabigatran etexilate (Pradaxa) can be given (Middeldorp, 2015). It is typically discontinued during labor and birth and then restarted during the postpartum period.

Promoting Adequate Circulation

The mainstay of venous thromboembolic conditions is anticoagulation, while interventions such as thrombolysis and inferior vena cava filters are reserved for limited circumstances. For the woman with superficial venous thrombosis, administer NSAIDs for analgesia, provide for rest and elevation of the affected leg, apply warm compresses to the affected area to promote healing, and use antiembolism stockings to promote circulation to the extremities.

Implement bed rest or limited ambulation if ordered and elevation of the affected extremity for the woman with DVT. These actions help to reduce interstitial swelling and promote venous return from that leg. Apply antiembolism stockings to both extremities as ordered. Fit the stockings correctly to avoid excess pressure and constriction and urge the woman to wear them at all times. Sequential compression devices can also be used for women with varicose veins, a history of thrombophlebitis, or a surgical birth.

Anticoagulant therapy using a continuous intravenous infusion of low molecular-weight heparin along with vitamin K antagonists usually is initiated to prolong the clotting time and prevent extension of the thrombosis. Monitor the woman's coagulation studies closely; these might include activated partial thromboplastin time (aPTT), whole-blood partial thromboplastin time, and platelet levels. A therapeutic aPTT value typically ranges from 35 to 45 seconds, depending on which standard values are used (Pagana, Pagana, & Pagana, 2014). Also apply warm moist compresses to the affected leg and administer analgesics as ordered to decrease the discomfort.

After several days of intravenous low molecular-weight heparin therapy, expect to begin oral anticoagulant therapy as ordered. In most cases, the woman will continue to take this medication for several months after discharge.

For the woman who develops a pulmonary embolism, institute emergency measures immediately. The objectives of treatment are to prevent growth or multiplication of thrombi in the lower extremities, prevent more thrombi from traveling to the pulmonary vascular system, and provide cardiopulmonary support if needed. Administer oxygen via mask or cannula as ordered and initiate intravenous low molecular-weight heparin therapy titrated according to the results of the coagulation studies. Maintain the client on bed rest, and administer analgesics as ordered for pain relief. Be prepared to assist with administering thrombolytic agents, such as alteplase (tPA), which might be used to dissolve pulmonary emboli and the source of the thrombus in the pelvis or deep leg veins, thus reducing the potential for a recurrence.

Educating the Client

Provide teaching about the use of anticoagulant therapy and danger signs that should be reported (Teaching Guidelines 22.1). Provide anticipatory guidance, support, and education about associated signs of complications and risks.

Teaching Guidelines 22.1

TEACHING TO PREVENT BLEEDING RELATED TO ANTICOAGULANT THERAPY

• Watch for possible signs of bleeding and notify your health care provider if any occur:
  • Nosebleeds
  • Bleeding from the gums or mouth
  • Black tarry stools
  • Brown "coffee grounds" vomitus
  • Red to brown speckled mucus from a cough
  • Oozing at incision, episiotomy site, cut, or scrape
  • Pink, red, or brown-tinged urine
  • Bruises, "black and blue marks"

- Increased lochia discharge (from present level)
- Practice measures to reduce your risk of bleeding:
  - Brush your teeth gently using a soft toothbrush.
  - Use an electric razor for shaving.
  - Avoid activities that could lead to injury, scrapes, bruising, or cuts.
  - Do not use any over-the-counter products containing aspirin or aspirin-like derivatives.
  - Avoid consuming alcohol.
  - Inform other health care providers about the use of anticoagulants, especially dentists.
- Be sure to comply with follow-up laboratory testing as scheduled.
- If you accidentally cut or scrape yourself, apply firm direct pressure to the site for 5 to 10 minutes. Do the same after receiving any injections or having blood specimens drawn.
- Wear an identification bracelet or band that indicates that you are taking an anticoagulant.
- Elimination of modifiable risk factors for DVT (smoking, use of oral contraceptives, a sedentary lifestyle, and obesity).
- Importance of using compression stockings.
- Avoidance of constrictive clothing and prolonged standing or sitting in a motionless, leg-dependent position.
- Danger signs and symptoms (sudden onset of chest pain, dyspnea, and tachypnea) to report to the health care provider.

POSTPARTUM INFECTION

Infection during the postpartum period is a common cause of maternal morbidity and mortality. Overall, postpartum infection is estimated to occur in up to 8% of all births and accounts for 15% of global maternal mortality. There is a higher occurrence in cesarean births than in vaginal births (Mattson & Smith, 2016). Postpartum infection is defined as a fever of 100.4° F (38° C) or higher after the first 24 hours after childbirth, occurring on at least 2 of the first 10 days after birth, exclusive of the first 24 hours (Dalton & Castillo, 2014).

Risk factors include surgical birth, prolonged rupture of membranes, long labor with multiple vaginal examinations, inadequate hand hygiene, internal fetal monitoring, uterine manipulation, chorioamnionitis, instrumental birth, obesity, untreated infection prior to birth, retained placental fragments, obesity, gestational diabetes, extremes of client age, low socioeconomic status, and anemia during pregnancy (Jordan et al., 2014).

Infections can easily enter the female genital tract externally and ascend through the internal genital structures. Postpartum women possess an increased risk for infection due to tissue trauma during birth, vulnerability from placenta separation site, and the incision from cesarean section. In addition, the normal physiologic changes of childbirth increase the risk of infection by decreasing the vaginal acidity due to the presence of amniotic fluid, blood, and lochia, all of which are alkaline. An alkaline environment encourages the growth of bacteria.

Postpartum infections usually arise from organisms that constitute the normal vaginal flora, typically a mix of aerobic and anaerobic species. Generally, they are polymicrobial and involve the following microorganisms: *Staphylococcus aureus, Escherichia coli, Klebsiella, Gardnerella vaginalis,* gonococci, coliform bacteria, group A or B hemolytic streptococci, *Chlamydia trachomatis,* and the anaerobes that are common to bacterial vaginosis. Prevention can be achieved by screening and treating vaginal colonization during pregnancy (Callahan, 2016). Common postpartum infections include metritis, surgical site infections, urinary tract infections, and mastitis.

Metritis

Although usually referred to clinically as endometritis, postpartum uterine infections typically involve more than just the endometrial lining. **Metritis** is an infectious condition that involves the endometrium, decidua, and adjacent myometrium of the uterus. Extension of metritis can result in parametritis, which involves the broad ligament and possibly the ovaries and fallopian tubes, or septic pelvic thrombophlebitis, which results when the infection spreads along venous routes into the pelvis. It occurs within the first two days postpartum or as late as two to six weeks postpartum (King et al., 2015).

The uterine cavity is sterile until rupture of the amniotic sac. As a consequence of labor, birth, and associated manipulations, anaerobic and aerobic bacteria can contaminate the uterus. In most cases, the bacteria responsible for pelvic infections are those that normally reside in the bowel, vagina, perineum, and cervix, such as *E. coli, Klebsiella pneumoniae,* or *G. vaginalis.*

The risk of metritis increases dramatically after a cesarean birth; it complicates from 10% to 20% of cesarean births. This is typically an extension of chorioamnionitis that was present before birth (indeed, that may have been why the cesarean birth was performed). In addition, trauma to the tissues and a break in the skin (incision) provide entrances for bacteria to enter the body and multiply.

ACOG (2014b) recommends use of one dose of prophylactic antibiotic therapy administered one hour before any cesarean section and this has become standard practice in the United States today. Once rupture of the amniotic membranes occurs during labor and birth, the uterus becomes more susceptible to colonization and infection, especially if it is a prolonged labor. Any area traumatized during childbirth is susceptible to infection.

Surgical Site Infections

Any break in the skin or mucous membranes provides a portal for bacteria. In the postpartum woman, sites of wound infection include cesarean surgical incisions, the episiotomy site in the perineum, and genital tract lacerations (Fig. 22.2). Wound infections are usually not identified until the woman has been discharged from the hospital because symptoms may not show up until 24 to 48 hours after birth.

Urinary Tract Infections

Urinary tract infections are most commonly caused by bacteria often found in bowel flora, including *E. coli, Klebsiella, Proteus*, and *Enterobacter* species. Invasive manipulation of the urethra (e.g., urinary catheterization), frequent vaginal examinations, and genital trauma increase the likelihood of a urinary tract infection. It is the most common cause of a fever in the postpartum woman.

Mastitis

Mastitis is defined as inflammation of the mammary gland. A common problem that may occur within the first 2 days to 2 weeks postpartum. An estimated 5% of breast-feeding women develop lactational mastitis (Spiliopoulos & Mastrogiannis, 2014). Risk factors associated with mastitis include stasis of milk due to infrequent, inconsistent breastfeeding, and nipple trauma. As well as causing significant discomfort, it is a frequent reason for women to stop breast-feeding. It can result from any event that creates milk stasis: insufficient drainage of the breast, rapid weaning, oversupply of milk, pressure on the breast from a poorly fitting bra, a blocked duct, missed feedings, and breakdown of the nipple via fissures, cracks, or blisters (Nagtalon-Ramos, 2014). The most common infecting organism is *S. aureus,* which comes from the breast-feeding infant's mouth or throat. *Staphylococcus albus, E. coli,* and streptococci are also causative agents, but found less frequently. Infection can be transmitted from the lactiferous ducts to a secreting lobule, from a nipple fissure to periductal lymphatics, or by circulation (Amir, 2014) (Fig. 22.3). A breast abscess may develop if mastitis is not treated adequately. Flu-like symptoms are often the first symptoms experienced by the mother. Breasts are red, tender, and hot to the touch. The upper, outer quadrant of the breast is the most common site for mastitis to occur because most of the breast tissue is located there with both the right and left breasts being equally affected. Effective milk removal, pain medication, and antibiotic therapy have been the mainstays of treatment.

Therapeutic Management

METRITIS

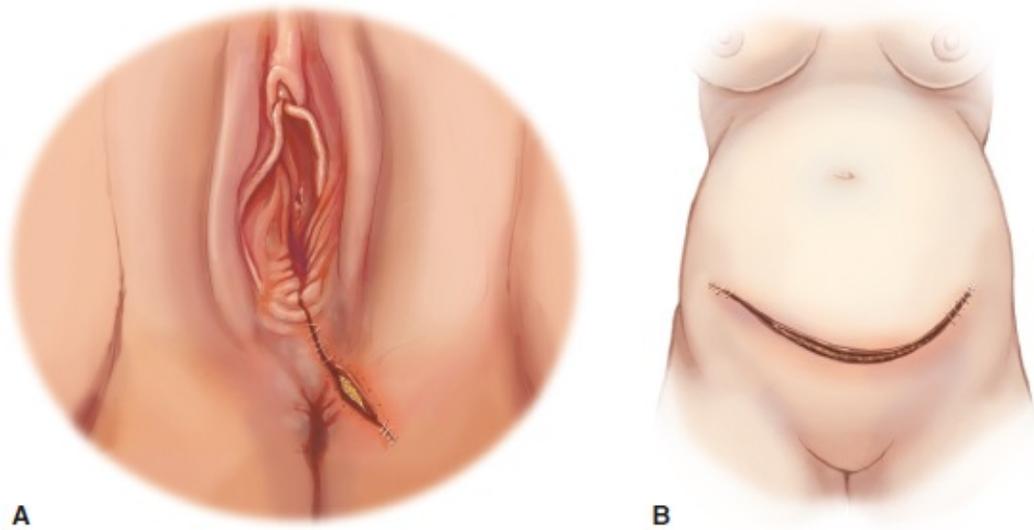
When metritis occurs, broad-spectrum antibiotics are used to treat the infection. Management also includes measures to restore and promote fluid and electrolyte balance, provide analgesia, and provide emotional support. In most treated women, fever drops and symptoms cease within 48 to 72 hours after the start of antibiotic therapy.


FIGURE 22.2 Postpartum wound infections. **A.** Infected episiotomy site. **B.** Infected cesarean birth incision.
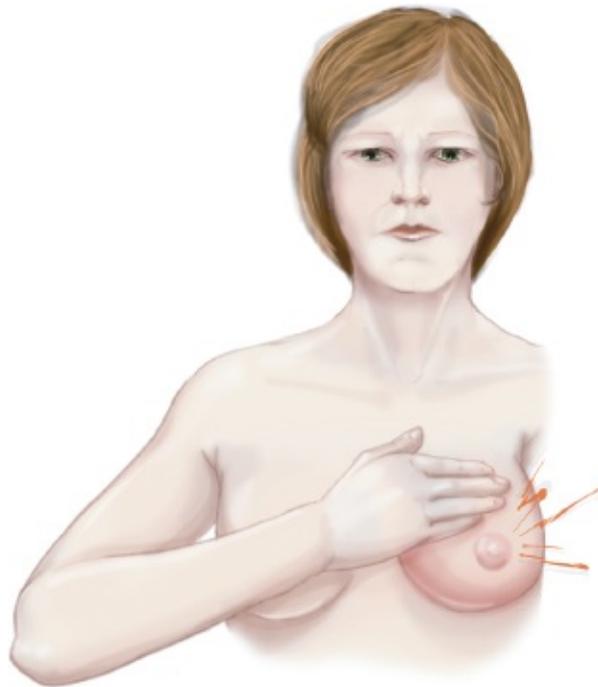

FIGURE 22.3 With mastitis, an area on one breast is tender, hot, red, and painful.

SURGICAL SITE INFECTIONS

Management for surgical site infections involves recognition of the infection, followed by opening of the wound to allow drainage. Aseptic wound

management with sterile gloves and frequent dressing changes if applicable, good hand hygiene, frequent perineal pad changes, hydration, and ambulation to prevent venous stasis and improve circulation are initiated to prevent development of a more serious infection or spread of the infection to adjacent structures. Parenteral antibiotics are the mainstay of treatment. Analgesics are also important, because women often experience discomfort at the wound site.

URINARY TRACT INFECTIONS

Urinary tract infections are common during the postpartum period and could be prevented by timely removal of urinary catheters used during labor or surgical births. Risk factors include catheterization, epidural anesthesia, and vaginal procedures. If the woman develops a urinary tract infection, fluids are used to treat dehydration. General nutrition measures include acidifying the urine by taking large doses of vitamin C or a regular intake of cranberry juice. Cranberry juice contains a substance with biologic activity that inhibits the growth of *E. coli* in the urinary tract (Wong & Rosh, 2015). Antibiotics may also be ordered if appropriate.

MASTITIS

Treatment of mastitis focuses on two areas: emptying the breasts and controlling the infection. Frequent breast emptying helps both infectious and noninfectious mastitis. The breast can be emptied either by the infant sucking or by manual expression. Increasing the frequency of nursing is advised. Lactation need not be suppressed. Control of infection is achieved with antibiotics. In addition, ice or warm packs and analgesics may be needed. In addition to antibiotics, management of lactational breast infections includes symptomatic treatment, assessment of the infant's attachment to the breast, and reassurance, emotional support, education, and support for ongoing breast-feeding.

Take Note!

Regardless of the etiology of mastitis, the focus is on reversing milk stasis, maintaining milk supply, and continuing breast-feeding, along with providing maternal comfort and preventing recurrence.

Nursing Assessment

Perinatal nurses are the primary caregivers for postpartum women and have a unique opportunity to identify subtle changes that place women at risk for infection. Nurses play a key role in identifying signs and symptoms that suggest a postpartum infection. Today women are commonly discharged 24 to 48 hours after giving birth. Therefore, nurses must assess new mothers for risk factors and identify early, subtle signs and symptoms of an infectious process. Factors that place a woman at risk for a PPI are highlighted in Box 22.1.

Review the client's history and physical examination and labor and birth record for factors that might increase her risk for developing an infection. Then complete the assessment (using the "BUBBLE-EE" parameters discussed in Chapter 16), paying particular attention to areas such as the abdomen and fundus, breasts, urinary tract, episiotomy, lacerations, or incisions and being alert for signs and symptoms of infection (Table 22.3).

Take Note!

A PPI is commonly associated with an elevated temperature, as mentioned previously. Other generalized signs and symptoms may include chills, foul-smelling vaginal discharge, headache, malaise, restlessness, anxiety, and tachycardia. In addition, the woman may have specific signs and symptoms based on the type and location of the infection.

The acronym REEDA is frequently used for assessing a woman's perineum status. It is derived from five components that have been identified to be associated with the healing process of the perineum. These include:

1. Redness—area may also feel warm to touch
2. Edema—may indicate infection or a hematoma
3. Ecchymosis—may indicate vaginal trauma
4. Discharge—should follow the expected lochia pattern
5. Approximation of skin edges— should be well aligned without gaps

Each category is assessed and a number assigned (0 to 3 points) for a total REEDA score ranging from 0 to 15. The higher scores indicate increased tissue

trauma (Kaur et al., 2015). See Figure 22.4 for the REEDA method for assessing perineum healing.

BOX 22.1

FACTORS PLACING A WOMAN AT RISK FOR POSTPARTUM INFECTION

- Prolonged (>18 to 24 hours) premature rupture of membranes (removes the barrier of amniotic fluid so bacteria can ascend)
- Cesarean birth (allows bacterial entry due to break in protective skin barrier)
- Urinary catheterization (could allow entry of bacteria into bladder due to break in aseptic technique)
- Regional anesthesia that decreases perception of need to void (causes urinary stasis and increases risk of urinary tract infection)
- Staff attending to woman are ill (promotes droplet infection from personnel)
- Compromised health status, such as anemia, obesity, smoking, drug abuse (reduces the body's immune system and decreases ability to fight infection)
- Pre-existing colonization of lower genital tract with bacterial vaginosis, *Chlamydia trachomatis,* group B streptococci, *S. aureus,* and *E. coli* (allows microbes to ascend)
- Retained placental fragments (provides medium for bacterial growth)
- Manual removal of a retained placenta (causes trauma to the lining of the uterus and thus opens up sites for bacterial invasion)
- Insertion of fetal scalp electrode or intrauterine pressure catheters for internal fetal monitoring during labor (provides entry into uterine cavity)
- Instrument-assisted childbirth, such as forceps or vacuum extraction (increases risk of trauma to genital tract, which provides bacteria access to grow)
- Trauma to the genital tract, such as episiotomy or lacerations (provides a portal of entry for bacteria)
- Prolonged labor with frequent vaginal examinations to check progress (allows time for bacteria to multiply and increases potential exposure to microorganisms or trauma)
- Poor nutritional status (reduces body's ability to repair tissue)

- Gestational diabetes (decreases body's healing ability and provides higher glucose levels on skin and in urine, which encourages bacterial growth)
- Break in aseptic technique during surgery or birthing process (allows entry of bacteria)

Monitor the woman's vital signs, especially her temperature. Changes may also signal an infection.

TABLE 22.3 SIGNS AND SYMPTOMS OF POSTPARTUM INFECTIONS

Postpartum Infection	Signs and Symptoms
Metritis	Lower abdominal tenderness or pain on one or both sides Temperature elevation (>38° C) Foul-smelling lochia Anorexia Nausea Fatigue and lethargy Leukocytosis and elevated sedimentation rate
Wound infection	Weeping serosanguineous or purulent drainage Separation of or unapproximated wound edges Edema Erythema Tenderness Discomfort at the site Maternal fever Elevated white blood cell count
Urinary tract infection	Urgency Frequency Dysuria Flank pain Low-grade fever Urinary retention Hematuria Urine positive for nitrates Cloudy urine with strong odor
Mastitis	Flu-like symptoms, including malaise, fever, and chills Tender, hot, red, painful area on one breast Inflammation of breast area Breast tenderness Cracking of skin around nipple or areola Breast distention with milk

Nursing Management

Nursing management focuses on preventing postpartum infections. Use the following guidelines to reduce the incidence of postpartum infections:

• Maintain aseptic technique when performing invasive procedures such as urinary catheterization, when changing dressings, and during all surgical procedures.

REEDA Method for Assessing Perineum Healing

- Redness
  - none = 0 points
  - Redness within .25 cm of incision bilaterally = 1
  - Redness within .50 cm of incision bilaterally = 2
  - Redness reaching beyond .5 cm of incision bilaterally = 3
- Edema – the more swelling present, the high the score
  - None = 0 points
  - < 1 cm from incision = 1 point
  - 1 to 2 cm from incision = 2 points
  - > 2 cm from incision = 3 points
- Ecchymosis – the more bruising observed, the higher the score
  - None = 0 points
  - 1-2 cm from incision = 1 point
  - .25 cm-1 cm bilaterally or .5-2 cm unilaterally = 2 points
  - > 1 cm bilaterally or 2 cm unilaterally = 3 points
- Discharge – range would be from none present to profuse
  - None = 0 points
  - Serum discharge present = 1 point
  - Serosanguineous discharge present = 2 points
  - Bloody, purulent discharge present = 3 points
- Approximation of skin edges
  - Closed, skin edges approximated well = 0 points
  - Skin separated 3 cm or less = 1 point
  - Skin and subcutaneous fat separated = 2 points
  - Skin, subcutaneous fat and facial separation = 3 points

FIGURE 22.4 REEDA method for assessing perineum healing. Adapted from Davidson, N. (1974). REEDA: Evaluating postpartum healing. *Journal of Nurse Midwifery 19*(2), 6–8; and Nikpour, M.,

Shirvani, M. A., Azadbakht, M., Zanjani, R., & Mousavi, E. (2014). The effect of honey gel on abdominal wound healing in cesarean section: A triple blind randomized clinical trial. *Oman Medical Journal*, *29*(4), 255–259.

- Use good hand hygiene technique before and after each client care activity.
- Reinforce measures for maintaining good perineal hygiene.
- Practice standard precautions whenever in contact with blood, body fluids, and excretions.
- Use adequate lighting and turn the client to the side to assess the episiotomy site.
- Use extreme caution when handling sharp instruments, specimens, and waste disposal.
- Screen all visitors for any signs of active infections to reduce the client's risk of exposure.
- Review the client's history for pre-existing infections or chronic conditions.
- Monitor vital signs and laboratory results for any abnormal values.
- Monitor the frequency of vaginal examinations and length of labor.
- Assess frequently for early signs of infection, especially fever and the appearance of lochia.
- Inspect wounds frequently for inflammation and drainage.
- Encourage rest, adequate hydration, and healthy eating habits.
- Reinforce preventive measures during any interaction with the client.

If the woman develops an infection, review treatment measures, such as antibiotic therapy if ordered, and any special care measures, such as dressing changes, that might be needed (Nursing Care Plan 22.1).

Postpartum women should be offered advice on the signs and symptoms of life-threatening conditions, including sepsis. Information should include the importance of good hand and perineal hygiene and of the need to seek immediate medical care if feeling unwell. Client teaching is a priority due to today's short lengths of stay after childbirth. Some infections may not manifest until after discharge. Review the signs and symptoms of infection, emphasizing the danger signs that need to be reported to the health care provider. Most importantly, stress proper hand hygiene, especially after perineal care and before

and after breast-feeding. Also reinforce measures to promote breast-feeding, including proper breast care (see Chapter 16). Teaching Guidelines 22.2 highlights the major teaching points for a woman with a postpartum infection.

Teaching Guidelines 22.2

TEACHING FOR THE WOMAN WITH A POSTPARTUM INFECTION

- Continue your antibiotic therapy as prescribed.
- Take the medication exactly as ordered and continue with the medication until it is finished.
- Do not stop taking the medication even when you are feeling better.
- Check your temperature every day and call your health care provider if it is above 100.4° F (38° C).
- Watch for other signs and symptoms of infection, such as chills, increased abdominal pain, change in the color or odor of your lochia, or increased redness, warmth, swelling, or drainage from a wound site such as your cesarean incision or episiotomy. Report any of these to your health care provider immediately.
- Practice good infection prevention:
- Always wash your hands thoroughly before and after eating, using the bathroom, touching your perineal area, or providing care for your newborn.
- Wipe from front to back after using the bathroom.
- Remove your perineal pad using a front-to-back motion. Fold the pad in half so that the inner sides of the pad that were touching your body are against each other. Wrap in toilet tissue or place in a plastic bag and discard.
- Wash your hands before applying a new pad.
- Apply a new perineal pad using a front-to-back motion. Handle the pad by the edges (top and bottom or sides) and avoid touching the inner aspect of the pad that will be against your body.
- When performing perineal care with a peribottle, angle the spray of water to

that it flows from front to back.

- Drink plenty of fluids each day and eat a variety of foods that are high in vitamins, iron, and protein.
- Be sure to get adequate rest at night and periodically throughout the day.

POSTPARTUM AFFECTIVE DISORDERS

The postpartum period involves extraordinary physiologic, psychological, and sociocultural changes in the life of a woman and her family. It is an exhilarating time for most women, but for others it may not be what they had expected. Women have varied reactions to their childbearing experiences, exhibiting a wide range of emotions. Typically, the delivery of a newborn is associated with positive feelings such as happiness, joy, and gratitude for the birth of a healthy infant. However, women may also feel weepy, overwhelmed, or unsure of what is happening to them. They may experience fear about loss of control; they may feel scared, alone, or guilty, or as if they have somehow failed. During the postpartum period, up to 85% of women experience some type of mood disorder (Joy, Mattingly, & Templeton, 2015).

Postpartum affective disorders have been documented for years, but only recently have they received medical attention. Plummeting levels of estrogen and progesterone immediately after birth can contribute to postpartum mood disorders. Reproductive hormones influence every biologic system and many women are particularly sensitive to the effects of perinatal changes in hormone levels after childbirth. It is believed that the greater the change in these hormone levels between pregnancy and postpartum, the greater the chance for developing a mood disorder (Schiller, Meltzer-Brody, & Rubinow, 2015).

NURSING CARE PLAN 22.1

Overview of the Woman with a Postpartum Complication

Jennifer, a 16-year-old G1P1, gave birth to a boy 3 days ago. It was a cesarean birth due to cephalopelvic disproportion following 25 hours of labor with ruptured membranes. Her temperature is 102.6° F (39.2° C). She is complaining of chills and malaise and says, "My incision really hurts." Jennifer rates her pain as 7 to 8 out of 10. The incision site is red, swollen, and very warm to the touch. A 5-cm area of purulent drainage is noted on the dressing; a 3-cm area of the incision is slightly opened, with the wound edges separated. Jennifer's lochia is scant and dark red, with a strong odor. She asks the nurse to take her baby back to the nursery because she doesn't feel well enough to care for him.

NURSING DIAGNOSIS: Ineffective thermoregulation related to bacterial invasion as evidenced by fever, complaints of chills and malaise, and statement of not feeling well

Outcome Identification and Evaluation
The client will exhibit a return to normothermia as evidenced by a body temperature being maintained below 99° F (37.2° C), reports of a decrease in chills and malaise, and statements of feeling better.

Interventions: *Promoting Fever Reduction*
• Assess vital signs every 2 to 4 hours and record results *to monitor progress of infection.*
• Administer antipyretics as ordered *to reduce temperature and help combat infection.*
• Encourage fluid intake *to promote fluid balance.*
• Document intake and output *to assess hydration status.*
• Offer cool bed bath or shower *to reduce temperature.*
• Place cool cloth on forehead and/or back of neck *to provide comfort.*
• Change bed linen and gown when damp from diaphoresis *to provide comfort and hygiene.*

NURSING DIAGNOSIS: Impaired skin integrity related to wound infection as evidenced by purulent drainage, redness, swelling, and separation of wound edges

Outcome Identification and Evaluation
The client will experience a resolution of wound infection as evidenced by a reduction in redness, swelling, and drainage from wound; absence of purulent drainage; and beginning signs and symptoms of wound healing.

Interventions: *Promoting Wound Healing*
• Administer antibiotic therapy as ordered *to treat infection.*
• Perform frequent dressing changes and wound care as ordered *to promote wound healing;* monitor dressing for drainage, including amount, color, and characteristics, *to evaluate for resolution of infection.*
• Use aseptic technique *to prevent spread of infection.*
• Encourage fluid intake *to maintain fluid balance;* encourage adequate dietary intake, including protein, *to promote healing.*

NURSING DIAGNOSIS: Acute pain related to infectious process

Outcome Identification and Evaluation
The client will report a decrease in pain as evidenced by pain rating of 0 or 1 on pain scale, verbalization of relief with pain management, and statements of feeling better and ability to rest comfortably.

Interventions: Relieving Pain
• Place client in semi-Fowler's position *to facilitate drainage and relieve pressure.*
• Assess pain level on pain scale of 0 to 10 to quantify pain level; reassess pain level after intervening *to determine effectiveness of intervention.*
• Assess fundus gently *to ensure appropriate involution.*
• Administer analgesics as needed and on time as ordered *to maintain pain relief.*
• Provide for rest periods *to allow for healing.*
• Assist with positioning in bed with pillows *to promote comfort.*
• Offer nonpharmacologic pain measures such as a backrub *to ease aches and*

discomfort if desired and enhance effectiveness of analgesics.

NURSING DIAGNOSIS: Risk for impaired parent–infant attachment related to effects of postpartum infection as evidenced by mother's request to take baby back to the nursery

Outcome Identification and Evaluation
The client will begin to bond with newborn appropriately with each exposure as evidenced by desire to spend time with newborn, expression of positive feelings toward newborn when holding him, increasing participation in care of newborn as client's condition improves, and statements about help and support at home to care for self and newborn.

Interventions: *Promoting Mother–Newborn Interaction*
• Promote adequate rest and sleep *to ensure adequate energy for interaction and wound healing.*
• Bring newborn to mother after she is rested and has had an analgesic *to allow mother to focus her energies on the child.*
• Progressively allow the client to care for her infant or comfort him as her energy level and pain level improve *to promote self-confidence in caring for the newborn.*
• Offer praise and positive reinforcement for caretaking tasks; stress positive attributes of newborn to mother while caring for him *to facilitate bonding and attachment.*
• Contact family members to participate in care of the newborn *to allow mother to rest and recover from infection.*
• Encourage mother to care for herself first and then the newborn *to ensure adequate energy for newborn's care.*
• Arrange for assistance and support after discharge from hospital *to provide necessary backup.*
• Refer to community health nurse for follow-up care of mother and newborn at home *to foster continued development of maternal–infant relationship.*

Many types of affective disorders occur in the postpartum period. Although their description and classification may be controversial, the disorders are commonly classified on the basis of their severity as postpartum or baby blues,

postpartum depression, and postpartum psychosis.

Postpartum Blues

Many postpartum women (approximately 80%) experience the "blues" (Callahan, 2016). The woman experiences rapid cycling mood symptoms during the first postpartum week typically. The woman exhibits mild depressive symptoms of anxiety, irritability, mood swings, tearfulness, increased sensitivity, despondency, feelings of being overwhelmed, difficulty thinking clearly, and fatigue (Pop et al., 2015). Emotional lability is the most prominent symptom of the maternity blues. The "blues" typically peak on postpartum days 4 and 5 and usually resolve by postpartum day 10. Biologic, psychological, and social factors have been hypothesized as relevant to blues causation, but no studies have validated this. Although the woman's symptoms may be distressing, they do not reflect psychopathology and usually do not affect the mother's ability to function and care for her infant.

Baby blues are usually self-limiting and require no formal treatment other than reassurance and validation of the woman's experience, as well as assistance in caring for herself and the newborn. However, follow-up of women with postpartum blues is important; because up to 20% go on to develop postpartum depression (Alexander et al., 2014).

Postpartum Depression

Depression is more prevalent in women than in men, which may be related to biologic, hormonal, and psychosocial factors. **Postpartum depression (PPD)** is a form of clinical depression that can affect women, and less frequently men, after childbirth. It affects as many as 20% of all mothers in the United States, and as many as 60% of adolescent mothers (ACOG, 2014c; CDC,2015c; Joy et al., 2015). Unlike the postpartum blues, women with postpartum depression feel worse over time, and changes in mood and behavior do not go away on their own. Postpartum depression may persist for a minimum of six months if untreated. Different from the baby blues, the symptoms of PPD last longer, are more severe, and require treatment. Some signs and symptoms of PPD include feeling the following:

• Restless
• Worthless
• Guilty
• Hopeless
• Moody
• Sad
• Overwhelmed
• Loss of enjoyment
• Low energy level
• Loss of libido

The new mother may also:

• Cry a lot
• Exhibit a lack of energy and motivation
• Be unable to make decisions or focus
• Lose her memory
• Experience a lack of pleasure
• Have changes in, sleep, or weight
• Show a lack of concern for herself

• Withdraw from friends and family

• Have pains in her body that do not subside

• Feel negatively toward her baby

• Appetite disturbances

• Feelings of isolation from others

• Lack interest in her baby

• Worry about hurting the baby

• Act detached toward others and infant

• Have recurrent thoughts of suicide and death (Bobo & Yawn, 2014).

Postpartum depression affects not only the woman but also the entire family. Identifying depression early can substantially improve the client and family outcomes. PPD usually has a gradual onset and becomes evident within the first 6 weeks postpartum.

The cause of PPD is not known, but research suggests that it is multifactorial. According to ACOG (2014c), "postpartum depression is likely to result from body, mind, and lifestyle factors combined." The levels of estrogen, progesterone, serotonin, and thyroid hormone decrease sharply and return to normal during the immediate postpartum period, which can trigger depression and can change a woman's mood and behavior. Other aspects that can lead to PPD include:

• Unresolved feelings about the pregnancy

• Fatigue after delivery from lack of sleep or broken sleep

• Feelings of being less attractive

• Inadequate assistance from partner

• Lack of social support network

• History of sexual or physical abuse

• Unemployment or financial insecurity

• Doubts about the ability to be a good mother

• Stress from changes in work and home routines

• Loss of freedom and old identity (Finley & Brizendine, 2015).

PPD may lend itself to prophylactic intervention because its onset is

predictable, the risk period for illness is well defined, and women at high risk potentially could be identified using a screening tool. This is not the case for all women, however (see Evidence-Based Practice 22.1). Prophylaxis starts with a prenatal risk assessment and education. Based on the woman's history of prior depression, prophylactic antidepressant therapy may be needed during the third trimester or immediately after giving birth. Management mirrors that of any major depression: a combination of antidepressant medication, antianxiety medication, adequate sleep and rest, and psychotherapy in an outpatient or inpatient setting (Callahan, 2016). Marital counseling may be necessary if marital problems are contributing to the woman's depressive symptoms.

The significant other's or partner's emotional health should not be overlooked during the woman's pregnancy and throughout the first postpartum year. PPD, once expected only in new mothers, occurs in new significant others or partners as well. Up to 50% of significant others or partners whose partners suffer from PPD also have depressive symptoms, and little is known about the impact of maternal PPD on them. Depressive symptoms are likely to decrease their ability to provide maternal support. Significant other's or partner's PPD can be difficult to identify. New partners or significant others may seem more angry and anxious than sad, yet depression is present. When left untreated, partner's PPD limits the significant other's or partner's capacity to provide emotional support to their partners and children. The highest rates of depression among fathers have been reported between 3 and 6 months postpartum. Factors that increase the risk of paternal PPD include a personal history of depression and/or anxiety, a low level of marital satisfaction, excessive financial stressors, a lack of significant other or partner's parental leave, and the feeling that there is a great discrepancy between one's expectations of parenthood and its realities (Feeley et al., 2015).

EVIDENCE-BASED PRACTICE 22.1 A SYSTEMATIC REVIEW OF THE RELATIONSHIP BETWEEN POSTPARTUM SLEEP DISTURBANCE AND POSTPARTUM DEPRESSION

STUDY

Sleep is closely associated with psychological well-being. Insufficient sleep leads to adverse medical and psychological consequences and a poorer quality of life. Despite commonly held beliefs of joy and happiness, women are vulnerable to mood disorders during the postpartum period. Nighttime feedings and frequent nocturnal awakenings contribute to sleep maternal disturbances. Poor and fragmented sleep patterns are associated with a poor quality of life, a decrease in attentiveness and general well-being. More importantly, it may be a risk factor for postpartum depression. Postpartum depression has been linked with a series of psychosocial sequelae for mothers and their newborns. The purpose of this review was to analyze the relationship between postpartum sleep disturbance and postpartum depression.

Findings

A systematic review was conducted on thirteen observational studies which included 3,793 women. The findings from all thirteen studies revealed a consistent strong relationship between sleep disturbance and postpartum depression. Short sleep duration and insomnia are related to a range of impaired functional outcomes that may negatively impact the daily life of postpartum women and their newborns.

Nursing Implications

Based on this evidence, nurses can counsel postpartum women about the importance of getting adequate sleep when they are discharged and the link between sleep disturbances to postpartum depression. Nurses can suggest several interventions to assist the new mother in obtaining adequate sleep such as bathing the newborn at night before bedtime, asking for help from family to assist in nighttime diaper changes, and taking naps throughout the day when the newborn sleeps. These simple helpful interventions may be a valuable prevention measure to assist in increasing the mother's wellness and reduce the risk of postpartum depression.

Adapted from Bhati, S., & Richards, K. (2015). A systematic review of the relationship between postpartum sleep disturbance and postpartum depression. *Journal of Obstetric, Gynecologic, & Neonatal Nursing*, 44(3), 350–357.

Assessing partner's PPD is not easy. Nevertheless, it is important for all nurses who have contact with new partners to remain open to the notion that new partners are predisposed to PPD, particularly if their partner is afflicted. Delving deeper into understanding behaviors of withdrawing, indecisiveness, cynicism, avoiding, drinking, using drugs, fighting, partner violence, extramarital affairs, and feelings of heightened irritation will reveal important insights. Asking new partners candidly if they are feeling depressed, anxious, or angry can open the door to further exploration of these emotions (Weissman, 2014).

Although partner depression is only now beginning to be defined and measured, sufficient evidence exists to warrant nurses' attention and concern. Nurses may be most able to help a new partner devastated by PPD when they plant seeds of awareness that the disorder exists, that they are not alone, and that help is available.

Despite the negative outcomes associated with PPD, rates of diagnosis and treatment are low mainly because of lack of recognition by the health care provider. In addition, PPD is the most misinterpreted, frequently dismissed, and most undiagnosed postpartum complication. Early recognition of PPD can eliminate the length of time that women and men have to suffer with this debilitating condition and can decrease the potentially harmful effects on the

infants involved.

Screening for symptoms of PPD in both men and women is an important preliminary step to diagnosis and treatment, but the effectiveness of depression screening is dependent on the reliability and validity of the screening instruments in the population. Both the Edinburgh Postnatal Depression Scale (EPDS) and the Postpartum Depression Predictor Scale (PDSS) have been used to screen mothers for PPD, but it is not clear which instrument best predicts a diagnosis of postpartum depression (Thombs et al., 2014).

The EPDS is a self-report, quick, and easy screening tool for PPD that consists of 10 questions with four possible responses. The couple fill out the tool according to their symptoms during the past 7 days, with each response given a score of 0 to 3 points, creating a maximum score of 30. Using a cutoff score of 9 or 10, the sensitivity is 86%; the specificity, 78%; and positive predictive value, 73% (Zhao et al., 2015).

The PDSS is a self-report, 35-item Likert-type response scale divided into seven conceptual domains:

1. Anxiety/insecurity

2. Sleep/eating disturbance

3. Emotional liability

4. Loss of self-esteem

5. Guilt/shame

6. Cognitive impairment

7. Suicidal thoughts

The scores range from 35 to 175. The scale has five symptoms for each domain, and the woman is asked to identify her degree of disagreement or agreement on the basis of her feelings over the past 2 weeks. The sensitivity of the PDSS is 91%; the specificity is 72% for detecting PPD. The PDSS takes 5 to 10 minutes to administer and is used during the postpartum period (King et al., 2015).

Early identification, screening, prevention, and treatment of PPD are crucial for improving overall outcomes for the mother and infant, as well as for decreasing mortality and morbidity. This is why it is crucial for nurses to understand and know about the risk factors, signs and symptoms, prevention, and use and interpretation of screening tools and to make appropriate referrals

for treatment. Mass screening for PPD using a validated screening tool has been proven to improve the rates of detection and treatment of PPD and should be implemented in obstetricians' and pediatricians' offices and in primary care settings. The Edinburgh tool is shown in Figure 22.5.

Postpartum Psychosis

At the severe end of the continuum of postpartum emotional disorders is postpartum psychosis, which occurs in 1 in 1000 live births (Doyle, Carballedo, & O'Keane, 2015). Postpartum psychosis, an emergency psychiatric condition, can result in a significant increased risk for suicide and infanticide. Symptoms of postpartum psychosis, such as mood lability, delusional beliefs, hallucinations, and disorganized thinking, can be frightening for the women who are affected and for their families. It generally surfaces within 3 months of giving birth and is manifested by sleep disturbances, fatigue, depression, and hypomania. The mother will be tearful, confused, and preoccupied with feelings of guilt and worthlessness. Early symptoms resemble those of depression, but they may escalate to delirium, hallucinations, extreme disorganization of thought, anger toward herself and her infant, bizarre behavior, delusions, disorientation, depersonalization, delirium-like appearance, manifestations of mania, and thoughts of hurting herself and the infant. The mother frequently loses touch with reality and experiences a severe regressive breakdown, associated with a high risk of suicide or infanticide (del Corral Serrano, 2015). Women with postpartum psychosis should not be left alone with their infants. Most women with postpartum psychosis are hospitalized for up to several months. Psychotropic drugs are almost always part of treatment, along with individual psychotherapy and support group therapy.

 Take Note!

The greatest hazard of postpartum psychosis is suicide. Infanticide and child abuse are also risks if the woman is left alone with her infant. Early recognition and prompt treatment of this disorder are imperative.

Nursing Assessment

Postpartum affective disorders are often overlooked and go unrecognized despite the large percentage of women who experience them. The postpartum period is a time of increased vulnerability, but few women receive education about the possibility of depression after birth. In addition, many women may feel ashamed

of having negative emotions at a time when they "should" be happy; thus, they do not seek professional help. Nurses can play a major role in providing guidance about postpartum affective disorders, detecting manifestations, and assisting women to obtain appropriate care.

Consider This

Even though I was an assertive practicing attorney in my thirties, my first pregnancy was filled with nagging feelings of doubt about this upcoming event in my life. Throughout my pregnancy I was so busy with trial work that I never had time to really evaluate my feelings. I was always reading about the bodily changes that were taking place, and on one level I was feeling excited, but on another level I was emotionally drained. Shortly after the birth of my daughter, those suppressed nagging feelings of doubt surfaced big time and practically immobilized me. I felt exhausted all the time and was only too glad to have someone else care for my daughter. I didn't breast-feed because I thought it would tie me down too much. Although at the time I thought this "low mood" was normal for all new mothers, I have since found out it was postpartum depression. How could any woman be depressed about this wondrous event?

    Thoughts: *Now that postpartum depression has been "taken out of the closet" and recognized as a real emotional disorder, it can be treated. This woman showed tendencies during her pregnancy but was able to suppress the feelings and go forward. Her description of her depression is very typical of many women who suffer in silence, hoping to get over these feelings in time. What can nurses do to promote awareness of this disorder? Can it be prevented?*

Edinburgh Postnatal Depression Scale

Name: _____   Address: _____

Your Date of Birth: _____   _____

Baby's Date of Birth: _____   Phone: _____

_____

As you are pregnant or have recently had a baby, we would like to know how you are feeling. Please check the answer that comes closest to how you have felt **IN THE PAST 7 DAYS**, not just how you feel today.

Here is an example, already completed.

I have felt happy:
- ☐ Yes, all the time
- ☒ Yes, most of the time   This would mean: "I have felt happy most of the time" during the past week.
- ☐ No, not very often   Please complete the other questions in the same way.
- ☐ No, not at all

In the past 7 days:

1. I have been able to laugh and see the funny side of things
   - ☐ As much as I always could
   - ☐ Not quite so much now
   - ☐ Definitely not so much now
   - ☐ Not at all

2. I have looked forward with enjoyment to things
   - ☐ As much as I ever did
   - ☐ Rather less than I used to
   - ☐ Definitely less than I used to
   - ☐ Hardly at all

*3. I have blamed myself unnecessarily when things went wrong
   - ☐ Yes, most of the time
   - ☐ Yes, some of the time
   - ☐ Not very often
   - ☐ No, never

4. I have been anxious or worried for no good reason
   - ☐ No, not at all
   - ☐ Hardly ever
   - ☐ Yes, sometimes
   - ☐ Yes, very often

*5 I have felt scared or panicky for no very good reason
   - ☐ Yes, quite a lot
   - ☐ Yes, sometimes
   - ☐ No, not much
   - ☐ No, not at all

*6. Things have been getting on top of me
   - ☐ Yes, most of the time I haven't been able to cope at all
   - ☐ Yes, sometimes I haven't been coping as well as usual
   - ☐ No, most of the time I have copied quite well
   - ☐ No, I have been coping as well as ever

*7 I have been so unhappy that I have had difficulty sleeping
   - ☐ Yes, most of the time
   - ☐ Yes, sometimes
   - ☐ Not very often
   - ☐ No, not at all

*8 I have felt sad or miserable
   - ☐ Yes, most of the time
   - ☐ Yes, quite often
   - ☐ Not very often
   - ☐ No, not at all

*9 I have been so unhappy that I have been crying
   - ☐ Yes, most of the time
   - ☐ Yes, quite often
   - ☐ Only occasionally
   - ☐ No, never

*10 The thought of harming myself has occurred to me
   - ☐ Yes, quite often
   - ☐ Sometimes
   - ☐ Hardly ever
   - ☐ Never

Administered/Reviewed by _____   Date _____

FIGURE 22.5 Adapted from Edinburgh Postnatal Depression Scale (EPDS). From Cox, J. L., Holden, J. M., & Sagovsky, R. (1987). Detection of postnatal depression: Development of the 10-item Edinburgh Postnatal Depression Scale. *British Journal of Psychiatry, 150,* 782–786.

Begin the assessment by reviewing the history to identify general risk factors that could predispose a woman to depression:

• Poor coping skills

• First pregnancy

• Low self-esteem

• Numerous life stressors

• History of abuse

• Mood swings and emotional stress

• Previous psychological problems or a family history of psychiatric disorders

• Substance abuse

• Limited or lack of social support network

Also review the history for specific pregnancy and birth factors that may increase the woman's risk for depression. These may include a history of PPD, evidence of depression during the pregnancy, prenatal anxiety, a difficult or complicated pregnancy, traumatic birth experience, or birth of a high-risk or special-needs infant (Callahan, 2016).

Be alert for physical findings. Assess the woman's activity level, including her level of fatigue. Ask about her sleeping habits, noting any problems with insomnia. When interacting with the woman, observe for verbal and nonverbal indicators of anxiety as well as her ability to concentrate during the interaction. Difficulty concentrating and anxious behaviors suggest a problem. Also assess her nutritional intake: weight loss due to poor food intake may be seen. Assessment can identify women with a high-risk profile for depression, and the nurse can educate them and make referrals for individual or family counseling if needed. Some common assessment findings associated with PPD are listed in Box 22.2.

Nursing Management

Nurses need to educate themselves about this disorder to facilitate early recognition of signs and symptoms of it, which, in turn, would make early treatment possible, thus supporting recovery. Furthermore, greater knowledge could contribute to providing more effective and compassionate care to these women. Nursing management focuses on assisting any postpartum woman to

cope with the changes of this period. Encourage the client to verbalize what she is going through and emphasize the importance of keeping her expectations realistic. Assist the woman in structuring her day to regain a sense of control over the situation. Encourage her to seek help if necessary, using available support systems. Also reinforce the need for good nutrition and adequate exercise and sleep (Bobo & Yawn, 2014).

The nurse can play an important role in assisting women and their partners with postpartum adjustment. Providing facts about the enormous changes that occur during the postpartum period is critical. This information would include changes in the woman's body. Review the signs and symptoms of all three affective disorders. This information is typically included as part of prenatal visits and childbirth education classes. Know the risk factors associated with these disorders and review the history of clients and their families. Use specific, nonthreatening questions to aid in early detection, such as "Have you felt down, depressed, or hopeless lately?" and "Have you felt little interest or pleasure in doing things recently?"

BOX 22.2

COMMON ASSESSMENT FINDINGS ASSOCIATED WITH POSTPARTUM DEPRESSION

• Loss of pleasure or interest in life
• Low mood, especially in the morning, sadness, tearfulness
• Exhaustion that is not relieved by sleep
• Feelings of guilt
• Weight loss
• Low energy
• Irritability
• Poor personal hygiene
• Constipated
• Preoccupied and unfocused
• Indecisiveness
• Diminished concentration
• Anxiety
• Despair
• Compulsive thoughts
• Loss of libido
• Loss of confidence
• Sleep difficulties (insomnia)
• Loss of appetite
• Bleak and pessimistic view of the future
• Not responding to infant's cries or cues for attention
• Social isolation, won't answer the door or the phone
• Feelings of failure as a mother

Discuss factors that may increase a woman's vulnerability to stress during the postpartum period, such as sleep deprivation and unrealistic expectations, so couples can understand and respond to those problems if they occur. Stress that many women need help after childbirth and that help is available from many sources, including people they already know. Assisting women to learn how to ask for help is important so they can gain the support they need. Also provide educational materials about postpartum emotional disorders. Have available referral sources for psychotherapy and support groups appropriate for women experiencing postpartum adjustment difficulties. See Evidence-Based Practice 22.1.

KEY CONCEPTS

- Postpartum hemorrhage is a potentially life-threatening complication of both vaginal and cesarean births. It is the leading cause of maternal mortality in the United States.
- A good way to remember the causes of postpartum hemorrhage is the "5 Ts": tone, tissue, trauma, thrombin, and traction.
- Uterine atony is the most common cause of early postpartum hemorrhage, which can lead to hypovolemic shock.
- Oxytocin (Pitocin), misoprostol (Cytotec), dinoprostone (Prostin E2), methylergonovine maleate (Methergine), and prostaglandin PGF2α (carboprost [Hemabate]) are commonly used drugs used to manage postpartum hemorrhage.
- Failure of the placenta to separate completely and be expelled interferes with the ability of the uterus to contract fully, thereby leading to hemorrhage.
- Causes of subinvolution include retained placental fragments, distended bladder, uterine myoma, and infection.
- Lacerations should always be suspected when the uterus is contracted and

bright-red blood continues to trickle out of the vagina.

- Conditions that cause coagulopathies may include idiopathic thrombocytopenic purpura, von Willebrand disease, and disseminated intravascular coagulation.

- Pulmonary embolism is a potentially fatal condition that occurs when the pulmonary artery is obstructed by a blood clot that has traveled from another vein into the lungs, causing obstruction and infarction.

- The major causes of a thrombus formation (blood clot) are venous stasis and hypercoagulation, both of which are common in the postpartum period.

- Postpartum infection is defined as a fever of 100.4° F (38° C) or higher after the first 24 hours after childbirth, occurring on at least 2 of the first 10 days exclusive of the first 24 hours.

- Common postpartum infections include metritis, wound infections, urinary tract infections, and mastitis.

- Postpartum emotional disorders are commonly classified on the basis of their severity: "baby blues," postpartum depression, and postpartum psychosis.

- Management of postpartum depression mirrors the treatment of any major depression: a combination of antidepressant medication, antianxiety medication, and psychotherapy in an outpatient or inpatient setting.

CHAPTER **WORKSHEET**

MULTIPLE CHOICE QUESTIONS

1. A postpartum mother appears very pale and states she is bleeding heavily. The nurse should first:

    a. Call the client's health care provider immediately.

    b. Immediately set up an intravenous infusion of magnesium sulfate.

    c. Assess the fundus and ask her about her voiding status.

d. Reassure the mother that this is a normal finding after childbirth.

2. A postpartum woman reports hearing voices and says, "The voices are telling me to do bad things to my baby." The clinic nurse interprets these findings as suggesting postpartum:

a. Psychosis

b. Anxiety disorder

c. Depression

d. Blues

3. When implementing the plan of care for a multigravida postpartum woman who gave birth just a few hours ago, the nurse vigilantly monitors the client for which complication?

a. Deep venous thrombosis

b. Postpartum psychosis

c. Uterine infection

d. Postpartum hemorrhage

4. Which of the following would the nurse expect to include in the plan of care for a woman with mastitis who is receiving antibiotic therapy?

a. Stop breast-feeding and apply lanolin

b. Administer analgesics and bind both breasts

c. Apply warm or cold compresses and administer analgesics

d. Remove the nursing bra and expose the breast to fresh air

5. While assessing a postpartum multiparous woman, the nurse detects a boggy uterus midline 2 cm above the umbilicus. Which intervention would be the priority?

a. Assessing vital signs immediately

b. Measuring her next urinary output

c. Massaging her fundus

d. Notifying the woman's obstetrician

6. Methergine has been ordered for a postpartum woman because of excessive

bleeding. The nurse should question this order if which of the following is present?

a. Mild abdominal cramping

b. Tender inflamed breasts

c. Pulse rate of 68 beats per minute

d. Blood pressure of 158/96 mm Hg

7. Which of the following findings would lead the nurse to suspect that a woman is developing a postpartum complication?

a. Moderate lochia rubra for the first 24 hours

b. Clear lung sounds upon auscultation

c. Temperature of 100° F

d. Chest pain experienced when ambulating

8. Which of the following factors in a postpartum woman's history would lead the nurse to monitor the woman closely for an infection?

a. Hemoglobin of 12 mg/dL

b. Manually extracted placenta

c. Labor of 10 hours length

d. Multiparity of 5 pregnancies

CRITICAL THINKING EXERCISES

1. Mrs. Griffin had a 22-hour labor before a cesarean birth. Her membranes ruptured 20 hours before she came to the hospital. Her fetus showed signs of fetal distress, so internal electronic fetal monitoring was used. Her most recent test results indicate she is anemic.

a. What postpartum complication is this new mother at highest risk for? Why?

b. What assessments need to be done to detect this complication?

c. What nursing measures will the nurse use to prevent this complication?

2. Tammy, a 32-year-old G9P9, had a spontaneous vaginal birth 2 hours ago. Tammy has been having a baby each year for the past 9 years. Her lochia has been heavy, with some clots. She hasn't been up to void since she had epidural

anesthesia and has decreased sensation to her legs.

a. What factors place Tammy at risk for postpartum hemorrhage?

b. What assessments are needed before planning interventions?

c. What nursing actions are needed to prevent a postpartum hemorrhage?

3. Lucy, a 25-year-old G2P2, gave birth 2 days ago and is expected to be discharged today. She had severe postpartum depression 2 years ago with her first child. Lucy has not been out of bed for the past 24 hours, is not eating, and provides no care for herself or her newborn. Lucy states she already has a boy at home and not having a girl this time is disappointing.

a. What factors/behaviors place Lucy at risk for an affective disorder?

b. Which interventions might be appropriate at this time?

c. What education does the family need prior to discharge?

STUDY ACTIVITIES

1. Compare and contrast postpartum blues, postpartum depression, and postpartum psychosis in terms of their features and medical management.

2. Visit and select a website from the Student Resources for Chapter 22. Critique the website regarding its helpfulness to parents, the correctness of the information, and when it was last updated.

3. Interview a woman who has given birth and ask if she had any complications and what was most helpful to her during the experience.

4. The number one cause of postpartum hemorrhage is _____.

5. When giving report to the nurse who will be caring for a woman and her newborn in the postpartum period, what information should the labor nurse convey?

BRINGING IT ALL TOGETHER: CASE STUDY

Sheila is an 18-year-old G1P1 Hispanic who had her first child 2 days ago via primary cesarean section. Her pregnancy was uneventful, but she didn't attend prenatal clinic very often. She presented to the hospital in labor at 39 weeks of

gestation with ruptured membranes. The client reported that her membranes had been ruptured for a "couple of days," but she wasn't really sure. Upon admission, she was dilated 2 cm/40% effacement. She labored for about 7 hours when the health care provider came in to check her. She was only 5 cm/completely effaced at that time. She was receiving IV antibiotics for her "prolonged rupture" status as per CDC guidelines. The health care provider inserted an internal fetal monitor with a scalp electrode and also an intrauterine pressure catheter because she was obese and the nurse was having difficulty in picking up the FHR tracing. She had no progress for the next four hours and the fetus was noted to develop tachycardia with a baseline heart rate increase to 170 bpm. A primary cesarean section was performed and she was given perioperative antibiotic prophylaxis at the time of surgery. Infant was LGA and Apgar scores were 9/9 at one minute and 5 minutes, respectively.

