Continuous internal monitoring is usually indicated for women or fetuses considered to be at high risk. Possible conditions might include multiple gestation, decreased fetal movement, abnormal FHR on auscultation, IUGR, maternal fever, preeclampsia, dysfunctional labor, preterm birth, or medical conditions such as diabetes or hypertension. It involves the placement of a spiral electrode into the fetal presenting part, usually the head, to assess FHR, and a pressure transducer placed internally within the uterus to record uterine contractions (Fig. 14.6). The fetal spiral electrode is considered the most accurate method of detecting fetal heart characteristics and patterns because it involves receiving a signal directly from the fetus (Chez, & Baird, 2011). Trained labor and birth nurses can place the spiral electrode on the fetal head when the membranes rupture in some health care facilities, but they do not place the intrauterine pressure catheter in the uterus. Internal monitoring does not have to include both an intrauterine pressure catheter and a scalp electrode. A fetal scalp electrode can be used to monitor the fetal heartbeat without monitoring the maternal intrauterine pressure.

**FIGURE 14.6** Continuous internal electronic fetal monitoring.

Both the FHR and the duration and interval of uterine contractions are recorded on the graph paper. This method permits evaluation of baseline heart rate and changes in rate and pattern.

Four specific criteria must be met for this type of monitoring to be used:

- Ruptured membranes
- Cervical dilation of at least 2 cm
- Presenting fetal part low enough to allow placement of the scalp electrode
- Skilled practitioner available to insert spiral electrode (ICSI, 2011)

Compared to external monitoring, continuous internal monitoring can accurately detect both short-term (moment-to-moment) changes and variability (fluctuations within the baseline) and FHR dysrhythmias. In addition, maternal position changes and movement do not interfere with the quality of the tracing.

### Determining FHR Patterns

Assessment parameters of the FHR include baseline fetal heart rate and variability, presence of accelerations, periodic or episodic decelerations, and changes or trends of fetal heart rate patterns over time. The nurse must be able to interpret the various parameters to determine if the fetal heart rate pattern is a *category I*, which is strongly predictive of normal fetal acid–base status at the time of observation and needs no intervention; a *category II*, which is not predictive of abnormal fetal acid–base status and but does require evaluation and continued monitoring; or a *category III*, which is predictive of abnormal fetal acid–base status at the time of observation

TABLE 14.1 INTERPRETING FHR PATTERNS	
Category I: normal	<p><i>Predictive of normal fetal acid–base status</i></p> <ul style="list-style-type: none"> <li>• Baseline rate (110–160 bpm)</li> <li>• Baseline variability moderate</li> <li>• Present or absent accelerations</li> <li>• Present or absent early decelerations</li> <li>• No late or variable decelerations</li> </ul>
Category II: indeterminate	<p><i>Not predictive of abnormal fetal acid–base status:</i></p> <ul style="list-style-type: none"> <li>• Fetal tachycardia (&gt;160 bpm) present</li> <li>• Bradycardia (&lt;110 bpm) not accompanied by absent baseline variability</li> <li>• Absent baseline variability not accompanied by recurrent decelerations</li> <li>• Minimal or marked variability</li> <li>• Recurrent late decelerations with moderate baseline variability</li> <li>• Recurrent variable decelerations accompanied by minimal or moderate baseline variability; overshoots, or shoulders</li> <li>• Prolonged decelerations &gt;2 min but &lt;10 min</li> </ul>
Category III: abnormal	<p><i>Predictive of abnormal fetus acid–base status</i></p> <ul style="list-style-type: none"> <li>• Fetal bradycardia (&lt;110 bpm)</li> <li>• Recurrent late decelerations</li> <li>• Recurrent variable decelerations</li> <li>• Sinusoidal pattern (smooth, undulating baseline)</li> </ul>

and requires prompt evaluation and interventions such as giving maternal oxygen, changing maternal position, discontinuing labor augmentation medication, and/or treating maternal hypotension (Gilbert, 2011). Table 14.1 summarizes these categories.

#### BASELINE FHR

**Baseline fetal heart rate** refers to the average FHR that occurs during a 10-minute segment that excludes periodic or episodic rate changes, such as tachycardia or bradycardia. It is assessed when the woman has no

contractions and the fetus is not experiencing episodic FHR changes. The normal baseline FHR ranges between 110 and 160 beats per minute (bpm) (National Institute of Child Health and Human Development [NICHD], 2011). The normal baseline FHR can be obtained by auscultation, ultrasound, or Doppler, or by a continuous internal direct fetal electrode.

Fetal bradycardia occurs when the FHR is below 110 bpm and lasts 10 minutes or longer (Mattson, & Smith, 2011). It can be the initial response of a healthy fetus to asphyxia. Causes of fetal bradycardia might include fetal hypoxia, prolonged maternal hypoglycemia, fetal acidosis, administration of analgesic drugs to the mother, hypothermia, anesthetic agents (epidural), maternal hypotension, fetal hypothermia, prolonged umbilical cord compression, and fetal congenital heart block (Gilbert, 2011). Bradycardia may be benign if it is an isolated event, but it is considered an ominous sign when accompanied by a decrease in baseline variability and late decelerations.

Fetal tachycardia is a baseline FHR greater than 160 bpm that lasts for 10 minutes or longer (NICHD, 2011). It can represent an early compensatory response to asphyxia. Other causes of fetal tachycardia include fetal hypoxia, maternal fever, maternal dehydration, amnionitis, drugs (e.g., cocaine, amphetamines, nicotine), maternal hyperthyroidism, maternal anxiety, fetal anemia, prematurity, fetal infection, chronic hypoxemia, congenital anomalies, fetal heart failure, and fetal arrhythmias. Fetal tachycardia is considered an ominous sign if it is accompanied by a decrease in variability and late decelerations (Miller et al., 2011).

## BASELINE VARIABILITY

**Baseline variability** is defined as irregular fluctuations in the baseline fetal heart rate, which is measured as the amplitude of the peak to trough in bpm (Doret et al., 2011). It represents the interplay between the parasympathetic and sympathetic nervous systems. The constant interplay (push-and-pull effect) on the FHR from the parasympathetic and sympathetic systems produces a

moment-to-moment change in the FHR. Because variability is in essence the combined result of autonomic nervous system branch function, its presence implies that the both branches are working and receiving adequate oxygen (Chez, & Baird, 2011). Thus, variability is one of the most important characteristics of the FHR. Variability is described in four categories as follows:

- *Absent*: fluctuation range undetectable
- *Minimal*: fluctuation range observed at <5 bpm
- *Moderate (normal)*: fluctuation range from 6 to 25 bpm
- *Marked*: fluctuation range >25 bpm

Absent or minimal variability typically is caused by fetal acidemia secondary to uteroplacental insufficiency, cord compression, a preterm fetus, maternal hypotension, uterine hyperstimulation, abruptio placenta, or a fetal dysrhythmia. Interventions to improve uteroplacental blood flow and perfusion through the umbilical cord include lateral positioning of the mother, increasing the IV fluid rate to improve maternal circulation, administering oxygen at 8 to 10 L/min by mask, considering internal fetal monitoring, documenting findings, and reporting to the health care provider. Preparation for a surgical birth may be necessary if no changes occur after attempting the interventions.

Moderate variability indicates that the autonomic and central nervous systems of the fetus are well developed and well oxygenated. It is considered a good sign of fetal well-being and correlates with the absence of significant metabolic acidosis (Fig. 14.7).

Marked variability occurs when there are more than 25 beats of fluctuation in the FHR baseline. Causes of this include cord prolapse or compression, maternal hypotension, uterine hyperstimulation, and abruptio placenta. Interventions include determining the cause if possible, lateral positioning, increasing IV fluid rate, administering oxygen at 8 to 10 L/min by mask, discontinuing oxytocin infusion, observing for changes in tracing, considering internal fetal monitoring, communicating an abnormal pattern to the health care provider, and preparing for a surgical birth if no change in pattern is noted (Freeman, Garite, Nageotte, & Miller, 2012).

FIGURE 14.7 Long-term variability (average or moderate).

FHR variability is an important clinical indicator that is predictive of fetal acid–base balance and cerebral tissue perfusion. It is influenced by fetal oxygenation status, cardiac output, and drug effects (Mattson, & Smith, 2011). As the central nervous system is desensitized by hypoxia and acidosis, FHR decreases until a smooth baseline pattern appears. Loss of variability may be associated with a poor outcome.

**Take Note!**

External electronic fetal monitoring cannot assess variability accurately. Therefore, if external monitoring shows a baseline that is smoothing out, use of an internal spiral electrode should be considered to gain a more accurate picture of the fetal health status.

**PERIODIC BASELINE CHANGES**

**Periodic baseline changes** are temporary, recurrent changes made in response to a stimulus such as a contraction. The FHR can demonstrate patterns of acceleration or deceleration in response to most stimuli. Fetal **accelerations** are transitory abrupt increases in the FHR above the baseline that last <30 seconds from onset to peak. They are associated with sympathetic nervous stimulation. They are visually apparent, with elevations of FHR of more than 15 bpm above the baseline, and their duration is >15 seconds, but less than 2 minutes

(NICHD, 2011). They are generally considered reassuring and require no interventions. Accelerations denote fetal movement and fetal well-being and are the basis for nonstress testing.

A **deceleration** is a transient fall in FHR caused by stimulation of the parasympathetic nervous system. Decelerations are described by their shape and association to a uterine contraction. They are classified as early, late and variable only (Fig. 14.8).

*Early decelerations* are visually apparent, usually symmetrical, and characterized by a gradual decrease in the FHR in which the nadir (lowest point) occurs at the peak of the contraction. They rarely decrease more than 30 to 40 bpm below the baseline. Typically, the onset, nadir, and recovery of the deceleration occur at the same time as the onset, peak, and recovery of the contraction. They are most often seen during the active stage of any normal labor, during pushing, crowning, or vacuum extraction. They are thought to be a result of fetal head compression that results in a reflex vagal response with a resultant slowing of the FHR during uterine contractions. Early decelerations are not indicative of fetal distress and do not require intervention.

*Late decelerations* are visually apparent, usually symmetrical, transitory decreases in FHR that occur after the peak of the contraction. The FHR does not return to baseline levels until well after the contraction has ended.

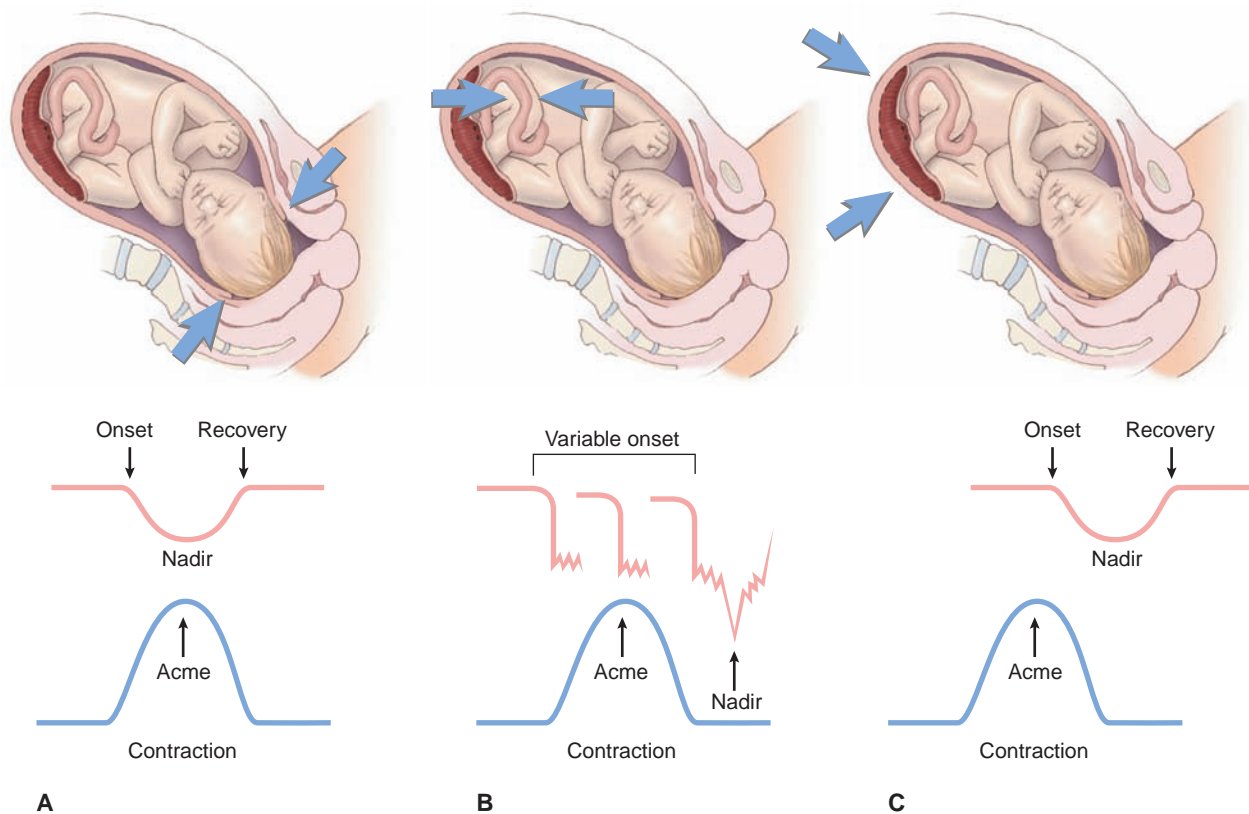

FIGURE 14.8 Decelerations. (A) Early. (B) Variable. (C) Late.

Delayed timing of the deceleration occurs, with the nadir of the uterine contraction. Late decelerations are associated with uteroplacental insufficiency, which occurs when blood flow within the intervillous space is decreased to the extent that fetal hypoxia or myocardial depression exists (Buonocore, Bracci & Weidling, 2012). Conditions that may decrease uteroplacental perfusion with resultant decelerations include maternal hypotension, gestational hypertension, placental aging secondary to diabetes and postmaturity, hyperstimulation via oxytocin infusion, maternal smoking, anemia, and cardiac disease. They imply some degree of fetal hypoxia. Recurrent or intermittent late decelerations are always category II (indeterminate) or category III (abnormal) regardless of depth of deceleration. Acute episodes with moderate variability are more likely to be correctable, whereas chronic episodes with loss of variability are less likely to be correctable (Gilbert, 2011). Box 14.1 highlights interventions for category III decelerations rather than what it says now.

#### BOX 14.1

#### INTERVENTIONS FOR CATEGORY III PATTERNS

- Notify the health care provider about the pattern and obtain further orders, making sure to document all interventions and their effects on the FHR pattern.
- Reduce or discontinue oxytocin or other uterotonic agent as dictated by the facility's protocol, if it is being administered.
- Turn the client on her left or right lateral, knee-chest, or hands and knees to increase placental perfusion or relieve cord compression.
- Administer oxygen via nonrebreather face mask to increase fetal oxygenation.
- Increase the IV fluid rate to improve intravascular volume and correct maternal hypotension.
- Assess the client for any underlying contributing causes.
- Provide reassurance that interventions are to effect pattern change.
- Modify pushing in the second stage of labor to improve fetal oxygenation.
- Document any and all interventions and any changes in FHR patterns.
- Prepare for an expeditious surgical birth if the pattern is not corrected in 30 minutes.

Adapted from American College of Obstetricians and Gynecologists [ACOG]. (2010b). Management of intrapartum fetal heart rate tracings. Practice bulletin number 116. *Obstetrics & Gynecology*, 116, 1232–1240; King, T. L., & Parer, J. T. (2011). On electronic fetal heart rate monitoring. *Journal of Obstetric, Gynecologic & Neonatal Nursing*, 40(6), 669–671; and Stout, M., & Cahill, A. (2011). Electronic fetal monitoring: Past, present, and future. *Clinics in Perinatology*, 38(1), 127–142.

*Variable decelerations* present as visually apparent abrupt decreases in FHR below baseline and have an unpredictable shape on the FHR baseline, possibly demonstrating no consistent relationship to uterine contractions. The shape of variable decelerations may be U, V, or W, or they may not resemble other patterns (Freeman, Garite, Nageotte & Miller, 2012). Variable decelerations usually occur abruptly with quick deceleration. They are the most common deceleration pattern found in the laboring woman and are usually transient and correctable (Gardner, Carter, Enzman-Hines, & Hernandez, 2011). Variable decelerations are associated with cord compression. However, they are classified either as category II or III depending on the accompanying change in baseline variability (ICSI, 2011). The pattern of variable deceleration consistently related to the contractions with a slow return to FHR baseline warrants further monitoring and evaluation.

*Prolonged decelerations* are abrupt FHR declines of at least 15 bpm that last longer than 2 minutes, but less than 10 minutes (NICHD, 2011). The rate usually drops to less than 90 bpm. Many factors are associated with this pattern, including prolonged cord compression, abruptio placenta, cord prolapse, supine maternal position, vaginal examination, fetal blood sampling, maternal seizures, regional anesthesia, or uterine rupture (Gilbert, 2011). Prolonged decelerations can be remedied by identifying the underlying cause and correcting it.

A *sinusoidal pattern* is described as having a visually apparent smooth, sinewave-like undulating pattern in the FHR baseline with a cycle frequency of 3 to 5 bpm that persists for >20 minutes. It is attributed to a derangement of central nervous system (CNS) control of FHR and occurs when a severe degree of hypoxia secondary to fetal anemia and hypovolemia is present. It is always considered a category III pattern and to correct it, a fetal intrauterine transfusion would be needed (Buonocore, Bracci & Weidling, 2012).

Combinations of FHR patterns obtained by electronic fetal monitoring during labor are not infrequent. Category II and III patterns are more significant if they are mixed, persist for long periods, or have frequent prolonged late decelerations, absent or minimal variability, bradycardia or tachycardia, and prolonged variable decelerations lower than 60 bpm. The likelihood of fetal compromise is increased if category II and III patterns are associated with decreased baseline variability or abnormal contraction patterns (ICSI, 2011).

## Other Fetal Assessment Methods

In situations suggesting the possibility of fetal compromise, such as category II or Category III FHR patterns, further ancillary testing such as umbilical cord blood analysis and fetal scalp stimulation may be used to validate the FHR findings and assist in planning interventions.

### Take Note!

During the past decade, the use of fetal scalp sampling has decreased, being replaced by techniques that yield similar information.

## Umbilical Cord Blood Analysis

Neonatal and childhood mortality and morbidity, including cerebral palsy, are often attributed to fetal acidosis, as defined by a low cord pH at birth. Umbilical cord blood acid–base analysis drawn at birth provides an objective method of evaluating a newborn’s condition, identifying the presence of intrapartum hypoxia and acidemia. This test is considered the most reliable indication of fetal oxygenation and acid–base condition at birth (Mattson, & Smith, 2011). The normal mean pH value range is 7.2 to 7.3. The pH values are useful for planning interventions for the newborn born with low 5-minute Apgar scores, severe IUGR, category II and III patterns during labor, umbilical cord prolapse, uterine rupture, maternal fever, placental abruption, meconium-stained amniotic fluid, and post-term births (Yeh, Emary, & Imprey, 2012). The interventions needed for the compromised newborn might include providing an optimal extrauterine environment, fluids, oxygen, medications, and other treatments.

## Fetal Scalp Stimulation

An indirect method used to evaluate fetal oxygenation and acid–base balance to identify fetal hypoxia is fetal scalp stimulation and vibroacoustic stimulation. If the fetus does not have adequate oxygen reserves, carbon dioxide builds up, leading to acidemia and hypoxemia. These metabolic states are reflected in abnormal FHR patterns as well as fetal inactivity. Fetal stimulation is performed to promote fetal movement with the hope that FHR accelerations will accompany the movement.

Fetal movement can be stimulated with a vibroacoustic stimulator (artificial larynx) applied to the woman’s lower abdomen and turned on for a few seconds to produce sound and vibration or by placing a gloved finger on the fetal scalp and applying firm pressure. A well-oxygenated fetus will respond when stimulated (tactile or by noise) by moving in conjunction with an acceleration of 15 bpm above the baseline heart rate that lasts at least 15 seconds. This FHR acceleration reflects a pH of more than 7 and a fetus with an intact CNS. Fetal scalp stimulation is not done if the fetus is preterm, or if the woman has an intrauterine infection, a diagnosis of placenta previa (which could lead to hemorrhage), or a fever (which increases the risk of an ascending infection) (Gilbert, 2011). If no acceleratory response by the fetus is exhibited with either scalp stimulation or vibroacoustic stimulation, further evaluation of the fetus is warranted.

## PROMOTING COMFORT AND PROVIDING PAIN MANAGEMENT DURING LABOR

Pain during labor is a universal experience, although the intensity of the pain may vary. Although labor and child-birth are viewed as natural processes, both can produce significant pain and discomfort. The physical causes of pain during labor include cervical stretching, hypoxia of the uterine muscle due to a decrease in perfusion during contractions, pressure on the urethra, bladder, and rectum, and distention of the muscles of the pelvic floor (Leonard, 2012). A woman’s pain perception can be influenced by her previous experiences with pain, fatigue, pain anticipation, genetics, positive or negative support system, labor and birth environment, cultural expectations, and level of emotional stress and anxiety (Nur Rachmawati, 2012).

The techniques used to manage the pain of labor vary according to geography and culture. For example, some Appalachian women believe that placing a hatchet or knife under the bed of a laboring woman may help “cut the pain of childbirth,” and a woman from this background may wish to do so in the hospital setting (Bowers, 2012). Asian, Latino, and Orthodox Jewish women may request that their own mothers, not their husbands, attend their births; husbands do not actively participate in the birthing process. Cherokee, Hmong, and Japanese women will often remain quiet during labor and birth and not complain of pain because outwardly expressing pain is not appropriate in their cultures. Never interpret their quietness as freedom from pain (Bowers, 2012).

Culturally diverse childbearing families present to the labor and birth suites with the same needs and desires of all families. Give them the same respect and sense of welcome shown to all families. Make sure they have a high-quality birth experience: uphold their religious, ethnic, and cultural values and integrate them into care.

Today, women have many safe nonpharmacologic and pharmacologic choices for the management of pain during labor and birth, which may be used separately or in combination with one another.

Nurses are in an ideal position to provide childbearing women with balanced, clear, concise information about effective nonpharmacologic and pharmacologic measures to relieve pain. Pain management standards issued by the Joint Commission mandate that pain be assessed in all clients admitted to a health care facility (Ismail, Shahzad, & Shafiq, 2012). Thus, it is important for nurses to be knowledgeable about the most recent scientific research on labor pain relief modalities, to make sure that accurate and unbiased information about effective pain relief measures is available to laboring women, to be sure that the woman determines what is an acceptable labor pain level for her, and to allow the woman the choice of pain relief method.

## Nonpharmacologic Measures

Nonpharmacologic measures may include continuous labor support, hydrotherapy, ambulation and position changes, acupuncture and acupressure, attention focusing and imagery, therapeutic touch and massage, breathing techniques, and effleurage. Most of these methods are based on the “gate control” theory of pain, which proposes that local physical stimulation can interfere with pain stimuli by closing a hypothetical gate in the spinal cord, thus blocking pain signals from reaching the brain (Westbrook, & D’Arcy, 2012). It has long been a standard of care for labor nurses to first provide or encourage a variety of nonpharmacologic measures before moving to the pharmacologic interventions.

Nonpharmacologic measures are usually simple, safe, and inexpensive to use. Many of these measures are taught in childbirth classes, and women should be encouraged to try a variety of methods prior to the real labor. Many of the measures need to be practiced for best results and coordinated with the partner/coach. The nurse provides support and encouragement for the woman and her partner using nonpharmacologic methods. Although women can’t consciously direct the labor contractions, they can control how they respond to them, thereby enhancing their feelings of control. See Evidence-Based Practice 14.1 for more information.

## Continuous Labor Support

Continuous labor support involves offering a sustained presence to the laboring woman by providing emotional

support, comfort measures, advocacy, information and advice, and support for the partner (Mallory, 2010). A woman’s family, a midwife, a nurse, a doula, or anyone else close to the woman can provide this continuous presence. A support person can assist the woman to ambulate, reposition herself, and use breathing techniques. A support person can also aid with the use of acupressure, massage, music therapy, or therapeutic touch. During the natural course of childbirth, a laboring woman’s functional ability is limited secondary to pain, and she often has trouble making decisions. The support person can help make them based on his or her knowledge of the woman’s birth plan and personal wishes.

Research has validated the value of continuous labor support versus intermittent support in terms of fewer operative deliveries, cesarean births, and requests for pain medication (AWHONN, 2011).

### Take Note!

The human presence is of immeasurable value to make the laboring woman feel secure.

## Hydrotherapy

Hydrotherapy is a nonpharmacologic measure that may involve showering or soaking in a regular tub or whirlpool bath. When showering is the selected method of hydrotherapy, the woman stands or sits in a shower chair in a warm shower and allows the water to gently glide over her abdomen and back. If a tub or whirlpool is

### EVIDENCE-BASED PRACTICE 14.1

#### THE EFFECTS OF COMPLEMENTARY AND ALTERNATIVE THERAPIES FOR PAIN MANAGEMENT IN LABOR ON MATERNAL AND PERINATAL MORBIDITY

##### STUDY

The pain of labor can be intense, with tension, anxiety, and fear making it worse. Many women would like to labor without using drugs and turn to alternatives to manage pain. These alternative methods include acupuncture, mind–body techniques, massage, reflexology, herbal medicines or homoeopathy, hypnosis, and music. This review examined currently available evidence supporting the use of alternative and complementary therapies for pain management in labor. Fourteen trials were included in the review, with data reporting on 1,537 women using different modalities of pain management; 1,448 women were included in the meta-analysis.

##### Findings

Acupuncture and hypnosis may help relieve labor pain. There is insufficient evidence about the benefits of music, massage, relaxation, white noise, acupressure, and

aromatherapy, and no evidence about the effectiveness of massage or other complementary therapies. In summary, acupuncture and hypnosis may be beneficial for the management of pain during labor; however, the number of women studied has been small. Few other complementary therapies have been subjected to proper scientific study.

##### Nursing Implications

Although this study did not offer conclusive evidence that alternative therapies for pain management work better than pharmacologic or invasive methods, they should not be discounted. Many women wish to avoid artificial means to control the discomfort of labor. The nurse should be supportive and open-minded about a woman’s efforts to meet her pain management goals.

Adapted from Smith, C. A., Collins, C. T., Cyna, A. M., & Crowther, C. A. (2010). Complementary and alternative therapies for pain management in labor. *Cochrane Database of Systematic Reviews* 2010(5). doi: 10.1002/14651858.CD003521.pub2.

chosen, the woman immerses herself in warm water for relaxation and relief of discomfort. When the woman enters the warm water, the warmth and buoyancy help to release muscle tension and can impart a sense of well-being (Westbrook, & D'Arcy, 2012). Warm water provides soothing stimulation of nerves in the skin, promoting vasodilation, reversal of sympathetic nervous response, and a reduction in catecholamines (Stark, Craig, & Miller, 2011). Contractions are usually less painful in warm water because the warmth and buoyancy of the water have a relaxing effect. Recent research findings reported that women who used hydrotherapy had significantly reduced surgical birth rates, a shorter second stage of labor, reduced analgesic requirements, and a lower incidence of perineal trauma (Stark et al., 2011). The research concluded that hydrotherapy during labor significantly aids the labor process, minimizes the use of analgesic medications, offers fast- and short-acting pain and anxiety relief, and should be considered as a safe and effective birthing aid (Stark et al., 2011).

A wide range of hydrotherapy options are available, from ordinary bathtubs to whirlpool baths and showers, combined with low lighting and music. Many hospitals provide showers and whirlpool baths for laboring women for pain relief. However, hydrotherapy is more commonly practiced in birthing centers managed by midwives. The recommendation for initiating hydrotherapy is that the woman be in active labor (more than 5 cm dilated) to prevent the slowing of labor contractions secondary to muscular relaxation. The woman's membranes can be intact or ruptured. Women are encouraged to stay in the bath or shower as long as they feel they are comfortable. The water temperature should not exceed body temperature.

Hydrotherapy is an effective pain management option for many women. Women who are experiencing a healthy pregnancy can be offered this option. The potential risks associated with hydrotherapy including hyperthermia, hypothermia, changes in maternal heart rate, fetal tachycardia, and unplanned underwater birth. The benefits include reducing pain, relieving anxiety, and promoting a sense of control during labor (Schrock, & Harraway-Smith, 2012).

## Ambulation and Position Changes

Ambulation and position changes during labor are another extremely useful comfort measure. Historically, women adopted a variety of positions during labor, rarely using the recumbent position until during the first half of the twentieth century. The medical profession has favored recumbent positions during labor, but without evidence to demonstrate their appropriateness. A recent Cochran database systematic review reported there is evidence that walking and upright positions in the first stage of labor reduce the length of labor and do not seem to be associated with increased intervention or negative effects

on mothers' and babies' well-being (Gupta, Hofmeyr & Smyth 2009). Women should be encouraged to take up whatever position they find most comfortable in the first stage of labor (Pridijan, 2011).

Changing position frequently (every 30 minutes or so)—sitting, walking, kneeling, standing, lying down, getting on hands and knees, and using a birthing ball—helps relieve pain (Fig. 14.9). Position changes also may help to speed labor by adding the benefits of gravity and changing the shape of the pelvis. Research has found that the position that the woman assumes and the frequency of position changes have a profound effect on uterine activity and efficiency. Allowing the woman to obtain a position of comfort frequently facilitates a favorable fetal rotation by altering the alignment of the presenting part with the pelvis. As the mother continues to change position based on comfort, the optimal presentation is afforded (Gilbert, 2011). Supine positions should be avoided, since they may interfere with labor progress and can cause compression of the vena cava and decrease blood return to the heart.

Swaying from side to side, rocking, or other rhythmic movements may also be comforting. If labor is progressing slowly, ambulating may speed it up again. Upright positions such as walking, kneeling forward, or doing the lunge on the birthing ball give most women a greater sense of control and active movement than just lying down. Table 14.2 highlights some of the more common positions that can be used during labor and birth.

## Acupuncture and Acupressure

Acupuncture and acupressure can be used to relieve pain during labor. Although controlled research studies of these methods are limited, there is adequate evidence that both are useful in relieving pain associated with labor and birth. However, both methods require a trained, certified clinician, and such a person is not available in many birth facilities (Lee, 2012).

Acupuncture involves stimulating key trigger points with needles. This form of Chinese medicine has been practiced for approximately 3,000 years. Classical Chinese teaching holds that throughout the body there are meridians or channels of energy (*qi*) that when in balance regulate body functions. Pain reflects an imbalance or obstruction of the flow of energy. The purpose of acupuncture is to restore *qi*, thus diminishing pain (Xu, & MacKenzie, 2012). Stimulating the trigger points causes the release of endorphins, reducing the perception of pain.

Acupressure involves the application of a firm finger or massage used in acupuncture to reduce the pain sensation. The amount of pressure is important. The intensity of the pressure is determined by the needs of the woman. Holding and squeezing the hand of a woman in labor may trigger the point most commonly used for both techniques. Some acupressure points are found along the spine, neck, shoulder, toes, and soles of the feet. Pressure

**FIGURE 14.9** Various positions for use during labor. **(A)** Ambulation. **(B)** Leaning forward. **(C)** Sitting in a chair. **(D)** Using a birthing ball.

along the side of the spine can help relieve back pain during labor (Melchart, Jack, & Kashanian, 2011). A Cochrane collaboration review found that acupuncture may indeed reduce labor pain, increasing satisfaction with pain management and reduced use of pharmacologic management. However, there is a need for further research (Smith, Collins, Crowther, & Levett, 2011).

### Application of Heat and Cold

Superficial applications of heat and/or cold, in various forms, are popular with laboring women. They are easy to use, inexpensive, require no prior practice, and have minimal negative side effects when used properly. Heat

is typically applied to the woman's back, lower abdomen, groin, and/or perineum. Heat sources include a hot water bottle, heated rice-filled sock, warm compress (washcloth soaked in warm water and wrung out), electric heating pad, warm blanket, and warm bath or shower. In addition to being used for pain relief, heat is used to relieve chills or trembling, decrease joint stiffness, reduce muscle spasm, and increase connective tissue extensibility (Mattson, & Smith, 2011).

Cold therapy, or cryotherapy, is usually applied on the woman's back, chest, and/or face during labor. Forms of cold include a bag or surgical glove filled with ice, a frozen gel pack, camper's "ice," a hollow, plastic rolling pin or bottle filled with ice, a washcloth dipped

**TABLE 14.2** COMMON POSITIONS FOR USE DURING LABOR AND BIRTH

in cold water, soda cans chilled in ice, and even a frozen bag of vegetables. “Instant” cold packs, often available in hospitals, usually are not cold enough to effectively relieve labor pain. Women who feel cold usually need to feel warm before they can comfortably tolerate using a cold pack. Chilled soda cans and rolling pins filled with ice give the added benefit of mechanical pressure when rolled on the low back. Cold has the additional effects of relieving muscle spasms and reducing inflammation and edema (Tharpe et al., 2013).

Efficacy has been established in reducing pain, as well as reducing inflammation, edema, and muscle spasm. With appropriate safety precautions, heat and cold offer comfort and relief, and their use should be dictated by the desires and responses of the laboring woman.

## Attention Focusing and Imagery

Attention focusing and imagery use many of the senses and the mind to focus on stimuli. The woman can focus on tactile stimuli such as touch, massage, or stroking. She may focus on auditory stimuli such as music, humming, or verbal encouragement. Visual stimuli might be any object in the room, or the woman can imagine the beach, a mountaintop, a happy memory, or even the contractions of the uterine muscle pulling the cervix

open and the fetus pressing downward to open the cervix. Some women focus on a particular mental activity such as a song, a chant, counting backwards, or a Bible verse. Breathing, relaxation, positive thinking, and positive visualization work well for mothers in labor. The use of these techniques keeps the sensory input perceived during the contraction from reaching the pain center in the cortex of the brain (Gedde-Dahl, & Fors, 2012).

## Therapeutic Touch and Massage

Therapeutic touch and massage use the sense of touch to promote relaxation and pain relief. Massage works as a form of pain relief by increasing the production of endorphins in the body. Endorphins reduce the transmission of signals between nerve cells and thus lower the perception of pain. Because touch receptors go to the brain faster than pain receptors, massage—anywhere on the body—can block the pain message to the brain. In addition, light touch has been found to release endorphins and induce a relaxed state. In addition, touching and massage distract the woman from discomfort. Massage involves manipulation of the body's soft tissues. It is commonly used to help relax tense muscles and to soothe and calm the individual. Massage may help to relieve pain by assisting with relaxation, inhibiting sensory

transmission in the pain pathways, or improving blood flow and oxygenation of tissues (Smith, Levett, Collins, & Jones, 2011).