ASSESSMENT

On day 1, as the nurse caring for this client, you obtain a set of postpartum vital signs: T—101.6, P—102, BP—110/80, R—18. Sheila appears pale and is diaphoretic. Her lochia rubra is of moderate amount and foul smelling. She complains of uterine tenderness when you palpate her fundus. Her surgical site is intact without redness or drainage. She states she didn't have the breakfast that was served because she had no appetite. Her breasts are nontender and full upon palpation. She plans to bottle feed and has a supportive bra on. Sheila ambulates well and does her own peri-care.

The Newborn at Risk

23

Nursing Care of the Newborn with Special Needs

KEY TERMS

appropriate for gestational age
asphyxia
extremely low birth weight
full term newborn
large for gestational age (LGA)
late preterm newborn
low birth weight (LBW)
post-term newborn
preterm newborn

retinopathy of prematurity (ROP)
small for gestational age (SGA)
very low birth weight

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Examine factors that assist in identifying a newborn at risk due to variations in birth weight and gestational age.
2. Detect contributing factors and common complications associated with dysmature infants and their management.
3. Compare and contrast a small-for-gestational-age newborn and a large-for-gestational-age newborn; a post-term and preterm newborn.
4. Differentiate associated conditions that affect the newborn with variations in birth weight and gestational age, including appropriate management.
5. Outline the nurse's role in helping parents experiencing perinatal grief or loss.
6. Integrate knowledge of the risks associated with late preterm births into nursing interventions, discharge planning, and parent education.

Anna and her husband were stunned when she went into labor at 7 months' gestation. They couldn't understand what would cause her to give birth early, but it happened. When they approached the neonatal intensive care unit (NICU), Anna took a deep breath and looked down at her tiny baby with tubes coming from everywhere. What feelings might they be experiencing at this moment?

Words of Wisdom

Guiding a parent's hand to touch a frail or ill newborn demonstrates courage and compassion under very difficult circumstances and is a powerful tool in helping

them to deal with the newborn's special needs.

Every family looks forward to the birth of a healthy newborn. Most newborns are born between 38 and 42 weeks' gestation and weigh 6 to 8 pounds, but variations in birth weight or gestational age can occur, and newborns with these variations have special needs. Gestational age at birth is inversely correlated with the risk that the infant will experience physical, neurologic, or developmental sequelae (March of Dimes, 2015a). In some cases, however, unexpected difficulties and challenges occur along the way and some newborns are born very ill and need special advanced care to survive. Some complications are unexpected and occur without warning. Other times, there are risk factors that increase the risk of problems in newborns.

When a woman gives birth to a newborn with problems involving immaturity or birth weight, especially one who is considered high risk, she may go through a grieving process in which she mourns the loss of the healthy full-term newborn she had expected. Through this process she learns to come to terms with the experience she now faces.

The development of new technologies and regionalized care centers for the care of newborns with special needs has resulted in significant improvements. Nurses need to have a sound knowledge base to identify the newborn with special needs and to provide coordinated care.

The key to identify a newborn with special needs related to birth weight or gestational age variation is an awareness of the factors that could place a newborn at risk. These factors are similar to those that would suggest a high-risk pregnancy. Being able to anticipate the birth of a newborn at risk allows the birth to take place at a health care facility equipped with the resources to meet the mother's and newborn's needs. This is important in reducing mortality and morbidity.

Healthy People 2020 identifies preterm births and low birth weight as important national health goals (U.S. Department of Health and Human Services, 2010). (See *Healthy People 2020* 23.1.)

This chapter discusses the nursing management of newborns with special needs related to variations in birth weight and gestational age. It also describes selected associated conditions affecting these newborns. Due to the frailty of these newborns, the care of the family experiencing perinatal loss and the role of the nurse in helping the family cope also are addressed.

BIRTH-WEIGHT VARIATIONS

Fetal growth is influenced by maternal nutrition, genetics, placental function, environment, and a multitude of other factors. Assigning size to a newborn is a way to measure and monitor the growth and development of the newborn at birth. Newborns can be classified according to their weight and weeks of gestation. Knowing the group into which a newborn fits is important.

HEALTHY PEOPLE 2020 • 23.1

Objective	Nursing Significance
MICH-8 Reduce low birth weight (LBW) and very low birth weight (VLBW) by 10% by 2020.	Will help to emphasize the issue of LBW as a risk factor associated with newborn death, helping to promote measures to reduce this risk factor and thus contributing to significant reductions in infant mortality.
MICH-9 Reduce preterm births by 10% by 2020.	Will help to emphasize the role of preterm birth as the leading cause of newborn deaths unrelated to birth defects.
MICH-33 Increase the proportion of VLBW infants born at level III hospitals or subspecialty perinatal centers by 10% by 2020.	Will aid in promoting an overall reduction in infant illness, disability, and death.

Healthy People objectives based on data from http://www.healthypeople.gov.

Appropriate for gestational age (AGA) characterizes approximately 80% of newborns and describes a newborn with a normal length, weight, head circumference, and body mass index (Panda, 2015). Being in the AGA group confers the lowest risk for any problems. These infants have lower morbidity and mortality than other groups.

Small for gestational age (SGA) describes newborns who typically weigh less than 2,500 grams (5 lb 8 oz) at term due to less growth in utero than expected. A newborn is also classified as SGA if his or her birth weight is at or below the 10th percentile as correlated with the number of weeks of gestation on a growth chart.

Large for gestational age (LGA) describes newborns whose birth weight is above the 90th percentile on a growth chart and who weigh more than 4,000 g (8 lb 13 oz) at term due to accelerated overgrowth for length of gestation (Sacks et al., 2015). The following terms describe other newborns with marginal weights at birth and of any gestational age:

• **Low birth weight:** less than 2,500 g (5.5 lb) (Fig. 23.1)

• **Very low birth weight:** less than 1,500 g (3 lb 5 oz)

• **Extremely low birth weight:** less than 1,000 g (2 lb 3 oz)

Small-for-Gestational-Age Newborns

Newborns are considered SGA when they weigh less than 2,500 g (5 lb 8 oz) or fall below the 10th percentile for length, weight, or head circumference on a growth chart for gestational age. These infants can be preterm, term, or post-term.

FIGURE 23.1 A low–birth-weight newborn in an isolette.

Concept Mastery Alert

Planning Priority Care for the Small for Gestational Age Infant

Infants who are small for gestational age (SGA) are different from preterm infants who often have underdeveloped respiratory systems. SGA infants often have developed respiratory systems, but need frequent observations for hypoglycemia because of inadequate glycogen stores. This leads to the need for frequent and early feedings.

In some SGA newborns, the rate of growth does not meet the expected growth pattern. Termed fetal growth restriction, these newborns also are considered at risk, with the perinatal morbidity and mortality rate increased substantially compared with that of the AGA newborn (Cunningham et al., 2014). Fetal

growth restriction is the pathologic counterpart of SGA. However, an important distinction to make between SGA and fetal growth restriction newborns is that not all who are SGA have growth restriction. The converse also is true: not all newborns who have fetal growth restriction are SGA. Some SGA newborns are constitutionally small; that is, they are statistically small but otherwise healthy.

Historically, fetal growth restriction has been categorized as symmetric or asymmetric. Symmetric fetal growth restriction (an insult that occurs early at less than 28 weeks in the gestation) refers to fetuses with equally poor growth rates of the head, the abdomen, and the long bones. All parameters of growth are affected. Typically these infants have the poorest long-term prognosis and are never able to catch up in size when compared with unaffected children (Nagtalon-Ramos, 2014). Asymmetric fetal growth restriction (insult occurs late —at more than 28 weeks' gestation) refers to infants whose head and long bones are spared compared with their abdomen and internal organs. The brain and heart are spared and are larger, but overall weight and organ sizes are reduced. Generally, the asymmetrical fetal growth restriction infant has a better prognosis than one who is symmetrically fetal growth restriction. Once the infant is born, optimal nutrition usually restores normal growth potential. The current belief is that in most cases fetal growth restriction is a continuum from symmetrical (early stages) to asymmetrical (late stages). There is a strong association between stillbirth and fetal growth restriction. Early detection and management of fetal growth restriction can lead to reduced morbidity and mortality. A recent study found that combined screening of maternal factors and biophysical profiles conducted at 30 to 34 weeks' gestation can identify a large proportion of pregnancies that subsequently will have SGA newborns (Bakalis et al., 2015).

Fetal growth is dependent on genetic, placental, and maternal factors. Cognitive and motor development during infancy forms the basis for children's subsequent development. Newborns that experience nutritional deficiencies in utero and are born SGA are at risk for cognitive deficits that can undermine their academic performance throughout their lives. SGA infants are associated with increased neonatal morbidity and mortality as well as short stature, cardiovascular disease, insulin resistance, diabetes mellitus type 2, dyslipidemia, and end-stage renal disease in adulthood. In addition, SGA children have decreased levels of intelligence and cognition, although the effects are mostly subtle. The overall outcome of each child is the result of a complex interaction between intrauterine and extrauterine factors (Oros et al., 2014).

The fetus is thought to have an inherent growth potential that, under normal

circumstances, yields a healthy newborn of appropriate size. The maternal–placental–fetal units act in harmony to meet the needs of the fetus during gestation. However, growth potential in the fetus can be limited, and this is analogous to failure to thrive in the infant. The causes of both can be intrinsic or environmental. Factors that can contribute to the birth of an SGA newborn are highlighted in Box 23.1.

Nursing Assessment

Assessment of the SGA infant begins by reviewing the maternal history to identify risk factors such as smoking, drug abuse, alcohol consumption, preeclampsia, anemia, uteroplacental insufficiency, intrauterine viral infection, cord prolapse, chronic maternal illness, hypertension, multiple gestation, or genetic disorders. This information allows the nurse to anticipate a possible problem and to be prepared to intervene quickly should one occur. At birth, perform a thorough physical examination, closely observing the newborn for typical characteristics, including:

• Head disproportionately large compared with rest of body

• Wasted appearance of extremities

BOX 23.1

POTENTIAL FACTORS CONTRIBUTING TO THE BIRTH OF SMALL-FOR-GESTATIONAL-AGE NEWBORNS

Maternal Causes

• Chronic hypertension

• Diabetes mellitus with vascular disease

• Autoimmune diseases

• Living at a high altitude (hypoxia)

• Smoking or exposure to passive smoke

• Periodontal disease of the mouth

• Maternal age of <20 or >34 years old

• Failure to seek any prenatal care

• Substandard living conditions

• Low socioeconomic status

• Abuse and violence

• Substance abuse (heroin, cocaine, methamphetamines)

• Hemoglobinopathies (sickle cell anemia)

• Preeclampsia

• Exposure to occupational hazards

• Chronic renal disease

• Maternal nutrition (malnutrition or obesity)

• Extreme maternal stress

• TORCH group infections

Placental Factors

- Abnormal cord insertion
- Chronic abruption
- Decreased surface area, infarction
- Decreased placental weight
- Placenta previa
- Placental insufficiency

• Reduced subcutaneous fat stores

• Jittery secondary to hypoglycemia

• Temperature instability

• Decreased amount of breast tissue

• Scaphoid abdomen (sunken appearance)

• Wide skull sutures secondary to inadequate bone growth

• Poor muscle tone over buttocks and cheeks

• Loose and dry skin that appears oversized

• Thin umbilical cord

Also assess the SGA newborn for any congenital malformations, neurologic insults, or indications of infection. SGA newborns commonly face problems after birth because of the decrease in placental function during gestation. Table 23.1 highlights some of the common problems associated with SGA newborns and others experiencing a variation in birth weight or gestational age. Anticipate the need for and provide resuscitation as indicated by the newborn's condition.

Nursing Management

Interventions for the SGA infant may include obtaining weight, length, and head circumference, comparing them with standards, and documenting the findings. Perform frequent serial blood glucose measurements as ordered and monitor vital signs, being particularly alert for changes in respiratory status that might indicate respiratory distress. Institute measures to maintain a neutral thermal environment to prevent cold stress and acidosis.

Metabolic needs are increased for catch-up growth. Initiate early and frequent oral feedings unless contraindicated. At birth the newborn's glucose level is approximately 70% of the mother's serum glucose. Neonatal hypoglycemia is a major cause of brain injury since the brain needs glucose continuously as a primary source of energy (Chandran et al., 2015). Any newborn stressed at birth uses up available glucose stores with resulting hypoglycemia, a plasma glucose concentration at or below 40 mg/dL (Nagtalon-Ramos, 2014). With the loss of the placenta at birth, the newborn now must assume control of glucose homeostasis through intermittent oral feedings. If oral feedings are not accepted, an intravenous infusion with 10% dextrose in water may be needed to maintain the glucose level above 40 mg/dL. Weigh the newborn daily and ensure that he or she has adequate rest periods to decrease metabolic requirements. Monitor feeding tolerance, sucking, and swallowing ability.

POLYCYTHEMIA

Polycythemia is not uncommon and is a potentially serious disorder of newborns. It is defined as a venous hematocrit above 65% and hemoglobin of more than 20 g. The hematocrit in a newborn peaks between 6 to 12 hours of age and decreases gradually after that. Polycythemia occurs in up to 12% of neonates, and occurs commonly in SGA newborns 6 to 12 hours after birth (Lessaris, 2015). The relationship between hematocrit and viscosity is almost linear until 65% and exponential thereafter. Increased viscosity of blood is associated with symptoms of hypoperfusion. Clinical features related to hyperviscosity may affect all organ systems. Hyperviscosity of blood results in increased resistance to blood flow and decreased oxygen delivery. In the newborn, hyperviscosity can cause abnormalities of central nervous system function, hypoglycemia, decreased renal function, cardiorespiratory distress, and coagulation disorders. Hyperviscosity has been reported to be associated with long-term motor and cognitive neurodevelopmental disorders (Fanaroff &

Fanaroff, 2014). SGA newborns, infants of mothers with diabetes, newborns with jaundice, and multiple births are at risk for polycythemia. They should therefore undergo screening at 2, 12, and 24 hours of age (Alsafadi et al., 2014).

TABLE 23.1 COMMON PROBLEMS ASSOCIATED WITH NEWBORNS EXPERIENCING A VARIATION IN BIRTH WEIGHT OR GESTATIONAL AGE

Problem	Occurrence	Etiology/Pathophysiology	Assessment Findings	Nursing Implications
Perinatal asphyxia	SGA newborns (common)	Poor tolerance to stress of labor, frequently leading to acidosis and hypoxia Living in hypoxic environment prior to birth due to placental insufficiency, leaving little to no oxygen reserves available to withstand stress of labor: – Uterine contractions increase hypoxic stress – Possible depletion of glycogen stores due to chronic hypoxic state, leading to fetal distress – Impaired uteroplacental circulation due to maternal and uterine conditions predisposing to perinatal depression Compromised newborn at birth experiencing difficulty adjusting to extrauterine environment	Fetal distress (bradycardia, decelerations) during labor Low Apgar scores Potential meconium passage into amniotic fluid	Anticipate possible problem; assess for maternal risk factors. Initiate resuscitation measures immediately at birth.
	Post-term newborns	Placental deprivation or oligohydramnios, leading to cord compression and subsequent reduction in perfusion to fetus		
	Preterm newborns (common)	Surfactant deficiency Unstable chest wall Immaturity of respiratory control centers in the CNS Small respiratory passages, increasing risk for obstruction Inability to clear mucus from airways		
Difficulty with thermoregulation	SGA newborns (common)	Less muscle mass, less brown fat, less heat-preserving subcutaneous fat, and limited ability to control skin capillaries Associated with depleted glycogen stores, poor subcutaneous fat stores, and disturbances in CNS thermoregulation due to hypoxia Increased risk for acidosis and hypoglycemia secondary to metabolic stress	Temperature <36.4° C; temperature instability; skin cool to touch; cyanosis of hands and feet Bradypnea (<25 breaths/min) and tachypnea (>60 breaths/min) Tremors, irritability Wheezing, crackles, retractions Restlessness, lethargy Hypotonia	Maintain a neutral thermal environment to promote stabilization of newborn's temperature. Assess skin temperature and respiration characteristics. Monitor arterial blood gases and blood glucose levels.
	Post-term newborns	Loss of subcutaneous fat secondary to placental insufficiency Use of stored nutrients for nutrition due to lost ability of placenta to nourish fetus Subsequent wasting of subcutaneous fat, muscle, or both	Weak or high-pitched cry Seizures Poor feeding Grunting Acidosis	Eliminate sources of heat loss: – Dry newborn thoroughly. – Wrap in warmed blanket with stockinette cap on head –Use radiant heat source.

Problem	Occurrence	Etiology/Pathophysiology	Assessment Findings	Nursing Implications
	Preterm newborns (common)	Loss of natural insulation (subcutaneous fat) important in temperature regulation Immaturity of CNS (temperature-regulating center) interferes with ability to regulate body temperature Inadequate amounts of subcutaneous fat Lack of muscle tone and flexion to conserve heat		
	Late preterm infant (common)	Inadequate brown fat to generate heat Limited muscle mass activity, reducing ability to produce own heat Inability to shiver to generate heat		
Hypoglycemia	SGA newborns (common)	Increased metabolic rate and lack of adequate glycogen stores to meet newborn's metabolic needs	Often subtle Lethargy, tachycardia Respiratory distress	Monitor blood glucose levels, initially on arrival to nursery and hourly thereafter.
	LGA newborns (common)	Commonly associated with infants of mothers with diabetes Abrupt cessation of high-glucose maternal blood supply with birth and continued insulin production by the newborn	Jitteriness Drowsiness Poor feeding, feeble sucking Hypothermia, temperature instability	Maintain fluid and electrolyte balance. Watch for subtle changes. Initiate early oral feedings if possible; if not, administer IV infusion with 10% dextrose in water.
	Post-term newborns	Limited ability to release glucagons and catecholamines, which normally stimulate glucagon breakdown and glucose release Hypoxia secondary to depleted glycogen reserves Placental insufficiency secondary to placental aging contributing to chronic fetal nutritional deficiency further depleting glycogen stores	Diaphoresis Weak cry Seizures Hypotonia Blood glucose levels <40 mg/dL for term newborns, <20 mg/dL for preterm newborns	
	Preterm newborns	Immature sucking and swallowing leading to insufficient intake Perinatal hypoxia		
	Late preterm infants	Increased energy expenditure Decreased subcutaneous and brown fat with little to no glycogen stores		

Polycythemia	SGA newborns	Chronic mild hypoxia secondary to placental insufficiency Stimulation of erythropoietin release, leading to increased RBC production	Venous hematocrit >65% Plethora (ruddy appearance) Weak sucking reflex Tachypnea Jaundice Lethargy Jitteriness Hypotonia Irritability Feeding Difficulties Difficulty in arousing Seizures	Ensure adequate hydration (orally or IV) Monitor hematocrit levels (goal is ~60%) Administer partial exchange transfusion, albumin, or normal saline IV to reduce RBC volume and increase fluid volume (controversial).
	LGA newborns	Secondary to fetal hypoxia, trauma with bleeding, increased erythropoietin production, or delayed cord clamping		
	Post-term newborns	Intrauterine hypoxia triggers increased RBC cell production to compensate for lower oxygen levels.		
Meconium aspiration	SGA newborns	Release of meconium into amniotic fluid prior to birth Inhalation of meconium-containing amniotic fluid by the newborn, leading to aspiration	Green amniotic fluid with rupture of membranes during labor Green staining of the umbilical cord or fingernails Difficulty initiating respirations	Initiate resuscitation measures as necessary. Suction airways and support ventilation (see Chapter 24 for more information).
	Post-term newborns	Commonly associated with chronic intrauterine hypoxia Struggling by fetus making respiratory efforts and bearing down with abdominal muscles, leading to expulsion of meconium into amniotic fluid Normal sucking and swallowing by fetus leads to meconium filling airways.		
Hyperbilirubinemia	LGA newborns (common)	Associated with polycythemia and RBC breakdown Inability to tolerate feedings in the first few days of life, leading to increased enterohepatic circulation of bilirubin	Elevated serum bilirubin levels Jaundice Tea-colored urine Clay-colored stools	Ensure adequate hydration. Institute early feedings if possible. Administer phototherapy (see Chapter 24 for more information).
	Preterm newborns	Excessive bruising secondary to birth trauma, leading to higher-than-normal bilirubin levels		
	Late preterm infants	Increased breakdown of RBCs and immature liver function to handle excess load		
Birth trauma	LGA newborns	Large size requiring use of operative birth procedure	Obvious deformities Bruising Edema Asymmetrical movement	Perform complete physical and neurologic assessment of the newborn. Note symmetry of structure and function. Assist parents in understanding situation (see Chapter 24 for more information).

Adapted from Fanaroff, A. A., & Fanaroff, J. M. (2014). *Klaus and Fanaroff's care of the high-risk neonate* (6th ed.). Philadelphia, PA: Elsevier; Creasy, R. K., Resnik, R., Iams, J. D., Lockwood, C. J., Moore, T., & Greene, M. F. (2014). *Creasy and Resnik's maternal-fetal medicine: Principles and practice* (7th ed.). St. Louis, MO: Saunders Elsevier; Nagtalon-Ramos, J. (2014). *Maternal-newborn nursing care: Best evidence-based practices.* Philadelphia, PA: F.A. Davis Company; and Verklan, M. T., & Walden, M. (2014). *Core curriculum for neonatal intensive care nursing.*(5th ed.). St. Louis, MO: Saunders Elsevier.

Observe for clinical signs of polycythemia (respiratory distress, cyanosis, jitteriness, jaundice, ruddy skin, lethargy) and monitor blood results. Asymptomatic newborns with a hematocrit between 65% and 70% may simply be supported with fluids, close observation, and a repeat hematocrit level in 12 hours (Mahajan, Une, & Bansal, 2015). If the newborn is symptomatic, a partial exchange transfusion with replacement of removed red blood cell volume with volume expanders may be used, but this treatment is considered controversial and not validated by current evidence-based practice research.

Provide anticipatory guidance to parents about any treatments and procedures that are being done. Emphasize the need for close follow-up and careful monitoring of the infant's growth in length, weight, and head circumference and feeding patterns throughout the first year of life to confirm any "catch-up" growth taking place.

Large-for-Gestational-Age Newborns

A newborn whose weight is above the 90th percentile on growth charts is defined as LGA. The range of weight is 4,000 to 5,000 g, or more than 9 lb. LGA infants may be preterm, term, or post-term. Based on these definitions, up to 10% of all births involve an LGA newborn. This large size can place the mother and fetus or newborn at risk for adverse outcomes (Creasy et al., 2014).

Because of the newborn's large size, vaginal birth may be difficult and occasionally results in birth injury. In addition, shoulder dystocia, clavicular fractures, and facial palsies are common. The incidence of cesarean births is very high with LGA newborns to avoid arrested labor and birth trauma.

Take Note!

Maternal diabetes is commonly associated with LGA newborns. However, due to poor placental perfusion, the newborn may experience fetal growth restriction and be SGA.

Nursing Assessment

Assessment of the LGA newborn begins with a review of the maternal history, which can provide clues as to whether the woman has an increased risk of giving birth to a LGA newborn. Maternal factors that increase the chance of bearing a LGA newborn include maternal diabetes mellitus or glucose intolerance, multiparity, prior history of a macrosomic infant, post-term gestation, maternal obesity, paternal height, gestational weight gain, male fetus, and genetics (Donnelley et al., 2014).

At birth, assess the newborn for common characteristics. The typical LGA newborn has a large body and appears plump and full faced. The increase in body size is proportional. However, the head circumference and body length are in the upper limits of intrauterine growth. These newborns have poor motor skills and have difficulty regulating behavioral states. LGA newborns are more difficult to arouse to a quiet alert state (Neonatal Handbook, 2015a).

Thoroughly assess the LGA newborn at birth to identify traumatic birth injuries such as fractured clavicles, brachial palsy, facial paralysis, phrenic nerve

palsy, skull fractures, or hematomas. Perform a neurologic examination to identify any nerve palsies, looking for abnormalities such as immobility of the upper arm. Observe and document any injuries discovered to allow for early intervention and improved outcomes.

LGA infants are at risk for hypoglycemia related to early depletion of glycogen stores in the liver. Obtain frequent blood glucose levels as ordered to evaluate for hypoglycemia. The clinical signs are often subtle and include lethargy, apathy, drowsiness, irritability, tachypnea, weak crying, temperature instability, jitteriness, seizures, apnea, bradycardia, cyanosis or pallor, feeble sucking and poor feeding, hypotonia, and coma. Other disorders, including septicemia, severe respiratory distress, and congenital heart disease, may present with similar findings. In addition, be alert for other common problems, such as polycythemia and hyperbilirubinemia (see Table 23.1 earlier in this chapter).

Nursing Management

Hypoglycemia in a neonate is defined as blood glucose value below 40 mg/dL. It is commonly associated with a variety of neonatal conditions like prematurity, fetal growth restriction, fetal growth restriction, and maternal diabetes. It may be asymptomatic in some newborns. Screening for hypoglycemia in high-risk LGA infants is essential. Supervised breast-feeding or formula feeding may be initial treatment options in asymptomatic hypoglycemia. However, symptomatic hypoglycemia should always be treated with a continuous infusion of parenteral dextrose. LGA infants needing dextrose infusion rates above 12 mg/kg/min should be investigated for a definite cause of hypoglycemia. Hypoglycemia has been linked to poor neurodevelopmental outcome, and hence aggressive screening and treatment are recommended (Mitanchez et al., 2015).

Assist in stabilizing the LGA newborn. Monitor blood glucose levels within 30 minutes of birth and repeat the screening every hour. Recheck levels before feedings and also immediately in any infant suspected of having or showing clinical signs of hypoglycemia, regardless of age. To help prevent hypoglycemia, initiate feedings, which can be formula or breast milk, with intravenous glucose supplementation as needed. Monitor and record intake and output and obtain daily weights to aid in evaluating nutritional intake.

Observe for signs of polycythemia and hyperbilirubinemia and report any immediately to the health care provider so that early interventions can be taken to prevent poor long-term neurologic development outcomes. Polycythemia and

hyperviscosity are associated with fine and gross motor delays, speech delays, and neurologic sequelae (Neonatal Handbook, 2015b). Increasing fluid volume aids in decreasing blood viscosity. Partial exchange transfusion with plasma or normal saline may be used to lower hematocrit and decrease blood viscosity, but this treatment remains controversial (Lessaris, 2015). Hydration, early feedings, and phototherapy are used to treat hyperbilirubinemia (see Chapter 24 for more information about hyperbilirubinemia). Provide parental guidance about the treatments and procedures being done and about the need for follow-up care for any abnormalities identified.

GESTATIONAL AGE VARIATIONS

The mean duration of pregnancy, calculated from the first day of the last normal menstrual period, is approximately 280 days, or 40 weeks. Gestational age is typically measured in weeks: a newborn born before completion of 37 weeks is classified as a preterm newborn and one born after completion of 42 weeks is classified as a post-term newborn. An infant born from the first day of the 38th week through 42 weeks is classified as a term newborn. An additional classification has been added, the late preterm newborn (near term)—one who is born between 34 weeks and 36 weeks, 6 days of gestation.

• **Preterm newborn:** before 37 completed weeks of gestation

• **Late preterm newborn** (near term): 34 to $36^6/_7$ weeks

• **Full term newborn:** 38 through 41 completed weeks of gestation

• **Post-term newborn:** 42 weeks or more

Precise knowledge of a newborn's gestational age is imperative for effective postnatal management. Determination of gestational age by the nurse assists in planning appropriate care for the newborn and provides important information regarding potential problems that need interventions. See Chapter 18 for more information on assessing gestational age.

Take Note!

Although preterm and post-term newborns may appear to be at opposite ends of the gestational age spectrum and are very different in size and appearance, both are at high risk and need special care.

Preterm Newborn

A preterm newborn is one who is born before the completion of 37 weeks' gestation. There has been improved survival of preterm infants due to the advancing technology and improved evidence-based perinatal care. Although the national birth rate has been declining since the 1990s, the preterm birth rate has been climbing rapidly. Approximately one in nine infants, or nearly half a million infants, is born before the 37th week of gestation (March of Dimes, 2015b). Prematurity is now the leading cause of death worldwide, and can cause long-term health problems for these infants throughout their lives and affect their education and ability to work. Prematurity costs society more than $26 billion annually and takes a high toll on families.

The etiology of about 40% of all preterm births is unknown (March of Dimes, 2015c). Research suggests that four main etiologies may lead to spontaneous premature labor and birth:

• *Infections/inflammation*. Studies suggest that premature labor is often triggered by the body's natural immune response to certain bacterial infections, such as those involving the genital and urinary tracts and fetal membranes. Even infections far away from the reproductive organs, such as periodontal disease, may contribute to premature births.

• *Maternal or fetal stress*. Chronic psychosocial stress in the mother or physical stress (such as insufficient blood flow from the placenta) in the fetus appears to result in production of a stress-related hormone called corticotropin-releasing hormone (CRH). CRH may stimulate production of a cascade of other hormones that trigger uterine contractions and premature birth.

• *Bleeding*. The uterus may bleed because of problems such as placental abruption. Bleeding triggers the release of various proteins involved in blood clotting that also appear to stimulate uterine contractions.

• *Stretching*. The uterus may become overstretched by the presence of two or more fetuses, excessive amounts of amniotic fluid, or uterine or placental abnormalities, leading to the release of chemicals that stimulate uterine contractions (March of Dimes, 2015d).

Preterm births take an enormous financial toll, estimated to be in the billions of dollars. They also take an emotional toll on those involved.

Changes in perinatal care practices, including regional care, have reduced newborn mortality rates. Transporting high-risk pregnant women to a tertiary center for birth rather than transferring the neonate after birth is associated with a reduction in neonatal mortality and morbidity (Kaneko et al., 2015). Despite increasing survival rates, preterm infants continue to be at high risk for neurodevelopmental disorders such as cerebral palsy, intellectual disability, intraventricular hemorrhage, congenital anomalies, neurosensory impairment, behavioral problems, high frequency attention problems, psychiatric disorders, and chronic lung disease (Wilson-Costello & Payne, 2016). Making sure that all pregnant women receive quality prenatal care throughout pregnancy is a major method for preventing preterm births.

Effects of Prematurity on Body Systems

Since the preterm newborn did not remain in utero long enough, every body system may be immature, affecting the newborn's transition from intrauterine to extrauterine life and placing him or her at risk for complications. Without full development, organ systems are not capable of functioning at the level needed to maintain extrauterine homeostasis (Salam et al., 2014).

> *Recall Anna, who was described at the beginning of the chapter; she gave birth to a newborn at 7 months' gestation. What problems would you anticipate that her newborn might have?*

RESPIRATORY SYSTEM

The respiratory system is one of the last body systems to mature. Therefore, the preterm newborn is at great risk for respiratory complications. A few of the problems that affect the preterm newborn's breathing ability and adjustment to extrauterine life include:

• Surfactant deficiency, leading to the development of respiratory distress syndrome

• Unstable chest wall, leading to atelectasis

• Immature respiratory control centers, leading to apnea

• Smaller respiratory passages, leading to an increased risk for obstruction

• Inability to clear fluid from passages, leading to transient tachypnea

CARDIOVASCULAR SYSTEM

The preterm newborn has great difficulty making the transition from intrauterine to extrauterine life in terms of changing from a fetal to a newborn circulation pattern. Higher oxygen levels in the circulation once air breathing begins spur this transition. If the oxygen levels remain low secondary to perinatal asphyxia, the fetal pattern of circulation may persist, causing blood flow to bypass the lungs. Another problem affecting the cardiovascular system is the increased incidence of congenital anomalies associated with continued fetal circulation—patent ductus arteriosus and an open foramen ovale. In addition, impaired regulation of blood pressure in preterm newborns may cause fluctuations throughout the circulatory system. Of special note is cerebral blood flow, which may predispose the fragile blood vessels in the brain to rupture, causing intracranial hemorrhage (Fanaroff & Fanaroff, 2014).

GASTROINTESTINAL SYSTEM

Preterm newborns usually lack the neuromuscular coordination required to maintain the sucking, swallowing, and breathing regimen necessary for sufficient calorie and fluid intake to support growth. Perinatal hypoxia causes shunting of blood from the gut to more important organs such as the heart and brain. Subsequently, ischemia and damage to the intestinal wall can occur. This combination of shunting, ischemia, damage to the intestinal wall, and poor sucking ability places the preterm infant at risk for malnutrition and weight loss.

In addition, preterm newborns have a small stomach capacity, weak abdominal muscles, compromised metabolic function, limited ability to digest proteins and absorb nutrients, and weak or absent suck and gag reflexes. All of these limitations place the preterm newborn at risk for nutritional deficiency and subsequent growth and development delays (Neonatal Handbook, 2015c).

The preterm infant's ability to coordinate sucking, swallowing, and breathing are challenged. As a result, preterm infants often require enteral or intravenous feeding. Enteral tube feeding will help to conserve energy even in an infant who is able to suck. The exact nutritional needs of preterm infants depend on their gestational age, postnatal age, weight, route of nutritional intake, growth rate, activity, and thermal environment. Preterm infants that are ill or experiencing stressful situations have higher energy requirements. Preterm infants take time to establish enteral intakes, and parenteral nutrition is now an integral component of care, but safe amounts of macronutrients, and the optimal amino acid and lipid composition remains an uncertainty (Embleton, Morgan, & King, 2015).

Currently, minimal enteral feeding is used to prepare the preterm newborn's gut to overcome the many feeding difficulties associated with gastrointestinal immaturity. It involves the introduction of small amounts, usually 0.5 to 1 mL/kg/hr, of enteral feeding to induce surges in gut hormones that enhance maturation of the intestine. This minute amount of breast milk or formula given via gavage (tube) feeding prepares the gut to absorb future introduction of nutrients. It builds mucosal bulk, stimulates development of enzymes, enhances pancreatic function, stimulates maturation of gastrointestinal hormones, reduces gastrointestinal distention and malabsorption, and enhances transition to oral feedings (Koletzko, Poindexter, & Uauy, 2014).

RENAL SYSTEM

The renal system of the preterm newborn is immature, reducing the baby's ability to concentrate urine and slowing the glomerular filtration rate. As a result, the risk for fluid retention, with subsequent fluid and electrolyte disturbances, increases. In addition, preterm newborns have limited ability to clear drugs from their systems, thereby increasing the risk of drug toxicity. Close monitoring of the preterm newborn's acid–base and electrolyte balance is critical to identify metabolic inconsistencies. Prescribed medications require strict evaluation to prevent overwhelming the preterm baby's immature renal system.

IMMUNE SYSTEM

The preterm newborn's immune system is very immature, increasing his or her susceptibility to infections. A deficiency of IgG may occur because transplacental transfer does not occur until after 34 weeks' gestation. This protection is lacking if the baby was born before this time. In addition, preterm newborns have an impaired ability to manufacture antibodies to fight infection if they were exposed to pathogens during the birth process. Moreover, the preterm newborn's thin skin and fragile blood vessels provide a limited protective barrier, adding to the increased risk for infection. Thus, anticipating and preventing infections is the goal; preventing infections has a better outcome than treating them.

CENTRAL NERVOUS SYSTEM

The preterm newborn is susceptible to injury and insult to the central nervous system, increasing the potential for long-term disability into adulthood. Like all

newborns, preterm newborns have difficulty with temperature regulation and maintaining stability. However, their risk for heat loss is compounded by inadequate amounts of insulating subcutaneous fat; lack of muscle tone and flexion to conserve heat; inadequate brown fat to generate heat; limited muscle mass activity, reducing the possibility of producing their own heat; inability to shiver to generate heat; and an immature temperature-regulating center in the brain (Kenner & Lott, 2014). It is crucial to prevent cold stress, which would increase the newborn's metabolic and oxygen needs. The goal is to create a neutral thermal environment in which oxygen consumption is minimal but body temperature is maintained (Fanaroff & Fanaroff, 2014).

In addition, the preterm newborn is especially susceptible to hypoglycemia due to immature glucose control mechanisms, decreased glucose stores, and a reduced availability of alternative fuels such as ketone bodies.

Take Note!

Glucose is needed by the brain and central nervous system to maintain and support numerous body system functions.

Nursing Assessment

Preterm newborns are at high risk for numerous problems and require special care. When preterm labor develops and cannot be stopped by medical interventions, plans are necessary for appropriate management of the mother and the preterm newborn, such as transporting them to a regional center with facilities to care for preterm newborns or notifying the facility's NICU. Depending on the degree of prematurity, the preterm newborn may be kept in the NICU for months.

A thorough assessment of the preterm newborn upon admission to the nursery provides a baseline from which to identify changes in clinical status. Be aware of the common physical characteristics and be able to identify any deviation from the expected (Fig. 23.2). Common physical characteristics of preterm infants may include:

• Birth weight of less than 5.5 lb

• Scrawny appearance

• Head disproportionately larger than chest circumference

- Poor muscle tone
- Minimal subcutaneous fat
- Undescended testes in males
- Prominent clitoris and labia minora in females
- Plentiful lanugo (soft, downy hair), especially over the face and back
- Poorly formed ear pinna, with soft, pliable cartilage
- Fused eyelids
- Soft and spongy skull bones, especially along suture lines
- Matted scalp hair, woolly in appearance
- Absent-to-a-few creases in the soles and palms
- Minimal scrotal rugae in male infants;
- Thin, transparent skin with visible veins
- Breast and nipples not clearly delineated
- Abundant vernix caseosa (Verklan & Walden, 2014).

Be alert for evidence that might suggest that the preterm newborn is developing a complication (see Table 23.1).

Review the maternal history to identify risk factors for preterm birth and check antepartum and intrapartum records for maternal infections to anticipate the need for treatment. Maternal risk factors associated with preterm birth include a previous preterm delivery, low socioeconomic status, preeclampsia, hypertension, poor maternal nutrition, smoking, multiple gestation, infection, advanced maternal age, and substance abuse.

Assess the newborn's gestational age and assess for fetal growth restriction if appropriate. Inspect the newborn's skin closely, especially skin color. Assess vital signs, including temperature via skin probe to identify hypothermia or fever, and heart rate for tachycardia or bradycardia. Evaluate the newborn's respiratory effort and respiratory rate. Observe for periods of apnea lasting longer than 20 seconds. Monitor oxygen saturation levels by pulse oximetry to validate perfusion status. Note and report any signs of respiratory distress. Auscultate lung and heart sounds, being especially alert for possible murmur, which would indicate the presence of patent ductus arteriosus in a preterm newborn. Assess neurologic status by observing the newborn's behavior. Note any restlessness, hypotonia, or weak cry or sucking effort and report unusual

findings.

FIGURE 23.2 Characteristics of a preterm newborn. **A.** Few plantar creases. **B.** Soft, pliable ear cartilage, matted hair, and fused eyelids. **C.** Lax posture with poor muscle tone. **D.** Breast and nipple area barely visible. **E.** Male genitalia with minimal rugae on scrotum. **F.** Female genitalia with prominent labia and clitoris.

Monitor laboratory studies such as hemoglobin and hematocrit for signs of polycythemia. Screen for hypoglycemia upon admission and then hourly, always observing for nonspecific signs of hypoglycemia such as lethargy, poor feeding, and seizures. Evaluate serum bilirubin concentrations.

Finally, assess the mother and family members. Identify family strengths and coping mechanisms to establish a basis for intervention.

Nursing Management

During the past 50 years in the United States, the rising preterm birth rate, a progressive decrease in preterm mortality, and a lowering of the limit of viability have made preterm birth a significant public health problem. It is estimated that, each day throughout the world, over 40,000 infants are born prematurely.

Preterm birth creates a crisis for the mother and family. Multiple studies have found that hospitalization for preterm newborns is often followed by negative mental health/behavioral outcomes, anxiety and depressive disorders, and long-term neurologic sequelae. Emerging evidence suggests that partners/significant others experience high rates of psychological stress in the first few months after a preterm birth (Treyvaud, 2014). Preterm newborns present with immaturity of all organ systems, abundant physiologic challenges, and significant morbidity and mortality globally (Salam et al., 2014). The nurse must be vigilant for complications when managing preterm newborns (Fig. 23.3 and Nursing Care Plan 23.1).

FIGURE 23.3 The physical condition of a preterm newborn demands skilled assessment and nursing care.

PROMOTING OXYGENATION

Newborns normally start to breathe without assistance and often cry after birth, being stimulated by a change in pressure gradients and environmental temperature. The work of taking that first breath is primarily due to overcoming the surface tension of the walls of the terminal lung units at the gas–tissue interface. Subsequent breaths require less inspiratory pressure since there is an increase in functional capacity and air retained. By 1 minute of age, most newborns are breathing well. A newborn who fails to establish adequate, sustained respiration after birth is said to have **asphyxia** (perinatal acidosis), which is the deprivation of oxygen during the birth process, resulting in fetal hypoxia that can lead to organ damage. Asphyxia is the most common clinical insult in the perinatal period that results in brain injury, which may lead to intellectual disability, cerebral palsy, or seizures (Herrera-Marschitz et al., 2015).

The preterm infant lacks surfactant. Surfactant lowers surface tension in the alveoli and stabilizes them to prevent their collapse. Even if preterm newborns can initiate respirations, they have a limited ability to retain air due to insufficient surfactant. Therefore, preterm newborns develop atelectasis quickly without alveoli stabilization. The inability to initiate and establish respirations leads to hypoxemia and ultimately hypoxia (decreased oxygen), acidosis (decreased pH), and hypercarbia (increased carbon dioxide). This change in the

newborn's biochemical environment may inhibit the transition to extrauterine circulation, thus allowing fetal circulation patterns to persist.

Failure to initiate extrauterine breathing or failure to breathe well after birth leads to hypoxia (too little oxygen in the cells of the body). As a result, the heart rate falls, cyanosis develops, temperature decreases, blood pressure decreases, and respirations are altered (apnea, tachypnea, retractions, grunting, and nasal flaring) and the newborn becomes hypotonic and unresponsive. Although this can happen with any newborn, the risk is higher in preterm newborns.

Prevention and early identification of at risk newborns are essential. Prenatal risk factors that can help identify the newborn that may need resuscitation at birth secondary to asphyxia include:

• History of substance abuse

• Gestational hypertension

• Fetal distress due to hypoxia before birth

• Chronic maternal diseases such as diabetes or a heart or renal condition

• Maternal or perinatal infection

• Placental problems (placenta previa or abruptio placentae)

• Umbilical cord problems (nuchal or prolapsed)

• Difficult or traumatic birth

• Multiple births

• Congenital heart disease

• Maternal anesthesia or recent analgesia

• Preterm or post-term birth (Neonatal Handbook, 2015d).

NURSING CARE PLAN 23.1

Overview of the Care of a Preterm Newborn

Alice, an 18-year-old, felt that she had done everything right during her first pregnancy and certainly didn't anticipate giving birth to a preterm newborn at 32 weeks' gestation. When Mary Kaye was born, she had respiratory distress and hypoglycemia and couldn't stabilize her temperature. Assessment revealed the following: newborn described as scrawny in appearance; skin thin and transparent with prominent veins over abdomen; hypotonia with lax, extended positioning; weak sucking reflex when nipple offered; respiratory distress with tachypnea (70 breaths/min), nasal flaring, and sternal retractions; low blood glucose level suggested by lethargy, tachycardia, jitteriness; axillary temperature of 96.8° F (36° C) despite warmed blanket; weight 2,146 g (4.73 lb); length 45 cm (17.72 in).

NURSING DIAGNOSIS: Ineffective breathing pattern related to immature respiratory system and respiratory distress as evidenced by tachypnea, nasal flaring, and sternal retractions

Outcome Identification and Evaluation
The newborn's respiratory status will return to an adequate level of functioning as evidenced by rate remaining within 30 to 60 breaths/min, maintenance of acceptable oxygen saturation levels, and minimal to absent signs of respiratory distress.

Interventions: *Promoting Optimal Breathing Pattern*
- Assess gestational age and risk factors for respiratory distress *to allow early detection.*
- Anticipate need for bag and mask setup and wall suction *to allow for prompt intervention should respiratory status continue to worsen.*
- Assess respiratory effort (rate, character, effort) *to identify changes.*
- Assess heart rate for tachycardia and auscultate heart sounds *to determine worsening of condition.*
- Observe for cues (grunting, shallow respirations, tachypnea, apnea, tachycardia, central cyanosis, hypotonia, increased effort) *to identify need*

for additional oxygen.
- Maintain slight head elevation *to prevent upper airway obstruction.*
- Assess skin color *to evaluate tissue perfusion.*
- Monitor oxygen saturation level via pulse oximetry *to provide objective indication of perfusion status.*
- Provide supplemental oxygen as indicated and ordered *to ensure adequate tissue oxygenation.*
- Assist with any ordered diagnostic tests, such as chest x-ray and arterial blood gases (ABGs), *to determine effectiveness of treatments.*
- Cluster nursing activities *to reduce oxygen consumption.*
- Maintain a neutral thermal environment *to reduce oxygen consumption.*
- Monitor hydration status *to prevent fluid volume deficit or overload.*
- Explain all events and procedures to the parents *to help alleviate anxiety and promote understanding of the newborn's condition.*

NURSING DIAGNOSIS: Ineffective thermoregulation related to lack of fat stores and hypotonia as evidenced by extended positioning, low axillary temperature despite warmed blanket, respiratory distress, and lethargy

Outcome Identification and Evaluation
The newborn will demonstrate ability to regulate temperature as evidenced by temperature remaining in normal range 97.7° to 99.5° F (36.5° to 37.5° C) and absent signs of cold stress.

Interventions: *Promoting Thermoregulation*
- Assess the axillary temperature every hour or use a thermistor probe *to monitor for changes.*
- Review maternal history *to identify risk factors contributing to problem.*
- Monitor vital signs, including heart rate and respiratory rate, every hour *to identify deviations.*
- Check radiant heat source or isolette *to ensure maintenance of appropriate temperature of the environment.*
- Assess environment for sources of heat loss or gain through evaporation, conduction, convection, or radiation *to minimize risk of heat loss.*
- Avoid bathing and exposing newborn *to prevent cold stress.*
- Warm all blankets and equipment that come in contact with newborn; place

warmed cap on the newborn's head and keep it on *to minimize heat loss.*
- Encourage kangaroo care (mother or father holds preterm infant underneath clothing skin-to-skin and upright between breasts) *to provide warmth.*
- Educate parents on how to maintain a neutral thermal environment, including importance of keeping the newborn warm with a cap and double-wrapping with blankets and changing them frequently to keep dry *to promote newborn's adjustment.*
- Demonstrate ways *to safeguard warmth and prevent heat loss.*

NURSING DIAGNOSIS: Risk for imbalanced nutrition: less than body requirements related to poor sucking and lack of glycogen stores necessary to meet the newborn's increased metabolic demands as evidenced by weak sucking reflex, low birth weight, and signs and symptoms of hypoglycemia, including lethargy, tachycardia, and jitteriness

Outcome Identification and Evaluation
The newborn will demonstrate adequate nutritional intake, remaining free of signs of hypoglycemia as evidenced by blood glucose levels being maintained above 45 mg/dL, enhanced sucking ability, and appropriate weight gain.

Interventions: *Promoting Optimal Nutrition*
- Identify newborn at risk based on behavioral characteristics, body measurements, and gestational age *to establish a baseline and allow for early detection.*
- Assess blood glucose levels as ordered *to determine status and establish a baseline for interventions.*
- Obtain blood glucose measurements upon admission to nursery and every 1 to 2 hours as indicated *to evaluate for changes.*
- Observe behavior for signs of low blood glucose *to allow early identification.*
- Initiate early oral feedings or gavage feedings *to maintain blood glucose levels.*
- If oral or gavage feedings aren't tolerated, initiate an IV glucose infusion *to aid in stabilizing blood glucose levels.*
- Assess skin for pallor and sweating *to identify signs of hypoglycemia.*
- Assess neurologic status for tremors, seizures, jitteriness, and lethargy *to identify further drops in blood glucose levels.*

- Monitor weight daily for changes *to determine effectiveness of feedings.*
- Maintain temperature using warmed blankets, radiant warmer, or warmed isolette *to prevent heat loss and possible cold stress and reduce energy demands.*
- Monitor temperature *to prevent cold stress resulting in decreased blood glucose levels.*
- Offer opportunities for nonnutritive sucking on premature-size pacifier *to satisfy sucking needs.*
- Monitor for tolerance of oral feedings, including intake and output, *to determine effectiveness.*
- Administer IV dextrose if newborn is symptomatic *to raise blood glucose levels quickly.*
- Decrease energy requirements, including clustering care activities and providing rest periods, *to conserve glucose and glycogen stores.*
- Inform parents about procedures and treatments, including rationale for frequent blood glucose levels, *to help reduce their anxiety.*

Note the newborn's Apgar score at 1 and 5 minutes. If after 15 seconds of tactile stimulation without effective respirations or an increase in heart rate above 100 bpm, the infant should be resuscitated (Yousaf, Hayat, & Afzal, 2015). Several diagnostic studies may be done to identify underlying etiologies. For example, a chest x-ray helps to identify structural abnormalities that might interfere with respirations. Blood studies may be done, such as cultures to rule out an infectious process, a toxicology screen to detect any maternal drugs in the newborn, and a metabolic screen to identify any metabolic conditions (Fanaroff & Fanaroff, 2014). Monitor vital signs continually, check blood glucose levels for hypoglycemia secondary to stress, and maintain a neutral thermal environment to promote energy conservation and minimize oxygen consumption.

Resuscitating The Newborn. Any newborn can be born with asphyxia without warning. Approximately 10% of newborns require some assistance to begin breathing at birth. The aim of neonatal resuscitation is to prevent neonatal death and adverse long term neurodevelopmental sequelae associated with perinatal asphyxia. Anticipation, adequate preparation, accurate evaluation, and prompt initiation of support are critical for successful newborn resuscitation. Have all

basic equipment immediately available and in working order. Ensure that the equipment is evaluated daily, and document its condition and any needed repairs. Box 23.2 lists the equipment needed for basic newborn resuscitation.

BASIC EQUIPMENT FOR NEWBORN RESUSCITATION

• A wall vacuum suction apparatus

• Infant size stethoscope

• Pulse oximeter

• Epinephrine

• Volume expander intravenous fluids

• A wall source or tank source of 100% oxygen with a flow meter

• A neonatal self-inflating ventilation bag with correctly sized face masks

• A selection of endotracheal tubes (2.5, 3.0, or 3.5 mm) with introducers

• A laryngoscope with a small, straight blade and spare batteries and bulbs

• Ampules of naloxone (Narcan) with syringes and needles

• A wall clock to document timing of activities and events

• A supply of disposable gloves in a variety of sizes for staff to use

Determine the need for resuscitation by performing a rapid assessment using the following three questions:

1. What is the newborn's heart rate?

2. What is the gestational age of this newborn?

3. Is the newborn breathing or crying now?

4. Does the newborn have good muscle tone?

If the answer to all questions is "yes," then routine care is initiated: provide warmth, clear the airway, dry the newborn, and assess color. If the answer to any of these questions is "no," the newborn should receive one or more of the following actions, according to this sequence:

1. Stabilization. Dry the newborn thoroughly with a warm towel; provide warmth by placing him or her under a radiant heater to prevent rapid heat loss through evaporation; position the head in a neutral position to open the

airway; clear the airway with a bulb syringe or suction catheter; and stimulate breathing. At times, handling and rubbing the newborn with a dry towel may be all that is needed to stimulate respirations.

2. Assess for breathing – bag the newborn if not breathing

3. Place pulse oximeter on newborn's right hand to determine oxygen saturation

4. Ventilation if needed

5. Assess heart rate

6. Chest compressions if needed

7. Administration of epinephrine and/or volume expansion (Vali, Mathew, & Lakshminrusimha, 2015).

The decision to progress from one set of actions to the next and the need for further resuscitative efforts is determined by the assessment of respirations, heart rate, and color (American Academy of Pediatrics [AAP] & American Heart Association [AHA], 2014). Nurses need to remember that preterm infants have immature lungs that may be more difficult to ventilate and are also more vulnerable to injury by positive-pressure ventilation. They also have immature blood vessels in the brain that are prone to hemorrhage; thin skin and a large surface area, which contribute to rapid heat loss; increased susceptibility to infection; and increased risk of hypovolemic shock related to small blood volume. Anticipation, adequate preparation, accurate evaluation, and prompt initiation of support are critical for successful neonatal resuscitation.

When performing newborn resuscitation, use the mnemonic "ABCDs" (airway, breathing, circulation, and drugs) to remember the sequence of steps (Box 23.3).

Resuscitation measures are continued until the newborn has a pulse above 100 bpm, a good (healthy) cry, or good breathing efforts and a pink tongue. This last sign indicates a good oxygen supply to the brain. Effective ventilation is the key to successful neonatal resuscitation (AAP & AHA, 2014).

Throughout the resuscitation period, keep the parents informed of what is happening to their newborn and what is being done and why. Provide support through this initial crisis. Once the newborn has been stabilized, encourage bonding by having them stroke, touch, and, when appropriate, hold the newborn.

> **BOX 23.3**
>
> **ABCDS OF NEWBORN RESUSCITATION**
>
> • **A**irway
>   • Place infant's head in "sniffing" position.
>   • Suction mouth, then nose.
>   • Suction trachea if meconium-stained and newborn is NOT vigorous (strong respiratory effort, good muscle tone, and heart rate >100 bpm).
> • **B**reathing
>   • Use positive-pressure ventilation (PPV) for apnea, gasping, or pulse <100 bpm.
>   • Ventilate at rate of 40 to 60 breaths/min.
>   • Listen for rising heart rate, audible breath sounds.
>   • Look for slight chest movement with each breath.
>   • Use carbon dioxide detector after intubation.
> • **C**irculation
>   • Start compressions if heart rate is <60 after 30 seconds of effective PPV.
>   • Give three compressions: 1 breath every 2 seconds.
>   • Compress one third of the anterior–posterior diameter of the chest.
> • **D**rugs
>
>   • Give epinephrine if heart rate is <60 after 30 seconds of compressions and ventilation.
>   • *Caution:* Epinephrine dosage is different for endotracheal and IV routes!
>   • Epinephrine: 1:10,000 concentration
>   • 0.1 to 0.3 mL/kg IV
>   • 0.3 to 1 mL/kg via endotracheal tube (AAP & AHA, 2014).

Administering Oxygen. Oxygen administration is a common therapy in newborn nurseries. Although it has been used in newborns for over 75 years,

there is no universal agreement on the most appropriate range at which oxygen levels should be maintained for newborns experiencing hypoxia, nor is there a standard time frame for oxygen to be administered (Neonatal Handbook, 2015d). Although this uncertainty continues, nurses will experience a wide variation in practice in terms of modes of administration, monitoring, blood levels, and target ranges for both short- and long-term oxygen therapy.

A guiding principle, however, is that oxygen therapy should be targeted to levels appropriate to the condition, gestational age, oxygenation saturation level, and postnatal age of the newborn.

Oxygen therapy must be used judiciously to prevent **retinopathy of prematurity (ROP)**, a major cause of blindness in preterm newborns in the past. It is a disease that affects immature vasculature in the eyes of preterm infants. It remains a significant threat to vision for preterm infants despite the availability of therapeutic modalities of treatment. ROP is a potentially blinding eye disorder that occurs when abnormal blood vessels grow and spread through the retina, eventually leading to retinal detachment. The incidence of ROP is inversely proportional to the preterm baby's birth weight. Despite current treatments, ROP remains a major cause of blindness in premature infants and the incidence is increasing with increased survival of infants born at very early gestational ages. ROP is a persistent and often devastating morbidity associated with premature and low–birth-weight infants. It continues to be a frequent diagnosis in the NICU, despite technological advances and increased knowledge.

The incidence of ROP varies with birth weight, but approximately 15,000 infants in the United States have ROP. About 90% of all infants with ROP have a mild form and do not need treatment. However, each year in the United States, about 400 to 600 infants do become legally blind or severely visually impaired from ROP (Hartnett, 2015).

The AAP has updated practice guideline recommendations for ROP screening and treatment that aid in creating a consistent and reliable ROP protocol (Sabri, 2016). Although the role of oxygen in the pathogenesis of ROP is unclear, current evidence suggests that it is linked to the duration of oxygen use rather than the concentration. Thus, the use of 100% oxygen to resuscitate a newborn should not pose a problem (National Eye Institute, 2015). However, an ophthalmology consult for follow-up after discharge is essential for preterm infants who have received extensive oxygen therapy.

Respiratory distress in preterm infants is commonly caused by a deficiency of surfactant, retained fluid in the lungs (wet lung syndrome), meconium aspiration,

pneumonia, hypothermia, or anemia. The principles of care are the same regardless of the cause of respiratory distress:

• First, keep the newborn warm, preferably in a warmed isolette or with an overhead radiant warmer, to conserve the baby's energy and prevent cold stress.