Therapeutic touch is an energy therapy and is based on the premise that the body contains energy fields that lead to either good or ill health and that the hands can be used to redirect the energy fields that lead to pain (Staud, 2011). To be done correctly, this technique must be learned and practiced. Some women prefer a light touch, while others find a firmer touch more soothing. Massage of the neck, shoulders, back, thighs, feet, and hands can be very comforting. The use of firm counterpressure in the lower back or sacrum is especially helpful for back pain during contractions (Fig. 14.10). Contraindications for massage include skin rashes, varicose veins, bruises, or infections (Leonard, 2012).

Effleurage is a light, stroking, superficial touch of the abdomen, in rhythm with breathing during contractions. It is used as a relaxation and distraction technique from discomfort. External fetal monitor belts may interfere with the ability to accomplish this.

## Breathing Techniques

Conscious use of breath by the woman has the power to profoundly influence her labor and how she engages with it. The first action we take in any situation is a breath. The breath affects the lungs, immediately cueing the nervous system. The nervous system responds

**FIGURE 14.10** Nurse massaging the client's back during a contraction while she ambulates during labor.

by sending messages, which impact our entire psychophysiological system. Messages sent from the nervous system affect us physically, emotionally, and mentally. If we alter how we breathe, we alter the constellation of messages and reactions in our entire mind–body experience (Cheng & Caughey, 2012).

Breathing techniques are effective in producing relaxation and pain relief through the use of distraction. If the woman is concentrating on slow-paced rhythmic breathing, she is not likely to fully focus on contraction pain. Breathing techniques are often taught in childbirth education classes (see Chapter 12 for additional information).

Controlled breathing helps reduce the pain experienced by using stimulus–response conditioning. The woman selects a focal point within her environment to stare at during the first sign of a contraction. This focus creates a visual stimulus that goes directly to her brain. The woman takes a deep cleansing breath, which is followed by rhythmic breathing. Verbal commands from her partner supply an ongoing auditory stimulus to her brain. Benefits of practicing patterned breathing include:

- Breathing becomes an automatic response to pain.
- Breathing increases relaxation and can be used for deal with life's everyday stresses.
- The steady rhythm of breathing is calming during labor.
- Breathing provides a sense of well-being and a measure of control.
- Breathing brings purpose to each contraction, making them more productive.
- Breathing provides more oxygen for the mother and fetus (American Pregnancy Association, 2011).

Many couples learn patterned-paced breathing during their childbirth education classes. Three levels may be taught, each beginning and ending with a cleansing breath. In the first pattern, also known as slow-paced breathing, the woman inhales slowly through her nose and exhales through pursed lips. The breathing rate is typically 6 to 9 bpm. In the second pattern, also called shallow or modified-paced breathing, the woman inhales and exhales through her mouth at a rate of four breaths every 5 seconds. The rate can be accelerated to two breaths per second to assist her to relax. The third pattern, patterned-paced breathing, is similar to modified-paced breathing except that the breathing is punctuated every few breaths by a forceful exhalation through pursed lips. All breaths are kept equal and rhythmic and can increase as contractions increase in intensity (Mattson, & Smith, 2011).

Many childbirth educators do not recommend specific breathing techniques or try to teach parents to breathe the “right” way during labor and birth. Couples are encouraged to find breathing styles that enhance their relaxation and use them. There are numerous benefits to

controlled and rhythmic breathing in childbirth (outlined above), and many women choose these techniques to manage their discomfort during labor.

## Pharmacologic Measures

With varying degrees of success, generations of women have sought ways to relieve the pain of childbirth. Pharmacologic pain relief during labor includes systemic analgesia and regional or local anesthesia. Women have seen dramatic changes in pharmacologic pain management options over the years. Methods have evolved from biting down on a stick to a more complex pharmacologic approach such as epidural/intrathecal analgesia. Systemic analgesia and regional analgesia/anesthesia have become less common, while newer neuraxial analgesia/anesthesia techniques involving minimal motor blockade have become more popular. **Neuraxial analgesia/anesthesia** is the administration of analgesic (opioids) or anesthetic (capable of producing a loss of sensation in an area of the body) agents, either continuously or intermittently, into the epidural or intrathecal space to relieve pain. Low-dose and ultra-low-dose epidural analgesia, spinal analgesia, and combined spinal–epidural analgesia have replaced the traditional epidural for labor. Neuraxial analgesia does not interfere with the progress or outcome of labor. There is no need to withhold neuraxial analgesia until the active stage of labor (Orbach-Zinger, Bessler, & Arnovetzky et al., 2012). This shift in pain management techniques allows a woman to be an active participant in labor.

### Take Note!

Regardless of which approach is used during labor, the woman has the right to choose the methods of pain control that will best suit her and meet her needs.

## Systemic Analgesia

Systemic analgesia involves the use of one or more drugs administered orally, intramuscularly, or intravenously; they become distributed throughout the body via the circulatory system. Depending on which administration method is used, the therapeutic effect of pain relief can occur within minutes and last for several hours. The most important complication associated with the use of this class of drugs is respiratory depression. Therefore, women given these drugs require careful monitoring. Opioids given close to the time of birth can cause CNS depression in the newborn, necessitating the administration of naloxone (Narcan) to reverse the depressant effects of the opioids.

Several drug categories may be used for systemic analgesia:

- Ataractics, such as hydroxyzine (Vistaril), promethazine (Phenergan), or prochlorperazine (Compazine)
- Benzodiazepines, such as diazepam (Valium) or midazolam (Versed)

Drug Guide 14.1 highlights some of the major drugs used for systemic analgesia.

Systemic analgesics are typically administered parenterally, usually through an existing intravenous (IV) line. Nearly all medications given during labor cross the placenta and have a depressant effect on the fetus; therefore, it is important for the woman to receive the least amount of systemic medication that relieves her discomfort so that it does not cause any harm to the fetus (Cheng, & Caughey, 2011). Historically opioids have been administered by nurses, but in the past decade there has been increasing use of client-controlled intravenous analgesia (patient-controlled analgesia). With this system, the woman is given a button connected to a computerized pump on the IV line. When the woman desires analgesia, she presses the button and the pump delivers a preset amount of medication. This system provides the woman with a sense of control over her own pain management and active participation in the childbirth process.

## Opioids

Opioids are morphine-like medications that are most effective for the relief of moderate to severe pain. Opioids typically are administered IV. Of all of the synthetic opioids (butorphanol [Stadol], nalbuphine [Nubain], fentanyl [Sublimaze], and meperidine [Demerol]), meperidine is the most commonly used opioid for the management of pain during labor. All opioids are lipophilic and cross the placental barrier, but do not affect labor progress in the active phase. Opioids are associated with newborn respiratory depression, decreased alertness, inhibited sucking, and a delay in effective feeding (King, & Brucker, 2011).

Opioids decrease the transmission of pain impulses by binding to receptor site pathways that transmit the pain signals to the brain. The effect is increased tolerance to pain and respiratory depression related to a decrease in sensitivity to carbon dioxide (Skidmore-Roth, 2012).

All opioids are considered good analgesics. However, respiratory depression can occur in the mother and fetus depending on the dose given. They may also cause a decrease in FHR variability identified on the fetal monitor strip. This FHR pattern change is usually transient. Other systemic side effects include nausea, vomiting, pruritus, delayed gastric emptying, drowsiness, hypoventilation, and newborn depression. To reduce the incidence of newborn depression, birth should occur within 1 hour or after 4 hours of administration to prevent the fetus from receiving the peak concentration (Cheng, & Caughey, 2012).

A recent Cochrane review reported that parenteral opioids provide some relief from pain in labor, but are associated with adverse effects. Maternal satisfaction with

### DRUG GUIDE 14.1 COMMON AGENTS USED FOR SYSTEMIC ANALGESIA

Type	Drug	Comments
Opioids	Morphine 2–5 mg IV	May be given IV or epidurally Rapidly crosses the placenta, causes a decrease in FHR variability Can cause maternal and neonatal CNS depression Decreases uterine contractions
	Meperidine (Demerol) 25–75 mg IV	May be given IV, intrathecally, or epidurally with maximal fetal uptake 2–3 hr after administration Can cause CNS depression Decreases fetal variability
	Butorphanol (Stadol) 1–2 mg IV	Is given IV
	Q 2–4 hr	Is rapidly transferred across the placenta Causes neonatal respiratory depression
	Nalbuphine (Nubain) 10–20 mg IV	Is given IV Causes less maternal nausea and vomiting Causes decreased FHR variability, fetal bradycardia, and respiratory depression
	Fentanyl (Sublimaze) 50–100 mcg IV	Is given IV or epidurally Can cause maternal hypotension, maternal and fetal respiratory depression Rapidly crosses placenta
Antiemetics	Hydroxyzine (Vistaril) 50–100 mg IM	Does not relieve pain but reduces anxiety and potentiates opioid analgesic effects; can not be given IV Is used to decrease nausea and vomiting
	Promethazine (Phenergan) 25–50 mg IV or IM	Is used for antiemetic effect when combined with opioids Causes sedation and reduces apprehension May contribute to maternal hypotension and neonatal depression
	Prochlorperazine (Compazine) 5–10 mg IV or IM	Frequently given with morphine sulfate for sleep during prolonged latent phase; counteracts the nausea that opioids can produce
Benzodiazepines	Diazepam (Valium) 2–5 mg IV	Is given to enhance pain relief of opioid and cause sedation May be used to stop eclamptic seizures Decreases nausea and vomiting Can cause newborn depression; therefore, lowest possible dose should be used
	Midazolam (Versed) 1–5 mg IV	Is not used for analgesic but amnesia effect Is used as adjunct for anesthesia Is excreted in breast milk

Adapted from Cheng, Y., & Caughey, A. B. (2012). Normal labor and delivery. *eMedicine*. Retrieved from <http://emedicine.medscape.com/article/260036-overview#aw2aab6b2>; King, T. L., & Brucker, M. C. (2011). *Pharmacology for women's health*. Sudbury, MA: Jones & Bartlett; and Skidmore-Roth, L. (2012). *Mosby's 2012 nursing drug reference* (25th ed.). St. Louis, MO: Mosby Elsevier.

opioid analgesia appeared moderate at best (Ullman, Smith, Burns, Mori, & Dowswell, 2011).

Opioid antagonists such as naloxone (Narcan) are given to reverse the effects of the CNS depression, including respiratory depression, caused by opioids. Opioid antagonists also are used to reverse the side effects of neuraxial opioids, such as pruritus, urinary retention, nausea, and vomiting, without significantly decreasing analgesia (Skidmore-Roth, 2012). Consult a current drug guide for more specifics on these drug categories.

### Antiemetics

The antiemetic group of medications is used in combination with an opioid to decrease nausea and vomiting and lessen anxiety. These adjunct drugs potentiate the effectiveness of the opioid so that a lesser dose can be given. They may also be used to increase sedation. Promethazine (Phenergan) can be given IV, but hydroxyzine (Vistaril) must be given by mouth or by intramuscular injection into a large muscle mass. Neither drug affects the progress of labor, but either may cause a decrease

in FHR variability and possible newborn depression (Skidmore-Roth, 2012). Prochlorperazine (Compazine) is typically given IV or IM with morphine sulfate for sleep during a prolonged latent phase. It counteracts the nausea associated with opioids (King, & Brucker, 2011).

### Benzodiazepines

Benzodiazepines are used for minor tranquilizing and sedative effects. Diazepam (Valium) also is given IV to stop seizures resulting from eclampsia. It can be administered to calm a woman who is out of control, thereby enabling her to relax enough so that she can participate effectively during her labor process rather than fighting against it. Lorazepam (Ativan) can also be used for its tranquilizing effect, but increased sedation is experienced with this medication (Skidmore-Roth, 2012). Midazolam (Versed), also given IV, produces good amnesia but no analgesia. It is most commonly used as an adjunct for anesthesia. Diazepam and midazolam cause CNS depression for both the woman and the newborn.

### Regional Analgesia/Anesthesia

Regional analgesia/anesthesia provides pain relief without loss of consciousness. It involves the use of local anesthetic agents, with or without added opioids, to bring about pain relief or numbness through the drug's effects on the spinal cord and nerve roots. Obstetric regional analgesia generally refers to a partial or complete loss of

pain sensation below the T8 to T10 level of the spinal cord (Mattson & Smith, 2011).

The routes for regional pain relief include epidural block, combined spinal–epidural, local infiltration, pudendal block, and intrathecal (spinal) analgesia/ anesthesia. Local and pudendal routes are used during birth for episiotomies (surgical incision into the perineum to facilitate birth); epidural and intrathecal routes are used for pain relief during active labor and birth. The major advantage of regional pain management techniques is that the woman can participate in the birthing process and still have good pain control.

### Epidural Analgesia

Epidural analgesia for labor and birth involves the injection of a local anesthetic agent (e.g., lidocaine or bupivacaine) and an opioid analgesic agent (e.g., morphine or fentanyl) into the lumbar epidural space. A small catheter is then passed through the epidural needle to provide continuous access to the epidural space for maintenance of analgesia throughout labor and birth (Fig. 14.11). Epidural analgesia does increase the duration of the second stage of labor and may increase the rate of instrument-assisted vaginal deliveries as well as that of oxytocin administration (Hawkins, 2010). Approximately 60% of laboring women in the United States receive an epidural for pain relief during labor. In urban areas, many hospitals approach 90% use of epidurals (Gilbert, 2011).

**FIGURE 14.11** Epidural catheter insertion. **(A)** A needle is inserted into the epidural space. **(B)** A catheter is threaded into the epidural space; the needle is then removed. The catheter allows medication to be administered intermittently or continuously to relieve pain during labor and childbirth.

When the epidural is properly performed, the woman remains in an awakened and almost pain-free state throughout the entire process of labor and birth (Wright, & Cabrera, 2011).

An epidural involves the injection of a drug into the epidural space, which is located outside the dura mater between the dura and the spinal canal. The epidural space is typically entered through the third and fourth lumbar vertebrae with a needle, and a catheter is threaded into the epidural space. An epidural can be used for both vaginal and cesarean births. It has evolved from a regional block producing total loss of sensation to analgesia with minimal blockade. The effectiveness of epidural analgesia depends on the technique and medications used. Theoretically, epidural local anesthetics could block all labor pain if used in large volumes and high concentrations. However, pain relief is balanced against other goals such as walking during the first stage of labor, pushing effectively in the second stage, and minimizing maternal and fetal side effects.

An epidural is contraindicated for women with a previous history of spinal surgery or spinal abnormalities, coagulation defects, infections, and hypovolemia. It also is contraindicated for the woman who is receiving anticoagulation therapy.

Complications include nausea and vomiting, hypotension, fever, pruritus, intravascular injection, maternal fever, allergic reaction, and respiratory depression. Effects on the fetus during labor include fetal distress secondary to maternal hypotension (Gilbert, 2011). Ensuring that the woman avoids a supine position after an epidural catheter has been placed will help to minimize hypotension.

The addition of opioids, such as fentanyl or morphine, to the local anesthetic helps decrease the amount of motor block obtained. Continuous infusion pumps can be used to administer the epidural analgesia, allowing the woman to be in control and administer a bolus dose on demand (Jones, Othman, & Dowswell et al., 2012).

### Combined Spinal–Epidural Analgesia

Another epidural technique is combined spinal–epidural (CSE) analgesia. This technique involves inserting the epidural needle into the epidural space and subsequently inserting a small-gauge spinal needle through the epidural needle into the subarachnoid space. An opioid, without a local anesthetic, is injected into this space. The spinal needle is then removed and an epidural catheter is inserted for later use.

CSE is advantageous because of its rapid onset of pain relief (within 3 to 5 minutes) that can last up to 3 hours. It also allows the woman's motor function to remain active. Her ability to bear down during the second stage of labor is preserved because the pushing reflex is not lost, and her motor power remains intact. The CSE technique provides greater flexibility

### Consider This

When I was expecting my first child, I was determined to put my best foot forward and do everything right. I was an experienced OB nurse, and in my mind doing everything right was expected behavior. I was already 2 weeks past my calculated due date and I was becoming increasingly worried. That particular day I went to work with a backache but felt no contractions.

I managed to finish my shift but felt completely wiped out. As I walked to my car outside the hospital, my water broke and I felt the warm fluid run down my legs. I went back inside to be admitted for this much-awaited event.

Although I had helped thousands of women go through their childbirth experience, I was now the one in the bed and not standing alongside it. My husband and I had practiced our breathing techniques to cope with the discomfort of labor, but this “discomfort” in my mind was more than I could tolerate. So despite my best intentions of doing everything right, within an hour I begged for a painkiller to ease the pain. While the medication took the edge off my pain, I still felt every contraction and truly now appreciate the meaning of the word “labor.” Although I wanted to use natural childbirth without any medication, I know that I was a full participant in my son's birthing experience, and that is what “doing everything right” was for me!

Thoughts: Doing what is right varies for each individual, and as nurses we need to support whatever that is. Having a positive outcome from the childbirth experience is the goal; the means it takes to achieve it is less important. How can nurses support women in making their personal choices to achieve a healthy outcome? Are any women “failures” if they ask for pain medication to tolerate labor? How can nurses help women overcome this stigma of being a “wimp”?

and reliability for labor than either spinal or epidural analgesia alone (Fanning, Arzole, Balki, & Carvalho, 2012). When compared with traditional epidural or spinal analgesia, which often keeps the woman lying in bed, CSE allows her to ambulate (“walking epidural”) (Loubert, Hinova, & Fernando, 2011). Ambulating during labor provides several benefits: it may help control pain better, shorten the first stage of labor, increase the intensity of the contractions, and decrease the possibility of an operative vaginal or cesarean birth.

Although women can walk with CSE, they often choose not to because of sedation and fatigue. Often health care providers do not encourage or assist women to ambulate for fear of injury. Nurses need to evaluate for ambulation safety that includes no postural hypotension and normal leg strength by demonstrating a partial knee bend while standing; they also need to assist

with ambulation at all times (Gilbert, 2011). Currently, anesthesiologists are performing walking epidurals using continuous infusion techniques as well as CSE and client-controlled epidural analgesia (Wright, & Cabrera, 2012).

Complications include maternal hypotension, intravascular injection, accidental intrathecal blockade, postdural puncture headache, inadequate or failed block, maternal fever, and pruritus. Hypotension and associated FHR changes are managed with maternal positioning (semi-Fowler's position), intravenous hydration, and supplemental oxygen (Arendt, Tessmer-Tuck, & Hebl, 2012).

### Patient-Controlled Epidural Analgesia

Patient-controlled epidural analgesia (PCEA) involves the use of an indwelling epidural catheter with an infusion of medication and a programmed pump that allows the woman to control the dosing. This method allows the woman to have a sense of control over her pain and reach her own individually acceptable analgesia level. When compared with traditional epidural analgesia, PCEA provides equivalent analgesia with lower anesthetic use, lower rates of supplementation, and higher client satisfaction (Haydon et al., 2011).

With PCEA, the woman uses a handheld device connected to an analgesic agent that is attached to an epidural catheter. When she pushes the button, a bolus dose of agent is administered via the catheter to reduce her pain. This method allows her to manage her pain at will without having to ask a staff member to provide pain relief.

### Local Infiltration

Local infiltration involves the injection of a local anesthetic, such as lidocaine, into the superficial perineal nerves to numb the perineal area. This technique is done by the physician or midwife just before performing an episiotomy or before suturing a laceration. Local infiltration does not alter the pain of uterine contractions, but it does numb the immediate area of the episiotomy or laceration. Local infiltration does not cause side effects for the woman or her newborn.

### Pudendal Nerve Block

A pudendal nerve block refers to the injection of a local anesthetic agent (e.g., bupivacaine, ropivacaine) into the pudendal nerves near each ischial spine. It provides pain relief in the lower vagina, vulva, and perineum (Fig. 14.12).

A pudendal block is used for the second stage of labor, an episiotomy, or an operative vaginal birth with outlet forceps or vacuum extractor. It must be administered about 15 minutes before it would be needed to ensure its full

FIGURE 14.12 Pudendal nerve block.

effect. A transvaginal approach is generally used to inject an anesthetic agent at or near the pudendal nerve branch. Neither maternal nor fetal complications are common.

### Spinal (Intrathecal) Analgesia/Anesthesia

The spinal (intrathecal) pain management technique involves injection of an anesthetic “caine” agent, with or without opioids, into the subarachnoid space to provide pain relief during labor or cesarean birth. The subarachnoid space is a fluid-filled area located between the dura mater and the spinal cord. Spinal anesthesia is frequently used for elective and emergent cesarean births. The contraindications are similar to those for an epidural block. Adverse reactions for the woman include hypotension and spinal headache.

The subarachnoid injection of opioids alone, a technique termed intrathecal narcotics, has been gaining popularity since it was introduced in the 1980s. A narcotic is injected into the subarachnoid space, providing rapid pain relief while still maintaining motor function and sensation (Yeomans, 2010). An intrathecal narcotic is given during the active phase (more than 5 cm of dilation) of labor. Compared with epidural blocks, intrathecal narcotics are easy to administer, require a smaller volume of medication, produce excellent muscular relaxation, provide rapid-onset pain relief, are less likely to

cause newborn respiratory depression, and do not cause motor blockade (Hawkins, 2010). Although pain relief is rapid with this technique, it is limited by the narcotic's duration of action, which may be only a few hours and not last through the labor. Additional pain measures may be needed to sustain pain management.

## General Anesthesia

General anesthesia is typically reserved for emergency cesarean births when there is not enough time to provide spinal or epidural anesthesia or if the woman has a contraindication to the use of regional anesthesia. It can be started quickly and causes a rapid loss of consciousness. General anesthesia can be administered by IV injection, inhalation of anesthetic agents, or both. Commonly, thiopental, a short-acting barbiturate, is given IV to produce unconsciousness. This is followed by administration of a muscle relaxant. After the woman is intubated, nitrous oxide and oxygen are administered. A volatile halogenated agent may also be administered to produce amnesia (Cheng, & Caughey, 2012).

All anesthetic agents cross the placenta and affect the fetus. The primary complication with general anesthesia is fetal depression, along with uterine relaxation and potential maternal vomiting and aspiration.

Although the anesthesiologist or nurse anesthetist administers the various general anesthesia agents, the nurse needs to be knowledgeable about the pharmacologic aspects of the drugs used and must be aware of airway management. Ensure that the woman is NPO and has a patent IV. In addition, administer a nonparticulate (clear) oral antacid (e.g., Bicitra or sodium citrate) or a proton pump inhibitor (Protonix) as ordered to reduce gastric acidity. Assist with placement of a wedge under the woman's right hip to displace the gravid uterus and prevent vena cava compression in the supine position. Once the newborn has been removed from the uterus, assist the perinatal team in providing supportive care.

### NURSING CARE DURING LABOR AND BIRTH

Childbirth, a physiologic process that is fundamental to all human existence, is one of the most significant cultural, psychological, spiritual, and behavioral events in a woman's life. Although the act of giving birth is a universal phenomenon, it is a unique experience for each woman. Continuous evaluation and appropriate intervention for women during labor are key to promoting a positive outcome for the family.

The nurse's role in childbirth is to ensure a safe environment for the mother and her newborn. Nurses begin evaluating the mother and fetus during the admission procedures at the health care agency and continue to do

so throughout labor. It is critical to provide anticipatory guidance and explain each procedure (fetal monitoring, intravenous therapy, medications given and expected reactions) and what will happen next. This will prepare the woman for the upcoming physical and emotional challenges, thereby helping to reduce her anxiety. Acknowledging members of her support system (family or partner) helps allay their fears and concerns, thereby assisting them in carrying out their supportive role. Knowing how and when to evaluate a woman during the various stages of labor is essential for all labor and birth nurses to ensure a positive maternal experience and a healthy newborn.

A major focus of care for the woman during labor and birth is assisting her with maintaining control over her pain, emotions, and actions while being an active participant. Nurses can help and support women to be actively involved in their childbirth experience by allowing time for discussion, offering companionship, listening to worries and concerns, paying attention to the woman's emotional needs, and offering information to help her understand what is happening in each stage of labor.

### Nursing Care During the First Stage of Labor

Depending on how far advanced the woman's labor is when she arrives at the facility, the nurse will determine assessment parameters of maternal–fetal status and plan care accordingly. The nurse will provide high-touch, low-tech supportive nursing care during the first stage of labor when admitting the woman and orienting her to the labor and birth suite. The nurse is usually the primary gatekeeper of observations, interventions, treatments, and often the management of labor in the inpatient perinatal setting. Nursing care during this stage will include taking an admission history (reviewing the prenatal record); checking the results of routine laboratory tests and any special tests such as chorionic villi sampling, amniocentesis, genetic studies, and biophysical profile done during pregnancy; asking the woman about her childbirth preparation (birth plan, classes taken, coping skills); and completing a physical assessment of the woman to establish baseline values for future comparison.

Key nursing interventions include:

- Identifying the estimated date of birth from the client and the prenatal chart
- Validating the client's prenatal history to determine fetal risk status
- Determining fundal height to validate dates and fetal growth
- Performing Leopold's maneuvers to determine fetal position, lie, and presentation
- Checking FHR
- Performing a vaginal examination (as appropriate) to evaluate effacement and dilation progress

- Instructing the client and her partner about monitoring techniques and equipment
- Assessing fetal response and FHR to contractions and recovery time
- Interpreting fetal monitoring strips
- Checking FHR baseline for accelerations, variability, and decelerations
- Repositioning the client to obtain an optimal FHR pattern
- Recognizing FHR problems and initiating corrective measures
- Checking amniotic fluid for meconium staining, odor, and amount
- Comforting client throughout testing period and labor
- Documenting times of notification for team members if problems arise
- Knowing appropriate interventions when abnormal FHR patterns present
- Supporting the client's decisions regarding intervention or avoidance of intervention
- Assessing the client's support system and coping status frequently

In addition to these interventions to promote optimal outcomes for the mother and fetus, the nurse must document care accurately and in a timely fashion. Accurate and timely documentation helps to decrease professional liability exposure, minimize the risk of preventable injuries to women and infants during labor and birth, and preserve families (Wagner, Meirowitz, Shah, & Nanda et al., 2012). Guidelines for recording care include documenting:

- All care rendered, to prove that standards were met
- Conversations with all providers, including notification times
- Nursing interventions before and after notifying provider
- Use of the chain of command and response at each level
- All flow sheets and forms, to validate care given
- All education given to client and response to it
- Facts, not personal opinions
- Detailed descriptions of any adverse outcome
- Initial nursing assessment, all encounters, and discharge plan
- All telephone conversations (Hemman, 2011)

This standard of documentation is needed to prevent or defend against litigation, which is prevalent in the childbirth arena.

## Assessing the Woman Upon Admission

The nurse usually first comes in contact with the woman either by phone or in person. The nurse should ascertain whether the woman is in true or false labor and whether

she should be admitted or sent home. Upon admission to the labor and birth suite, the highest priorities include assessing FHR, assessing cervical dilation/effacement, and determining whether membranes have ruptured or are intact. These assessment data will guide the critical thinking in planning care for the client.

If the initial contact is by phone, establish a therapeutic relationship with the woman. Speaking in a calm caring tone facilitates this. Nurses providing a telephone triage service need to have sufficient clinical experience and have clear lines of responsibility to enable sound decision making. When completing a phone assessment, include questions about the following:

- Estimated date of birth, to determine if term or preterm
- Fetal movement (frequency in the past few days)
- Other premonitory signs of labor experienced
- Parity, gravida, and previous childbirth experiences
- Time from start of labor to birth in previous labors
- Characteristics of contractions, including frequency, duration, and intensity
- Appearance of any vaginal bloody show
- Membrane status (ruptured or intact)
- Presence of supportive adult in household or if she is alone

When speaking with the woman over the telephone, review the signs and symptoms that denote true versus false labor, and suggest various positions she can assume to provide comfort and increase placental perfusion. Also suggest walking, massage, and taking a warm shower to promote relaxation. Outline what foods and fluids are appropriate for oral intake in early labor. Throughout the phone call, listen to the woman's concerns and answer any questions clearly.

Reducing the risk of liability exposure and avoiding preventable injuries to mothers and fetuses during labor and birth can be accomplished by adhering to two basic tenets of clinical practice: (1) use applicable evidence and/or published standards and guidelines as the foundation of care, and (2) whenever a clinical choice is presented, choose client safety (Grobman, 2012). With these two tenets in mind, advise the woman on the phone to contact her health care provider for further instructions or to come to the facility to be evaluated, since ruling out true labor and possible maternal–fetal complications cannot be done accurately over the phone.

Additional nursing responsibilities associated with a phone assessment include:

- Consulting the woman's prenatal record for parity status, estimated date of birth, and untoward events
- Calling the health care provider to inform him or her of the woman's status
- Preparing for admission to the perinatal unit to ensure adequate staff assignment
- Notifying the admissions office of a pending admission

If the nurse's first encounter with the woman is in person, an assessment is completed to determine

whether she should be admitted to the perinatal unit or sent home until her labor advances. Entering a facility is often an intimidating and stressful event for women since it is an unfamiliar environment. Giving birth for the first time is a pivotal event in the lives of most women. Therefore, demonstrate respect when addressing the client; listen carefully and express interest and concern. Nurses must value and respect women and promote their self-worth and sense of control by allowing them to participate in making decisions. Allowing them a fair amount of autonomy in their childbirth decisions, supporting their personal worth, knowing them holistically, and using caring communication will increase client satisfaction (Records, & Wilson, 2011).

An admission assessment includes maternal health history, physical assessment, fetal assessment, laboratory studies, and assessment of psychological status. Usually the facility has a form that can be used throughout labor and birth to document assessment findings (Fig. 14.13).

### Maternal Health History

A maternal health history should include typical biographical data such as the woman's name and age and the name of the delivering health care provider. Other information that is collected includes the prenatal record data, including the estimated date of birth, a history of the current pregnancy, and the results of any laboratory and diagnostic tests, such as blood type, Rh status, and group B streptococcal status; past pregnancy and obstetric history; past health history and family history; prenatal education; list of medications; risk factors such as diabetes, hypertension, and use of tobacco, alcohol, or illicit drugs; reason for admission, such as labor, cesarean birth, or observation for a complication; history of potential domestic violence; history of previous preterm births; allergies; time of last food ingestion; method chosen for infant feeding; name of birth attendant and pediatrician; and pain management plan.

Ascertaining this information is important so that an individualized plan of care can be developed for the woman. If, for example, the woman's due date is still 2 months away, it is important to establish this information so interventions can be initiated to arrest the labor immediately or notify the intensive perinatal team to be available. In addition, if the woman has diabetes, it is critical to monitor her glucose levels during labor, to prepare for a surgical birth if dystocia of labor occurs, and to alert the newborn nursery of potential hypoglycemia in the newborn after birth. By collecting important information about each woman they care for, nurses can help improve the outcomes for all concerned.

Be sure to observe the woman's emotions, support system, verbal interaction, body language and posture, perceptual acuity, and energy level. Also note her cultural background and language spoken. This psychosocial

information provides cues about the woman's emotional state, culture, and communication systems. For example, if the woman arrives at the labor and birth suite extremely anxious, alone, and unable to communicate in English, how can the nurse meet her needs and plan her care appropriately? It is only by assessing each woman physically and psychosocially that the nurse can make astute decisions regarding proper care. In this case, an interpreter would be needed to assist in the communication process between the staff and the woman to initiate proper care.

It is important to acknowledge and try to understand the cultural differences in women with cultural backgrounds different from that of the nurse. Attitudes toward childbirth are heavily influenced by the culture in which the woman has been raised. As a result, within every society, specific attitudes and values shape the woman's childbearing behaviors. Be aware of what these are. When carrying out a cultural assessment during the admission process, ask questions (Box 14.2) to help plan culturally competent care during labor and birth.

### Physical Examination

The physical examination typically includes a generalized assessment of the woman's body systems, including hydration status, vital signs, auscultation of heart and lung sounds, and measurement of height and weight. The physical examination also includes the following assessments:

- Fundal height measurement
- Uterine activity, including contraction frequency, duration, and intensity

#### BOX 14.2

#### QUESTIONS FOR PROVIDING CULTURALLY COMPETENT CARE DURING LABOR AND BIRTH

- Where were you born? How long have you lived in the United States?
- What languages do you speak and read?
- Who are your major support people?
- What are your religious practices?
- How do you view childbearing?
- Are there any special precautions or restrictions that are important?
- Is birth considered a private or a social experience?
- How would you like to manage your labor discomfort?
- Who will provide your labor support?

FIGURE 14.13 Sample documentation form used for admission to the perinatal unit. (Used with permission. Briggs Corporation, 2001.)

- Status of membranes (intact or ruptured)
- Cervical dilation and degree of effacement
- Fetal status, including heart rate, position, and station
- Pain level

These assessment parameters form a baseline against which the nurse can compare all future values throughout labor. The findings should be similar to those of the woman's prepregnancy and pregnancy findings, with the exception of her pulse rate, which might be elevated secondary to her anxious state with beginning labor.

### Laboratory Studies

On admission, laboratory studies typically are done to establish a baseline. Although the exact tests may vary among facilities, they usually include a urinalysis via clean-catch urine specimen and complete blood count (CBC). Blood typing and Rh factor analysis may be necessary if the results of these are unknown or unavailable. In addition, if the following test results are not included in the maternal prenatal history, it may be necessary to perform them at this time. They include syphilis screening, hepatitis B (HbsAg) screening, group B streptococcus, HIV testing (if woman gives consent), and possible drug screening if the history is positive.

Group B streptococcus (GBS) is a gram-positive organism that colonizes in the female genital tract and rectum and is present in 10% to 30% of all healthy women (Mattson, & Smith, 2011). These women are asymptomatic carriers but can cause GBS disease of the newborn through vertical transmission during labor and horizontal transmission after birth. The mortality rate of infected newborns varies according to time of onset (early or late). Risk factors for GBS include maternal intrapartum fever, prolonged ruptured membranes (>12 to 18 hours), previous birth of an infected newborn, and GBS bacteriuria in the present pregnancy.

In 2010, the Centers for Disease Control and Prevention (CDC), ACOG and the American Academy of Pediatrics issued renewed guidelines that advised universal screening of pregnant women at 35 to 37 weeks' gestation for GBS and intrapartum antibiotic therapy for GBS carriers. These new guidelines reaffirmed the major prevention strategy—universal antenatal GBS screening and intrapartum antibiotic prophylaxis for culture-positive and high-risk women—and include new recommendations for laboratory methods for identification of GBS colonization during pregnancy, algorithms for screening and intrapartum prophylaxis for women with preterm labor and premature rupture of membranes, updated prophylaxis recommendations for women with a penicillin allergy, and a revised algorithm for the care of newborn infants (Baker, Byington, & Polin, 2011). Maternal infections associated with GBS include acute chorioamnionitis, endometritis, and urinary tract infection. Neonatal

clinical manifestations include pneumonia and sepsis. Identified GBS carriers receive IV antibiotic prophylaxis (penicillin G or ampicillin) at the onset of labor or ruptured membranes.

The ACOG, CDC, AWHONN and the U.S. Preventive Services Task Force all recommend that all pregnant women be offered a screening test for HIV antibodies on their first prenatal visit, again during the third trimester if engaging in high-risk behaviors, and on admission to the labor and birth area (Gilbert, 2011).

If her HIV status is not documented, the woman being admitted to the labor and birth suite should have rapid HIV testing done. To reduce perinatal transmission, women who are HIV positive are given zidovudine (ZDV) (2 mg/kg IV over an hour, and then a maintenance infusion of 1 mg/kg per hour until birth) or a single 200-mg oral dose of nevirapine at the onset of labor; the newborn is given ZDV orally (2 mg/kg body weight every 6 hours) and should be continued for 6 weeks (Gardner et al., 2011). To further reduce the risk of perinatal transmission, ACOG and the U.S. Public Health Service recommend that women who are infected with HIV and have plasma viral loads of more than 1,000 copies per milliliter be counseled regarding the benefits of elective cesarean birth (Kelly, Alderdice, Lohan, & Spence, 2012). Additional interventions to reduce the transmission risk would include avoiding use of a scalp electrode for fetal monitoring or doing a scalp blood sampling for fetal pH, delaying amniotomy, encouraging formula feeding after birth, and avoiding invasive procedures such as forceps or vacuum-assisted devices. The nurse stresses the importance of all interventions and the goal to reduce transmission of HIV to the newborn.

### Continuing Assessment During the First Stage of Labor

After the admission assessment is complete, assessment continues for changes that would indicate that labor is progressing as expected. Assess the woman's knowledge, experience, and expectations of labor. Typically, blood pressure, pulse, and respirations are assessed every hour during the latent phase of labor unless the clinical situation dictates that vital signs be taken more frequently. During the active and transition phases, they are assessed every 30 minutes. The temperature is taken every 4 hours throughout the first stage of labor and every 2 hours after membranes have ruptured to detect an elevation indicating an ascending infection.

Vaginal examinations are performed periodically to track labor progress. This assessment information is shared with the woman to reinforce that she is making progress toward the goal of birth. Uterine contractions are monitored for frequency, duration, and intensity every 30 to 60 minutes during the latent phase, every 15 to

30 minutes during the active phase, and every 15 minutes during transition. Note the changes in the character of the contractions as labor progresses, and inform the woman of her progress. Continually determine the woman's level of pain and her ability to cope and use relaxation techniques effectively.

When the fetal membranes rupture, spontaneously or artificially, assess the FHR and check the amniotic fluid for color, odor, and amount. Assess the FHR intermittently or continuously via electronic monitoring. During the latent phase of labor, assess the FHR every 30 to 60 minutes; in the active phase, assess FHR at least every 15 to 30 minutes. Also, be sure to assess the FHR before ambulation, before any procedure, and before administering analgesia or anesthesia to the mother. Table 14.3 summarizes assessments for the first stage of labor.

*Remember Sheila from the chapter-opening scenario? What is the nurse's role with Sheila in active labor? What additional comfort measures can the labor nurse offer Sheila?*

## Nursing Interventions

Nursing interventions during the admission process should include:

- Asking about the client's expectations of the birthing process
- Providing information about labor, birth, pain management options, and relaxation techniques
- Presenting information about fetal monitoring equipment and the procedures needed
- Monitoring FHR and identifying patterns that need further intervention
- Monitoring the mother's vital signs to obtain a baseline for later comparison
- Reassuring the client that her labor progress will be monitored closely and nursing care will focus on ensuring fetal and maternal well-being throughout

As the woman progresses through the first stage of labor, nursing interventions include:

- Encouraging the woman's partner to participate
- Keeping the woman and her partner up to date on the progress of the labor
- Orienting the woman and her partner to the labor and birth unit and explaining all of the birthing procedures

TABLE 14.3

SUMMARY OF ASSESSMENTS DURING THE FIRST STAGE OF LABOR

Assessments*	Latent Phase (0–3 cm)	Active Phase (4–7 cm)	Transition (8–10 cm)
Vital signs (BP, pulse, respirations)	Every 30–60 min	Every 30 min	Every 15–30 min
Temperature	Every 4 hr; more frequently if membranes are ruptured	Every 4 hr; more frequently if membranes are ruptured	Every 4 hr; more frequently if membranes are ruptured
Contractions (frequency, duration, intensity)	Every 30–60 min by palpation or continuously if EFM	Every 15–30 min by palpation or continuously if EFM	Every 15 min by palpation or continuously if EFM
Fetal heart rate	Every hour by Doppler or continuously by EFM	Every 30 min by Doppler or continuously by EFM	Every 15–30 min by Doppler or continuously by EFM
Vaginal examination	Initially on admission to determine phase and as needed based on maternal cues to document labor progression	As needed to monitor labor progression	As needed to monitor labor progression
Behavior/psychosocial	With every client encounter: talkative, excited, anxious	With every client encounter: self-absorbed in labor; intense and quiet now	With every client encounter: discouraged, irritable, feels out of control, declining coping ability

\*The frequency of assessments is dictated by the health status of the woman and fetus and can be altered if either one of their conditions changes. EFM, electronic fetal monitoring.

Adapted from Gilbert, E. S. (2011). *Manual of high risk pregnancy and delivery* (5th ed.). St. Louis, MO: Mosby Elsevier; Groll, K. G. (2012). *Fast facts for the labor and delivery nurse*. New York, NY: Springer; and Mattson, S., & Smith, J. E. (2011). *Core curriculum for maternal–newborn nursing* (4th ed.). St. Louis, MO: Saunders Elsevier.

- Providing clear fluids (e.g., ice chips) as needed or requested
- Maintaining the woman's parenteral fluid intake at the prescribed rate if she has an IV
- Initiating or encouraging comfort measures, such as backrubs, cool cloths to the forehead, frequent position changes, ambulation, showers, slow dancing, leaning over a birth ball, side-lying, or counterpressure on lower back (Teaching Guidelines 14.1)
- Encouraging the partner's involvement with breathing techniques
- Assisting the woman and her partner to focus on breathing techniques
- Informing the woman that the discomfort will be intermittent and of limited duration; urging her to rest between contractions to preserve her strength; and encouraging her to use distracting activities to lessen the focus on contractions
- Changing bed linens and gown as needed
- Keeping the perineal area clean and dry
- Supporting the woman's decisions about pain management
- Monitoring maternal vital signs frequently and reporting any abnormal values
- Ensuring that the woman takes deep cleansing breaths before and after each contraction to enhance gas exchange and oxygen to the fetus
- Educating the woman and her partner about the need for rest and helping them plan strategies to conserve strength
- Monitoring FHR for baseline, accelerations, variability, and decelerations
- Checking on bladder status and encouraging voiding at least every 2 hours to make room for birth
- Repositioning the woman as needed to obtain optimal heart rate pattern
- Communicating requests from the woman to appropriate personnel
- Respecting the woman's sense of privacy by covering her when appropriate
- Offering human presence by being present with the woman, not leaving her alone for long periods
- Being patient with the natural labor pattern to allow time for change
- Encourage maternal movement throughout labor to increase the woman's level of comfort
- Dim the lights in the room when pushing and request softened voices be used to maintain a calm and centered ambiance
- Reporting any deviations from normal to the health care professional so that interventions can be initiated early to be effective (Groll, 2012; Steen, 2012)

See Nursing Care Plan 14.1.

*Remember Sheila, who was admitted in active labor? She has progressed to the transition phase (dilated 8 cm) and is becoming increasingly more uncomfortable. She is using a patterned-paced breathing pattern now but is thrashing around in the hospital bed.*

### Teaching Guidelines 14.1

#### **POSITIONING DURING THE FIRST STAGE OF LABOR**

- Walking with support from the partner (adds the force of gravity to contractions to promote fetal descent)
- Slow-dancing position with the partner holding you (adds the force of gravity to contractions and promotes support from and active participation of your partner)
- Side-lying with pillows between the knees for comfort (offers a restful position and improves oxygen flow to the uterus)
- Semi-sitting in bed or on a couch leaning against the partner (reduces back pain because fetus falls forward, away from the sacrum)
- Sitting in a chair with one foot on the floor and one on the chair (changes pelvic shape)
- Leaning forward by straddling a chair, a table, or a bed or kneeling over a birth ball (reduces back pain, adds the force of gravity to promote descent; possible pain relief if partner can apply sacral pressure)
- Sitting in a rocking chair or on a birth ball and shifting weight back and forth (provides comfort because rocking motion is soothing; uses the force of gravity to help fetal descent)
- Lunge by rocking weight back and forth with foot up on chair during contraction (uses force of gravity by being upright; enhances rotation of fetus through rocking)
- Open knee–chest position (helps to relieve back discomfort) (Mattson, & Smith, 2011; Tharpe et al., 2013).

### **Nursing Management During the Second Stage of Labor**

Nursing care during the second stage of labor focuses on supporting the woman and her partner in making active decisions about her care and labor management, implementing strategies to prolong the early passive

## NURSING CARE PLAN 14.1

## Overview of a Woman in the Active Phase of the First Stage of Labor

Candice, a 23-year-old gravida 1, para 0 (G1,P0), is admitted to the labor and birth suite at 39 weeks' gestation having contractions of moderate intensity every 5 to 6 minutes. A vaginal examination reveals her cervix is 80% effaced and 5 cm dilated. The presenting part (vertex) is at 0 station and her membranes ruptured spontaneously 4 hours ago at home. She is admitted and an IV is started for hydration and vascular access. An external fetal monitor is applied. FHR is 140 bpm and regular. Her partner is present at her bedside. Candice is now in the active phase of the first stage of labor, and her assessment findings are as follows: cervix dilated 7 cm, 80% effaced; moderate to strong contractions occurring regularly, every 3 to 5 minutes, lasting 45 to 60 seconds; at 0 station on pelvic examination; FHR auscultated loudest below umbilicus at 140 bpm; vaginal show—pink or bloody vaginal mucus; currently apprehensive, inwardly focused, with increased dependency; voicing concern about ability to cope with pain; limited ability to follow directions.

**NURSING DIAGNOSIS:** Anxiety related to labor and birth process and fear of the unknown related to client's first experience

### Outcome Identification and Evaluation

The client will remain calm and in control as evidenced by ability to make decisions and use positive coping strategies.

### Interventions: *Promoting Positive Coping Strategies*

- Provide instruction regarding the labor process to allay anxiety.
- Reorient the woman to the physical environment and equipment as necessary to keep her informed of events.
- Encourage verbalization of feelings and concerns to reduce anxiety.
- Listen attentively to woman and partner to demonstrate interest and concern.
- Inform woman and partner of standard procedures/processes to ensure adequate understanding of events and procedures.
- Frequently update woman of progress and labor status to provide positive reinforcement for actions.
- Reinforce relaxation techniques and provide instruction if needed to aid in coping.
- Encourage participation of the partner in the coaching role; role-model to facilitate partner participation in labor process to provide support and encouragement to the client.
- Provide a presence and remain with the client as much as possible to provide comfort and support.

**NURSING DIAGNOSIS:** Acute pain related to uterine contractions and stretching of the cervix and birth canal

### Outcome Identification and Evaluation

The client will maintain a tolerable level of pain and discomfort as evidenced by statements of pain relief, pain rating of 2 or less on pain rating scale, and absence of adverse effects in client and fetus from analgesia or anesthesia.

## NURSING CARE PLAN 14.1

**Overview of a Woman in the Active Phase of the First Stage of Labor** (continued)**Interventions: *Providing Pain Relief***

- Monitor vital signs, observe for signs of pain, and have client rate pain on a scale of 0 to 10 to provide baseline for comparison.
- Encourage client to void every 1 to 2 hours to decrease pressure from a full bladder.
- Assist woman to change positions frequently to increase comfort and promote labor progress.
- Encourage use of distraction to reduce focus on contraction pain.
- Suggest pelvic rocking, massage, or back counter-pressure to reduce pain.
- Assist with use of relaxation and breathing techniques to promote relaxation.
- Use touch appropriately (backrub) when desired by the woman to promote comfort.
- Integrate use of nonpharmacologic measures for pain relief, such as warm water, birthing ball, or other techniques to facilitate pain relief.
- Administer pharmacologic agents as ordered when requested to control pain.
- Provide reassurance and encouragement between contractions to foster self-esteem and continued participation in labor process.

**NURSING DIAGNOSIS:** Risk of infection related to multiple vaginal examinations following rupture of membranes and tissue trauma

**Outcome Identification and Evaluation**

The client will remain free of infection as evidenced by the absence of signs and symptoms of infection, vital signs and FHR within acceptable parameters, lab test results within normal limits, and clear amniotic fluid without odor.

**Interventions: *Preventing Infection***

- Monitor vital signs (every 2 hours after rupture of membranes [ROM]) and FHR frequently as per protocol to allow for early detection of problems; report fetal tachycardia (early sign of maternal infection) to ensure prompt treatment.
- Provide frequent perineal care and pad changes to maintain good perineal hygiene.
- Change linens and woman's gown as needed to maintain cleanliness.
- Ensure that vaginal examinations are performed only when needed to prevent introducing pathogens into the vaginal vault.
- Monitor lab test results such as white blood cell count to assess for elevations indicating infection.
- Use aseptic technique for all invasive procedures to prevent infection transmission.
- Carry out good handwashing techniques before and after procedures and use standard precautions as appropriate to minimize risk of infection transmission.
- Document amniotic fluid characteristics—color, odor—to establish baseline for comparison.

phase of fetal descent, supporting involuntary bearing-down efforts, providing instruction and assistance, and using maternal positions that can enhance descent and reduce pain (Aasheim, Nilsen, Lukasse, & Reinar, 2012). Women in the past gave birth unaided by following their bodies signals to birth their babies, so the role of the nurse should be to support the woman in her choice of pushing method and to encourage confidence in her maternal instinct of when and how to push. In the absence of any complications, nurses should not be controlling

this stage of labor, but empowering women to achieve a satisfying experience. The primary rationale for directing women to push is to shorten the second stage of labor. Common practice in many labor units is still to coach women to use closed glottis pushing with every contraction, starting at 10 cm of dilation, a practice that is not supported by research. Research suggests that directed pushing during the second stage may be accompanied by a significant decline in fetal pH and may cause maternal muscle and nerve damage if done too

early (Naranjo, Puertas, & López, 2011). Shortening the phase of active pushing and lengthening the early phase of passive descent can be achieved by encouraging the woman not to push until she has a strong desire to do so and until the descent and rotation of the fetal head are well advanced. Effective pushing can be achieved by assisting the woman to assume a more upright or squatting position. Supporting spontaneous pushing and encouraging women to choose their own method of pushing should be accepted as best clinical practice (Prins, Boxem, Lucas, & Hutton, 2011).

Perineal lacerations or tears can occur during the second stage when the fetal head emerges through the vaginal introitus. The extent of the laceration is defined by depth: a first-degree laceration extends through the skin; a second-degree laceration extends through the muscles of the perineal body; a third-degree laceration continues through the anal sphincter muscle; and a fourth-degree laceration also involves the anterior rectal wall. Special attention needs to be paid to third- and fourth-degree lacerations to prevent fecal incontinence. Risks for third- or fourth-degree lacerations included nulliparity, being Asian or Pacific Islander, increased birth weight of newborn, operative vaginal birth, episiotomy, and longer second stage of labor. Increasing body mass index was associated with fewer lacerations (Landy et al., 2011). The primary care provider should repair any lacerations during the third stage of labor.

An **episiotomy** is an incision made in the perineum to enlarge the vaginal outlet and theoretically to shorten the second stage of labor. Alternative measures such as warm compresses and continual massage with oil have been successful in stretching the perineal area to prevent cutting it. Certified nurse midwives can cut and repair episiotomies, but they frequently use alternative measures if possible.

### Take Note!

Further research needs to be done to validate the efficacy of natural measures versus the episiotomy.

The midline episiotomy is the most commonly used one in the United States because it can be easily repaired and causes the least amount of pain. The application of warmed compresses is associated with a decrease in trauma to the perineal area and reduced the need for an episiotomy (Aasheim, Nilsen, Lukasse, & Reinar, 2011). Routine episiotomy has declined since liberal usage has been discouraged by ACOG. Anal sphincter laceration rates with spontaneous vaginal delivery have decreased, likely reflecting the decreased usage of episiotomy. The decline in operative vaginal delivery corresponds to a sharp increase in cesarean births, which may indicate that practitioners are favoring cesarean births for difficult births (Browne, Jacobs, Lahiff, & Miller, 2010). Figure 14.14 shows episiotomy locations.

## Assessment

Assessment is continuous during the second stage of labor. Hospital policies dictate the specific type and timing of assessments, as well as the way in which they are documented. Assessment involves identifying the signs typical of the second stage of labor, including:

- Increase in apprehension or irritability
- Spontaneous rupture of membranes
- Sudden appearance of sweat on upper lip
- Increase in blood-tinged show
- Low grunting sounds from the woman
- Complaints of rectal and perineal pressure
- Beginning of involuntary bearing-down efforts

**A**

**B**

**FIGURE 14.14** Location of an episiotomy. **(A)** Midline episiotomy. **(B)** Right and left mediolateral episiotomies.

**TABLE 14.4** SUMMARY OF ASSESSMENTS DURING THE SECOND, THIRD, AND FOURTH STAGES OF LABOR

Assessments*	Second Stage of Labor (Birth of Neonate)	Third Stage of Labor (Placenta Expulsion)	Fourth Stage of Labor (Recovery)
Vital signs (BP, pulse, respirations)	Every 5–15 min	Every 15 min	Every 15 min
Fetal heart rate	Every 5–15 min by Doppler or continuously by EFM	Apgar scoring at 1 and 5 min	Newborn—complete head-to-toe assessment; vital signs every 15 min until stable
Contractions/uterus	Palpate every one	Observe for placental separation	Palpating for firmness and position every 15 min for first hour
Bearing down/pushing	Assist with every effort	None	None
Vaginal discharge	Observe for signs of descent—bulging of perineum, crowning	Assess bleeding after expulsion	Assess every 15 min with fundus firmness
Behavior/psychosocial	Observe every 15 min: cooperative, focus is on work of pushing newborn out	Observe every 15 min: often feelings of relief after hearing newborn crying; calmer	Observe every 15 min: usually excited, talkative, awake; needs to hold newborn, be close, and inspect body

\*The frequency of assessments is dictated by the health status of the woman and fetus and can be altered if either one of their conditions changes. EFM, electronic fetal monitoring.

Adapted from Groll, K. G. (2012). *Fast facts for the labor and delivery nurse*. New York, NY: Springer; Institute for Clinical Systems Improvement [ICSI]. (2011). *ICSI health care guidelines: Management of labor*. Retrieved from [http://www.icsi.org/guidelines\\_and\\_more/gl\\_os\\_prot/womens\\_health/labor/labor\\_management\\_of\\_\\_2.html](http://www.icsi.org/guidelines_and_more/gl_os_prot/womens_health/labor/labor_management_of__2.html); and Mattson, S., & Smith, J. E. (2011). *Core curriculum for maternal–newborn nursing* (4th ed.). St. Louis, MO: Saunders Elsevier.

Other ongoing assessments include the contraction frequency, duration, and intensity; maternal vital signs every 5 to 15 minutes; fetal response to labor as indicated by FHR monitor strips; amniotic fluid for color, odor, and amount when membranes are ruptured; and the woman and her partner's coping status (Table 14.4).

Assessment also focuses on determining the progress of labor. Associated signs include bulging of the perineum, labial separation, advancing and retreating of the newborn's head during and between bearing-down efforts, and **crowning** (fetal head is visible at vaginal opening; Fig. 14.15).

A vaginal examination is completed to determine if it is appropriate for the woman to push. Pushing is appropriate if the cervix has fully dilated to 10 cm and the woman feels the urge to do so.

## Nursing Interventions

Nursing interventions during this stage focus on motivating the woman, encouraging her to put all her efforts to pushing this newborn to the outside world, and giving her feedback on her progress. If the woman is pushing and not making progress, suggest that she keep her eyes open during the contractions and look toward where the infant is coming out. Changing positions frequently will

also help in making progress. Positioning a mirror so the woman can visualize the birthing process and how successful her pushing efforts are can help motivate her.

During the second stage of labor, an ideal position would be one that opens the pelvic outlet as wide as possible, provides a smooth pathway for the fetus to descend through the birth canal, takes advantage of gravity to assist the fetus to descend, and gives the mother a sense of being safe and in control of the labor process (Steen, 2012). Some suggestions for positions in the second stage include:

- Lithotomy with feet up in stirrups: most convenient position for caregivers
- Semi-sitting with pillows underneath knees, arms, and back
- Lateral/side-lying with curved back and upper leg supported by partner
- Sitting on birthing stool: opens pelvis, enhances the pull of gravity, and helps with pushing
- Squatting/supported squatting: gives the woman a sense of control
- Kneeling with hands on bed and knees comfortably apart

Other important nursing interventions during the second stage include:

- Providing continuous comfort measures such as mouth care, encouraging position changes, changing bed

linen and underpads, and providing a quiet, focused environment

- Instructing the woman on the following bearing-down positions and techniques:
- Pushing only when she feels an urge to do so
- Delaying pushing for up to 90 minutes after complete dilation
  - Using abdominal muscles when bearing down
  - Using short pushes of 6 to 7 seconds
  - Focusing attention on the perineal area to visualize the newborn
  - Relaxing and conserving energy between contractions
  - Pushing several times with each contraction
  - Pushing with an open glottis and slight exhalation (Kelly et al., 2010)
- Continuing to monitor contraction and FHR patterns to identify problems
- Providing brief, explicit directions throughout this stage
- Continuing to provide psychosocial support by reassuring and coaching
- Facilitating the upright position to encourage the fetus to descend
- Continuing to assess blood pressure, pulse, respirations, uterine contractions, bearing-down efforts, FHR, and coping status of the client and her partner
- Providing pain management if needed
- Providing a continuous nursing presence
- Offering praise for the client's efforts
- Preparing for and assisting with delivery by:
  - Notifying the health care provider of the estimated time frame for birth

FIGURE 14.15 Crowning.

- Preparing the delivery bed and positioning client
- Preparing the perineal area according to the facility's protocol
- Offering a mirror and adjusting it so the woman can watch the birth
- Explaining all procedures and equipment to the client and her partner
- Setting up delivery instruments needed while maintaining sterility
- Receiving newborn and transporting him or her to a warming environment, or covering the newborn with a warmed blanket on the woman's abdomen
- Providing initial care and assessment of the newborn (see the Birth section that follows)

*Sheila is completely dilated now and experiencing the urge to push. How can the nurse help Sheila with her pushing efforts? What additional interventions can the labor nurse offer Sheila now?*

## Birth

The second stage of labor ends with the birth of the newborn. The maternal position for birth varies from the standard lithotomy position to side-lying to squatting to standing or kneeling, depending on the birthing location, the woman's preference, and standard protocols. Once the woman is positioned for birth, cleanse the vulva and perineal areas. The primary health care provider then takes charge after donning protective eyewear, masks, gowns, and gloves and performing hand hygiene.

Once the fetal head has emerged, the primary care provider explores the fetal neck to see if the umbilical cord is wrapped around it. If it is, the cord is slipped over the head to facilitate delivery. As soon as the head emerges, the health care provider suctions the newborn's mouth first (because the newborn is an obligate nose breather) and then the nares with a bulb syringe to prevent aspiration of mucus, amniotic fluid, or meconium (Fig. 14.16). The umbilical cord is double-clamped and cut between the clamps. With the first cries of the newborn, the second stage of labor ends. For care of the woman undergoing a surgical birth, the reader is referred to Chapter 21.

*In addition to encouraging Sheila to rest between pushing and offering praise for her efforts, what is the nurse's role during the birthing process?*

**FIGURE 14.16** Suctioning the newborn immediately after birth.

### Immediate Care of the Newborn

Once birth takes place, the newborn is placed under a radiant warmer, dried, assessed, wrapped in warmed blankets, and placed on the woman's abdomen for warmth and closeness. In some health care facilities, the newborn is placed on the woman's abdomen immediately after birth and covered with a warmed blanket without being dried or assessed. In either scenario, the stability of the newborn dictates the location of aftercare. The nurse can also assist the mother with breast-feeding her newborn for the first time.

Assessment of the newborn begins at the moment of birth and continues until the newborn is discharged. Drying the newborn and providing warmth to prevent heat loss by evaporation is essential to help support thermoregulation and provide stimulation. Placing the newborn under a radiant heat source and putting on a stockinette cap will further reduce heat loss after drying.

Assess the newborn by assigning an Apgar score at 1 and 5 minutes. The Apgar score assesses five parameters—heart rate (absent, slow, or fast), respiratory effort (absent, weak cry, or good strong yell), muscle tone (limp, or lively and active), response to irritation

**FIGURE 14.17** An example of a security sensor applied to a newborn's arm.

stimulus, and color—that evaluate a newborn's cardio-respiratory adaptation after birth. The parameters are arranged from the most important (heart rate) to the least important (color). The newborn is assigned a score of 0 to 2 in each of the five parameters. The purpose of the Apgar assessment is to evaluate the physiologic status of the newborn; see Chapter 18 for additional information on Apgar scoring.

Secure two identification bands on the newborn's wrist and ankle that match the band on the mother's wrist to ensure the newborn's identity. This identification process is completed in the birthing suite before anyone leaves the room. Some health care agencies also take an early photo of the newborn for identification in the event of abduction (National Center for Missing and Exploited Children [NCMEC], 2009).

Other types of newborn security systems can also be used to prevent abduction. Some systems have sensors that are attached to the newborn's identification bracelet or cord clamp. An alarm is set off if the bracelet or clamp activates receivers near exits. Others have an alarm that is activated when the sensor is removed from the newborn (Fig. 14.17). Even with the use of electronic sensors, the parents, nursing staff, and security personnel are responsible for prevention strategies and ensuring the safety and protection of all newborns (NCMEC, 2009). Nurses can help in preventing newborn abduction by educating parents about abduction risks, using identically numbered bands on the baby and parents, taking color photographs of the infant, wearing color photograph ID badges themselves, discouraging parents/families from publishing birth notices in the public media, controlling access to nursery/postpartum unit, and utilizing infant security tags or abduction alarm systems (McChesney, & Moore, 2011).

*Sheila gave birth to a healthy 7-pound, 7-ounce baby girl. She is eager to hold and nurse her newborn. What is the initial care of the newborn? How can the nurse meet the needs of both the newborn and Sheila, who is exhausted but eager to bond with her newborn?*

## Nursing Management During the Third Stage of Labor

During the third stage of labor, strong uterine contractions continue at regular intervals under the continuing influence of oxytocin. The uterine muscle fibers shorten, or retract, with each contraction, leading to a gradual decrease in the size of the uterus, which helps shear the placenta away from its attachment site. The third stage is complete when the placenta is delivered. Nursing care during the third stage of labor primarily focuses on immediate newborn care and assessment and being available to assist with the delivery of the placenta and inspecting it for intactness.

Three hormones play important roles in the third stage. During this stage the woman experiences peak levels of oxytocin and endorphins, while the high adrenaline levels that occurred during the second stage of labor to aid with pushing begin falling. The hormone oxytocin causes uterine contractions and helps the woman to enact instinctive mothering behaviors such as holding the newborn close to her body and cuddling the baby.

Skin-to-skin contact immediately after birth and the newborn's first attempt at breast-feeding further augment maternal oxytocin levels, strengthening the uterine contractions that will help the placenta to separate and the uterus to contract to prevent hemorrhage. Endorphins, the body's

natural opiates, produce an altered state of consciousness and aid in blocking out pain. In addition, the drop in adrenaline level from the second stage, which had kept the mother and baby alert at first contact, causes most women to shiver and feel cold shortly after giving birth.

### Take Note!

A crucial role for nurses during this time is to protect the natural hormonal process by ensuring unhurried and uninterrupted contact between mother and newborn after birth, providing warmed blankets to prevent shivering, and allowing skin-to-skin contact and breast-feeding.

## Assessment

Assessment during the third stage of labor includes:

- Monitoring placental separation by looking for the following signs:
  - Firmly contracting uterus
  - Change in uterine shape from discoid to globular ovoid
  - Sudden gush of dark blood from vaginal opening
  - Lengthening of umbilical cord protruding from vagina
- Examining placenta and fetal membranes for intactness the second time (the health care provider assesses the placenta for intactness the first time) (Fig. 14.18)
- Assessing for any perineal trauma, such as the following, before allowing the birth attendant to leave:
  - Firm fundus with bright-red blood trickling: laceration
  - Boggy fundus with red blood flowing: uterine atony
  - Boggy fundus with dark blood and clots: retained placenta
- Inspecting the perineum for condition of episiotomy, if performed
- Assessing for perineal lacerations and ensuring repair by birth attendant

FIGURE 14.18 Placenta. (A) Fetal side. (B) Maternal side.

## Nursing Interventions

Interventions during the third stage of labor include:

- Describing the process of placental separation to the couple
- Instructing the woman to push when signs of separation are apparent
- Administering an oxytocic agent if ordered and indicated after placental expulsion
- Providing support and information about episiotomy and/or laceration
- Cleaning and assisting client into a comfortable position after birth, making sure to lift both legs out of stirrups (if used) simultaneously to prevent strain
- Repositioning the birthing bed to serve as a recovery bed if applicable
- Assisting with transfer to the recovery area if applicable
- Providing warmth by replacing warmed blankets over the woman
- Applying an ice pack to the perineal area to provide comfort to episiotomy if indicated
- Explaining what assessments will be carried out over the next hour and offering positive reinforcement for actions
- Ascertaining any needs
- Monitoring maternal physical status by assessing:
  - Vaginal bleeding: amount, consistency, and color
  - Vital signs: blood pressure, pulse, and respirations taken every 15 minutes
  - Uterine fundus, which should be firm, in the midline, and at the level of the umbilicus
- Recording all birthing statistics and securing primary caregiver's signature
- Documenting birthing event in the birth book (official record of the facility that outlines every birth event), detailing any deviations

### Nursing Management During the Fourth Stage of Labor

The fourth stage of labor begins after the placenta is expelled and lasts up to 4 hours after birth, during which time recovery takes place. This recovery period may take place in the same room where the woman gave birth, in a separate recovery area, or in her postpartum room. During this stage, the woman's body is beginning to undergo the many physiologic and psychological changes that occur after birth. The focus of nursing management during the fourth stage of labor involves frequent close observation for hemorrhage, provision of comfort measures, and promotion of family attachment.

## Assessment

Assessments during the fourth stage center on the woman's vital signs, status of the uterine fundus and perineal

area, comfort level, lochia amount, and bladder status. During the first hour after birth, vital signs are taken every 15 minutes, then every 30 minutes for the next hour if needed. The woman's blood pressure should remain stable and within normal range after giving birth. A decrease may indicate uterine hemorrhage; an elevation might suggest preeclampsia.

The pulse usually is typically slower (60 to 70 bpm) than during labor. This may be associated with a decrease in blood volume following placental separation. An elevated pulse rate may be an early sign of blood loss. The blood pressure usually returns to its prepregnancy level and therefore is not a reliable early indicator of shock. Fever is indicative of dehydration (less than 100.4° F or 38° C) or infection (above 101° F), which may involve the genitourinary tract. Respiratory rate is usually between 16 and 24 breaths per minute and regular. Respirations should be unlabored unless there is an underlying preexisting respiratory condition.

Assess fundal height, position, and firmness every 15 minutes during the first hour following birth. The fundus needs to remain firm to prevent excessive postpartum bleeding. The fundus should be firm (feels like the size and consistency of a grapefruit), located in the midline and below the umbilicus. If it is not firm (boggy), gently massage it until it is firm (see Nursing Procedure 22.1 for more information). Once firmness is obtained, stop massaging.

### Take Note!

If the fundus is displaced to the right of the midline, suspect a full bladder as the cause.

The vagina and perineal areas are quite stretched and edematous following a vaginal birth. Assess the perineum, including the episiotomy if present, for possible hematoma formation. Suspect a hematoma if the woman reports excruciating pain or cannot void or if a mass is noted in the perineal area. Also assess for hemorrhoids, which can cause discomfort.

Assess the woman's comfort level frequently to determine the need for analgesia. Ask the woman to rate her pain on a scale of 1 to 10; it should be less than 3. If it is higher, further evaluation is needed to make sure there aren't any deviations contributing to her discomfort.

Assess vaginal discharge (lochia) every 15 minutes for the first hour and every 30 minutes for the next hour. Palpate the fundus at the same time to ascertain its firmness and help to estimate the amount of vaginal discharge. In addition, palpate the bladder for fullness, since many women receiving an epidural block experience limited sensation in the bladder region. Voiding should produce large amounts of urine (diuresis) each time. Palpation of the woman's bladder after each

voiding helps to ensure complete emptying. A full bladder will displace the uterus to either side of the midline and potentiate uterine hemorrhage secondary to bogginess.

## Nursing Interventions

Nursing interventions during the fourth stage might include:

- Providing support and information to the woman regarding episiotomy repair and related pain relief and self-care measures
- Applying an ice pack to the perineum to promote comfort and reduce swelling
- Assisting with hygiene and perineal care; teaching the woman how to use the perineal bottle after each pad change and voiding; helping the woman into a new gown
- Monitoring for return of sensation and ability to void (if regional anesthesia was used)
- Encouraging the woman to void by ambulating to the bathroom, listening to running water, or pouring warm water over the perineal area with the peribottle
- Monitoring vital signs and fundal and lochia status every 15 minutes and documenting them
- Promoting comfort by offering analgesia for afterpains and warm blankets to reduce chilling
- Offering fluids and nourishment if desired
- Encouraging parent–infant attachment by providing privacy for the family
- Being knowledgeable about and sensitive to typical cultural practices after birth
- Assisting the mother to nurse, if she chooses, during the recovery period to promote uterine firmness (the release of oxytocin from the posterior pituitary gland stimulates uterine contractions)
- Teaching the woman how to assess her fundus for firmness periodically and to massage it if it is boggy
- Describing the lochia flow and normal parameters to observe for postpartum
- Teaching safety techniques to prevent newborn abduction
- Demonstrating the use of the portable sitz bath as a comfort measure for her perineum if she had a laceration or an episiotomy repair
- Explaining comfort/hygiene measures and when to use them
- Assisting with ambulation when getting out of bed for the first time
- Providing information about the routine on the mother–baby unit or nursery for her stay
- Observing for signs of early parent–infant attachment: fingertip touch to palm touch to enfolding of the infant (Leonard, 2012)

## KEY CONCEPTS

- A nurse provides physical and emotional support during the labor and birth process to assist a woman to achieve her goals.
- When a woman is admitted to the labor and birth area, the admitting nurse must assess and evaluate the risk status of the pregnancy and initiate appropriate interventions to provide optimal care for the client.
- Completing an admission assessment includes taking a maternal health history; performing a physical assessment on the woman and fetus, including her emotional and psychosocial status; and obtaining the necessary laboratory studies.
- The nurse's role in fetal assessment for labor and birth includes determining fetal well-being and interpreting signs and symptoms of possible compromise. Determining the fetal heart rate (FHR) pattern and assessing amniotic fluid characteristics are key.
- FHR can be assessed intermittently or continuously. Although the intermittent method allows the client to move about during labor, the information obtained intermittently does not provide a complete picture of fetal well-being from moment to moment.
- Assessment parameters of the FHR are classified as baseline rate, baseline variability, and periodic changes in the rate (accelerations and decelerations).
- The nurse monitoring the laboring client needs to be knowledgeable about which category the FHR pattern is in so that appropriate interventions can be instituted.
- For a category III FHR pattern, the nurse should notify the health care provider about the pattern and obtain further orders, making sure to document all interventions and their effects on the FHR pattern.
- In addition to interpreting assessment findings and initiating appropriate interventions for the laboring client, accurate and timely documentation must be carried out continuously.
- Today's women have many safe nonpharmacologic and pharmacologic choices for the management of pain during childbirth. They may be used individually or in combination to complement one another.
- Nursing management for the woman during labor and birth includes comfort measures, emotional support, information and instruction, advocacy, and support for the partner.
- Nursing care during the first stage of labor includes taking an admission history (reviewing the prenatal

record), checking the results of routine laboratory work and special tests done during pregnancy, asking the woman about her childbirth preparation (birth plan, classes taken, coping skills), and completing a physical assessment of the woman to establish baseline values for future comparison.