• Handle the newborn as little as possible, because stimulation often increases the oxygen requirement.

• Provide energy through calories via intravenous dextrose or gavage or continuous tube feedings to prevent hypoglycemia.

• Treat cyanosis with an oxygen hood or blow-by oxygen placed near the newborn's face if respiratory distress is mild and short-term therapy is needed.

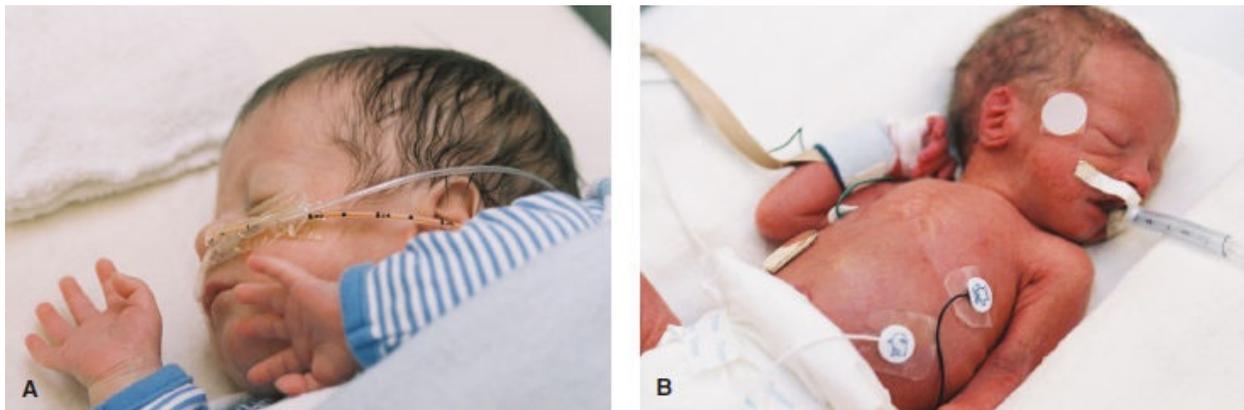
• Record the following important observations every hour or more frequently if indicated, and document any deterioration or changes in respiratory status:
  • Respiratory rate, quality of respirations, and respiratory effort
  • Airway patency, including removal of secretions per facility policy


FIGURE 23.4 **A.** A preterm newborn receiving oxygen therapy via a nasal cannula. The newborn also has an enteral feeding tube inserted for nutrition. **B.** A preterm newborn receiving mechanical ventilation.

• Skin color, including any changes to duskiness, blueness, or pallor

• Lung sounds on auscultation to differentiate breath sounds in upper and lower fields

• Equipment required for oxygen delivery, such as:
  • Blow-by oxygen delivered via mask or tube for short-term therapy
  • Oxygen hood (oxygen is delivered via a plastic hood placed over the

newborn's head)

- Nasal cannula (oxygen is delivered directly through the nares) (Fig. 23.4A)
- Continuous positive airway pressure, which prevents collapse of unstable alveoli and delivers high levels of inspired oxygen into the lungs
- Mechanical ventilation, which delivers consistent assisted ventilation and oxygen therapy, reducing the work of breathing for the fatigued infant (see Fig. 23.4B)

- Correct placement of endotracheal tube (if present)
- Heart rate, including any changes
- Monitor the infant's respiratory status, clinically as well as by oxygen saturation, ABG, and chest x-ray
- Oxygen saturation levels via pulse oximetry to evaluate need for therapy modifications based on hemoglobin
- Suction as needed to remove secretions to maintain a patent airway and enhance oxygenation
- Maintenance of appropriate concentration of oxygen determined by ABG assay
- Nutritional intake, including calories provided, to prevent hypoglycemia and method of feeding, such as gavage, intravenous, or continuous enteral feedings
- Decrease stimulation; cluster all care to allow for rest
- Hydration status, including any signs and symptoms of fluid overload
- Maintain a neutral thermal environment
- Laboratory tests, including ABGs, to determine effectiveness of oxygen therapy
- Administration of medication, such as exogenous surfactant
- Offer emotional support and progress reports on infant's condition to the family

If the newborn shows worsening cyanosis or if oxygen saturation levels fall below 87%, prepare to give additional oxygen as ordered. Throughout, maintain trict asepsis, including hand hygiene, which is vital to reduce the risk of infection.

MAINTAINING THERMAL REGULATION

An optimal thermal environment is desirable for preterm infants. When an infant becomes chilled, it attempts to conserve body heat by vasoconstriction and

thermogenesis by metabolizing brown adipose tissue and increasing oxygen consumption. This increase in energy expenditure reduces the newborn's ability to gain weight. Immediately after birth, dry the newborn with a warmed towel and then place him or her in a second warm, dry towel before performing the assessment. This drying prevents rapid heat loss secondary to evaporation. Newborns who are active, breathing well, and crying are stable and can be placed on their mother's chest ("kangaroo care") to promote warmth and prevent hypothermia. Preterm newborns who are not considered stable may be placed under a radiant warmer or in a warmed isolette after they have been dried with a warmed towel.

Typically newborns use nonshivering thermogenesis for heat production by metabolizing their own brown adipose tissue. However, the preterm newborn has an inadequate supply of brown fat because he or she left the uterus early, before the supply was adequate. The preterm newborn also has decreased muscle tone and thus cannot assume the flexed fetal position, which reduces the amount of skin exposed to a cooler environment. In addition, preterm newborns have large body surface areas compared with weight. This allows an increased transfer of heat from their bodies to the environment.

Usually, a preterm newborn who is having problems with thermal regulation is cool-to-cold to the touch. The hands, feet, and tongue may appear cyanotic. Respirations are shallow or slow, or signs of respiratory distress are present. The newborn is lethargic and hypotonic, feeds poorly, and has a feeble cry. Blood glucose levels are probably low, leading to hypoglycemia, due to the energy expended to keep warm.

When promoting thermal regulation for the preterm newborn:

• Remember the four mechanisms for heat transfer and ways to prevent loss:

  • *Convection*: heat loss through air currents (avoid drafts near the newborn)

  • *Conduction*: heat loss through direct contact (warm everything the newborn comes in contact with, such as blankets, mattress, stethoscope)

  • *Radiation*: heat loss without direct contact (keep isolettes away from cold sources and provide insulation to prevent heat transfer)

  • *Evaporation*: heat loss by conversion of liquid into vapor (keep the newborn dry and delay the first bath until the baby's temperature is stable)

• Frequently assess the temperature of the isolette or radiant warmer, adjusting the temperature as necessary to prevent hypo- or hyperthermia.

- Utilize plastic wraps and bags, skin-to-skin contact, or transwarmer mattresses if available to keep infants warmer and decrease the incidence of hypothermia
- Assess the newborn's temperature every hour until stable.
- Observe for clinical signs of cold stress, such as respiratory distress, central cyanosis, hypoglycemia, lethargy, weak cry, abdominal distention, apnea, bradycardia, and acidosis.
- Remember the complications of hypothermia and frequently assess the newborn for signs:
  - Metabolic acidosis secondary to anaerobic metabolism used for heat production, which results in the production of lactic acid
  - Hypoglycemia due to depleted glycogen stores
  - Pulmonary hypertension secondary to pulmonary vasoconstriction
- Monitor the newborn for signs of hyperthermia such as tachycardia, tachypnea, apnea, warm to touch, flushed skin, lethargy, weak or absent cry, and central nervous system depression; adjust the environmental temperature appropriately.
- Explain to the parents the need to maintain the newborn's temperature, including the measures used; demonstrate ways to safeguard warmth and prevent heat loss.

PROMOTING NUTRITION AND FLUID BALANCE

Providing nutrition is challenging for preterm newborns because their needs are great but their ability to take in optimal amounts of energy/calories is reduced due to their compromised health status. Individual nutritional needs are highly variable.

FIGURE 23.5 Infants who are ill at birth often need supplemental feedings by nasogastric or gastrostomy tubes. (Copyright Caroline Brown, RNC, MS, DEd.)

Depending on their gestational age, preterm newborns receive nutrition orally, enterally, or parenterally via infusion. Several different methods can be used to provide nutrition: parenteral feedings administered through a percutaneous central venous catheter for long-term venous access with delivery of total parenteral nutrition, or enteral feedings, which can include oral feedings (formula or breast milk), continuous nasogastric tube feedings, or intermittent gavage tube feedings (Fig. 23.5). Gavage feedings are commonly used for compromised newborns to allow them to rest during the feeding process. Many have a weak suck and become fatigued and thus cannot consume enough calories to meet their needs.

Most newborns born after 34 weeks' gestation without significant complications can feed orally. Those born before 34 weeks' gestation typically start with parenteral nutrition within the first 24 hours of life. Then enteral nutrition is introduced and advanced based on the degree of maturity and clinical condition. Ultimately, enteral nutrition methods replace parenteral nutrition.

To promote nutrition and fluid balance in the preterm newborn:

• Measure daily weight and plot it on a growth curve.

• Monitor intake; calculate fluid and caloric intake daily.

• Assess fluid status by monitoring weight; urinary output; urine specific gravity; laboratory test results such as serum electrolyte levels, blood urea nitrogen, creatinine, and hematocrit; skin turgor; and fontanels (Koletzko, Poindexter, & Uauy, 2014). Be alert for signs of dehydration, such as a decrease in urinary

output, sunken fontanels, temperature elevation, lethargy, and tachypnea.

- Continually assess for enteral feeding intolerance; measure abdominal girth, auscultate bowel sounds, and measure gastric residuals before the next tube feeding.

- Encourage and support breast-feeding by facilitating maternal breast pumping.

- Encourage nuzzling at the breast in conjunction with kangaroo care if the newborn is stable.

Take Note!

When assessing the fluid status of a preterm newborn, palpate the fontanels. Sunken fontanels suggest dehydration; bulging fontanels suggest overhydration.

PREVENTING INFECTION

Prevention of infection is critical when caring for preterm newborns. Infections are the most common cause of morbidity and mortality in the NICU population (Ohlin et al., 2015). Nursing assessment and early identification of problems are imperative to improve outcomes.

Preterm newborns are at risk for infection because their early birth deprived them of maternal antibodies needed for passive protection. They are also susceptible to infection because of their limited ability to produce their own antibodies, asphyxia at birth, and thin, friable skin that is easily traumatized, providing a portal of entry for microorganisms.

Early detection is crucial. The clinical manifestations can be nonspecific and subtle: apnea, diminished activity, poor feeding, temperature instability, respiratory distress, seizures, tachycardia, hypotonia, irritability, pallor, jaundice, and hypoglycemia. Report any of these to the primary care provider immediately so that treatment can be instituted.

Include the following interventions when caring for a preterm or post-term newborn to prevent infection:

- Assess for risk factors in maternal history that place the newborn at increased risk.

- Monitor for changes in vital signs such as temperature instability, tachycardia, or tachypnea.

- Assess oxygen saturation levels and initiate oxygen therapy as ordered if oxygen saturation levels fall below acceptable parameters.
- Assess feeding tolerance, typically an early sign of infection.
- Monitor laboratory test results for changes.
- Avoid using tape on the newborn's skin to prevent tearing.
- Use equipment that can be thrown away after use.
- Adhere to standard precautions; use clean gloves to handle dirty diapers and dispose of them properly.
- Use sterile gloves when assisting with any invasive procedure; attempt to minimize the use of invasive procedures.
- Remove all jewelry on your hands prior to washing hands; wash hands upon entering the nursery and in between caring for newborns.
- Administer antibiotics as ordered and monitor for therapeutic and adverse effects
- Avoid coming to work when ill, and screen all visitors for contagious infections.

PREVENTING COMPLICATIONS

Preterm newborns face a myriad of possible complications as a result of their fragile health status or the procedures and treatments used. Some of the more common complications in preterm newborns include respiratory distress syndrome, apnea, periventricular–intraventricular hemorrhage, bronchopulmonary dysplasia, ROP, hyperbilirubinemia, anemia, necrotizing enterocolitis, hypoglycemia, infection or septicemia, delayed growth and development, and mental or motor delays (March of Dimes, 2015c). Several of these complications are described in Chapter 24.

> *Remember Anna, who was in a state of shock when she entered the NICU to see her preterm baby for the first time? How could the nurse have prepared her for this event? What information needs to be given at the isolette to reduce her anxiety and fear now?*

PROVIDING APPROPRIATE STIMULATION

Newborn stimulation involves a series of activities to encourage normal development. Research on developmental interventions shows that when preterm newborns, in particular, receive sensorimotor interventions such as rocking, kangaroo (skin-to-skin) contact with parents, containment (swaddling and surrounded by blanket rolls), soft singing or music, nonnutritive sucking (Fig. 23.6), breast-feeding, cuddling, gentle stroking of the infant's skin, colorful mobiles, gentle massage, passive exercise involving flexion and extension of limbs, holding, or sleeping on waterbeds, they gain weight faster, progress in feeding abilities more quickly, and show improved interactive behavior compared with preterm newborns who were not stimulated. In the hospital, tactile and kinesthetic stimulation has shown to have a positive effect, contributing toward adjustment and self-regulation of behavior in the preterm infant (Sayed et al., 2015). Conversely, overstimulation may have negative effects by reducing oxygenation and causing stress. The NICU environment lends itself to persistent and unpredictable sounds that are in stark contrast to the protective sounds inside the mother. A newborn reacts to stress by flaying the hands or bringing an arm up to cover the face. When overstimulated (e.g., by noise, lights, excessive handling, alarms, and procedures) and stressed, heart and respiratory rates decrease and periods of apnea or bradycardia may follow (Gardner et al., 2016).

The NICU environment can be altered to provide periods of calm and rest for the newborn by dimming the lights, lowering the volume and tone of conversations, closing doors gently, setting the telephone ringer to the lowest volume possible, clustering nursing activities, and covering the isolette with a blanket to act as a light shield to promote rest at night.

FIGURE 23.6 A preterm newborn receiving nonnutritive sucking with pacifier.

Encourage parents to hold and interact with their newborn. Doing so helps to acquaint the parents with their newborn, promotes self-confidence, and fosters parent–newborn attachment (Fig. 23.7).

FIGURE 23.7 A mother bonding with her preterm newborn.

Think back to Anna, the woman who gave birth to a preterm newborn at 7 months' gestation. Anna will be discharged but her newborn will be staying in the NICU for a while. What interventions would be appropriate to facilitate bonding despite their separation? What support can be provided specifically to her family?

MANAGING PAIN

Pain control and prevention is imperative for ethical and clinical reasons and is required by the AAP and the Joint Commission as a standard of excellence. Pain is an unpleasant sensory and emotional experience felt by all humans. Unlike adults, infants are incapable of rating their pain on a scale of 0 to 10, and yet from the moment they take their first breath, newborns are exposed to heel sticks, circumcisions, injections, and immunizations, all which cause pain. Newborns feel pain and require the same level of pain assessment and management as adults. Awareness of the importance of pain in newborn babies has increased during recent years, but it remains a challenging area of clinical practice. Preterm infants show cortical, biochemical, physiologic, and behavioral responses to painful procedures. Common indicators of pain in the newborn who

is unable to vocalize include facial expressions, body movements, and physiologic changes such as oxygen saturation (Hatfield & Ely, 2014). Untreated pain in newborns may result in increased morbidity and length of stay in the NICU, exaggerated responses to pain in later life, and altered psychosocial development (Valeri, Holsti, & Linhares, 2015). Parents commonly expect that health care providers will use appropriate measures to prevent pain in their newborns, but there are gaps in knowledge about the most effective way to accomplish this.

Assessing Pain in Newborns. Assessment of pain in the newborn remains a contentious and vexing problem. Newborns in the NICU are subjected to repeated procedures that cause them pain. Newborns, whether preterm, full term, or post-term, do experience pain, but the pain is difficult to validate with consistent behaviors. Considering that ill newborns undergo multiple noxious stimuli from invasive procedures, such as lumbar punctures, heel sticks, venipuncture, line insertions, chest tube placement, specimen collections, endotracheal intubation and suctioning, and mechanical ventilation. Common sense would suggest that newborns experience pain from these many activities and interventions. However, pain management in infants was not addressed formally until various professional and accrediting organizations issued position statements and clinical recommendations in an effort to promote effective pain management (Lee et al., 2014). An international consortium established principles of newborn pain prevention and management that all nurses must be familiar with and apply (Box 23.4).

NEWBORN PAIN PREVENTION AND MANAGEMENT GUIDELINES

- Newborn pain frequently goes unrecognized and undertreated.
- Pain assessment is an essential activity prior to pain management.
- Newborns experience pain, and analgesics should be given.
- A procedure considered painful for an adult should also be considered painful for a newborn.
- Developmental maturity and health status must be considered when assessing for pain in newborns.
- Newborns may be more sensitive to pain than adults.
- Pain behavior is frequently mistaken for irritability and agitation.
- Newborns are more susceptible to the long-term effects of pain.
- Adequate pain management may reduce complications and mortality.
- Nonpharmacologic measures can prevent, reduce, or eliminate newborn pain.
- Sedation does not provide pain relief and may mask pain responses.
- A newborn's response to both pharmacologic and nonpharmacologic pain therapy should be assessed within 30 minutes of administration or intervention.
- Health care professionals are responsible for pain assessment and treatment.
- Written guidelines are needed on each newborn unit.

Adapted from Kenner, C., & Lott, J. W. (2014). *Comprehensive neonatal care* (5th ed.). New York, NY: Springer Publishing Company; and Sabic, D., Blattner, C., & Metts, M. (2015). Newborn and infant pain control. *Clinical Pediatrics*, 54(7), 613–614.

Several psychometric tools are available to assess pain in the newborn, but, unfortunately they are only rarely used in clinical practice examples include the Pain Assessment Tool (PAT), which evaluates respirations, heart rate, oxygen

saturation, and blood pressure; the Premature Infant Pain Profile Revised, which assesses heart rate and oxygen saturation; the CRIES tool (cry, requires oxygen, increased vital signs, expression and sleeplessness); the Neonatal Infant Acute Pain Assessment Tool which assesses five behavioral and three physiologic indicators for pain; and the Neonatal Infant Pain Scale, which evaluates respiratory patterns. Most are based on facial expressions, crying patterns, changes in vital signs, and body movements (Reavey et al., 2014).

Nurses play a key role in assessing a newborn's pain level. Assess the newborn frequently. Pain is considered the "fifth vital sign" and should be assessed as frequently as the other four vital signs. Differentiate pain from agitation by observing for changes in vital signs, behavior, facial expression, and body movement. Suspect pain if the newborn exhibits the following:

• Sudden high-pitched cry

• Facial grimace with furrowing of brow and quivering chin

• Increased muscle tone

• Oxygen desaturation

• Increase in heart rate

• Body posturing, such as squirming, kicking, and arching

• Limb withdrawal and thrashing movements

• Increase in heart rate, blood pressure, pulse, and respirations

• Fussiness and irritability (Verklan & Walden, 2014).

Pain Management Strategies. The goals of pain management are to minimize the amount, duration, and severity of pain and to assist the newborn in coping. It is essential that pain-related stress in preterm infants is accurately identified, appropriately managed, and that pain management strategies are evaluated for protective or adverse effects in the long term. Effective pain management strategies for newborns include preventing, limiting, or avoiding noxious stimuli; using nonpharmacologic techniques to reduce pain; and administering pharmacologic agents when appropriate. Box 23.5 lists some of the more commonly used nonpharmacologic pain management techniques for the preterm newborn.

Nonpharmacologic pain management strategies include nonnutritive sucking, breast-feeding, skin-to-skin contact, radiant heat source, and sweetened solutions. Recent research findings suggested that infants be given an

appropriate-sized pacifier for comfort during painful procedures. Administration of oral sucrose with and without nonnutritive sucking is frequently used as a nonpharmacologic intervention for procedural pain relief in neonates also. The recommended sucrose concentration is a 24% solution and radiant heat for effective analgesia (Gray et al., 2015). Nurses need to be informed about the effectiveness of nonpharmacologic pain management strategies and how to use them and incorporate it into their practice.

The number of analgesics available for use with preterm newborns is limited. Morphine and fentanyl, usually administered intravenously, are the most commonly used opioids for moderate to severe pain. Acetaminophen is effective for mild pain. Benzodiazepines are used as sedatives during painful procedures and can be combined with opioids for more effectiveness. Local or topical anesthetics (e.g., EMLA cream) also may be used before procedures such as venipuncture, lumbar puncture, and intravenous catheter insertion (Sabic, Blattner, & Metts, 2014).

Be vigilant in assessing for adverse effects (respiratory depression or hypotension) when administering pharmacologic agents for pain management, especially in preterm newborns with neurologic impairment. These negative effects are usually dose and route related, so be knowledgeable about the pharmacokinetics and therapeutic dosing of any drug administered.

NONPHARMACOLOGIC TECHNIQUES TO REDUCE PAIN IN THE PRETERM NEWBORN

- Gentle handling, rocking, caressing, cuddling, and massaging
- Rest periods before and after painful procedures
- Kangaroo care (skin-to-skin contact) during procedure
- Breast-feeding, if able, to reduce pain from minor procedures
- Use of a facilitated tuck (holding arms and legs in a flexed position)
- Application of topical anesthetics prior to venipuncture or lumbar puncture
- Swaddling and positioning to establish physical boundaries
- Non-nutritive sucking (pacifier dipped in sucrose) prior to procedure
- Minimal use of tape, with gentle removal to avoid skin tears
- Warm blankets for wrapping to facilitate relaxation
- Reduction of environmental stimuli by removing or turning down noxious stimuli such as noise from alarms, beepers, loud conversations, and bright lights
- Distraction, such as with colored objects or mobiles

PROMOTING GROWTH AND DEVELOPMENT

In the late 1990s, researchers evaluated the NICU environment in terms of light and sound levels, caregiving activities, and handling of newborns. As a result of this research, many environmental modifications were made to reduce the stress and overstimulation of the NICU, and the concept of developmentally supportive

care was introduced. Developmentally supportive care is defined as care of a newborn or infant to support positive growth and development. Developmental care focuses on what newborns or infants can do at that stage of development; it uses therapeutic interventions only to the point that they are beneficial; and it provides for the development of the newborn–family unit (White-Traut, 2015).

Developmental care is a philosophy of care that requires rethinking the relationships between newborns, families, and health care providers. Family presence and participation in the care in the NICU is fundamental to the recovery and well-being of the sick neonate and family. The basis of family-centered, developmentally supportive care is the recognition that the newborn infant is a human being, in which caregivers need to be guided by the current needs of the infant and family, not their own. It includes a variety of activities designed to manage the environment and individualize the care of the preterm or high-risk ill newborn based on behavioral observations. Promoting kangaroo care in the NICU for preterm infants holds many benefits for the mother-infant dyad (see Evidence-Based Practice 23.1). Neonatal developmental care has evolved as a method of care that acknowledges that infant health depends on neonatal reactions to the environment and that each infant reacts to the environment favorably or unfavorably in an individual manner that depends on gestational and neurodevelopmental maturity. Key aspects of this care approach include attention to environmental infant stressors such as ambient light and sound levels, as well as individual infant and family needs including privacy and respect for diversity of cultural or other beliefs. Developmental care and family centered care notably not only improve parental satisfaction but influence the infant's health and well-being long after the NICU stay (Kiechl-Kohlendarfer et al., 2015).

Parents of NICU infants experience stress related to feelings of helplessness, exclusion and isolation, and lack sufficient knowledge regarding parenting and interacting with their newborn. There are several developmental interventions that nurses can do to help parents and newborns while in the NICU. Developmental care includes these strategies:

• Clustering care to promote rest and conserve the infant's energy

• Flexed positioning to simulate in utero positioning

• Environmental management to reduce noise and visual stimulation

• Kangaroo care to promote skin-to-skin sensation

• Placement of twins in the same isolette or open crib to reduce stress

- Activities to promote self-regulation and state regulation:
  - Surrounding the newborn with nesting rolls/devices
  - Swaddling with a blanket to maintain the flexed position
  - Providing sheepskin or a waterbed to simulate the uterine environment
    - Providing nonnutritive sucking (calms the infant)
    - Providing objects to grasp (comforts the newborn)
- Promotion of parent–infant bonding by making parents feel welcome in the NICU
- Open, honest communication with parents and staff
- Collaboration with the parents in planning the infant's care (Gardner et al., 2016).

EVIDENCE-BASED PRACTICE 23.1 UNDERSTANDING KANGAROO CARE AND ITS BENEFITS

STUDY

Holding an infant with ventral skin-to-skin contact in an upright position on the chest of the parent is referred to as kangaroo care. The purpose of kangaroo care is to facilitate infant transition to extrauterine life, promote early bonding, relieve pain, and establish exclusive breastfeeding. Numerous benefits of its use have been reported which include physiologic (thermoregulation, cardiorespiratory stability), behavioral (better sleep, breastfeeding duration, and degree of exclusivity), relieves procedural pain, and improves neurodevelopment. This review analyses current literature about the benefits of kangaroo care for preterm infants.

Findings

After the review of the literature and meta-analysis and two Cochrane reviews, there is current evidence that supports kangaroo care improves sleep, neurodevelopment, and growth, length of breastfeeding, homeostasis, maternal-infant bonding, and relieves pain from procedures. Evidence supports the influence of kangaroo care increases maternal milk volume and increases breastfeeding duration in preterm infants. Yet, despite beneficial findings of kangaroo care, the adoption of it as routine clinical practice remains variable in many NICU settings.

Developmental care can be fostered by clustering the lights in one area so that no lights are shining directly on newborns, installing visual alarm systems and limiting overhead pages to minimize noise, and monitoring continuous and peak noise levels. Nurses can play an active role by serving on committees that address these issues. In addition, nurses can provide direct developmentally supportive care. Doing so involves careful planning of nursing activities to provide the ideal environment for the newborn's development. For example:

• Dim the lights and cover isolettes at night to simulate nighttime.

• Support early extubation from mechanical ventilation.

• Encourage early and consistent feedings with breast milk.

• Administer prescribed antibiotics judiciously.

• Position the newborn as if he or she was still in utero (a nesting fetal position).

• Promote kangaroo care by encouraging parents to hold the newborn against the chest for extended periods each day.

• Coordinate care to respect sleep and awake states.

Throughout the newborn's stay, work with the parents to develop a collaborative partnership so they feel comfortable caring for their newborn. Be prepared to make referrals to community support groups to enhance coping (Cano Gimenez & Sanchez-Luna, 2015).

PROMOTING PARENTAL COPING

Generally, pregnancy and the birth of a newborn are exciting times, but when the newborn has serious, perhaps life-threatening problems, the exciting experience suddenly changes to one of anxiety, fear, guilt, loss, and grief. The birth of a preterm infant is an acutely stressful event for parents/partners, significant others.

Parents are typically unprepared for the birth of a preterm newborn and commonly experience an array of emotions, including disappointment, fear for the survival of the newborn, and anxiety due to the separation from their newborn immediately after birth. Gaining insight into the experience of parents of premature infants can help nurses ensure services more effectively meet the needs of these families (Vitale & Falco, 2014). Early interruptions in the bonding process and concern about the newborn's survival can create extreme anxiety and interfere with attachment (Yaman & Altay, 2015).

Nursing interventions aimed at reducing parental anxiety include:

• Reviewing with them the events that have occurred since birth

• Providing simple relaxation and calming techniques (visual imagery, breathing)

• Exploring their perception of the newborn's condition and offering explanations

• Validating their anxiety and behaviors as normal reactions to stress and trauma

• Providing a physical presence and support during emotional outbursts

• Exploring the coping strategies they used successfully in the past and encouraging their use now

• Encouraging frequent visits to the NICU

• Providing individualized support to parents while in NICU

• Encouraging parental involvement with their newborn in NICU

• Addressing their reactions to the NICU environment and explaining all equipment used

• Identifying family and community resources available to them (Stacey, Osborn, & Salkovskis, 2015).

PREPARING FOR DISCHARGE

Discharge planning typically begins with evidence that recovery of the newborn is certain. However, the exact date of discharge may not be predictable. The goal

of the discharge plan is to make a successful transition to home care. Essential elements for discharge are a physiologically stable infant, a family who can provide the necessary care with appropriate support services in place in the community, and a pediatrician or family practice physician or nurse practitioner available for ongoing care.

The care of each high-risk newborn after discharge requires careful coordination to provide ongoing multidisciplinary support for the family. The discharge planning team typically includes the parents, primary care physician, neonatologists, neonatal nurses, and a social worker. Other health care providers, such as surgical specialists and pediatric subspecialists, occupational, physical, speech, and respiratory therapists, nutritionists, home health care nurses, and a case manager, may be included as needed. Critical components of discharge planning are summarized in Box 23.6.

Nurses involved in the discharge process are instrumental in bridging the gap between the hospital and home. Interventions typically include:

• Assessing the physical status of the mother and the newborn

• Discussing the early signs of complications and what to do if they occur

• Reinforcing instructions for infant care and safety

• Stressing the importance of proper car seat use

• Providing instructions for medication administration

• Reinforcing instructions for equipment operation, maintenance, and troubleshooting

• Teaching infant cardiopulmonary resuscitation and emergency care

• Demonstrating techniques for special care procedures such as dressings, ostomy care, artificial airway maintenance, chest physiotherapy, suctioning, and infant stimulation

• Providing breast-feeding support or instruction on gavage feedings

- Assisting with defining roles in the adjustment period at home
- Assessing the parents' emotional stability and coping status
- Providing support and reassurance to the family
- Reporting abnormal findings to the health care team for intervention
- Following up with parents to assure them that they have a "lifeline"

Late Preterm ("Near Term") Newborn

A late preterm newborn is an infant born between 34 0/7 and 36 6/7 weeks of gestation. In recent years, the subject of late preterm birth has received much attention, since this population of preterm newborns represents more than 72% of all preterm births in the United States and has increased by 30% in the past 20 years (CDC, 2015). The rise in elective induced births in the past decade is believed to have contributed to the rise in number of late preterm births. The largest increase in incidence of late preterm births is in the non-Hispanic White population. The underlying causes are poorly understood, although genetic, social, and environmental factors all likely play a role. Reasons for this might include an increased demand for assisted reproductive technology, older couples having babies, and higher rates of surgical births and inductions of labor (Horgan, 2015).

With birth weights typically ranging from 2,000 to 2,500 grams, late preterm infants may appear physically well developed when compared with their more premature counterparts. Consequently, it may be easy for nurses to overlook the fact that biologically and developmentally, these infants may be 4 to 6 weeks less mature than their full-term counterparts. Recent research has indicated that these infants are at heightened risk for a number of complications that are not normally seen in the healthy newborn population. They have more clinical problems, longer lengths of stay, and higher costs when compared with full-term infants (Kenner & Lott, 2015).

Late preterm babies are more likely than term babies to suffer complications at birth such as respiratory distress; require intensive and prolonged hospitalization; incur higher medical costs; die within the first year of life; and suffer brain injury that can result in long-term neurodevelopmental problems. Accordingly, increased high levels of late preterm births are an important public health issue (Baker, 2015). Perinatal nurses need to understand the risks of late preterm births and the unique needs of this population to facilitate timely assessment and intervention to improve outcomes.

Some additional challenges also facing the late preterm newborn include respiratory distress (secondary to cesarean births, maternal gestational diabetes, pulmonary hypertension, sepsis, chorioamnionitis, premature rupture of membranes, and fetal distress); thermoregulation issues related to limited ability to flex the trunk and extremities to decrease exposed surface area; hypoglycemia

related to the first two challenges (respiratory distress and cold stress); jaundice and hyperbilirubinemia related to a gestational age of 36 weeks or less; sepsis; and feeding difficulties related to immature sucking and swallowing reflexes (Bird, 2014).

Recent research suggests that after the neonatal period, the risks continue with behavioral problems, 80% increased risk for attention-deficit/hyperactivity disorder (ADHD), and developmental and school-readiness delays (Ramenghi, 2015). These challenges are similar to those facing the preterm newborn and require similar management. Parents should be taught about these risks so that they will be aware of the unique risks and the need to remain vigilant. Health risks for the late preterm infant include:

- *Respiratory system dysfunction*—due to surfactant deficiency leading to distress
- *Glycemic instability*—due to increased energy demands needed for temperature regulation and increased respiratory effort, which cause the blood glucose to remain low for prolonged periods of time
- *Jaundice*—due to feeding difficulties and inability of liver to conjugate bilirubin
- *Inadequate oral intake*—due to a decreased ability to suck and swallow
- *Susceptibility to infection*—due to immaturity of the immune system
- *Neurologic immaturity*—due to reduced cortical development, which occurs during the 34th and 40th week of gestation (Baker, 2015; Kenner & Lott, 2015).

Nurses and parents must be aware of the risks associated with late preterm births to optimize care and outcomes for this group of newborns. Late preterm infants should not be discharged home before at least 48 hours of age; they should have demonstrated thermal stability when clothed in an open crib, normal vital signs, the ability to take feeds orally, a weight loss of less than 7% of birth weight, and the ability to pass stools spontaneously. Other assessments before discharge include metabolic and genetic screening together with hearing screening and a successful car seat challenge (Pappas & Robey, 2014).

Encourage and empower parents of a late preterm infant with appropriate teaching and ongoing support. Stress that although the infant may seem equivalent to the term infant in many ways, there are specific risks that should be addressed not only in the first year of life, but beyond. Close surveillance,

follow-up, and referral to appropriate support services can optimize outcomes.

Post-Term Newborn

A pregnancy that extends beyond 42 weeks' gestation (294 days) produces a post-term newborn. Another term used to describe this late birth is *postmature infant*. Post-term newborns may be LGA, SGA, or dysmature (newborn weighs less than established normal parameters for estimated gestational age [fetal growth restriction]), depending on placental function. A postmature infant's appearance typically shows the effects of progressive placental insufficiency.

The reason why some pregnancies last longer than others is not completely understood. What is known is that women who experience one post-term pregnancy are at increased risk of doing so again in subsequent pregnancies. The incidence of prolonged pregnancy, beyond 42 weeks, is approximately 10% (Walker & Gan, 2015).

The ability of the placenta to provide adequate oxygen and nutrients to the fetus after 42 weeks' gestation is thought to be compromised, leading to perinatal mortality and morbidity. After 42 weeks, the placenta begins aging. Deposits of fibrin and calcium, along with hemorrhagic infarcts occur and the placental blood vessels begin to degenerate. All of these changes affect diffusion of oxygen to the fetus. As the placenta loses its ability to nourish the fetus, the fetus uses stored nutrients to stay alive, and wasting occurs. This wasted appearance at birth is secondary to the loss of muscle mass and subcutaneous fat. A recent study found that mortality risk in post-term infants was strongly related to fetal growth restriction, not gestational age (Morken, Klungsoyr, & Skjaerven, 2014).

Nursing Assessment

A thorough assessment of the post-term newborn upon admission to the nursery provides a baseline from which to identify changes in clinical status. Review the maternal history for any risk factors associated with post-term birth. Also be aware of the common physical characteristics and be able to identify any deviation from the expected. Post-term newborns typically exhibit the following characteristics:

• Dry, cracked, peeling, wrinkled skin

• Absence of vernix caseosa and lanugo

• Long, thin extremities

- Creases that cover the entire soles of the feet
- Wide-eyed, alert expression
- Abundant hair on scalp
- Thin umbilical cord
- Long fingernails
- Limited vernix and lanugo
- Meconium-stained skin and fingernails (Mattson & Smith, 2016)

Assess the newborn's gestational age and complete a physical examination to identify any abnormalities. Review the medical record to determine the color of the amniotic fluid when membranes ruptured and observe for a meconium-stained umbilical cord and fingernails to assess for possible meconium aspiration. Careful suctioning at the time of birth and afterward, if the condition dictates it, reduces the incidence of meconium aspiration. Also be alert for other typical complications associated with a post-term newborn, such as perinatal asphyxia (caused by placental aging or oligohydramnios [decreased amniotic fluid]), hypoglycemia (caused by acute episodes of hypoxia related to cord compression, which exhausts carbohydrate reserves), hypothermia (caused by loss of subcutaneous fat), and polycythemia (caused by an increased production of red blood cells to compensate for a reduced oxygen environment). Be prepared to initiate early interventions (see Table 23.1).

Nursing Management

The birth of a post-term newborn may create stress for the mother and her family. In most situations, birth of a newborn requiring special care was not anticipated. Post-term newborns are susceptible to several birth challenges secondary to placental dysfunction that place them at risk for asphyxia, hypoglycemia, and respiratory distress. The nurse must be vigilant for complications when managing these newborns.

The post-term newborn is at high risk for perinatal asphyxia, which is usually attributed to placental deprivation or oligohydramnios that leads to cord compression, thereby reducing perfusion to the fetus. Anticipating the need for newborn resuscitation is a priority. The newborn resuscitation team needs to be available in the birthing suite for immediate backup. The newborn may require transport to the NICU for continuous assessment, monitoring, and treatment,

depending on his or her status after resuscitation.

Monitor and maintain the post-term newborn's blood glucose levels once stabilized. Intravenous dextrose 10% and/or early initiation of feedings will help stabilize the blood glucose levels to prevent central nervous system sequelae. Also monitor the post-term newborn's skin temperature, respiration characteristics, results of blood studies, such as ABGs and serum bilirubin levels, and neurologic status. Institute measures to prevent or reduce the risk of hypothermia by eliminating sources of heat loss: thoroughly dry the newborn at birth, wrap him or her in a warmed blanket, and place a stockinette cap on the newborn's head. Providing environmental warmth via a radiant heat source will help stabilize the newborn's temperature.

Closely assess all post-term newborns for polycythemia, which contributes to hyperbilirubinemia due to red blood cell destruction. Providing adequate hydration helps to reduce the viscosity of the newborn's blood to prevent thrombosis. Be alert to the early, often subtle signs to promote early identification and prompt treatment to prevent any neurodevelopmental delays.

Consider This

I had been waiting for this baby since I can remember and now I was told to wait even longer. I was into my third week past my due date and was just told that if I didn't go into labor on my own, the doctor would induce me on Monday. As I walked out of his office into the hot summer sun, I thought about all the comments that would await me at the office: "You're not still pregnant, are you?" "Weren't you due last month?" "You look as big as a house." "Are you sure you aren't expecting triplets?" I started to get into my car when I felt warm fluid slide down my legs. Although I was embarrassed at my wetness, I was thrilled I wouldn't have to go back to the office and drove myself to the hospital. Within hours my wait was finally over with the birth of my son, a post-term infant with peeling skin and a thick head of hair. He was certainly worth the wait!

Thoughts: Although most due dates are within plus or minus 2 weeks, we can't "go to the bank with it" because so many factors influence the start of labor. This woman was anxious about her overdue status, but nature

prevailed. The old adage "when the fruit is ripe, it will fall" doesn't always bring a good outcome: many women need a little push to bring a healthy newborn forth. What happens when the fetus stays inside the uterus too long? What other features are typical of post-term infants?

Dealing With Perinatal Loss

It is estimated that over 7 million perinatal losses occur globally each year. More than 1 million fetal deaths occur in the United States each year. Social determinants associated with perinatal loss include lack of education, poverty, overcrowded living conditions, poor sanitation, poor air quality, malnourishment, and war zones (Callister, 2014). Perinatal loss, defined as any pregnancy loss and/or neonatal death up to 1 month of age, continues to be a common occurrence although major advances have taken place in perinatal health care. The prevalence of perinatal death reflects a very real possibility that all nurses will meet and care for a woman who has experienced the death of a baby. Openness to expressions of grief, helping couples mobilize support, considering readiness for another pregnancy, and directing couples to useful Internet sites are essential nursing interventions (Callister, 2014).

Perinatal loss is a profound experience for the family. It engenders a unique kind of mourning since the infant is so much a part of the parents' identity. Instead of celebrating a new life as they expected, parents are mourning the loss of dreams and hopes and the loss of an extension of themselves. NICU nurses face a difficult situation when caring for newborns who may not survive. Newborn death is incomprehensible to most parents/partners/significant others. They are commonly offered time to see their infant, memory items, and support. This frequently makes the grieving process more difficult because what is happening "can't be real." Deciding whether to see, touch, or hold the dying newborn is extremely difficult for many parents/partners/ significant others. Nurses play a major role in assisting parents to make their dying newborn "real" to them by providing them with as many memories as possible and encouraging them to see, hold, touch, dress, and take care of the infant and take photographs. These actions help to validate the parents' sense of loss, relive the experience, and attach significance to the meaning of loss. A lock of hair, a name card, a photo, or an identification bracelet may serve as important mementoes that can ease the grieving process. The memories created by these interventions can be useful allies in the grieving process and in resolving grief (Jaffe, 2014).

A nurse's willingness to sit quietly and observe, to remain open and nonjudgmental, and to explore what might be helpful is a useful strategy to bridge cultural differences. Statements such as "Help me understand how your family cares for someone who is dying" or "What would be important for me to

know about how best to care for your baby's body?" convey a nurse's willingness to learn what is most important to each family. Parents' answers may help guide nurses in providing culturally appropriate care for diverse populations. Nurses who are attentive to learning what is most important to parents, and subsequently work to incorporate such interventions into their care, foster relationships between parents and their infant (Robinson, 2014).

Parent–newborn interaction is vital to the normal processes of attachment and bonding. The detachment process involved in a newborn's death is equally important for parents. Nurses can aid in this process by helping parents to see their newborn through the maze of equipment, explaining the various procedures and equipment, encouraging them to express their feelings about the newborn's status, and providing time for them to be with their dying newborn (Randolph, Hruby, & Sharif, 2015).

A common reaction by many people when learning that a newborn is not going to survive is one of avoidance. Nurses are no exception. It is difficult to initiate a conversation about such a sensitive issue without knowing how the parents are going to react and cope with the impending loss. One way to begin a conversation with the parents is to convey concern and acknowledge their loss. Active listening can give parents a safe place to begin the healing process. The relationship that the nurse establishes with the parents is a unique one, providing an opportunity for both the nurse and the parents to share their feelings.

Be aware of personal feelings about loss and how these feelings are part of one's own life and personal belief system. Actively listen to the parents when they are talking about their experiences. Communicate empathy (understanding and feeling what another person is feeling), respect their feelings, and respond to them in helpful and supportive ways (Verklan & Walden, 2014). Table 23.2 highlights appropriate interventions for a family experiencing a perinatal loss before and after a newborn dies.

In a time of crisis or loss, individuals are often more sensitive to other people's reactions. For example, the parents may be extremely aware of the nurse's facial expressions, choice of words, and tone of voice. Talking quickly, in a businesslike fashion, or ignoring the loss may inhibit parents from discussing their pain or how they are coping with it. Parents may need to vent their frustrations and anger, and the nurse may become the target. Validate their feelings and attempt to reframe or refocus the anger toward the real issue of loss. An example would be to say, "I understand your frustration and anger about this situation. You have experienced a tremendous loss and it must be difficult not to

have an explanation for it at this time." Doing so helps to defuse the anger while allowing them to express their feelings.

The death of an infant will more than likely be one of the toughest moments in a family's life. Giving families some sense of control in an otherwise hopeless situation can provide some comfort. Some ideas to provide them a sense of control include:

• Ask the family who they wish to have present as the infant dies.

• Give the family a choice of rooms in which they can say good-bye to their infant.

• Provide privacy for the family during this time period by placing a sign on the door.

• Provide ideas for making or selecting memorial items for a memory box.

• The family should never be left to handle their emotions alone unless they request it.

• Respect a family's wishes if they refuse to be with their infant during the dying process or afterward. Everyone grieves differently.

When assisting bereaved parents, start where the parents are in the grief process to avoid imposing your own agenda on them. You may feel uncomfortable at not being able to change the situation or take the pain away. The nurse's role is to provide immediate emotional support and facilitate the grieving process. Supporting and strengthening the family bond in the face of perinatal loss is essential.

TABLE 23.2 ASSISTING PARENTS TO COPE WITH PERINATAL LOSS

Before the newborn's death	Respect variations in the family's spiritual needs and readiness. Assess cultural beliefs and practices that may bring comfort; respect culturally appropriate requests for truth telling and informed refusal. Initiate spiritual comfort by calling the hospital clergy if appropriate; offer to pray with the family if appropriate. Encourage the parents to take photographs, make memory boxes, and record their thoughts in a journal. Explore with family members how they dealt with previous losses. Discuss techniques to reduce stress, such as meditation and relaxation. Recommend that family members maintain a healthy diet and get adequate rest and exercise to preserve their health. Participate in early and repeated care conferencing to reduce family stress. Allow family to be present at both medical rounds and resuscitation; provide explanations of all procedures, treatments, and findings; answer questions honestly and as completely as possible. Provide opportunities for the family to hold the newborn if they choose to. Assess the family's support network. Provide suggestions as to how friends can be helpful to the family.
After the newborn's death	Help the family to accept the reality of death by using the word "died." Acknowledge their grief and the fact that their newborn has died. Help the family to work through their grief by validating and listening. Provide the family with realistic information about the causes of death. Offer condolences to the family in a sincere manner. Encourage the father to cry and grieve with his partner. Provide opportunities for the family to hold the newborn if they desire.
At the time of the release of the newborn's body	Reassure the family that their feelings and grieving responses are normal. Encourage the parents to have a funeral or memorial service to bring closure. Suggest that the parents plant a tree or flowers to remember the infant. Address attachment issues concerning subsequent pregnancies. Provide information about local support groups. Provide anticipatory guidance regarding the grieving process. Present information about any impact on future childbearing, and refer the parents to appropriate specialists or genetic resources.

(2014). Review of interventions to reduce stress among mothers of infants in the NICU. *Advances in Neonatal Care*, 14(1), 30–37; Jaffe, J. (2014). The reproductive story: Dealing with miscarriage, stillbirth, or other perinatal demise. In *Women's reproductive mental health across the lifespan* (pp. 159–176). Springer International Publishing; and Kissane, D. W., & Parnes, F. (Eds.). (2014). *Bereavement care for families*. New York, NY: Routledge.

Comforting the family after the infant's death is vital to give them a sense of closure and start the healing process. Some things the nurse can do to help the family during this time include:

• Sending the family a card from the nursing staff, signed by all who worked with their infant within a week of leaving the hospital.

• Attending the funeral to allow for a public good-bye and to support others in their time of loss.

• Providing the family with a memory box, which might contain an outfit worn by their infant, a blanket used to cover their infant, a lock of hair, and a card with hand and foot prints, a photo with someone holding their infant, etc.

• Remembering their infant at various anniversaries by sending a card or calling the family to see how they are doing.

• Donating to a charity such as March of Dimes in memory of the infant.

- Providing the family with resources that might help them. Information might include listings of local or online support groups as well as grief web sites such as Share.org.

   Being present during this traumatic event for families is tough. Serving infants and their families by bearing witness to their pain and grief is a special privilege. Being present for the family with compassion, comfort, support, and resources during their time of loss is truly an honorable gesture. Nurses are remembered years later for their kindness and guidance of the family members through this adverse event with dignity (Green et al., 2015).

Take Note!

Infants born prematurely between 34 0/7 and 36 6/7 weeks are at higher risk for morbidity and mortality than those born before 28 weeks or after 37 weeks due to their physiologic and metabolic immunity (Boyle et al., 2015).

KEY CONCEPTS

- Variations in birth weight and gestational age can place a newborn at risk for problems that require special care.
- Variations in birth weight include the following categories: small for gestational age, appropriate for gestational age, and large for gestational age. Newborns who are small or large for gestational age have special needs.
- The SGA newborn faces problems related to a decrease in placental function in utero; these problems may include perinatal asphyxia, hypothermia, hypoglycemia, polycythemia, and meconium aspiration.
- Risk factors for the birth of a LGA infant include maternal diabetes mellitus or glucose intolerance, multiparity, prior history of a macrosomic infant, postdated gestation, maternal obesity, male fetus, and genetics. LGA newborns face problems such as birth trauma due to cephalopelvic disproportion, hypoglycemia, and jaundice secondary to hyperbilirubinemia.
- Variations in gestational age include post-term and preterm newborns. Post-term newborns may be large or small for gestational age or dysmature, depending on placental function.

- The post-term newborn may develop several complications after birth, including fetal hypoxia, hypoglycemia, hypothermia, polycythemia, and meconium aspiration.

- Preterm birth is the leading cause of death within the first month of life and the second leading cause of all infant deaths.

- The preterm newborn is at risk for complications because his or her organ systems are immature, thereby impeding the transition from intrauterine life to extrauterine life.

- Newborns can experience pain, but their pain is difficult to validate with consistent behaviors.

- Newborns with gestational age variations, primarily preterm newborns, benefit from developmental care, which includes a variety of activities designed to manage the environment and individualize the care based on behavioral observations.

- Nurses play a key role in assisting the parents and family of a newborn with special needs to cope with this crisis situation, including dealing with the possibility that the newborn may not survive. Nurses working with parents experiencing a perinatal loss can help by actively listening, understanding the parents' experiences, and communicating empathy.

- The goal of discharge planning is to make a successful transition to home care.

CHAPTER **WORKSHEET**

MULTIPLE CHOICE QUESTIONS

1. The nurse documents that a newborn is post-term based on the understanding that he was born after:

   a. 38 weeks' gestation

   b. 40 weeks' gestation

   c. 42 weeks' gestation

   d. 44 weeks' gestation

2. SGA and LGA newborns have an excessive number of red blood cells because of:

   a. Hypoxia

   b. Hypoglycemia

   c. Hypocalcemia

   d. Hypothermia

3. Because subcutaneous and brown fat stores were used for survival in utero, the nurse would assess an SGA newborn for which of the following?

   a. Hyperbilirubinemia

   b. Hypothermia

   c. Polycythemia

   d. Hypoglycemia

4. In assessing a preterm newborn, which of the following findings would be of greatest concern?

   a. Milia over the bridge of the nose

   b. Thin transparent skin

   c. Poor muscle tone

   d. Heart murmur

5. In dealing with parents experiencing a perinatal loss, which of the following nursing interventions would be most appropriate?

   a. Sheltering the parents from the bad news

   b. Making all the decisions regarding care

   c. Encouraging them to participate in the newborn's care

d. Leaving them by themselves to allow time to grieve

6. The nurse is providing care to several newborns with variations in gestational age and birth weight. When developing the plan of care for these newborns, the nurse focuses on energy conservation to promote growth and development. Which measures would the nurse include in the nursing plans of care? Select all that apply.

   a. Keeping the handling of the newborn to a minimum

   b. Maintaining a neutral thermal environment

   c. Decreasing environmental stimuli

   d. Initiating early oral feedings

   e. Using thermal warmers in all cribs

   f. Promoting kangaroo care by caretakers

7. Which of the following concepts would the nurse incorporate into the plan of care when assessing pain in a newborn with special needs?

   a. Newborns experience pain primarily with surgical procedures.

   b. Preterm newborns in the NICU are at the least risk for pain.

   c. Pain assessment needs to be comprehensive and frequent.

   d. A newborn's facial expression is the primary indicator of pain.

8. The term evidence-based refers to the use of which of the following to validate a nurse's practice interventions?

   a. Research findings

   b. Written guidelines

   c. Unit procedure manual

   d. Institutional policies

9. A preterm infant is placed under the radiant heat warmer after birth. The nurse evaluates the temperature frequently to prevent which of the following:

   a. Cold stress

   b. Respiratory depression

   c. Tachycardia

d. Thermogenesis

10. Which of the following lab values need to be monitored by the nurse when providing care for a large for gestational age infant?

a. White cell count

b. Direct Coombs test

c. Blood glucose

d. Potassium level

CRITICAL THINKING EXERCISE

1. After fetal distress was noted on the monitor, a post-term newborn was delivered via a difficult vacuum extraction. The newborn had low Apgar scores and had to be resuscitated before being transferred to the nursery. Once admitted, the nurse observed the following behaviors: jitteriness, tremors, hypotonia, lethargy, and rapid respirations.

a. What might these behaviors indicate?

b. For what other conditions might this newborn be at high risk?

c. What intervention is needed to address this newborn's condition?

2. A preterm newborn was born at 35 weeks following an abruptio placentae due to a car accident. He was transported to the NICU at a nearby regional medical center. After being stabilized, he was placed in an isolette close to the door and placed on a cardiac monitor. A short time later, the nurse notices that he is cool to the touch and lethargic, has a weak cry, and has an axillary temperature of 36° C.

a. What might have contributed to this newborn's hypothermic condition?

b. What transfer mechanism may have been a factor?

c. What intervention would be appropriate for the nurse to initiate?

3. A term SGA newborn weighing 4 lb was brought to the nursery for admission a short time after birth. The labor and birth nurse reports the mother was a heavy smoker, a cocaine addict, and experienced physical abuse throughout her pregnancy. After stabilizing the newborn and correcting the hypoglycemia with oral feedings, the nurse observes the following: acrocyanosis, ruddy

color, poor circulation to the extremities, tachypnea, and irritability

a. What complication might this SGA newborn be manifesting?

b. What factors may have contributed to this complication?

c. What would be an appropriate intervention for managing this condition?

STUDY ACTIVITIES

1. At a community health department maternity clinic, secure permission to interview the parents of a special needs child. Ask about their feelings throughout the experience. How are they managing and coping now?

2. Visit the March of Dimes web site and review this group's national campaign to reduce the incidence of prematurity. Are their strategies workable or not? Explain your reasoning.

3. A common metabolic disorder present in both SGA and LGA newborns after birth is _____.

4. A 10-lb LGA newborn is brought to the nursery after a difficult vaginal birth. The nursery nurse should focus on detecting birth injuries such as _____.

BRINGING IT ALL TOGETHER: CASE STUDY

A pregnant woman drops in to the local hospital emergency room in labor. She has been inconsistent in attending her prenatal clinic appointments and is not sure of the date of her last menstrual period. She admits to smoking a pack of cigarettes per day, but states she has cut back from a two-pack a day habit prior to this pregnancy. Her membranes rupture for meconium stained fluid and she gives birth to a female infant weighing 2,200 g with low Apgar scores, who is taken to the nursery for observation.

ASSESSMENT

Upon admission to the nursery, the nurse observes the following: loose, wrinkled, peeling dry skin, long, thin extremities, small amounts of vernix caseosa and lanugo, and long green finger nails. When plotted on a weight for gestational age chart, the infant falls below the 10th percentile. A physical

examination was done to identify any abnormalities.

Go to thePoint to find questions to consider about this case.

Nursing Management of the Newborn at Risk: Acquired and Congenital Newborn Conditions

alcohol-related birth defects
anencephaly
asphyxia
bilirubin encephalopathy
caput succedaneum
cephalhematoma
congenital diaphragmatic hernia

developmental dysplasia of the hip
epispadias
fetal alcohol spectrum disorders (FASD)
gastroschisis
hydrocephalus
hyperbilirubinemia
hypospadias
infant of a diabetic mother (IDM)
meconium aspiration syndrome (MAS)
meningocele
microcephaly
myelomeningocele
neonatal abstinence syndrome (NAS)
neonatal sepsis
neural tube defect (NTD)
omphalocele
respiratory distress syndrome (RDS)
spina bifida

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Describe the most common acquired conditions affecting the newborn.
2. Construct the nursing management of a newborn experiencing respiratory distress syndrome.
3. Outline the birthing room preparation and procedures necessary to prevent meconium aspiration syndrome in the newborn at birth.
4. Devise parent education for the follow-up care needed by newborns with retinopathy of prematurity (ROP).
5. Select risk factors for the development of necrotizing enterocolitis.
6. Examine the impact of maternal diabetes on the newborn and the care needed.
7. Research the assessment and interventions for a newborn experiencing substance withdrawal after birth.
8. Outline the assessment and nursing management needed for newborns sustaining birth trauma.
9. Plan the assessment, interventions, prevention, and management of hyperbilirubinemia in newborns.
10. Summarize the interventions appropriate for a newborn with neonatal sepsis.
11. Compare and contrast the four classifications of congenital heart disease.
12. Evaluate the major acquired congenital anomalies affecting the central nervous system, respiratory system, gastrointestinal system, genitourinary system, and musculoskeletal system that can occur in a newborn.
13. Distinguish between three inborn errors of metabolism.
14. Formulate a plan of care for a newborn with an acquired or congenital condition.
15. Characterize the importance of parental participation in care of the newborn with an acquired or congenital condition, including the nurse's role in facilitating parental involvement.