- Nursing care during the second stage of labor focuses on supporting the woman and her partner in making decisions about her care and labor management, implementing strategies to prolong the early passive phase of fetal descent, supporting involuntary bearing-down efforts, providing support and assistance, and encouraging the use of maternal positions that can enhance descent and reduce the pain.
- Nursing care during the third stage of labor primarily focuses on immediate newborn care and assessment and being available to assist with the delivery of the placenta and inspecting it for intactness.
- The focus of nursing management during the fourth stage of labor involves frequently observing the mother for hemorrhage, providing comfort measures, and promoting family attachment.

## MULTIPLE-CHOICE QUESTIONS

- When a client in labor is fully dilated, which instruction would be most effective to assist her in encouraging effective pushing?
  - Hold your breath and push through entire contraction.
  - Use chest-breathing with the contraction.
  - Pant and blow during each contraction.
  - Instruct her to wait until she feels the urge to push.
- During the fourth stage of labor, the nurse assesses the woman at frequent intervals after giving childbirth. What assessment data would cause the nurse the most concern?
  - Moderate amount of dark red lochia drainage on peripad
  - Uterine fundus palpated to the right of the umbilicus
  - An oral temperature reading of 100.6° F
  - Perineal area bruised and edematous beneath her ice pack
- When managing a client's pain during labor, nurses should:
  - Make sure the agents given do not prolong labor
  - Know that all pain relief measures are similar
  - Support the client's decisions and requests
  - Not recommend nonpharmacologic methods
- When caring for a client during the active phase of labor without continuous electronic fetal monitoring, the nurse would intermittently assess FHR every:
  - 15 to 30 minutes
  - 5 to 10 minutes
  - 45 to 60 minutes
  - 60 to 75 minutes
- The nurse notes the presence of transient fetal accelerations on the fetal monitoring strip. Which intervention would be most appropriate?
  - Reposition the client on the left side.
  - Begin 100% oxygen via face mask.
  - Document this normal pattern.
  - Call the health care provider immediately.

## CRITICAL THINKING EXERCISES

- Carrie, a 20-year-old primigravida at term, comes to the birthing center in active labor (dilation 5 cm and 80% effaced, -1 station) with ruptured membranes. She states she wants an "all-natural" birth without medication. Her partner is with her and appears anxious but supportive. On the admission assessment, Carrie's prenatal history is unremarkable; vital signs are within normal limits; FHR via Doppler ranges between 140 and 144 bpm and is regular.
  - Based on your assessment data and the woman's request not to have medication, what nonpharmacologic interventions could you offer her?
  - What positions might be suggested to facilitate fetal descent?
- Several hours later, Carrie complains of nausea and turns to her partner and angrily tells him to not touch her and to go away.
  - What assessment needs to be done to determine what is happening?
  - What explanation can you offer Carrie's partner regarding her change in behavior?

## STUDY ACTIVITIES

- Share experiences within a postclinical conference group regarding the pain management interventions of the clients to which you were assigned. Compare and evaluate the effectiveness of different methods used, maternal behavior observed, and neonatal outcome in terms of Apgar scores.
- On the fetal heart monitor, the nurse notices an elevation of the fetal baseline with the onset of contractions. This elevation would describe \_\_\_\_\_.
- Compare and contrast a local birthing center to a community hospital's birthing suite in terms of the pain management techniques and fetal monitoring used.
- Select a childbirth website for expectant parents and critique the information provided in terms of its educational level and amount of advertising.

puerperium  
taking-hold phase  
taking-in phase  
uterine atony

## Postpartum Adaptations

### Learning Objectives

*Upon completion of the chapter, you will be able to:*

- 1.** Define the key terms used in this chapter.
- 2.** Examine the systemic physiologic changes occurring in the woman after childbirth.
- 3.** Assess the phases of maternal role adjustment and accompanying behaviors.
- 4.** Analyze the psychological adaptations occurring in the mother's partner after childbirth.

*Betsy had been home only 3 days when she called the OB unit where she had given birth and asked to speak to the lactation consultant. She reported pain in both breasts. Her nipples were tender due to frequent breast-feeding and she described her breasts as heavy, hard, and swollen.*

#### **Words of Wisdom**

A new mother's expectations are seen through rose-colored glasses, and at times her fantasy is better than the reality.

The postpartum period is a critical transitional time for a woman, her newborn, and her family on physiologic and psychological levels. The **puerperium** period begins after the delivery of the placenta and lasts approximately 6 weeks. During this period the woman's body begins to return to its prepregnant state, and these changes generally resolve by the sixth week after giving birth. However, the postpartum period can also be defined to include the changes in all aspects of the mother's life that occur during the first year after a child is born. Some believe that the postpartum adjustment period lasts well into the first year, making the fourth phase of labor the longest. Keeping this in mind, the true postpartum period may last between 9 and 12 months as the mother works to lose the weight she gained while pregnant, adjusts psychologically to the changes in her life, and takes on the new role of mother.

Nurses caring for childbearing families should consider all aspects of culture, including communication, space, and family roles. Communication encompasses an understanding of not only a person's language, and loudness of speech, but also the meaning of touch and gestures. The concept of personal space and the dimensions of comfort zones differ from culture to culture. Touching, placing clients in proximity to others, and taking away personal possessions can reduce client's personal security and heighten their anxiety. Nurses must be sensitive to how people respond when being touched and should refrain from touching if the client's response indicates that it is unwelcome. Cultural norms also have an impact on family roles, expectations, and behaviors associated with a member's position in the family. For example, culture may influence whether a man actively participates in the pregnancy and childbirth. Maternity health care professionals in the United States expect men to be involved, but this role expectation may conflict with that of many of the diverse groups now living in the United States. Mexican Americans, Arab Americans, Asian Americans, and Orthodox Jewish Americans, for example, usually view the birthing experience as a woman's affair (Lewallen, 2011).

Our major role as nurses is to provide safe and evidence-based care to promote optimal birth outcomes for all women, regardless of their cultural background. Nurses need to remember that there is more than one way to provide this care. Nurses are important cultural brokers as they welcome women and their families into our obstetrical units, where nurses share with those families one of the most intimate experiences of their lives (Sanchez-Birkhead, Kennedy, Callister, & Miyamoto, 2011).

This chapter describes the major physiologic and psychological changes that occur in a woman after childbirth. Various systemic adaptations take place throughout the woman's body. In addition, the mother and the family adjust to the new addition psychologically. The birth of a child changes the family structure and the roles of the

family members. The adaptations are dynamic and continue to evolve as physical changes occur and new roles emerge.

## MATERNAL PHYSIOLOGIC ADAPTATIONS

During pregnancy, the woman's entire body changed to accommodate the needs of the growing fetus. After birth, the woman's body once again undergoes significant changes in all body systems to return her body to its prepregnant state.

### Reproductive System Adaptations

The reproductive system goes through tremendous adaptations to return to the prepregnancy state. All organs and tissues of the reproductive system are involved. The female reproductive system is unique in its capacity to remodel itself throughout the woman's reproductive life. The events after birth, with the shedding of the placenta and subsequent uterine involution, involve substantial tissue destruction and subsequent repair and remodeling. For example, the woman's menstrual cycle, interrupted during pregnancy, will begin to return several weeks after childbirth. The uterus, which has undergone tremendous expansion during pregnancy to accommodate progressive fetal growth, will return to its prepregnant size over several weeks. The mother's breasts have grown to prepare for lactation and do not return to their prepregnant size as the uterus does.

#### Uterus

The uterus returns to its normal size through a gradual process of **involution**, which involves retrogressive changes that return it to its nonpregnant size and condition. Involution involves three retrogressive processes:

1. Contraction of muscle fibers to reduce those previously stretched during pregnancy
2. Catabolism, which reduces enlarged, individual myometrial cells
3. Regeneration of uterine epithelium from the lower layer of the decidua after the upper layers have been sloughed off and shed during lochial discharge (Bae, Ahn, Oh, Kim, & Hong, 2012).

The uterus, which weighs approximately 1,000 g (2.2 lb) soon after birth, undergoes physiologic involution as it returns to its nonpregnant state. Approximately 1 week after birth, the uterus shrinks in size by 50% and weighs about 500 g (1 lb); at the end of 6 weeks, it weighs approximately 60 g (2 oz), about the weight before the pregnancy (Mattson & Smith, 2011) (Fig. 15.1). During the first few days after birth, the uterus typically

FIGURE 15.1 Uterine involution.

descends from the level of the umbilicus at a rate of 1 cm (1 fingerbreadth) per day. By 3 days, the fundus lays 2 to 3 fingerbreadths below the umbilicus (or slightly higher in multiparous women). By the end of 10 days, the fundus usually cannot be palpated because it has descended into the true pelvis.

If these retrogressive changes do not occur as a result of retained placental fragments or infection, subinvolution of the uterus results. Subinvolution is generally responsive to early diagnosis and treatment. Factors that facilitate uterine involution include complete expulsion of amniotic membranes and placenta at birth, a complication-free labor and birth process, breast-feeding, and early ambulation. Factors that inhibit involution include a prolonged labor and difficult birth, incomplete expulsion of amniotic membranes and placenta, uterine infection, overdistention of uterine muscles (such as by multiple gestation, hydramnios, or a large singleton fetus), a full bladder (which displaces the uterus and interferes with contractions), anesthesia (which relaxes uterine muscles), and close child-birth spacing (frequent and repeated distention decreases tone and causes muscular relaxation).

## LOCHIA

**Lochia** is the vaginal discharge that occurs after birth. It results from involution, during which the superficial layer of the decidua basalis becomes necrotic and is sloughed off. Immediately after childbirth, lochia is bright red and consists mainly of blood, fibrinous products, decidual cells, and red and white blood cells. The lochia from the uterus is alkaline but becomes acidic as it passes through the vagina. It is roughly equal to the amount occurring during a heavy menstrual period. The average amount of

lochial discharge is 240 to 270 mL (8 to 9 oz) (Bope & Kellerman, 2012).

Women who have had cesarean births tend to have less flow because the uterine debris is removed manually along with delivery of the placenta. Lochia is present in most women for at least 3 weeks after childbirth, but it persists in some women for as long as 6 weeks.

Lochia passes through three stages:

- *Lochia rubra* is a deep-red mixture of mucus, tissue debris, and blood that occurs for the first 3 to 4 days after birth. As uterine bleeding subsides, it becomes paler and more serous.
- *Lochia serosa* is the second stage. It is pinkish brown and is expelled 3 to 10 days postpartum. Lochia serosa primarily contains leukocytes, decidual tissue, red blood cells, and serous fluid.
- *Lochia alba* is the final stage. The discharge is creamy white or light brown and consists of leukocytes, decidual tissue, and reduced fluid content. It occurs from days 10 to 14 but can last 3 to 6 weeks postpartum in some women and still be considered normal.

Lochia at any stage should have a fleshy smell; an offensive odor usually indicates an infection, such as endometritis.

### Take Note!

A danger sign is the reappearance of bright-red blood after lochia rubra has stopped. Reevaluation by a health care professional is essential if this occurs.

## AFTERPAINS

Part of the involution process involves uterine contractions. Subsequently, many women are frequently bothered by painful uterine contractions termed *afterpains*. All women experience afterpains, but they are more acute in multiparous and breast-feeding women secondary to repeated stretching of the uterine muscles from multiple pregnancies or stimulation during breast-feeding with oxytocin released from the pituitary gland. Primiparous women typically experience mild afterpains because their uterus is able to maintain a contracted state. Breast-feeding and administration of exogenous oxytocin both cause powerful and painful uterine contractions. Afterpains usually respond to oral analgesics.

### Take Note!

Afterpains are usually stronger during breast-feeding because oxytocin released by the sucking reflex strengthens the contractions. Mild analgesics can reduce this discomfort.

## Cervix

The cervix typically returns to its prepregnant state by week 6 of the postpartum period. The cervix gradually

closes but never regains its prepregnant appearance. Immediately after childbirth, the cervix is shapeless and edematous and is easily distensible for several days. The cervical os gradually closes and returns to normal by 2 weeks, whereas the external os widens and never appears the same after childbirth. The external cervical os is no longer shaped like a circle, but instead appears as a jagged slit-like opening, often described as a “fish mouth” (Fig. 15.2).

## Vagina

Shortly after birth, the vaginal mucosa is edematous and thin, with few rugae. As ovarian function returns and estrogen production resumes, the mucosa thickens and rugae return in approximately 3 weeks. The vagina gapes at the opening and is generally lax. The vagina returns to its approximate prepregnant size by 6 to 8 weeks postpartum but will always remain a bit larger than it had been before pregnancy.

Normal mucus production and thickening of the vaginal mucosa usually return with ovulation. The vagina gradually decreases in size and regains tone over several weeks. By 3 to 4 weeks, the edema and vascularity have decreased. The vaginal epithelium is generally restored by 6 to 8 weeks postpartum (Schuiling, & Likis, 2013). Localized dryness and coital discomfort (dyspareunia) usually plague most women until menstruation returns. Water-soluble lubricants can reduce discomfort during intercourse.

## Perineum

The perineum is often edematous and bruised for the first day or two after birth. If the birth involved an episiotomy or laceration, complete healing may take as long as 4 to 6 months in the absence of complications at the site, such as hematoma or infection (Coad, & Dunstall, 2012). Perineal lacerations may extend into the anus and cause considerable discomfort for the mother when she is attempting to defecate or ambulate. The presence of

swollen hemorrhoids may also heighten discomfort. Local comfort measures such as ice packs, pouring warm water over the area via a peribottle, witch hazel pads, anesthetic sprays, and sitz baths can relieve pain. See Evidence-Based Practice 15.1.

Supportive tissues of the pelvic floor are stretched during the childbirth process, and restoring their tone may take up to 6 months. Pelvic relaxation can occur in any woman experiencing a vaginal birth. Nurses should encourage all women to practice Kegel exercises to improve pelvic floor tone, strengthen the perineal muscles, and promote healing.

### Take Note!

Failure to maintain and restore perineal muscular tone leads to urinary incontinence later in life for many women.

## Cardiovascular System Adaptations

The cardiovascular system undergoes dramatic changes after birth. During pregnancy, the heart is displaced slightly upward and to the left. This reverses as the uterus undergoes involution. Cardiac output remains high for the first few days postpartum and then gradually declines to nonpregnant values within 3 months of birth.

Blood volume, which increases substantially during pregnancy, drops rapidly after birth and returns to normal within 4 weeks postpartum (Jacob, 2012). The decrease in both cardiac output and blood volume reflects the birth-related blood loss (an average of 500 mL with a vaginal birth and 1,000 mL with a cesarean birth). Blood plasma volume is further reduced through diuresis, which occurs during the early postpartum period (Cheng, & Caughey, 2012). Despite the decrease in blood volume, the hematocrit level remains relatively stable and may even increase, reflecting the predominant loss of plasma. Thus, an acute decrease in hematocrit is not an expected finding and may indicate hemorrhage.

## Pulse and Blood Pressure

The increase in cardiac output and stroke volume during pregnancy begins to diminish after birth once the placenta has been delivered. This decrease in cardiac output is reflected in bradycardia (40 to 60 bpm) for up to the first 2 weeks postpartum. This slowing of the heart rate is related to the increased blood that flows back to the heart and to the central circulation after it is no longer perfusing the placenta. This increase in central circulation brings about an increased stroke volume and allows a slower heart rate to provide ample maternal

**FIGURE 15.2** Appearance of the cervical os. **(A)** Before the first pregnancy. **(B)** After pregnancy.

**EVIDENCE-BASED PRACTICE 15.1****DIET OR EXERCISE, OR BOTH, FOR WEIGHT REDUCTION IN POSTPARTUM WOMEN**

Women naturally gain weight during pregnancy and many gradually lose it afterward. Some women, though, find it difficult to lose the pregnancy-related weight during the postpartum period and there is concern that this may be a health risk. The retention of weight gained during pregnancy may contribute to obesity. Obesity in the general population increases the risk of diabetes, heart disease, and high blood pressure. It is suggested that women who return to their prepregnancy weight by about 6 months after childbirth have a lower risk of being overweight 10 years later. The objectives of this review were to evaluate the effect of diet, exercise, or both for weight reduction in women after childbirth, and to assess the impact of these interventions on maternal body composition, cardiorespiratory fitness, breast-feeding performance, and other child and maternal outcomes.

**STUDY**

All published and unpublished randomized controlled trials and quasi-randomized trials of diet or exercise or both among women during the postpartum period were reviewed. Six trials involving 245 women were included. Women who exercised did not lose significantly more weight than women in the usual care group (one trial;  $n = 33$ ; MD 0.00 kg; 95% confidence interval [CI]  $-8.63$  to  $8.63$ ). Women who took part in a diet (one trial;  $n = 45$ ; MD  $-1.70$  kg; 95% CI  $-2.08$  to  $-1.32$ ),

or diet plus exercise program (four trials;  $n = 169$ ; MD  $-2.89$  kg; 95% CI  $-4.83$  to  $-0.95$ ), lost significantly more weight than women in the usual care.

**Findings**

There was no difference in the magnitude of weight loss between diet and diet plus exercise group. The interventions seemed not to affect breast-feeding performance adversely. Preliminary evidence from this study suggests that both diet and exercise together and diet alone help women to lose weight after childbirth. Nevertheless, it may be preferable to lose weight through a combination of diet and exercise because this improves maternal cardiorespiratory fitness and preserves fat-free mass, while diet alone reduces fat-free mass. This needs confirmation in large trials.

**Nursing Implications**

Based on the findings of this study, nurses can recommend to their postpartum mothers desiring to lose their pregnancy weight to include diet and exercise in their weight loss plan. Breast-feeding mothers can be reassured that this dual weight loss plan will not impact their newborn breast-feeding practices negatively. Although the results are not conclusive without larger trials, nurses can feel confident enough to discuss this with their clients.

Adapted from Amorim A., Linne, A. R., & Lourenco, P. M. (2012). Diet or exercise, or both, for weight reduction in women after childbirth. *Cochrane Database of Systematic Reviews*, 2012(3). doi: 10.1002/14651858.CD005627.pub2.

circulation. Gradually, cardiac output returns to pre-pregnant levels by 3 months after childbirth (Estensen, Grindheim, & Remme, et al., 2012).

Tachycardia (heart rate above 100 bpm) in the postpartum woman warrants further investigation. It may indicate hypovolemia, dehydration, or hemorrhage. However, because of the increased blood volume during pregnancy, a considerable loss of blood may be well tolerated and not cause a compensatory cardiovascular response such as tachycardia. In most instances of postpartum hemorrhage, blood pressure and cardiac output remain increased because of the compensatory increase in heart rate. Thus, a decrease in blood pressure and cardiac output are not expected changes during the postpartum period. Early identification is essential to ensure prompt intervention.

Blood pressure values should be similar to those obtained during the labor process. In some women there may be a slight transient increase lasting for about a week after childbirth (Impey, & Child, 2012). A significant increase accompanied by headache might indicate preeclampsia and requires further investigation. Decreased blood pressure may suggest an infection or a uterine hemorrhage.

**Coagulation**

Normal physiologic changes of pregnancy, including alterations in hemostasis that favor coagulation, reduced fibrinolysis, and pooling and stasis of blood in the lower limbs, place women at risk for blood clots. Smoking, obesity, immobility, and postpartum factors such as infection, bleeding, and emergency surgery (including emergency cesarean section) also increase the risk of coagulation disorders (Tharpe, Farley, & Jordan, 2013).

Clotting factors that increased during pregnancy tend to remain elevated during the early postpartum period. Giving birth stimulates this hypercoagulability state further. As a result, these coagulation factors remain elevated for 2 to 3 weeks postpartum (Rubio-Jurado, Iniguez-Franco, & Reyes, et al., 2012). This hypercoagulable state, combined with vessel damage during birth and immobility, places the woman at risk for thromboembolism (blood clots) in the lower extremities and the lungs.

**Blood Cellular Components**

Red blood cell production ceases early in the puerperium, causing mean hemoglobin and hematocrit levels

to decrease slightly in the first 24 hours. During the next 2 weeks, both levels rise slowly. The white blood count, which increases in labor, remains elevated for first 4 to 6 days after birth but then falls to 6,000 to 10,000/mm<sup>3</sup>. This white blood cell elevation can complicate a diagnosis of infection in the immediate postpartum period.

## Urinary System Adaptations

Pregnancy and birth can have profound effects on the urinary system. During pregnancy, the glomerular filtration rate and renal plasma flow increase significantly. Both usually return to normal by 6 weeks after birth.

Many women have difficulty feeling the sensation to void after giving birth if they received an anesthetic block during labor (which inhibits neural functioning of the bladder) or if they received oxytocin to induce or augment their labor (antidiuretic effect). These women will be at risk for incomplete emptying, bladder distention, difficulty voiding, and urinary retention. In addition, urination may be impeded by:

- Perineal lacerations
- Generalized swelling and bruising of the perineum and tissues surrounding the urinary meatus
- Hematomas
- Decreased bladder tone as a result of regional anesthesia
- Diminished sensation of bladder pressure as a result of swelling, poor bladder tone, and numbing effects of regional anesthesia used during labor (Bope & Kellerman, 2012)

Difficulty voiding can lead to urinary retention, bladder distention, and ultimately urinary tract infection. Urinary retention and bladder distention can cause displacement of the uterus from the midline to the right and can inhibit the uterus from contracting properly, which increases the risk of postpartum hemorrhage. Urinary retention is a major cause of **uterine atony**, which allows excessive bleeding. Frequent voiding of small amounts (less than 150 mL) suggests urinary retention with overflow, and catheterization may be necessary to empty the bladder to restore tone.

Postpartum diuresis occurs as a result of several mechanisms: the large amounts of intravenous fluids given during labor, a decreasing antidiuretic effect of oxytocin as its level declines, the buildup and retention of extra fluids during pregnancy, and a decreasing production of aldosterone—the hormone that decreases sodium retention and increases urine production (Coad, & Dunstall, 2012). All of these factors contribute to rapid filling of the bladder within 12 hours of birth. Diuresis begins within 12 hours after childbirth and continues throughout the first week postpartum. Normal function returns within a month after birth (Mattson, & Smith, 2011).

### Consider This

Have you ever felt like a real idiot by not being able to complete a simple task in life? I had a beautiful baby boy after only 6 hours of labor. My epidural worked well and I actually felt very little discomfort throughout my labor. Because it was in the middle of the night when they brought me to my postpartum room, I felt a few hours of sleep would be all I needed to be back to normal. During an assessment early the next morning, the nurse found my uterus had shifted to the right from my midline, and I was instructed to empty my bladder. I didn't understand why the nurse was concerned about where my uterus was located and, besides, I didn't feel any sensation of a full bladder. But I did get up anyway and tried to comply. Despite all the nurse's tricks of running the faucet for sound effects, in addition to having warm water poured over my thighs via the peribottle, I was unable to urinate. How could I not accomplish one of life's simplest tasks?

Thoughts: Women who receive regional anesthesia frequently experience reduced sensation to their perineal area and do not feel a full bladder. The nursing assessment revealed a displaced uterus secondary to a full bladder. What additional "tricks" can be used to assist this woman to void? What explanation should be offered to her regarding why she is having difficulty urinating?

## Gastrointestinal System Adaptations

The gastrointestinal system quickly returns to normal after birth because the gravid uterus is no longer filling the abdominal cavity and producing pressure on the abdominal organs. Progesterone levels, which caused relaxation of smooth muscle during pregnancy and diminished bowel tone, also are declining.

Regardless of the type of delivery, most women experience decreased bowel tone and sluggish bowels for several days after birth. Decreased peristalsis occurs in response to analgesics, surgery, diminished intra-abdominal pressure, low-fiber diet, insufficient fluid intake, and diminished muscle tone. In addition, women with an episiotomy, perineal laceration, or hemorrhoids may fear pain or damage to the perineum with their first bowel movement and may attempt to delay it. Subsequently, constipation is a common problem during the postpartum period. A stool softener can be prescribed for this reason.

Most women are hungry and thirsty after childbirth, commonly related to NPO restrictions and the energy expended during labor. Their appetite returns to normal immediately after giving birth.

**Take Note!**

Anticipate the woman's need to replenish her body with food and fluids, and provide both soon after she gives birth.

## Musculoskeletal System Adaptations

The effects of pregnancy on the muscles and joints vary widely. Musculoskeletal changes associated with pregnancy, such as increased ligament laxity, weight gain, change in the center of gravity, and carpal tunnel syndrome, revert back during the postpartum period. During pregnancy, the hormones relaxin, estrogen, and progesterone relax the joints. After birth, levels of these hormones decline, resulting in a return of all joints to their prepregnant state, with the exception of the woman's feet. Parous women will note a permanent increase in their shoe size (Dunn, Dunn, Habbu, Bohay, & Anderson, 2012).

Woman commonly experience fatigue and activity intolerance and have a distorted body image for weeks after birth secondary to declining relaxin and progesterone levels, which cause hip and joint pain that interferes with ambulation and exercise. Good body mechanics and correct positioning are important during this time to prevent low back pain and injury to the joints. Within 6 to 8 weeks after delivery, joints are completely stabilized and return to normal.

During pregnancy, stretching of the abdominal wall muscles occurs to accommodate the enlarging uterus. This stretching leads to a loss in muscle tone and possibly separation of the longitudinal muscles (rectus abdominis muscles) of the abdomen. Separation of the rectus abdominis muscles, called diastasis recti, is more common in women who have poor abdominal muscle tone before pregnancy. After birth, muscle tone is diminished and the abdominal muscles are soft and flabby. Specific exercises are necessary to help the woman regain muscle tone. Fortunately, diastasis responds well to exercise, and abdominal muscle tone can be improved. (See Chapter 16 for more information about exercises to improve muscle tone.)

**Take Note!**

If rectus muscle tone is not regained through exercise, support may not be adequate during future pregnancies.

## Integumentary System Adaptations

Another system that experiences lasting effects of pregnancy is the integumentary system. As estrogen and progesterone levels decrease, the darkened pigmentation on the abdomen (linea nigra), face (melasma), and nipples gradually fades. Some women experience hair loss during pregnancy and the postpartum periods.

Approximately 90% of hairs are growing at any one time, with the other 10% entering a resting phase. Because of the high estrogen levels present during pregnancy, an increased number of hairs go into the resting phase, which is part of the normal hair loss cycle. The most common period for hair loss is within 3 months after birth, when estrogen returns to normal levels and more hairs are allowed to fall out. This hair loss is temporary, and regrowth generally returns to normal levels in 4 to 6 months in two thirds of women and by 15 months in the remainder, although hair may be less abundant than before pregnancy (Blackburn, 2013).

Striae gravidarum (stretch marks) that developed during pregnancy on the breasts, abdomen, and hips gradually fade to silvery lines. However, these lines do not disappear completely. Although many products on the market claim to make stretch marks disappear, their effectiveness is highly questionable.

The profuse diaphoresis (sweating) that is common during the early postpartum period is one of the most noticeable adaptations in the integumentary system. Many women will wake up drenched with perspiration during the puerperium. This postpartum diaphoresis is a mechanism to reduce the amount of fluids retained during pregnancy and restore prepregnant body fluid levels. It can be profuse at times. It is common, especially at night during the first week after birth. Reassure the client that this is normal and encourage her to change her gown to prevent chilling.

## Respiratory System Adaptations

Respirations usually remain within the normal adult range of 16 to 24 breaths per minute. As the abdominal organs resume their nonpregnant position, the diaphragm returns to its usual position. Anatomic changes in the thoracic cavity and rib cage caused by increasing uterine growth resolve quickly. As a result, discomforts such as shortness of breath and rib aches are relieved. Tidal volume, minute volume, vital capacity, and functional residual capacity return to prepregnant values, typically within 1 to 3 weeks of birth (Chelmow, O'Grady, & Guzman, 2011).

## Endocrine System Adaptations

The endocrine system rapidly undergoes several changes after birth. Levels of circulating estrogen and progesterone drop quickly with delivery of the placenta. Decreased estrogen levels are associated with breast engorgement and with the diuresis of excess extracellular fluid accumulated during pregnancy (Tharpe, Farley, & Jordan, 2013). Estrogen is at its lowest level a week after birth. For the woman who is not breast-feeding, estrogen levels begin to increase by 2 weeks after birth. For the breast-feeding woman, estrogen levels remain low until breast-feeding frequency decreases.

Other placental hormones (human chorionic gonadotropin [hCG], human placental lactogen [hPL], progesterone) decline rapidly after birth. hCG levels are nonexistent at the end of the first postpartum week, and hPL is undetectable within 1 day after birth (Mattson & Smith, 2011). Progesterone levels are undetectable by 3 days after childbirth, and production is reestablished with the first menses. Prolactin levels decline within 2 weeks for the woman who is not breast-feeding, but remain elevated for the lactating woman (Chelmow et al., 2011).

*Think back to Betsy, the woman experiencing painful changes in her breasts. What is Betsy describing to the lactation consultant? Why has the condition of her breasts changed compared to when she was in the hospital?*

### Global Health of Childbearing Women

Globalization has changed our society in numerous ways, yet the health of women is remaining stagnant or growing worse in many parts of the world. Many women in developing countries are denied their fundamental right to enjoy a complete state of health as defined by the World Health Organization (Christler, 2012). More than half a million women die each year from complications during and after childbirth, the vast majority of them in Africa and Asia (Murthy, & Smith, 2010).

Women throughout the world continue to face enormous obstacles in attempting to access obstetric care. Nurses throughout the world can help advocate for cost-effective, evidence-based interventions to prevent and battle complications from childbirth to save women's lives. The challenge is to guarantee that every pregnant woman who needs care gets it. Nurses can make a difference outside their own country's borders by advocating for all international women through their governmental political systems and encouraging those governments to offer help and save lives.

### Lactation

**Lactation** is the secretion of milk by the breasts. It is thought to be brought about by the interaction of progesterone, estrogen, prolactin, and oxytocin. Breast milk typically appears within 4 to 5 days after childbirth.

During pregnancy, the breasts increase in size and functional ability in preparation for breast-feeding. Estrogen stimulates growth of the milk collection (ductal) system, whereas progesterone stimulates growth of the milk production system. Within the first month of gestation, the ducts of the mammary glands grow branches, forming more lobules and alveoli. These structural changes make the breasts larger, more tender, and heavy. Each

breast gains nearly 1 lb in weight by term, the glandular cells fill with secretions, blood vessels increase in number, and the amounts of connective tissue and fat cells increase (Coad, & Dunstall, 2012).

Prolactin from the anterior pituitary gland, secreted in increasing levels throughout pregnancy, triggers the synthesis and secretion of milk after the woman gives birth. During pregnancy, prolactin, estrogen, and progesterone cause synthesis and secretion of colostrum, which contains protein and carbohydrate but no milk fat. It is only after birth takes place, when the high levels of estrogen and progesterone are abruptly withdrawn, that prolactin is able to stimulate the glandular cells to secrete milk instead of colostrum. This takes place within 4 to 5 days after giving birth. Oxytocin acts so that milk can be ejected from the alveoli to the nipple. Therefore, sucking by the newborn will release milk. A decrease in the quality of stimulation causes a decrease in prolactin surges and thus a decrease in milk production. Prolactin levels increase in response to nipple stimulation during feedings. Prolactin and oxytocin result in milk production if stimulated by sucking (Gardner, Carter, Enzman-Hines, & Hernandez, 2011) (Fig. 15.3). If the stimulus (sucking) is not present, as with a woman who is not breast-feeding, breast engorgement and milk production will subside within days postpartum.

Researchers realizing a newborn instinct they named the *breast crawl* that helps initiate breast-feeding immediately after childbirth. This instinct arises occurs when a newborn, left undisturbed and skin-to-skin on the mother's trunk following birth, moves toward her mother's breast for the purpose of locating and self-attaching for the first feeding. From there, the newborn uses leg and arm movements to propel herself toward the breast. Upon reaching the sternum, the newborn will bounce her head up and down and side to side. As the newborn approaches the nipple, her mouth opens and, after several attempts, latch-on and suckling take place. Newborns have senses and skills that enable early initiation of feeding at the breast. Nurses can help facilitate the breast crawl as a continuation of the birthing process. Nurses have a responsibility to promote the health of their childbearing families and provide evidence-based care. Encouraging use of the breast crawl can be the first step in health promotion for every newborn (Henderson, 2011).

Breast milk production can be summarized as follows:

- Prolactin levels increase at term with a decrease in estrogen and progesterone levels.
- Estrogen and progesterone levels decrease after the placenta is delivered.
- Prolactin is released from the anterior pituitary gland and initiates milk production.
- Oxytocin is released from the posterior pituitary gland to promote milk let-down.
- Infant sucking at each feeding provides continuous stimulus for prolactin and oxytocin release (Mattson, & Smith, 2011).

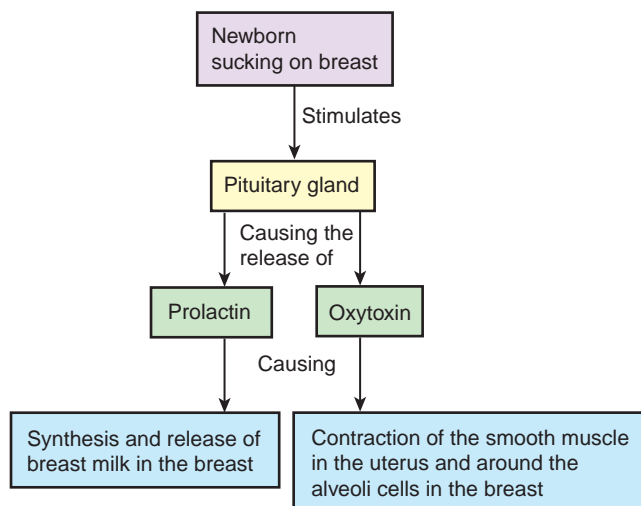

FIGURE 15.3 Physiology of lactation.

Typically, during the first 2 days after birth, the breasts are soft and nontender. The woman also may report a tingling sensation in both breasts, which is the let-down reflex that occurs immediately before or during breast-feeding. After this time, breast changes depend on

whether the mother is breast-feeding or taking measures to prevent lactation.

**Engorgement** is swelling of the breast tissue as a result of an increase in blood and lymph supply as a precursor to lactation (Fig. 15.4). Breast engorgement

FIGURE 15.4 (A) Image of engorged breasts. Note swelling and inflammation of both breasts. (B) Breast engorgement can disrupt breast-feeding: (1) When sucking at a normal breast, the infant's lips compress the areola and fit neatly against the sides of the nipple. The infant also has adequate room to breathe. (2) When a breast is engorged, however, the infant has difficulty grasping the nipple and breathing ability is compromised. (From Pillitteri, A. [2010], *Maternal and Child Nursing* (6th ed.), Philadelphia, PA: Lippincott Williams & Wilkins.)

usually peaks in 3 to 5 days postpartum and usually subsides within the following 24 to 36 hours (Chapman, 2011). Engorgement can occur from infrequent feeding or ineffective emptying of the breasts and typically lasts about 24 hours. Breasts increase in vascularity and swell in response to prolactin 2 to 4 days after birth. If engorged, the breasts will be hard and tender to touch. They are temporarily full, tender, and very uncomfortable until the milk supply is ready. Frequent emptying of the breasts helps to minimize discomfort and resolve engorgement. Standing in a warm shower or applying warm compresses immediately before feedings will help to soften the breasts and nipples in order to allow the newborn to latch on easier.

Treatments to reduce the pain of breast engorgement include heat or cold applications, cabbage leaf compresses, breast massage and milk expression, ultrasound, breast pumping, and anti-inflammatory agents (King, & Brucker, 2011). A nonprescription anti-inflammatory medication can also be taken for the breast discomfort and swelling resulting from engorgement. These measures will also enhance the let-down reflex. Between feedings, applying cold compresses to the breasts helps to reduce swelling. To maintain milk supply, the breasts need to be stimulated by a nursing infant, a breast pump, or manual expression of the milk (Fig. 15.5).

*Remember Betsy, with the breast discomfort? The lactation consultant explained that she was experiencing normal breast engorgement and offered several suggestions to help her. What relief measures might she have suggested? What reassurance can be given to Betsy at this time?*

**FIGURE 15.5** Nurse instructs the new breast-feeding mother about use of a breast pump. (Copyright B. Proud.)

Various pharmacologic and nonpharmacologic interventions have been used to suppress lactation after childbirth and relieve associated symptoms. Despite the large volume of literature on the subject, there is currently no universal guideline on the most appropriate approach for suppressing lactation in postpartum women (Oladapo, 2010). It is estimated that more than 30% of women in the United States do not breast-feed their infants, and a larger proportion discontinues breast-feeding within 2 weeks of childbirth (Karp, & Lutenbacher, 2011). Although physiologic cessation of lactation eventually occurs in the absence of physical stimulus such as infant suckling, a large number of women experience moderate to severe milk leakage and discomfort before lactation ceases.

Up to two thirds of non-breast-feeding women experience moderate to severe engorgement and breast pain when no treatment is applied (Chelmow et al., 2011).

If a woman is not breast-feeding, some relief measures include wearing a tight, supportive bra 24 hours daily, applying ice to her breasts for approximately 15 to 20 minutes every other hour, avoiding sexual stimulation, and not stimulating the breasts by squeezing or manually expressing milk from the nipples. In addition, avoiding exposing the breasts to warmth (e.g., a hot shower) will help relieve breast engorgement. In women who are not breast-feeding, engorgement typically subsides within 2 to 3 days with application of these measures.

### Ovulation and Return of Menstruation

Changing hormone levels constantly interact with one another to produce bodily changes. Four major hormones are influential during the postpartum period: estrogen, progesterone, prolactin, and oxytocin. Estrogen plays a major role during pregnancy, but levels drop profoundly at birth and reach their lowest level a week into the postpartum period. Progesterone quiets the uterus to prevent a preterm birth during pregnancy, and its increasing levels during pregnancy prevent lactation from starting before birth takes place. As with estrogen, progesterone levels decrease dramatically after birth and are undetectable 72 hours after birth. Progesterone levels are reestablished with the first menstrual cycle (Byrom et al., 2010).

During the postpartum period, oxytocin stimulates the uterus to contract during the breast-feeding session and for as long as 20 minutes after each feeding. Oxytocin also acts on the breast by eliciting the milk let-down reflex during breast-feeding. Prolactin is also associated with the breast-feeding process by stimulating milk production. In women who breast-feed, prolactin levels remain elevated into the sixth week after birth (Bope & Kellerman, 2012). The levels of the hormone increase and decrease in proportion to nipple stimulation. Prolactin levels decrease in non-lactating women, reaching prepregnant levels by the

third postpartum week. High levels of prolactin have been found to delay ovulation by inhibiting ovarian response to follicle-stimulating hormone (Jackson, & Glasier, 2011).

The timing of first menses and ovulation after birth differs between women who are breast-feeding and women who are not breast-feeding. For nonlactating women, menstruation may resume as early as 7 to 9 weeks after giving birth, but the majority take up to 3 months, with the first cycle being anovulatory (Mattson, & Smith, 2011). The return of menses in the lactating woman depends on breast-feeding frequency and duration. It can return anytime from 3 to 18 months after childbirth, depending on whether the woman is exclusively breast-feeding or supplementing with formula.

### Take Note!

Ovulation may occur before menstruation. Therefore, breast-feeding is not a totally reliable method of contraception unless the mother exclusively breast-feeds, has had no menstrual period since giving birth, and whose infant is younger than 6 months old (Queenan, 2012).

*Betsy tries several of the measures the lactation consultant suggested to relieve her breast discomfort, but is still having heaviness and pain. She feels discouraged and tells the nurse she is thinking of reducing her breast-feeding and using formula to feed her newborn. Is that a good choice? Why or why not? What interventions will help Betsy get through this difficult time?*

## CULTURAL CONSIDERATIONS FOR THE POSTPARTUM PERIOD

Nurses practice in an increasingly multicultural society. Therefore, they must be open, respectful, nonjudgmental, and willing to learn about ethnically diverse populations. Although childbirth and the postpartum period are unique experiences for each individual woman, how the woman perceives and makes meaning of them is culturally defined. Two areas that are significantly different from Western culture involve beliefs about the balance of hot and cold and confinement after childbirth (Purnell, 2012).

For many cultures, good health requires the balancing of hot and cold substances. Because childbirth involves the loss of blood, which is considered hot, the postpartum period is considered cold, so the mother must balance that with the intake of hot food. Foods consumed should be hot in nature, and cold foods, such as fruits

and vegetables, avoided. Western practices frequently use cold packs or sitz baths to reduce perineal swelling and discomfort. These practices are not acceptable to women of many cultures and can be viewed as harmful. Hot-cold beliefs are common among Latin American, African, and Asian people (Mattson, & Smith, 2011).

To reduce infant and mother vulnerability and potential illness, women may practice a monthlong confinement period after childbirth. During this confinement period, new mothers rest and recuperate. The postpartum period is a time to avoid cold—both in temperature and foods. Women are kept warm, stay inside to prevent becoming chilled, bathe infrequently, and avoid exercise (Etienne, & Pavlovich-Danis, 2010).

Postpartum nurses need to understand these diverse cultural beliefs and provide creative strategies for encouraging hygiene (sponge baths, perineal care), exercise, and balanced nutrition, while remaining respectful of the cultural significance of these practices. The best approach is to ask each woman to describe what cultural practices are important to her and plan accordingly.

## PSYCHOLOGICAL ADAPTATIONS

The process of becoming a mother requires extensive psychological, social, and physical work. Women experience heightened vulnerability and face tremendous challenges as they make this transition. Nurses have a remarkable opportunity to help women learn, gain confidence, and experience growth as they assume the mother identity.

Mothers' and fathers' experiences of pregnancy are necessarily different, and this difference continues after childbirth as they both adjust to their new parenting roles. Parenting involves caring for infants physically and emotionally to foster the growth and development of responsible, caring adults. During the early months of parenthood, mothers experience more life changes and get more satisfaction from their new roles than fathers. However, fathers interact with their newborns much like mothers (Tach, Mincy, & Edin, 2010). Other members of the newborn's family, such as siblings and grandparents, also experience changes related to the birth of the newborn (see Chapter 16). Early parent-infant contact after birth improves attachment behaviors.

## Parental Attachment Behaviors

The postpartum period is a unique time distinguished by the inseparable relationship parents have with their newborn. To enable an attachment to be built, closeness of this family unit is essential. **Attachment** is the formation of a relationship between a parent and his or her newborn through a process of physical and emotional interactions (Hammonds, 2012). Maternal attachment has the potential to affect both child development and parenting.

Attachment begins before birth, during the prenatal period where acceptance and nurturing of the growing fetus takes place. It continues after giving birth as parents learn to recognize their newborn's cues, adapt to the newborn's behaviors and responses, and meet their newborn's needs.

Early and sustained contact between newborns and their parents is vital for initiating their relationship. Nurses play a crucial role in assisting the attachment process by promoting early parent–newborn interactions. In addition, nurses can facilitate skin-to-skin contact (kangaroo care) by placing the infant onto the bare chests of mothers and fathers to enhance parent–newborn attachment. This activity will enable them to get close to their newborn and experience an intense feeling of connectedness and evoke feelings of being nurturing parents. Encouraging breast-feeding is another way to foster attachment between mothers and their newborns. Finally, nurses can encourage nurturing activities and contact such as touching, talking, singing, comforting, changing diapers, feeding—in short, participating in routine newborn care.

The process of attachment is complex and is influenced by many factors including environmental circumstances, the newborn's health status, and the quality of nursing care (Kearvell, & Grant, 2010). Nurses need to minimize parent–newborn separation by promoting parent–newborn interactions through kangaroo care, breast-feeding, and participation in their newborn care. Nurses who provide positive psychosocial support and clear communication to parents will help support the attachment process within family units.

## Maternal Psychological Adaptations

Childbirth is supposed to be the most joyous period in a woman's life and involves the almost spiritual experience of giving birth and being able to give life to another being. For many, this can be a life-changing event and through the centuries have been anticipated with excitement and joy and has even been referred to as a blessing. In reality, childbirth and child rearing are very stressful, financially challenging, and emotionally demanding.

In the postpartum period, mood disorders can be divided into three distinct entities in ascending order of severity: maternal (baby) blues, postpartum depression, and psychosis. These disorders, however, have not been clearly demarcated and it is a matter of much debate whether they are discrete disorders or a single disorder that ranges along a continuum of severity (Miles, 2011).

Many women experience the “maternal blues,” also known as the “baby blues,” which are characterized by mild depressive symptoms, anxiety, irritability, mood swings, tearfulness (often for no discernible reason), increased sensitivity, and fatigue. The “blues” typically peak

on postpartum days 4 and 5, may last hours to days, and usually resolve by day 10. Although these symptoms may be distressing, they do not reflect psychopathology, and they typically do not affect the mother's ability to function and care for her child.

Different from the baby blues, symptoms of postpartum depression last longer, are more severe, and require treatment. Some signs and symptoms of depression include feeling:

- Restless
- Worthless
- Guilty
- Hopeless
- Moody
- Sad
- Overwhelmed (Blackmore, & Chaudron, 2012).

Postpartum depression affects the transition to the maternal role for many mothers. Between 60% and 80% of new mothers suffer from the short-lived postpartum mood disorder termed “baby blues.” In addition, each year in the United States, about 15% of new mothers or more suffer debilitating postpartum depression, a prevalence that continues unabated (Joy, & Contag, 2012). There is growing evidence of the adverse impact of postpartum depression on the emotional, behavioral, and cognitive development of the newborn (Davalos, Yadon, & Tregellas, 2012). Behavior patterns of mothers experiencing postpartum depression, such as withdrawal and detachment, are likely to have a negative impact on the infant, which may lead to poor mother–baby bonding (Miles, 2011). Postpartum depression can lead to alienation from loved ones, daily dysfunction secondary to overwhelming sorrow and disorientation, and, at its most extreme, personal terror resulting in dangerous thoughts and violent actions. For additional information, see Chapter 22.

The woman experiences a variety of responses as she adjusts to a new family member and to postpartum discomforts, changes in her body image, and the reality of change in her life. In the early 1960s, Reva Rubin identified three phases that a mother goes through to adjust to her new maternal role. Rubin's maternal role framework can be used to monitor the client's progress as she “tries on” her new role as a mother. The absence of these processes or inability to progress through the phases satisfactorily may impede the appropriate development of the maternal role (Rubin, 1984). Although Rubin's maternal role development theories are of value, some of her observations regarding the length of each phase may not be completely relevant for the contemporary woman of the 21st century. Today, many women know their infant's gender, have “seen” their fetus in utero through four-dimensional ultrasound, and have a working knowledge of childbirth and child care. They are less passive than in years past and progress through the phases of attaining the maternal role at a much faster pace than Rubin

would have imagined. Still, Rubin's framework is timeless for assessing and monitoring expected role behaviors when planning care and appropriate interventions.

### Taking-In Phase

The **taking-in phase** is the time immediately after birth when the client needs sleep, depends on others to meet her needs, and relives the events surrounding the birth process. This phase is characterized by dependent behavior. During the first 24 to 48 hours after giving birth, mothers often assume a very passive role in meeting their own basic needs for food, fluids, and rest, allowing the nurse to make decisions for them concerning activities and care. They spend time recounting their labor experience to anyone who will listen. Such actions help the mother integrate the birth experience into reality—that is, the pregnancy is over and the newborn is now a unique individual, separate from herself. When interacting with the newborn, new mothers spend time claiming the newborn and touching him or her, commonly identifying specific features in the newborn, such as “he has my nose” or “his fingers are long like his father’s” (Fig. 15.6).

#### Take Note!

The taking-in phase typically lasts 1 to 2 days and may be the only phase observed by nurses in the hospital setting because of the shortened postpartum stays that are the norm today.

### Taking-Hold Phase

The **taking-hold phase**, the second phase of maternal adaptation, is characterized by dependent and independent maternal behavior. This phase typically starts on the second to third day postpartum and may last several weeks.

**FIGURE 15.6** Mother bonding with newborn during the taking-in phase.

As the client regains control over her bodily functions during the next few days, she will be taking hold and becoming preoccupied with the present. She will be particularly concerned about her health, the infant's condition, and her ability to care for her or him. She demonstrates increased autonomy and mastery of her own body's functioning, and a desire to take charge with support and help from others. She will show independence by caring for herself and learning to care for her newborn, but she still requires assurance that she is doing well as a mother. She expresses a strong interest in caring for the infant by herself.

### Letting-Go Phase

In the **letting-go phase**, the third phase of maternal adaptation, the woman reestablishes relationships with other people. She adapts to parenthood through her new role as a mother. She assumes the responsibility and care of the newborn with a bit more confidence now (Edelman, & Mandel, 2013). The focus of this phase is to move forward by assuming the parental role and to separate herself from the symbiotic relationship that she and her newborn had during pregnancy. She establishes a lifestyle that includes the infant. The mother relinquishes the fantasy infant and accepts the real one.

Nurses have recognized the importance of the process of becoming a mother (BAM) to maternal–infant nursing since Rubin's report on maternal role attainment (MRA). Mothers' perceptions of their competence or confidence, or both, in mothering and their expressions of love for their infants included age, relationship with the father, socioeconomic status, birth experience, experienced stress, available support, personality traits, self-concept, child-rearing attitudes, role strain, health status, preparation during pregnancy, relationships with own mother, depression, and anxiety. Infant variables identified as influencing MRA/BAM include appearance, responsiveness, temperament, and health status (Wendy, 2010).

More current research has led to renaming the four stages a woman progresses through in establishing a maternal identity in BAM:

1. Commitment, attachment to the unborn baby, and preparation for delivery and motherhood during pregnancy
2. Acquaintance/attachment to the infant, learning to care for the infant, and physical restoration during the first 2 to 6 weeks following birth
3. Moving toward a new normal
4. Achievement of a maternal identity through redefining self to incorporate motherhood (around 4 months). The mother feels self-confident and competent in her mothering and expresses love for and pleasure interacting with her infant (Mercer, & Walker, 2006)

The woman's work in the first stage is to make a commitment to the pregnancy and to the safe birth and care of her unborn child. This commitment is associated with a positive adaptation to motherhood.

During the second stage while the mother is placing the infant in her family context and learning how to care for her infant, her attachment and attitude toward her infant, and her self-confidence or sense of competence in mothering, or both, consistently indicate an interdependence of these two variables. The nursing care provided during the first two stages is especially important in assisting mothers as they begin to mother. Follow-up is needed as mothers move toward a new normal and recognize a transformation of self in BAM can continue to reinforce their capabilities (Mercer, 2006).

To foster maternal role attainment, two specific interventions for nurses were identified in a review of the literature (Miles, Holditch-Davis, Burchinal, & Brunssen, 2011). First, instructions about infant care and the infant's capabilities are more effective if they are specifically focused on that particular mother's infant. Second, mothers prefer live classes rather than videotapes so they can ask questions. In short, interactive nurse–client relationships are associated with positive maternal growth. Nurses who interact with clients long term during pregnancy, childbirth and during well child care help build maternal competence. Pregnancy, birth, and becoming a mother collectively represent a critical period of physical and emotional upheaval in a woman's life. The need for a holistic care approach that supports the emotional and physical health of the dyad is imperative (Foulkes, 2011).

## Partner Psychological Adaptations

For partners, whether they are husbands, significant others, boyfriends, same-sex life partners, or just friends, becoming a parent or just sharing the childbirth experience can be a perplexing time as well as a time of great change. This transition is influenced by many factors, including participation in childbirth, relationships with significant others, competence in child care, the family role organization, the individual's cultural background, and the method of infant feeding.

The transition from being merely a partner to being a father can propel many men to reorganize their lifestyles. During the postpartum period, men frequently find themselves struggling to balance personal and work needs with the new demands of father status and their new self-image. The complexities of the transitional process involved in forging a fatherhood identity can be viewed at three different levels: readjustment to a new self-image, formation of a triadic family relationship, and adaptation to redefining himself and his relationship with

his partner: the “more united tag team” (Chin, Hall, & Daiches, 2011).

Nurses can play a key role in supporting men's transition to fatherhood by keeping fathers informed about birth and postpartum routines, reporting on their newborn's health status, and reviewing infant development. They can also contribute by creating “participative space” for new fathers during the postpartum period. This can be achieved, for example, by helping fathers take on their new role by supporting and promoting their degree of involvement in the process. They can also be encouraged to actively participate in caring for, and maintaining contact with, their newborns.

### Take Note!

Most research findings stress the importance of early contact between the father or significant other and the newborn, as well as participation in infant care activities, to foster the relationship (Discenza, 2010).

Infants have a powerful effect on their fathers and others, who become intensely involved with them (Fig. 15.7). The father's or significant other's developing bond with the newborn—a time of intense absorption, preoccupation, and interest—is called *engrossment*.

## Engrossment

**Engrossment** is characterized by seven behaviors:

1. Visual awareness of the newborn—the father or partner perceives the newborn as attractive, pretty, or beautiful.
2. Tactile awareness of the newborn—the father or partner has a desire to touch or hold the newborn and considers this activity to be pleasurable.

FIGURE 15.7 Engrossment of the father and his newborn.

3. Perception of the newborn as perfect—the father or partner does not “see” any imperfections.
4. Strong attraction to the newborn—the father or partner focuses all attention on the newborn when he is in the room.
5. Awareness of distinct features of the newborn—the father or partner can distinguish his newborn from others in the nursery.
6. Extreme elation—the father or partner feels a “high” after the birth of his child.
7. Increased sense of self-esteem—the father or partner feels proud, “bigger,” more mature, and older after the birth of his child (Sears, & Sears, 2010).

Frequently, fathers or partners are portrayed as well meaning but bumbling when caring for newborns. However, they have their own unique way of relating to their newborns and can become as nurturing as mothers. A father or partner’s nurturing responses may be less automatic and slower to unfold than a mother’s, but they are capable of a strong bonding attachment to their newborns (Sears, & Sears, 2010). Encouraging fathers or partners to express their feelings by seeing, touching, and holding their son or daughter and by cuddling, talking to, and feeding him or her will help to cement this new relationship. Reinforcement of this engrossing behavior helps fathers or partners to make a positive attachment during this critical period.

### Three-Stage Role Development Process

Similar to mothers, fathers or partners also go through a predictable three-stage process during the first 3 weeks as they too “try on” their roles as parents. The three stages are expectations, reality, and transition to mastery (Sears, & Sears, 2010).

#### STAGE 1: EXPECTATIONS

New fathers or partners pass through stage 1 (expectations) with preconceptions about what home life will be like with a newborn. Many men may be unaware of the dramatic changes that can occur when this newborn comes home to live with them. For some, it is an eye-opening experience.

#### STAGE 2: REALITY

Stage 2 (reality) occurs when fathers or partners realize that their expectations in stage 1 are not realistic. Their feelings change from elation to sadness, ambivalence, jealousy, and frustration. Many wish to be more involved in the newborn’s care and yet do not feel prepared to do so. Some find parenting fun but at the same time do not feel fully prepared to take on that role.

Men’s stress, irritability and frustration in the days, weeks, and months after the birth of their child can turn into depression, just like new mothers experience. Unfortunately, men rarely discuss their feelings or ask for help,

especially during a time when they are supposed to be the “strong one” for the new mother. Depression in men can cause marital conflicts, reckless or violent behavior, poor job performance, and substance abuse. In addition, paternal depression following childbirth can have a detrimental effect on a couple’s relationship, the parent–child relationship, and on their children’s future development (Wee, Skouteris, Pier, Richardson, & Milgrom, 2011).

Risk factors for male postpartum depression include previous history of depression, financial problems, a poor relationship with his partner, and an unplanned pregnancy. Symptoms of depression appear 1 to 3 weeks after birth and can include feelings of being very stressed and anxious, being discouraged, fatigued, resentment toward the infant and the attention he or she is getting, and headaches. Men experiencing these symptoms should understand that it is not a sign of weakness and professional help can be helpful for them.

#### STAGE 3: TRANSITION TO MASTERY

In stage 3 (transition to mastery), the father or partner makes a conscious decision to take control and be at the center of his newborn’s life regardless of his preparedness. This adjustment period is similar to that of the mother’s letting-go phase, when she incorporates the newest member into the family.

#### KEY CONCEPTS

- The puerperium period refers to the first 6 weeks after delivery. During this period, the mother experiences many physiologic and psychological adaptations to return her to the prepregnant state.
- Involution involves three processes: contraction of muscle fibers to reduce stretched ones, catabolism (which reduces enlarged, individual cells), and regeneration of uterine epithelium from the lower layer of the decidua after the upper layers have been sloughed off and shed in lochia.
- Lochia passes through three stages: lochia rubra, lochia serosa, and lochia alba during the postpartum period.
- Maternal blood plasma volume decreases rapidly after birth and returns to normal within 4 weeks postpartum.
- Reva Rubin (1984) identified three phases the mother goes through to adjust to her new maternal role: the taking-in, taking-hold, and letting-go phase.
- The transition to fatherhood is influenced by many factors, including participation in childbirth, relationships with significant others, competence in child care, the family role organization, the father’s

cultural background, and the method of infant feeding.

- Like mothers, men go through a predictable three-stage process during the first 3 weeks as they too “try on” their roles as fathers or partners. The three stages include expectations, reality, and transition to mastery.

## MULTIPLE-CHOICE QUESTIONS

- Postpartum breast engorgement occurs 48 to 72 hours after giving birth. What physiologic change influences breast engorgement?
  - An increase in blood and lymph supply to the breasts
  - An increase in estrogen and progesterone levels
  - Colostrum production increases dramatically
  - Fluid retention in the breasts due to the intravenous fluids given during labor
- In the taking-in maternal role phase described by Rubin (1984), the nurse would expect the woman's behavior to be characterized as which of the following?
  - Gaining self-confidence
  - Adjusting to her new relationships
  - Being passive and dependent
  - Resuming control over her life
- The nurse is explaining to a postpartum woman 48 hours after her giving childbirth that the afterpains she is experiencing can be the result of which of the following?
  - Abdominal cramping is a sign of endometriosis
  - A small infant weighing less than 8 lb
  - Pregnancies that were too closely spaced
  - Contractions of the uterus after birth
- The nurse would expect a postpartum woman to demonstrate lochia in which sequence?
  - Rubra, alba, serosa
  - Rubra, serosa, alba
  - Serosa, alba, rubra
  - Alba, rubra, serosa
- The nurse is assessing Ms. Smith, who gave birth to her first child 5 days ago. What findings by the nurse would be expected?
  - Cream-colored lochia; uterus above the umbilicus
  - Bright-red lochia with clots; uterus 2 fingerbreadths below umbilicus
  - Light pink or brown lochia; uterus 4 to 5 fingerbreadths below umbilicus
  - Yellow, mucousy lochia; uterus at the level of the umbilicus
- Prioritize the postpartum mother's needs 4 hours after giving birth by placing a number 1, 2, 3, or 4 in the blank before each need.
 

\_\_\_\_\_ Learn how to hold and cuddle the infant.

\_\_\_\_\_ Watch a baby bath demonstration given by the nurse.

\_\_\_\_\_ Sleep and rest without being disturbed for a few hours.

\_\_\_\_\_ Interaction time (first 30 minutes) with the infant to facilitate bonding.

## CRITICAL THINKING EXERCISE

- A new nurse assigned to the postpartum mother–baby unit makes a comment to the oncoming shift that Ms. Griffin, a 25-year-old primipara, seems lazy and shows no initiative in taking care of herself or her baby. The nurse reported that Ms. Griffin talks excessively about her labor and birth experience and seems preoccupied with herself and her needs, not her newborn's care. She wonders if something is wrong with this mother because she seems so self-centered and has to be directed to do everything.
  - Is there something “wrong” with Ms. Griffin's behavior? Why or why not?
  - What maternal role phase is being described by the new nurse?
  - What role can the nurse play to support the mother through this phase?
- Mrs. Lenhart, a primipara, gave birth to a healthy baby boy yesterday. Her husband John seemed elated at the birth, calling his friends and family on his cell phone minutes after the birth. He passed out cigars and praised his wife for her efforts. Today, when the nurse walked into their room, Mr. Lenhart seemed very anxious around his new son and called for the nurse whenever the baby cried or needed a diaper change. He seemed standoffish when asked to hold his son, and he spent time talking to other fathers in the waiting room, leaving his wife alone in the room.
  - Would you consider Mr. Lenhart's paternal behavior to be normal at this time?
  - What might Mr. Lenhart be feeling at this time?
  - How can the nurse help this new father adjust to his new role?

## STUDY ACTIVITIES

- Find an Internet resource that discusses general postpartum care for new mothers who might have questions after discharge. Evaluate the web site's information as to how credible, accurate, and current the information is.
- Prepare a teaching plan for new mothers, outlining the various physiologic changes that will take place after discharge.
- The term that describes the return of the uterus to its prepregnant state is \_\_\_\_\_.
- A deviated fundus to the right side of the abdomen would indicate a \_\_\_\_\_.

sitz bath

# Nursing Management During the Postpartum Period

## Learning Objectives

*Upon completion of the chapter, you will be able to:*

1. Define the key terms used in this chapter.
2. Characterize the normal physiologic and psychological adaptations to the postpartum period.
3. Determine the parameters that need to be assessed during the postpartum period.
4. Compare and contrast bonding to the attachment process.
5. Select behaviors that enhance or inhibit the attachment process.
6. Outline nursing management for the woman and her family during the postpartum period.
7. Examine the role of the nurse in promoting successful breast-feeding.
8. Plan areas of health education needed for discharge planning, home care, and follow-up.

*Raina is a 24-year-old Muslim primipara who has just been admitted to the postpartum unit. Her husband sits at the bedside but doesn't seem to give her any physical or emotional support after her lengthy labor and difficult birth.*

### **Words of Wisdom**

Parenting is an intimate, interactive, continuous, lifelong process.

**The** postpartum period is a time of major adjustments and adaptations not just for the mother, but for all members of the family. It is during this time that parenting starts and a relationship with the newborn begins. A positive, loving relationship between parents and their newborn promotes the emotional well-being of all. This relationship endures and has profound effects on the child's growth and development.

### Take Note!

Parenting is a skill that is often learned by trial and error, with varying degrees of success. Successful parenting, a continuous and complex interactive process, requires the parents to learn new skills and to integrate the new member into the family.

Once the infant is born, each system in the mother's body takes several weeks to return to its nonpregnant state. The physiologic changes in women during the postpartum period are dramatic. Nurses should be aware of these changes and should be able to make observations and assessments to validate normal occurrences and detect any deviations.

This chapter describes the nursing management of the woman and her family during the postpartum period. (See Chapter 21 for a detailed discussion of the postpartum care of the woman undergoing a surgical birth.) Nursing management during the postpartum period focuses on assessing the woman's ability to adapt to the physiologic and psychological changes occurring at this time (see Chapter 15 for a detailed discussion of these adaptations). The chapter outlines physical assessment parameters for new mothers and newborns. It also focuses on bonding and attachment behaviors; nurses need to be aware of these behaviors so they can perform appropriate interventions. Family members are also assessed to determine how well they are making the transition to this new stage.

Based on assessment findings, the nurse plans and implements care to address the family's needs. Steps to address physiologic needs such as comfort, self-care, nutrition, and contraception are described. Ways to help the woman and her family adapt to the birth of the newborn are also discussed (Fig. 16.1). Because of today's shortened lengths of stay, the nurse may be able to focus only on priority needs and may need to arrange for follow-up in the home to ensure that all the family's needs are met.

## SOCIAL SUPPORT AND CULTURAL CONSIDERATIONS

In addition to physical assessment and care of the woman in the postpartum period, strong social support is vital to help her integrate the baby into the family. In today's mobile society, extended families may live far away and may be unable to help care for the new

**FIGURE 16.1** Parents and grandmother interacting with the newborn.

family. As a result, many new parents turn to health care professionals for information as well as physical and emotional support during this adjustment period. Nurses can be an invaluable resource by serving as mentors, teaching about self-care measures and baby care basics, and providing emotional support. Nurses can “mother” the new mother by offering physical care, emotional support, information, and practical help. The nurse's support and care through this critical time can increase the new parents' confidence, giving them a sense of accomplishment in their parenting skills. One important intervention during the postpartum period is promotion of breast-feeding. *Healthy People 2020* includes breast-feeding as a goal for maternal, infant, and child health (U.S. Department of Health and Human Resources [USDHHS], 2010).

### HEALTHY PEOPLE 2020

#### Objective

Increase the proportion of mothers who breast-feed their babies.  
 Increase the number of mothers who breast-feed ever from a baseline of 74% to 81.9%.  
 Increase the number of mothers who breast-feed at 6 months from a baseline of 43.5% to 60.6%.  
 Increase the number of mothers who breast-feed at 1 year from a baseline of 22.7% to 34.1%.

#### Nursing Significance

- Will provide infants with the most complete form of nutrition, improving their health, growth and development, and immunity
- Will improve maternal health via breast-feeding's beneficial effects
- Will increase the rate of breast-feeding, particularly among low-income and certain racial and ethnic populations who are less likely to begin

(continued)

**HEALTHY PEOPLE 2020** (continued)**Objective**

Increase the number of mothers who breast-feed exclusively through 3 months from a base-line of 33.6% to 46.2%.  
 Increase the number of mothers who breast-feed exclusively through 6 months from a base-line of 14.1% to 25.5%.

*Healthy People* objectives based on data from <http://www.healthy-people.gov>.

**Nursing Significance**

breast-feeding in the hospital or to sustain it through the infant's first year

As in all nursing care, nurses should provide culturally competent care during the postpartum period. The nurse should engage in ongoing cultural self-assessment and overcome any stereotypes that perpetuate prejudice or discrimination against any cultural group (Bowers, 2012). Providing culturally competent nursing care during the postpartum period requires time, open-mindedness, and patience. The skill set needed by nurses to provide culturally competent care to postpartum clients and their families includes understanding their beliefs, experiences, and family environment; facilitating their language through appropriate use of interpreters so that the information provided can be understood; and compassionately respecting clients and their human rights (Kersey-Matusiah, 2012). To promote positive outcomes, the nurse should be sensitive to the woman's and family's culture, religion, and ethnic influences (see "Providing Optimal Cultural Care" in the Nursing Interventions section).

*Remember the couple introduced at the beginning of the chapter? When the postpartum nurse comes to examine Raina, her husband quickly leaves the room and returns a short time later after the examination is complete. How do you interpret his behavior toward his wife? What might you communicate to this couple?*

**NURSING ASSESSMENT**

Comprehensive nursing assessment begins within an hour after the woman gives birth and continues through discharge.

**Take Note!**

Nurses need a firm grasp of normal findings so that they can recognize abnormal findings and intervene appropriately.

This postpartum assessment includes vital signs and physical and psychosocial assessments. It also includes assessing the parents and other family members, such as siblings and grandparents, for attachment and bonding with the newborn.

Although the exact protocol may vary among facilities, postpartum assessment typically is performed as follows:

- During the first hour: every 15 minutes
- During the second hour: every 30 minutes
- During the first 24 hours: every 4 hours
- After 24 hours: every 8 hours (Mattson, & Smith, 2011; Simpkin, & James, 2012)

During each assessment, keep in mind risk factors that may lead to complications, such as infection or hemorrhage, during the recovery period (Box 16.1). Early identification is critical to ensure prompt intervention.

Nurses need to be aware of the normal physiologic and psychological changes that take place in clients' bodies and minds in order to provide comprehensive care during the postpartum period. In

**BOX 16.1****FACTORS INCREASING A WOMAN'S RISK FOR POSTPARTUM COMPLICATIONS****Risk Factors for Postpartum Infection**

- Operative procedure (forceps, cesarean birth, vacuum extraction)
- History of diabetes, including gestational-onset diabetes
- Prolonged labor (more than 24 hours)
- Use of indwelling urinary catheter
- Anemia (hemoglobin < 10.5 mg/dL)
- Multiple vaginal examinations during labor
- Prolonged rupture of membranes (>24 hours)
- Manual extraction of placenta
- Compromised immune system (HIV positive)

**Risk Factors for Postpartum Hemorrhage**

- Precipitous labor (less than 3 hours)
- Uterine atony
- Placenta previa or abruptio placenta
- Labor induction or augmentation
- Operative procedures (vacuum extraction, forceps, cesarean birth)
- Retained placental fragments
- Prolonged third stage of labor (more than 30 minutes)
- Multiparity, more than three births closely spaced
- Uterine overdistention (large infant, twins, hydramnios)

addition to client and family teaching, one of the most significant responsibilities of the postpartum nurse is to recognize potential complications after childbirth.