Kelly, a 27-year-old G2P1, comes to the labor and birth area in active labor. She tells you she is overdue and relieved to finally be giving birth. Her membranes rupture on admission, revealing meconium-stained fluid. What additional nursing assessments need to be carried out now? What risk factors need to be considered when developing Kelly's plan of care?

Words of Wisdom

Courage and faith in oneself project onto others, giving them the strength to persevere.

INTRODUCTION

Advances in prenatal and neonatal medical and nursing care throughout the industrialized world have led to a marked increase in the number of newborns who have survived a high-risk pregnancy but experience acquired or congenital conditions. These newborns are considered one of our most vulnerable at-risk populations; that is, they are susceptible to morbidity and mortality because of the acquired or congenital disorder. Several national health goals address the issues of acquired and congenital conditions in newborns (U.S. Department of Health and Human Services, 2010). See *Healthy People 2020* 24.1.

During the past several decades, technological, genomic discoveries and pharmacologic advances, in conjunction with standardized policies and procedures have significantly improved survival rates for at-risk newborns. However, the risk of morbidity remains. For example, some of these newborns are at risk for continuing health problems that require long-term technological support. Other newborns remain at risk for physical and developmental problems into the school years and beyond. Although challenges remain in application of these advances to improve the newborn's health, the high-risk newborn will increasingly benefit from them in the future. Providing the complex care needed to maintain the child's health and well-being will have a tremendous emotional and economic impact on the family. Nurses are challenged to provide support to mothers and their families when neonatal well-being is threatened.

HEALTHY PEOPLE 2020 • 24.1

Objective	Nursing Significance

1. Reduce fetal and infant deaths:
    Decrease the number of all infant deaths (within 1 year) from a baseline of 6.2/1,000 live births to 5.6/1,000 live births (a 10% improvement).
    Decrease the number of neonatal deaths (within the first 28 days of life) from a baseline of 4.5 to 4.1 deaths/1,000 live births (a 10% improvement).
    Decrease the number of postneonatal deaths from a baseline of 2.2 to 2.0 deaths/1,000 live births (a 10% improvement).
    Reduce the number of deaths related to all birth defects from a baseline of 1.4 to 1.3 deaths/1,000 live births (a 10% improvement).
	• Will foster early and consistent prenatal care, including education to place infants on their backs for naps and sleeping to prevent SIDS and avoidance of exposing the newborn to cigarette smoke.

2. Reduce the occurrence of developmental disabilities:
    Reduce the number of children with cerebral palsy who were born as low-weight infants (<2,500 g) from 50% to 45%.
    Reduce the number of children with autism spectrum disorder.
	• Will promote measures for close antepartal and intrapartal monitoring of women at risk, subsequently reducing the incidence of disabilities, leading to a reduction in long-term effects and costs of care.

3. Reduce the occurrence of spina bifida and other neural tube defects: Reduce the number of new cases of spina bifida or other neural tube defects from a baseline of 34.2 to 30.8 new cases/100,000 live births.	• Will help to increase awareness of the need for all women of childbearing age to take a multivitamin containing at least 400 mg of folic acid and consume foods high in folic acid.
4. Reduce the occurrence of fetal alcohol syndrome. No target goal set for 2020.	• Will foster programs for at-risk groups, including adolescents, about the effects of substance abuse, especially alcohol, during pregnancy.

5. Ensure appropriate newborn blood spot screening, follow-up testing, and referral to services:
    Ensure all newborns are screened at birth for conditions as mandated by their state-sponsored newborn screening programs.
    Ensure that follow-up diagnostic testing for screening positives is performed within an appropriate time period.
    Ensure that infants with diagnosed disorders are enrolled in appropriate service interventions within an appropriate time period.
	• Will help in the development of protocols and procedures to ensure appropriate screening and follow-up for all newborns.

Healthy People objectives based on data from http://www.healthypeople.gov.

Acquired disorders typically occur at or soon after birth. They may result from problems or conditions experienced by the woman during her pregnancy or at birth, such as diabetes, maternal infection, or substance abuse or conditions associated with labor and birth, such as prolonged rupture of membranes or fetal distress. However, there may be no identifiable cause for the disorder.

Congenital disorders can be defined as structural or functional or metabolic abnormalities which are present at birth. According to the World Health Organization (WHO), an estimated 1 in 33 infants or over 3 million fetuses and infants globally are born each year with major congenital disorders. They are

found in approximately 3% of all newborns. The most common serious congenital disorders are congenital heart defects, neural tube defects (NTDs), and Down syndrome (WHO, 2015a). Congenital disorders, which typically involve a problem with inheritance, include structural anomalies (commonly referred to as birth defects), chromosomal disorders, and inborn errors of metabolism. Most congenital disorders have a complex etiology, involving many interacting genes, gene products, and social and environmental factors during organogenesis (the origin and development of organs). Some alterations can be prevented or compensated for with pharmacologic, nutritional, or other types of interventions, while others cannot be changed. The field of genomics and genetic medicine has witnessed an explosion of new knowledge, much of it learned from the Human Genome Project. Advances in understanding of the genetic basis of development and function, as well as the interaction of genes and the environment, continue to foster new insights into human health. Only through increased insight into the complex interplay of genetic, environmental, social, and cultural factors can these devastating and life-changing outcomes be prevented (Francine, Pascale, & Aline, 2014).

This chapter addresses selected acquired and congenital newborn conditions. In addition, it describes the nurse's role in assessment and management, emphasizing parental education and support. Nurses play a key role in helping the parents cope with the stress of having an ill newborn.

ACQUIRED DISORDERS

Congenital disorders are passed genetically from a parent to their offspring. These disorders are attained prior to birth. Acquired disorders are not passed genetically or caused by hereditary or developmental factors; they are obtained after birth, by a reaction to environmental influences outside of the body. A few examples might include respiratory distress syndrome (RDS), retinopathy of prematurity (ROP), birth trauma, hyperbilirubinemia, and newborn infections.

Perinatal Asphyxia

At birth, the lungs of newborns are filled with fluid. This fluid must be cleared and replaced with air after birth. As the newborn makes the transition to life outside the fluid-filled intrauterine environment, dramatic changes must occur to facilitate newborn respirations.

Perinatal asphyxia occurs when pulmonary oxygenation is delayed or interrupted. This insult can lead to death if not reestablished. Perinatal asphyxia interferes with newborn development, resulting in long-term deficits associated with mental and neurologic conditions with delayed onsets (Herrera-Marschitz et al., 2014).

Asphyxia is the most common clinical insult in the perinatal period. As many as 10% of newborns require some degree of active resuscitation to stimulate their breathing at birth (Cunningham et al., 2014). According to the World Health Organization (WHO, 2015b), up to 10 million cases of neonatal asphyxia occur annually worldwide, accounting for approximately 24% of all newborn deaths. More than a million newborns who survive asphyxia at birth develop long-term problems such as cerebral palsy, intellectual disability, and speaking, hearing, visual, and learning disabilities (WHO, 2015b).

Pathophysiology

Physiologically, asphyxia can be defined as impaired gas exchange resulting in a decrease in blood oxygen levels (hypoxemia) and an excess of carbon dioxide (hypercarbia) or hypercapnia that leads to metabolic acidosis. Any condition that reduces oxygen delivery to the fetus can result in asphyxia. These conditions may include maternal hypoxia, such as from cardiac or respiratory disease, anemia, or postural hypotension; maternal vascular disease that leads to placental insufficiency, such as diabetes or hypertension; cord problems such as compression or prolapse; and post-term pregnancies, which may trigger meconium release into the amniotic fluid.

Initially, the newborn uses compensatory mechanisms including tachycardia and vasoconstriction to help bring oxygen to the vital organs for a time. However, without intervention, these mechanisms fail, leading to hypotension, bradycardia, and eventually cardiopulmonary arrest.

With failure to breathe well after birth, the newborn will develop hypoxia (too

little oxygen in the cells of the body). As a result, the heart rate falls, cyanosis develops, and the newborn becomes hypotonic and unresponsive. Newborn resuscitation is needed to help initiate breathing in newborns who fail to breathe spontaneously at birth.

> *Think back to Kelly, described at the beginning of the chapter. She gives birth to a son weighing approximately 2,500 g; he appears post-term and small for gestational age. His skin is stained yellow-green and he is limp, cyanotic, and apneic at birth. The initial assessment once the newborn is under the radiant warmer indicates that resuscitation and tracheal suctioning are needed. What is the nurse's role during resuscitation? What assessments will be needed during this procedure?*

Nursing Assessment

The key to successful treatment of newborn asphyxia is early identification and recognition of newborns who may be at risk. Review the perinatal history for risk factors, including:

• *Trauma*: injury to the central or peripheral nervous system secondary to a long or difficult labor, a precipitous birth, multiple gestation, abnormal presentation, cephalopelvic disproportion, shoulder dystocia, or extraction by forceps or vacuum.

• *Intrauterine asphyxia*: for example, fetal hypoxia secondary to maternal hypoxia, diabetes, hypertension, anemia, cord compression, fetal bradycardia, or meconium aspiration.

• *Sepsis*: acquired bacterial or viral organisms from infected amniotic fluid, maternal infection, or direct contact while passing through the birth canal.

• *Malformation*: congenital anomalies including facial or upper airway deformities, renal anomalies, pulmonary hypoplasia, neuromuscular disorders, esophageal atresia, or NTDs.

• *Hypovolemic shock*: secondary to abruptio placentae, placenta previa, or cord rupture resulting in blood loss to the fetus.

• *Medication*: drugs given to mother during labor that can affect the fetus by causing placental hypoperfusion and hypotension; use of hypnotics, analgesics, anesthetics, narcotics administered to the mother within 4 hours of birth,

oxytocin, and street drugs during pregnancy.

At birth, assess the newborn immediately. Observe the infant's color, noting any pallor or cyanosis. Assess the work of breathing. Be alert for apnea, tachypnea, gasping respirations, grunting, nasal flaring, or retractions. Evaluate heart rate and note bradycardia. Assess the newborn's temperature, noting hypothermia. Based on the initial assessment if poor, begin resuscitation measures until the Apgar score is above 7.

Anticipate diagnostic testing to identify etiologies for the newborn's asphyxia. For example, a chest x-ray may identify structural abnormalities that might interfere with respiration. A blood culture may identify an infectious process. A blood toxicology screen may detect any maternal drugs in the newborn. Severe fetal and neonatal asphyxia impair the physiologic transitions to extrauterine life (Verklan & Walden, 2014).

Nursing Management

Management of the newborn experiencing asphyxia includes immediate resuscitation. Ensure that the equipment needed for resuscitation is readily available and in working order. Essential equipment includes:

• wall suction apparatus

• oxygen source

• newborn ventilation bag

• infant warmer

• surgical blue towels

• endotracheal tubes (2 to 3 mm)

• laryngoscope

• ampules of naloxone (Narcan) with syringes and needles for administration.

Effective ventilation is the key to successful newborn resuscitation. Ventilation is frequently initiated with a manual resuscitation bag and face mask followed by endotracheal intubation if respiratory depression continues. (See Chapter 23 for a more detailed discussion of resuscitation.)

Dry the newborn quickly with a warm towel and then place him or her under a radiant heater to prevent rapid heat loss through evaporation. Handling and rubbing the newborn with a dry towel may be all that is needed to stimulate

breathing. If the newborn fails to respond to stimulation, then active resuscitation is needed.

The procedure for newborn resuscitation is easily remembered by the ABCDs—**a**irway, **b**reathing, **c**irculation, and **d**rugs (see Chapter 23, Box 23.3). Continue resuscitation until the newborn has a pulse above 100 bpm, a good (healthy) cry, or good breathing efforts and a pink tongue. This last sign indicates a good oxygen supply to the brain (Jaques & Kennea, 2015).

Take Note!

According to the American Heart Association (AHA) and American Academy of Pediatrics (AAP) Guidelines for Neonatal Resuscitation, resuscitation efforts may be stopped if the newborn exhibits no heartbeat and no respiratory effort after 10 minutes of continuous and adequate resuscitation (AHA & AAP, 2014).

Provide continued observation and assessment of the newborn who has been successfully resuscitated. Monitor the newborn's vital signs and oxygen saturation levels closely for changes. Maintain a neutral thermal environment to prevent hypothermia, which would increase the newborn's metabolic and oxygen demands. Check the blood glucose level and observe for signs of hypoglycemia; if this develops, it can further stress the newborn.

FIGURE 24.1 A father and sibling interacting with their newborn once the newborn's condition has stabilized.

The need for resuscitative measures can be extremely upsetting for the parents. Explain to them the initial resuscitation activities being performed and offer ongoing explanations about any procedures being done, equipment being used, or medications given. Provide physical and emotional support to the parents through the initial crisis and throughout the newborn's stay. When the newborn is stable, allow family to spend time with their newborn to promote bonding (Fig. 24.1). Point out the newborn's positive attributes (color, activity level, healthy cry) and give frequent updates on his or her status. Role-model techniques for holding, interacting with, and caring for the newborn to decrease the parents' anxiety post-resuscitation.

Remember Kelly, the young woman described at the beginning of the chapter? Her son is intubated and tracheal suctioning is performed. Positive-pressure ventilation is also started with a self-inflating bag and 50% oxygen. Ventilation is continued for 1 minute and then gradually discontinued. The heart rate is now 120 bpm, and spontaneous respirations are noted. When free-flow oxygen is administered, the newborn begins to cry and turn pink. What continued care is needed in the special care nursery? What explanation should be offered to Kelly regarding her son's treatment?

Transient Tachypnea of the Newborn

Transient tachypnea of the newborn (TTN) is a self-limiting condition involving a mild degree of respiratory distress. TTN is the result of a delay in clearance of fetal lung liquid. In the past, respiratory distress was thought to be a problem of relative surfactant deficiency, but is now characterized by an airspace-fluid burden secondary to the inability to absorb fetal lung liquid. It usually occurs within a few hours of birth and resolves over a 48- to 72-hour period. It occurs in approximately 1% of live births and incidence is higher in males than females (Subramanian et al., 2015). Although TTN is thought to be benign at birth, there is increasing data to link it to a newborn's risk to developing a wheezing syndrome early in life (Johnson, 2015).

Pathophysiology

Most newborns make the transition from fetal to newborn life without incident. During fetal life, the lungs are filled with a serous fluid because the placenta, not the lungs, is used for nutrient and gas exchange. During and after birth, this fluid must be removed and replaced with air. An infant born by cesarean birth is at risk of having excessive pulmonary fluid as a result of not having experienced all of the stages of labor. Passage through the birth canal during a vaginal birth compresses the thorax, which helps remove the majority of this fluid. Surgical births bypass the lessening of lung fluid for the newborn and place them at increased risk of TTN. Pulmonary circulation and the lymphatic drainage remove the remaining fluid shortly after birth. TTN occurs when the liquid in the lung is removed slowly or incompletely. The excess lung fluid results in decreased pulmonary compliance. Tachypnea develops to compensate for the increased workload of breathing associated with reduced compliance.

Nursing Assessment

Astutely observe the newborn with respiratory distress because TTN is a diagnosis of exclusion. Initially it might be difficult to distinguish this condition from RDS or group B streptococcal pneumonia, because the clinical picture is similar. However, the symptoms of transient tachypnea rarely last more than 72 hours. If symptoms progress beyond 72 hours, further investigation into another cause should be considered (Kim, Yang, & Kim, 2015).

HEALTH HISTORY AND PHYSICAL EXAMINATION

Review the perinatal history for contributing factors. TTN is commonly seen in newborns whose mothers have been heavily sedated in labor or have been born via cesarean birth. Also check the history for evidence of a prolonged labor, fetal macrosomia, inadequate initial resuscitation, breech births, when labor and birth are rapid, infants experiencing hypothermia, infants born before 38 weeks' gestation, infants born to a mother with diabetes, and maternal asthma and smoking. These factors are associated with a higher incidence of TTN.

Closely assess the newborn for signs of TTN. Within the first few hours of birth, observe for tachypnea, expiratory grunting, mild intercostal retractions, decreased breath sounds due to reduced air entry, labored breathing, nasal flaring, crackles on auscultation, and mild cyanosis. Mild to moderate respiratory distress is present by 6 hours of age, with respiratory rates as high as 100 to 140 breaths per minute (Lee, 2015). Also inspect the newborn's chest for hyperextension or a barrel shape. Auscultate breath sounds, which may be slightly diminished secondary to reduced air entry.

LABORATORY AND DIAGNOSTIC TESTING

To aid in the diagnosis, a chest x-ray may be done. It usually reveals mild symmetric lung hyperaeration and prominent perihilar interstitial markings and streaking. These findings correlate with lymphatic engorgement of retained fetal fluid. In addition, an arterial blood gas (ABG) assessment is important to ascertain the degree of gas exchange and acid–base balance. It typically demonstrates mild hypoxemia, mildly elevated CO_2 level, and a normal pH (Subramanian et al., 2015).

Nursing Management

Management of TTN is supportive. As the retained lung fluid is absorbed by the infant's lymphatic system, the pulmonary status improves. Nursing management focuses on providing adequate oxygenation and determining whether the newborn's respiratory manifestations appear to be resolving or persisting. Provide supportive care while the retained lung fluid is reabsorbed. Administer intravenous fluids and/or gavage feedings until the respiratory rate decreases enough to allow safe oral feeding. Withhold oral feedings until the respiratory status has improved. Provide supplemental oxygen via a nasal cannula or oxygen hood to maintain adequate oxygen saturation. Maintain a neutral thermal

environment with minimal stimulation to minimize oxygen demand.

Provide ongoing assessment of the newborn's respiratory status. As TTN resolves, the newborn's respiratory rate declines to 60 breaths per minute or less, cyanosis resolves as do the nasal flaring and grunting sounds, the oxygen requirement decreases, the ABG values return to the normal range, bilateral breath sounds demonstrate good air entry, and the chest x-ray shows resolution of the perihilar streaking. Provide reassurance and progress reports to the parents to help them cope with this crisis.

Respiratory Distress Syndrome

Despite improved survival rates and advances in perinatal care, many high-risk newborns are at risk for respiratory problems, particularly **respiratory distress syndrome (RDS)**, a breathing disorder resulting from lung immaturity and lack of alveolar surfactant, which keeps the air sacs in the lungs from collapsing and allows them to inflate easily. Without surfactant, the alveoli collapse at the end of expiration. RDS is characterized by compromised lung expansion, poor gas exchange, and ventilator failure. Since the link between RDS and surfactant deficiency was discovered more than 30 years ago, tremendous strides have been made in understanding the pathophysiology and treatment of this disorder. The introduction of prenatal steroids to accelerate lung maturity and the development of synthetic surfactant can be credited with the dramatic improvements in the outcome of newborns with RDS.

RDS affects up to 25,000 infants born alive in the United States annually. The incidence declines with degree of maturity at birth. It occurs in 50% of preterm newborns of less than 28 weeks' gestation, 30% of those born at 28 to 34 weeks, and less than 5% of those born after 34 weeks. Intensive respiratory care, usually with mechanical ventilation, may be necessary.

Pathophysiology

Lung immaturity and surfactant deficiency contribute to the development of RDS. Surfactant is a complex mixture of phospholipids and proteins that adheres to the alveolar surface of the lungs. Anatomically, the immature lung cannot support oxygenation and ventilation because the alveolar sacs are insufficiently developed, causing a deficient surface area for gas exchange. Physiologically, the amount of surfactant is insufficient to prevent collapse of unstable alveoli. Surfactant forms a coating over the inner surface of the alveoli, reducing the surface tension and preventing alveolar collapse at the end of expiration. In the affected newborn, surfactant is deficient or lacking, and this deficit results in stiff lungs and alveoli that tend to collapse, leading to diffuse atelectasis (Fig. 24.2).

The work of breathing is increased because increased pressure similar to that required to initiate the first breath is needed to inflate the lungs with each successive breath. Hypoxemia and acidemia result, leading to vasoconstriction of the pulmonary vasculature. Right-to-left shunting occurs and alveolar

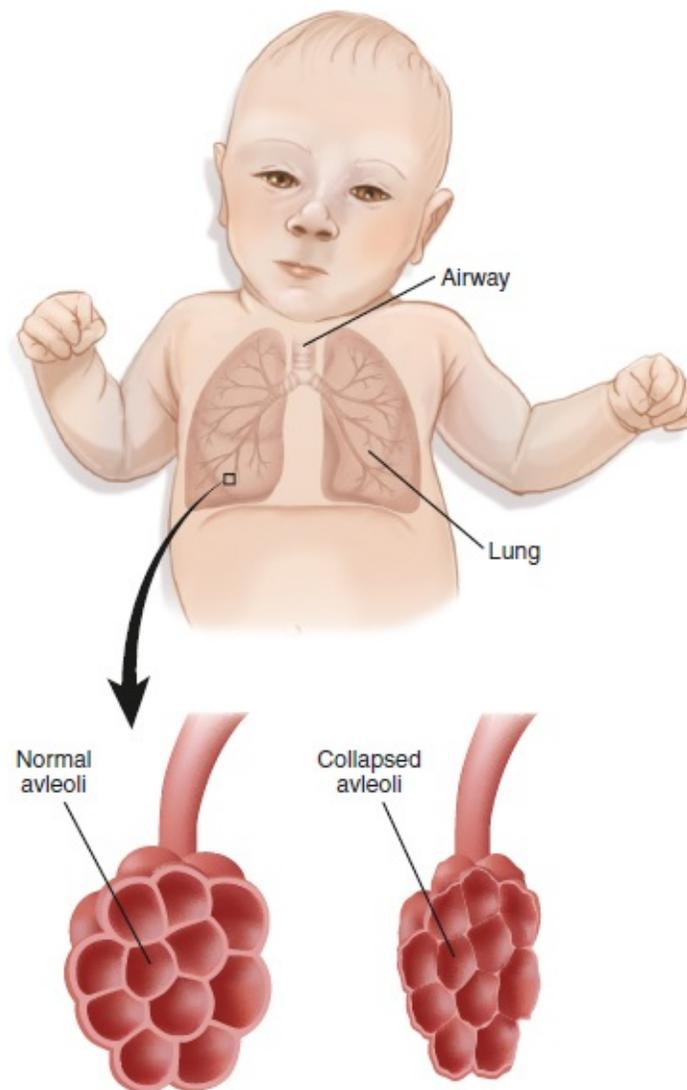
capillary circulation is limited, further inhibiting surfactant production. As the disease progresses, fluid and fibrin leak from the pulmonary capillaries, causing hyaline membranes to form in the bronchioles, alveolar ducts, and alveoli. Hyaline membranes produce a glassy appearance in the lung membranes which is seen on x-rays. These membranes further decrease gas exchange. These factors decrease the total surface area of the gas exchange membrane. The end result is hypoxemia, academia, and worsening respiratory distress. A vicious circle is created, compounding the problem (Moses, 2015).


FIGURE 24.2 Pathophysiology of neonatal respiratory distress syndrome. Comparison of normal and collapsed alveoli.

Nursing Assessment

Nursing assessment focuses on keen observation to identify the signs and symptoms of respiratory distress. In addition, assessment aids in differentiating RDS from other respiratory conditions, such as TTN or group B streptococcal pneumonia.

HEALTH HISTORY AND PHYSICAL EXAMINATION

Review the history for risk factors associated with RDS. These include a preterm birth, perinatal asphyxia regardless of gestational age, neonatal sepsis, previous birth of an infant with RDS, cesarean birth in the absence of preceding labor (due to the lack of thoracic squeezing), male gender, perinatal asphyxia, cold stress, and maternal diabetes (produces high levels of insulin which inhibit surfactant production). It is believed that each of these conditions has an impact on surfactant production, thus resulting in RDS in the term infant (Saker & Martin, 2015).

Take Note!

Prolonged rupture of membranes, fetal growth restriction, gestational hypertension, maternal heroin addiction, and use of prenatal corticosteroids reduce the newborn's risk for RDS because of the physiologic stress imposed on the fetus. Chronic stress experienced by the fetus in utero accelerates the production of surfactant before the 35th week of gestation and, thus, reduces the incidence of RDS at birth.

The newborn with RDS usually demonstrates signs at birth or within a few hours of birth. Observe the infant for expiratory grunting, shallow breathing, nasal flaring, chest wall retractions (Fig. 24.3), see-saw respirations, and generalized cyanosis. Auscultate the heart and lungs, noting tachycardia (rates above 150 to 180), fine inspiratory crackles, and tachypnea (rates above 60 breaths per minute). Use the Silverman–Anderson index assessment tool to determine the degree of respiratory distress. The index involves observation of five features, each of which is scored as 0, 1, or 2 (Fig. 24.4). The higher the score, the greater the respiratory distress. A score over 7 suggests severe respiratory distress.

LABORATORY AND DIAGNOSTIC TESTING

The diagnosis of RDS is based on the clinical picture, a lung ultrasound or x-ray and ABGs which show hypoxemia and acidosis. A chest x-ray reveals hypoaeration, underexpansion, and a "ground-glass" pattern. Other lab tests are done to rule out infection and sepsis as a cause of the respiratory distress (Pramanik, Rangaswamy, & Gates, 2015).

FIGURE 24.3 Sternal retractions are a sign of respiratory distress requiring immediate intervention, such as mechanical ventilation and other monitoring devices. (Copyright Caroline Brown, RNC, MS, DEd.)

Feature observed	0	1	2
Chest movement	Synchronized respirations	Lag on respirations	Seesaw respirations
Intercostal retraction	None	Just visible	Marked
Xiphoid retraction	None	Just visible	Marked
Nares dilation	None	Minimal	Marked
Expiratory grunt	None	Audible by stethoscope	Audible by unaided ear

A controlled clinical trial of effects of water mist on obstructive respiratory signs, death rate, and necroscopy findings among premature infants. *Pediatrics, 17*[4], 1–9.)

Nursing Management

If untreated, RDS will worsen. However, it can be a self-limiting disease, with respiratory symptoms declining after 72 hours. This decline parallels the production of surfactant in the alveoli (Rubarth & Quinn, 2015). The newborn needs supportive care until surfactant is produced. Several therapies for established RDS include conventional mechanical ventilation, continuous positive airway pressure (CPAP), or positive end-expiratory pressure (PEEP) to prevent volume loss during expiration, and surfactant therapy. The use of

exogenous surfactant replacement therapy to stabilize the newborn's lungs until postnatal surfactant synthesis matures has become a standard of care, but is not necessarily evidence based. Knowledge of the surfactant proteins and lipids produced by the epithelial II cells was critical in the development of surfactant replacement preparations used to treat RDS, which enabled widespread use of these preparations used to prevent and treat RDS. This preparation has dramatically improved morbidity and mortality in preterm infants (Eibisberger, Resch, & Resch, 2015; Whitsett, Wert, & Weaver, 2015).

Despite recent advances in the perinatal management of neonatal RDS, controversies still exist. Strong evidence exists for the role of a single course of prenatal steroids in RDS prevention, but the potential benefit and long-term safety of repeated courses are unclear. A Cochrane review concluded that the incidence of RDS was reduced in infants born before 48 hours and between one and seven days of treatment of mothers with antenatal corticosteroids, but not those born <24 hours of administration (Gaur et al., 2015). Many practices involved in preterm neonatal stabilization at birth are not evidence based, including oxygen administration and positive-pressure lung inflation, and they may at times be harmful. Surfactant replacement therapy is crucial in the management of RDS, but the best preparation, optimal dose, and timing of administration at different gestations are not always clear. Respiratory support in the form of mechanical ventilation may also be lifesaving, but can cause lung injury, and protocols should be directed at avoiding mechanical ventilation where possible by using nasal CPAP or nasal ventilation. For newborns with RDS to experience the best outcomes, it is essential that they have optimal supportive care, including maintenance of a normal body temperature, proper fluid management, good nutritional support, and support of the circulation to maintain adequate tissue perfusion (Gardner et al., 2016).

As recommended, care of the newborn with RDS is primarily supportive and requires a multidisciplinary approach to obtain the best outcomes. Therapy focuses on improving oxygenation and maintaining optimal lung volumes. Expect to transfer the newborn to the neonatal intensive care unit (NICU) soon after birth. Apply the basic principles of newborn care, such as thermoregulation, cardiovascular and nutritional support, normal glucose level maintenance, and infection prevention, to achieve the therapeutic goals of reducing mortality and minimizing lung trauma.

Anticipate the administration of surfactant replacement therapy, prophylactically or as a rescue approach. With prophylactic administration,

surfactant is given within minutes after birth, thus providing replacement surfactant before severe RDS develops. Rescue treatment is indicated for newborns with established RDS who require mechanical ventilation and supplemental oxygen. It is typically given within 2 hours after birth and repeated again at 4 hours. The earlier the surfactant is administered, the better the effect on gas exchange. Following surfactant administration, the newborn must be closely monitored, and preparation for reduced need for oxygenation and ventilation must be anticipated (Blennow & Bohlin, 2015).

Administer the prescribed oxygen concentration via nasal cannula. Anticipate the need for ventilator therapy, which has greatly improved in the past several years, with significant advances in conventional and high-frequency ventilation therapies (Fig. 24.5). Recent studies show no difference in outcomes for newborns who received early treatment with high-frequency oscillatory ventilation compared with those receiving conventional mechanical ventilation. They are both equally effective in prevention of bronchopulmonary dysplasia (BPD) without being associated with increased mortality or brain damage (Beam et al., 2014). Although mechanical ventilation has increased survival rates, it is also a contributing factor to BPD, pulmonary hypertension, and ROP (Cunningham et al., 2014).

FIGURE 24.5 A newborn with RDS receiving mechanical ventilation.

In addition, support the newborn with RDS using the following interventions:

• Continuously monitor the infant's cardiopulmonary status via invasive or noninvasive means (e.g., arterial lines or auscultation, respectively).
• Monitor oxygen saturation levels continuously; assess pulse oximeter values to

determine oxygen saturation levels.

- Closely monitor vital signs, acid–base status, and ABGs.

- Administer broad-spectrum antibiotics if blood cultures are positive.

- Administer sodium bicarbonate or acetate as ordered to correct metabolic acidosis.

- Provide fluids and vasopressor agents as needed to prevent or treat hypotension.

- Test blood glucose levels and administer dextrose as ordered for prevention or treatment of hypoglycemia.

- Cluster caretaking activities to avoid overtaxing and compromising the newborn.

- Place the newborn in the prone position to optimize respiratory status and reduce stress.

- Perform gentle suctioning to remove secretions and maintain a patent airway.

- Assess level of consciousness to identify intraventricular hemorrhage.

- Monitor x-ray studies to detect atelectasis or air leak.

- Provide a neutral thermal environment to reduce metabolic and oxygen demands.

- Provide sufficient calories via gavage and intravenous feedings.

- Maintain adequate hydration and assess for signs of fluid overload.

- Provide information to the parents about treatment modalities; give thorough but simple explanations about the rationales for interventions and provide support.

- Encourage the parents to participate in care (Mattson & Smith, 2015; Nagtalon-Ramos, 2014).

Provide ongoing assessment and be alert for complications. These may include air leak syndrome, BPD (chronic lung disease), patent ductus arteriosus, congestive heart failure, intraventricular hemorrhage, ROP, necrotizing enterocolitis (NEC), complications resulting from intravenous catheter use (infection, thrombus formation), and developmental delay or disability (Pramanik, Rangaswamy, & Gates, 2015).

Meconium Aspiration Syndrome

Meconium is a viscous green substance composed primarily of water and other gastrointestinal secretions that can be noted in the fetal gastrointestinal tract as early as 10 to 16 weeks' gestation. Meconium is sterile and does not contain bacteria, the primary factor that differentiates it from stool. Intrauterine distress can cause passage into the amniotic fluid. Factors that promote the passage in utero include placental insufficiency, maternal hypertension, preeclampsia, oligohydramnios, fetal hypoxia, transient umbilical cord compression, and maternal drug abuse, especially of tobacco and cocaine. Meconium can be aspirated before or during labor and after birth. Because meconium is rarely found in the amniotic fluid prior to 34 weeks' gestation, it mainly affects infants born at term and post-term (Haakonsen Lindenskov et al., 2015). It is usually expelled as the newborn's first stool after birth.

Meconium aspiration syndrome (MAS) occurs when the newborn inhales particulate meconium mixed with amniotic fluid into the lungs while still in utero or on taking the first breath after birth. It is a common cause of newborn respiratory distress and can lead to severe illness. Meconium staining of the amniotic fluid, with the possibility of aspiration, occurs in approximately 12% of pregnancies at term (Cunningham et al., 2014). Aspiration induces airway obstruction, surfactant dysfunction, hypoxia, and chemical pneumonitis with inflammation of pulmonary tissues. In severe cases, it progresses to persistent pulmonary hypertension and death (Cunningham et al., 2014). Of the up to 10% of infants born through meconium-stained amniotic fluid, only about 10% develop MAS and of that percentage, approximately 5% of infants with MAS die. The use of surfactant and inhaled nitric oxide has led to the decreased mortality and the need for extracorporeal membrane oxygenation use (Clark & Clark, 2015).

Pathophysiology

The pathophysiology of MAS is complex, and the timing of the insult resulting in it remains controversial. Meconium may be passed in utero secondary to hypoxic stress. Intrauterine fetal gasping, mechanical airway obstruction, pneumonitis, surfactant inactivation, persistent pulmonary hypertension, and damage of umbilical vessels all play roles in the pathophysiology of MAS.

Hypoxia induces the fetus to gasp or attempt to breathe. The fetus may bear down and pass meconium into the amniotic fluid or he or she may experience a vagal reflex that causes relaxation of the anal sphincter, allowing meconium to be passed into the amniotic fluid. The fetus then sucks or swallows this amniotic fluid in utero, or the infant may aspirate meconium with the first breath after birth as air rushes into the lungs.

Although the etiology is not well understood, the effects of meconium can be harmful to the fetus. Meconium alters the amniotic fluid by reducing antibacterial activity and subsequently increasing the risk of perinatal bacterial infection. Additionally, meconium is very irritating because it contains enzymes from the fetal pancreas.

When aspirated into the lungs, meconium blocks the bronchioles, causing an inflammatory reaction as well as a decrease in surfactant production. Gas exchange is impaired and atelectasis occurs. A ball-valve effect occurs when air is inspired into the alveoli but cannot be fully expired secondary to reduced airway diameter. Significant respiratory distress is followed by persistent pulmonary hypertension, right-to-left shunting of blood, and patent ductus arteriosus. Conventional mechanical ventilation, extracorporeal membrane oxygenation, nitric oxide, high-frequency ventilation, or liquid ventilation may be necessary.

Nursing Assessment

Review prenatal and birth records to identify newborns who may be at high risk for meconium aspiration. Predisposing factors for MAS include post-term pregnancy; breech, forceps, or vacuum extraction births; nulliparity; ethnicity (Pacific Islander, Indigenous Australian, African-American); intrapartum fever; low Apgar score; prolonged or difficult labor associated with fetal distress in a term or post-term newborn; birth weight of >4,500 g; Apgar score of <8 at 5 minutes of age; maternal infection; infants delivered by cesarean section; maternal hypertension or diabetes; oligohydramnios; fetal growth restriction; prolapsed cord; or acute or chronic placental insufficiency (Choi et al., 2015).

Assess the amniotic fluid for meconium staining when the maternal membranes rupture. Green-stained amniotic fluid suggests the presence of meconium in the amniotic fluid and should be reported immediately. After birth, note any yellowish-green staining of the umbilical cord, nails, and skin. This staining indicates that meconium has been present for some time.

Consider Kelly, the 27-year-old woman who gave birth to a son who required resuscitation. What findings would lead the nurse to suspect that her son had aspirated meconium? What risk factors in Kelly's history would support the diagnosis of meconium aspiration syndrome?

 Take Note!

Standard prevention and treatment for MAS previously included suctioning the mouth and nares upon head delivery before body delivery. However, recent evidence suggests that aspiration occurs in utero, not at delivery; therefore, the infant's birth should not be impeded for suctioning. After full delivery, the infant should be handed to a neonatal team for evaluation and treatment. Although infants previously have been given intubation and airway suctioning, routine tracheal suction is recommended only for depressed infants (e.g., nonvigorous with depressed tone and respirations and/or heart rate <100 bpm) and those with respiratory symptoms. Use of orogastric suctioning to prevent MAS is not supported by evidence from current studies. Guidelines suggest not stimulating infants with vigorous sucking born with meconium staining at birth, to avoid aspiration (Hudson, 2015).

Observe the newborn for a barrel-shaped chest with an increased anterior–posterior chest diameter (similar to that found in a client with chronic obstructive pulmonary disease), prolonged tachypnea, progression from mild to severe respiratory distress, intercostal retractions, end-expiratory grunting, and cyanosis (Clark & Clark, 2015). Auscultate the lungs, noting coarse crackles and rhonchi.

Chest x-rays show patchy, fluffy infiltrates unevenly distributed throughout the lungs and marked hyperaeration mixed with areas of atelectasis. ABG analysis will indicate metabolic acidosis with a low blood pH, decreased PaO_2, and increased $PaCO_2$ (Karabayir, Demirel, & Bayramoglu, 2015). Direct visualization of the vocal cords for meconium staining using an appropriate size laryngoscope is needed. Expect to administer hyperoxygenation to dilate the pulmonary vasculature and close the ductus arteriosus or nitric oxide inhalation to decrease pulmonary vascular resistance, or to use high-frequency oscillatory ventilation to increase the chance of air trapping (Clark & Clark, 2015). In addition, administer vasopressors and pulmonary vasodilators as prescribed and

administer surfactant as ordered to counteract inactivation by meconium. Monitor ABG results for changes and assist with measures to correct acid–base imbalances to facilitate perfusion of tissues and prevent pulmonary hypertension (Brooke-Vincent, 2015). If these measures are ineffective, be prepared to assist with the use of extracorporeal membrane oxygenation, a modified type of heart–lung machine. In addition, perform the following interventions:

• Cluster newborn care to minimize oxygen demand.

• Maintain an optimal thermal environment to minimize oxygen consumption.

• Prevent and treat any complications such as hypotension, metabolic acidosis, or anemia.

• Administer broad-spectrum antibiotics to treat bacterial pneumonia.

• Pay careful attention to systemic blood volume and blood pressure to decrease right-to-left shunting through the patent ductus.

• Administer sedation to reduce agitation and oxygen consumption.

• Continuously monitor the newborn's condition—cardiac and respiratory status, oximetry.

• Provide continuous reassurance and support to the parents throughout the experience (Gardner et al., 2016; Verklan & Walden, 2014).

Persistent Pulmonary Hypertension of the Newborn

Persistent pulmonary hypertension of the newborn (PPHN), previously referred to as persistent fetal circulation, is a cardiopulmonary disorder characterized by marked pulmonary hypertension that causes right-to-left extrapulmonary shunting of blood and hypoxemia. It occurs when the newborn's circulatory system does not have a normal transition after birth. PPHN can occur idiopathically or as a complication of perinatal asphyxia, MAS, maternal smoking, hypocalcemia, maternal obesity, maternal asthma, pneumonia, congenital heart defects, metabolic disorders such as hypoglycemia, hypothermia, hypovolemia, hyperviscosity, acute hypoxia with delayed resuscitation, sepsis, and RDS. It occurs in 1 per 1,000 live births of term, near-term, or post-term infants. Current research findings link increased risk of developing PPHN to exposure to selective serotonin reuptake inhibitors (SSRIs) (antidepressants) in late pregnancy (Gadot & Koren, 2015; Huybrechts et al., 2015). Treatment of depression with antidepressants is complicated by the mother's needs. Careful consideration must be given to the risks, benefits, and alternatives of in utero medication exposure and discussed with the woman.

Pathophysiology

Normally, pulmonary artery pressure decreases when the newborn takes the first breath. However, interference with this ability to breathe allows pulmonary pressures to remain increased. Hypoxemia and acidosis also occur, leading to vasoconstriction of the pulmonary artery. These events cause an elevation in pulmonary vascular resistance. Normally, the decrease in pulmonary artery pressure and pulmonary vascular resistance with breathing leads to the closure of the ductus arteriosus and foramen ovale. However, with PPHN, pulmonary vascular resistance is elevated to the point that venous blood is diverted to some degree through fetal shunts (i.e., the ductus arteriosus and foramen ovale) into the systemic circulation, bypasses the lungs, and results in systemic arterial hypoxemia.

Nursing Assessment

Assess the newborn's status closely. A newborn with persistent pulmonary hypertension demonstrates tachypnea within 12 hours after birth. Observe for

marked cyanosis, grunting, respiratory distress with tachypnea, and retractions. Auscultate the heart, noting a systolic ejection harsh sound (tricuspid insufficiency murmur), and measure blood pressure for hypotension resulting from both heart failure and persistent hypoxemia (Kenner & Lott, 2014). Measure oxygen saturation via pulse oximetry and report low values. Prepare the new born for an echocardiogram, which will reveal right-to-left shunting of blood that confirms the diagnosis.

Nursing Management

Nursing management focuses on ensuring adequate tissue perfusion and minimizing oxygen demand and energy expenditure. Caring for the newborn with PPHN includes identifying signs and symptoms associated with it which may include: murmur, respiratory distress, decreased pulmonary blood flow, hypoxia, hypercarbia, hypoglycemia, cyanosis, metabolic acidosis, and hypotension (late sign) (Kenner & Lott, 2014). Usually the newborn is transferred to the NICU for close monitoring.

Maintain a neutral thermal environment, including placing the newborn under a radiant warmer or in a warmed Isolette® to prevent hypothermia. In addition, minimize handling to reduce energy expenditure and oxygen consumption that could lead to further hypoxemia and acidosis.

Administer oxygen therapy as ordered via nasal cannula or with positive-pressure ventilation. Monitor oxygen saturation levels via pulse oximetry to evaluate the newborn's response to treatment and to detect changes. Increased pulmonary pressures associated with PPHN may cause blood to be shunted away from the lungs. The newborn may exhibit uneven pulmonary ventilation, with hyperinflation in some areas and atelectasis in others. This leads to poor perfusion and subsequent hypoxemia, which in turn may increase pulmonary vasoconstriction and a worsening of hypoxemia and acidosis. Blood is diverted to some degree through fetal structures such as the ductus arteriosus or foramen ovale, causing them to remain open, leading to a right-to-left shunting of blood into the systemic circulation. This diversion of blood bypasses the lungs, resulting in systemic arterial hypoxemia.

When caring for the newborn with persistent pulmonary hypertension, pay meticulous attention to detail, with continuous monitoring of the newborn's oxygenation and perfusion status and blood pressure. The goals of therapy include improving alveolar oxygenation, inducing metabolic alkalosis by

administering sodium bicarbonate, correcting hypovolemia and hypotension with the administration of volume replacement and vasopressors, and anticipating use of extracorporeal membrane oxygenation when support has failed to maintain acceptable oxygenation (Davidson, 2014).

Provide immediate resuscitation after birth and administer oxygen therapy as ordered. Early and effective resuscitation and correction of acidosis and hypoxia are helpful in preventing persistent pulmonary hypertension. Monitor ABGs frequently to evaluate the effectiveness of oxygen therapy. Provide respiratory support, which frequently necessitates the use of mechanical ventilation. Administer prescribed medications, monitor cardiopulmonary status, cluster care to reduce stimulation, and provide ongoing support and education to the parents.

 Take Note!

Almost any procedure, such as suctioning, weighing, changing diapers, or positioning, can precipitate severe hypoxemia due to the instability of the pulmonary vasculature. Therefore, minimize the newborn's exposure to stimulation as much as possible.

Bronchopulmonary Dysplasia/Chronic Lung Disease

BPD, a type of chronic lung disease, commonly occurs in infants who have experienced a lung injury resulting in the need for continued use of oxygen after the initial neonatal period (28 days of life). Approximately 5,000 to 10,000 new cases of BPD occur each year. White male infants seem to be at greatest risk for developing BPD (American Lung Association [ALA], 2015). The average length of intensive in-hospital care for infants with BPD is 120 days. The overall costs of treating BPD in the United States are estimated to be $2.5 billion annually (ALA, 2015). Newborns with BPD need intensive hospital care and home oxygen therapy after being discharged.

Pathophysiology

BPD results from an underlying lung injury. However, the etiology of the lung injury is multifactorial, complex, and remains incompletely understood. It is associated with surfactant deficiency, genetic predisposition, prematurity, oxygen toxicity, pulmonary edema, lung immaturity, lung injury from mechanical ventilation, inflammation, and fluid overload. Lung injury commonly occurs secondary to mechanical ventilation and oxygen toxicity, usually in infants who have had RDS. This lung damage results from the complex interplay between impairments in the premature lung such as surfactant deficiency, perinatal insults such as infection, and damage resulting from supportive care of the infant due to mechanical ventilation and oxygen toxicity from supplemental oxygen administration. These factors trigger an inflammatory cascade in the infant lung with recurring cycles of lung damage and repair that may impair alveolarization and vascularization in the developing lungs. High levels of inspired oxygen concentrations cause an inflammatory process in the lungs that leads to parenchymal damage. Various toxic factor exposure can injure small airways, which interferes with alveolarization (alveolar septation), leading to a reduction in the overall surface area for gas exchange (Zhang, Gien, & Dysart, 2015). This damage includes epithelial stretching, invasion by macrophages and polymorphonuclear leukocytes, airway edema interfering with the growth and development of lung structures, loss of cilia, and a decrease in the number of alveoli.

Therapeutic Management

BPD remains the most common severe adverse pulmonary outcome of preterm birth. It is associated with significant mortality, morbidity, and resource utilization. Low gestational age and birth weight are the strongest risk factors for the development of BPD, but the pathogenesis is complex. The strategy for respiratory support immediately after birth and during the initial neonatal period may have a critical impact on the development of BPD. The preterm lung is highly susceptible to injury. Excessive oxygen use in preterm infants increases the risk of BPD. The recently developed practices for oxygen saturation levels during the neonatal transition phase have become part of the newly revised resuscitation guidelines. For term neonates, starting resuscitation with air, rather than 100% oxygen, is now advised. Preterm infants may require a higher initial inspiratory oxygen concentration than term infants; however, the ideal level is not yet defined. Primary intubation is no longer a prerequisite for preterm survival. Recent studies have demonstrated that even very preterm infants can be safely stabilized after birth with CPAP and later be selectively treated with surfactant for RDS. This initially less invasive strategy has the advantage of reducing the need for mechanical ventilation and, thereby, the risk of lung injury (Iyengar & Davis, 2015).

BPD can be prevented by administering steroids to the mother in the antepartal period and exogenous surfactant to the newborn to help reduce the risk for RDS and its severity. In addition, the following better practices may help reduce the incidence of BPD:

• Use lower target oxygen saturation levels.

• Close the patent ductus arteriosus early, either medically or surgically.

• Monitor and minimize tidal volumes on ventilators.

• Use postnatal steroid therapy judiciously.

• Stem cell therapy.

• Inspired oxygen tensions should be kept as low as possible.

• Administer the antioxidant vitamin A.

• Maintain adequate nutritional status (Gardner et al., 2016).

Supplemental oxygen, antibiotics, and fluid restriction and diuretics to decrease fluid accumulation in the lungs are used. Bronchodilators are used to open the airways. Intravenous feedings are given to meet the infant's nutrition

needs, and physical therapy is used to improve muscle performance and to help the lungs expel mucus.

Nursing Assessment

Although BPD is most common in preterm newborns, it can also occur in full-term ones who had respiratory problems during their first days of life. Thus, it is essential to assess the newborn's history for risk factors, including male gender, preterm birth (<32 weeks), nutritional deficiencies, White race, pulmonary hypertension, excessive fluid intake during the first few days of life, presence of patent ductus arteriosus, anemia, low Apgar score, severe RDS treated with mechanical ventilation for more than 1 week, and sepsis (Mattson & Smith, 2015). Also review the history for use of supplemental oxygen, the length of exposure to oxygen therapy, and the use of ventilatory support.

Assess the infant for signs and symptoms of BPD. These may include tachypnea, poor weight gain related to the increased metabolic workload, tachycardia, sternal retractions (see Fig. 24.2), episodes of cyanosis, nasal flaring, and bronchospasm with abnormal breath sounds (crackles, rhonchi, and wheezes). Hypoxia, as evidenced by abnormal blood gas results, and acidosis and hypercapnia also are noted. Chest x-rays will show hyperinflation, infiltrates, and cardiomegaly.

Nursing Management

The focus of management is to improve supportive care and minimize additional lung injury by decreasing the workload of breathing and normalizing gas exchange, thus promoting growth and development of the respiratory system. Nursing care includes providing continuous ventilatory and oxygen support and optimal nutrition to support growth, and administering bronchodilators, anti-inflammatory agents, and diuretics as ordered. Continuously monitor the newborn's respiratory status to determine the need for continued ventilatory assistance. When the newborn is clinically stable and ready, expect to wean him or her slowly so that he or she can compensate for the changes. Supplemental oxygen may be needed after discharge from the hospital. Provide a high caloric intake to promote growth and to compensate for the calories expended due to the increased work of breathing. Some infants may require high-calorie formulas to foster adequate growth.

Newborns with BPD may require continued care at home. When planning for

discharge, educate the family caretaker about how to manage a chronically ill child who may be oxygen dependent for an extended time. Provide ongoing support to parents as they learn to meet their infant's needs. Also instruct the family about the safe use of oxygen in the home, including the need to notify emergency medical services and utility companies that a technology-dependent child is living in their district. In addition, initiate a social service referral to help the family access community resources and obtain necessary support (Bowen & Maxwell, 2014).

Despite decades of promising research, primary prevention of BPD has proven elusive. Future management of BPD will involve strategies that emphasize prevention. Because few accepted therapies currently prevent BPD, many therapeutic modalities are used to treat it, which may in fact exacerbate it.

Retinopathy of Prematurity

ROP is a potentially blinding retinal vascular eye disease that occurs in very low birth weight and preterm infants. Supplemental oxygen, birth weight, multiple births, White race, mechanical ventilation, and gestational age are the major risk factors for the development of ROP. The incidence of ROP in preterm newborns is inversely proportional to their birth weight. Of the approximately 4 million infants born in the United States annually, about 28,000 weigh 1,500 g (2.75 lb) or less. According to the National Eye Institute (NEI), each year an estimated 1,400 to 1,600 infants in the United States develop ROP severe enough to require medical treatment. Of these infants, 400 to 600 become legally blind from ROP annually (National Eye Institute [NEI] 2015). ROP can also lead to vitreous hemorrhage and retinal detachment, which is the major cause of visual impairment and blindness (Subramanian, Bahri, & Vicente, 2015).

Predisposing factors for the development of ROP include preterm birth, low birth weight, level of oxygen saturation, genetics, and the severity of underlying illnesses present at birth. Additionally, the level of oxygen saturation and genetics seem to play a role in the severity of ROP.

Pathophysiology

The eye begins to develop early in gestation, at approximately 16 weeks. Blood vessels begin to form and grow to supply the retina, which transmits visual information to the brain, with oxygen and nutrients. These vessels continue to grow gradually until about the last 12 weeks of pregnancy (between 28 and 40 weeks' gestation), at which time the eye undergoes rapid development. Thus, an infant born at term has retinal vessels that are almost completely developed. However, when the infant is born preterm, normal blood vessel development is interrupted. In terms of the developing retina, preterm birth interrupts the normal development of the vascular bed that will nourish the eye. The lack of blood vessels in the retina initiates anaerobic metabolism, further increasing the already existing hypoxia. Without blood flow through the eye, the retina is deprived of oxygen and its metabolic needs go unmet.

ROP typically develops in both eyes secondary to an injury such as hyperoxemia due to prolonged assistive ventilation and high oxygen exposure, acidosis, and shock. Exposure to high oxygen concentrations leads to severe

retinal vasoconstriction with endothelial damage and vessel obliteration. Abnormal blood vessels develop in an attempt to nourish the retina. These vessels, which proliferate in the retina, are highly fragile and bleed easily, leading to the formation of scar tissue. They also can enlarge and twist, pulling the retina away from the wall of the eye and resulting in retinal detachment.

Take Note!

Although the precise levels of hyperoxemia that can be sustained without causing retinopathy are not known, very immature newborns who develop respiratory distress often must be given high oxygen concentrations to maintain life (Cunningham et al., 2014).

ROP is classified in five stages, ranging from mild (stage I) to severe (stage V). The grades are based on three criteria: (1) severity, (2) location by zones in the retina, and (3) extent or proportion of the retinal circumference (Hartnett, 2015). The degree of abnormal blood vessel growth and evidence of retinal detachment are used to stage this disorder.

Therapeutic Management

With the increasing survival of premature infants and increased incidence of ROP, it is important to screen for ROP risk and treat at-risk clients in a timely manner to preserve their visual function and reduce complications. The key to treating ROP is prevention by minimizing the risk of preterm birth through providing quality prenatal care and health counseling to all pregnant women. When ROP does develop, treatment depends on the stage and degree of retinal findings. Typically, stages I and II resolve on their own and require only periodic evaluation by the ophthalmologist. For more advanced stages, surgical intervention such as laser photocoagulation therapy or cryotherapy can be done. Laser photocoagulation is the most common treatment modality. A laser is directed to a designated spot to destroy abnormal vessels and seal leaks. Vascular endothelial growth factor inhibitors such as bevacizumab are the newest treatment option, but more research into dosage, safety, and long-term outcomes must be performed (Jordan, 2014).

Nursing Assessment

The newborn who develops ROP exhibits no signs or symptoms, so assessment involves identifying the newborn at risk. Review the maternal prenatal history for risk factors such as substance abuse, hypertension, preeclampsia, heavy cigarette smoking, or evidence of placental insufficiency. Also assess the newborn's gestational age and weight. Be especially alert for newborns weighing 1,500 g or less or those born at 28 weeks' gestation or less. Evaluate the newborn's history for the duration of intubation and the use of oxygen therapy, intraventricular hemorrhage, and sepsis (Verklan & Walden, 2014). Prepare the infant for an ophthalmologic examination.

Nursing Management

By integrating the most recent evidence-based practice guidelines with clinical practice management, newborn outcomes can be improved. In light of the growing body of evidence regarding ROP prevention, many NICUs have adopted lower oxygen saturation ranges for preterm infants. Oxygen saturation target ranges in the mid-80s to lower mid-90s are usually safe and can reduce the severity of ROP in newborns <32 weeks' gestation. Recent research reported that using a low oxygen saturation approach reduced the severe ROP by 50% and BPD/lung problems by 25%, but further randomized trials are needed to provide definite conclusions and to assess whether reducing oxygen saturation has an impact on mortality among very and extremely low birth weight infants (Kaufman et al., 2014). Institute measures for prevention. Administer oxygen therapy cautiously and monitor oxygen saturation levels to ensure that the lowest oxygen concentration possible is used and for the shortest possible duration. Cover the Isolette® with a blanket and dim the surrounding lights to protect the newborn's eyes.

Clear evidence exists that lower oxygen saturation levels once considered insufficient are in fact safe, and have fewer harmful effects (Enomoto et al., 2015; Tataranno et al., 2015). It is essential that nurses understand the evidence base on which preventive strategies are founded, so they can help improve the visual outcomes for all preterm infants assigned to their care.

 Take Note!

Any newborn with a birth weight of less than 1,500 g or born at less than 28 weeks' gestation should be examined by a pediatric ophthalmologist within 4 to 6 weeks after birth.

Assist with scheduling an ophthalmic examination for the newborn. Expect to administer a mydriatic eye agent to dilate the newborn's pupils approximately 1 hour prior to the examination as ordered. During this time, take extra care to protect the newborn's eyes from bright light. If necessary, provide assistance with the examination by holding the newborn's head. Assist with scheduling follow-up eye examinations, usually every 2 to 3 weeks depending on the severity of the clinical findings at the first examination (Mannan, Moni, & Shahidullah, 2015).

The AAP has issued practice guideline recommendations for ROP screening and treatment that aid in creating a consistent and reliable ROP protocol. Newborns with ROP are at risk of developing strabismus (abnormal alignment of the eyes), nystagmus (rapid involuntary movements of the eyes), high myopia (eyeball stretches and becomes too long which can lead to retinal detachment, and abnormal retinal structure and should therefore receive continued long-term follow-up. Challenges exist though in screening for and treating ROP, including delayed or omitted exams, lack of qualified examiners, and lack of parental adherence to instructions in following up after leaving the hospital (Subramanian, Bahri, & Vicente, 2015).