As with any assessment, always review the woman's medical record for information about her pregnancy, labor, and birth. Note any preexisting conditions, any complications that occurred during pregnancy, labor, birth, and immediately afterward, and any treatments provided.

Postpartum assessment of the mother typically includes vital signs, pain level, epidural site inspection for infection, and a systematic head-to-toe review of body systems. The acronym BUBBLE-EEE—breasts, uterus, bladder, bowels, lochia, episiotomy/perineum/epidural site, extremities, and emotional status—can be used as a guide for this head-to-toe review (Derricott, 2010).

While assessing the woman and her family during the postpartum period, be alert for danger signs (Box 16.2). Notify the primary health care provider immediately if any are noted.

## Vital Signs Assessment

Obtain vital signs and compare them with the previous values, noting and reporting any deviations. Vital sign changes can be an early indicator of complications.

### Temperature

Use a consistent measurement technique (oral, axillary, or tympanic) to get the most accurate readings.

#### BOX 16.2

#### POSTPARTUM DANGER SIGNS

- Fever more than 100.4° F (38° C)
- Foul-smelling lochia or an unexpected change in color or amount
- Large blood clots, or bleeding that saturates a peripad in an hour
- Severe headaches or blurred vision
- Visual changes, such as blurred vision or spots, or headaches
- Calf pain with dorsiflexion of the foot
- Swelling, redness, or discharge at the episiotomy, epidural, or abdominal sites
- Dysuria, burning, or incomplete emptying of the bladder
- Shortness of breath or difficulty breathing without exertion
- Depression or extreme mood swings

Typically, the new mother's temperature during the first 24 hours postpartum is within the normal range. Some women experience a slight fever, up to 100.4° F (38° C), during the first 24 hours. This elevation may be the result of dehydration because of fluid loss during labor. Temperature should be normal after 24 hours with replacement of fluids lost during labor and birth (Wong, & Rosh, 2012).

A temperature above 100.4° F (38° C) at any time or an abnormal temperature after the first 24 hours may indicate infection and must be reported. Abnormal temperature readings warrant continued monitoring until an infection can be ruled out through cultures or blood studies. An elevated temperature can identify maternal sepsis, which results in significant maternal morbidity and mortality worldwide. To improve the outcome, it is essential that nurses be vigilant in obtaining accurate values and monitoring their client's temperature.

### Pulse

Pulse rates of 40 to 80 beats per minute (bpm) are normal during the first week after birth. This pulse rate is called puerperal bradycardia. During pregnancy, the heavy gravid uterus causes a decreased flow of venous blood to the heart. After giving birth, there is an increase in intravascular volume. The cardiac output is most likely caused by an increased stroke volume from the venous return now. The elevated stroke volume leads to a decreased heart rate. Orthostatic hypotension may occur when a woman sits up from a reclining position (Mattson, & Smith, 2011).

Tachycardia in the postpartum woman can suggest anxiety, excitement, fatigue, pain, excessive blood loss or delayed hemorrhage, infection, or underlying cardiac problems. Further investigation is warranted to rule out complications.

### Respirations

Respiratory rates in the postpartum woman should be within the normal range of 16 to 20 breaths per minute. Pulmonary function typically returns to the prepregnant state after childbirth when the diaphragm descends and the organs revert to their normal positions. Any change in respiratory rate out of the normal range might indicate pulmonary edema, atelectasis, a side effect of epidural anesthesia, or pulmonary embolism and must be reported. Lungs should be clear on auscultation.

### Blood Pressure

Assess the woman's blood pressure and compare it with her usual range. Report any deviation from this

range. Immediately after childbirth, the blood pressure should remain the same as during labor. An increase in blood pressure could indicate gestational hypertension, whereas a decrease could indicate shock or orthostatic hypotension or dehydration, a side effect of epidural anesthesia.

Blood pressure also may vary based on the woman's position, so assess blood pressure with the woman in the same position every time. Be alert for orthostatic hypotension, which can occur when the woman moves rapidly from a lying or sitting position to a standing one.

### Pain

Pain, the fifth vital sign, is assessed along with the other four parameters. Question the woman about the type of pain and its location and severity. Have the woman rate the pain using a numeric scale from 0 to 10 points.

Many postpartum orders will have the nurse pre-medicate the woman routinely for afterbirth pains rather than wait for her to experience them first. The goal of pain management is to have the woman's pain scale rating maintained between 0 to 2 points at all times, especially after breast-feeding. This can be accomplished by assessing the woman's pain level frequently and preventing pain by administering analgesics. If the woman has severe pain in the perineal region despite use of physical comfort measures, check for a hematoma by inspecting and palpating the area. If one is found, notify the health care provider immediately.

## Physical Assessment

Physical assessment of the postpartum woman focuses on assessing the breasts, uterus, bladder, bowels, lochia, episiotomy/perineum and epidural site and extremities.

### Breasts

Inspect the breasts for size, contour, asymmetry, engorgement, or erythema. Check the nipples for cracks, redness, fissures, or bleeding, and note whether they are erect, flat, or inverted. Flat or inverted nipples can make breast-feeding challenging for both mother and infant. Cracked, blistered, fissured, bruised, or bleeding nipples in the breast-feeding woman are generally indications that the baby is improperly positioned on the breast. Palpate the breasts lightly to ascertain if they are soft, filling, or engorged, and document your findings. For women who are not breast-feeding, use a gentle, light touch to avoid breast stimulation, which would exacerbate engorgement. As milk is starting to come in, the breasts become firmer; this is charted as "filling." Engorged breasts are hard, tender, and taut. Ask the woman if she is having any nipple discomfort. Palpate the breasts for any nodules, masses, or areas of warmth, which may indicate a

plugged duct that may progress to mastitis if not treated promptly. Any discharge from the nipple should be described and documented if it is not colostrum (creamy yellow) or foremilk (bluish white).

### Uterus

Assess the fundus (top portion of the uterus) to determine the degree of uterine involution. If possible, have the woman empty her bladder before assessing the fundus and auscultate her bowel sounds prior to uterine palpation. If the client has had a cesarean birth and has a PCA pump, instruct her to self-medicate prior to fundal assessment to decrease her discomfort.

Using a two-handed approach with the woman in the supine position with her knees flexed slightly and the bed in a flat position or as low as possible, palpate the abdomen gently, feeling for the top of the uterus while the other hand is placed on the lower segment of the uterus to stabilize it (Fig. 16.2).

The fundus should be midline and should feel firm. A boggy or relaxed uterus is a sign of uterine atony. This can be the result of bladder distention, which displaces the uterus upward and to the right, or retained placental fragments. Either situation predisposes the woman to hemorrhage.

Once the fundus is located, place your index finger on the fundus and count the number of fingerbreadths between the fundus and the umbilicus (1 fingerbreadth is approximately equal to 1 cm). One to 2 hours after birth, the fundus typically is between the umbilicus and

FIGURE 16.2 Palpating the fundus.

the symphysis pubis. Approximately 6 to 12 hours after birth, the fundus usually is at the level of the umbilicus. If the fundal height is above the umbilicus, which would be an abnormal finding, investigate this immediately to prevent excessive bleeding. Frequently the woman's bladder is full, thus displacing the uterus up and to either side of the midline. Ask the woman to empty her bladder and reassess the uterus again.

Normally, the fundus progresses downward at a rate of one fingerbreadth (or 1 cm) per day after childbirth and should be nonpalpable by 10 days postpartum (Cunningham et al., 2010). On the first postpartum day, the top of the fundus is located 1 cm below the umbilicus and is recorded as u/1. Similarly, on the second postpartum day, the fundus would be 2 cm below the umbilicus and should be recorded as u/2, and so on. Health care agencies differ according to how fundal heights are charted, so follow their protocols for this. If the fundus is not firm, gently massage the uterus using a circular motion until it becomes firm.

## Bladder

Considerable diuresis—as much as 3,000 mL—begins within 12 hours after childbirth and continues for several days (Mattson & Smith, 2011). However, many postpartum women do not sense the need to void even if their bladder is full. In this situation the bladder can become distended and displace the uterus upward and to the side, which prevents the uterine muscles from contracting properly and can lead to excessive bleeding. Urinary retention as a result of decreased bladder tone and emptying can lead to urinary tract infections (UTIs). It is imperative that nurses monitor clients for signs of UTI, including fever, urinary frequency and/or urgency, difficult or painful urination, and tenderness over the costovertebral angle (Jarvis, 2012). Women who received regional anesthesia during labor are at risk for bladder distention and for difficulty voiding until sensation returns within several hours after birth.

Assess for voiding problems by asking the woman the following questions:

- Have you (voided, urinated, gone to the bathroom) yet?
- Have you noticed any burning or discomfort with urination?
- Do you have any difficulty passing your urine?
- Do you feel that your bladder is empty when you finish urinating?
- Do you have any signs of infection such as urgency, frequency, or pain?
- Are you able to control the flow of urine by squeezing your muscles?
- Have you noticed any leakage of urine when you cough, laugh, or sneeze?

Assess the bladder for distention and adequate emptying after efforts to void. Palpate the area over the symphysis pubis. If empty, the bladder is not palpable. Palpation of a rounded mass suggests bladder distention. Also percuss the area: a full bladder is dull to percussion. If the bladder is full, lochia drainage will be more than normal because the uterus cannot contract to suppress the bleeding.

### Take Note!

Note the location and condition of the fundus; a full bladder tends to displace the uterus up and to the right.

After the woman voids, palpate and percuss the area again to determine adequate emptying of the bladder. If the bladder remains distended, the woman may be retaining urine in her bladder, and measures to initiate voiding should be instituted. Be alert for signs of infection, including infrequent or insufficient voiding (less than 200 mL), discomfort, burning, urgency, or foul-smelling urine (Simpkin I, & James, 2012). Document urine output.

## Bowels

Spontaneous bowel movements may not occur for 2 to 3 days after giving birth because of a decrease in muscle tone in the intestines as a result of elevated progesterone levels. Normal patterns of bowel elimination usually return within a week after birth (Mattson, & Smith, 2011). Often women are hesitant to have a bowel movement due to pain in the perineal area resulting from an episiotomy, lacerations, or hemorrhoids. Some are fearful that they may “rip their stitches” should they strain. Nurses should reassure their clients that stool softeners and/or laxatives to treat constipation have been prescribed for them to reduce discomfort.

Inspect the woman's abdomen for distention, auscultate for bowel sounds in all four quadrants prior to palpating the uterine fundus, and palpate for tenderness. The abdomen typically is soft, nontender, and nondistended. Bowel sounds are present in all four quadrants. Ask the woman if she has had a bowel movement or has passed gas since giving birth, because constipation is a common problem during the postpartum period and most women do not offer this information unless asked about it. Normal assessment findings are active bowel sounds, passing gas, and a nondistended abdomen.

## Lochia

Assess lochia in terms of amount, color, odor, and change with activity and time. To assess how much a woman is bleeding, ask her how many perineal pads she has used in the past 1 to 2 hours and how much drainage was on each pad. For example, did she saturate

the pad completely, or was only half of the pad covered with drainage? Ask about the color of the drainage, odor, and the presence of any clots. Lochia has a definite musky scent, with an odor similar to that of menstrual flow without any large clots (fist size). Foul-smelling lochia suggests an infection, and large clots suggest poor uterine involution, necessitating additional intervention.

To determine the amount of lochia, observe the amount of lochia saturation on the perineal pad and relate it to time (Fig. 16.3). Also, take into consideration the specific type of peripad used, because some are more absorbent than others. Lochia flow will increase when the woman gets out of bed (lochia pools in the vagina and the uterus while she is lying down) and when she breast-feeds (oxytocin release causes uterine contractions). A woman who saturates a perineal pad within 30 to 60 minutes is bleeding much more than one who saturates a pad in 2 hours.

Typically, the amount of lochia is described as follows:

- *Scant*: a 1- to 2-inch lochia stain on the perineal pad or approximately a 10-mL loss
- *Light or small*: an approximately 4-inch stain or a 10- to 25-mL loss
- *Moderate*: a 4- to 6-inch stain with an estimated loss of 25 to 50 mL
- *Large or heavy*: a pad is saturated within 1 hour after changing it (Bope & Kellerman, 2012)

The total volume of lochial discharge varies from 150 to 400 mL, and the amount decreases daily (Mattson, & Smith, 2011). Check under the woman to make sure additional blood is not hidden and not absorbed on her perineal pad. This also a good time to assess for the presence and condition of hemorrhoids since the nurse is visually inspecting the perineum.

Report any abnormal findings, such as heavy, bright-red lochia with large tissue fragments or a foul odor.

FIGURE 16.3 Assessing lochia.

If excessive bleeding occurs, the first step would be to massage the boggy fundus until it is firm to reduce the flow of blood. Document all findings.

Women who had a cesarean birth will have less lochia discharge than those who had a vaginal birth, but stages and color changes remain the same. Although the woman's abdomen will be tender after surgery, the nurse must palpate the fundus and assess the lochia to make sure they are within the normal range and that there is no excessive bleeding.

Anticipatory guidance to give the woman at discharge should include information about lochia and the expected changes. Urge the woman to notify her health care provider if lochia rubra returns after the serosa and alba transitions have taken place. This is abnormal and may indicate subinvolution or that the woman is too active and needs to rest more. Lochia is an excellent medium for bacterial growth. Explain to the woman that frequent changing of perineal pads, continued use of her peribottle for rinsing her perineal area, and hand-washing before and after pad changes are important infection control measures.

### Episiotomy/Perineum and Epidural Site

To assess the episiotomy and perineal area, position the woman on her side with her top leg flexed upward at the knee and drawn up toward her waist. If necessary, use a penlight to provide adequate lighting during the assessment. Wearing gloves and standing at the woman's side with her back to you, gently lift the upper buttock to expose the perineum and anus (Fig. 16.4). Inspect the episiotomy for irritation, ecchymosis, tenderness, or hematomas. Assess for hemorrhoids and their condition.

During the early postpartum period, the perineal tissue surrounding the episiotomy is typically edematous and slightly bruised. The normal episiotomy site should not have redness, discharge, or edema. The majority of

FIGURE 16.4 Inspecting the perineum.

healing takes place within the first 2 weeks, but it may take 4 to 6 months for the episiotomy to heal completely (Tharpe, Farley, & Jordan, 2013).

Lacerations to the perineal area sustained during the birthing process that were identified and repaired also need to be assessed to determine their healing status. Lacerations are classified based on their severity and tissue involvement:

- *First-degree laceration:* involves only skin and superficial structures above muscle
- *Second-degree laceration:* extends through perineal muscles
- *Third-degree laceration:* extends through the anal sphincter muscle
- *Fourth-degree laceration:* continues through anterior rectal wall

Assess the episiotomy and any lacerations at least every 8 hours to detect hematomas or signs of infection. Large areas of swollen, bluish skin with complaints of severe pain in the perineal area indicate pelvic or vulvar hematomas. Redness, swelling, increasing discomfort, or purulent drainage may indicate infection. Both findings need to be reported immediately.

A white line the length of the episiotomy is a sign of infection, as is swelling or discharge. Severe, intractable pain, perineal discoloration, and ecchymosis indicate a perineal hematoma, a potentially dangerous condition. Report any unusual findings. Ice can be applied to relieve discomfort and reduce edema; sitz baths also can promote comfort and perineal healing (see “Promoting Comfort” in the Nursing Interventions section).

If the woman has had an epidural during her labor, assessment of the epidural wound site is important as well as checking for any side effects of the medication injected such as itching, nausea and vomiting, or urinary retention. Visual inspection of the epidural site and an accurate documentation of intake and output is essential.

## Extremities

During pregnancy, the state of hypercoagulability protects the mother against excessive blood loss during childbirth and placental separation. However, this hypercoagulable state can increase the risk of thromboembolic disorders during pregnancy and postpartum. Three factors predispose women to thromboembolic disorders during pregnancy: stasis (compression of the large veins because of the gravid uterus), altered coagulation (state of pregnancy), and localized vascular damage (may occur during the birthing process). All of these factors increase the risk of clot formation.

While inspecting the woman’s extremities, also determine the degree of sensory and motor function return (recovery from anesthesia) by asking the woman if she feels sensation at various areas the nurse touches and also by observing her ambulation stability.

### Take Note!

Pulmonary embolism occurs in 1 in 2,000 pregnancies and is a major cause of maternal mortality (McLintock, Brighton, & Chunilal et al., 2012).

Pulmonary emboli typically result from dislodged deep vein thrombi in the lower extremities. Risk factors associated with thromboembolic conditions include:

- Anemia
- Diabetes mellitus
- Cigarette smoking
- Obesity
- Preeclampsia secondary to exaggeration of hypercoagulable state
- Hypertension
- Severe varicose veins
- Pregnancy
- Oral contraceptive use
- Cesarean birth
- Severe infection
- Previous thromboembolic disease
- Multiparity
- Bed rest or immobility for 4 days or more
- Advanced maternal age (Gilbert, 2011)

Because of the subtle presentation of thromboembolic disorders, the physical examination may not be enough to detect them. An accurate diagnosis of pulmonary embolism is needed because it requires (1) prolonged therapy ( $\leq 9$  months of heparin during pregnancy), (2) prophylaxis during future pregnancies, and (3) avoidance of oral contraceptive pills. The woman may report lower extremity tightness or aching when ambulating that is relieved with rest and elevation of the leg. Edema in the affected leg (typically the left), along with warmth and tenderness, and a low-grade fever may also be noted. A duplex ultrasound (two-dimensional ultrasound and Doppler ultrasound that compresses the vein to assess for changes in venous flow) in conjunction with the physical findings frequently is needed for a conclusive diagnosis (McLintock, Brighton, & Chunilal et al., 2012).

Women with an increased risk for this condition during the postpartum period should wear antiembolism stockings or use sequential compression devices to reduce the risk of venous stasis by preventing blood from pooling in the calves of the legs. Encouraging the client to ambulate after childbirth reduces the incidence of thrombophlebitis.

## Psychosocial Assessment

Psychosocial assessment of the postpartum woman focuses on emotional status and bonding and attachment.

### Emotional Status

Assess the woman’s emotional status by observing how she interacts with her family, her level of independence,

energy levels, eye contact with her infant (within a cultural context), posture and comfort level while holding the newborn, and sleep and rest patterns. Be alert for mood swings, irritability, or crying episodes.

*Remember Raina and her “quiet” husband, the Muslim couple? The postpartum nurse informs Raina that her doctor, Nancy Schultz, has been called away for emergency surgery and won’t be available the rest of the day. The nurse explains that Dr. Robert Nappo will be making rounds for her. Raina and her husband become upset. Why? Is culturally competent care being provided to this couple?*

### Bonding and Attachment

Nurses can be instrumental in promoting attachment by assessing attachment behaviors (positive and negative) and intervening appropriately if needed. Nurses must be able to identify any family discord that might interfere with the attachment process. Remember, however, that mothers from different cultures may behave differently from what is expected in your own culture. For example, Native American mothers tend to handle their newborns less often and use cradle boards to carry them. Native American mothers and many Asian American mothers delay breast-feeding until their milk comes in, because colostrum is considered harmful for the newborn (Bowers, 2012). Don’t assume that different behavior is wrong.

Meeting the newborn for the first time after birth can be an exhilarating experience for parents. Although the mother has spent many hours dreaming of her unborn and how he or she will look, it is not until after birth that they meet face to face. They both need to get to know one another and to develop feelings for one another.

**Bonding** is the close emotional attraction to a newborn by the parents that develops during the first 30 to 60 minutes after birth. It is unidirectional, from parent to infant. It is thought that optimal bonding of the parents to a newborn requires a period of close contact within the first few minutes to a few hours after birth. Bonding is really a continuation of the relationship that began during pregnancy (Sears, & Sears, 2011a). It is affected by a multitude of factors, including the parent’s socioeconomic status, family history, role models, support systems, cultural factors, and birth experiences. The mother initiates bonding when she caresses her infant and exhibits certain behaviors typical of a mother tending her child. The infant’s responses to this, such as body and eye movements, are a necessary part of the process. During this initial period, the infant is in a quiet, alert state, looking directly at the holder.

#### Take Note!

The length of time necessary for bonding depends on the health of the infant and mother, as well as the circumstances surrounding the labor and birth (Nagasawa, Okabe, Mogi, & Kikisusi, 2012).

**Attachment** is the development of strong affection between an infant and a significant other (mother, father, sibling, and caretaker). This attachment is reciprocal; both the significant other and the newborn exhibit attachment behaviors (Ding, Xu, Wang, Li, & Wang, 2012). This tie between two people is psychological rather than biologic, and it does not occur overnight. The process of attachment follows a progressive or developmental course that changes over time. Attachment is an individualized and multifactorial process that differs based on the health of the infant, the mother, environmental circumstances, and the quality of care the infant receives. The newborn responds to the significant other by cooing, grasping, smiling, and crying. Nurses can assess for attachment behaviors by observing the interaction between the newborn and the person holding him or her (Jacob, 2012). It occurs through mutually satisfying experiences. Maternal attachment begins during pregnancy as the result of fetal movement and maternal fantasies about the infant and continues through the birth and postpartum periods. Attachment behaviors include seeking, staying close to, touching, kissing, cuddling, choosing the *en face* position while holding the newborn, expressing pride in the newborn and exchanging gratifying experiences with the infant (Feldman, 2012). In a high-risk pregnancy, the attachment process may be complicated by premature birth (lack of time to develop a relationship with the unborn baby) and by parental stress due to the fetal and/or maternal vulnerability.

Bonding is a vital component of the attachment process and is necessary in establishing parent–infant attachment and a healthy, loving relationship. During this early period of acquaintance, mothers touch their infants in a very characteristic manner. Mothers visually and physically “explore” their infants, initially using their fingertips on the infant’s face and extremities and progressing to massaging and stroking the infant with their fingers. This is followed by palm contact on the trunk. Eventually, mothers draw their infant toward them and hold the infant. Mothers also interact with their infants through eye-to-eye contact in the **en face position** (Jacob, 2012) (Fig. 16.5).

Generally, research on attachment has found that the process is similar for fathers as for mothers, but the pace may be different. Like mothers, fathers manifest attachment behaviors during pregnancy. Indeed, Lucassen et al., (2011) found that the best predictors of early postnatal attachment for fathers were those who viewed the paternal caregiving role as important and also had

FIGURE 16.5 *En face* position.

greater marital quality. Higher levels of paternal sensitivity were associated with better infant–father attachment. Becoming a father requires a man to build on the experiences he has had throughout childhood and adolescence. Fathers develop an emotional tie with their infants in a variety of ways. They seek and maintain closeness with the infant and can recognize characteristics of the infant. Another study further described paternal attachment as a permanent, cyclical concept characterized by changes in response to the child’s developmental stage (Sekimori, 2011).

Attachment is a process; it does not occur instantaneously, even though many parents believe in a romanticized version of attachment, which happens right after birth. A delay in the attachment process can occur if a mother’s physical and emotional states are adversely affected by exhaustion, pain, the absence of a support system, separation, a traumatic birth experience, anesthesia, or an unwanted outcome (Beebe et al., 2010).

#### Take Note!

Touch is a basic instinctual interaction between a parent and his or her infant and has a vital role in the infant’s early development. Parents provide a variety of tactile stimulation while addressing their infant’s daily care routines (O’Brien & Lynch, 2011).

The developmental task for the infant is learning to differentiate between trust and mistrust. If the mother or caretaker is consistently responsive to the infant’s care, meeting the baby’s physical and psychological needs, the infant will likely learn to trust the caretaker, view the world as a safe place, and grow up to be secure, self-reliant, trusting, cooperative, and helpful. However,

if the infant’s needs are not met, the child is more likely to face developmental delays, neglect, and child abuse (Bryanton, & Beck, 2010).

“Becoming” a parent may take 4 to 6 months. The transition to parenthood, according to Mercer (2006), involves four stages:

1. Commitment, attachment, and preparation for an infant during pregnancy
2. Acquaintance with and increasing attachment to the infant, learning how to care for the infant, and physical restoration during the first weeks after birth
3. Moving toward a new normal routine in the first 4 months after birth
4. Achievement of a parenthood role around 4 months

The stages overlap, and the timing of each is affected by variables such as the environment, family dynamics, and the partners (Mercer, 2006).

### FACTORS AFFECTING ATTACHMENT

Attachment behaviors are influenced by three major factors:

1. Parents’ background (includes the care that the parents received when growing up, cultural practices, relationship within the family, experience with previous pregnancies and planning and course of events during pregnancy, postpartum depression)
2. Infant (includes the infant’s temperament and health at birth)
3. Care practices (the behaviors of physicians, midwives, nurses, and hospital personnel, care and support during labor, first day of life in separation of mother and infant, and rules of the hospital or birthing center) (Steele, Murphy, & Steele, 2010).

Attachment occurs more readily with the infant whose temperament, health, appearance, and gender fit the parent’s expectations. If the infant does not meet these expectations, attachment can be delayed (Ding, Xu, Wang, Li, & Wang, 2012).

Factors associated with the health care facility or birthing unit can also hinder attachment. These include:

- Separation of infant and parents immediately after birth and for long periods during the day
- Policies that discourage unwrapping and exploring the infant
- Intensive care environment, restrictive visiting policies
- Staff indifference or lack of support for parent’s care-taking attempts and abilities

### CRITICAL ATTRIBUTES OF ATTACHMENT

The terms *bonding* and *attachment* are often used interchangeably, even though they involve different time frames and interactions. Attachment stages include proximity, reciprocity, and commitment.

*Proximity* refers to the physical and psychological experience of the parents being close to their infant. This attribute has three dimensions:

1. *Contact*: The sensory experiences of touching, holding, and gazing at the infant are part of proximity-seeking behavior.
2. *Emotional state*: The emotional state emerges from the affective experience of the new parents toward their infant and their parental role.
3. *Individualization*: Parents are aware of the need to differentiate the infant's needs from themselves and to recognize and respond to them appropriately, making the attachment process also, in some way, one of detachment.

*Reciprocity* is the process by which the infant's abilities and behaviors elicit parental response. Reciprocity is described by two dimensions: complementary behavior and sensitivity. Complementary behavior involves taking turns and stopping when the other is not interested or becomes tired. An infant can coo and stare at the parent to elicit a similar parental response to complement his or her behavior. Parents who are sensitive and responsive to their infant's cues will promote their development and growth. Parents who become skilled at recognizing the ways their infant communicates will respond appropriately by smiling, vocalizing, touching, and kissing.

*Commitment* refers to the enduring nature of the relationship. The components of this are twofold: centrality and parent role exploration. In centrality, parents place the infant at the center of their lives. They acknowledge and accept their responsibility to promote the infant's

safety, growth, and development. Parent role exploration is the parents' ability to find their own way and integrate the parental identity into themselves (Sears & Sears, 2011c).

### POSITIVE AND NEGATIVE ATTACHMENT BEHAVIORS

Positive bonding behaviors include maintaining close physical contact, making eye-to-eye contact, speaking in soft, high-pitched tones, and touching and exploring the infant. Table 16.1 highlights typical positive and negative attachment behaviors.

## NURSING INTERVENTIONS

In terms of postpartum hospital stays today, "less is more." If the woman had a vaginal delivery, she may be discharged within 48 hours. If she had a cesarean birth, she may remain hospitalized for up to 96 hours. This shortened stay leaves little time for nurses to prepare the woman and her family for the many changes that will occur when she returns home. Nurses need to use this limited time to address the following topics: pain and discomfort, immunizations, nutrition, activity and exercise, lactation, discharge teaching, sexuality and contraception, and follow-up (see Nursing Care Plan 16.1).

### Take Note!

Always adhere to standard precautions when providing direct care to reduce the risk of disease transmission.

**TABLE 16.1 POSITIVE AND NEGATIVE ATTACHMENT BEHAVIORS**

	Positive Behaviors	Negative Behaviors
Infant	Smiles; is alert; demonstrates strong grasp reflex to hold parent's finger; sucks well, feeds easily; enjoys being held close; makes eye-to-eye contact; follows parent's face; appears facially appealing; is consolable when crying	Feeds poorly, regurgitates often; cries for long periods, colicky and inconsolable; shows flat affect, rarely smiles even when prompted; resists holding and closeness; sleeps with eyes closed most of time; stiffens body when held; is unresponsive to parents; doesn't pay attention to parents' faces
Parent	Makes direct eye contact; assumes <i>en face</i> position when holding infant; claims infant as family member, pointing out common features; expresses pride in infant; assigns meaning to infant's actions; smiles and gazes at infant; touches infant, progressing from fingertips to holding; names infant; requests to be close to infant as much as allowed; speaks positively about infant	Expresses disappointment or displeasure in infant; fails to "explore" infant visually or physically; fails to claim infant as part of family; avoids caring for infant; finds excuses not to hold infant close; has negative self-concept; appears uninterested in having infant in room; frequently asks to have infant taken back to nursery to be cared for; assigns negative attributes to infant and calls infant inappropriate, negative names (e.g., frog, monkey, tadpole)

## NURSING CARE PLAN 16.1

## Overview of the Postpartum Woman

Belinda, a 26-year-old G2P2, is a client on the mother–baby unit after giving birth to a term 8-lb, 12-oz baby boy yesterday. The night nurse reports that she has an episiotomy, complains of a pain rating of 7 points on a scale of 1 to 10, is having difficulty breast-feeding, and had heavy lochia most of the night. The nurse also reports that the client seems focused on her own needs and not on those of her infant. Assessment this morning reveals the following:

- B: Breasts are soft with colostrum leaking; nipples cracked
- U: Uterus is one fingerbreadth below the umbilicus; deviated to right
- B: Bladder is palpable; client states she hasn't been up to void yet
- B: Bowels have not moved; bowel sounds present; passing flatus
- L: Lochia is moderate; peripad soaked from night accumulation
- E: Episiotomy site intact; swollen, bruised; hemorrhoids present
- 
- E: Extremities; no edema over tibia, no warmth or tenderness in calf
- E: Emotional status is “distressed” as a result of discomfort and fatigue

**NURSING DIAGNOSIS:** Impaired tissue integrity related to episiotomy

**Outcome Identification and Evaluation**

The client will remain free of infection, without any signs and symptoms of infection, and exhibit evidence of progressive healing as demonstrated by clean, dry, decreased/absent edema, and an intact episiotomy site.

**Interventions: Promoting Tissue Integrity**

- Monitor episiotomy site for redness, edema, warmth or discharge *to identify infection.*
- Assess vital signs at least every 4 hours *to identify changes suggesting infection.*
- Apply ice pack to episiotomy site *to reduce swelling.*
- Instruct client on use of sitz bath *to promote healing, hygiene, and comfort.*
- Encourage frequent perineal care and peripad changes *to prevent infection.*
- Recommend ambulation *to improve circulation and promote healing.*
- Instruct client on positioning *to relieve pressure on perineal area.*
- Demonstrate use of anesthetic sprays *to numb perineal area.*

**NURSING DIAGNOSIS:** Pain related to episiotomy, sore nipples, and hemorrhoids

**Outcome Identification and Evaluation**

The client will experience a decrease in pain as evidenced by reporting that her pain has diminished to a tolerable level and rating it as 2 points or less.

**Interventions: Providing Pain Relief**

- Thoroughly inspect perineum *to rule out hematoma as cause of pain.*
- Administer analgesic medication as ordered as needed *to promote comfort.*
- Carry out comfort measures to episiotomy as outlined earlier *to reduce pain.*
- Explain discomforts and reassure the client that they are time limited *to assist in coping with pain.*
- Apply Tucks pads to swollen hemorrhoids *to induce shrinkage and reduce pain.*
- Suggest frequent use of sitz bath *to reduce hemorrhoid pain.*
- Administer stool softener and laxative *to prevent straining with first bowel movement.*
- Observe positioning and latching-on technique while breast-feeding. Offer suggestions based on observations to correct positioning/latching on *to minimize trauma to the breast.*

(continued)

## NURSING CARE PLAN 16.1

**Overview of the Postpartum Woman** (continued)

- Suggest air-drying of nipples after breast-feeding and use of plain water *to prevent nipple cracking.*
- Teach relaxation techniques when breast-feeding *to reduce anxiety and discomfort.*

**NURSING DIAGNOSIS:** Risk for ineffective coping related to mood alteration and pain

**Outcome Identification and Evaluation**

The client will cope with mood alterations, as evidenced by positive statements about newborn and participation in newborn care.

**Interventions: Promoting Effective Coping**

- Provide a supportive, nurturing environment and encourage the mother to vent her feelings and frustrations *to relieve anxiety.*
- Provide opportunities for the mother to rest and sleep *to combat fatigue.*
- Encourage the mother to eat a well-balanced diet *to increase her energy level.*
- Provide reassurance and explanations that mood alterations are common after birth secondary to waning hormones after pregnancy *to increase the mother's knowledge.*
- Allow the mother relief from newborn care *to afford opportunity for self-care.*
- Discuss with partner expected behavior from mother and how additional support and help are needed during this stressful time *to promote partner's participation in care.*
- Make appropriate community referrals for mother–infant support *to ensure continuity of care.*
- Encourage frequent skin-to-skin contact and closeness between mother and infant *to facilitate bonding and attachment behaviors.*
- Encourage client to participate in infant care and provide instructions as needed *to foster a sense of independence and self-esteem.*
- Offer praise and reinforcement of positive mother–infant interactions *to enhance self-confidence in care.*

**Providing Optimal Cultural Care**

As the face of America is becoming more diverse, nurses must be prepared to care for childbearing families from various cultures. In many cultures, women and their families are cared for and nurtured by their community for weeks and even months after the birth of a new family member. Box 16.3 highlights some of the major cultural variants during the postpartum period.

Nurses need to remember that childbearing practices and beliefs vary from culture to culture. To provide appropriate nursing care, the nurse should determine the client's preferences before intervening. Cultural practices may include dietary restrictions, certain clothes, taboos, activities for maintaining mental health, and the use of silence, prayer, or meditation. Restoring health may involve taking folk medicines or conferring with a tribal healer (Purnell, 2012). Providing culturally diverse care within our global community is challenging for all nurses, because they must remember that one's culture cannot be easily summarized in a reference book, but must be viewed through one's own life experiences.

*Raina and her husband are upset at the thought of having a male doctor care for Raina because Muslim women are very modest and prefer having a same-sex care provider. What should the nurse do in this situation?*

**Promoting Comfort**

The postpartum woman may have discomfort and pain from a variety of sources, such as an episiotomy, perineal lacerations, backache as a result of the epidural, pain from a full bladder, an edematous perineum, inflamed hemorrhoids, engorged breasts, afterbirth pains secondary to uterine contractions in breast-feeding and multiparous mothers, and sore nipples if breast-feeding. Relieving the underlying problem is the first step in pain management. Most practices traditionally employed for postpartum discomforts are not evidence based, so both nonpharmacologic and pharmacologic measures are often used in tandem (King, & Brucker, 2011).