Provide support to the parents. This is an extremely difficult time for them; in addition to learning to meet the needs of their preterm newborn, they must also deal with the possibility that their baby may have a condition that could lead to blindness. Consider the family's needs and provide individualized support and guidance. Provide information about the newborn's condition and treatment options. Stress the need for follow-up vision screenings, because ROP is considered a lifelong disease. Post-discharge follow-up of infants who are still at risk for severe ROP is paramount for timely detection and treatment.

Periventricular–Intraventricular Hemorrhage

Periventricular–intraventricular hemorrhage (PVH–IVH) is defined as bleeding that usually originates in the subependymal germinal matrix region of the brain, with extension into the ventricular system. The germinal matrix is the embryonic structure that is unique to preterm infants, which provides vascular supply for 24 to 32 weeks of gestation. It is primitive, and made of smooth endothelial cells which are highly vascular and prone to bleeding (Ballabh, 2014). It is a common problem in preterm infants, especially in those born before 32 weeks. It remains a significant cause of both morbidity and mortality in infants who are born prematurely. Sequelae of PVH–IVH include lifelong neurologic deficits, such as cerebral palsy, developmental delay, and seizures (Annibale, 2015).

When a fetus is born prematurely, the infant is suddenly thrust from a well-controlled uterine environment into a highly stimulating, hostile one. The tremendous physiologic stress and shock experienced by a premature infant after birth may cause the periventricular capillaries to rupture. Bleeding occurs initially in the immediate periventricular areas causing a periventricular hemorrhage (PVH). If the bleeding persists, the expanding volume of blood dissects into the adjacent lateral ventricles leading to an intraventricular hemorrhage (IVH).

A significant number of these newborns will incur brain injury, leading to complications that may include hydrocephalus, seizure disorders, periventricular leukomalacia (an ischemic injury resulting from inadequate perfusion of the white matter adjacent to the ventricles), cerebral palsy, learning disabilities, vision or hearing deficits, language difficulties, behavioral and personality disorders, and intellectual disability. Unfortunately, the different areas of the cerebral cortex are not even used by an infant for months or even years after birth, so it may take this length of time before developmental problems resulting from damage to the cerebral cortex become evident. This emphasizes the need for long-term developmental follow-up for high-risk infants. Identifying preventive strategies to reduce the incidence of these brain insults is a national public health priority (Marcdante & Kliegman, 2015).

The incidence of ventricular hemorrhage depends on the gestational age at birth. Up to 50% of newborns weighing 1,500 g or less or born at 30 weeks' gestation or less will have evidence of hemorrhage, whereas only about 4% of term newborns show evidence of ventricular hemorrhage. Very low birth weight

infants have the earliest onset of hemorrhage and the highest mortality rate (Annibale, 2015).

Pathophysiology

The pathogenesis of IVH is attributed to the intrinsic weakness of germinal vasculature and to the fluctuation in the cerebral blood flow. The fluctuation in the cerebral blood flow is attributed to the cardiorespiratory and hemodynamic instability associated with preterm infants, including hypotension, hypoxia, pneumothorax, and patent ductus arteriosus. Genetics appears to also play a role in this condition (Szpecht et al., 2015). The preterm newborn is at greatest risk for PVH–IVH because cerebrovascular development is immature, making it more vulnerable to injury. The more premature the newborn is, the greater the likelihood for brain damage. While all areas of the brain can be injured, the periventricular area is the most vulnerable.

Each ventricular area contains a rich network of capillaries that are very thin and fragile and can rupture easily. The causes of rupture vary and include fluctuations in systemic and cerebral blood flow, increases in cerebral blood flow from hypertension, intravenous infusions, seizure activity, increases in cerebral venous pressure due to vaginal delivery, hypoxia, and respiratory distress. With a preterm birth, the fetus is suddenly transported from a well-controlled uterine environment into a highly stimulating one. This tremendous physiologic stress and shock may contribute to the rupture of periventricular capillaries and subsequent hemorrhage. Most hemorrhages occur in the first 72 hours after birth (Cunningham et al., 2014).

The diagnosis of PVH–IVH is commonly done with a cranial ultrasound or a computed tomography (CT), or a magnetic resonance imaging (MRI) and then classified according to a grading system of I to V (least severe to most severe) (Wang et al., 2015). The prognosis is guarded, depending on the grade and severity of the hemorrhage. Generally, newborns with mild hemorrhage (grades I and II) have a much better developmental outcome than those with severe hemorrhage (grades III and IV).

Nursing Assessment

The signs of PVH–IVH vary significantly; no clinical signs may be evident. Approximately 50% of PVH–IVH occurs by 24 hours of age, and 90% occurs by 72 hours of age. Closely monitor newborns who are at an increased risk, such as

those who are preterm or of low birth weight. Also assess for risk factors such as acidosis, asphyxia, unstable blood pressure, meningitis, seizures, acute blood loss, hypovolemia, respiratory distress with mechanical ventilation, intubation, apnea, hypoxia, suctioning, use of hyperosmolar solutions, rapid volume expansion, and activities that involve handling.

Evaluate the newborn for an unexplained drop in hematocrit, pallor, and poor perfusion as evidenced by respiratory distress and oxygen desaturation. Note seizures, lethargy or other changes in level of consciousness, bulging fontanel, weak sucking, metabolic acidosis, high-pitched cry, or hypotonia/flaccidity. Palpate the anterior fontanel for tenseness. Assess vital signs, noting bradycardia and hypotension. Evaluate laboratory data for changes indicating metabolic acidosis or glucose instability (Annibale, 2015). Frequently a bleed can progress rapidly and result in shock and death. Prepare the newborn for cranial ultrasonography, the diagnostic tool of choice to detect hemorrhage.

Nursing Management

Prevention of preterm birth is essential in preventing periventricular–intraventricular hemorrhage. Promote community awareness of factors that may contribute to PVH–IVH, such as a lack of prenatal care, maternal infection, alcohol consumption, and smoking (Kenner & Lott, 2014). Identify risk factors that can lead to hemorrhage and focus care on interventions to decrease the risk of hemorrhage. For example, institute measures to prevent perinatal asphyxia and birth trauma and provide developmental care in the NICU. If a preterm birth is expected, having the mother deliver at a tertiary care facility with a NICU would be preferable.

Care of the newborn with PVH–IVH is primarily supportive. Correct anemia, acidosis, and hypotension with fluids and medications. Administer fluids slowly to prevent fluctuations in blood pressure. Avoid rapid volume expansion to minimize changes in cerebral blood flow. Keep the newborn in a flexed, contained position with the head elevated to prevent or minimize fluctuations in intracranial pressure. Continuously monitor the newborn for signs of hemorrhage, such as changes in the level of consciousness, bulging fontanel, seizures, apnea, and reduced activity level. Also, measuring head circumference daily to assess for expansion in size is essential in identifying complications early.

Minimize handling of the newborn by clustering nursing care, and limit

stimulation in the newborn's environment to reduce stress. Also reduce the newborn's exposure to noxious stimuli to avoid a fluctuation in blood pressure and energy expenditure. Provide adequate oxygenation to promote tissue perfusion but controlled ventilation to decrease the risk of pneumothorax. Developmental care principles include avoiding lifting the lower extremities above the midline with diaper changes, giving rapid fluid boluses, and high oxygen and ventilation, as these can all increase the chance of more cranial hemorrhage.

Support for the parents to cope with the diagnosis and potential long-term sequelae is essential. The long-term neurodevelopmental outcome is determined by the severity of the bleed. Provide education and emotional support for the parents throughout the newborn's stay. Discuss expectations for short-term and long-term care needs with the parents and assist them in obtaining the necessary support from appropriate community resources.

Necrotizing Enterocolitis

NEC is an inflammatory disease of the bowel which can cause ischemic and necrotic injury in the gastrointestinal tract. It is the most common and most serious acquired gastrointestinal disorder among hospitalized preterm neonates, and is associated with significant acute and chronic morbidity and mortality. This inflammatory bowel disease results in inflammation and bacterial invasion of the bowel wall. It represents a significant clinical problem and affects close to 10% of infants who weigh less than 1,500 g, with mortality rates of 50% or more depending on severity (Springer & Annibale, 2015). Population studies estimate the incidence of NEC at between 0.3 and 2.4 per 1,000 live births in the United States, with a predominance of cases among preterm neonates born at the earliest gestational ages. Also, more males than females are affected (about 3 to 1). The disease burden of NEC includes an overall disease-specific mortality rate of 15% to 20%, with yet higher rates among earliest gestations. The NEC burden also includes an increase in hospital costs approximating $100,000/case, as well as severe late sequelae including parenteral nutrition-associated liver disease and short bowel syndrome (Schanler, 2014).

Ways to improve gastrointestinal function and reduce the risk of NEC include enteral antibiotics, judicious administration of parenteral fluids, human breast milk feedings, antenatal corticosteroids, enteral probiotics (*Lactobacillus acidophilus*), and slow continuous-drip feedings. Meta-analysis of prospective randomized controlled trials evaluating probiotics as measures to prevent NEC have all provided encouraging results. Consequently, it has been argued that there is already evidence to warrant change in clinical practice and practice guidelines (Lau & Chamberlain, 2015) (see Evidence-Based Practice 24.1). Despite that, and despite major efforts toward its eradication, NEC has persisted and appears to be increasing due to the increasing numbers of preterm births (Neu, 2014).

EVIDENCE-BASED PRACTICE 24.1 PROBIOTIC ADMINISTRATION CAN PREVENT NECROTIZING ENTEROCOLITIS IN PRETERM INFANTS: A META-ANALYSIS

STUDY

Necrotizing enterocolitis (NEC) is a serious disease that affects the bowel of premature infants in the first few weeks of life. Although the cause of NEC is not entirely known, milk feedings and bacterial growth play a role. Probiotics (dietary supplements containing potentially beneficial bacteria or yeast) have been used to prevent NEC. Early intervention and aggressive treatment have improved clinical outcomes, but considerable morbidity continues. This meta-analysis examines the impact of probiotics on the incidence of NEC and complications among very low birth weight infants.

Findings

A comprehensive review of the literature search was conducted for all published randomized controlled trials assessing the use of probiotics to prevent NEC. Twenty studies were found involving 5,982 preterm infants. The risk of NEC was reduced by 49% and overall mortality by 27% among infants receiving probiotics. An 8% reduction of sepsis was also observed in infants receiving probiotics. The meta-analysis found that the use of probiotic supplementation in preterm infants is associated with a significant reduction in the risk of NEC and overall mortality.

Nursing Implications

The study confirmed the effectiveness of probiotics in the prevention of neonatal NEC and the associated mortality. Enteral supplementation of probiotics prevents severe NEC and all-cause mortality in preterm infants. This updated review of available evidence strongly supports a change in practice. Nurses can integrate the findings of this study into their practice when caring for newborns who are at risk for developing NEC. Additional research studies are needed to assess the most effective preparations, timing, doses, and length of therapy to be used. Nurses can participate in collecting data for these future studies.

Pathophysiology

The pathophysiology of NEC is poorly understood and is thought to be multifactorial in nature. Current research points to five major pathologic mechanisms that lead to NEC: bowel hypoxic ischemia events, perinatal stressors, an immature intestinal barrier, abnormal bacterial colonization in the gut, and formula feeding. The intestine of a premature infant is characterized by underdeveloped immune defenses and compromised mucosal barrier function. As a result, the immature intestine is susceptible to bacterial colonization by opportunistic pathogens, which follows oral feeding, which in turn incites an inflammatory response culminating in the adverse sequelae of NEC (Lim, Golden, & Ford, 2015).

During perinatal or postnatal stress, oxygen is shunted away from the gut to more important organs such as the heart and brain. Ischemia and intestinal wall damage occur, allowing bacteria to invade. High-solute feedings allow bacteria to flourish. Mucosal or transmucosal necrosis of part of the intestine occurs (National Institutes of Health, 2015). Although any region of the bowel can be affected, the distal ileum and proximal colon are the regions most commonly involved. NEC usually occurs between 3 and 12 days of life, but it can occur

weeks later in some newborns.

Nursing Assessment

NEC can be devastating, and astute assessment is crucial. Assessing the newborn for the development of NEC includes the health history and physical examination as well as laboratory and diagnostic testing. The onset of NEC is heralded by the development of feeding intolerance, abdominal distention, and bloody stools in a preterm infant receiving enteral feedings. As the disease worsens, the infant develops signs and symptoms of septic shock (respiratory distress, temperature instability, lethargy, hypotension, and oliguria). Nurses need to be suspicious of this condition in caring for this type of preterm infant.

HEALTH HISTORY AND PHYSICAL EXAMINATION

Assess the newborn's history for risk factors associated with NEC. In addition to preterm birth, prenatal and postnatal predisposing risk factors are highlighted in Box 24.1.

Also observe the newborn for common signs and symptoms, which may include:

• Cardiorespiratory baseline changes

• Feeding intolerance

• Abdominal distention and tenderness

• Bloody or hemoccult-positive stools

• Diarrhea

• Respiratory distress

• Metabolic acidosis

• Temperature instability

• Decreased or absent bowel sounds

• Signs of sepsis

• Lethargy

• Apnea

• Shock (Fox & Thacker, 2015).

BOX 24.1

PREDISPOSING FACTORS FOR THE DEVELOPMENT OF NECROTIZING ENTEROCOLITIS

- Preterm labor
- Prolonged rupture of membranes
- Preeclampsia
- Maternal sepsis
- Amnionitis
- Uterine hypoxia

Postnatal Factors

• Respiratory distress syndrome

• Patent ductus arteriosus

• Congenital heart disease

• Exchange transfusion

• Low birth weight

• Polycythemia

• Acute hypoxic event

• Enteral feedings with formula

• Low Apgar scores

• Umbilical catheterization

• Hypothermia

• Gastrointestinal infection

• Hypoglycemia

• Perinatal stress and asphyxia

Always keep the possibility of NEC in mind when dealing with preterm newborns, especially when enteral feedings are being administered. Note respiratory distress, cyanosis, lethargy, decreased activity level, temperature instability, feeding intolerance, diarrhea, bile-stained emesis, or grossly bloody stools. Assess blood pressure, noting hypotension. Evaluate the neonate's abdomen for distention, tenderness, and visible loops of bowel (Nagtalon-Ramos, 2014). Measure the abdominal circumference and if there is an increase or not. Determine residual gastric volume prior to feeding; when it is elevated, be suspicious for NEC.

LABORATORY AND DIAGNOSTIC TESTING

Tests used to diagnose NEC include ABGs (to assess for metabolic acidosis); complete blood count (to see counts of white blood cells and red blood cells, and

platelets); blood culture (to identify the organism causing an infection); and an abdominal x-ray (to demonstrate dilated bowel loops, abnormal gas patterns, intramural air bubbles that occur from bacteria, and thickened bowel walls (Kenner & Lott, 2014;Springer & Annibale, 2015).

Nursing Management

Nursing management of the newborn with NEC focuses on maintaining fluid and nutritional status, providing supportive care, and teaching the family about the condition and prognosis. Therapeutic medical management initially consists of bowel rest and antibiotic therapy. Serial kidney, ureter, and bladder x-rays and C-reactive protein (CRP) levels are used to assess the resolution or progression of NEC. If medical treatment fails to stabilize the newborn or if free air is present on a left lateral decubitus film (where the infant is lying down on the left side), surgical intervention will be necessary to resect the portion of necrotic bowel while preserving as much of the intestinal length as possible. Surgery for NEC usually requires the placement of a proximal enterostomy until the anastomosis site is ready for reconnection. After surgery, postoperative supportive care includes fluids, total parenteral nutrition (TPN), antibiotics, and bowel rest for 10 to 14 days.

NEC is usually limited to a short period and resolves within 48 hours of stopping oral feedings, but surgically treated NEC can be a much lengthier process. The amount of bowel that has necrosed, as determined during the bowel resection, significantly increases the likelihood of long-term medical problems. Short bowel syndrome may result from a large resection of the bowel. Reassure the family that although some infants have more involved cases of NEC, today's improved parenteral nutrition formulations have improved the outcomes for these infants. Provide education about ostomy care if surgery is required. Promote interaction with the newborn. Nursing actions of active engagement with parents and the sick infant (providing NICU orientation and physical care), providing cautious guidance (offering information and instruction on infant care), and nurses' subtle presence (overseeing parents' interaction with their infant) all contribute to fostering a positive, trusting relationship with parents (Gardner et al., 2016).

MAINTAINING FLUID AND NUTRITIONAL STATUS

If NEC is suspected, immediately stop enteral feedings until a diagnosis is made.

Administer intravenous fluids initially to restore proper fluid balance. If ordered, administer TPN to keep the newborn supported nutritionally. Give prescribed intravenous antibiotics to prevent sepsis from the necrotic bowel (if surgery is required, antibiotics may be needed for an extended period). Institute gastric decompression as ordered with an orogastric tube attached to low intermittent suction. Carefully monitor intake and output. Restart enteral feedings once the disease has resolved (normal abdominal examination and kidney, urinary, and bladder x-rays negative for pneumatosis) or as determined postoperatively by the surgeon.

PROVIDING SUPPORTIVE CARE

Manage pain by administering analgesics as ordered. Infection control is important, with an emphasis on careful hand hygiene. In addition, implement these interventions in an ongoing manner:

• Check stools for evidence of blood and report any positive findings.

• Measure the abdominal girth for an increase in size.

• Monitor blood pressure for hypotension.

• Palpate the abdomen for tenderness and rigidity.

• Monitor blood gases and oxygen saturation.

• Offer emotional support for parents.

• Auscultate for the presence or absence of bowel sounds in all four quadrants.

• Observe the abdomen for redness or shininess, which indicates peritonitis.

EDUCATING THE FAMILY

The diagnosis of NEC may cause significant family anxiety. Listen to the family's worries and fears. Answer their questions honestly. Inform the family that medically treated NEC places the infant at higher risk verses surgical treatment. Management of these risks is best achieved through comprehensive preconception care and making healthy choices, both prior to and during pregnancy.

Infant of a Diabetic Mother

An **infant of a diabetic mother (IDM)** is one born to a woman with pregestational or gestational diabetes (see Chapter 20 for additional information). The newborn of a woman who has diabetes is at high risk for numerous health-related complications, especially hypoglycemia. The prevalence of type 2 diabetes mellitus continues to rise worldwide. More women who are in the reproductive age group have diabetes, resulting in more pregnancies complicated by type 2 diabetes, thus placing both mother and fetus at risk for lifelong complications. In light of the increasing incidence of type 2 diabetes among women of childbearing age, it is important to educate women about the potential impact of poor glycemic control on their offspring.

Impact of Diabetes on the Newborn

For more than a century, it has been known that diabetes during pregnancy can have severe adverse effects on fetal and newborn outcomes. Infants of mothers with diabetes have increased morbidity and mortality in the perinatal period. The incidence of major congenital anomalies is much greater for these newborns than for other newborns. Poor glycemic control in the first trimester, during organogenesis, is thought to be a major reason for congenital malformations. The most common types of malformations in infants of mothers with diabetes involve the cardiovascular, skeletal, central nervous, gastrointestinal, and genitourinary systems. Cardiac anomalies are the most common (Nagtalon-Ramos, 2014).

Infants of mothers with diabetes can be large for gestational age (LGA) or small for gestational age (SGA), depending on the vascular impact of this chronic systemic disease on the mother prior to and during the pregnancy. Fetal macrosomia occurs in 25% to 42% of diabetic pregnancies because of hyperinsulinemia (Verklan, 2014). LGA infants (>90th percentile on growth chart) are longer and weigh more than 4,000 g with the majority of the excess weight composed of fat. They also have increased organ weights (organomegaly) and excessive fat deposits on their shoulders and trunk, contributing to the increased overall body weight and predisposing them to shoulder dystocia, brachial plexus injury, fracture, neonatal depression or cesarean birth (Korkmazer, Solak, & Tokgoz, 2015). These oversized newborns frequently

require cesarean births for cephalopelvic disproportion and dysfunctional labor patterns. They are frequently hypoglycemic in the first few hours after birth.

SGA infants (<10th percentile on growth chart) of mothers with diabetes usually suffer from intrauterine malnutrition and have few glucose reserves to tolerate the rigors of labor and birth. Uteroplacental circulation is often impaired, leading to poor growth patterns and hypoxemia. Despite their increased or decreased size and weight, they may be remarkably frail, showing behaviors similar to those of a preterm newborn. Thus, birth weight may not be a reliable criterion of maturity. Newborns of women with diabetes but without vascular complications often tend to be LGA, whereas those of women with diabetes and vascular disease are usually SGA.

Pathophysiology

The large size of the IDM arises secondary to exposure to high levels of maternal glucose crossing the placenta into the fetal circulation. Maternal hyperglycemia acts as a fuel to stimulate increased production of fetal insulin, which in turn promotes somatic growth within the fetus. The fetus responds to these high levels by producing more insulin, which acts as a growth factor in the fetus (Potter & Kicklighter, 2016). How the fetus will be affected and the problems that the newborn will experience depend on the severity, duration, and control of the diabetes in the mother. Table 24.1 summarizes the common problems that may occur in infants of mothers with diabetes.

Nursing Assessment

Assessment begins in the prenatal period by identifying women with diabetes and taking measures to control maternal glucose levels. (See Chapter 20 for information on management of the pregnant woman with diabetes.)

PHYSICAL EXAMINATION

At birth, inspect the newborn for the following characteristic features (Fig. 24.6):

• Full rosy cheeks with a ruddy skin color

• Short neck (some describe "no-neck" appearance)

• Buffalo hump over the nape of the neck

• Massive shoulders with a full intrascapular area

• Distended upper abdomen due to organ overgrowth

• Excessive subcutaneous fat tissue, producing fat extremities

Be alert for hypoglycemia, which may occur immediately or within an hour after birth. Assess blood glucose levels, which should remain above 40 mg/dL. Closely assess the newborn for signs of hypoglycemia, including listlessness, hypotonia, apathy, poor feeding, apneic episodes with a drop in oxygen saturation, cyanosis, temperature instability, pallor and sweating, tremors, irritability, and seizures.

Pulmonary function may be affected in the IDM manifesting itself in TTN or RDS. Hyperinsulinemia has a negative impact on the maturity of the lung's surfactant system by reducing production and manufacturing an unstable surfactant. Polycythemia is another problem for the IDM because of the increased metabolic workload. Hyperinsulinemia and hyperglycemia increase fetal oxygen consumption and may lead to hypoxia, which stimulates the production of erythropoietin. Producing more red blood cells to compensate for the hypoxic environment may decrease the number of platelets produced. Frequency of congenital heart disease in IDM is typically over 50%. Careful evaluation and early diagnosis in this high risk group are needed along with an echocardiogram done on all IDMs as soon as possible (Muhammad et al., 2014).

Assess the newborn for signs of birth trauma involving the head (tense, bulging fontanels, cephalhematoma, skull fractures, and facial nerve paralysis), shoulders and extremities (posturing, paralysis), and skin (bruising). Inspect the newborn for compromised oxygenation by examining the skin for cyanosis, pallor, mottling, and sluggish capillary refill. Take the newborn's temperature frequently and provide a neutral thermal environment to prevent cold stress, which would increase the glucose utilization and contribute to the hypoglycemic state.

LABORATORY AND DIAGNOSTIC TESTING

Determine baseline serum calcium, magnesium, and bilirubin levels and monitor them frequently for changes (Table 24.2). Hypocalcemia is typically manifested in the first 2 to 3 days of life as a result of birth injury or a prolonged delay in parathyroid hormone production. Hypomagnesemia parallels calcium levels and is suspected only when hypocalcemia does not respond to calcium replacement therapy. Red blood cell breakdown leads to increased hematocrit and polycythemia. In addition, hyperbilirubinemia may be caused by slightly

decreased extracellular fluid volume, hepatic immaturity, and birth trauma forming enclosed hemorrhages. It can appear within the first 24 hours of life (pathologic) or after 24 hours of life (physiologic).

TABLE 24.1 COMMON PROBLEMS OF INFANTS OF MOTHERS WITH DIABETES

Condition	Description	Effects
Macrosomia	Newborn with an excessive birth weight; arbitrarily defined as a birth weight >4,000 g (8 lb 13 oz) to 4,500 g (9 lb 15 oz) or >90th percentile for gestational age Complication in 10% of all pregnancies in the United States	Increased risk for shoulder dystocia, traumatic birth injury, birth asphyxia Risks for newborn hypoglycemia and hypomagnesemia, polycythemia, and electrolyte disturbances Increased maternal risk for surgical birth, postpartum hemorrhage and infection, and birth canal lacerations Increased risk of developing type 2 diabetes later in life for both Higher weight and accumulation of fat in childhood and a higher rate of obesity in adults
Respiratory distress syndrome (RDS)	Cortisol-induced stimulation of lecithin/sphingomyelin (phospholipids) necessary for lung maturation is antagonized due to the high-insulin environment within the fetus due to mother's hyperglycemia. Less mature lung development than expected for gestational age Decrease in the phospholipid phosphatidylglycerol (PG), which stabilizes surfactant, compounding risk	Most commonly, baby is breathing normally at birth but develops labored, grunting respiration with cough and a hoarse complaining cry within a few hours, with chest retractions and varying degrees of cyanosis. Infants of mothers with diabetes who also have vascular disease seldom develop RDS because the chronic stress of poor intrauterine perfusion leads to increased production of steroids, which accelerates lung maturation.

Hypoglycemia	Glucose is the major source of energy for organ function. Typical characteristics: • Poor feedings • Jitteriness • Lethargy • High-pitched or weak cry • Apnea • Cyanosis and seizures Some newborns are asymptomatic.	Low blood glucose levels are problematic during the early postbirth period due to abrupt cessation of high-glucose maternal blood supply and the continuation of insulin production by the newborn. Limited ability to release glucagon and catecholamines, which normally stimulate glucagon breakdown and glucose release Prolonged and untreated hypoglycemia leads to serious, long-term adverse neurologic sequelae such as learning disabilities and intellectual disability.
Hypocalcemia and hypomagnesemia	Hypocalcemia (drop in calcium levels) is manifested by tremors, hypotonia, apnea, high-pitched cry, and seizures due to abrupt cessation of maternal transfer of calcium to the fetus, which occurs primarily in the third trimester and if the infant experiences birth asphyxia Associated hypomagnesemia is directly related to the maternal level before birth. About half of infants of mothers with diabetes are affected.	Newborn is at risk for a prolonged delay in parathyroid hormone production and cardiac dysrhythmias.
Polycythemia	Venous hematocrit of >65% in the newborn Increased oxygen consumption by neonate secondary to fetal hyperglycemia and hyperinsulinemia Increased fetal erythropoiesis secondary to intrauterine hypoxia due to placental insufficiency from maternal diabetes Hypoxic stimulation of increased red blood cell (RBC) production as compensatory mechanism	Increased viscosity, resulting in poor blood flow that predisposes newborn to decreased tissue oxygenation and development of microthrombi

Condition	Description	Effects
Hyperbilirubinemia	Usually seen within the first few days after birth; manifested by a yellow appearance of the sclera and skin Excessive red cell hemolysis necessary to break down increased RBCs in circulation due to polycythemia Resultant elevated bilirubin levels Excessive bruising secondary to birth trauma of macrosomic infants, further adding to high bilirubin levels	If untreated, high levels of unconjugated bilirubin may lead to kernicterus (neurologic syndrome that results in irreversible damage) with long-term sequelae that include cerebral palsy, sensorineural hearing loss, and intellectual disability.
Congenital anomalies	Occur in up to 10% of infants of mothers with diabetes, accounting for 30% to 50% of perinatal deaths Incidence is greatest among SGA newborns. Overall, infants of mothers with diabetes have ~3 times the usual incidence of congenital anomalies compared to newborns from the nondiabetic general population.	Most common anomalies: • Coarctation of the aorta • Atrial and ventricular septal defects • Transposition of the great vessels • Sacral agenesis • Hip and joint malformations • Anencephaly • Spina bifida • Caudal dysplasia • Hydrocephalus

Nursing Management

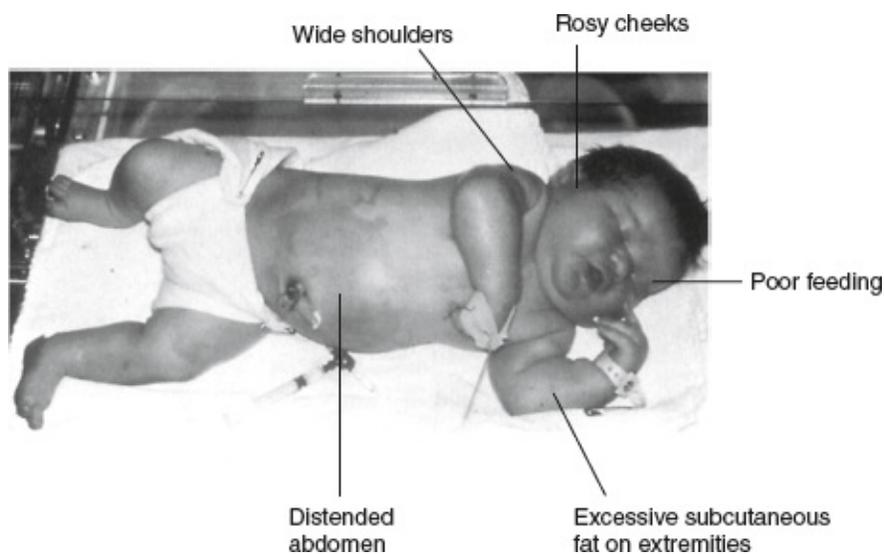
The focus of care for these infants is early detection and initiation of therapy to address potential problems (Nursing Care Plan 24.1). Perform a head-to-toe physical assessment to identify congenital anomalies. Institute measures to correct hypoglycemia, hypocalcemia, hypomagnesemia, dehydration, and jaundice. Provide oxygenation and ventilatory support as necessary. The focus of care includes correcting hypoglycemia, and hypocalcemia, providing phototherapy for jaundice, administering fluid therapy and maintaining oxygen and ventilation if required.


FIGURE 24.6 Characteristics of an infant of a diabetic mother (IDM). A macrosomic IDM has head circumference and length that are at the 90th percentile; the IDM's body weight greatly exceeds the 90th percentile. The IDM has considerable fat deposition in the shoulder and intrascapular area. (MacDonald, M. G., Seshia, M. M. K., & Mullett, M. D. [2005]. *Avery's neonatology pathophysiology & management of the newborn* [6th ed.]. Philadelphia, PA: Lippincott Williams & Wilkins.)

PREVENTING HYPOGLYCEMIA

Prevent hypoglycemia by providing early oral feedings with breast milk or formula at frequent intervals (every 2 to 3 hours). Feedings help to control glucose levels, reduce hematocrit, and promote bilirubin excretion. Maintain a neutral thermal environment to avoid cold stress, which may stimulate the metabolic rate, thereby increasing the demand for glucose. Provide rest periods to decrease energy demand and expenditure.

TABLE 24.2 CRITICAL LABORATORY VALUES FOR INFANTS OF MOTHERS WITH DIABETES

Hypoglycemia	<50 mg/dL
Hypocalcemia	<7 mg/dL
Hypomagnesemia	<1.5 mg/dL
Hyperbilirubinemia	>12 mg/dL (term infant)
Polycythemia	>65% (venous hematocrit)

Adapted from Potter, C. F., & Kicklighter, S. D. (2016). Infant of a diabetic mother. *eMedicine*. Retrieved from http://emedicine.med-scape.com/article/974230-overview; Davidson, M. R. (2014). *Fast facts for the neonatal nurse: A nursing orientation and care guide in a nutshell*. New York, NY: Springer Publishers; Kenner, C., & Lott, J. W. (2014). *Comprehensive neonatal nursing care* (5th ed.). New York, NY: Springer Publishers; and King, T. L., Brucker, M. C., Kriebs, J. M., Fahey, J. O., Gegor, C. L., & Varney, H. (2015). *Varney's midwifery* (5th ed.). Burlington, MA: Jones & Bartlett Learning.

Monitor blood glucose levels via heel stick every hour for the first 4 hours of life and then every 3 to 4 hours until stable. Document the results. Report unstable glucose values if oral feedings do not maintain and stabilize the newborn's blood glucose levels. If glucose levels are not stabilized, initiate intravenous glucose infusions as ordered and ensure that the infusions are flowing at the prescribed rate.

MAINTAINING FLUID AND ELECTROLYTE BALANCE

Monitor serum calcium levels for changes indicating the need for supplementation, such as with oral or intravenous calcium gluconate. Assess the newborn for signs of hypocalcemia, such as tremors, jitteriness, twitching, seizures, and high-pitched cry.

Also administer fluid therapy as ordered to maintain adequate hydration. Monitor serum bilirubin levels and institute phototherapy if the newborn is over 24 hours old.

PROVIDING PARENTAL SUPPORT

Good communication between the nurse and the family is essential. It should be supported by evidence-based, written information tailored to meet the woman's individual needs. Assist the parents and family in understanding the newborn's condition and need for frequent monitoring. Offer support and information to the parents and family about the benefits of breast-feeding for herself and the infant. They may erroneously interpret the newborn's large size as an indication that the newborn is free of problems. Encourage open communication and listen with empathy to the family's fears and concerns. Provide frequent opportunities for the parents to interact with their newborn. Make appropriate referrals to social services and community resources as necessary to help the family cope.

Birth Trauma

Injuries to the newborn from the forces of labor and birth are categorized as birth trauma. In the past, numerous injuries were associated with difficult births requiring external or internal version or mid- or high forceps deliveries. Today, however, cesarean births have contributed to the decline in birth trauma. Damage occurs to the tissues and organs of the newborn caused by mechanical forces during childbirth often accompanied by impaired blood circulation and organ functioning. The most frequent and significant birth injuries are to the skull, brain, and spinal cord (Malcolm, 2015).

Significant birth trauma accounts for fewer than 3% of neonatal deaths and stillbirths in the United States. They estimate that birth trauma in the United States occurs in approximately 29 per 1,000 births with the three most frequently diagnosed birth trauma conditions being injuries to the scalp, injuries to the skeleton, and fracture of the clavicle (Laroia, 2015). Improved prenatal diagnosis and monitoring during labor have helped to reduce the incidence of birth injuries today.

Pathophysiology

The process of birth is a blend of compression, contractions, torques, and traction. When fetal size, presentation, or neurologic immunity complicates this process, the forces of labor and birth may lead to tissue damage, edema, hemorrhages, or fractures in the newborn. For example, birth trauma may result from the pressure of birth, especially in a prolonged or abrupt labor, abnormal or difficult presentation, cephalopelvic disproportion, or mechanical forces, such as forceps or vacuum used during delivery. Table 24.3 summarizes the most common types of birth trauma.

Nursing Assessment

Recognition of trauma and birth injuries is imperative so that early treatment can be initiated. Review the labor and birth history for risk factors, such as a prolonged or abrupt labor, abnormal or difficult presentation, cephalopelvic disproportion, or mechanical forces, such as forceps or vacuum used during delivery. Also review the history for multiple fetus deliveries, large-for-date infants, extreme prematurity, large fetal head, or newborns with congenital

anomalies.

Complete a careful physical and neurologic assessment of every newborn admitted to the nursery to establish whether injuries exist. Inspect the head for lumps, bumps, or bruises. Note if swelling or bruising crosses the suture line. Assess the eyes and face for facial paralysis, observing for asymmetry of the face with crying or appearance of the mouth being drawn to the unaffected side. Ensure that the newborn spontaneously moves all extremities. Note any absence of or decrease in deep tendon reflexes or abnormal positioning of extremities.

NURSING CARE PLAN 24.1

Overview of the Infant of a Mother with Diabetes

Jamie, a 38-year-old Hispanic woman, gave birth to a term large-for-gestational-age newborn weighing 10 lb. She had a history of gestational diabetes but had not received any prenatal care. She arrived at the hospital in active labor. Despite macrosomia, the newborn's Apgar scores were 8 and 9 at 1 and 5 minutes, respectively. No resuscitative measures were needed.

One hour after birth, assessment revealed a pale, irritable newborn with sweating and several episodes of apnea. A glucose level obtained at this time via a heel stick was 35 mg/dL. Two hours later, the newborn begins exhibiting signs of respiratory distress—grunting, nasal flaring, retractions, tachypnea (respiratory rate 72 breaths/minute), and tachycardia (heart rate 176 bpm).

NURSING DIAGNOSIS: Risk for unstable glucose level related to hypoglycemia secondary to intrauterine hyperinsulinemic state resulting from maternal gestational diabetes as evidenced by low blood glucose level, irritability, pallor, sweating, and apnea.

Outcome Identification and Evaluation
The newborn will exhibit adequate glucose control as evidenced by maintaining blood glucose levels above 40 mg/dL and an absence of clinical signs of hypoglycemia.

Interventions: *Promoting Glucose Control*
• Monitor blood glucose levels hourly for the first 4 hours and then every 3 to 4 hours or as necessary *to detect hypoglycemia, which would be <40 mg/dL.*
• Continue to observe for manifestations of hypoglycemia, such as pallor, tremors, jitteriness, lethargy, and poor feeding, to allow for early *detection and prompt intervention, thereby minimizing the risk of complications associated with hypoglycemia.*
• Monitor temperature frequently and institute measures to maintain a neutral thermal environment *to prevent cold stress, which would increase metabolic demands and further deplete glycogen stores.*

- Initiate early feedings every 2 to 3 hours or as appropriate or administer glucose supplements as ordered to prevent hypoglycemia caused by the newborn's *hyperinsulinemic state.* Administer IV glucose infusions as ordered *to correct hypoglycemia if glucose levels do not stabilize with feeding.*
- Cluster infant care activities and provide for rest periods *to conserve the newborn's energy and reduce use of glucose and glycogen stores.*
- Reduce environmental stimuli by dimming lights and speaking softly *to reduce energy demands and further utilization of glucose.*
- Explain all events and procedures to the mother *to help alleviate anxiety and promote understanding of the newborn's condition.*

NURSING DIAGNOSIS: Impaired gas exchange related to respiratory distress secondary to delayed lung maturity resulting from inhibition of pulmonary surfactant production due to fetal hyperinsulinemia as evidenced by grunting, nasal flaring, retractions, tachypnea, and tachycardia.

Outcome Identification and Evaluation
The newborn will demonstrate signs of adequate oxygenation without respiratory distress as evidenced by respiratory rate and vital signs within acceptable parameters, absence of nasal flaring, retractions, and grunting, and oxygen saturation and ABG levels within acceptable parameters.

Interventions: *Promoting Oxygenation*
- Monitor newborn's vital signs to establish a baseline and evaluate for changes.
- Assess airway patency and perform gentle suctioning as ordered to ensure patency and allow for adequate oxygen intake.
- Position the newborn prone to optimize respiratory status and reduce stress.
- Assess lung sounds for changes to allow early detection of change in status.
- Continuously monitor oxygen saturation levels via pulse oximetry to determine adequacy of tissue perfusion.
- Assess ABG results to detect changes indicating acidosis, hypoxemia, or hypercarbia, which would suggest hypoxia. Administer medications as ordered to correct acidosis.
- Administer oxygen as ordered to promote adequate tissue perfusion.
- Assess newborn's skin to identify cyanosis, pallor, and mottling to detect

changes indicating compromised oxygenation.
- Administer surfactant replacement therapy as ordered to aid in stabilizing the newborn's lungs until postnatal surfactant synthesis improves.
- Institute measures to maintain normal blood glucose levels and a neutral thermal environment, cluster care activities, and reduce excessive stimuli to reduce oxygen demand and consumption.

Assess and document symmetry of structure and function. Be prepared to assist with scheduling diagnostic studies to confirm trauma or injuries, which will be important in determining treatment modalities.

Nursing Management

Nursing management is primarily supportive and focuses on assessing for resolution of the trauma or any associated complications along with providing support and education to the parents. Provide the parents with explanations and reassurance that these injuries usually resolve with minimal or no treatment. Parents are alarmed when their newborn is unable to move an extremity or demonstrates asymmetric facial movements. Provide parents with a realistic picture of the situation to gain their understanding and trust. Be readily available to answer questions and teach them how to care for the newborn, including any modifications that might be necessary. Allow parents adequate time to understand the implications of the birth trauma or injury and what treatment modalities are needed, if any. Provide them with information about the length of time until the injury will resolve and when and if they need to seek further medical attention for the condition. Spending time with the parents and providing them with support, information, and teaching are important to allow them to make decisions and care for their newborn. Anticipate the need for community referral for ongoing follow-up and care, if necessary.

Newborns of Substance-Abusing Mothers

It is generally assumed that all pregnant women want to provide a healthy environment for their unborn child and know how to avoid harm. However, women who use tobacco, alcohol, or illicit substances during pregnancy place themselves and their newborns at risk for numerous complications before and after birth. Perinatal substance abuse is a persistent and significant public health issue particularly affecting children, with high rates of reported abuse, neglect, and foster care placement. The illicit drug abuse will only worsen as the use and misuse of prescription medications are significantly increasing in the United States.

Substance use during pregnancy also exposes the fetus to the possibility of IUGR, prematurity, neurobehavioral and neurophysiologic dysfunction, birth defects, infections, and long-term developmental sequelae. Infants of mothers who abuse substances are more likely to suffer substantiated harm, enter foster care, and have more negative child protection outcomes. The effects of fetal alcohol spectrum disorders (FASD) are well documented in the literature; studies attest to developmental delays, intellectual disabilities, attention disorders, and psychopathologies during the child's lifetime (AAP, 2015).

The full extent of the effects of prenatal drug exposure on a child is not known. However studies show that various drugs of abuse may result in premature birth, miscarriage, low birth weight, and a variety of behavioral and cognitive problems. It is difficult to establish the true prevalence of substance use in pregnant women; many women deny taking any nonprescribed substance because of the associated social stigma and legal implications. The National Institute on Drug Abuse (NIDA, 2015) suggests that approximately 6% of pregnant women 15 to 44 years old use illicit drugs. In the United States, approximately 225,000 infants yearly are exposed to illicit substances. Drug exposure may go unrecognized in these newborns, and they may be discharged from the newborn nursery at risk for medical and social problems, including abuse and neglect.

TABLE 24.3 COMMON TYPES OF BIRTH TRAUMA

Type	Description	Findings	Treatment
Fractures	Most often occur during breech births or shoulder dystocia in newborns with macrosomia Midclavicular fractures are the most common type of fracture, secondary to shoulder dystocia. Long bone fractures of the humerus or femur, usually midshaft, also can occur.	Midclavicular fractures: the newborn is irritable and does not move the arm on the affected side either spontaneously or when the Moro reflex is elicited. Femoral or humeral long bone fractures: the newborn shows loss of spontaneous leg or arm motion, respectively; usually swelling and pain accompany the limited movement. X-rays confirm the fracture.	Midclavicular fractures typically heal rapidly and uneventfully; arm motion may be limited by pinning the newborn's sleeve to the shirt. Femoral and humeral shaft fractures are treated with splinting. Healing and complete recovery are expected within 2–4 weeks without incident. Explanation to the parents and reassurance are needed.
Brachial plexus injury	Primarily in large babies, babies with shoulder dystocia, or breech delivery Results from stretching, hemorrhage within a nerve, or tearing of the nerve or the roots associated with cervical cord injury Associated traumatic injuries include fracture of the clavicle or humerus or subluxations of the shoulder or cervical spine. Erb's palsy is an upper brachial plexus injury. Klumpke's palsy is an injury to the lower brachial plexus (lower brachial injuries are less common).	In Erb's palsy, the involved extremity usually presents adducted, prone, and internally rotated; shoulder movement is absent; Moro, bicep, and radial reflexes are absent, but the grasp reflex is usually present. Klumpke's palsy is manifested by weakness in the hand and wrist; grasp reflex is absent.	Erb's palsy usually involves immobilization of the upper arm across the upper abdomen/ chest to protect the shoulder from excessive motion for the first week; then gentle passive range-of-motion exercises are performed daily to prevent contractures. There is usually no associated sensory loss, and this condition usually improves rapidly. Treatment for Klumpke's palsy involves placing the hand in a neutral position and using passive range-of-motion exercises. In some cases deficits may persist, requiring continuing observation.
Cranial nerve trauma	Most common is facial nerve palsy. Frequently attributed to pressure resulting from forceps May also result from pressure on the nerve in utero, related to fetal positioning such as the head lying against the shoulder	Physical findings include asymmetry of the face when crying; mouth may be drawn toward the unaffected side; wrinkles are deeper on the unaffected side. The paralyzed side may be smooth, with a swollen appearance. Eye is persistently open on the affected side.	Most infants begin to recover in the first week, but full resolution may take up to several months; parents need reassurance about this. In most cases, treatment is not necessary, only observation. If the eye is affected and unable to close, protection with patches and synthetic tears may be necessary. Parents need instruction about how to feed the newborn, since he or she cannot close the lips around the nipple without having milk seep out.

| Head trauma | Mild trauma can cause soft tissue injuries such as cephalhematoma and caput succedaneum; greater trauma can cause depressed skull fractures. **Cephalhematoma** (subperiosteal collection of blood secondary to the rupture of blood vessels between the skull and periosteum) occurs in 2.5% of all births and typically appears within hours after birth. **Caput succedaneum** (soft tissue swelling) is caused by edema of the head against the dilating cervix during the birth process. Subarachnoid hemorrhage (one of the most common types of intracranial trauma) may be due to hypoxia/ischemia, variations in blood pressure, and the pressure exerted on the head during labor. Bleeding is of venous origin, and underlying contusions also may occur. Subdural hemorrhage (hematomas) occurs less often today because of improved obstetric techniques. Typically, tears of the major veins or venous sinuses overlying the cerebral hemispheres or cerebellum (most common in newborns of primigravida and large newborns, or after an instrumented birth) are the cause. Increased pressure on the blood vessels inside the skull leads to tears. Depressed skull fractures (rare) may result from the pressure of a forceps delivery; can also occur during spontaneous or cesarean births and may be associated with other head trauma causing subdural bleeding, subarachnoid hemorrhage, or brain trauma. | In cephalhematoma, suture lines delineate its extent; usually located on one side, over the parietal bone. In caput succedaneum, swelling is not limited by suture lines: it extends across the midline and is associated with head molding. It does not usually cause complications other than a misshapen head. Swelling is maximal at birth and then rapidly decreases in size. In subarachnoid hemorrhage, some RBCs may appear in the cerebrospinal fluid (CSF) of full-term newborns. Newborns may present with apnea, seizures, lethargy, or abnormal findings on a neurologic examination. Subdural hemorrhage can be asymptomatic, or the neonate can exhibit seizures, enlarging head size, decreased level of consciousness, or abnormal findings on a neurologic examination, with hypotonia, a poor Moro reflex, or extensive retinal hemorrhages. Depressed skull fractures can be observed and palpated as depressions. Confirmation by x-ray is necessary. | Cephalhematoma resolves gradually over 2–3 weeks without treatment (see Chapter 18). Caput succedaneum usually resolves over the first few days without treatment (see Chapter 18). Subarachnoid hemorrhage requires minimal handling to reduce stress. Subdural hematoma requires aspiration; it can be life-threatening if it is in an inaccessible location and cannot be aspirated. Depressed skull fractures typically require a neurosurgical consultation. |

(2014). *Core curriculum for neonatal intensive care nursing* (5th ed.). St. Louis, MO: Saunders Elsevier.

Tobacco, alcohol, and marijuana are the substances most commonly abused during pregnancy. The incidence of drug and alcohol abuse has increased dramatically during the past decade due to an increase in prenatal maternal opiate use. Other drugs may include opioids such as morphine, codeine,

methadone, SSRIs, meperidine, and heroin; central nervous system stimulants such as methamphetamines and cocaine; central nervous system depressants such as barbiturates, diazepam (Valium), and sedative-hypnotics; and hallucinogens, such as lysergic acid diethylamide (LSD), inhalants, glue, paint thinner, nail polish remover, and nitrous oxide (NIDA, 2015). Table 24.4 highlights commonly used substances and their effects on the fetus and newborn.

Substance abuse during pregnancy is the subject of much controversy. The type of substance used, the timing of use during embryogenesis and fetal development, and the duration and amount used all contribute to the impact on a woman's pregnancy and to the fetal and newborn effects. Frequently, the woman uses more than one substance, which compounds the problem. Nurses must be knowledgeable about the issues of substance abuse and must be alert for opportunities to identify, prevent, manage, and educate women and families about this key public health issue.

Fetal Alcohol Spectrum Disorders

Alcohol abuse during pregnancy is currently among the fastest growing health care challenges in the United States. Years ago, alcohol was not commonly recognized as a teratogen, an agent that can disrupt the development of a fetus. Today, it is known that prenatal alcohol exposure induces a variety of adverse effects on physical, neurologic, and behavioral development. Alcohol now is recognized as the leading preventable cause of birth defects and developmental disorders in the United States (Glass, Ware, & Mattson, 2014). The adverse effects of alcohol consumption have been recognized for centuries, but the associated pattern of fetal anomalies was not labeled until the early 1970s. The distinctive pattern identified three specific findings: a distinct pattern of facial dysmorphology, pre- and postnatal growth deficiencies, and central nervous system dysfunction. These distinctive findings are called **fetal alcohol spectrum disorders (FASD)**, characterized by physical and mental disorders that appear at birth and remain problematic throughout the child's life. However, there are also circumstances in which the effects of prenatal alcohol exposure are apparent but the newborn does not meet all of the criteria. In an attempt to include those who do not meet the strict criteria, the terms *fetal alcohol effects, alcohol-related birth defects*, and *alcohol-related neurologic defects* are used to describe children with a variety of problems thought to be related to alcohol consumption during pregnancy. The Institutes of Medicine coined the term FASD as a way of

describing the broader effects of prenatal alcohol exposure. Children with fetal alcohol syndrome (FAS) are at the severe end of the spectrum.

The disabilities associated with FASD can persist throughout life and place heavy emotional and financial burdens on individuals, families, and society (Artigas, 2015). Newborns with some but not all of the symptoms of FAS are described as having **alcohol-related birth defects** (ARBD). Fetal alcohol effects (FAE) may include such problems as low birth weight, developmental delays, and hyperactivity. The term FASD refers to a spectrum of conditions that includes FAS, FAE, alcohol-related neurodevelopmental disorder (ARND), and ARBD. Although disorders within the spectrum can be diagnosed, the term FASD itself is not intended for use as a clinical diagnosis (Substance Abuse and Mental Health Services Administration, 2015). Box 24.2 summarizes the manifestations of FAS.

Worldwide, the incidence of FAS is 1 to 3 cases per 1,000 live births, and that of FAE is 3 to 5 per 1,000 live births. About one in eight women drink alcohol during pregnancy (March of Dimes, 2015a). Current estimates indicate that approximately 19% of women of childbearing age are either problem drinkers or alcoholics; therefore, the number of fetuses exposed to alcohol in utero increases dramatically (March of Dimes, 2015a). Alcohol consumption during pregnancy results in brain, craniofacial, and heart defects, neurotoxicity, and immune dysfunction. The preferred action taken to prevent alcohol consumption during pregnancy is abstinence. However, the detection, diagnosis, and treatment of FASD remain major public health needs in this country and throughout the world. Despite the preventable nature of alcohol ingestion during pregnancy, the prevalence of alcohol consumption is increasing around the world. In addition, the majority of pregnancies are unintended, thus women are consuming alcohol while they are pregnant and are not even aware of the harm of it (Popova & Chambers, 2014).

Alcohol in the maternal circulation crosses the placenta, which results in direct fetal exposure. The mechanism of fetal exposure is likely related to three main factors: a teratogenic effect, hypoxia as a result of increased oxygen consumption, and a diminished ability to use amino acids in protein synthesis. The expression of fetal alcohol exposure ranges from subtle to extreme and depends on the timing of exposure, the dose, length of exposure, and the genetic sensitivity of the fetus to the effects of alcohol (Centers for Disease Control and Prevention [CDC], 2015a).

TABLE 24.4 SUBSTANCES AND THEIR EFFECTS ON THE FETUS AND NEWBORN

Substance	Description	Effects on Fetus and Newborn	Nursing Implications
Alcohol	Consumption is pervasive and widely accepted, with use, abuse, and addiction affecting all levels of society. It is a common misconception that a substance sold to the public without restriction is safe.	Fetal alcohol syndrome (one of the most common known causes of intellectual disability) Fetal alcohol spectrum disorders Alcohol-related birth defects: Facial features—flattened philtrum (groove in upper lip up to nose), thin upper lip, short palpebral; growth deficit—in weight, height, and BMI; structural/functional CNS dysfunction—microcephaly, intellectual disability, psychiatric conditions, language, motor, and memory disorders. Symptoms of alcohol withdrawal: Hyperactivity, jitteriness, hyperreflexia, hypertonia, poor suck, tremors, seizures, poor sleep patterns, and diaphoresis	Provide education that decreasing or eliminating alcohol consumption during pregnancy is the only way to prevent fetal alcohol syndrome and fetal alcohol effects. Assist pregnant woman in finding a treatment program if possible. Inform all women who are pregnant or planning to become pregnant about the detrimental effects of alcohol during pregnancy. Educate women using a nonjudgmental, culturally connected approach. Warn women that there is no safe time to drink and that there is no safe amount of alcohol they can consume.
Tobacco/nicotine	Nicotine is an addictive substance. It causes epinephrine release from the adrenal cortex, leading to initial stimulation followed by depression and fatigue, causing the user to seek more nicotine. Increased numbers of women are smoking (at least 11% smoke during pregnancy). Over 2,500 chemicals are found in cigarette smoke, including nicotine, tar, carbon monoxide, and cyanide. It is unknown which are harmful, but nicotine and carbon monoxide are believed to play a role in causing adverse pregnancy outcomes.	Impaired oxygenation of mother and fetus due to nicotine crossing placenta and carbon monoxide combining with hemoglobin Increased risk for low birth weight (risk almost doubled), small for gestational age, and preterm birth Increased risk for sudden infant death syndrome (SIDS) and chronic respiratory illness	Provide teaching to women about healthy behaviors. Provide support for smoking cessation. Individualize counseling based on factors associated with the woman's smoking and challenges faced (why woman smokes, stressors in life, and social support network). Suggest options such as group smoking cessation programs, relaxation techniques, individual counseling, hypnosis, and partner-support counseling.
Marijuana	Most widely used illicit psychoactive substance in Western world and most commonly used illicit drug in the United States Derived from *Cannabis sativa* plant	Not shown to have teratogenic effects on fetus; no consistent types of malformations identified Fetal growth restriction is common due to delivery of carbon monoxide to fetus Increased risk for small for gestational age	Provide teaching to women about healthy behaviors. Provide support for cessation of marijuana use.

Substance	Description	Effects on Fetus and Newborn	Nursing Implications
		Altered responses to visual stimuli, sleep-pattern abnormalities, photophobia, lack of motor control, hyperirritability, increased tremulousness, and high-pitched cry noted in infants of mothers who smoked marijuana Research on long-term effects is continuing	
Methamphetamines	Addictive stimulant; use releases high levels of dopamine, which stimulates brain cells, enhancing mood and body movement High potential for abuse and addiction; can be inhaled, injected, smoked, or taken orally Many street names, such as speed, meth, ice, and chalk Primary effects include accelerated heart and respiratory rate, elevated blood pressure, papillary dilation; secondary effects include loss of appetite. Used medically as treatment for obesity and narcolepsy in adults and hyperactivity in children	Little research on use during pregnancy because its use is less common than cocaine or narcotics Fetal effects similar to cocaine (suggesting vasoconstriction as possible underlying mechanism) Possible maternal malnutrition, leading to problems with fetal growth and development Increased risk for preterm birth and low-birth-weight newborns Infants may have withdrawal symptoms, including dysphoria, agitation, jitteriness, poor weight gain, abnormal sleep patterns, poor feeding, frantic fist sucking, high-pitched cry, respiratory distress soon after birth, frequent infections, and significant lassitude Long-term effects are not known.	Provide teaching to women about healthy behaviors. Provide support for cessation of methamphetamine use. Monitor the woman for weight changes; emphasize the need for adequate nutritional intake to support fetal growth and development.
Cocaine	Strong CNS stimulant that interferes with reabsorption of dopamine Physical effects: vasoconstriction; pupillary dilation; increased temperature, heart rate, and blood pressure Taken orally, sublingually, intranasally, intravenously, and via inhalation Estimated that 30%–40% of cocaine addicts are female Maternal cocaine use during pregnancy is a significant health problem Increased potential for use of multiple drugs if mother using cocaine	Preterm birth and lower birth weight Unclear impact on later development Speculation that cocaine interferes with infant's cognitive development, leading to learning and memory difficulties later in life Associated congenital anomalies: GU, cardiac, and CNS defects, and prune belly syndrome Other typical newborn characteristics: smaller head circumference, piercing cry (indicative of neurologic dysfunction), limb defects, ambiguous genitalia, poor feeding, poor visual and auditory responses, poor sleep patterns, decreased impulse control, stiff, hyperextended positioning, irritability and hypersensitivity (hard to console when crying), inability to respond to caretaker	Educate the woman about the effects of cocaine use on the fetus and newborn. Assess for use of other substances. Provide teaching to women about healthy behaviors. Provide support and guidance for cessation of cocaine and other substance use.

Substance	Description	Effects on Fetus and Newborn	Nursing Implications
Heroin	Illegal, highly addictive opiate derived from morphine that can be sniffed, smoked, or injected Possible consequences include HIV infection, tuberculosis, crime, violence, and family disruption. Severe physical addiction; CNS depressant producing mental dullness and drowsiness	Newborns of heroin-addicted mothers are born dependent on heroin. Increased risk for transmission of hepatitis B and C and HIV to newborns when mothers share needles Significantly increased rates of stillbirth, IUGR, preterm birth, and newborn mortality (3–7 times greater) Small-for-gestational-age newborns, meconium aspiration, high incidence of SIDS, and delayed effects from subacute withdrawal (restlessness, continual crying, agitation, sneezing, vomiting, fever, diarrhea, seizures, irritability, and poor socialization [possibly persisting for 4–6 months]) Intrauterine death or preterm birth is possible with abrupt cessation of heroin use.	Educate the woman about the effects of heroin use on the fetus and newborn. Assess for use of other substances. Provide teaching to women about healthy behaviors. Warn the woman not to abruptly stop heroin use. Encourage her to enroll in a methadone maintenance program.
Methadone	Synthetic opiate narcotic used primarily as maintenance therapy for heroin addiction	Improvement in many of the detrimental fetal effects associated with heroin use Withdrawal symptoms are common in newborns. Possible low birth weight due to symmetric fetal growth restriction Increased severity and longer period of withdrawal (due to methadone's longer half-life) Seizures (commonly severe) do not usually occur until 2–3 weeks of age, when the newborn is at home. Increased rate of SIDS (3–4 times higher)	Methadone maintenance programs are the standard of care for women with narcotic addiction. Inform the woman about the benefits and risks of methadone use vs. heroin use. Advantages include improved fetal and newborn growth, reduced risk of fetal death, and reduced risk of HIV infections. Advise the woman that she will need to return consistently to receive the prescribed methadone dose. Reinforce the need for continued prenatal care. Inform the woman that she can breast-feed her newborn while receiving methadone. Teach mother and caregivers about signs and symptoms of methadone withdrawal.

BOX 24.2

CLINICAL PICTURE OF FETAL ALCOHOL SYNDROME

- Microcephaly (head circumference <10th percentile)*
- Small palpebral (eyelid) fissures*
- Abnormally small eyes
- Intrauterine growth restriction
- Maxillary hypoplasia (flattened or absent)
- Epicanthal folds (folds of skin of the upper eyelid over the eye)
- Thin upper lip*
- Missing vertical groove in median portion of upper lip*
- Short upturned nose
- Short birth length and low birth weight
- Joint and limb defects
- Altered palmar crease pattern
- Prenatal or postnatal growth ≤10th percentile*
- Congenital cardiac defects (septal defects)
- Delayed fine and gross motor development
- Poor eye–hand coordination
- Clinically significant brain abnormalities*
- Intellectual disability
- Narrow forehead
- Performance substantially below expected level in cognitive or developmental functioning, executive or motor functioning, and attention or hyperactivity; social or language skills*
- Inadequate sucking reflex and poor appetite

*Diagnosis of fetal alcohol syndrome requires the presence of three findings:

1 Documentation of all three facial abnormalities

2 Documentation of growth deficits (height, weight, or both below 10th

percentile)

3 Documentation of central nervous system abnormalities (structural, neurologic, or functional)

Adapted from Centers for Disease Control and Prevention [CDC]. (2015b). *Fetal alcohol spectrum disorders*. Retrieved from http://www.cdc.gov/ncbddd/fasd/facts.html; Hamdan, A. H. (2015). Neonatal abstinence syndrome. *eMedicine*. Retrieved from http://emedicine.medscape.com/article/978763-overview; and Substance Abuse and Mental Health Services Administration [SAMHSA]. (2015). *Fetal alcohol spectrum disorders*. Retrieved from http://fasdcenter.samhsa.gov/fasdfaqs.aspx

FAS is one of the most common known causes of nongenetic intellectual disability, and it is the only cause that is entirely preventable. Recent studies suggest that deficits in attention, learning, impaired social cognition, and memory, emotional dysregulation, and executive functioning are core deficits present (Rangmar et al., 2015). The effects last a lifetime. Children with this syndrome have varying degrees of psychological and behavioral problems and often find it difficult to hold a job and live independently. There is no cure for FASD, but research shows that early intervention treatment services can improve a child's development.

Decreasing or eliminating alcohol consumption during pregnancy is the only way to prevent fetal alcohol syndrome and fetal alcohol effects. No level of alcohol has been proven to be safe for the fetus, so alcohol should be completely avoided when planning for conception and during pregnancy and it is not recommended during breast-feeding. Nurses are in prime positions for primary prevention of FASD through work with women of childbearing age and secondary prevention through work with affected individuals whose lives can be greatly improved via tailored intervention. Women are frequently more receptive to making lifestyle changes during pregnancy than any other time during their lives. Offering nonjudgmental advice that can be easily understood is more effective than mass media in motivating women to choose to stop drinking. When more than a million infants are born each year with permanent brain damage from a known and preventable cause, a nurse's response should be immediate, determined, sustained, and educational for mothers who drink. Actions at every level of society are needed to encourage abstinence from alcohol during pregnancy to prevent its devastating impact.

Neonatal Abstinence Syndrome

Neonatal abstinence syndrome (NAS) comprises a constellation of drug-withdrawal symptoms that result from chronic intrauterine exposure to a variety of substances, including opioids, barbiturates, SSRIs, alcohol, benzodiazepines, caffeine, and nicotine. More than 6% of all live births occur in women who use illicit drugs during pregnancy. Maternal substance abuse is associated with adverse neonatal outcomes. Newborns of women who abuse tobacco, illicit substances (heroin, methamphetamines), prescription drugs (fentanyl, OxyContin, methadone, SSRIs, morphine, meperidine), caffeine, and alcohol can exhibit withdrawal behavior. These substances cross the placenta and may cause the fetus to develop a dependency; when fetal exposure to the substance(s) terminates at birth, the newborn is at risk for a spectrum of withdrawal symptoms (e.g., autonomic dysfunction, respiratory distress, gastrointestinal compromise) that may necessitate prolonged treatment, intensive monitoring, and extended hospitalization. Withdrawal symptoms usually result when an abrupt discontinuation of an addicting drug occurs, usually after prolonged drug exposure. Drug-exposed newborns begin a withdrawal process of varying degrees after birth.

Primary treatment for NAS consists of opioid replacement therapy with either morphine or methadone. Buprenorphine is emerging as a treatment option with promising results. Most nonopioid fetal drug exposures result in limited clinical manifestations, respond well to supportive care measures, and rarely require pharmacologic intervention. However, chronic opioid exposure does require pharmacotherapy to mitigate withdrawal signs in the newborn, especially when there has been maternal polysubstance consumption (Wiles et al., 2014).

NAS can be described as a generalized multisystem disorder of the drug-exposed newborn, which progresses to seizures. It manifests by central nervous system irritability, short, irregular sleep patterns, myoclonic jerks, gastrointestinal dysfunction—excessive sucking, poor feeding, vomiting, loose stools, poor weight gain, excessive, high-pitched crying, sleep and feeding disturbances, increased muscle tone and tremors, seizures, and excessive sneezing, yawning, and nasal stuffiness (Artigas, 2015). Although often treated as a single entity, NAS is not a single pathologic condition. The manifestations of withdrawal are a function of the drug's half-life, the specific drug or combination of drugs used, dosage, route of administration, timing of drug exposure, and length of drug exposure (Hamdan, 2015). NAS has both medical

and developmental consequences for the newborn.

Nursing Assessment

A comprehensive prenatal medical and drug history, especially with respect to polydrug use, is vital. Fear of referral to child welfare agencies or the legal system has prompted women to conceal their drug abuse history. Frequently, the first inkling of drug use appears in the newborn when symptoms of withdrawal begin within 72 hours after birth. Typically the infant has been discharged by this time, unless the nurse has a high degree of suspicion that would prompt toxicology testing earlier. Several assessment tools can be used to assess a drug-exposed newborn. Figure 24.7 shows an example. Regardless of the tool used for assessment, address these key areas:

• Maternal history to identify risk behaviors for substance abuse:

  • Previous unexplained fetal demise

  • Lack of prenatal care

  • Incarceration

  • Prostitution

  • Cigarette smoking

  • Fetal growth restriction

  • Mental health disorders

  • History of intimate partner violence

  • History of missed prenatal appointments

  • Severe mood swings

  • Preterm birth

  • History of sexually transmitted infections (STIs) (hepatitis C and human immunodeficiency virus (HIV)

  • Precipitous labor

  • Poor nutritional status

  • Abruptio placentae

  • Hypertensive episodes

  • History of drug abuse

• Laboratory test results (toxicology) to identify substances in mother and

newborn

- Signs of neonatal abstinence syndrome (use the "WITHDRAWAL" acronym; see Box 24.4)
- Evidence of seizure activity and need for protective environment

The newborn's behavior often prompts the health care provider or nurse to suspect intrauterine drug exposure (Box 24.3). The newborn physical examination may also reveal low birth weight for gestational age or drug- or alcohol-related birth defects and dysfunction. Assess the newborn for signs of NAS (see Box 24.4).

Take Note!

Cocaine-exposed newborns are typically fussy, irritable, and inconsolable at times. They demonstrate poor coordination of sucking and swallowing, making feeding time frustrating for the newborn and caregiver alike.

Assist with obtaining diagnostic studies to identify the severity of withdrawal. In general, a urine screen signifies only recent newborn exposure to maternal use of drugs. It can detect marijuana use up to a month earlier, cocaine use up to 96 hours earlier, heroin use 24 to 48 hours earlier, and methadone use up to 10 days earlier (Hamdan, 2015). Toxicology screening of the newborn's blood, urine, and meconium identifies the substances to which the newborn has been exposed.

Nursing Management

The needs of the substance-exposed newborn are multiple, complex, and costly, both to the health care system and to society. Substance abuse takes place among people of all colors, sizes, shapes, incomes, types, and conditions. Most pregnant women are unaware of the adverse impact their substance abuse can have on the newborn. Pregnant women dependent on opioids are maintained on methadone as the current standard of care, which provides multiple benefits including improved prenatal care, reduced fetal mortality, and improved fetal growth (Jansson, 2015).

Nurses are in a unique position to help because they interact with high-risk mothers and newborns in many settings, including the community, health care

facilities, and family agencies. It is the responsibility of all nurses to identify, educate, counsel, and refer pregnant women with substance-abusing problems. For example, nurses can be instrumental in increasing the number of pregnant women who make a serious attempt to quit smoking by using the "5 A's" approach:

• *Ask*: ask all women if they smoke and would like to quit.

• *Advise*: encourage the use of clinically proven treatment plans.

• *Assess*: provide motivation by discussing the "5 R's":

• *Relevance* of quitting to the woman

• *Risk* of continued smoking to the fetus

• *Rewards* of quitting for both

• *Roadblocks* to quitting

• *Repeat* at every visit

• *Assist*: help the woman to protect her fetus and newborn from the negative effects of smoking.

• *Arrange*: schedule follow-up visits to reinforce the woman's commitment to quit.

CENTRAL NERVOUS SYSTEM DISTURBANCES												
SIGNS AND SYMPTOMS	SCORE	AM						PM				
Excessive high-pitched cry	2											
Continuous high-pitched cry	3											
Sleeps <1 hour after feeding	3											
Sleeps <2 hours after feeding	2											
Sleeps <3 hours after feeding	1

BOX 24.3

MANIFESTATIONS OF NEONATAL ABSTINENCE SYNDROME

CNS Dysfunction

• Tremors

• Generalized seizures

• Hyperactive reflexes

• Restlessness

• Irritability

• Hypertonic muscle tone, constant movement

• Shrill, high-pitched cry

• Disturbed sleep patterns

Metabolic, Vasomotor, and Respiratory Disturbances

• Fever
• Frequent yawning
• Mottling of the skin
• Sweating
• Nasal stuffiness
• Temperature instability
• Frequent sneezing
• Nasal flaring
• Tachypnea >60 bpm
• Apnea

Gastrointestinal Dysfunction

• Poor feeding

• Frantic sucking or rooting

• Uncoordinated sucking

• Poor weight gain

• Loose or watery stools

• Regurgitation or projectile vomiting (Artigas, 2015)

Irritability

Frequent sneezing

Shrill, high-pitched cry

Vomiting

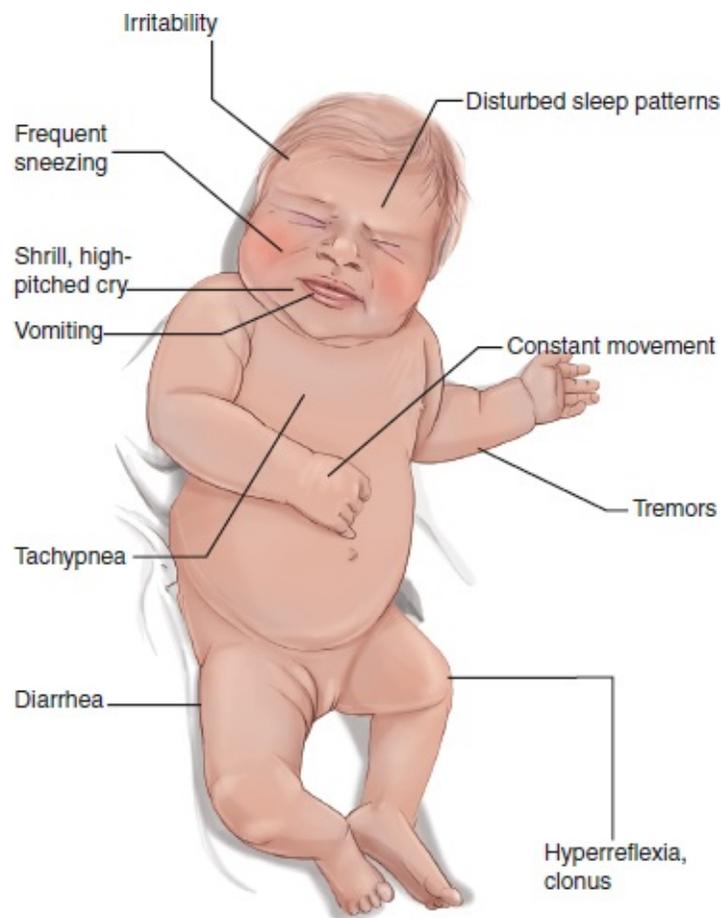
Tachypnea

Diarrhea

Disturbed sleep patterns

Constant movement

Tremors

Hyperreflexia, clonus


WITHDRAWAL ACRONYM

Assess the newborn for signs of NAS using the acronym WITHDRAWAL to focus the assessment:

W = **W**akefulness: sleep duration less than 3 hours after feeding

I = **I**rritability

T = **T**emperature variation, tachycardia, tremors

H = Hyperactivity, high-pitched persistent cry, hyperreflexia, hypertonus

D = **D**iarrhea, diaphoresis, disorganized suck

R = **R**espiratory distress, rub marks, rhinorrhea

A = **A**pneic attacks, autonomic dysfunction

W = **W**eight loss or failure to gain weight

A = **A**lkalosis (respiratory)

L = **L**acrimation (Hamdan, 2015).

Although this approach is geared to smoking cessation, nurses can adapt it to focus on cessation for any substance use. Early, supportive, ongoing nursing care is critical to the well-being of the mother and her newborn. Nurses have an ethical responsibility to provide evidence-based and nonjudgmental care to this highly vulnerable aggregate.

Caring for a substance-exposed newborn remains a major challenge to health care providers. The major goals include providing comfort to the newborn by relieving symptoms, improving feeding and weight gain, preventing seizures, promoting parent–newborn interactions, and reducing the incidence of newborn mortality and abnormal development (Jordan et al., 2014).

PROMOTING COMFORT

Supportive interventions to promote comfort include swaddling, low lighting, gentle waking, quiet environment with little stimulation, use of soft voices, pacifiers to promote "self-soothing," frequent smaller feedings, vertical rocking

during infant disorganization to decrease neurologic hyperactivity, increased opportunities for nonnutritive sucking, rooming-in and positioning (Artigas, 2015). Keep environmental stimuli to a minimum. For example, decrease stimuli by dimming the lights in the nursery, and swaddle the newborn tightly to decrease irritability behaviors. Other techniques such as gentle rocking, using a flexed position, and offering a pacifier can help manage central nervous system irritability. A pacifier also helps satisfy the newborn's need for nonnutritive sucking. Oscillating cribs and avoidance of abrupt changes in the infant's environment can also be helpful. Use a calm, gentle approach when handling the newborn and plan activities to avoid overstimulating the newborn, allowing time for rest periods.

MEETING NUTRITIONAL NEEDS

Newborns suffering from NAS may have impaired feeding behaviors, such as excessive sucking, poor feeding, regurgitation, and diarrhea, which may cause weight loss. To improve weight gain, supplement with high-calorie formula. When feeding the newborn, use small amounts and position the newborn upright to prevent aspiration and to facilitate rhythmic sucking and swallowing. Burp the infant frequently to minimize vomiting, regurgitation, and the potential for aspiration. Frequent, small feedings that provide 150 to 250 kcal/kg per 24 hours for proper growth of the infant undergoing significant withdrawal are preferable (MacMullen, Dulski, & Blobaum, 2014).

Breast-feeding is encouraged unless the mother is still using drugs. Monitor the newborn's weight daily to evaluate the success of food intake. Assess hydration; check skin turgor and fontanels. Assess the frequency and characteristics of bowel movements and monitor the newborn's fluid and electrolyte and acid–base status.

PREVENTING COMPLICATIONS

Pharmacologic treatment is warranted if conservative measures, such as swaddling and decreased environmental stimulation, are not adequate. The AAP recommends that, for newborns with confirmed drug exposure, drug therapy is indicated if the newborn has seizures, diarrhea, and vomiting, resulting in excessive weight loss and dehydration, poor feeding, inability to sleep, and fever unrelated to infection (Thigpen & Melton, 2014). The optimal treatment regimen for NAS has not been established. Based on the current literature, oral morphine and methadone are used as first-line therapies. Clonidine or phenobarbital is also

recommended as an alternative therapy for those newborns who don't respond to a single pharmacologic agent (Artigas, 2015).

New research suggests that infants born to women addicted to opioids have fewer symptoms of NAS when their mothers receive buprenorphine, a partial mu-opioid agonist, during pregnancy compared with their counterparts whose mothers receive methadone. A multicenter randomized controlled trial comparing buprenorphine and methadone in pregnant women with opioid dependency showed that neonates whose mothers received buprenorphine required significantly less morphine, had shorter hospital stays, and had shorter duration of treatment for NAS (Maguire, 2014). Administer the prescribed medications and document the newborn's behavioral responses.

The newborn is at risk for skin breakdown. Weight loss, diarrhea, dehydration, and irritability can contribute to this risk. Provide meticulous skin care and protect the newborn's elbows and knees against friction and abrasions. Apply barrier ointments to avoid skin breakdown and diaper rash. If breakdown becomes severe, clear transparent dressings over reddened or excoriated areas may help avoid further progression of the skin breakdown.

PROMOTING PARENT–NEWBORN INTERACTION

For a mother who abuses substances, the birth of a drug-exposed newborn is both a crisis and an opportunity. The mother may feel guilty about the newborn's condition. Many of these newborns are unresponsive and have disorganized sleeping and feeding patterns. When awake, they can be easily overstimulated and irritated. Such characteristics make parent–newborn interactions difficult and frustrating, leading to possible detachment and avoidance. Some symptoms of withdrawal may last for up to 6 months (King et al., 2015). In addition, the mother may be a victim of physical and sexual abuse and may have a limited support system. Many of these mothers may have had poor parenting themselves, lack information about characteristic infant behaviors, and have unrealistic expectations about the newborn's abilities. Drug-exposed infants and their mothers experience a difficult early period together. Mothers need assistance in recognizing early cues from their infant signaling a need for caregiving. Communicate and provide referral to social services or other community agencies for follow-up post-discharge. Nursing support is essential if maternal–infant attachment is to occur and potential neglect and abuse are to be avoided (McKeever, Spaeth-Brayton, & Sheerin, 2014). Encourage the maternal–infant relationship through support for breast-feeding and rooming-in

if there are no contraindications. Instruct the mother or caretaker on how to care for the newborn, including what to do after the newborn goes home (Teaching Guidelines 24.1).

Teaching Guidelines 24.1

CARING FOR YOUR NEWBORN AT HOME

• Position your newborn with the head elevated to prevent choking.

• To aid your newborn's sucking and swallowing during feeding, position the chin downward and support it with your hand. Do not overfeed.

• Place your newborn on his or her back to sleep or nap, never on the stomach.

• Keep a bulb syringe close by to suction your newborn's mouth in case of choking.

• Cluster newborn care (bathing, feeding, dressing) to prevent overstimulation.

• If your newborn is fussy or crying, try these measures to help calm him or her:

  • Wrap your newborn snugly in a blanket and gently rock in rocking chair.

  • Take the baby for a ride in the car (using a newborn car seat).

  • Play soothing music and "dance" with the newborn.

  • Use a wind-up swing with calming music.

• To help your newborn get to sleep, try these measures:

  • Schedule a bath with a gentle massage prior to bedtime.

  • Change diaper and clothes to make the baby comfortable.

  • Feed the baby just prior to bedtime.

  • If the newborn cries when put in crib and all needs are met, allow him or her to cry.

  • Use a rocking chair to feed and sing a soft lullaby.

• Call your primary care provider if you observe heightened withdrawal

behaviors such as:

• Slight tremors (shaking) of hands and legs

• Stiff posture when held in your arms

• Irritability and frequent fussiness

• High-pitched cry, excessive sucking motions

• Erratic sleep pattern

• Frequent yawning, nasal stuffiness, sweating

• Prolonged time needed to feed

• Frequent vomiting after feeding

It is possible that the newborn may be a powerful motivator for the mother to undergo treatment and seek recovery. Refer the mother to community agencies to address her addiction and the infant's developmental needs (Nagtalon-Ramos, 2014). The nurse can play a pivotal role in assisting the mother to abstain from drug use and to promote effective parenting skills.

Hyperbilirubinemia

Jaundice is a yellow discoloration of the skin and sclera of the eyes caused by increased levels of unconjugated bilirubin in the newborn's circulation. Newborns produce large quantities of bilirubin, which is a by-product of the breakdown of red blood cells. It is processed in the liver and normally excreted out of the body in the urine and stools. In response to this increase, sometimes the skin and eyes turn yellow. It is usually harmless and clears up without treatment within 10 to 14 days. In some newborns, their bilirubin levels rise and further therapy is warranted because unconjugated bilirubin is neurotoxic and can cause mortality in newborns and lifelong neurologic issues in infants who survive.

Consider This

I admit I had led a reckless life since I was a teen. I rebelled against my mother's authority and started smoking and doing drugs just to "check out" of my painful world. It was one big blast after another with a high and then a low. I never considered the consequences of my behavior then and never thought it would hurt anyone until I learned I was about 4 months pregnant. I convinced myself that if I cut back, everything would be fine.

Now, as I stand here in the NICU watching my tiny son struggle for air and tremble all over, I am not so convinced that I didn't hurt anyone except myself. As I witness my son fight against MY nicotine and drug addiction, my heart is heavy with guilt. I wonder how I could have thought that my troubles wouldn't become another's plight sooner or later. What must I have been thinking to isolate my addiction and not consider the impact that it would have on me as a mother and my son?

Thoughts: This woman honestly regrets what her addiction has done to her son as she stands watching him go through withdrawal. Her lifestyle choices do affect others, despite her previous denial. One problem with addiction is the difficulty in getting help after deciding to finally quit. There aren't enough rehab centers to deal with the large numbers of people needing their services

and it can be difficult to get into one. What can be offered to pregnant women who abuse substances? How can nurses increase community awareness about the impact of this problem, especially during pregnancy?

Hyperbilirubinemia is a total serum bilirubin level above 5 mg/dL resulting from unconjugated bilirubin being deposited in the skin and mucous membranes (Hansen, 2015). The mean peak of total bilirubin plasma levels occur between 48 and 92 hours after birth and the average values are between 7 and 9 mg/dL (King et al., 2015). Hyperbilirubinemia is exhibited as jaundice (yellowing of the body tissues and fluids). Newborn jaundice is one of the most common reasons for hospital readmission. It occurs in up to 80% of term newborns in the first week of life and in virtually all preterm newborns (National Institute for Health and Care Excellence [NICE], 2015). African-American neonates have a lower overall risk for neonatal hyperbilirubinemia versus White, Greek, Native American, or Asian infants (Muchowski, 2014). Some infants are at higher risk for developing elevated bilirubin levels. Some of these risk factors include:

• Bruising at birth

• Prematurity

• Dehydration

• Congenital infection

• Maternal substance abuse

• History of a sibling with jaundice

• Inadequate breast-feeding

• Hemolytic disease

• Birth trauma

• Polycythemia

• Delayed cord clamping

• Biliary obstruction

• Prematurity

• Maternal diabetes

• Male infants

• Jaundice prior to 24 hours of age

• East Asian, American Indian, or Mediterranean descent

• Cephalhematoma (NICE, 2015; Wong & Bhutani, 2015).

Pathophysiology

Bilirubin has two forms—unconjugated or indirect, which is fat soluble and toxic to body tissues, and conjugated or direct, which is water soluble and nontoxic. Elevated serum bilirubin levels are manifested as jaundice in the newborn. Typically the total serum bilirubin level rises over the first 3 to 5 days and then declines.

Newborn jaundice results from an imbalance in the rate of bilirubin production and bilirubin elimination. This imbalance determines the pattern and degree of newborn hyperbilirubinemia (Mattson & Smith, 2015). During the newborn period, a rapid transition from the intrauterine to the extrauterine pattern of bilirubin physiology occurs. Fetal unconjugated bilirubin is normally cleared by the placenta and the mother's liver in utero, so total bilirubin at birth is low. After the umbilical cord is cut, the newborn must conjugate bilirubin (convert a lipid-soluble pigment into a water-soluble pigment) in the liver on his or her own. The rate and amount of bilirubin conjugation depend on the rate of red blood cell breakdown, the bilirubin load, the maturity of the liver, and the number of albumin-binding sites (Hansen, 2015). Bilirubin production increases after birth mainly because of a shortened red blood cell life span (70 days in the newborn vs. 90 days in the adult) combined with an increased red blood cell mass. Therefore, the amount of bilirubin the newborn must deal with is large compared with that of an adult.

PHYSIOLOGIC JAUNDICE

Physiologic jaundice is the manifestation of the normal hyperbilirubinemia seen in newborns, appearing during the third to fourth day of life, due to the limitations and abnormalities of bilirubin metabolism. By then, the newborn has been discharged home in the care of the parents. Serum bilirubin levels reach up to 10 mg/dL and then decline rapidly over the first week after birth (Cunningham et al., 2014). Most newborns have been discharged by the time this jaundice peaks (at about 72 hours).

Physiologic jaundice may result from an increased bilirubin load because of relative polycythemia, a shortened red blood cell life span, immature hepatic uptake and conjugation process, and increased enterohepatic circulation.

Newborns with delayed passage of meconium are more likely to develop physiologic jaundice (El-Radhi, 2015).

Physiologic jaundice differs between breast-fed and bottle-fed newborns in relation to the onset of symptoms. Breast-fed newborns typically have peak bilirubin levels by the fourth day of life; levels for bottle-fed newborns usually peak on the third day of life. The rate of bilirubin decline is less rapid in breast-fed newborns compared with bottle-fed newborns because bottle-fed newborns tend to have more frequent bowel movements. Jaundice associated with breast-feeding presents in two distinct patterns: early-onset breast-feeding jaundice and late-onset breast-feeding jaundice.

Early-Onset Breast-Feeding Jaundice. Early-onset breast-feeding jaundice is probably associated with ineffective breast-feeding practices because of relative caloric deprivation in the first few days of life. Decreased volume and frequency of feedings may result in mild dehydration and the delayed passage of meconium. This delayed defecation allows enterohepatic circulation reuptake of bilirubin and an increase in the serum level of unconjugated bilirubin. To prevent this, strategies to promote early effective and frequent breast-feeding are important. The AAP guidelines that have recently been reaffirmed recommend early and frequent breast-feeding without supplemental water or dextrose-water because those supplements do not prevent hyperbilirubinemia and may lead to hyponatremia (Deshpande, 2015). Early frequent feedings can provide the newborn with adequate calories and fluid volume (via colostrum) to stimulate peristalsis and passage of meconium to eliminate bilirubin.

Late-Onset Breast-Feeding Jaundice. Late-onset breast-feeding jaundice occurs later in the newborn period, with the bilirubin level usually peaking in the 6th to 14th day of life. Total serum bilirubin levels may be 12 to 20 mg/dL, but the levels are not considered pathologic (Rosenthal, 2014). The specific cause of late-onset breast milk jaundice is not entirely understood, but it may be related to a change in the milk composition resulting in enhanced enterohepatic circulation. Additional research is needed to determine the cause. Interrupting breast-feeding is not recommended unless bilirubin levels reach dangerous levels; if this occurs, breast-feeding is stopped for only 1 or 2 days. Substituting formula during this short break usually results in a prompt decline of bilirubin levels, but interrupting breast-feeding is not necessary or advisable.

PATHOLOGIC JAUNDICE

Pathologic jaundice is manifested within the first 24 hours of life when total bilirubin levels increase by more than 5 mg/dL/day and the total serum bilirubin level is higher than 17 mg/dL in a full-term infant (Ives, 2015).

Conditions that alter the production, transport, uptake, metabolism, excretion, or reabsorption of bilirubin can cause pathologic jaundice in the newborn. A few conditions that contribute to red blood cell breakdown and thus higher bilirubin levels include polycythemia, blood incompatibilities, and systemic acidosis. These altered conditions can lead to high levels of unconjugated bilirubin, possibly reaching toxic levels and resulting in a severe condition called acute or chronic bilirubin encephalopathy.

The most common condition associated with pathologic jaundice is hemolytic disease of the newborn secondary to incompatibility of blood groups of the mother and the newborn. The most frequent conditions are Rh factor and ABO incompatibilities.

Bilirubin encephalopathy (yellow nucleus) is a preventable neurologic disorder characterized by encephalopathy, motor abnormalities, hearing and vision loss, and death (Cunningham et al., 2014). It can be acute or chronic in nature. Neurotoxicity develops because unconjugated bilirubin has a high affinity for brain tissue, and bilirubin not bound to albumin is free to cross the blood–brain barrier and damage cells of the central nervous system.

In the acute stage, acute bilirubin encephalopathy, the newborn becomes lethargic, sucks poorly, irritable, may have seizures, and can become hypotonic. If the hyperbilirubinemia is not treated, the newborn becomes hypertonic, with truncal arching and seizures. A high-pitched cry may be noted. These changes can occur rapidly, so all newborns must be assessed for jaundice and tested if indicated so that treatment can be initiated.

In the chronic stage, chronic bilirubin encephalopathy or kernicterus, the newborn may experience the following symptoms: severe cerebral palsy, dental enamel dysplasia, auditory dysfunction, and paralysis of their upward gaze. Cases of kernicterus should not be occurring today, but delays in diagnosing pathologic causes of prolonged jaundice are still being missed or overlooked (Ives, 2015).

Take Note!

Significant jaundice in a newborn less than 24 hours of age should be immediately reported to the physician, because it may indicate a pathologic process.

Nursing Assessment

Neonatal jaundice first becomes visible in the face and forehead. Identification is aided by pressure on the skin, since blanching reveals the underlying color. Jaundice then gradually becomes visible on the trunk and extremities. This cephalocaudal progression is well described. Jaundice disappears in the opposite direction. Nurses play an important role in early detection and identification of jaundice in the newborn. Keen observation skills are essential.

HEALTH HISTORY AND PHYSICAL EXAMINATION

Review the history for factors that might predispose the newborn to hyperbilirubinemia, such as:

• Polycythemia

• Significant bruising or cephalhematoma, which increases bilirubin production

• Infections such as TORCH (toxoplasmosis, hepatitis B, rubella, cytomegalovirus, herpes simplex virus)

• Use of drugs during labor and birth such as diazepam (Valium) or oxytocin (Pitocin)

• Prematurity

• Gestational age of 34 to 36 weeks

• Hemolysis due to ABO incompatibility or Rh isoimmunization

• Macrosomic infant of a mother with diabetes

• Delayed cord clamping, which increases the erythrocyte volume

• Decreased albumin binding sites to transport unconjugated bilirubin to the liver because of acidosis

• Delayed meconium passage, which increases the amount of bilirubin that returns to the unconjugated state and can be absorbed by the intestinal mucosa

• Siblings who had significant jaundice

• Inadequate breast-feeding leading to dehydration, decreased caloric intake, weight loss, and delayed passage of meconium

• Ethnicity, such as Asian American, Mediterranean, or Native American

• Male gender (Gardner et al., 2016; NICE, 2015).

Perform a complete physical examination. Assess the skin, mucous membranes, sclera, and body fluids (tears, urine) for a yellow color. Detect jaundice by observing the infant in a well-lit room and blanching the skin with digital pressure over a bony prominence. Typically, jaundice begins on the head and gradually progresses to the abdomen and extremities. Also inspect for pallor (anemia), excessive bruising (bleeding), and dehydration (sluggish circulation), which may contribute to the development of jaundice and the risk for kernicterus.

Assess the newborn for Rh incompatibility. Be alert for clinical manifestations such as ascites, anemia, congestive heart failure, edema, pallor, jaundice, hepatosplenomegaly, hydramnios, thick placenta, and dilation of the umbilical vein (Salem & Singer, 2015).

The hydropic newborn appears pale, edematous, and limp at birth and typically requires resuscitation. The new born with immune hydrops exhibits severe generalized edema, organ hypertrophy and enlargement, and effusion of fluid into body cavities.

COMPARISON CHART 24.1 RH VERSUS ABO INCOMPATIBILITY

Clinical Picture	Rh Incompatibility	ABO Incompatibility
First-born	Rare	Common
Later pregnancies	More severe	No increase in severity
Jaundice	Moderate to severe	Mild
Hydrops fetalis	Frequent	Rare
Anemia	Frequently severe	Rare
Ascites	Frequent	Rare
Hepatosplenomegaly	Frequent	Common

LABORATORY AND DIAGNOSTIC TESTING

Determine maternal and fetal blood types, checking for incompatibilities (Comparison Chart 24.1). Assess laboratory values for bilirubin (both unconjugated and conjugated). Bilirubin levels establish the diagnosis of hyperbilirubinemia. The newborn with Rh incompatibility demonstrates a rapidly rising unconjugated bilirubin level at birth or in the first 24 hours. Also expect to obtain alkaline phosphatase, liver enzymes, and prothrombin time and partial thromboplastin time, as well as:

- *Direct Coombs test*—to identify hemolytic disease of the newborn; positive results indicate that the newborn's red blood cells have been coated with antibodies and thus are sensitized
- *Hemoglobin concentration*—for evidence of anemia
- *Blood type*—to determine Rh status and any incompatibility of the newborn
- *Total serum protein*—to detect reduced binding capacity of albumin
- *Reticulocyte count*—to identify an elevated level indicating increased hemolysis

Assist with obtaining blood specimens. Use cord blood for hemoglobin concentration measurements; use a heel stick for direct Coombs testing and bilirubin levels. Prepare the parents and newborn for radiologic evaluation if necessary to determine abnormalities that may be causing the jaundice.

Nursing Management

Nursing management of a newborn with hyperbilirubinemia requires a comprehensive approach. As members of the health care team, nurses share in the responsibility for early detection and identification, family education, management, and follow-up of the mother and newborn. Documentation of the timing of onset of jaundice is essential to differentiate between physiologic (>24 hours) and pathologic (<24 hours) jaundice. Nurses can improve care by offering their presence and support and by following the AAP guidelines for preventing hyperbilirubinemia:

- Promote and support successful breast-feeding.
- Establish nursery protocols for identifying jaundice, including when a serum bilirubin can be ordered by a nurse.
- Measure total serum bilirubin on jaundiced infants in the first 24 hours.

- Assess for risk factors that may increase bilirubin levels.
- Interpret all bilirubin levels according to the infant's age in hours.
- Do not use a visual estimation of jaundice, which is inaccurate; instead, use labs.
- Consider infants <38 weeks, particularly if breast-fed, at high risk for jaundice.
- Perform risk assessment on all newborns prior to discharge.
- Treat jaundiced newborns with phototherapy, if indicated.
- Provide parents with written and oral information about jaundice at discharge.
- Provide follow-up care and referrals based on time of discharge and risk.
- Empower parents to make appropriate decisions once home (Green, 2016;Griffin & Celenza, 2014).

REDUCING BILIRUBIN LEVELS

Encourage early initiation of feedings to prevent hypoglycemia and provide protein to maintain the albumin levels to transport bilirubin to the liver. Ensure newborn feedings (breast milk or formula) every 2 to 3 hours to promote prompt emptying of bilirubin from the bowel. Encourage the mother to breast-feed (8 to 12 feedings per day) to prevent inadequate intake and thus dehydration. Supplement breast milk with formula to supply protein if bilirubin levels continue to increase with breast-feeding only. Monitor serum bilirubin levels frequently to reduce the risk of severe hyperbilirubinemia.

Phototherapy. Phototherapy is the use of visible light for the treatment of hyperbilirubinemia in the newborn. This relatively common therapy lowers the serum bilirubin level by transforming bilirubin into water-soluble isomers that can be eliminated without conjugation in the liver. For the newborn with jaundice, regardless of its etiology, phototherapy is used to convert unconjugated bilirubin to the less toxic water-soluble form that can be excreted. Phototherapy, via special lights placed above the newborn or a fiber-optic blanket placed under the newborn and wrapped around him or her, uses blue wavelengths of light to alter unconjugated bilirubin in the skin.

For the newborn receiving phototherapy, place the newborn under the lights or on the fiber-optic blanket, exposing as much skin as possible. Cover the newborn's genitals and shield the eyes to protect them from becoming irritated or burned when using direct lights. Assess the intensity of the light source to

prevent burns and excoriation (Fig. 24.8). Turn the newborn every 2 hours to maximize the area of exposure, removing the newborn from the lights only for feedings. Maintain a neutral thermal environment to decrease energy expenditure, and assess the newborn's neurologic status frequently. A recent study's findings indicated that intermittent phototherapy with 12 hours on and 12 hours off cycles was as efficacious as continuous phototherapy to lower bilirubin levels in term and late preterm infants (Sachdeva et al., 2014).

Assess the newborn's temperature every 3 to 4 hours as indicated. Monitor fluid intake and output closely and assess daily weights for gains or losses. Check skin turgor for evidence of dehydration.

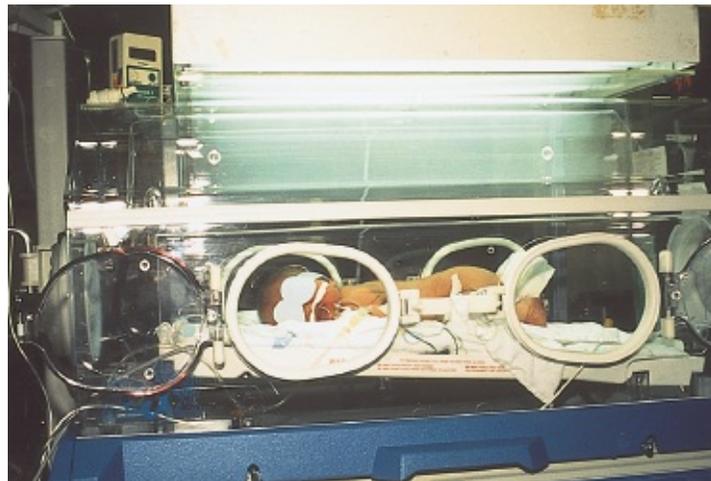
With feedings, remove the newborn from the lights and remove the eye shields to allow interaction with the newborn. Encourage breast or bottle feedings every 2 to 3 hours. Follow agency policy about removing the eye shields periodically to assess the eyes for discharge or corneal irritation secondary to eye shield pressure. Typically, the eyes are assessed and eye shields are removed once a shift.


FIGURE 24.8 A newborn receiving phototherapy.

Monitor stool for consistency and frequency. Unconjugated bilirubin excreted in the feces will produce a greenish appearance, and typically stools are loose. Lack of frequent green stools is a cause for concern.

Provide meticulous skin care. Assess skin surfaces frequently for dryness and irritation secondary to the dehydrating effects of phototherapy and irritation from highly acidic stool to prevent excoriation and skin breakdown. Nursing responsibilities include ensuring effective irradiance delivery, maximizing skin

exposure, providing eye protection and eye care, paying careful attention to thermoregulation, monitoring the newborn's skin turgor, maintaining adequate hydration, promoting elimination, and supporting parent–infant interactions (Nagtalon-Ramos, 2014). A summary of the nursing care for the newborn undergoing phototherapy is as follows:

• Support parents, encouraging them to interact with their infant.

• Support breast-feeding with one-on-one instruction and patience.

• Place infants on their back to expose as much naked skin as possible.

• Provide eye care/protection every time the infant is exposed to the phototherapy light.

• Check temperature and environment around infant to prevent overheating.

• Take daily weights to make sure the infant is not becoming dehydrated.

Exchange Transfusion. If the total serum bilirubin level remains elevated after intensive phototherapy, an exchange transfusion with albumin administered before the transfusion, the quickest method for lowering serum bilirubin levels, may be necessary (Hansen, 2015). In the presence of hemolytic disease, severe anemia, or a rapid rise in the total serum bilirubin level, an exchange transfusion is recommended. An exchange transfusion removes the newborn's blood and replaces it with nonhemolyzed red blood cells from a donor. During the transfusion, monitor the newborn's cardiovascular status continuously because serious complications can arise, such as acid–base imbalances, infection, hypovolemia, and fluid and electrolyte imbalances. Exchange transfusion is used only as a second-line therapy after phototherapy has failed to yield results. Intensive nursing care is needed.

Assist the physician with an exchange transfusion if necessary. Monitor the newborn's status closely for changes, especially in vital signs and heart rate and rhythm, before, during, and after the procedure.

PROVIDING PARENT TEACHING AND SUPPORT

Nurses can help the parents to understand the diagnostic tests and treatment modalities by offering individualized teaching. Nurses are the ones who give discharge instructions to the family. Explore with the family their understanding of jaundice and treatment modalities to reduce anxiety and gain their cooperation in monitoring the infant. Teach the parents about jaundice and its potential risk

using written and verbal material. Also show the parents how to identify newborn behaviors that might indicate rising bilirubin levels. Emphasize the need to seek treatment from their pediatrician should any of the following occur:

• Lethargy, sleepiness, poor muscle tone, floppiness

• Poor sucking, lack of interest in feeding

• High-pitched cry

Teach the parents how to assess their newborn for signs of jaundice because physiologic jaundice may not occur until after the newborn is discharged. Reinforce the need for appropriate follow-up with their pediatrician within 48 to 72 hours after discharge to assess jaundice status (Mattson & Smith, 2015). A general rule to follow is that any infant discharged at less than age 72 hours old should be seen within 2 days of discharge unless there is little risk of subsequent hyperbilirubinemia, in which case a later follow-up is appropriate. This follow-up can be provided in an office, clinic, or home and by a physician, physician's assistant, or nurse practitioner. Both written and oral information should be provided to all parents about newborn jaundice, for example the pamphlet titled *Jaundice and Your Newborn* published by the AAP (Maisels et al., 2014).

The need for phototherapy can be anxiety producing for the parents. Explain the rationale for the procedure and demonstrate techniques that the parents can use to interact with their newborn. Additional education about phototherapy may be necessary when home phototherapy is used (Teaching Guidelines 24.2).

Teaching Guidelines 24.2

CARING FOR YOUR NEWBORN RECEIVING HOME PHOTOTHERAPY

• Inspect your newborn's skin, eyes, and mucous membranes for a yellow color.

• Remember that a home health nurse will come to visit and help you set up the light system.

• Keep the lights about 12 to 30 inches above your newborn.

• Cover your newborn's eyes with patches or cotton balls and gauze to protect

them.

- Keep the newborn undressed except for the diaper area; fold the diaper down below the newborn's navel in the front and as far as possible in the back to expose as much skin as possible.

- Turn your newborn every 2 hours so that all areas of the body are exposed.

- Remove the newborn from the lights only for feeding.

- Remove the eye patches during feedings so that you can interact with your newborn.

- Record your newborn's temperature, weight, and fluid intake daily.

- Document the frequency, color, and consistency of all stools; the stools should be loose and green as the bilirubin is broken down.

- Keep the skin clean and dry to prevent irritation.

Neonatal Sepsis

Neonatal sepsis is defined as a clinical syndrome of bacteremia with systemic signs and symptoms of infection in the first month of life (Molyneux & Gest, 2015). Newborns are susceptible to infections because their immune system is immature and slow to react, and they have a poorly developed skin barrier. The antibodies that newborns received from the mother during pregnancy and from breast milk help protect them from invading organisms. However, these need time to reach optimal levels.

Bacterial infections of the newborn remain a major cause of illness and death in the neonatal period. Making the diagnosis of sepsis in newborns is difficult due to its nonspecific symptoms. The mortality rate from newborn sepsis may be as high as 50% if untreated. Infection is a major cause of death during the first month of life, contributing to 13% to 15% of all neonatal deaths (Anderson-Berry, Bellig, & Ohning, 2015).

Pathophysiology

When a pathologic organism overcomes the newborn's defenses, infection and sepsis result. Neonatal sepsis is the presence of bacterial, fungal, or viral microorganisms or their toxins in blood or other tissues. Infections that have an onset within the first month of life are termed newborn infections. Exposure to a pathogenic organism, whether a virus, fungus, or bacteria, occurs, and it enters the newborn's body and begins to multiply.

Newborn infections are usually grouped into three classes according to their time of onset: congenital infection, acquired in utero (intrauterine infections) by vertical transmission with onset before birth; early-onset infections, acquired by vertical transmission in the perinatal period, either shortly before or during birth; and late-onset infections, acquired by horizontal transmission in the nursery. As many as 85% of neonatal infections have their onset in the first 2 days of life and usually are pneumonia and meningitis (Deleon, Shattuck, & Jain, 2015).

EARLY-ONSET NEONATAL INFECTIONS

Early-onset neonatal infections (<48 hours) are associated with acquisition of microorganisms from the mother. Transplacental infection or an ascending infection from the cervix may be caused by organisms that colonize in the

mother's genitourinary tract, with acquisition of the microbe by passage through a colonized birth canal at delivery. The microorganisms most commonly associated with early-onset infection include group B streptococci (GBS), *Escherichia coli,* coagulase-negative *Staphylococcus, Haemophilus influenzae,* and *Listeria monocytogenes.*

LATE-ONSET NEONATAL INFECTIONS

Late-onset infections (>48 hours), acquired in the postpartum period, are primarily through horizontal transmission from family members or caregivers or through environmental exposures. Infections can be acquired through breast-feeding (HIV and cytomegalovirus; discussed in more detail in Chapter 20) or by direct contact with family members or health care providers. These types of contacts and exposures are especially important in infants, primarily preterm, with prolonged hospital stays, where they are more likely to be exposed to multidrug-resistant hospital-associated organisms potentially from contact with caregivers or contaminated equipment. Organisms that cause late-onset sepsis include *Staphylococcus aureus, E. Coli, Klebsiella, Pseudomonas, Enterobacter, Candida,* and *Anaerobes.* Comparison Chart 24.2 compares the three classes of newborn infections.

Nursing Assessment

Diagnosis of neonatal infections is challenging. Most infants will have some risk factors and the presenting symptoms are many and nonspecific, including poor feeding, breathing difficulty, apnea and bradycardia, gastrointestinal problems, increased oxygen requirement or ventilator support needs, lethargy or hypotension, decreased or elevated temperature, unusual skin rash or color change, persistent crying or irritability. Adding to the challenge of correctly identifying the infection, the list of conditions to consider in the differential diagnosis is extensive, including metabolic and congenital abnormalities (Randolph & McCulloh, 2014).

COMPARISON CHART 24.2 INTRAUTERINE VERSUS EARLY-ONSET VERSUS LATE-ONSET NEWBORN INFECTIONS

	Intrauterine (Congenital)	Early-Onset Infections	Late-Onset Infections
Risk factors	– Immature immune system IgM, IgA, and T lymphocytes – Decreased gastric acid, which is needed to reduce organisms	– Prolonged rupture of membranes – Urinary tract infections – Preterm labor – Prolonged or difficult labor – Maternal fever – Colonization with group B streptococci – Maternal infections	– Low birth weight – Prematurity – Meconium staining – Need for resuscitation – Birth asphyxia – Improper handwashing
Common causative organisms	– Cytomegalovirus – Rubella – Toxoplasmosis – Syphilis	– *Escherichia coli* – Group B streptococci – *Klebsiella pneumoniae* – *Listeria monocytogenes* – Other enteric gram-negative bacilli	– *Candida albicans* – Coagulase-negative staphylococci – *Staphylococcus aureus* – *E. coli* – *Enterobacter* – *Klebsiella* – *Serratia* – *Pseudomonas* – Group B streptococci
Mechanism of infection	– Organism crossing placenta into fetal circulatory system; organism residing in amniotic fluid – Ascent of organism via the vagina, ultimately infecting membranes and causing rupture and leading to respiratory and gastrointestinal tract infections	Most occur during birthing process when newborn comes into contact with infected birth canal (newborn cannot defend against host organisms). – Newborn susceptibility to infection by exogenous organisms possibly due to inadequacy of physical barriers (thin, friable skin with little subcutaneous tissue) – Lack of gastric acidity, possibly resulting in easy colonization by environmental organisms – Aspiration of microorganisms during birth with development of pneumonia	More common in newborns undergoing invasive procedures such as endotracheal intubation or catheter insertion; break in skin or mucosal protection barrier

Adapted from Anderson-Berry, A. L., Bellig, L. L., & Ohning, B. L. (2015). Neonatal sepsis. *eMedicine*. Retrieved from http://emedicine.medscape.com/article/978352-overview; and Simonsen, K. A., Anderson-Berry, A. L., Delair, S. F., & Davies, H. D. (2014). Early-onset neonatal sepsis. *Clinical Microbiology Reviews*, 27(1), 21–47.

Nursing assessment focuses on early identification of a newborn at risk for infection to allow for prompt treatment, thus reducing mortality and morbidity. Be aware of the many risk factors associated with newborn sepsis. Among the factors that contribute to the newborn's overall vulnerability to infection are poor skin integrity, prematurity, poor maternal nutrition, low birth weight, birth trauma, invasive procedures, exposure to numerous caregivers, and an environment conducive to bacterial colonization (Green, 2016).

Few newborn infections are easy to recognize because manifestations usually are nonspecific. Early symptoms can be vague because of the newborn's inability to mount an inflammatory response. Often, the observation is that the newborn does not "look right." Assess the newborn for common nonspecific signs of infection, including:

• Hypotension

- Tachycardia
- Pallor or duskiness
- Hypotonia
- Temperature instability
- Cyanosis
- Poor weight gain
- Irritability
- Seizures
- Jaundice
- Grunting
- Respiratory distress
- Nasal flaring
- Apnea and bradycardia
- Lethargy
- Rash
- Petechiae
- Hypoglycemia
- Poor feeding (lack of interest in feeding)
- Abdominal distention (Gardner et al., 2016).

Since infection can be confused with other newborn conditions, laboratory and radiographic tests are needed to confirm the presence of infection. Be prepared to coordinate the timing of the various tests and assist as necessary. Evaluate the complete blood count with a differential to identify anemia, leukocytosis, or leukopenia. Elevated CRP levels may indicate inflammation. As ordered, obtain x-rays of the chest and abdomen, which may reveal infectious processes located there. Blood, cerebrospinal fluid (CSF), and urine cultures are indicated to identify the location and type of infection present. Positive cultures confirm that the newborn has an infection. Treatment is initially with ampicillin plus either gentamicin or cefotaxime, narrowed to organism-specific drugs as soon as the cultures identify the specific organism.

Nursing Management

To enhance the newborn's chance of survival, early recognition and diagnosis are key. Often the diagnosis of sepsis is based on a suspicious clinical picture. Antibiotic therapy is usually started before the laboratory results identify the infecting pathogen. Along with antibiotic therapy, circulatory, respiratory, nutritional, and developmental support is important. Antibiotic therapy is continued for 7 to 21 days if cultures are positive, or it is discontinued within 72 hours if cultures are negative. With the use of antibiotics along with early recognition and supportive care, mortality and morbidity rates have been reduced greatly.

Nurses possess the education and assessment tools to decrease the incidence of and reduce the impact of infections on women (see Chapter 20 for additional information) and their newborns. Implement measures for prevention and early recognition, including:

- Formulate a sepsis prevention plan that includes education of all members of the health care team on identification and treatment of sepsis.
- Maintain medical and surgical asepsis for all providing care.
- Screen all newborns daily for signs of sepsis.
- Monitor sepsis cases and outcomes to reinforce continued quality improvement measures or to modify current practices.
- Outline and carry out measures to prevent hospital-acquired infections, such as:
  - Monitor and support nutritional status.
  - Feed your newborn frequently to provide added fluid, protein, and calories.
  - Rock, cuddle, or hold the newborn to promote bonding when out of the lights.
  - Contact your pediatrician or home health care agency with any questions or changes, including refusing feedings, fewer than five wet diapers in one day, vomiting of complete amounts of feeding, or elevated temperature.
  - Keep appointments for follow-up laboratory testing to monitor bilirubin levels.
  - Provide frequent oral care and inspections of mucous membranes.
- Properly position and turn to prevent skin breakdown.
- Use strict aseptic technique for all wound care.
- Frequently monitor invasive catheter sites for signs of infection.
- Identify newborns at risk for sepsis by reviewing risk factors.

- Monitor vital sign changes and observe for subtle signs of infection.
- Monitor for signs of organ system dysfunction:
  - Cardiovascular compromise—tachycardia and hypotension
  - Respiratory compromise—respiratory distress and tachypnea
  - Renal compromise—oliguria or anuria
  - Systemic compromise—abnormal blood values
- Provide comprehensive sepsis treatment:
  - Circulatory support with fluids and vasopressors
  - Supplemental oxygen and mechanical ventilation
  - Obtaining culture samples as requested
  - Antibiotic administration as ordered, observing for side effects
  - Promoting newborn comfort
- Assess the family's educational needs and provide instructions as necessary.

Perinatal infections continue to be a public health problem, with severe consequences for those affected. By promoting a better understanding of newborn infections and appropriate use of therapies, nurses can lower the mortality rates associated with severe sepsis, especially with appropriate timing of interventions. The potential for nursing interventions to identify, prevent, and minimize the risk for sepsis is significant. Primary disease prevention must be a major focus for nurses. Family education plays a key role in the prevention of perinatal infections, in addition to following accepted practices in immunization.

CONGENITAL CONDITIONS

The human and economic toll of birth defects is significant and tragic—each year an estimated 8 million children—6% of the total births worldwide—are born with a serious birth defect. Approximately 120,000 infants are born with a birth defect in the United States annually (March of Dimes, 2015b).

Congenital conditions can arise from many etiologies, including single-gene disorders, chromosome aberrations, exposure to teratogens, and many sporadic conditions of unknown cause. Congenital conditions may be inherited or sporadic, isolated or multiple, apparent or hidden, gross or microscopic. They cause nearly half of all deaths in term newborns and cause long-term sequelae for many. The incidence varies according to the type of defect. When a serious anomaly is identified prenatally, the parents can decide whether or not to continue the pregnancy. When an anomaly is identified at or after birth, parents need to be informed promptly and given a realistic appraisal of the severity of the condition, the prognosis, and treatment options so that they can participate in all decisions pertaining to their child.