## BOX 16.3

**CULTURAL INFLUENCES DURING THE POSTPARTUM PERIOD****African American**

- Mother may share care of the infant with extended family members.
- Experiences of older women within the family influence infant care.
- Mothers may protect their newborns from strangers for several weeks.
- Mothers may not bathe their newborns for the first week. Oils are applied to skin and hair to prevent dryness and cradle cap.
- Silver dollars may be taped over the infant's umbilicus in an attempt to flatten the slightly protruding umbilical stump.
- Sleeping with parents is a common practice.

**Amish**

- Women consider childbearing their primary role in society.
- They generally oppose birth control.
- Pregnancy and childbirth are considered a private matter; they may conceal it from public knowledge.
- Women typically do not respond favorably when hurried to complete a self-care task. Nurses need to take cues from women indicating their readiness to complete morning self-care activities.

**Appalachian**

- Infant colic is treated by passing the newborn through a leather horse's collar or administering weak catnip tea.
- An asafetida bag (a gum resin with a strong odor) is tied around the infant's neck to ward off disease.
- Women may avoid eye contact with nurses and health care providers.
- Women typically avoid asking questions even though they do not understand directions.
- The grandmother may rear the infant for the mother.

**Filipino American**

- Grandparents often assist in the care of their grandchildren.
- Breast-feeding is encouraged, and some mothers breast-feed their children for up to 2 years.
- Women have difficulty discussing birth control and sexual matters.
- Strong religious beliefs prevail and bedside prayer is common.
- Families are very close-knit and numerous visitors can be expected at the hospital after childbirth.

**Japanese American**

- Cleanliness and protection from cold are essential components of newborn care. Nurses should bathe the infant daily.
- Newborns routinely are not taken outside the home because it is believed that they should not be exposed to outside or cold air. Infants should be kept in a quiet, clean, warm place for the first month of life.

- Breast-feeding is the primary method of feeding.
- Many women stay in their parents' home for 1 to 2 months after birth.
- Bathing the infant can be the center of family activity at home.

**Mexican American**

- The newborn's grandmother lives with the mother for several weeks after birth to help with house-keeping and child care.
- Most women will breast-feed for more than 1 year. The infant is carried in a *rebozo* (shawl) that allows easy access for breast-feeding.
- Women may avoid eye contact and may not feel comfortable being touched by a stranger. Nurses need to respect this feeling.
- Some women may bring religious icons to the hospital and may want to display them in their room.

**Muslim**

- Modesty is a primary concern; nurses need to protect the client's modesty.
- Muslims are not permitted to eat pork; check all food items before serving.
- Muslims prefer a same-sex health care provider; male–female touching is prohibited except in an emergency situation.
- A Muslim woman stays in the house for 40 days after birth, being cared for by the female members of her family.
- Most women will breast-feed, but religious events call for periods of fasting, which may increase the risk of dehydration or malnutrition.
- Women are exempt from obligatory five-times-daily prayers as long as lochia is present.
- Extended family is likely to be present throughout much of the woman's hospital stay. They will need an empty room to perform their prayers without having to leave the hospital.

**Native American**

- Women are secretive about pregnancies and do not reveal them early.
- Touching is not a typical female behavior and eye contact is brief.
- They resent being hurried and need time for sitting and talking.
- Most mothers breast-feed and practice birth control.

(2009). *Guide to culturally competent health care* (2nd ed.). Philadelphia, PA: F. A. Davis.

## Applications of Cold and Heat

Commonly, an ice pack is the first measure used after a vaginal birth to relieve perineal discomfort from edema, an episiotomy, or a laceration. An ice pack seems to minimize edema, reduce inflammation, decrease capillary permeability, and reduce nerve conduction to the site. It is applied during the fourth stage of labor and can be used for the first 24 hours to reduce perineal edema and to prevent hematoma formation, thus reducing pain and promoting healing. Ice packs are wrapped in a disposable covering or clean washcloth and are applied to the perineal area. Usually the ice pack is applied intermittently for 20 minutes and removed for 10 minutes. Many commercially prepared ice packs are available, but a surgical glove filled with crushed ice and covered can also be used if the mother is not allergic to latex. Ensure that the ice pack is changed frequently to promote good hygiene and to allow for periodic assessments.

The **peribottle** is a plastic squeeze bottle filled with warm tap water that is sprayed over the perineal area after each voiding and before applying a new perineal pad. Usually the peribottle is introduced to the woman when she is assisted to the bathroom to freshen up and void for the first time—in most instances, once vital signs are stable after the first hour. Provide the woman with instructions on how and when to use the peribottle. Reinforce this practice each time she changes her pad, voids, or defecates, making sure that she understands to direct the flow of water from front to back. The woman can take the peribottle home and use it over the next several weeks until her lochia discharge stops. The peribottle can be used by women who had either vaginal or cesarean births to provide comfort and hygiene to the perineal area.

After the first 24 hours, a **sitz bath** with room temperature water may be prescribed and substituted for the ice pack to reduce local swelling and promote comfort for an episiotomy, perineal trauma, or inflamed hemorrhoids. The change from cold to room temperature therapy enhances vascular circulation and healing (Francisco, de Oliveira, Santos, & da Silva, 2011). Before using a sitz bath, the woman should cleanse the perineum with a peribottle or take a shower using mild soap.

Most health care agencies use plastic disposable sitz baths that women can take home. The plastic sitz bath consists of a basin that fits on the commode; a bag filled with warm water is hung on a hook and connected via a tube onto the front of the basin (Fig. 16.6). Teaching Guidelines 16.1 highlights the steps in using a sitz bath.

Advise the woman to use the sitz bath several times daily to provide hygiene and comfort to the perineal area. Encourage her to continue this measure after discharge.

Some facilities have hygienic sitz baths called Suri-Gators in the bathroom that spray an antiseptic, water, or both onto the perineum. The woman sits on the toilet

FIGURE 16.6 Sitz bath setup.

with legs apart so that the nozzle spray reaches her perineal area.

Keep in mind that tremendous hemodynamic changes are taking place within the mother during this early postpartum period, and her safety must be a priority. Fatigue, blood loss, the effects of medications, and lack of food may cause her to feel weak when she stands up. Assisting the woman to the bathroom to instruct her on how to use the peribottle and sitz bath is necessary to ensure her safety. Many women become light-headed or dizzy when they get out of bed and need direct physical assistance. Staying in the woman's room, ensuring that the emergency call light is readily available, and being available if needed during this early period will ensure safety and prevent accidents and falls.

Recent reviews of the use of postpartum local cooling and warming interventions for perineal pain found limited evidence supporting their effectiveness. Additional studies are needed in the area of perineal pain and healing in order to develop evidence-based interventions in the future (Francisco et al., 2011; Petersen, 2011).

## Topical Preparations

Several treatments may be applied topically for temporary relief of perineal pain and discomfort. One such treatment is a local anesthetic spray such as Dermoplast or Americaine. These agents numb the perineal area and are used after cleansing the area with water via the peribottle and/or a sitz bath.

Postpartum women are predisposed to hemorrhoid development due to pressure during vaginal

## Teaching Guidelines 16.1

### USING A SITZ BATH

1. Close clamp on tubing before filling bag with water to prevent leakage.
2. Fill sitz bath basin and plastic bag with room-temperature water (comfortable to touch).
3. Place the filled basin on the toilet with the seat raised and the overflow opening facing toward the back of the toilet.
4. Hang the filled plastic bag on a hook close to the toilet or an IV pole.
5. Attach the tubing to the opening on the basin.
6. Sit on the basin positioned on the toilet seat and release the clamp to allow warm water to irrigate the perineum.
7. Remain sitting on the basin for approximately 15 to 20 minutes.
8. Stand up and pat the perineum area dry. Apply a clean peripad.
9. Tip the basin to remove any remaining water and flush the toilet.
10. Wash the basin with warm water and soap and dry it in the sink.
11. Store basin and tubing in a clean, dry area until the next use.
12. Wash hands with soap and water.

birth, constipation, relaxation of the smooth muscles in vein walls, and impaired blood return, all related to increased pressure from the heavy gravid uterus. Nonpharmacologic measures to reduce hemorrhoid discomfort include ice packs, ice sitz baths, and application of cool witch hazel pads, such as Tucks Pads. The pads are placed at the rectal area, between the hemorrhoids and the perineal pad. These pads cool the area, help relieve swelling, and minimize itching. Pharmacologic methods used to reduce hemorrhoid pain include local anesthetics (Nupercaine, Tronolane) or steroids (Anucort-HC, Anusol-HC, Preparation H hydrocortisone). Prevention or correction of constipation, encouraging the use of the side-lying position, proper toileting habits, assuming positions that minimize putting pressure on the hemorrhoids, and not straining during defecation will be helpful in reducing discomfort (King, & Brucker, 2011).

Nipple pain is difficult to treat, although a wide variety of topical creams, ointments, and gels are available to do so. This group includes beeswax, glycerin-based products, petrolatum, lanolin, and hydrogel products. Many women find these products comforting. Beeswax, glycerin-based products, and petrolatum all need to be removed before breast-feeding. These products should

be avoided in order to limit infant exposure because the process of removal may increase nipple irritation. Applying expressed breast milk to nipples and allowing it to dry has been suggested to reduce nipple pain. Usually the pain is due to incorrect latch-on and/or removal of the nursing infant from the breast. Early assistance with breast-feeding to ensure correct positioning can help prevent nipple trauma.

### Analgesics

Analgesics such as acetaminophen (Tylenol) and oral nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen (Motrin, Advil) or naproxen (Aleve, Anaprox) are prescribed to relieve mild postpartum discomfort. For moderate to severe pain, a narcotic analgesic such as codeine or oxycodone in conjunction with aspirin or acetaminophen may be prescribed. Instruct the woman about adverse effects of any medication prescribed. Common adverse effects of oral analgesics include dizziness, light-headedness, nausea and vomiting, constipation, and sedation (Skidmore-Roth, 2012).

Also inform the woman that the drugs are secreted in breast milk. Nearly all medications that the mother takes are passed into her breast milk; however, the mild analgesics (e.g., acetaminophen or ibuprofen) are considered relatively safe for breast-feeding mothers (King, & Brucker, 2011). Administering a mild analgesic approximately an hour before breast-feeding will usually relieve afterpains and/or perineal discomfort.

### Assisting With Elimination

The bladder is edematous, hypotonic, and congested immediately postpartum. Consequently, bladder distention, incomplete emptying, and inability to void are common. A full bladder interferes with uterine contraction and may lead to hemorrhage, because it will displace the uterus out of the midline. Encourage the woman to void. Often, assisting her to assume the normal voiding position on the commode facilitates this. If the woman has difficulty voiding, pouring warm water over the perineal area, hearing the sound of running tap water, blowing bubbles through a straw, taking a warm shower, drinking fluids, providing her with privacy, or placing her hand in a basin of warm water may stimulate voiding. If these actions do not stimulate urination within 4 to 6 hours after giving birth, catheterization may be needed. Palpate the bladder for distention and ask the woman if she is voiding in small amounts (less than 100 mL) frequently (retention with overflow). If catheterization is necessary, use sterile technique to reduce the risk of infection.

Decreased bowel motility during labor, high iron content in prenatal vitamins, postpartum fluid loss, and

the adverse effects of pain medications and/or anesthesia may predispose the postpartum woman to constipation. In addition, the woman may fear that bowel movements will cause pain or injury, especially if she had an episiotomy or a laceration that was repaired with sutures.

Usually a stool softener, such as docusate (Colace), with or without a laxative might be helpful if the client has difficulty with bowel elimination. Other measures, such as ambulating and increasing fluid and fiber intake, may also help. Nutritional instruction might include increasing fruits and vegetables in the diet; drinking plenty of fluids (8 to 12 cups) to keep the stool soft; drinking small amounts of prune juice and/or hot liquids to stimulate peristalsis; eating high-fiber foods such as bran cereals, whole grains, dried fruits, fresh fruits, and raw vegetables; and walking daily.

## Promoting Activity, Rest, and Exercise

The postpartum period is an ideal time for nurses to promote the importance of physical fitness, help women incorporate exercise into their lifestyle, and encourage them to overcome barriers to exercise. The lifestyle changes that occur postpartum may affect a woman's health for decades. Early ambulation is encouraged to reduce the risk of thromboembolism and to improve strengthening.

Many changes occur postpartum, and caring for a newborn alters the woman's eating and sleeping habits, work schedules, and time allocation. Postpartum fatigue is common during the early days after childbirth, and it may continue for weeks or months. Having adequate sleep is critical for new mothers because shorter sleep time, a high percentage of sleep disturbances, and greater fatigue are associated with depressive symptoms in postpartum women (Damato, & Burant, 2010). Working fathers with newborns experience fatigue during early fatherhood and are unable to recover due to interrupted and poor sleep patterns. This sleep deficit can compromise their work safety (Mellor, & St. John, 2012). It affects the mother's relationships with significant others and her ability to fulfill household and child care responsibilities. Be sure that the mother recognizes her need for rest and sleep and is realistic about her expectations. Some suggestions include the following:

- Nap when the infant is sleeping, because getting uninterrupted sleep at night is difficult.
- Reduce participation in outside activities and limit the number of visitors.
- Determine the infant's sleep-wake cycles and attempt to increase wakeful periods during the day so the baby sleeps for longer periods at night.
- Eat a balanced diet to promote healing and to increase energy levels.
- Share household tasks to conserve your energy.

- Ask the father or other family members to provide infant care during the night periodically so that mothers can get an uninterrupted night of sleep, if they aren't breast-feeding.
- Review your family's daily routine and see if you can "cluster" activities to conserve energy and promote rest.

The demands of parenthood may reduce or prevent exercise in even the most committed person. A targeted exercise program and proper body mechanics can help new mothers deal with the physical challenges of motherhood. Emphasize the benefits of a regular exercise program, which include:

- Helps the woman to lose pregnancy weight
- Increases energy level so the woman can cope with her new responsibilities
- Speeds the return to prepregnant size and shape
- Reduces risk of postpartum depression
- Reduces mental fatigue
- Provides an outlet for stress (Pruett, & Caputo, 2011)

More than one third of American women are overweight (Centers for Disease Control and Prevention [CDC] Office of Women's Health, 2010). Although the average gestational weight gain is small (approximately 25 to 35 lb), excess weight gain and failure to lose weight after pregnancy are important predictors of long-term obesity. Breast-feeding and exercise may help to control weight in the long term (American Academy of Pediatrics [AAP], 2010).

### Take Note!

Women who are unable to return to a healthy weight by 6 months postpartum increase their risk factors for the development of chronic diseases including metabolic syndrome, obesity, and cardiovascular disease (Davenport, Giroux, Sopper, & Mottola, 2011). Encourage women to lose their pregnancy weight by 6 months postpartum, and refer those who don't to community weight-loss programs.

The postpartum woman may face some obstacles to exercising, including physical changes (ligament laxity), competing demands (newborn care), lack of information about weight retention (inactivity equates to weight gain), and stress incontinence (leaking of urine during activity).

A healthy woman with an uncomplicated vaginal birth can resume exercise in the immediate postpartum period. Advise the woman to start slowly and increase the level of exercise over a period of several weeks as tolerated. Infant strollers/carriers may be an option for some women, allowing them to walk with their newborns for exercise. Jogging strollers can be used later when the infant is 6 to 12 months old and can hold his or her head up. Also, exercise videos and home exercise equipment allow mothers to work out while the newborn naps.

Exercising after giving birth promotes feelings of well-being and restores muscle tone lost during pregnancy. Routine exercise should be resumed gradually, beginning with Kegel exercises on the first postpartum day and, by the second week, progressing to abdominal, buttock, and thigh-toning exercises (Pruett, & Caputo, 2011). Walking is an excellent form of early exercise as long as the woman avoids jarring and bouncing movements, because joints do not stabilize until 6 to 8 weeks postpartum. Exercising too much too soon can cause the woman to bleed more and her lochia may return to bright red. If this occurs, instruct the woman to stop exercising and rest lying down until the bleeding slows. This increase in bleeding should be a warning to the woman that she is over doing it and needs to slow down her exercise routine.

Recommended exercises for the first few weeks postpartum include abdominal breathing, head lifts, modified sit-ups, double knee roll, and pelvic tilt (Teaching Guidelines 16.2). The number of exercises and their duration is gradually increased as the woman gains strength.

Remember that cultures have different attitudes toward exercise. Some cultures (e.g., Haitian, Arab American, and Mexican) expect new mothers to observe a specific period of bed rest or activity restriction; thus, it would be inappropriate to recommend active exercise during the early postpartum period (Bowers, 2012).

## Preventing Stress Incontinence

Fifty percent of all parous women develop some degree of pelvic prolapse in their lifetime that is associated with stress incontinence. Research suggests that having a vaginal delivery results in direct pelvic muscle trauma and disruption of fascial supports and also causes damage to the levator ani muscle and pudendal nerve injury (Albrich et al., 2012). The more vaginal deliveries a woman has had, the more likely she is to have stress incontinence. Stress incontinence can occur with any activity that causes an increase in intra-abdominal pressure. Postpartum women might consider low-impact activities such as walking, biking, swimming, or low-impact aerobics so they can resume physical activity while strengthening the pelvic floor.

Suggestions to prevent stress incontinence are:

- Start a regular program of Kegel exercises after childbirth.
- Lose weight if necessary; obesity is associated with stress incontinence.
- Avoid smoking; limit intake of alcohol and caffeinated beverages, which irritate the bladder.
- Adjust fluid intake to produce a 24-hourly urine output of 1,000 to 2,000 mL.
- Use either an intravaginal or intra-urethral device that puts pressure onto the urethra so that urine will not leak when bladder pressure rises (Busuttill-Leaver, 2011).

## Teaching Guidelines 16.2 POSTPARTUM EXERCISES

### Abdominal Breathing

1. While lying on a flat surface (floor or bed), take a deep breath through your nose and expand your abdominal muscles (they will rise up from your midsection).
2. Slowly exhale and tighten your abdominal muscles for 3 to 5 seconds.
3. Repeat this several times.

### Head Lift

1. Lie on a flat surface with knees flexed and feet flat on the surface.
2. Lift your head off the flat surface, tuck it onto your chest, and hold for 3 to 5 seconds.
3. Relax your head and return to the starting position.
4. Repeat this several times.

### Modified Sit-Ups

1. Lie on a flat surface and raise your head and shoulders 6 to 8 inches so that your outstretched hands reach your knees.
2. Keep your waist on the flat surface.
3. Slowly return to the starting position.
4. Repeat, increasing in frequency as your comfort level allows.

### Double Knee Roll

1. Lie on a flat surface with your knees bent.
2. While keeping your shoulders flat, slowly roll your knees to your right side to touch the flat surface (floor or bed).
3. Roll your knees back over your body to the left side until they touch the opposite side of the flat surface.
4. Return to the starting position on your back and rest.
5. Repeat this exercise several times.

### Pelvic Tilt

1. Lie on your back on a flat surface with your knees bent and your arms at your side.
2. Slowly contract your abdominal muscles while lifting your pelvis up toward the ceiling.
3. Hold for 3 to 5 seconds and slowly return to your starting position.
4. Repeat several times.

**Kegel exercises** help to strengthen the pelvic floor muscles if done properly and regularly (Perry, 2011). Kegel exercises were originally developed by Dr. Arnold Kegel in the 1940s as a method of controlling incontinence in women after childbirth. The principle behind

these exercises is that strengthening the muscles of the pelvic floor improves urethral sphincter function.

While providing postpartum care, instruct women on primary prevention of stress incontinence by discussing the value and purpose of Kegel exercises. Approach the subject sensitively, avoiding the term *incontinent*. The terms *leakage*, *loss of urine*, or *bladder control issues* are more acceptable to most women.

### Take Note!

When properly performed, Kegel exercises have been effective in preventing or improving urinary continence (Ferreira, Santos, Duarte, & Rodrigues, 2012).

Women can perform Kegel exercises, doing ten 5-second contractions, whenever they change diapers, talk on the phone, or watch TV. Teach the woman to perform Kegel exercises properly; help her to identify the correct muscles by trying to stop and start the flow of urine when sitting on the toilet (Teaching Guidelines 16.3). Kegel exercises can be done without anyone knowing.

## Assisting With Self-Care Measures

Demonstrate and discuss with the woman ways to prevent infection during the postpartum period. Because she

may experience lochia drainage for as long as a month after childbirth, describe practices to promote well-being and healing. These measures include:

- Frequently change perineal pads, applying and removing them from front to back to prevent spreading contamination from the rectal area to the genital area.
- Avoid using tampons after giving birth to decrease the risk of infection.
- Shower once or twice daily using a mild soap. Avoid using soap on nipples.
- Use a sitz bath after every bowel movement to cleanse the rectal area and relieve enlarged hemorrhoids.
- Use the peribottle filled with warm water after urinating and before applying a new perineal pad.
- Avoid tub baths for 4 to 6 weeks, until joints and balance are restored, to prevent falls.
- Wash your hands before changing perineal pads, after disposing of soiled pads, and after voiding (Mattson, & Smith, 2011).

To reduce the risk of infection at the episiotomy site, reinforce proper perineal care with the client, showing her how to rinse her perineum with the peribottle after she voids or defecates. Stress the importance of always patting gently from front to back and washing her hands thoroughly before and after perineal care. For hemorrhoids, have the client apply witch hazel-soaked pads (Tucks Pads), ice packs to relieve swelling, or hemorrhoidal cream or ointment if ordered.

### Teaching Guidelines 16.3

#### PERFORMING KEGEL EXERCISES

1. Identify the correct pelvic floor muscles by contracting them to stop the flow of urine while sitting on the toilet.
2. Repeat this contraction several times to become familiar with it.
3. Start the exercises by emptying the bladder.
4. Tighten the pelvic floor muscles and hold for 10 seconds.
5. Relax the muscle completely for 10 seconds.
6. Perform 10 exercises at least three times daily. Progressively increase the number that you perform.
7. Perform the exercises in different positions, such as standing, lying, and sitting.
8. Keep breathing during the exercises.
9. Don't contract your abdominal, thigh, leg, or buttocks muscles during these exercises.
10. Relax while doing Kegel exercises and concentrate on isolating the right muscles.
11. Attempt to tighten your pelvic muscles before sneezing, jumping, or laughing.
12. Remember that you can perform Kegel exercises anywhere without anyone noticing.

## Ensuring Safety

One of the safety concerns during the postpartum period is orthostatic hypotension. When the woman rapidly moves from a lying or sitting position to a standing one, her blood pressure can suddenly drop, causing her pulse rate to increase. She may become dizzy and faint. Be aware of this problem and initiate the following safeguards:

- Check blood pressure first before ambulating the client.
- Elevate the head of the bed for a few minutes before ambulating the client.
- Have the client sit on the side of the bed for a few moments before getting up.
- Help the client to stand up, and stay with her.
- Ambulate alongside the client and provide support if needed.
- Frequently ask the client how her head feels.
- Stay close by to assist if she feels light-headed.

Additional topics to address concern infant safety. Instruct the woman to place the newborn back in the crib on his or her back if she is feeling sleepy. If the woman falls asleep while holding the infant, she might drop him or her. Also, instruct mothers to keep the door to their room closed when their infant is in their

room with them. They should check the identification of anyone who enters their room or who wants to take the infant out of the room. This will prevent infant abduction.

## Counseling About Sexuality and Contraception

Pregnancy and childbirth are special periods in a woman's life that involve significant physical, hormonal, psychological, social, and cultural changes that may influence her own sexuality as well as the health of a couple's sexual relationship. This is often a time period filled with excitement, changes, and challenges. Mothers often face changes in their own sexuality in their adjustment to motherhood. Sexuality is an important part of every woman's life. Women want to get back to "normal" as soon as possible after giving birth, but a couple's sexual relationship cannot be isolated from the psychological and psychosocial adjustments that both partners are going through.

Postpartum women may hesitate to resume sexual relations for a number of reasons. Many postpartum women have fatigue, weakness, vaginal bleeding, perineal discomfort, hemorrhoids, sore breasts, decreased vaginal lubrication resulting from low estrogen levels, and dyspareunia. Fatigue, the physical demands made by the infant, and the stress of new roles and responsibilities may stress the emotional reserves of couples. New parents may not get much privacy or rest, both of which are necessary for sexual pleasure (Golanty, & Edlin, 2012).

Men may feel they now have a secondary role within the family, and they may not understand their partner's daily routine. These issues, combined with the woman's increased investment in the mothering role, can strain the couple's sexual relationship.

Although couples are reluctant to ask, they often want to know when they can safely resume sexual intercourse after childbirth. Typically, sexual intercourse can be resumed once bright-red bleeding has stopped and the perineum is healed from an episiotomy or lacerations. This is usually by the third to the sixth week postpartum. However, there is no set, prescribed time at which to resume sexual intercourse after childbirth. Each couple must set their own time frame when they feel it is appropriate to resume sexual intercourse. Despite fears and myths about sexual activity during pregnancy, maintaining a couple's sexual interactions throughout pregnancy and the postpartum period can promote sexual health and well-being and a greater depth of intimacy (Johnson, 2011).

When counseling the couple about sexuality, determine what knowledge and concerns the couple have about their sexual relationship. Inform the couple that fluctuations in sexual interest are normal. Reassure the breast-feeding mother that she may notice a let-down reflex during orgasm and find her breasts are very sensitive

when touched by her partner. Also inform the couple about how to prevent discomfort. Precoital vaginal lubrication may be impaired during the postpartum period, especially in women who are breast-feeding. Use of water-based gel lubricants (KY jelly, Astroglide) can help. Pelvic floor exercises, in addition to preventing stress incontinence, can also enhance sensation.

Initiation of contraception during the postpartum period is important to prevent unintended pregnancy and short birth intervals, which can lead to negative health outcomes for mother and infant. Contraceptive options should be included in the discussions with the couple so that they can make an informed decision before resuming sexual activity. Many couples are overwhelmed with the amount of new information given to them during their brief hospitalization, so many are not ready for a lengthy discussion about contraceptives. Presenting a brief overview of the options, along with literature, may be appropriate. It may be suitable to ask them to think about contraceptive needs and preferences and advise them to use a barrier method (condom with spermicidal gel or foam) until they choose another form of contraception. This advice is especially important if the follow-up appointment will not occur for 4 to 6 weeks after childbirth, because many couples will resume sexual activity before this time. Some postpartum women ovulate before their menstrual period returns and thus need contraceptive protection to prevent another pregnancy.

Recently, the CDC assessed evidence regarding the safety of combined hormonal contraceptive use during the postpartum period. They recommend that postpartum women not use combined hormonal contraceptives during the first 21 days after childbirth because of the high risk for venous thromboembolism (VTE) during this period. During days 21 to 42 postpartum, women without risk factors for VTE generally can initiate combined hormonal contraceptives, but women with risk factors for VTE (e.g., previous VTE or recent cesarean delivery) generally should not use these methods. After 42 days postpartum, no restrictions on the use of combined hormonal contraceptives based on postpartum status apply (CDC, 2011a).

Open and effective communication is necessary for effective contraceptive counseling so that information is clearly understood. Provide clear, consistent information appropriate to the woman and her partner's language, culture, and educational level. This will help the couple select the best contraceptive method. Research supports that postpartum education about contraception leads to more contraception use and fewer unplanned pregnancies. Both short-term and multiple-contact interventions had effects (Lopez, Hiller, & Grimes, 2010).

## Promoting Maternal Nutrition

The postpartum period can be a stressful one for myriad reasons, such as fatigue, the physical stress of pregnancy

and birth, and the nonstop work required to take care of the newborn and to meet the needs of other family members. As a result, the new mother may ignore her own nutrition needs. Whether she is breast-feeding or bottle-feeding, encourage the new mother to take good care of herself and eat a healthy diet so that the nutrients lost during pregnancy can be replaced and she can return to a healthy weight. In general, nutrition recommendations for the postpartum woman include the following:

- Eat a wide variety of foods with high nutrient density.
- Eat meals that require little or no preparation.
- Avoid high-fat fast foods.
- Drink plenty of fluids daily—at least 2,500 mL (approximately 84 oz).
- Avoid fad weight-reduction diets and harmful substances such as alcohol, tobacco, and drugs.
- Avoid excessive intake of fat, salt, sugar, and caffeine.
- Eat the recommended daily servings from each food group (Box 16.4).

The breast-feeding mother's nutritional needs are higher than they were during pregnancy. The mother's

diet and nutritional status influence the quantity and quality of breast milk. To meet the needs for milk production, the woman's nutritional needs increase as follows:

- **Calories:** +500 cal/day for the first and second 6 months of lactation
- **Protein:** +20 g/day, adding an extra 2 cups of skim milk
- **Calcium:** +400 mg daily—consumption of four or more servings of milk
- **Fluid:** +2 to 3 quarts of fluids daily (milk, juice or water); no sodas

Some foods eaten by the breast-feeding mother may affect the flavor of the breast milk or cause gastrointestinal problems for the infant. Not all infants are affected by the same foods. It is suggested that the mother identify the food item that may be causing a problem for the infant and reduce or eliminate her intake of it.

Nutritional needs for breast-feeding mothers are based on the nutritional content of breast milk and the energy expended to produce it. If intake of calories exceeds the energy expended, weight gain occurs. The highest incidence of obesity in women occurs during the childbearing years. Women need to be made aware that weight gained during their reproductive years will impact their health negatively as they age. Nurses can assist women in their postpartum weight management program by assessing their readiness to change to lose their pregnancy weight gain; assessing their breast-feeding status, dietary intake, and activity levels; and assessing them for stress and depressive symptoms, which might hinder their weight loss (Lutz, & Przytulski, 2011).

#### Take Note!

During a woman's brief stay in a health care facility, she may demonstrate a healthy appetite and eat well. Nutritional problems usually start at home when the mother needs to make her own food selections and prepare her own meals. This is a crucial area to address during follow-up.

#### BOX 16.4

### NUTRITIONAL RECOMMENDATIONS FOR NUTRITION DURING THE POSTPARTUM PERIOD

#### Recommendations for the Lactating Woman From the Food Guide Pyramid

- Fruits: 4 servings
- Vegetables: 4 servings
- Milk: 4 to 5 servings
- Bread, cereal, pasta: 12 or more servings
- Meat, poultry, fish, eggs: 7 servings
- Fats, oils, and sweets: 5 servings (Dudek, 2010)

#### General Dietary Guidelines for Americans from the Food Guide on MyPlate (for the Nonlactating Woman)

- Fruits: Make half of your plate fruits and vegetables.
- Vegetables: Eat red, orange, and dark-green vegetables.
- Milk: Switch to skim milk or 1%.
- Breads, grains, and cereals should be whole grains.
- Meat, poultry, fish, eggs: Eat seafood twice a week and beans, which are high in fiber.
- Eat the right amount of calories for you; enjoy your food, but eat less.
- Be physically active your way in activities that you enjoy.
- Fats, oils, and sweets: Cut back on these.
- Use food labels to help you make better choices (USDA & USDHHS, 2011).

### Supporting the Woman's Choice of Infant Feeding Method

Although there is considerable evidence that breast-feeding has numerous health benefits, many mothers choose to feed their infants formula for the first year of life. Nurses must be able to deliver sound, evidence-based information to help the new mother choose the best way to feed her infant and must support her in her decision. Research findings indicate that parents do listen to nurse's instruction on feeding practices (Olson, Horodyski, Brophy-Herb, & Iwanski, 2010).

Many factors affect a woman's choice of feeding method, such as culture, employment demands, support from significant others and family, and knowledge base. Although breast-feeding is encouraged, be sure that

couples have the information they need to make an informed decision. Whether a couple chooses to breast-feed or bottle-feed the newborn, support and respect their choice.

Certain women should not breast-feed. Drugs such as antithyroid drugs, antineoplastic drugs, alcohol, or street drugs (amphetamines, cocaine, PCP, marijuana) enter the breast milk and would harm the infant, so women taking these substances should not breast-feed. To prevent HIV transmission to the newborn, women who are HIV positive should not breast-feed. Other contraindications to breast-feeding include a newborn with an inborn error of metabolism such as galactosemia or phenylketonuria (PKU), or a mother with a serious mental health disorder that would prevent her from remembering to feed the infant consistently.

### Providing Assistance With Breast-Feeding and Bottle-Feeding

First-time mothers often have many questions about feeding, and even women who have had experience with feeding may have questions. Regardless of whether the postpartum woman is breast-feeding or bottle-feeding her newborn, she can benefit from instruction.

#### PROVIDING ASSISTANCE WITH BREAST-FEEDING

The AAP (2012) recommends breast-feeding for all full-term newborns. Exclusive breast-feeding is sufficient to support optimal growth and development for approximately the first 6 months of life. Breast-feeding should be continued for at least the first year of life and beyond for as long as mutually desired by mother and child. Educating a mother about breast-feeding will increase the likelihood of a successful breast-feeding experience.

At birth, all newborns should be quickly dried, assessed, and, if stable, placed immediately in uninterrupted skin-to-skin contact (kangaroo care) with their mother. This is good practice whether the mother is going to breast-feed or bottle-feed her infant. Kangaroo care provides the newborn with optimal physiologic stability, warmth, and opportunities for the first feed (Ludington-Hoe, 2011).

The benefits of breast-feeding are clear (see Chapter 18). To promote breast-feeding, the Baby-Friendly Hospital Initiative, an international program of the World Health Organization and the United Nations International Children's Emergency Fund (UNICEF), was started in 1991. As part of this program, the hospital or birth center should take the following 10 steps to provide "an optimal environment for the promotion, protection, and support of breast-feeding":

1. Have a written breast-feeding policy that is communicated to all staff.
2. Educate all staff to implement this written policy.
3. Inform all women about the benefits and management of breast-feeding.
4. Show all mothers how to initiate breast-feeding within 30 minutes of birth.
5. Give no food or drink other than breast milk to all newborns.
6. Demonstrate to all mothers how to initiate and maintain breast-feeding.
7. Encourage breast-feeding on demand.
8. Allow no pacifiers to be given to breast-feeding infants.
9. Establish breast-feeding support groups and refer mothers to them.
10. Practice rooming-in 24 hours daily (CDC 2011b; UNICEF, 2011).

The nurse is responsible for encouraging breast-feeding when appropriate. For the woman who chooses to breast-feed her infant, the nurse or lactation consultant will need to spend time instructing her about how to do so successfully. Many women have the impression that breast-feeding is simple. Although it is a natural process, women may experience some difficulty in breast-feeding their newborns. Nurses can assist mothers in smoothing out this transition. Assist and provide one-to-one instruction to breast-feeding mothers, especially first-time breast-feeding mothers, to ensure correct technique. Suggestions are highlighted in Teaching Guidelines 16.4.

#### Take Note!

Some newborns "latch on and catch on" right away, and others take more time and patience. Inform new mothers about this to reduce their frustration and uncertainty about their ability to breast-feed.