Congenital conditions can affect virtually any body system. This section describes common congenital conditions identified at or after birth. Some of these conditions warrant immediate treatment soon after birth. Other conditions, although identified in the newborn period, are long term with ongoing effects into childhood.

Ultimately, surveillance and research activities are translated into concrete strategies to prevent birth defects. In 1992, with solid evidence from epidemiologic research studies, the United States Public Health Service recommended that all women of childbearing age consume 400 mcg (0.4 mg) of folic acid daily to reduce the risk (up to 70%) of having a pregnancy affected by an NTD. This has spurred prevention activities at local and national levels to promote the folic acid message (CDC, 2015b).

Congenital Heart Disease

Congenital heart disease is a structural defect involving the heart, the great vessels, or both that is present at birth (AHA, 2015a). It is a broad term that can describe a number of abnormalities affecting the heart. At least 18 types of cardiovascular defects are recognized, with many additional anatomic variations. Approximately 8 newborns out of every 1,000 live births will have some form of congenital heart disease, or about 35,000 infants (1 out of every 125) are born with heart defects each year in the United States. Congenital heart disease causes more deaths during the first year of life than any other birth defect (AHA, 2015b). The defect may be very mild and the newborn appears healthy at birth, or it may be so severe that the newborn's life is in immediate jeopardy. Severe congenital cardiac defects usually present in the first few days or weeks of life, while the newborn's circulation is continuing to adapt to the demands of extrauterine life. Advances in diagnosis and medical and surgical interventions have led to dramatic increases in survival rates for newborns with serious heart defects.

Pathophysiology

In most cases, the exact cause of congenital heart disease is unknown. Most congenital heart defects develop during the first 8 weeks of gestation and are usually the result of genetic and environmental forces.

Typically, congenital heart disease is divided into four physiologic categories based on structural abnormalities and functional alterations (Table 24.5):

- *Septal wall defects*: defects causing increased pulmonary blood flow, such as atrial septal defect and ventricular septal defect
- *Obstruction defects*: defects causing obstructed blood flow out of the heart, such as pulmonary or aortic stenosis
- *Cyanotic heart lesions*: defects causing decreased pulmonary blood flow, such as tetralogy of Fallot
- *Defects of the great vessels*: defects involving mixing of saturated and desaturated blood, such as truncus arteriosus or transposition of the great arteries

TABLE 24.5 CLASSIFICATIONS OF CONGENITAL HEART DISEASE

Cardiac Defect	Examples	Pathophysiology	Clinical Picture
Increased pulmonary blood flow (left-to-right shunting)	Atrial septal defect (ASD) Ventricular septal defect (VSD) Patent ductus arteriosus (PDA)	Cardiac septum communication or abnormal connection between the great arteries permits blood to flow from higher pressure (left side of heart) to lower pressure (right side of heart).	Asymptomatic or murmur, fatigue with feedings, and symptoms of congestive heart failure (CHF): pallor, diminished peripheral blood flow, feeding difficulties, edema, diaphoresis, tachypnea, and tachycardia
Decreased pulmonary blood flow	Tetralogy of Fallot (TOF) Tricuspid atresia	Pulmonary blood flow obstruction accompanied by an anatomic defect such as ASD or VSD between the right and left sides of the heart, which allows desaturated blood to shunt right to left, causing desaturated blood to enter into the systemic circulation	Mild to severe oxygen desaturation, polycythemia, murmur, hypoxemia, dyspnea, increased cardiac workload, and marked exercise intolerance
Obstruction to blood flow out of the heart	Pulmonary stenosis Aortic stenosis Coarctation of the aorta	A narrowing or constriction of an opening causes pressure to rise in the area behind the obstruction and a decrease in blood available for systemic perfusion	CHF, decreased cardiac output, and pump failure
Mixed defects	Transposition of the great arteries Total anomalous pulmonary venous connection Truncus arteriosus Hypoplastic left heart syndrome	Fully saturated systemic blood flow mixes with desaturated pulmonary blood flow, causing desaturation of the systemic circulation. This leads to pulmonary congestion and a decrease in cardiac output. To support life, intervention must bring about a mixing of arterial and venous blood.	Decreased cardiac output, CHF, ruddiness, dusky or gray color, dyspnea

Adapted from Altman, C. A. (2015). Congenital heart disease in the newborn: Presentation and screening for critical CHD. *UpToDate*. Retrieved from http://www.uptodate.com/contents/congenital-heart-disease-chd-in-the-newborn-presentation-and-screening-for-critical-chd; American Academy of Pediatrics [AAP]. (2014). *Newborn screening for CCHD*. Retrieved from http://www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/PEHDIC/Pages/Newborn-Screening-for-CCHD.aspx; American Heart Association [AHA]. (2014a). *About congenital heart defects*. Retrieved from http://www.heart.org/HEARTORG/Conditions/CongenitalHeartDefects/AboutCongenitalHeartDefects/About-Congenital-Heart-Defects_UCM_001217_Article.jsp; and American Heart Association [AHA]. (2014b). *Common types of heart defects*. Retrieved from http://www.heart.org/HEARTORG/Conditions/CongenitalHeartDefects/AboutCongenitalHeartDefects/Common-Types-of-Heart-Defects_UCM_307017_Article.jsp

These four categories are more descriptive than the system used previously, which classified the disorder only as cyanotic or acyanotic. This previous classification was imprecise because some newborns with "acyanotic" defects developed cyanosis and delayed symptoms that often became apparent during infancy and early childhood. With the hemodynamic classification, the clinical picture of each grouping is more uniform and predictable.

Critical congenital heart disease (CCHD) is a group of the seven most severe congenital heart diseases. They include coarctation of the aorta, transposition of the great arteries, hypoplastic left heart syndrome, total anomalous pulmonary venous return, tetralogy of Fallot, and truncus arteriosus. Treatment is needed

very soon after birth or CCHD can be deadly (Altman, 2015).

Therapeutic Management

If the defect is mild, typically no treatment is necessary. However, for most congenital defects corrective surgery is necessary.

Nursing Assessment

Although most congenital heart defects cannot be prevented, several key areas need to be addressed to ensure the optimal health status for the woman and her fetus. A thorough health history of the woman and newborn and physical examination provide valuable information. Laboratory and diagnostic tests provide additional information about the defect and its severity.

HEALTH HISTORY AND PHYSICAL EXAMINATION

Ideally, nursing assessment begins prenatally by reviewing the maternal history for risk factors that might predispose the newborn to a congenital heart defect. Risk factors include:

• Maternal alcoholism

• Maternal diabetes mellitus

• Single-gene mutation or chromosomal disorders

• Maternal exposure to x-rays

• Maternal exposure to rubella infection

• Poor maternal nutrition during pregnancy

• Maternal age over 40

• Maternal use of amphetamines

• Genetic factors (family recurrence patterns)

• Maternal metabolic disorder of phenylketonuria

• Maternal use of anticonvulsants, estrogen, progesterone, lithium, warfarin (Coumadin), or isotretinoin (Accutane) (March of Dimes, 2015c).

After birth, carefully assess the newborn's cardiovascular and respiratory systems, looking for signs of respiratory distress, cyanosis, or congestive heart failure that might indicate a cardiac anomaly. Assess rate, rhythm, and heart

sounds, reporting any abnormalities immediately. Note any signs of heart failure, including edema, diminished peripheral pulses, poor feeding, poor growth, cyanotic, depending on the lesion, hepatomegaly, tachycardia, diaphoresis, respiratory distress with tachypnea, peripheral pallor, and irritability. Pulse oximetry screening is now recommended by the Department of Health and Human Services (HHS) and AAP when the infant is at least 24 hours old to detect seven of the CCHDs, but is not mandated in many states (AAP, 2014; Wood, 2015).

LABORATORY AND DIAGNOSTIC TESTS

Assist with diagnostic testing, such as:

• ABGs to determine oxygenation levels and to differentiate lung disease from heart disease as the cause of cyanosis

• Chest x-rays to identify cardiac size, shape, and position

• Performing pulse oximetry and recording it when infant is at least 24 hours old

• Magnetic resonance imaging to evaluate for cardiac malformations

• Electrocardiogram to detect atrial or ventricular hypertrophy and dysrhythmias

• Echocardiogram to evaluate heart anatomy and flow defects

• Blood studies to assess anemia, blood glucose, and electrolyte levels

• Catheterization to obtain data for definitive diagnosis or in preparation for cardiac surgery

Nursing Management

Like nursing assessment, nursing management ideally focuses on prevention with measures during the prenatal period. For example, ensure that all women are tested prior to pregnancy for immunity to rubella so that they can be immunized if necessary. Any chronic health problems, such as diabetes, hypertension, seizures, and phenylketonuria (PKU), should be controlled and any medication or dietary adjustments should be made before attempting conception. Once pregnant, the woman should be encouraged to avoid alcohol, smoking, and the use of unprescribed drugs. Refer the woman and her partner for genetic counseling if cardiac defects are present in the family to provide the parents with a risk assessment for future offspring. Some defects can be discovered on routine prenatal ultrasound. Therefore, stress the importance of

receiving prenatal care throughout pregnancy so that appropriate interventions can be initiated early if the need arises.

After birth of the newborn, nursing management focuses on ensuring adequate cardiac functioning. Provide continuous monitoring of the newborn's cardiac and respiratory status. Administer medications as ordered. Provide comfort measures to the newborn, who will be subjected to a variety of painful procedures. Be vigilant in ensuring the newborn's comfort, since he or she cannot report or describe pain. Assist in preventing pain as much as possible; interpret the newborn's cues suggesting pain and manage it appropriately.

Include the parents in the plan of care. Assess their ability to cope with the diagnosis, encouraging them to verbalize their feelings about the newborn's condition and treatment. Educate them about the specific cardiac defect; include written information and pictures to enhance understanding. Present an overview of the prognosis and possible interventions. Teach them about the medications prescribed, including side effects and doses, and how to observe for signs and symptoms indicating heart failure.

Assist them with making decisions about treatment, and support their decisions for the newborn's care. If surgical correction is planned, provide the parents with preoperative teaching and orient them to the NICU prior to surgery. Provide emotional support and guidance throughout the newborn's care.

The parents also need clear instructions about how to monitor the newborn at home, especially if the newborn will be discharged and then brought back later so the condition can be corrected. The parents also need instructions about caring for their newborn after the defect is corrected. Educate the parents about signs that need to be reported, such as weight loss, poor feeding, cyanosis, breathing difficulties, irritability, increased respiratory rate, and fever. Referrals to local support groups, national organizations, and websites also are helpful. Emphasize the importance of close supervision and follow-up care.

Neural Tube Defects

Neural tube defect (NTD) is the common name used to describe congenital central nervous system structural defects. NTDs are serious malformations involving the spine (spina bifida) and brain (anencephaly). NTDs affect approximately 3,000 newborns in the United States each year (Ellenbogen, 2015). NTD is the second most common major congenital anomaly worldwide, behind cardiac malformations, but NTD causes much more infant mortality and mortality. Worldwide there are more than 300,000 infants born annually with NTDs (CDC, 2015c). Significant ethnic differences in prevalence are recognized; people of Celtic origin have the highest rate of spina bifida. Hispanic women have higher rates of NTDs than non-Hispanic women in the United States. More females have NTDs, accounting for 60% to 70% of affected children (United States Preventive Services Task Force, 2014).

A worldwide decline in NTDs has occurred during the past few decades as a result of prevention (preconception folic acid supplementation and monitoring of maternal serum alpha-fetoprotein levels) and the use of ultrasonography and amniocentesis to identify affected fetuses. Based on this decline, the WHO recommends periconceptional folic acid supplementation to prevent NTD (Johnson & Prabhu, 2015). Despite this decline, still more infants could be born free of these birth defects if all women consumed the necessary amount (400 to 800 mg) of folic acid (CDC, 2015c).

Pathophysiology

NTDs occur when the neural tube that develops into the brain and spinal cord fails to close properly during early embryogenesis. The neural tube normally closes between the 17th and 30th day of gestation to form the brain and spinal cord of the embryo. NTDs develop during this first month, when most women are still unaware of their pregnancy and the embryo is estimated to be about the size of a grain of rice. In pregnancies in which the fetus has an NTD, the level of alpha-fetoprotein in the amniotic fluid and maternal serum is elevated. NTDs involve abnormalities in the region-specific neural tube closure junctions with the cranial and caudal levels of the neural tube. NTDs may be either closed (covered by skin or a membrane) or open (neural tissue exposed). These defects vary in their severity, depending on the type and level of the lesion. Common

NTDs include anencephaly, spina bifida, meningocele, and myelomeningocele.

ANENCEPHALY

Anencephaly, the most severe NTD, is the congenital absence of the cranial vault, with the cerebral hemispheres completely missing or reduced to small masses. The brain has been replaced by an undifferentiated mass of connective tissue and vessels. It most commonly involves the forebrain and variable amounts of the upper brain stem, where there is no brain tissue above the brain stem. The incidence is approximately 1.2 per 10,000 births, and both genetic and environmental insults appear to be responsible (National Institute of Neurological Disorders and Stroke [NINDS], 2015a). Anencephaly is apparent on visual inspection after birth, with exposed neural tissue without a cranium surrounding it. Prenatally, alpha-fetoprotein levels are elevated late in the first trimester. Most newborns with anencephaly are stillborn, usually blind, deaf, and unconscious and most anencephalic infants born alive die within a few days.

SPINA BIFIDA

Spina bifida is a general term used to refer to caudal defects (below the level of T12) involving spinal cord tissue. It is a disorder involving incomplete development of the brain, spinal cord, and/or their protective coverings caused by the failure of the fetus's spine to close properly during the first month of pregnancy. Although the spinal opening can be surgically repaired shortly after birth, the nerve damage is permanent, resulting in varying degrees of paralysis of the lower limbs. Spina bifida is the leading cause of infantile paralysis in the world today, affecting up to 2,000 infants born annually in the United States (NINDS, 2015b).

Spina bifida may be classified by the degree of spinal cord involvement as spina bifida occulta or spinal bifida cystica (Fig. 24.9). Spina bifida occulta involves a defect in the vertebrae without any protrusion or herniation of the spinal cord or meninges. It is a closed defect and is not visible externally. A hairy patch, dermal sinus tract, dimple, hemangioma, or lipoma may be noted in the thoracic, lumbar, or sacral area. This form of spina bifida rarely causes disability or symptoms.

Spina bifida cystica is a more serious NTD. It includes meningocele and myelomeningocele. **Meningocele**, a less severe form of spina bifida cystica, is an opening in the spine through a bony defect (spina bifida) where a herniation of the meninges and spinal fluid has protruded. The spinal cord and nerve roots

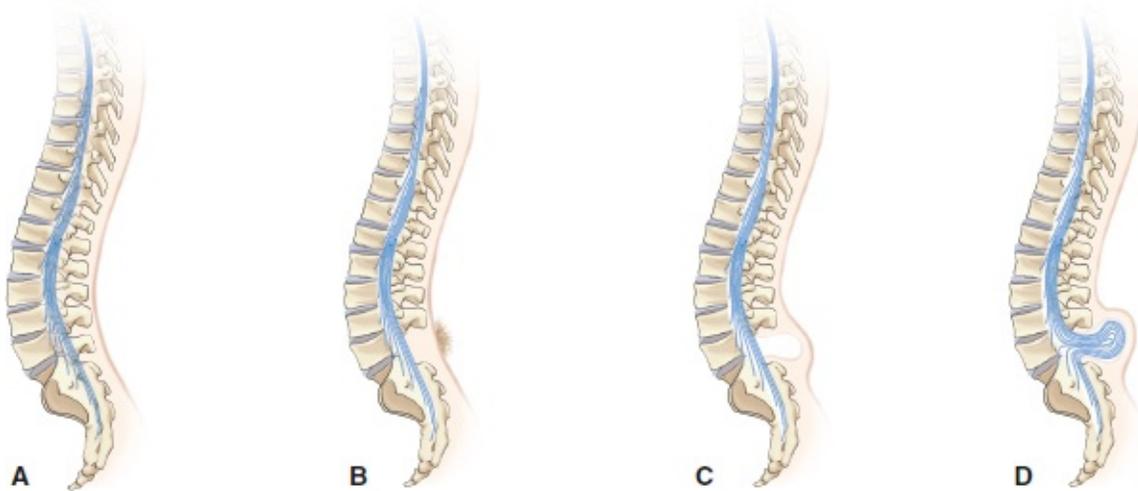
do not herniate into this dorsal dural sac. Some infants with meningocele may have few or no symptoms while others may experience such symptoms as complete paralysis with bladder and bowel dysfunction. Surgical treatment to close the defect is usually warranted.


FIGURE 24.9 Neural tube defects. **A.** Normal spine. **B.** Spina bifida occulta. **C.** Meningocele. **D.** Myelomeningocele.

A **myelomeningocele** is the most severe form of spina bifida cystica in which the spinal cord and nerve roots herniate into the sac through an opening in the spine, compromising the meninges. It is the most common form, accounting for 94% of cases (Foster & Kolaski, 2016). The incidence is 1 in 1,000 births; it affects up to 1,500 newborns in the United States each year (International Society for Pediatric Neurosurgery [ISPN], 2015). This complex condition, resulting from a neurodevelopmental disruption early in gestation, affects not just the spine but also the central nervous system. Hydrocephalus (abnormal accumulation of CSF within the ventricles and subarachnoid spaces) frequently accompanies this anomaly (Avellino, 2015). This protrusion is typically covered partially or completely by skin but is very fragile and may leak CSF if traumatized.

 Take Note!

Myelomeningoceles can arise at any point along the vertebral column, but they most commonly occur in the lower lumbar or sacral regions, causing neurologic

deficits below the level of the defect. Paralysis, bladder and bowel incontinence, and hydrocephalus are the most common complications.

Therapeutic Management

No immediate treatment is needed for spina bifida occulta. However, surgical intervention may be necessary later in life to treat complications associated with degenerative changes or spinal or nerve root involvement. For meningocele, surgery is performed to close the defect. For myelomeningocele, surgical repair is completed as soon as possible, usually within 72 hours after birth, to prevent infection and preserve neurologic function. Due to the severity and life-threating nature of these defects, fetal surgery for the repair of myelomeningoceles in the uterus is being advocated and done with encouraging results (Fuchs, 2015).

Nursing Assessment

Nursing assessment focuses on prevention. Assess all women of childbearing age for intake of folic acid and the use of folic acid supplementation. Review a pregnant woman's history for this supplementation throughout the pregnancy. In addition, monitor the pregnant woman's serum alpha-fetoprotein levels as indicated during pregnancy. Be alert for genetic and environmental risk factors associated with myelomeningocele, such as:

• Celtic or Hispanic ancestry (highest incidence)
• Female sex (accounting for 60% to 70% of affected newborns)
• Low socioeconomic status
• Maternal diabetes
• Use of anticonvulsants (valproic acid and carbamazepine)
• Previous newborn with an NTD
• Maternal obesity
• Maternal malnutrition
• Low folic acid intake (Cunningham et al., 2014).

  Inspect the newborn for abnormalities of the spine and back. Look for dimpling or a tuft of hair, which would suggest spina bifida occulta. Observe for a protrusion along the back that may be partially or completely covered with skin. Note the head circumference: a newborn with myelomeningocele often

exhibits hydrocephalus (Fig. 24.10).

Newborns with meningocele usually have normal examination findings and a covered (closed) dural sac. They typically do not have associated neurologic malformations.

FIGURE 24.10 A newborn with myelomeningocele and hydrocephalus.

Nursing Management

Nursing management of the newborn with spina bifida occulta is primarily supportive. Be sure that the parents understand the term used and that they do not confuse their newborn's condition with a more serious form of NTD. Teach them about the possibility of surgery in the future should complications develop.

For the child with meningocele, closely monitor the skin covering the area for evidence of CSF leakage. Prepare the newborn and parents for surgery.

Nursing management for a newborn with myelomeningocele involves the following actions to reduce the risk of infection and injury to the defect site:

• Use strict aseptic technique when caring for the defect to prevent infection.

• Avoid trauma to the sac (to prevent leakage of CSF or damage to the nerve tissue) through prone or side-lying positioning.

• Avoid placing a diaper over the sac to prevent rupture or infection by fecal contamination.

- Apply a sterile dressing or protective covering over the sac to prevent rupture and drying, with frequent changes to prevent the dressing from adhering to the defect.
- Frequently monitor the sac for signs of oozing fluid or drainage.
- Preserve skin integrity on and around the spinal defect.
- Meticulously clean the genital area to avoid contamination of the sac.
- In addition, ensure a neutral thermal environment and avoid hypothermia. Heat can be lost through the defect opening, placing the newborn at increased risk for cold stress.

Corrective surgery (pre/postnatal) correction is the usual modality of treatment for these congenital malformations of the nervous system. Intrauterine fetal surgery to repair spina bifida early in the pregnancy has decreased the number of infants developing hydrocephalus that would require a postnatal ventricular shunt (Copp et al., 2015). If the surgery is performed postnatally, the nurse will need to prepare the infant preoperatively and inform the parents of the necessity of closing the spinal defect as soon after birth as possible to preserve the neurologic function present. Intravenous antibiotics are administered to prevent infection pre- and postoperatively.

Assess movement and sensation below the defect; also assess urinary and bowel elimination, which may be affected based on the level of the lesion. Measure head circumference daily to observe for hydrocephalus.

Take Note!

Infants with myelomeningocele are at increased risk for latex allergy due to their repeated and numerous exposures to products containing latex during surgery and other necessary treatments.

Provide support and information to help the parents cope. Allow them to verbalize their feelings and ask questions. Encourage open discussions regarding the baby's prognosis and long-term care. Provide education about the care of the newborn, including measures to reduce the risk of infection and trauma to the sac. Encourage the parents to participate in their newborn's care as much as possible. As necessary, refer the parents to a support group.

Microcephaly

Microcephaly is a condition in which a small brain is located within a normal-sized cranium. Infants born with microcephaly will have a smaller than normal head that will fail to grow as they progress through infancy. It can be caused by genetic abnormalities or by drugs, alcohol, Zika virus, and toxins that the fetus is exposed to during the pregnancy.

Microcephaly is rare, affecting more than 25,000 infants in the United States each year. It is generally defined as a head circumference that is more than 2 standard deviations below the mean for age and sex, and if not present at birth, it usually develops before 2 years of age. There is no treatment for microcephaly that can return an infant's head to a normal size and shape. Treatment focuses on ways to decrease the impact of the associated deformities and neurologic disabilities (Foundation for Children with Microcephaly [FCM], 2015).

This implies neurologic impairment. Diagnosis is confirmed by a CT scan or MRI. Care is supportive since there is no known treatment to reverse the disorder. This defect may be caused by a number of factors: genetic, chromosomal disorders, environment, and factors of unknown origin. Risk factors for this anomaly include maternal viral infections (toxoplasmosis, rubella, cytomegalovirus, herpes, and syphilis), radiation exposure, diabetes, PKU, street drug exposure, alcohol consumption during pregnancy, and malnutrition (NINDS, 2015c). Inform parents about the potential cognitive impairment of their newborn. Ensure that appropriate community referrals are made to assist the parents and the child, who will have developmental delays.

Hydrocephalus

Hydrocephalus is an increase in CSF in the ventricles of the brain due to overproduction or impaired circulation and absorption. It may be congenital or acquired. CSF is produced constantly inside each of the four spaces—ventricles—inside the brain. Approximately 400 and 600 mL of CSF is produced each day. The CSF normally flows from one ventricle to another, out of the brain and down the spinal cord. If this drainage is prevented at any point, fluid accumulates in the ventricles causing them to swell, resulting in compression of the surrounding tissue (Fig. 24.11A,B1). The term *hydrocephalus* stems from the Greek words *hydro* (water) and *kephale* (head). It occurs in about 3 per 1,000 live births (Gardner et al., 2016).

Pathophysiology

Congenital hydrocephalus usually arises as a result of a malformation in the brain or an intrauterine infection (toxoplasmosis or cytomegalovirus). Hydrocephalus rarely occurs as an isolated defect; it is usually associated with spina bifida or other neural tube anomalies. Normal growth of the brain is altered secondary to the increase in intracranial pressure from the CSF.

Therapeutic Management

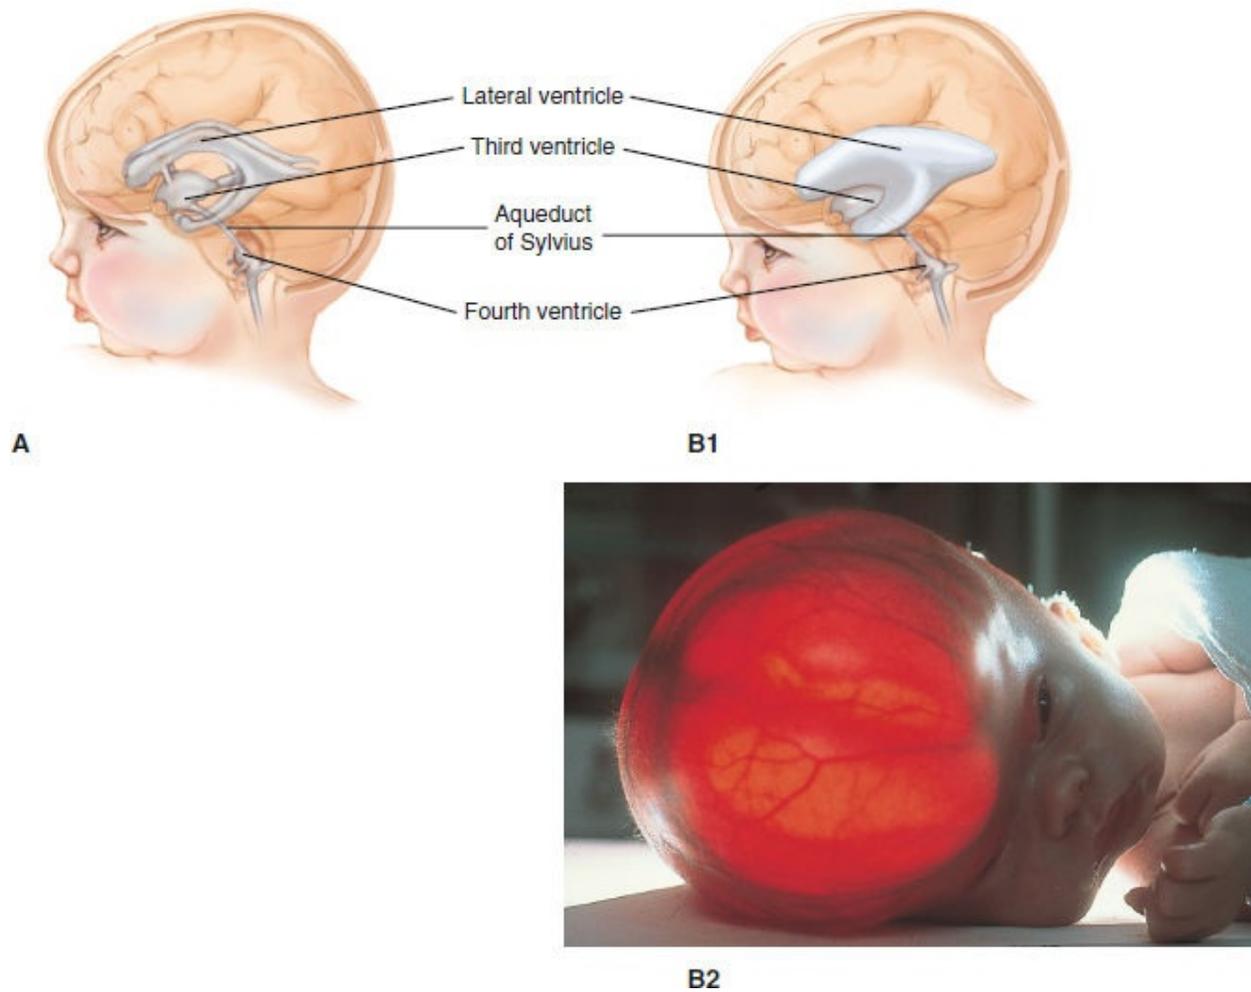
No treatment is available that can counteract the accumulation of CSF in the brain, but a surgical placement of shunt system helps reduce the accumulation of CSF The management of congenital hydrocephalus consists primarily of early shunting as soon after birth as possible. Therefore, surgery with the insertion of a ventricular shunt is a frequent treatment to relieve pressure within the cranium.


FIGURE 24.11 A. Infant *without* hydrocephalus. Note the ventricles of the brain and channels for the normal flow of cerebrospinal fluid. **B1, B2.** Infant *with* hydrocephalus. Note broadening of the forehead and large head size.

 Concept Mastery Alert

Treatment of Hydrocephalus

An infant with hydrocephalus is unable to move cerebral spinal fluid out of the cranium. The increased fluid causes pressure on the brain and ultimately brain damage. The only treatment available is surgery in order to halt any further damage to the brain.

Shunts are designed to maintain normal intracranial pressure by draining off excess CSF. A ventriculoperitoneal shunt is inserted from the ventricle in the brain and threaded down into the peritoneal cavity to allow drainage of excess CSF. The long-term prognosis for this condition varies and depends on the patency of the shunt, the presence of other CNS anomalies and their impact on the newborn, and the quality of care the newborn receives. Historically, hydrocephalus treatment has almost exclusively consisted of ventricular-peritoneal (VP) shunting due to ease of insertion of the shunt by neurosurgeons and immediate clinical response. However, VP shunts do have high failure rates predominantly due to infection, and endoscopic third ventriculostomy (ETV) is fast becoming a frontline treatment despite its complexities. ETV creates an opening in the floor of the third ventricle using an endoscope placed within the ventricular system through a burr hole. This allows the movement of CSF out of the blocked ventricular system and into the interpeduncular cistern (a normal CSF space) thereby shortcutting any obstruction. ETV is an alternative treatment method, which keeps the CSF within the brain and spinal cord, and is now considered a safe method of choice in the treatment of obstructive hydrocephalus, particularly when following a failed VP shunt (NINDS, 2015d).

Nursing Assessment

Nursing assessment focuses on obtaining a health history and performing a physical examination. Be alert for risk factors in the maternal history such as intrauterine infection or preterm birth. Assess the infant's head circumference and note any increases. Also note any visible scalp veins (Fig. 24.11B2). Palpate the infant's head, noting any widened sutures and wide, opened fontanels. Typically the fontanels will feel tense and bulging. Also observe for other signs of hydrocephalus, including poor feeding, "setting sun" eyes, vomiting, lethargy, and irritability. A CT scan or MRI confirms the diagnosis.

Nursing Management

Prior to shunt insertion or ETV, nursing management focuses on daily documentation of the newborn's head circumference and associated neurologic behaviors that might indicate an increase in intracranial pressure: irritability, high-pitched cry, poor feeding and sucking, lethargy or sleepiness, vomiting, bulging anterior fontanel when newborn is quiet, seizures or posturing, or a decrease in consciousness. Gently palpate the fontanels for bulging and

tenseness, and palpate the suture lines for increasing separation. Protect the enlarged head to prevent skin breakdown. Handle the head gently and use a sheepskin or a waterbed or egg-crate mattress. Change the newborn's position frequently to minimize pressure.

Postoperatively, strictly monitor the newborn's neurologic status and behavior and report any changes that might indicate increased intracranial pressure secondary to a blockage in the shunt. These findings may include pupillary dilation (increased intracranial pressure places pressure on the oculomotor nerve, producing dilation), increasing head size, bulging fontanels, and change in level of consciousness. Assess the abdomen for distention because drainage of CSF into the abdomen can cause peritonitis. Paralytic ileus is another possible postoperative complication due to distal catheter placement (Kenner & Lott, 2014).

After surgery, continue to provide protective and comfort measures for the enlarged head. Position the newborn's head so that he or she does not lie on the shunt area. Educate the parents about caring for the shunt and signs of infection or blockage. A referral for follow-up home care is appropriate. Stress the importance of close medical follow-up and prompt treatment of any health problems to prevent spread of infections to the shunt.

Choanal Atresia

Choanal atresia is an uncommon congenital malformation of the upper airway that involves a narrowing of the nasal airway due to membranous or bony tissue. It can be unilateral or bilateral and typically presents with other anomalies involving the heart and CNS. It occurs in 1 in approximately 8,000 live births, with a female preponderance. Half will have other congenital abnormalities in addition to choanal atresia (Kwong, 2015).

The cause of this congenital defect is unknown, but it is thought to result from persistence of the membrane between the nasal and oral spaces during fetal development. During attempted inspiration, the tongue is pulled to the palate and obstruction of the oral airway results. If the newborn cries and takes a breath through the mouth, the airway obstruction is momentarily relieved. When the crying stops, however, the mouth closes and the cycle of obstruction is repeated (Foster & Kolaski, 2016). This structural anomaly can result in significant respiratory distress in the newborn. If the nasal airway is completely obstructed, death from asphyxia may occur at birth.

Inability to pass a suction catheter through the nose into the pharynx is highly suggestive of choanal atresia. Other signs include respiratory distress, noisy breathing, cyanosis unless newborn is crying, and inability to suck and breathe simultaneously. The diagnosis can be confirmed with a CT scan. Surgery to remove the obstruction and establish a patent airway is needed. Full recovery is the usual outcome.

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) is a severe anomaly of failure in the development of the diaphragm that results in an abnormal insertion onto the inner chest wall, allowing some or all of the abdominal organs/contents to protrude into the thoracic cavity, impeding fetal lung development. CDH is characterized by pulmonary hypoplasia and decreased pulmonary vasculature. Newborns with CDH often require prompt treatment of severe respiratory distress and pulmonary hypertension to prevent death. Incidence of CDH in the United States is 1 in 2,000 to 3,000 live births and accounts for 8% of all major congenital anomalies. It has a worldwide incidence of 1 in 2,500 to 3,000 live births. CDH accounts for 8% of all major congenital anomalies (Steinhorn & Porta, 2015).

CDH is associated with other anomalies, including congenital cardiac defects, genital or renal anomalies, NTDs, choanal atresia, or chromosomal anomalies, such as trisomy 13 and 18. The survival rate of newborns with a diaphragmatic hernia varies widely.

Pathophysiology

The pathogenesis of CDH is complex and remains poorly understood. Although there is strong evidence implicating genetic and environmental factors in pathogenesis, few causal genes have been identified. It is thought that the diaphragm fails to close properly during early embryonic development. The abdominal contents then herniate into the thoracic cavity through a defect in the diaphragm (Fig. 24.12). The timing of the herniation and the amount of abdominal contents in the thoracic cavity greatly influence the clinical picture at birth and the survival rate. The presence of the abdominal contents in the chest compresses the lung, leads to pulmonary hypoplasia, and promotes persistent pulmonary hypertension in the newborn. Signs and symptoms of CDH include acute respiratory distress, cyanosis, sterna retractions, grunting, nasal flaring, tachycardia, rapid breathing, barrel-shaped chest, and a concave-shaped abdomen (Gardner et al., 2016).

Nursing Assessment

Assess the newborn closely for evidence of respiratory distress, including

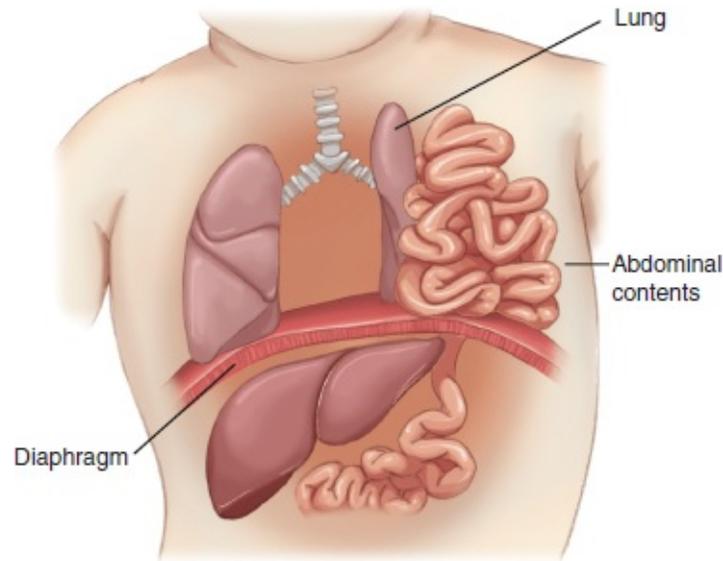
cyanosis. Affected newborns present with profound respiratory distress because at least one of the lungs cannot expand or may not have fully developed, resulting in persistent pulmonary hypertension shortly after birth. If present, institute resuscitation measures immediately.


FIGURE 24.12 Congenital diaphragmatic hernia. Note how some of the abdominal contents have entered the thoracic cavity, compressing the lung.

Inspect the chest and abdomen, noting a barrel-shaped chest and scaphoid-shaped abdomen. During auscultation, note absent breath sounds on the affected side of the chest and heart sounds displaced to the right. Also listen for bowel sounds, which would be heard in the chest.

Prepare the newborn for a chest x-ray or ultrasound, which will reveal evidence of air-filled bowel in the chest.

 Take Note!

Prenatal diagnosis of CDH is possible through ultrasound. This diagnosis should be considered when polyhydramnios is present.

Nursing Management

Initial treatment involves respiratory support with the goal of maintaining oxygenation and cardiovascular stability. Surgery to correct the anatomic

malformation is usually delayed until after the newborn's condition stabilizes. The surgical repair can also be delayed for months and done by minimally invasive surgery with the use of prosthetic material for closure of large defects. Extracorporeal membrane oxygenation, a process that mimics the gas exchange process of the lungs, may be ordered when the surgery is undertaken.

Nursing management focuses on maintaining optimal respiratory function until surgery is performed to correct the defect. Assist with endotracheal intubation and positive-pressure ventilation to aid in lung expansion and improvement of ventilation. Position the newborn on the affected side with the head and chest elevated to promote normal lung expansion. Monitor ventilatory pressures to prevent pneumothorax. If a pneumothorax occurs, assist with insertion of a chest tube and monitor chest tube drainage. Monitor oxygen saturation levels to evaluate systemic perfusion status. If the infant's condition does not stabilize, anticipate use of extracorporeal membrane oxygenation or high-frequency oscillatory ventilation. Be cognizant of potential complications postoperatively, which might include persistent pulmonary hypertension, gastric reflux, chronic lung disease, recurrent lung infections, and failure to thrive (McHoney, 2014).

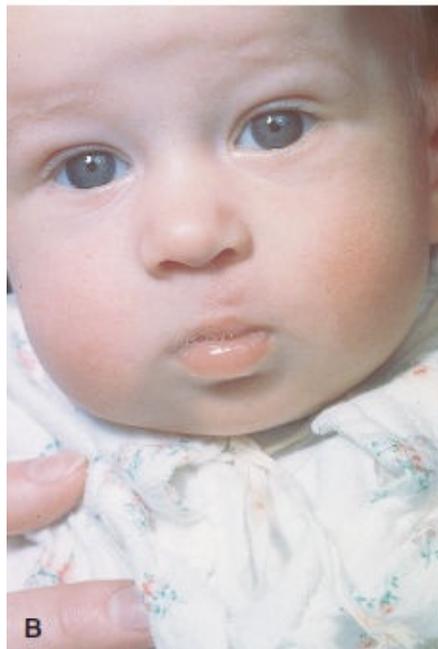
Administer prescribed medications as ordered. For example, give inotropics (drugs that affect the force of muscle contractions) to support systemic blood pressure. Administer surfactant, steroids, and inhaled nitric oxide as ordered to correct hypoxia and acid–base imbalance.

Monitor vital signs, weight, urinary output, and serum electrolytes to identify changes early. Maintain nothing by mouth (NPO) status to prevent aspiration, and ensure a neutral thermal environment to prevent cold stress and reduce oxygen demands. Minimize environmental stimuli to reduce agitation and oxygen demand. Assist with placement of an orogastric tube for gastric decompression.

Counseling is an essential component in the management of CDH. Parents should be informed about the severity of this condition, the treatment plan, the risk of poor outcomes, and the potential for several long-term morbidities. Assess the parental anxiety level and coping ability; provide emotional support and educate about CDH pathophysiology, potential complications, treatment risks and benefits, long-term medical surveillance to reduce risk of complications, and individualized prognosis. Refer for counseling on coping strategies as appropriate; provide written information on CDH to reinforce verbal education. Provide the parents with continuing updates about the

newborn's condition. Encourage the parents to see and touch the infant frequently to promote bonding. Assist parents with identifying newborn cues and responding to them.

Cleft Lip and Palate

Cleft lip with or without cleft palate is the most common congenital malformation of the head and neck. A cleft lip involves a congenital fissure or longitudinal opening in the lip; a cleft palate involves a congenital fissure or longitudinal opening in the roof of the mouth. The defect may be limited to the outer flesh of the upper lip or it may extend back through the midline of the upper jaw through the roof of the palate. It may occur as a single defect or as part of a syndrome of anomalies. It can be unilateral or bilateral. Unilateral cleft lip occurs more commonly on the left side. Bilateral cleft lip is usually accompanied by a cleft palate. Cleft palate can range from a cleft in the uvula to a complete cleft in the soft and hard palates that can be unilateral, bilateral, or in the midline (Fig. 24.13).


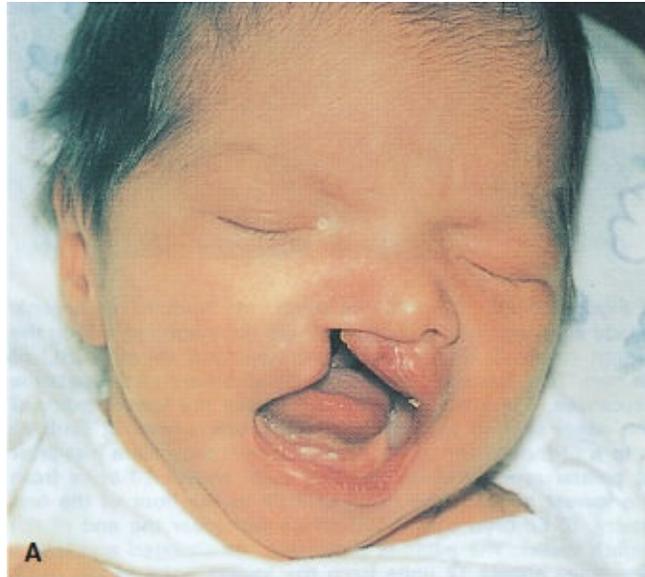


FIGURE 24.13 A. A newborn with a cleft lip. The defect may extend up through the roof of the palate. **B.** Infant with a surgical repair of a cleft lip. (Image **A** is from Moore, K. L., & Dalley, A. F. [2009]. *Clinical oriented anatomy* [6th ed.]. Baltimore, MD: Lippincott Williams & Wilkins.)

Cleft lip with cleft palate is a common craniofacial birth defect. It is more common in White and Asian males. It affects approximately 1 in 600 live births in the United States annually. In addition to immediate feeding difficulties, infants with cleft lip and palate may have problems with dentition, language acquisition, and hearing (Yadav et al., 2015).

Therapeutic Management

Repairing the facial anomaly as soon as possible is important to facilitate bonding between the newborn and the parents and to improve nutritional status. Treatment of cleft lip is surgical repair between the ages of 6 and 12 weeks. A rule of thumb for surgical readiness includes infant is 10 weeks old, weighs 10 pounds, and has hemoglobin of at least 10 g/dL. Successful surgery often leaves only a thin scar on the upper lip. The outcome of surgery depends on the severity of the defect: children with more severe cases will need additional surgery in stages (Crockett & Goudy, 2014).

The timing of the palate repair is more controversial, and there is not a universally correct recommendation. Surgical correction for cleft palate is typically done by 12 months of age to allow for developmental growth to occur. A plastic palate guard to form a synthetic palate may need to be used to allow for introduction of solid foods and to prevent aspiration in the interim.

Nursing Assessment

Obtain a thorough maternal history, noting the presence of any risk factors such as maternal use of phenytoin (Dilantin), alcohol, low folic acid intake, increased parental age, retinoic acid (Accutane), and cigarette smoking (Patel, 2014). Also assess for a family history of cleft lip or palate, which increases the risk. Keep in mind in the assessment that cleft lip and palate possess significant medical, psychological, social, and financial implications on the affected person and their family. In addition to the aesthetic disfigurement, the affected infant will suffer restricted maxillofacial growth, speech anomalies, swallowing and feeding difficulties, hearing loss and/or recurrent ear infections (Allam & Stone, 2014).

Inspect the lip for a visible deformity. Inspect and palpate the mouth for an opening, which may be small or involve the entire palate. Also observe for any feeding difficulties, which are common in newborns with cleft lip and palate.

Take Note!

Milk flow during feeding requires negative pressure and sucking pressure. Newborns with cleft lip and palate have feeding difficulties because they cannot generate a negative pressure in the mouth to facilitate sucking (Cleft Palate Foundation [CFF], 2015). Use special nipples, squeezable bottles, and feeders to

help meet the nutritional needs of infants with this anomaly.

Nursing Management

Nursing management focuses on providing adequate nutrition, promoting parental bonding, and providing parental education. Prevention should be considered the ultimate objective through preconception education of couples.

PROVIDING ADEQUATE NUTRITION

Many infants born with cleft lip and palate cannot be breast-fed. Those with cleft palate cannot produce the negative pressure necessary for suction. Mothers of infants with a unilateral cleft lip may succeed with breast-feeding when the infant is positioned so that the cleft in the lip is obstructed by the mother's breast. No single right or correct method of feeding has been identified. Parents working together with the health care provider and nursing staff should choose the method that is best for their infant.

Nurses need to instruct the mother to feed the infant in an upright position to prevent aspiration, and assess for achievement of adequate suction during feeding. Use high-calorie formula to improve caloric intake. Burp the infant frequently to reduce the risk for vomiting and aspiration; burp him or her in the sitting position on your lap to prevent trauma to the mouth on your shoulder. Limit feeding sessions to avoid poor weight gain due to fatigue. After feeding, position the newborn on his or her side in an infant seat.

PROMOTING PARENTAL BONDING

Prenatal diagnosis of cleft lip and palate has been available for over 25 years. Three-dimensional ultrasound has significantly improved prenatal screening and perinatal care. Surface rendering of the fetal face is frequently asked by parents during exam and it has been shown to substantially improve parental–fetal bonding. Studies support that prenatal diagnosis of cleft lip and palate is known to improve parental well-being during the perinatal period. Furthermore, in addition to improved diagnosis, 3D ultrasound also provides a better understanding and acceptance of the malformation by parents. Nurses need to develop interventions to help parents deal with the impact of social stigmatization and physical concerns of the cleft lip and palate condition (Juneja & Juneja, 2014).

On first glance, parents may be upset with the appearance of their newborn.

Encourage the parents to express their feelings about this highly visible anomaly. Emphasize the newborn's positive features and role-model nurturing behaviors when interacting with the infant. Encourage parents to interact with the newborn. Provide support to the parents, especially related to feeding difficulties. Allow them to vent their frustrations. Offer practical suggestions and continued encouragement for their efforts.

PROVIDING PARENTAL EDUCATION

The impact on quality of life for the infant and the family can be severe, particularly for unsuspecting families. Emotional and psychological needs must be recognized and addressed, in addition to surgical care, by all those caring for the infant. Outline treatment modalities and explain the staging of surgical interventions. Show the family photos taken before and after surgical repair in other babies. These photos can alleviate some of their anxiety. Start planning for discharge as soon as the parents feel comfortable with infant care. Provide anticipatory guidance and instructions for potential challenges they may face at home and into the future, which include feeding difficulties, frequent ear infections, speech difficulties, and dental problems. As part of the discharge plan, initiate appropriate referrals for community support and counseling as needed. Nurses can help parents/partners/significant others to trust in themselves and feel confident in their ability to nurture their newborns by listening, informing, and encouraging them (Tierney et al., 2015).

Esophageal Atresia and Tracheoesophageal Fistula

Esophageal atresia (EA) and tracheoesophageal fistula (TEF) are gastrointestinal anomalies in which the esophagus and trachea do not separate normally during early embryonic development (3 to 6 weeks). EA is a congenitally interrupted esophagus where the proximal and distal ends do not communicate; the upper esophageal segment ends in a blind pouch and the lower segment ends a variable distance above the diaphragm (Fig. 24.14). TEF is an abnormal communication between the trachea and esophagus. When associated with EA, the fistula most commonly occurs between the distal esophageal segment and the trachea. The lack of esophageal patency prevents swallowing. In addition to preventing normal feeding, this problem may cause infants to aspirate and literally drown in their own saliva, which quickly overflows the upper pouch of the obstructed esophagus. If a TEF is present, fluid (either saliva from above or gastric secretions from below) may flow directly into the lungs. The incidence of EA is 1 in 4,000 to 5,000 live births (Scorpio, 2014).

Concept Mastery Alert

Priority Concern in Esophageal Atresia

The priority concern for the infant with esophageal atresia (EA) is the risk for respiratory distress. Many infants with EA also have a TEF, which is a connection between the esophagus and the trachea. This connection can put the infant at high risk for respiratory distress, especially if the child is fed any food by mouth.

Pathophysiology

Several types of EA exist, but the most common anomaly is a fistula between the distal esophagus and the trachea, which occurs in 90% of newborns with an esophageal defect. EA and TEF are thought to be the result of incomplete separation of the lung bed from the foregut during early fetal development. A

large percentage (50% to 70%) of these newborns have other congenital anomalies involving the vertebrae, kidneys, heart, and musculoskeletal and gastrointestinal systems (Oermann, 2015). Most newborns have several anomalies.

Nursing Assessment

Review the maternal history for polyhydramnios. Often this is the first sign of EA because the fetus cannot swallow and absorb amniotic fluid in utero, leading to accumulation. Soon after birth, the newborn may exhibit copious, frothy bubbles of mucus in the mouth and nose, accompanied by drooling. Abdominal distention develops as air builds up in the stomach. In EA, an orogastric tube cannot be inserted beyond a certain point because the esophagus ends in a blind pouch. The newborn may have rattling respirations, excessive salivation and drooling, and "the three C's" (coughing, choking, and cyanosis) if feeding is attempted. The presence of a fistula increases the risk of respiratory complications such as pneumonitis and atelectasis due to aspiration of food and secretions (Davidson, 2014). Clinical manifestations of EA and TEF include:

• Excessive secretions

• Feeding intolerance

• Inability to pass orogastric tube

• Abdominal distention

• Respiratory distress

• Other anomalies involving the vertebrae, anus, cardiac system, and kidneys

Take Note!

The "three C's" of choking, coughing, and cyanosis in conjunction with feeding are considered the classic signs of TEF and EA.

Prepare the newborn and parents for radiographic evaluation. Diagnosis is made by x-ray, an ultrasound, or MRI: if the gastric tube appears coiled in the upper esophageal pouch, with air in the gastrointestinal tract, this indicates the presence of a fistula (Mattson & Smith, 2015). Once a diagnosis of EA is established, begin preparations for surgery if the newborn is stable.

Nursing Management

Once the diagnosis is established, an orogastric tube is placed in the upper esophageal pouch and set to low continuous suction to prevent aspiration of oral secretions. Nursing management focuses on preparing the newborn and parents for surgery and providing meticulous postoperative care. The type of esophageal defect dictates the surgical approach needed.

PROVIDING PREOPERATIVE CARE

Preoperative nursing interventions include the following measures:

• Initiate NPO status.

• Elevate the head of the bed 30 to 45 degrees to prevent reflux and aspiration.

• Monitor hydration status and fluid and electrolyte balance; administer and monitor parenteral intravenous fluid infusions.

• Assess and maintain the patency of the orogastric tube. Monitor the functioning of the tube, which is attached to low continuous suction. Avoid irrigation of the tube to prevent aspiration.

• Have oxygen and suctioning equipment readily available should the newborn experience respiratory distress.

• Assist with diagnostic studies to rule out other anomalies.

• Use comfort measures to minimize crying and prevent respiratory distress; provide nonnutritive sucking.

• Inform the parents about the rationales for the aspiration prevention measures.

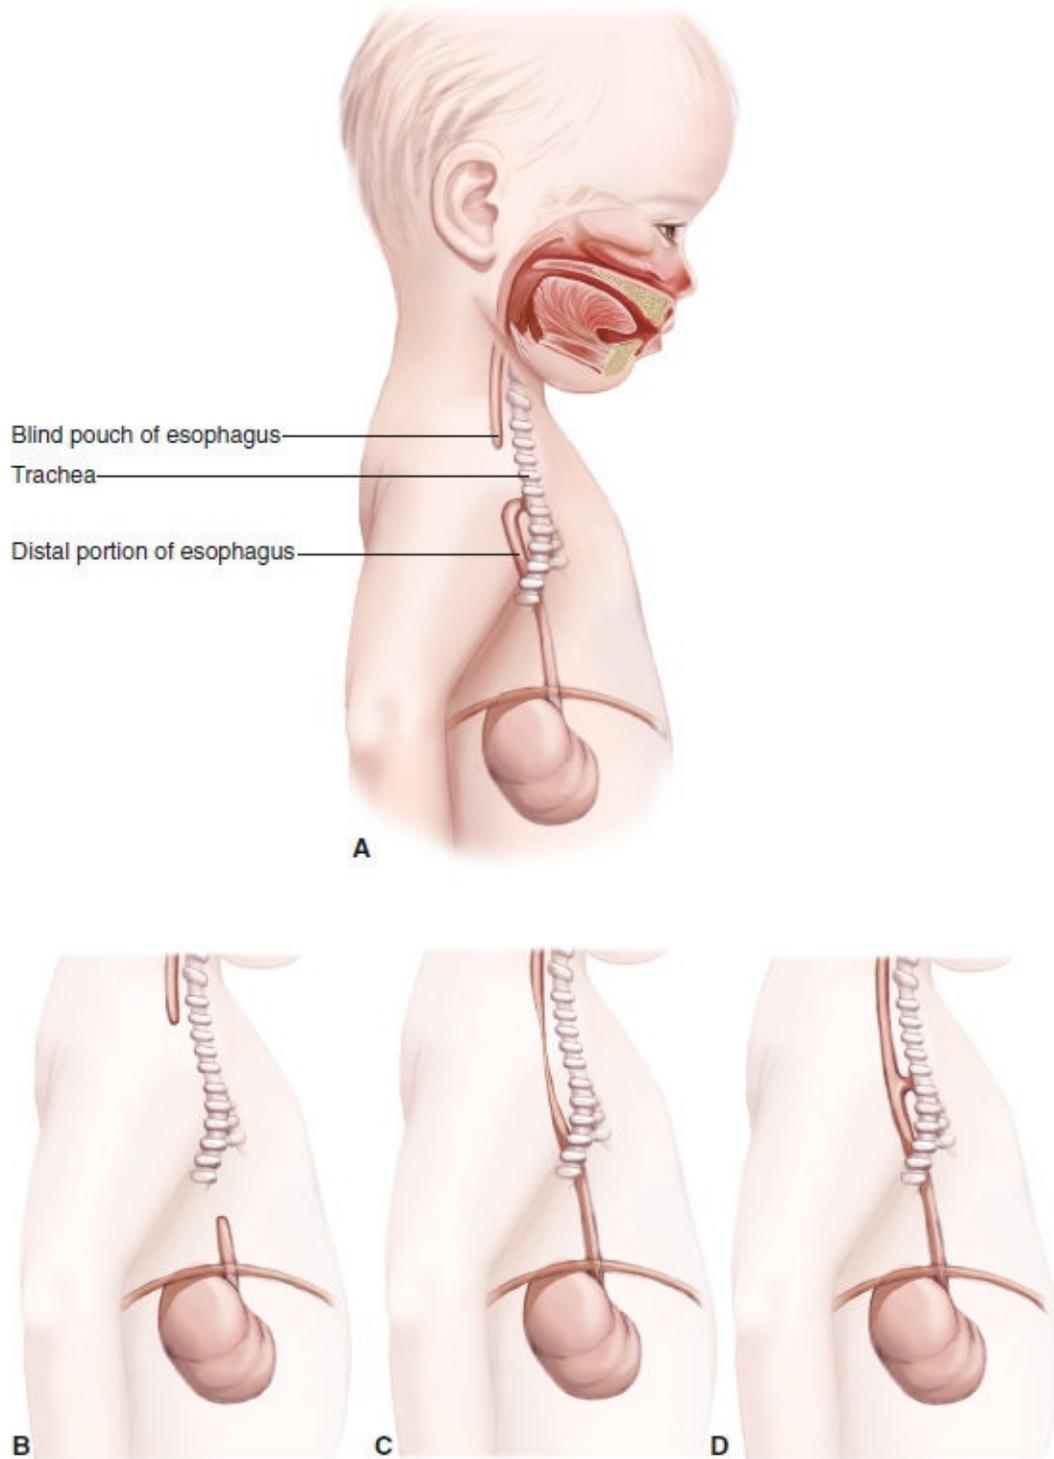
• Document frequent observations of the newborn's condition (Kenner & Lott, 2014).


FIGURE 24.14 Esophageal atresia and tracheoesophageal fistula. **A.** The most common type of esophageal atresia, in which the esophagus ends in a blind pouch and a fistula connects the trachea with the distal portion of the esophagus. **B.** The upper and distal portions of the esophagus end in a blind pouch. **C.** The esophagus is one segment, but a portion of it is narrowed. **D.** The upper portion of the esophagus connects

to the trachea via a fistula.

PROVIDING POSTOPERATIVE CARE

Surgery consists of closing the fistula and joining the two esophageal segments. Postoperative care involves closely observing all of the newborn's body systems to identify any complications. Expect to administer TPN and antibiotics until the esophageal anastomosis is proven intact and patent. Before initiating oral feedings, an esophagram is usually ordered to verify complete anastomotic healing and absence of any leaks. If that validates healing, then oral feedings are started, usually within a week after surgery (Shawyer, Pemberton, & Flageole, 2014). Keep the parents informed of their newborn's condition and progress. Closely assess the newborn during feeding and report any difficulty with swallowing. Provide parent teaching. Demonstrate and reinforce all teaching prior to discharge.

Omphalocele and Gastroschisis

Omphalocele and gastroschisis are congenital anomalies of the anterior abdominal wall at or near the umbilicus. An **omphalocele** is a defect of the umbilical ring that allows evisceration of the abdominal contents into an external peritoneal sac. Defects vary in size; they may be limited to bowel loops or may include the entire gastrointestinal tract and liver (Fig. 24.15). Bowel malrotation is common, but the displaced organs are usually normal. Omphaloceles are associated with other anomalies in more than 50% of the cases, most often trisomies 12, 18, or 21. This anomaly is usually detected during routine prenatal ultrasound of the fetus or during investigation of an increased alpha-fetoprotein level. Gastroschisis occurs in 1 out of 2,000 births and omphalocele occurs in 1 out of 4,000 births (Glasser, 2015).

   Gastroschisis is a full-thickness defect of the abdominal wall that occurs most commonly to the left or right of the umbilicus that exposes the extruded bowel to the amniotic fluid. It is typically not associated with other major anomalies (Verklan & Walden, 2014). Gastroschisis differs from omphalocele in that there is no peritoneal sac protecting the herniated organs, and thus exposure to amniotic fluid makes them thickened, edematous, and inflamed. Gastroschisis is associated with significant newborn mortality and morbidity rates. Despite surgical correction, feeding intolerance, short bowel syndrome, intestinal stricture, bowel obstruction, failure to thrive, and prolonged hospital stays occur in nearly all newborns with this anomaly (Markdante & Kliegman, 2014). Each of these diagnoses requires that a pediatric surgeon be available at birth to determine the extent of the defect and complications.

FIGURE 24.15 Omphalocele in a newborn. Note the large, protruding sac.

Nursing Assessment

Abdominal wall defects are readily diagnosed by prenatal ultrasound, which is helpful in planning for the birth and needed therapy. An early birth may be planned if the ultrasound reveals evidence of progressive bowel distention and thickening. Review the maternal history for factors associated with high-risk pregnancies, such as maternal illness and infection, drug use, smoking, and genetic abnormalities. These factors are also associated with omphalocele and gastroschisis. They contribute to placental insufficiency and the birth of an SGA or preterm newborn, the populations in which both of these abdominal defects most commonly occur.

Omphalocele and gastroschisis are readily observed. Note the appearance of the protrusion on the abdomen and evidence of a sac. Inspect the sac closely for the presence of organs, most commonly the intestines but sometimes the liver. Also inspect the contents for any twisting of the intestines. Note the color of the organs within the sac and measure the size of the omphalocele.

Also perform a complete physical examination of the newborn. Typically these congenital conditions are associated with other congenital anomalies, such as those involving the cardiovascular, genitourinary, and central nervous systems. Assessment findings of omphalocele and gastroschisis include:

• Usually detected on prenatal ultrasound exams

• Eviscerated bowel without peritoneal covering (gastroschisis)

• Eviscerated bowel with peritoneal covering (omphalocele)

The nurse should search for additional anomalies if omphalocele is diagnosed.

Nursing Management

Nursing management of newborns with omphalocele or gastroschisis focuses on preventing hypothermia, maintaining perfusion to the eviscerated abdominal contents by minimizing fluid loss, and protecting the exposed abdominal contents from trauma and infection. These objectives can be accomplished by placing the infant in a sterile drawstring bowel bag that maintains a sterile environment for the exposed contents, allows visualization, reduces heat and moisture loss, and allows heat from radiant warmers to reach the newborn. The newborn is placed feet-first into the bag and the drawstring is secured around the torso (Kallen, 2014a). Strict sterile technique is necessary to prevent contamination of the exposed abdominal contents.

An orogastric tube attached to low suction is used to prevent intestinal distention. Intravenous therapy is administered to maintain fluid and electrolyte balance and provide a route for antibiotic therapy. Monitor the newborn's fluid status frequently. Closely observe the exposed bowel for vascular compromise, such as changes in color or a decrease in temperature, and report these immediately.

PROVIDING POSTOPERATIVE CARE

Surgical repair of both defects occurs after initial stabilization and comprehensive evaluation for any other anomalies. It may have to occur in stages, depending on the defect (Box 24.5). Postoperative care involves providing pain management, monitoring respiratory and cardiac status, monitoring intake and output, assessing for vascular compromise, maintaining the orogastric tube to suction, documenting the amount and color of drainage, and administering ordered medications and treatments (Glasser, 2015). Also be alert for complications, such as short bowel syndrome.

PROMOTING PARENT–NEWBORN INTERACTION

The parents need continued support and progress reports on their newborn. They may be distraught at the sight of the anomaly, and they may be frightened to touch their newborn. Encourage the parents to touch the newborn and participate in care as much as possible. Because of the nature of this defect, bonding opportunities will be limited initially. However, strongly encourage frequent

visiting. In addition, provide information to the parents about the defect, treatment modalities, and prognosis. After surgery, instruct the parents in care measures and give them care instructions. Anticipate the need for a referral to a home health care agency and community resources for support.

SURGERY TO REPAIR OMPHALOCELE AND GASTROSCHISIS

Surgical repair of gastroschisis is an emergency due to the high risk of intestinal atresia, resulting in obstruction. Primary repair of gastroschisis is usually performed without incident unless the contents are unable to fit into the abdominal cavity. This occurs more often with a large omphalocele, requiring the surgeon to do a staged closure. This involves covering the defect with a synthetic material that is sequentially squeezed like toothpaste to reduce the defect into the abdominal cavity. After enough of the defect is in the abdominal cavity, a surgical repair is then performed (Glasser, 2015). If damage to the exposed organs occurs, such as necrosis, then the necrotic sections are removed during the repair. If a significant amount of small intestine is lost, then the complication of short bowel syndrome may occur.

Imperforate Anus

An imperforate anus is a gastrointestinal system malformation of the anorectal area that may occur in several forms. The rectum may end in a blind pouch that does not connect to the colon, or it may have fistulas (openings) between the rectum and the perineum, the vagina in girls or the urethra in boys (Fig. 24.16). The malformations occur during early fetal development and are associated with anomalies in other body systems. The etiology of such malformations remains unclear and is likely multifactorial.

Imperforate anus occurs in about 1 of every 3,500 live births, and predominantly affects males more than females (Rosen, 2015). The defect can be further classified as a high or low type, depending on its level. A fistula connection to the perineum or the urogenital tract is frequently present. The level significantly influences fecal continence and management (Coppola, 2014).

Surgical intervention is needed for both high and low types of imperforate anus. Surgery for a high type of defect involves a colostomy in the newborn period, with corrective surgery performed in stages to allow for growth. Surgery for the low type of anomaly, which frequently includes a fistula, involves closure of the fistula, creation of an anal opening, and repositioning of the rectal pouch into the anal opening. A major challenge for either type of surgical repair is finding, using, or creating adequate nerve and muscle structures around the rectum to provide for normal evacuation.

Nursing Assessment

In the newborn, observe for an appropriate anal opening. If the anal opening exists, observe for passage of meconium stool within the first 24 hours of life. Assess urine output to identify genitourinary problems. For the newborn with an imperforate anus, inspection of the perineal area would reveal absence of the usual opening, and meconium generally is not passed or present within 24 hours of birth.

In the infant with suspected imperforate anus, assess for common signs of intestinal obstruction, which may occur as a result of the malformation. These include abdominal distention and bilious vomiting.

Prepare the newborn and family for a perineal ultrasound and an abdominal x-ray that will be ordered to identify the level of defect in the absence of a perineal

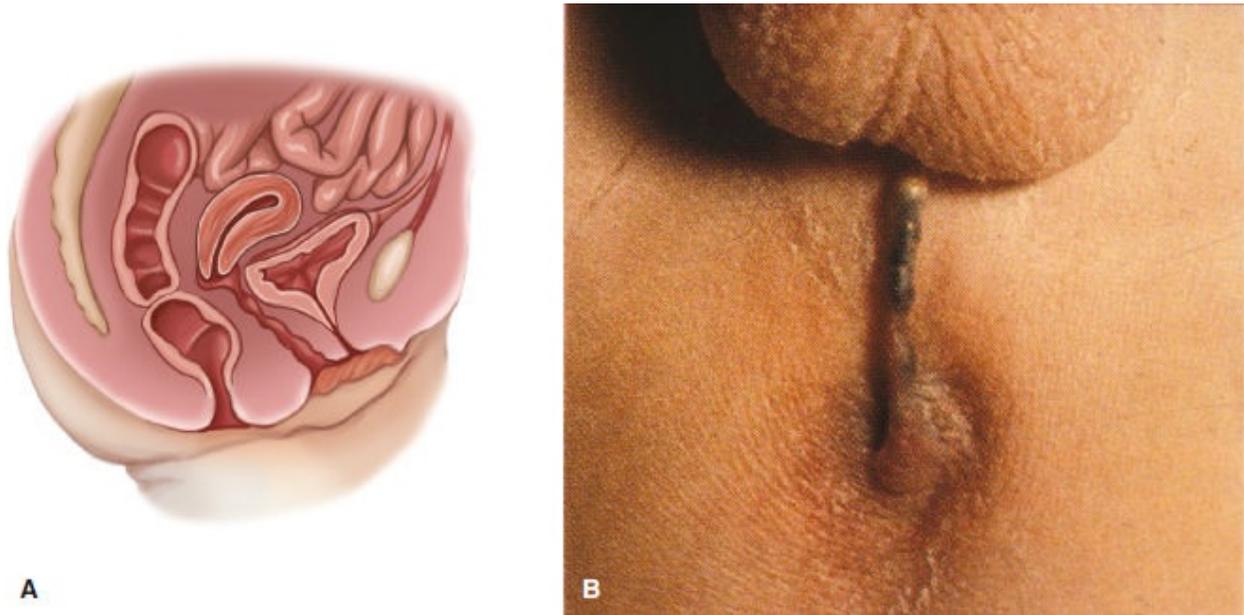
fistula and also to assess for complications associated with imperforate anus.


FIGURE 24.16 A. Imperforate anus, in which the rectum ends in a blind pouch. **B.** Imperforate anus without fistula. The visible meconium streak along the raphe is consistent with a low imperforate anus. (Courtesy of Kevin P. Lally, MD.)

Nursing Management

Nursing management focuses on preparing the newborn and parents for surgery and providing postoperative care. Preoperatively, maintain the newborn's NPO status and provide gastric decompression. Administer intravenous therapy and antibiotic therapy as ordered and monitor the newborn's hydration status. Provide a full explanation of the defect, surgical options, potential complications, typical postoperative course, and long-term care needed to the parents. Make sure they are aware of the available treatment modalities. Prepare them for the possibility that the newborn may require a colostomy. Provide support to the parents and family.

Postoperative care includes ensuring adequate pain relief, maintaining NPO status and gastric decompression until normal bowel function is restored, and providing colostomy care if applicable. Stoma care and teaching of the parents are paramount for home care of the infant.

Hypospadias

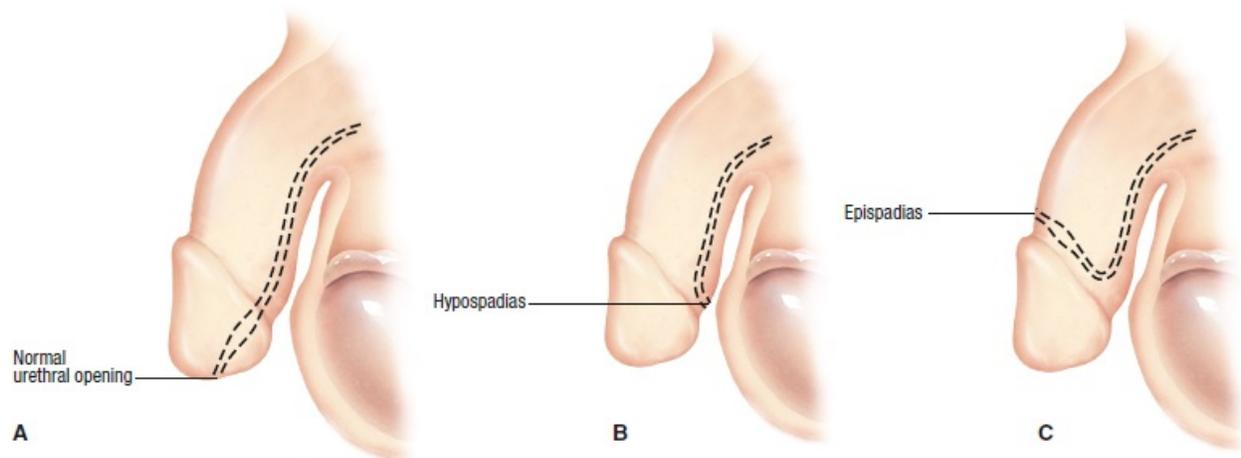
Hypospadias is a relatively common malformation of the male genital organ. It is an abnormal positioning of the urinary meatus on the underside of the penis (Fig. 24.17B). Scrotal and testicular anomalies are often associated, e.g., undescended testicle. Hypospadias is a relatively common birth defect that occurs in approximately 1 of every 250 male births in the United States (Kallen, 2014b).


FIGURE 24.17 Genitourinary tract structural anomalies.

The malformation is the result of incomplete fusion of the urethral folds, which usually occurs between 8 and 20 weeks of gestation (Gatti, Snyder, & Kirsch, 2015). The cause is unknown, but it is thought to be of multifactorial inheritance because it occasionally occurs in more than one male in the same family.

The degree of hypospadias depends on the location of the opening. It is often accompanied by a downward bowing of the penis (chordee), which can lead to urination and erection problems and infertility in adulthood.

Hypospadias can be corrected surgically. Depending on the severity, the correction can be completed in one or more procedures with good results. The success of hypospadias repair can be measured according to functional results, such as urinary flow rate, straight urine stream and lack of urinary tract infection, as well as a normal appearance of the penis, with a slit-like meatus at the tip of the glans. Surgical intervention should be completed during the latter

half of the first year of life to prevent any body image problems in the child.

Epispadias

Epispadias is a rare congenital genitourinary defect occurring in 1 in 10,000 to 50,000 male births. The male-to-female ratio is 2:1 (Kenner & Lott, 2014). The condition is usually diagnosed at birth or shortly thereafter. In boys with epispadias, the urethra generally opens on the top or side rather than the tip of the penis. In females, the urinary meatus is located between the clitoris and the labia. This anomaly often occurs in conjunction with exstrophy of the bladder (Foster & Kolaski, 2016). Surgical correction is necessary, and affected male newborns should not be circumcised. Surgery generally leads to the ability to control the flow of urine and a good cosmetic outcome (see Fig. 24.17C).

Bladder Exstrophy

In bladder exstrophy, the bladder protrudes onto the abdominal wall because the abdominal wall failed to close during embryonic development (Fig. 24.18). Wide separation of the rectus muscles and the symphysis pubis accompanies this defect. Virtually all affected male infants have associated epispadias. The upper urinary tract is usually normal. The incidence is approximately 1 in 30,000 live births, and happens in males slightly more than females (March of Dimes, 2015d).

Goals of therapy include restoring urinary continence, preserving renal function, and reconstructing functional and cosmetically acceptable genitalia. Initial bladder closure is completed within 48 hours after birth. Epispadias repair occurs at this time if possible. Further surgical reconstruction is performed in several stages at about 2 to 3 years of age (see Fig. 24.18B). Because of the potential long-term implications of exstrophy, family education is critical. Exstrophy support groups are established at several major medical centers.

Nursing management of the newborn with bladder exstrophy includes the following activities:

• Identify the genitourinary defect at birth so that immediate treatment can be provided.

• Cover the exposed bladder with a sterile clear nonadherent dressing to prevent hypothermia and infection.

• Irrigate the bladder surface with sterile saline after each diaper change to prevent infection.

• Assist with insertion and monitoring of a suprapubic catheter to drain the bladder and prevent obstruction.

• Administer antibiotic therapy as ordered to prevent infection.

• Schedule diagnostic tests to assess for additional anomalies.

• Assess the newborn frequently for any signs of infection.

• Inspect skin surfaces frequently to ensure skin integrity.

• Maintain modified Bryant traction for immobilization after surgery.

• Administer antispasmodics, analgesics, and sedatives as ordered to prevent bladder spasm and provide comfort.

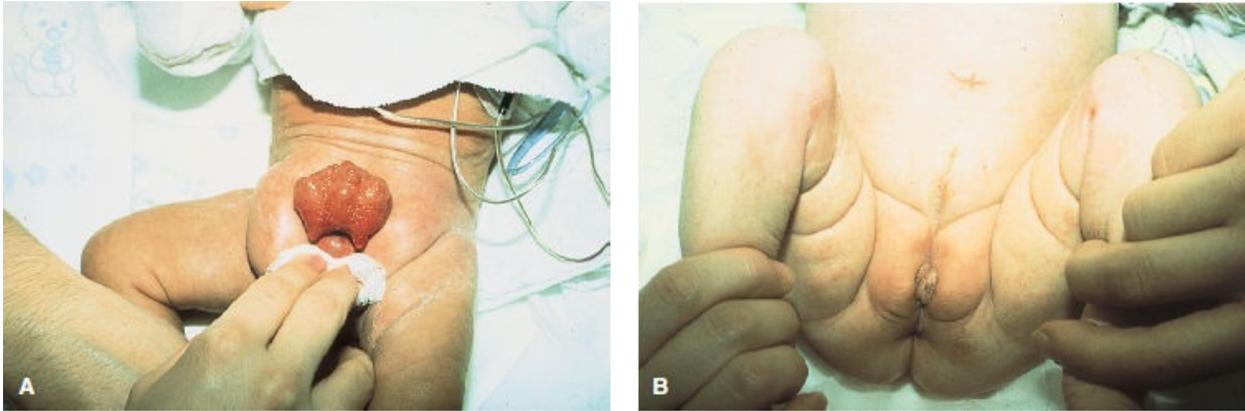
- Educate the parents about the care of the urinary catheter at home if applicable.
- Support the parents throughout.
- Promote bonding by encouraging the parents to visit and touch the newborn.
- Refer the parents to a support group to enhance their coping ability.
- Be a therapeutic listener to the family (Davidson, 2014; Kenner & Lott, 2014).


FIGURE 24.18 Bladder exstrophy. **A.** Before surgical repair. **B.** After surgery.

Congenital Clubfoot

Clubfoot, or talipes equinovarus, is a common congenital deformity affecting approximately 1 to 2 per 1,000 live births. It is bilateral in about half of the cases and affects boys twice as often as girls. It is characterized by an excessive turned in foot. It typically has four components: inversion and adduction of the forefoot, inversion of the heel and hindfoot, limitation of extension of the ankle and subtalar joint, and internal rotation of the leg (Patel & Herzenberg, 2015) (Fig. 24.19). Reducing or eliminating all of the components of the deformity is the goal to ensure that the newborn has a functional, mobile, painless foot that does not require the use of special or modified shoes (Gray et al., 2014).

Pathophysiology

Clubfoot is a complex, multifactorial deformity with genetic and intrauterine factors. Heredity and race seem to factor into the incidence, but the means of transmission and the etiology are unknown. Most newborns with clubfoot have no identifiable genetic, syndromal, or extrinsic cause.

Clubfoot can be classified into extrinsic (supple) type, which is essentially a severe positional or soft tissue deformity, or intrinsic (rigid) type, where manual reduction is not possible.

Therapeutic Management

Its management must begin shortly after birth. The type of clubfoot deformity determines the treatment course. Treatment for the extrinsic (supple) type consists of serial casting, followed by maintenance splinting. Treatment for the intrinsic (rigid) type includes initial casting followed by surgery. It is generally agreed that the initial treatment should be nonsurgical and started soon after birth.

Treatment for either type starts with serial casting, which is needed due to the rapid growth of the newborn. Casts initially are changed weekly and are applied until the deformity responds and is fully corrected. If serial casting is not successful in correcting the deformity, surgical intervention is necessary between 4 and 9 months of age. The standard treatment of clubfoot has changed greatly in the past 10 years. Previously, extensive surgery was common in children born with this condition. The publication of long-term evidence of good outcomes

with more minimally invasive methods, such as the Ponseti technique, has led surgeons worldwide to change their approach. Ponseti treatment consists of serial casting and percutaneous Achilles tenotomy of the affected feet followed by bracing to maintain the correction (Shabtai, Specht, & Herzenberg, 2014).

FIGURE 24.19 Clubfoot deformity. **A.** Initial appearance. **B.** Application of cast to correct clubfoot.

Nursing Assessment

On examination, the foot appears "down and in." It is smaller than a normal foot, with a flexible, softer heel because of the hypoplastic (underdeveloped) calcaneus. The heel is internally rotated, making the soles of the feet face each other when the deformity occurs bilaterally.

Nursing Management

Nursing management focuses on education, anticipatory guidance, and pain management. Educate the parents about their newborn's condition and the treatment protocol to reduce their anxiety, and provide reassurance that the clubfoot is not painful and will not hinder the child's development. Discuss challenges associated with sleep, play, and dressing. Inform them that slight modifications will be necessary to accommodate the plaster casts. Review positioning, bathing, and skin care along with pain management when new casts are applied. Stress the need to provide a calm, quiet environment to promote relaxation and sleep for their newborn.

Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH) involves abnormal growth or development of the hip that results in instability. This includes hips that are unstable, subluxated, or dislocated (luxated) or have a malformed acetabulum. The instability allows the femoral head to become easily displaced from the acetabulum. The incidence of hip instability is about 1.5 to 25 per 1,000 live births and is more common in females and breech presentations (Schwend, 2014). The etiology of DDH is unclear.

Therapeutic Management

Treatment is started as soon as DDH is identified. If the newborn examination reveals DDH, the newborn is referred to an orthopedist. The goal of treatment is to relocate the femoral head in the acetabulum to facilitate normal growth and development. The Pavlik harness is the most widely used device; it prevents adduction while allowing flexion and abduction to accomplish the treatment goal (Fig. 24.20). The harness is worn continuously until the hip is stable, which may take several months. If harnessing is not successful, surgery is necessary.

Nursing Assessment

Assess the history for risk factors, including racial background (Native Americans), genetic transmission (runs in families), intrauterine positioning (breech), sex (female), oligohydramnios, birth order (first-born), and postnatal infant-carrying positions (swaddling, which forces the hips to be adducted). The risk increases in cultures that tightly swaddle infants with their hips forcefully maintained in extension and adduction.

Take Note!

DDH is frequently not identified during the newborn examination, so newborns require careful evaluation for hip dysplasia at subsequent visits throughout the first year.

FIGURE 24.20 The Pavlik harness is used to treat developmental dysplasia of the hip.

Complete a physical examination. Typically, the newborn with DDH is otherwise healthy, usually without any other deformities. Pay particular attention to assessing hip instability. Perform Ortolani and Barlow maneuvers (see Chapter 18 for more information on these maneuvers). Ortolani's maneuver elicits the sensation of the dislocated hip reducing; Barlow's maneuver detects the unstable hip dislocating from the acetabulum. A hip "clunk" is felt when the infant's legs are abducted into a frog position. Although soft clicks are common, a sharp click indicates dislocation. Fractures may also be present and are characterized by limited movement and edematous, crepitant areas. Also observe for other physical signs of DDH, including an asymmetric number of skin folds on the thigh or buttock, an apparent or true short leg, and limited hip abduction (Rosenfeld, 2015) (Fig. 24.21).

Nursing Management

Nursing management related to DDH starts with recognition of the disorder and early reporting to the health care provider. Early diagnosis is the crucial aspect; education also is critical. Teach the parents how to care for their newborn while in the harness during treatment. Proper fit and adjustments for growth are essential for successful treatment. Frequent clinical assessment on an outpatient basis is needed to monitor progress. Through education, the nurse can be very

effective in helping the parents to adhere to the treatment.

Inborn Errors of Metabolism

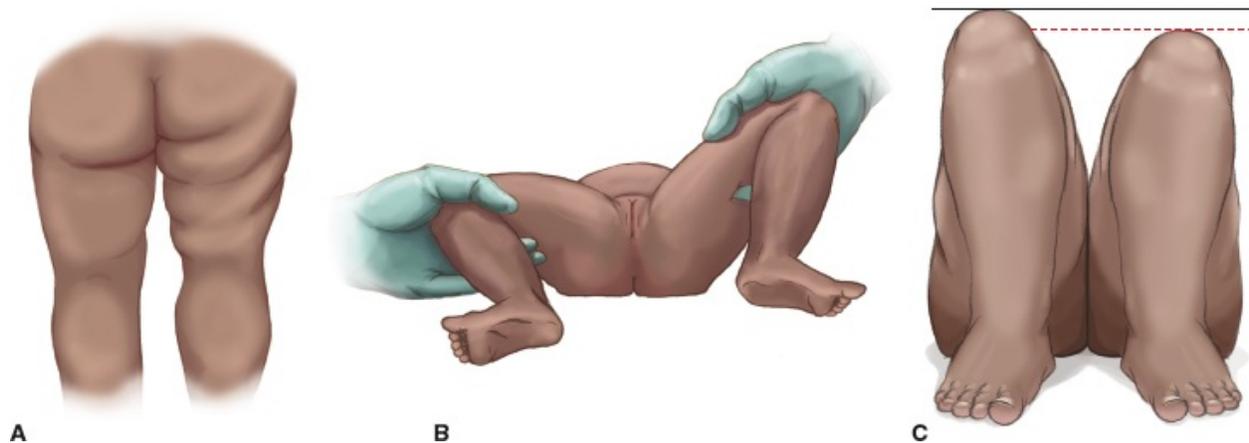
Inborn errors of metabolism are genetic disorders that disrupt normal metabolic function. Most are due to a defect in an enzyme or transport protein, resulting in a blocked metabolic pathway. Clinical symptoms are manifested secondary to toxic accumulations of substances before the block. When viewed individually, inborn errors of metabolism are rare, but collectively they are responsible for significant levels of infant mortality and morbidity. The incidence, collectively, is estimated to be approximately 1 in 4,000 live births (Weiner, 2015). Table 24.6 summarizes four common inborn errors.


FIGURE 24.21 Characteristics of developmental dysplasia of the hip. **A.** Asymmetric number of skin folds on the thigh or buttock. **B.** Limited hip abduction. **C.** Unequal knee height.

A successful outcome depends on early diagnosis and prompt intervention. Most inborn errors present in the newborn period with nonspecific and subtle manifestations—lethargy, hypotonia, respiratory distress, poor feeding and weight gain, vomiting, and seizures (Sutton, 2015). Identification of an inborn error of metabolism in a newborn depends largely on the awareness of the nurse and clues from the maternal history, laboratory work, and clinical examination.

TABLE 24.6 INBORN ERRORS OF METABOLISM

Condition	Incidence and Etiology	Clinical Picture	Management
Phenylketonuria (PKU)	1:10,000–15,000 live births Autosomal recessive genetic disorder caused by a deficiency of the hepatic enzyme phenylalanine hydroxylase Enzyme deficiency with subsequent accumulation of amino acid phenylalanine	Newborns appear normal at birth, but by 6 months of age signs of slow mental development are evident. Vomiting, poor feedings, failure to thrive, overactivity, irritability, musty-smelling urine If not treated, possible intellectual disability	Screening of all newborns at about 48 h after birth to ensure adequate intake of protein Dietary restriction of phenylalanine, with regular monitoring of serum phenylalanine levels (effective when started before the first month of age) Lifelong dietary restriction of phenylalanine
Maple syrup urine disease (MSUR)	1:86,000–185,000 live births; most prevalent among the Mennonite population in Lancaster, Pennsylvania Autosomal recessive inherited disorder Enzyme metabolism of certain amino acids is affected, with the buildup of acids causing ketoacidosis.	Lethargy, poor feeding, vomiting, weight loss, seizures, shrill cry, shallow respirations, loss of reflexes, coma, sweet maple syrup odor to urine	Dialysis to remove accumulated acids Lifelong low-protein diet to prevent neurologic deficits of disease
Galactosemia	1:60,000 live births Autosomal recessive inherited disorder in which an enzyme needed to convert galactose to glucose is missing and newborn cannot metabolize lactose	Vomiting, hypoglycemia, liver damage, hyperbilirubinemia, poor weight gain, cataracts, frequent infections	Routine newborn screening for galactosemia is performed in the majority of states. Lifelong lactose-restricted diet is needed to prevent intellectual disability, liver disease, and cataracts.
Congenital hypothyroidism	1:4,000 live births Multiple causes—absent or underdeveloped thyroid gland or biochemical defects in thyroid hormone	Large protruding tongue, slow reflexes, distended abdomen, large, open posterior fontanel, constipation, hypothermia, poor feeding, hoarse cry, dry skin, coarse hair, goiter, and jaundice If untreated, irreversible cognitive and motor impairment occurs. Decreased levels of thyroid hormone (T_4) and elevated levels of TSH	Newborn screening program in all states Lifelong thyroid replacement hormone therapy and continued monitoring of thyroid levels and clinical response to therapy

KEY CONCEPTS

- Asphyxia, the most common clinical insult in the perinatal period, results in brain injury and may lead to intellectual disability, cerebral palsy, or seizures.

- Transient tachypnea of the newborn occurs when the liquid in the lung is removed slowly or incompletely.

- Common risk factors for respiratory distress syndrome (RDS) include young gestational age, perinatal asphyxia regardless of gestational age, cesarean birth in the absence of labor (related to the lack of thoracic squeeze), male gender, and maternal diabetes.

- Meconium aspiration has three major pulmonary effects: airway obstruction, surfactant dysfunction, and chemical pneumonitis.

- The management of persistent pulmonary hypertension of the newborn requires meticulous attention

- to detail, with continuous monitoring of oxygenation, blood pressure, and perfusion.

- Retinopathy of prematurity (ROP) is a developmental abnormality that affects the immature vasculature of the retina; abnormal growth of blood vessels (neovascularization) takes place within the retina and vitreous.

- Periventricular–intraventricular hemorrhage is bleeding that usually originates in the subependymal germinal matrix region of the brain with extension into the ventricular system.

- Necrotizing enterocolitis (NEC) is a serious gastrointestinal disease of unknown etiology in newborns that can result in necrosis of a segment of the bowel.

- Infants of mothers with diabetes are at risk for malformations most frequently involving the cardiovascular, skeletal, central nervous, gastrointestinal, and genitourinary systems; cardiac anomalies are the most common.

- Factors that place the newborn at risk for birth trauma include cephalopelvic disproportion, maternal pelvic anomalies, oligohydramnios, prolonged or rapid labor, abnormal presentation, fetal prematurity, fetal macrosomia, and fetal abnormalities.

- Women who use drugs during their pregnancy expose their unborn child to the possibility of intrauterine growth restriction, prematurity, neurobehavioral and neurophysiologic dysfunction, birth defects, infections, and long-term developmental sequelae.

- Newborns of women who use tobacco, illicit substances, caffeine, and alcohol can exhibit withdrawal behavior.

- Physiologic jaundice is a common, normal newborn phenomenon that appears during the second or third day of life and then declines over the first week after birth. Pathologic jaundice is manifested within the first 24 hours of life when total bilirubin levels increase by more than 5 mg/dL/day and the total serum bilirubin level is higher than 17 mg/dL in a full-term infant.

- Newborn infections are usually classified according to the time of onset and grouped into three categories: congenital infection, acquired in utero by vertical transmission with onset before birth; early-onset neonatal infections, acquired by vertical transmission in the perinatal period, either shortly before or during birth; and late-onset neonatal infections, acquired by horizontal transmission in the nursery.

- Congenital conditions can arise from many etiologies, including single-gene disorders, chromosomal aberrations, exposure to teratogens, and many sporadic conditions of unknown cause. Congenital structural anomalies may be inherited or sporadic, isolated or multiple, apparent or hidden, and gross or microscopic.

- Congenital heart disease is commonly classified physiologically as defects that result in increased pulmonary blood flow, defects that result in decreased pulmonary blood flow, defects that cause obstruction to blood flow out of the heart, and defects that are mixed.

- A worldwide decline in neural tube defects has occurred during the past few decades due to improved prevention secondary to preconception folic acid supplementation, maternal serum alpha-fetoprotein monitoring, and use of ultrasonography and amniocentesis.

- Congenital respiratory tract structural disorders include choanal atresia and congenital diaphragmatic hernia. Evidence of bowel sounds in the chest suggests congenital diaphragmatic hernia.

- Cleft lip with cleft palate is the most common craniofacial birth defect. The newborn has immediate feeding difficulties and may have problems with dentition, language acquisition, and hearing.

- Esophageal atresia refers to a congenitally interrupted esophagus where the proximal and distal ends do not communicate; the upper esophageal segment ends in a blind pouch and the lower segment ends a variable distance above the diaphragm. Tracheoesophageal fistula is an abnormal communication between the trachea and esophagus.

- Omphalocele and gastroschisis are congenital anomalies of the anterior abdominal wall. An omphalocele is a defect of the umbilical ring that allows evisceration of abdominal contents into an external peritoneal sac. Gastroschisis is a herniation of abdominal contents through an abdominal wall defect, usually to the left or right of the umbilicus.
- Hypospadias and epispadias are genitourinary system structural anomalies. Epispadias often occurs in conjunction with bladder exstrophy, where the bladder protrudes onto the abdominal wall.
- Congenital clubfoot usually involves inversion and adduction of the forefoot, inversion of the heel and hindfoot, limitation of extension of the ankle and subtalar joint, and internal rotation of the leg.
- Developmental dysplasia of the hip includes dislocation, subluxation, or malformation of the acetabulum. Early recognition and prompt treatment are crucial.
- Inborn errors of metabolism are genetic disorders that disrupt normal metabolic function. Most are due to a defect in an enzyme or transport protein, resulting in a blocked metabolic pathway.

CHAPTER WORKSHEET

MULTIPLE CHOICE QUESTIONS

1. Which finding would lead the nurse to suspect that a newborn is experiencing respiratory distress syndrome?

   a. Abdominal distention

   b. Acrocyanosis

   c. Depressed fontanels

   d. Nasal flaring

2. When assessing the substance-exposed newborn, which finding would the nurse expect?

    a. Calm facial appearance

    b. Daily weight gain

    c. Increasing irritability

    d. Feeding and sleeping well

3. A newborn with tracheoesophageal fistula is likely to present with which assessment finding?

    a. Subnormal temperature

    b. Absent Moro reflex

    c. Inability to swallow

    d. Drooling from mouth

4. The nurse would be most alert for the development of transient tachypnea in a newborn who:

    a. Was born by cesarean birth

    b. Received no sedation

    c. Has a mother with heart disease

    d. Is small for gestational age

5. Which of the following would the nurse include in the teaching plan for an infant with cleft lip and palate?

    a. Feed the infant in a semi-lying position.

    b. Continue feeding the infant for as long as it takes.

    c. Burp the infant frequently during feedings.

    d. Avoid use of high-calorie formulas.

6. Which finding would the nurse expect to assess in an infant with developmental dysplasia of the hip?

    a. Symmetrical thigh folds

    b. Even knee height

    c. Full abduction of the hip

d. Audible clunk on hip abduction

7. A 30-week preterm male newborn is found to have tachypnea during the first few hours of life and oxygen administered via face mask at 100% doesn't improve his oxygen saturation level. Which of the following substances, if administered to the mother prenatally, could have prevented respiratory distress syndrome?

a. Insulin

b. Lecithin

c. Folic acid

d. Dexamethasone

8. A newborn suffering from respiratory distress syndrome is given supplemental oxygen. Which of the following is a possible consequence of oxygen therapy?

a. Cardiac anomalies

b. Blindness

c. Anosmia

d. Atelectasis

CRITICAL THINKING EXERCISES

1. As the nursery nurse, you receive a newborn from the labor and birth suite and place him under the radiant warmer. The nurse who reports states that the mother couldn't remember when her membranes broke before labor and that she ran a fever during labor for the past few hours. The Apgar scores were good, but the newborn seemed lethargic. As you begin your assessment, you note that he is pale and floppy and has a subnormal temperature; heart rate is 180 bpm and respiratory rate is 70 breaths per minute.

a. What in the mother's history should raise a red flag to the nurse?

b. What condition is this newborn at high risk for?

c. What interventions are appropriate for this condition?

2. Terry, a day-old baby girl, is very fretful, and calming measures do not seem to work. As the nursery nurse you notice that she is losing weight and her formula intake is poor, even though she is manifesting hungry behavior. The

mother received no prenatal care and denied drug use, but her drug screen was positive for heroin.

    a. What additional information do you need to obtain from the mother?

    b. What additional laboratory work might be needed for the infant?

    c. What specific measures need to be made for the infant's ongoing care?

3. A term newborn, was brought to the nursery. His mother received no prenatal care, but the newborn's Apgar scores were fine. As you carry out your newborn assessment, you note an imperforate anus and you palpate no testicles in the scrotal sac.

    a. What additional assessments should you complete?

    b. Are anorectal agenesis and genitourinary tract anomalies common?

    c. What diagnostic tests might be ordered? What might be included in the treatment plan for this newborn?

STUDY ACTIVITIES

1. Arrange for a tour of a regional NICU to see the nurse's role in caring for sick neonates. Ask the nurse to give a quick history of each newborn's condition. Was the nurse's role like you imagined? What was your impression of the NICU, and how would you describe it to expectant parents?

2. Visit and select a website from the list of resources that pertains to either an acquired or congenital newborn condition. What kind of information is given? How helpful would it be for parents with an infant diagnosed with a specific condition?

3. A herniation of a newborn's abdominal contents present at birth describes _____.

BRINGING IT ALL TOGETHER: CASE STUDY

A 4-day-old male infant born at 37 weeks to a 16-year-old G1P1 is brought to the well-baby clinic at the local health department. The young mother had an uneventful pregnancy and was induced with Pitocin for this birth. In the hospital, he was breast-fed every 3 hours, had adequate output, and had passed meconium. The newborn was discharged home on day 2 of life at which time his

weight was down 4% from his birth weight, a cephalohematoma was present on his head and he had mild facial jaundice. The mother's chief concern was that her infant looked like a "yellow canary" to her; he wasn't interested in breast-feeding and was increasingly fussy.

ASSESSMENT

Upon examination, the nurse takes a transcutaneous bilirubin level, which is 14 mg%. Vital signs were taken: T-37.8; P-162, R-54 and found to be in normal range. The newborn was markedly jaundiced, scleras of both eyes were icteric and newborn was irritable during the exam. The anterior fontanel was slightly sunken, the oral mucosa was tacky, and a resolving cephalohematoma was noted. At today's visit, there had been a 7% weight loss from birth and a history of "fair" urine output since discharge. Muscle tone and movement are normal.

Go to thePoint to find questions to consider about this case.

Appendix A
Standard Laboratory Values

PREGNANT AND NONPREGNANT WOMEN

Values	Nonpregnant	Pregnant
Hematologic		
Complete blood count (CBC)		
Hemoglobin, g/dL	12–16*	11.5–14*
Hematocrit, PCV, %	37–47	32–42
Red cell volume, mL	1,600	1,900
Plasma volume, mL	2,400	3,700
Red blood cell count, million/mm³	4–5.5	3.75–5.0
White blood cells, total per mm³	4,500–10,000	5,000–15,000
Polymorphonuclear cells, %	54–62	60–85
Lymphocytes, %	38–46	15–40
Erythrocyte sedimentation rate, mm/h	≤	30–90
MCHC, g/dL packed RBCs (mean corpuscular hemoglobin concentration)	30–36	No change
MCH (mean corpuscular hemoglobin per picogram)	29–32	No change
MCV/μm³ (mean corpuscular volume per cubic micrometer)	82–96	No change
Blood coagulation and fibrinolytic activity†		
Factors VII, VIII, IX, X		Increase in pregnancy, return to normal in early puerperium; factor VIII increases during and immediately after delivery
Factors XI, XIII		Decrease in pregnancy
Prothrombin time (protime), sec	60–70	Slight decrease in pregnancy
Partial thromboplastin time (PTT), sect	12–14	Slight decrease in pregnancy and again during second and third stages of labor (indicates clotting at placental site)
Bleeding time, min	1–3 (Duke) 2–4 (Ivy)	No appreciable change
Coagulation time, min	6–10 (Lee/White)	No appreciable change

Platelets	150,000–350,000/mm³	No significant change until 3–5 days after delivery, then marked increase (may predispose woman to thrombosis) and gradual return to normal
Fibrinolytic activity		Decreases in pregnancy, then abrupt return to normal (protection against thromboembolism)
Fibrinogen, mg/dL	250	400
Mineral and vitamin Concentrations		
Serum iron, mcg	75–150	65–120
Total iron-binding capacity, mcg	250–450	300–500
Iron saturation, %	30–40	15–30
Vitamin B_{12}, folic acid, ascorbic acid	Normal	Moderate decrease
Serum protein		
Total, g/dL	6.7–8.3	5.5–7.5
Albumin, g/dL	3.5–5.5	3.0–5.0
Globulin, total, g/dL	2.3–3.5	3.0–4.0
Blood sugar		
Fasting, mg/dL	70–80	65
2-hour postprandial, mg/dL	60–110	Under 140 after a 100-g carbohydrate meal is considered normal

Cardiovascular		
Blood pressure, mm Hg	120/80‡	114/65
Peripheral resistance, dyne/s · cm⁻⁵	120	100
Venous pressure, cm H_2O		
Femoral	9	24
Antecubital	8	8
Pulse, rate/min	70	80
Stroke volume, mL	65	75
Cardiac output, L/min	4.5	6
Circulation time (arm-tongue), sec	15–16	12–14
Blood volume, mL		
Whole blood	4,000	5,600
Plasma	2,400	3,700
Red blood cells	1,600	1,900
Plasma renin, units/L	3–10	10–80

Chest x-ray studies		
Transverse diameter of heart	–	1–2-cm increase
Left border of heart	–	Straightened
Cardiac volume	–	70-mL increase
Electrocardiogram	–	15-degree left axis deviation
V_1 and V_2	–	Inverted T-wave
kV_4	–	Low T
III	–	Q + inverted T
aVr	–	Small Q
Hepatic		
Bilirubin total	Not more than 1 mg/dL	Unchanged
Cephalin flocculation	Up to 2+ in 48 hr	Positive in 10%
Serum cholesterol, mg/dL	110–300	↑ 60% from 16–32 wks of pregnancy; remains at this level until after delivery
Thymol turbidity	0–4 units	Positive in 15%
Serum alkaline phosphatase	2–4.5 units (Bodansky)	↑ from week 12 of pregnancy to 6 wks after childbirth
Serum lactate dehydrogenase		Unchanged
Serum glutamic-oxaloacetic transaminase		Unchanged

Serum globulin albumin, g/dL	1.5–3.0	↑ slight
	4.5–5.3	↓ 3.0 g by late pregnancy
A/G ratio		Decreased
α_2-globulin		Increased
β-globulin		Increased
Serum cholinesterase		Decreased
Leucine aminopeptidase		Increased
Sulfobromophthalein (5 mg/kg)	5% dye or less in 45 min	Somewhat decreased
Renal		
Bladder capacity, mL	1,300	1,500
Renal plasma flow (RPF), mL/min	490–700	Increase by 25%, to 612–875
Glomerular filtration rate (GFR), mL/min	105–132	Increase by 50%, to 160–198
Nonprotein nitrogen (NPN), mg/dL	25–40	Decreases
Blood urea nitrogen (BUN), mg/dL	20–25	Decreases

Serum creatinine, mg/kg/24 hr	20–22	Decreases
Serum uric acid, mg/kg/24 hr	257–750	Decreases
Urine glucose	Negative	Present in 20% of gravidas
Intravenous pyelogram (IVP)	Normal	Slight to moderate hydroureter and hydronephrosis; right kidney larger than left kidney
Miscellaneous		
Total thyroxine concentration	5–12 mcg/dL thyroxine	↑ 9–16 mcg/dL thyroxine (however, unbound thyroxine not greatly increased)
Ionized calcium		Relatively unchanged
Aldosterone		↑ 1 mg/24 hr by third trimester
Dehydroisoandrosterone	Plasma clearance 6–8 L/24 hr	↑ plasma clearance 10-fold to 20-fold

(2015). *Davis's comprehensive handbook of laboratory & diagnostic tests with nursing implications.* (6th ed.), Philadelphia, PA: F. A. Davis.

*At sea level. Permanent residents of higher levels (e.g., Denver) require higher levels of hemoglobin.
†Pregnancy represents a hypercoagulable state.
‡For the woman about 20 years of age.
10 years of age: 103/70.
30 years of age: 123/82.
40 years of age: 126/84.

Appendix B
Clinical Paths

LABOR AND DELIVERY CLINICAL PATH—LABOR: EXPECTED OUTCOMES

	Active Phase	Expulsion/Pushing	Recovery First Hour Postpartum
CLIENT	Client coping with labor support Client utilizing appropriate labor options Client verbalizes satisfaction with plan Management interventions	Client demonstrates effective pushing technique Client coping effectively with pushing Support person coping effectively with labor	Bonding appropriately with baby
CLIENT'S STATUS	Cervix dilated 5 cm—complete Contraction regularly with progressive cervical change Maternal/fetal well-being maintained Hydration maintained If indicated: FSE and/or IUPC placed Pitocin IV started Epidural placed/WE encouraged Medicate with PRN pain meds	Vaginal birth	Placenta delivered Fundus firm Lochia small–moderate Without clots Perineum intact/repaired Hemodynamically stable EBL <500 mL

CONTINUUM OF CARE	Prenatal record available after 32 wks Prenatal labs WNL Preregistered to hospital Pediatrician identified Support after hospitalization identified Discharge plan discussed with client/family Communicates understanding of hospital and community resources		
ASSESSMENT/ TREATMENT	Assess: Continuous EFM or auscultation Q 15 of 30 min as indicated Vital signs hourly/temp Q4 hr if intact membranes/Q 2 hr if membranes ruptured Uterine by monitor or palpation Bladder for distention Hydration status Cervical dilation, effacement, station	Assess: Q 15 min monitoring of fetal well-being (low risk) and Q 5 min (high risk) Vital signs hourly/temp. Q 2–4 hr depending on membrane status Bladder for distention Hydration status Pushing effectiveness Descent of presenting part Caput	Assess: Uterus–fundus Vital signs Lochia Bladder Perineum Placenta
CLIENT EDUCATION	Reinforce comfort measures Encourage use of labor options Inform client/support person of plan of care	Teaching of upright pushing positions Discourage prolonged maternal breath holding Encourage to assume position of choice Inform client of progress	Baby status Breast-feeding

TESTS/ PROCEDURES	Hgb or Hct (if not done recently) T & S (if ordered) VE as indicated IV therapy AROM by MD or CNM: assess for color, amount, and odor, as appropriate FSE/IUPC placement if indicated	AROM: assess for color, amount, and odor, as appropriate	Cord blood or RhoGAM workup if appropriate Cord blood if O+ mother
THERAPIES	Comfort measures/birthing ball/ ambulate/telemetry/shower IV therapy Amnio infusion for variable decelerations If appropriate, pain management reviewed	Perineal massage Warm soaks to perineal area Allow to rest until feels the urge to push Frequent position changes Cool cloth/ice chips	Ice pack to perineum Warm blankets
MEDS	Antibiotics as indicated for + GBS Pitocin if indicated PRN pain medication (encourage WE if requesting this)	Pitocin if indicated	Pitocin IV
ACTIVITY/ SAFETY	Labor option usage Position changes	Provide wedge if supine Promote effective position for pushing: i.e., squatting, side lying, upright Breathing technique client/ support person most comfortable with	Assist with ambulate to bathroom Infant care Assist with positioning for breast-feeding Infant ID bands present
NUTRI- TION	Clear liquids Ice chips Others	Clear liquids Ice chips	Return to previous diet
UNIQUE CLIENT NEEDS			

INTEGRATED PLAN OF CARE FOR CESAREAN DELIVERY

	Expected Client Outcomes			
	Phase 1 Preadmission (Cesarean Delivery)	Phase 2 Surgery/ Immediate Postop/ Day of Surgery	Phase 3 Postop Day 1	
Usual time in phase assessment/ potential complications	**N/A Date Started:** VS WNL for client Hgb or Hct/values within normal SLH antepartum range	Up to 23 hr VS WNL for client Systems assessment: Skin warm, dry Clear ⇒ Alert & oriented ⇒ Neg. Homans sign ⇒ Breast soft/nipples intact ⇒ Lungs clear ⇒ Bowel sounds present ⇒ Fundus firm u/u or u 1–2 (–/+) Lochia sm—mod Dsg dry and intact No signs infiltration IV site Verbalizes comfort using pain rating scale 0–10	1 day VS WNL for client Afebrile Voiding without Foley ⇒ Passing flatus Incision without redness or drainage Lochia small amount Fundus firm u/1–2 Verbalizes comfort using pain scale 0–10 on oral pain meds	1–2 days Incision well approximated, without drainage or redness Passing flatus Lochia sm/mod amt Fundus firm u/1–2 Verbalizes comfort using pain medication as described
Client/family knowledge	**Date All Above Met** Verbalizes understanding of condition and need for surgery Verbalizes understanding of all preop teaching	**Date All Above Met** Verbalizes correct use of PCA/fentanyl pump and when to request pain medication Turn, cough, and deep breathe appropriately	**Date All Above Met** Can state criteria for when to call doctor for problems postdischarge ⇒ ↑ Bleeding ↑ Temperature ⇒ Incision redness, odor or drainage ⇒	**Date All Above Met** Verbalizes follow-up appointment date and time Verbalizes proper dosing of pain medication
ADLs/activity	**Date All Above Met** Verbalizes understanding of NPO status	**Date All Above Met** Able to ambulate with minimal assistance Tolerating clear/full liquid diet Bonding observed with newborn—taking-in phase ⇒	**Date All Above Met** Ambulating without assistance Tolerating soft to regular diet	**Date All Above Met** Ambulating in hall

Appendix E
Breast-Feeding and Medication Use

GENERAL CONSIDERATIONS

• Most medications are safe to use while breast-feeding; however, the woman should always check with the pediatrician, physician, or lactation specialist before taking any medications, including over-the-counter and herbal products.

• Inform the woman that she has the right to seek a second opinion if the physician does not perform a thoughtful risk-versus-benefit assessment before prescribing medications or advising against breast-feeding.

• Most medications pass from the woman's bloodstream into the breast milk. However, the amount is usually very small and unlikely to harm the baby.

• A preterm or other special needs neonate is more susceptible to the adverse effects of medications in breast milk. A woman who is taking medications and whose baby is in the neonatal intensive care unit or special care nursery should consult with the pediatrician or neonatologist before feeding her breast milk to the baby.

• If the woman is taking a prescribed medication, she should take the medication just after breast-feeding. This practice helps ensure that the lowest possible dose of medication reaches the baby through the breast milk.

• Some medications can cause changes in the amount of milk the woman produces. Teach the woman to report any changes in milk production.

LACTATION RISK CATEGORIES (LRC)

Lactation Category	Risk	Rationale
L1	Compatible	Clinical research or long-term observation of use in many breast-feeding women has not demonstrated risk to the infant.
L2	Probably compatible	Limited clinical research has not demonstrated an increase in adverse effects in the infant.
L3	Probably compatible	There is possible risk to the infant; however, the risks are minimal or nonthreatening in nature. These medications should be given only when the potential benefit outweighs the risk to the infant.
L4	Possibly hazardous	There is positive evidence of risk to the infant; however, in life-threatening situations or for serious diseases, the benefit might outweigh the risk.
L5	No data: Hazardous	The risk of using the medication clearly outweighs any possible benefit from breast-feeding.

POTENTIAL EFFECTS OF SELECTED MEDICATION CATEGORIES ON THE BREAST-FED INFANT

Narcotic Analgesics

• Codeine and hydrocodone appear to be safe in moderate doses. Rarely the neonate may experience sedation and/or apnea. (LRC: L3)

• Meperidine (Demerol) can lead to sedation of the neonate. (LRC: L3)

• Low to moderate doses of morphine appear to be safe. (LRC: L2)

• Trace-to-negligible amounts of fentanyl are found in human milk. (LRC: L2)

Nonnarcotic Analgesics and NSAIDs

• Acetaminophen and ibuprofen are approved for use. (LRC: L1)

• Naproxen may cause neonatal hemorrhage and anemia if used for prolonged periods. (LRC: L3 for short-term use and L4 for long-term use)

• The newer COX2 inhibitors, such as celecoxib (Celebrex), appear to be safe for use. (LRC: L2)

Antibiotics

• Levels in breast milk are usually very low.

• The penicillins and cephalosporins are generally considered safe to use. (LRC: L1 and L2)

• Tetracyclines can be safely used for short periods but are not suitable for long-term therapy (e.g., for treatment of acne). (LRC: L2)

• Sulfonamides should not be used during the neonatal stage (the first month of life). (LRC: L3)

Antihypertensives

• A high degree of caution is advised when antihypertensives are used during

breast-feeding.

- Some beta blockers can be used.

- Hydralazine and methyldopa are considered to be safe. (LRC: L2)

- Angiotensin-converting enzyme (ACE) inhibitors are not recommended in the early postpartum period.

Sedatives and Hypnotics

- Neonatal withdrawal can occur when antianxiety medications, such as lorazepam, are taken. Fortunately withdrawal is generally mild.

- Phenothiazines, such as Phenergan and Thorazine, may lead to sleep apnea and increase the risk for sudden infant death syndrome.

Antidepressants

- The risk to the baby is often higher if the woman is depressed and remains untreated, rather than taking the medication.

- The older tricyclics are considered to be safe; however they cause many bothersome side effects, such as weight gain and dry mouth, which may lead to noncompliance on the part of the woman.

- The selective serotonin uptake inhibitors (SSRIs) are also considered to be safe and have a lower side effect profile, which makes them more palatable to the woman. (LRC: L2 and L3)

Mood Stabilizers (Antimanic Medication)

- Lithium is found in breast milk and is best not used in the breast-feeding woman. (LRC: L4)

- Valproic acid (Depakote) seems to be a more appropriate choice for the woman with bipolar disorder. The infant will need periodic lab studies to check platelets and liver function.

Corticosteroids

- Corticosteroids do not pass into the milk in large quantities.

- Inhaled steroids are safe to use because they do not accumulate in the

bloodstream.

Thyroid Medication

- Thyroid medications, such as levothyroxine (Synthroid), can be taken while breast-feeding.
- Most are in LRC category L1.

MEDICATIONS THAT USUALLY ARE CONTRAINDICATED FOR THE BREAST-FEEDING WOMAN

• Amiodarone

• Antineoplastic agents

• Chloramphenicol

• Doxepin

• Ergotamine and other ergot derivatives

• Iodides

• Methotrexate and immunosuppressants

• Lithium

• Radiopharmaceuticals

• Ribavirin

• Tetracycline (prolonged use—more than 3 weeks)

• Pseudoephedrine (found in many over-the-counter medications)