Tell mothers that they need to believe in themselves and their ability to accomplish this task. They should not panic if breast-feeding does not go smoothly at first; it takes time and practice. Additional suggestions to help mothers relax and feel more comfortable breast-feeding, especially when they return home, include the following:

- Select a quiet corner or room where you won't be disturbed.
- Use a rocking chair to soothe both you and your infant.
- Take long, slow deep breaths to relax before nursing.
- Drink while breast-feeding to replenish body fluids.
- Listen to soothing music while breast-feeding.
- Cuddle and caress the infant while feeding.
- Set out extra cloth diapers within reach to use as burping cloths.
- Allow sufficient time to enjoy each other in an unhurried atmosphere.
- Involve other family members in all aspects of the infant's care from the start.

## Teaching Guidelines 16.4

### BREAST-FEEDING SUGGESTIONS

- Explain that breast-feeding is a learned skill for both parties.
- Offer a thorough explanation about the procedure.
- Instruct the mother to wash her hands before starting.
- Inform her that her afterpains will increase during breast-feeding.
- Make sure the mother is comfortable (pain-free) and not hungry.
- Tell the mother to start the feeding with an awake and alert infant showing hunger signs.
- Assist the mother to position herself correctly for comfort.
- Urge the mother to relax to encourage the let-down reflex.
- Guide the mother's hand to form a "C" to access the breast with thumb on top and other four fingers under the breast.
- Have the mother lightly tickle the infant's upper lip with her nipple to stimulate the infant to open the mouth wide.
- Aid her in helping the infant to latch on by bringing the infant rapidly to the breast with a wide-open mouth.
- Show her how to check that the newborn's mouth position is correct, and tell her to listen for a sucking noise.
- Demonstrate correct removal from the breast, using her finger to break the suction.
- Instruct the mother on how to burp the infant before changing from one breast to another.
- Show her different positions, such as cradle and football holds and side-lying positions (see Chapter 18).
- Reinforce and praise the mother for her efforts.
- Allow ample time to answer questions and address concerns.
- Refer the mother to support groups and community resources.

Because obesity in America is increasing in all walks of life, it is important for nurses to be knowledgeable about how it impacts breast-feeding and ways to support the obese mother. Research shows that mothers who are obese (BMI > 30) are less likely to initiate lactation, have difficulties with latching on, have delayed lactogenesis, and are prone to early cessation of breast-feeding (Gussler, & Arensberg, 2011). Obesity rates are highest among African American women, who have the lowest rate of breast-feeding initiation and shortest duration when compared to Hispanic and Caucasian women. Women who are overweight and obese have lowered prolactin responses to infant sucking, thus milk production may be inhibited. Lactation plays a significant role in preventing future obesity in both the mother and the infant (Gilbert, 2011).

Nurses can assist in managing obesity-related lactation challenges by keeping the mother and newborn together to facilitate early and frequent sucking to trigger prolactin and oxytocin production, which will help negate the obesity-related blunting of the prolactin response. Suggesting a sandwich technique to insert the mother's breast into the newborn's mouth to elicit sucking might be helpful for the mother with large breasts. In the sandwich technique, the mother is taught to grasp her breast by making a "C" with her thumb and index finger. The thumb stabilizes the top of the breast while the remaining four fingers support her breast from below. Massage or pumping the breast may soften and extend the nipple for easier infant latch-on. In short, nurses can make a difference by observing lactation, assessing infant

hydration and satisfaction, and reassuring the mother about her breast-feeding capacity.

### PROVIDING ASSISTANCE WITH BOTTLE-FEEDING

If the mother or couple has chosen to bottle-feed their newborn, the nurse should respect and support their decision. Discuss with the parents what type of formula they will use. Commercial formulas are classified as cow's milk-based (Enfamil, Similac), soy protein-based (Isomil, Prosoabee, Nursoy), or specialized or therapeutic formulas for infants with protein allergies (Nutramigen, Pregestimil, Alimentum). Commercial formulas can also be purchased in various forms: powdered (must be mixed with water), condensed liquid (must be diluted with equal amounts of water), ready to use (poured directly into bottles), and prepackaged (ready to use in disposable bottles).

Newborns need about 108 cal/kg or approximately 650 cal/day (Dudek, 2010). Therefore, explain to parents that a newborn will need 2 to 4 ounces to feel satisfied at each feeding. Until about age 4 months, most bottle-fed infants need six feedings a day. After this time, the number of feedings declines to accommodate other foods in the diet, such as fruits, cereals, and vegetables (Dudek, 2010). For more information on newborn nutrition and bottle feeding, see Chapter 18.

When teaching the mother about bottle-feeding, provide the following guidelines:

- Make feeding a relaxing time, a time to provide both food and comfort to your newborn.
- Use the feeding period to promote bonding by smiling, singing, making eye contact, and talking to the infant.
- Powdered formula mixes more easily and the lumps dissolve faster if you use room-temperature water.
- Store any formula prepared in advance in the refrigerator to keep bacteria from growing.
- Do not microwave formula; the microwave won't heat it evenly, causing hot spots.
- Always hold the newborn when feeding. Never prop the bottle.
- Use a comfortable position when feeding the newborn. Place the newborn in your dominant arm, which is supported by a pillow. Or have the newborn in a semi-upright position supported in the crook of your arm. (This position reduces choking and the flow of milk into the middle ear.)
- Tilt the bottle so that the nipple and the neck of the bottle are always filled with formula. This prevents the infant from taking in too much air.
- Stimulate the sucking reflex by touching the nipple to the infant's lips.
- Refrigerate any powdered formula that has been combined with tap water.
- Discard any formula not taken; do not keep it for future feedings.
- Burp the infant frequently, and place the baby on his or her back for sleeping.
- Use only iron-fortified infant formula for the first year (Foster, 2011).

## Teaching About Breast Care

Regardless of whether or not the mother is breast-feeding her newborn, urge her to wear a very supportive, snug bra 24 hours a day to support enlarged breasts and promote comfort. A woman who is breast-feeding should wear a supportive bra throughout the lactation period. A woman who is not nursing should wear it until engorgement ceases, and then should wear a less restrictive one. The bra should fit snugly while still allowing the mother to breathe without restriction. All new mothers should use plain water to clean their breasts, especially the nipple area; soap is drying and should be avoided.

### Assessing the Breasts

Instruct the mother how to examine her breasts daily. Daily assessment includes the milk supply (breasts will feel full as they are filling), the condition of the nipples (red, bruised, fissured, or bleeding), and the success of breast-feeding. The fullness of the breasts may progress to engorgement in the breast-feeding mother if feedings are delayed or breast-feeding is ineffective. Palpating both breasts will help identify whether the breasts are soft, filling, or engorged. A similar assessment of the breasts should be completed on the nonlactating mother to identify any problems, such as engorgement or mastitis.

### Alleviating Breast Engorgement

Breast engorgement usually occurs during the first week postpartum. It is a common response of the breasts to the sudden change in hormones and the presence of an increased amount of milk. Reassure the woman that this condition is temporary and usually resolves within 72 hours.

#### ALLEVIATING BREAST ENGORGEMENT IN THE BREAST-FEEDING WOMAN

If the mother is breast-feeding, encourage frequent feedings, at least every 2 to 3 hours, using manual expression just before feeding to soften the breast so the newborn can latch on more effectively. Advise the mother to allow the newborn to feed on the first breast until it softens before switching to the other side. See Chapter 18 for more information on alleviating breast engorgement and other common breast-feeding concerns.

#### ALLEVIATING BREAST ENGORGEMENT AND SUPPRESSING LACTATION IN THE BOTTLE-FEEDING WOMAN

If the woman is bottle-feeding, explain that breast engorgement is a self-limiting phenomenon that disappears as increasing estrogen levels suppress milk formation (i.e., lactation suppression). Encourage the woman to use ice packs, to wear a snug, supportive bra 24 hours a day, and to take mild analgesics such as acetaminophen. Encourage

## Teaching Guidelines 16.5

### SUPPRESSING LACTATION

1. Wear a supportive, snugly fitting bra 24 hours daily, but not one that binds the breasts too tightly or interferes with your breathing.
2. Suppression may take 5 to 7 days to accomplish.
3. Take mild analgesics to reduce breast discomfort.
4. Let shower water flow over your back rather than your breasts.
5. Avoid any breast stimulation in the form of sucking or massage.
6. Drink to quench your thirst. Restricting your fluid intake will not dry up your milk.
7. Reduce your salt intake to decrease fluid retention.
8. Use ice packs or cool compresses (e.g., cool cabbage leaves) inside the bra to decrease local pain and swelling; change them every 30 minutes (Simpkin, & James, 2012).

her to avoid any stimulation to the breasts that might foster milk production, such as warm showers or pumping or massaging the breasts. Medication is no longer given to hasten lactation suppression because these agents had limited effectiveness and adverse side effects. Teaching Guidelines 16.5 provides tips on lactation suppression.

## Promoting Family Adjustment and Well-Being

The postpartum period involves extraordinary physiologic, psychological, and sociocultural changes in the life of a woman and her family. Adapting to the role of a parent is not an easy process. The postpartum period is a “getting-to-know-you” time when parents begin to integrate the newborn into their lives as they reconcile the fantasy child with the real one. This can be a very challenging period for families. Nurses play a major role in assisting families to adapt to the changes, promoting a smooth transition into parenthood. Appropriate and timely interventions can help parents adjust to the role changes and promote attachment to the newborn (Fig. 16.7).

For couples who already have children, the addition of a new member may bring role conflict and challenges. The nurse should provide anticipatory guidance about siblings’ responses to the new baby, increased emotional tension, child development, and meeting the multiple needs of the expanding family. Although the multiparous woman has had experience with newborns, do not assume that her knowledge is current and accurate, especially if some time has elapsed since her previous child was born. Reinforcing information is important for all families.

## Promoting Parental Roles

Parents’ roles develop and grow when they interact with their newborn (see Chapter 15 for information on maternal and paternal adaptation). The pleasure they derive from this interaction stimulates and reinforces this behavior. With repeated, continued contact with the newborn, parents learn to recognize cues and understand the newborn’s behavior. This positive interaction contributes to family harmony.

Nurses need to know the stages parents go through as they make their new parenting roles fit into their life experience. Assess the parents for attachment behaviors (normal and deviant), adjustment to the new parental role, family member adjustment, social support system, and educational needs. To promote parental role adaptation and parent–newborn attachment, provide the following nursing interventions:

- Provide as many opportunities as possible for parents to interact with their newborn. Encourage parents to explore, hold, and provide care for their newborn. Praise them for their efforts.
- Model behaviors by holding the newborn close, calling the newborn’s name, and speaking positively.
- Speak directly to the newborn in a calm voice, while pointing out the newborn’s positive features to the parents.
- Evaluate the family’s strengths and weaknesses and readiness for parenting.
- Assess for risk factors such as lack of social support and the presence of stressors.
- Observe the effect of culture on the family interaction to determine healthy family dynamics.
- Monitor parental attachment behaviors to determine whether alterations require referral. Positive behaviors include holding the newborn closely or in an *en face* position, talking to or admiring the newborn, or demonstrating closeness. Negative behaviors include avoiding contact with the newborn, calling it names, or showing a lack of interest in caring for the newborn (see Table 16.1).
- Monitor the parents’ coping behaviors to determine alterations that need intervention. Positive coping behaviors include positive conversations between the partners, both parents wanting to be involved with newborn care, and lack of arguments between the parents. Negative behaviors include not visiting, limited conversations or periods of silence, and heated arguments or conflict.
- Identify the support systems available to the new family and encourage them to ask for help. Ask direct questions about home or community support. Make referrals to community resources to meet the family’s needs.
- Arrange for community home visits in high-risk families to provide positive reinforcement of parenting skills and nurturing behaviors with the newborn.

C

**FIGURE 16.7** Examples of family members carrying out roles to promote adjustment and well-being. **(A)** An aunt admiring the newest member of the family. **(B)** A father holding his newborn closely on his chest. **(C)** Grandparents welcoming the newest little one to the family circle.

- Provide anticipatory guidance about the following before discharge to reduce the new parents' frustration:
  - Newborn sleep–wake cycles (they may be reversed)
  - Variations in newborn appearance and developmental milestones (growth spurts)
  - How to interpret crying cues (hunger, wet, discomfort) and what to do about them
  - Sensory enrichment/stimulation (colorful mobile)
  - Signs and symptoms of illness and how to assess for fever
  - Important phone numbers, follow-up care, and needed immunizations
- Physical and emotional changes associated with the postpartum period
- Need to integrate siblings into care of the newborn; stress that sibling rivalry is normal and offer ways to reduce it
- Ways to make time together for the couple

In addition, nurses can help fathers to feel more competent in assuming their parental role by teaching and providing information (Fig. 16.8). Education can dispel any unrealistic expectations they may have, helping them to cope more successfully with the demands of fatherhood and thereby fostering a nurturing family relationship. See Evidence-Based Practice 16.1.

FIGURE 16.8 Father participating in newborn care.

### Explaining Sibling Roles

It can be overwhelming to a young child to have another family member introduced into his or her small, stable world. Although most parents try to prepare siblings for the arrival of their new little brother or sister, many young children experience stress. They may view the new infant as competition, or fear that they will be replaced in the parents' affection. All siblings need extra attention from their parents and reassurance that they are loved and important.

Many parents need reassurance that sibling rivalry is normal. Suggest the following to help parents minimize sibling rivalry:

- Expect and tolerate some regression (thumb sucking, bedwetting).

#### EVIDENCE-BASED PRACTICE 16.1

#### POSTNATAL PARENTAL EDUCATION FOR OPTIMIZING INFANT GENERAL HEALTH AND PARENT-INFANT RELATIONSHIPS

Parenting is important in the development of healthy children. New parents have much to learn soon after the birth of an infant and parents do not always have social support or role models to follow. This makes it essential to examine the effectiveness of interventions used by health personnel to educate new parents about caring for their newborn infants in the best possible way. Many learning needs arise in the early postpartum period, and it is important to examine interventions used to educate new parents about caring for their newborns during this time.

The primary objective was to assess the effects of structured postnatal education delivered by an educator to an individual or group on infant general health and parent-infant relationships.

#### STUDY

Randomized controlled trials of any structured postnatal education provided by an educator to individual parents or groups of parents within the first 2 months postbirth related to the care of an infant or parent-infant relationship. Of the 25 trials (3,689 mothers and 793 fathers) that met the inclusion criteria, only 15 (2,868 mothers and 613 fathers) reported usable data. Educational interventions included the following: 4 on infant sleep enhancement, 13 on infant behavior, 2 on general postbirth health, 2 on infant care, 3 on infant safety, and 1 on father involvement/skills with infants. Details of the randomization procedures, allocation concealment, blinding, and participant loss were often not reported. Of the outcomes analyzed, only six were measured similarly enough by more than one study to be combined in meta-analyses. Of these six meta-analyses, only two were found to have a low enough level of heterogeneity to provide an overall estimate of effect. Education on sleep enhancement resulted in a mean difference of 29 more nighttime minutes of infant sleep in 24 hours (95% confidence interval [CI], 18.53 to 39.73) than usual care. Education on infant behavior increased maternal knowledge of infant behavior by a mean difference of 2.85 points (95% CI, 1.78 to 3.91).

#### Findings

The benefits of educational programs to participants and their newborns remain unclear. Education on sleep enhancement appears to increase infant sleep and education about infant behavior potentially enhances mothers' knowledge; however more and larger, well-designed studies are needed to confirm this.

#### Nursing Implications

Although this study did not confirm the effectiveness of educating new parents in the postpartum period, nurses can continue to educate parents regarding infant care by demonstrating baby bathing techniques, feeding positions, swaddling, and home care. Postpartum education helps to enhance the preparedness of new parents when they are discharged and reduces their anxiety regarding infant care.

Adapted from Bryanton, J., & Beck, C. T. (2010). Postnatal parental education for optimizing infant general health and parent-infant relationships. *Cochrane Database of Systematic Reviews*, 2010(1). doi:10.1002/14651858.CD004068.pub3

- Explain childbirth in an appropriate way for the child's age.
- Encourage discussion about the new infant during relaxed family times.
- Encourage the sibling(s) to participate in decisions, such as the baby's name and toys to buy.
- Take the sibling on a tour of the maternity suite.
- Buy a T-shirt that says "I'm the [big brother or big sister]."
- Spend "special time" with the child.
- Read with the child. Some suggested titles include *Things to Do With a New Baby* (Ormerod, 1984); *Betsy's Baby Brother* (Wolde, 1975); *The Berenstain Bears' New Baby* (Berenstain, 1974); and *Mommy's Lap* (Horowitz, & Sorensen, 1993).
- Plan time for each child throughout the day.
- Role-play safe handling of a newborn, using a doll. Give the preschooler or school-age child a doll to care for.
- Encourage older children to verbalize emotions about the newborn.
- Purchase a gift that the child can give to the newborn.
- Purchase a gift that can be given to the child by the newborn.
- Arrange for the child to come to the hospital to see the newborn (Fig. 16.9).
- Move the sibling from his or her crib to a youth bed months in advance of the birth of the newborn.
- Show the older sibling photos of the baby growing in mommy's belly. Let them pat the baby beneath the bulge, talk to baby, and feel the baby kick.
- Encourage grandparents to pay attention to the older child when visiting.
- Tell the older sibling that their friends come and go, but siblings are forever.

FIGURE 16.9 Sibling visitation.

### Consider This

Katie and Molly have been excited about having a new baby sister ever since they were told about their mother's pregnancy. The 6-year-old twins are eagerly looking out the front window, waiting for their parents to bring their new sister, Jessica, home. The girls are big enough to help their mother care for their new sibling, and for the past few months they have been fixing up the new nursery and selecting baby clothes. They practiced diapering their dolls—their mother was specific about not using any powder or lotion on Jessica's bottom—and holding them correctly to feed them bottles. Finally, their mother arrives home from the hospital with Jessica in her arms!

The girls notice that their mother is very protective of Jessica and watches them carefully when they care for her. They fight over the opportunity to hold her or feed her. What is special to both of them is the time they spend alone with their parents. Although a new family member has been added, the twins still feel special and loved by their parents.

Thoughts: Bringing a new baby into an established family can cause conflict and jealousy. What preparation did the older siblings have before Jessica arrived? Why is it important for parents to spend time with each sibling separately?

- Encourage "Do unto others as you would have them do unto you" (Sears & Sears, 2011b).

### Discussing Grandparents' Role

Grandparents can be a source of support and comfort to the postpartum family if effective communication skills are used and roles are defined. The grandparents' role and involvement will depend on how close they live to the family, their willingness to become involved, and cultural expectations of their role. Just as parents and siblings go through developmental changes, so too do grandparents. These changes can have a positive or negative effect on the relationship.

Newborn care, feeding, and child-rearing practices have changed since the grandparents raised the parents. New parents may lack parenting skills but nonetheless want their parents' support without criticism. A grandparent's "take-charge approach" may not be welcome by new parents who are testing their own parenting roles, and family conflict may ensue. However, many grandparents respect their adult children's wishes for autonomy and remain "resource people" for them when requested.

### Take Note!

Grandparents' involvement can enrich the lives of the entire family if accepted in the right context and dose by the family.

Nurses can assist in the grandparents' role transition by assessing their communication skills, role expectations, and support skills during the prenatal period. Find out whether the grandparents are included in the couple's social support network and whether their support is wanted or helpful. If they are, and it is, then encourage the grandparents to learn about the parenting, feeding, and child-rearing skills their children have learned in childbirth classes. This information is commonly found in "grandparenting" classes, which introduce new parenting concepts and bring the grandparents up to date on today's childbirth practices.

### Teaching About Postpartum Blues

The postpartum period is typically a happy yet stressful time, because the birth of an infant is accompanied by enormous physical, social, and emotional changes. The postpartum woman may report feelings of emotional lability, such as crying one minute and laughing the next. **Postpartum blues** are transient emotional disturbances beginning in the first week after childbirth and are characterized by anxiety, irritability, insomnia, crying, loss of appetite, and sadness (Buttner, O'Hara, & Watson, 2012). These symptoms typically begin 3 to 4 days after childbirth and resolve by day 8 (Mattson, & Smith, 2011). These mood swings may be confusing to new mothers but usually are self-limiting. The blues typically resolve with restorative sleep.

Postpartum blues are thought to affect up to 75% of all new mothers; this condition is the mildest form of emotional disturbance associated with childbearing (March of Dimes, 2011). The mother maintains contact with reality consistently and symptoms tend to resolve spontaneously without therapy within 1 to 2 weeks.

#### Take Note!

Postpartum blues have been regarded as brief, benign, and without clinical significance, but several studies have proposed a link between blues and subsequent depression in the 6 months following childbirth (Yonkers, Vigod, & Ross, 2011).

Postpartum blues require no formal treatment other than support and reassurance because it does not usually interfere with the woman's ability to function and care for her infant. Further evaluation is necessary, however, if symptoms persist more than 2 weeks (Patel, Bailey, Jabeen, & Ali et al., 2012). Nurses can ease a mother's distress by encouraging her to vent her feelings and by demonstrating patience and understanding with her and her family. Suggest that getting outside help with housework and infant care might help her to feel less overwhelmed until the blues ease. Provide telephone numbers she can call when she feels down during the day. Making

women aware of this disorder while they are pregnant will increase their knowledge about this mood disturbance, which may lessen their embarrassment and increase their willingness to ask for and accept help if it does occur.

The postpartum woman also is at risk for postpartum depression and postpartum psychosis; these conditions are discussed in Chapter 22.

### Preparing for Discharge

The AAP and the American College of Obstetricians and Gynecologists (ACOG) state that the length of stay in the health care facility should be individualized for each mother and baby. A shortened hospital stay may be indicated if the following criteria are met:

- Mother is afebrile and vital signs are within normal range.
- Lochia is appropriate amount and color for stage of recovery.
- Hemoglobin and hematocrit values are within normal range.
- Uterine fundus is firm; urinary output is adequate.
- ABO blood groups and RhD status are known and, if indicated, anti-D immunoglobulin has been administered.
- Surgical wounds are healing and no signs of infection are present.
- Mother is able to ambulate without difficulty.
- Food and fluids are taken without difficulty.
- Self-care and infant care are understood and demonstrated.
- Family or other support system is available to care for both.
- Mother is aware of possible complications (AAP & ACOG, 2010).

### Providing Immunizations

Prior to discharge, check the immunity status for rubella for all mothers and give a subcutaneous injection of rubella vaccine if they are not serologically immune (titer less than 1:8). Be sure that the client signs a consent form to receive the vaccine. The rubella vaccine should not be given to any woman who is immune compromised, and the immune status of her close contacts needs to be determined before any vaccine is administered to her to prevent a more virulent case of the vaccine-preventable illness or potential death (King, & Brucker, 2011). Nursing mothers can be vaccinated because the live, attenuated rubella virus is not communicable. Inform all mothers receiving immunization about adverse effects (rash, joint symptoms, and a low-grade fever 5 to 21 days later) and the need to avoid pregnancy for at least 28 days after being vaccinated because of the risk of teratogenic effects (CDC, 2012).

If the client is Rh negative, check the Rh status of the newborn. Verify that the woman is Rh negative and

has not been sensitized, that her indirect Coombs' test (antibody screen) is negative, and that the newborn is Rh positive. Mothers who are Rh negative and have given birth to an infant who is Rh positive should receive an injection of Rh immunoglobulin within 72 hours after birth to prevent a sensitization reaction in the Rh-negative woman who received Rh-positive blood cells during the birthing process. Administering RhoGAM prevents initial isoimmunization in Rh-negative mothers by destroying fetal erythrocytes in the maternal system before maternal antibodies can develop and maternal memory cells become sensitized. This is a classic passive immunization technique. The usual protocol for the Rh-negative woman is to receive two doses of Rh immunoglobulin (RhoGAM), one at 28 weeks' gestation and the second dose within 72 hours after childbirth. The standard dose of Rho(D) immune globulin (RhoGAM) is 300 mcg given intramuscularly, which prevents the development of antibodies for an exposure of up to 15 mL of fetal red blood cells (King & Brucker, 2011). A signed consent form is needed after a thorough explanation is provided about the procedure, including its purpose, possible adverse effects, and effect on future pregnancies.

Administration of tetanus, diphtheria, and acellular pertussis ("whooping cough") vaccine (Tdap) in the postpartum period has been receiving increased attention due to the rising incidence of adult pertussis, which can be transmitted to the infant. The CDC/ACIP CDC's Advisory Committee on Immunization Practices and Joint Commission all recommend that postpartum women receive this vaccine before discharge if they have never been vaccinated or if they have not been vaccinated within the past 2 years (Tan, & Gerbie, 2010).

### Ensuring Follow-Up Care

New mothers and their families need to be attended to over an extended period of time by nurses knowledgeable about mother care, infant feeding (breast-feeding and bottle-feeding), infant care, and nutrition. Although continuous nursing care stops on discharge from the hospital or birthing center, extended episodic nursing care needs to be provided at home. Some of the challenges faced by families after discharge are described in Box 16.5.

Many new mothers are reluctant to "cut the cord" after their brief stay in the health care facility and need expanded community services. Women who are discharged too early from the hospital run the risk of uterine subinvolution, discomfort at an episiotomy or cesarean site, infection, fatigue, and maladjustment to their new role. Postpartum nursing care should include a range of family-focused care, including telephone calls, outpatient clinics, and home visits. Typically, public health nurses, community and home health nurses, and the health care provider's office staff will provide postpartum care after hospital discharge.

#### BOX 16.5

### CHALLENGES FACING FAMILIES AFTER DISCHARGE

- Lack of role models for breast-feeding and infant care
- Lack of support from the new mother's own mother if she did not breast-feed
- Increased mobility of society, which means that extended family may live far away and cannot help care for the newborn and support the new family
- Feelings of isolation and limited community ties for women who work full time
- Shortened hospital stays: parents may be overwhelmed by all the information they are given in the brief hospital stay
- Prenatal classes usually focus on the birth itself rather than on skills needed to care for themselves and the newborn during the postpartum period
- Limited access to education and support systems for families from diverse cultures

Adapted from Bope, E., & Kellerman, R. (2012). *Conn's current therapy 2012*. Philadelphia, PA: Saunders Elsevier.

### PROVIDING TELEPHONE FOLLOW-UP

Telephone follow-up typically occurs during the first week after discharge to check on how things are going at home. Calls can be made by perinatal nurses within the agency as part of follow-up care or by the local health department nurses. One disadvantage of a phone call assessment is that the nurse cannot see the client and thus must rely on the mother or the family's observations. The experienced nurse needs to be able to recognize distress and give appropriate advice and referral information if needed.

### PROVIDING OUTPATIENT FOLLOW-UP

For mothers with established health care providers such as private pediatricians and obstetricians, visits to the office are arranged soon after discharge. For the woman with an uncomplicated vaginal birth, an office visit is usually scheduled for 4 to 6 weeks after childbirth. A woman who had a cesarean birth frequently is seen within 2 weeks after hospital discharge. Hospital discharge orders will specify when these visits should be made. Newborn examinations and further diagnostic laboratory studies are scheduled within the first week.

#### Take Note!

The hospital stay of the mother and her healthy term newborn should be long enough to allow identification of early problems and to ensure that the family is able and prepared to care for the infant at home (AAP, 2010).

Outpatient clinics are available in many communities. If family members run into a problem, the local clinic is available to provide assessment and treatment. Clinic visits can replace or supplement home visits. Although these clinics are open during daytime hours only and the staff members are unfamiliar with the family, they can be a valuable resource for the new family with a problem or concern.

#### PROVIDING HOME VISIT FOLLOW-UP

Home visits are usually made within the first week after discharge to assess the mother and newborn. During the home visit, the nurse assesses for and manages common physical and psychosocial problems. In addition, the home nurse can help the new parents adjust to the change in their lives. The postpartum home visit usually includes the following:

- *Maternal assessment:* general well-being, vital signs, breast health and care, abdominal and musculoskeletal status, voiding status, fundus and lochia status, psychological and coping status, family relationships, proper feeding technique, environmental safety check, newborn care knowledge, and health teaching needed (Fig. 16.10 shows sample assessment forms.)
- *Infant assessment:* physical examination, general appearance, vital signs, home safety check, child development status, any education needed to improve parents' skills

The home care nurse must be prepared to support and educate the woman and her family in the following areas:

- Breast-feeding or bottle-feeding technique and procedures
- Appropriate parenting behavior and problem solving
- Maternal/newborn physical, psychosocial, and culture–environmental needs
- Emotional needs of the new family
- Warning signs of problems and how to prevent or eliminate them
- Sexuality issues, including contraceptive use
- Immunization needs for both mother and infant
- Family dynamics for smooth transition
- Links to health care providers and community resources

## KEY CONCEPTS

- The transitional adjustment period between birth and parenthood includes education about baby care basics, the role of the new family, emotional support, breast-feeding or bottle-feeding support, and maternal mentoring.
- Sensitivity to how childbearing practices and beliefs vary for multicultural families and how best to provide appropriate nursing care to meet their needs are important during the postpartum period.
- A thorough postpartum assessment is key to preventing complications as is frequent handwashing by the nurse, especially between handling mothers and infants.
- The postpartum assessment that uses the acronym BUBBLE-EE (breasts, uterus, bowel, bladder, lochia, episiotomy/perineum/epidural site, extremities, and emotions) is a helpful guide in performing a systematic head-to-toe postpartum assessment.
- Lochia is assessed according to its amount, color, and change with activity and time. It proceeds from lochia rubra to serosa to alba.
- Because of shortened agency stays, nurses must use this brief time with the client to address areas of comfort, elimination, activity, rest and exercise, self-care, sexuality and contraception, nutrition, family adaptation, discharge, and follow-up.
- The AAP advocates breast-feeding for all full-term newborns, maintaining that, ideally, breast milk should be the sole nutrient for the first 6 months and continued with foods until 12 months of life or longer.
- Successful parenting is a continuous and complex interactive process that requires the acquisition of new skills and the integration of the new member into the existing family unit.
- Bonding is a vital component of the attachment process and is necessary in establishing parent–infant attachment and a healthy, loving relationship; attachment behaviors include seeking and maintaining proximity to, and exchanging gratifying experiences with, the infant.
- Nurses can be instrumental in facilitating attachment by first understanding attachment behaviors (positive and negative) of newborns and parents, and intervening appropriately to promote and enhance attachment.
- New mothers and their families need to be attended to over an extended period of time by nurses knowledgeable about mother care, newborn feeding (breast-feeding and bottle-feeding), newborn care, and nutrition.

## MULTIPLE-CHOICE QUESTIONS

- When assessing a postpartum woman, which of the following would lead the nurse to suspect postpartum blues?
  - Panic attacks and suicidal thoughts
  - Anger toward self and infant
  - Periodic crying and insomnia
  - Obsessive thoughts and hallucinations
- Which of these activities would best help the postpartum nurse to provide culturally sensitive care for the childbearing family?
  - Taking a transcultural course
  - Caring for only families of his or her cultural origin
  - Teaching Western beliefs to culturally diverse families
  - Educating himself or herself about diverse cultural practices
- Which of the following suggestions would be most appropriate to include in the teaching plan for a postpartum woman who needs to lose weight?
  - Increase fluid intake and acid-producing foods in her diet.
  - Avoid empty-calorie foods and increase exercise.
  - Start a high-protein diet and restrict fluids.
  - Eat no snacks or carbohydrates.
- After teaching a group of breast-feeding women about nutritional needs, the nurse determines that the teaching was successful when the women state that they need to increase their intake of which nutrients?
  - Carbohydrates and fiber
  - Fats and vitamins
  - Calories and protein
  - Iron-rich foods and minerals
- Which of the following would lead the nurse to suspect that a postpartum woman was developing a complication?
  - Fatigue and irritability
  - Perineal discomfort and pink discharge
  - Pulse rate of 60 bpm
  - Swollen, tender, hot area on breast
- Which of the following would the nurse assess as indicating positive bonding between the parents and their newborn?
  - Holding the infant close to the body
  - Having visitors hold the infant
  - Buying expensive infant clothes
  - Requesting that the nurses care for the infant
- Which activity would the nurse include in the teaching plan for parents with a newborn and an older child to

reduce sibling rivalry when the newborn is brought home?

- Punishing the older child for bedwetting behavior
  - Sending the sibling to the grandparents' house
  - Planning a daily "special time" for the older sibling
  - Allowing the sibling to share a room with the infant
- The major purpose of the first postpartum homecare visit is to:
    - Identify complications that require interventions
    - Obtain a blood specimen for PKU testing
    - Complete the official birth certificate
    - Support the new parents in their parenting roles

## CRITICAL THINKING EXERCISES

- As a nurse working on a postpartum unit, you enter the room of Ms. Jones, a 22-year-old primipara, and find her chatting on the phone while her newborn is crying loudly in the bassinette, which has been pushed into the bathroom. You pick up and comfort the newborn. While holding the baby, you ask the client if she was aware her newborn was crying. She replies, "That's about all that monkey does since she was born!" You hand the newborn to her and she places the newborn on the bed away from her and continues her phone conversation.
  - What is your nursing assessment of this encounter?
  - What nursing interventions would be appropriate?
  - What specific discharge interventions may be needed?
- Jennifer Adamson, a 34-year-old single primipara, left the hospital after a 36-hour stay with her newborn son. She lives alone in a one-bedroom walk-up apartment. As the postpartum home health nurse visiting her 2 days later, you find the following:
  - Tearful client pacing the floor holding her crying son
  - Home cluttered and in disarray
  - Fundus firm and displaced to right of midline
  - Moderate lochia rubra; episiotomy site clean, dry, and intact
  - Vital signs within normal range; pain rating less than 3 points on scale of 1 to 10
  - Breasts engorged slightly; supportive bra on
  - Newborn assessment within normal limits
  - Distended bladder upon palpation; reporting urinary frequency
  - Which of these assessment findings warrants further investigation?
  - What interventions are appropriate at this time, and why?
  - What health teaching is needed before you leave this home?

3. The nurse walks into the room of Lisa Drew, a 24-year-old primigravida. She asks the nurse to hand her the bottle sitting on the bedside table, stating, "I'm going to finish it off because my baby only ate half of it 3 hours ago when I fed him."
  - a. What response by the nurse would be appropriate at this time?
  - b. What action should the nurse take?
  - c. What health teaching is needed for Lisa prior to discharge?
2. Find a web site that offers advice to new parents about breast-feeding. Critique the site, the author's credentials, and the accuracy of the content.
3. Outline instructions you would give to a new mother on how to use her peribottle.
4. Breast tissue swelling secondary to vascular congestion after childbirth and preceding lactation describes \_\_\_\_\_.
5. Listen to the postpartum story of one of your assigned clients and share it with your peers in class or as part of online discussion.

## STUDY ACTIVITIES

1. Identify three questions that a nurse would ask a postpartum woman to assess for postpartum blues.

*unit Six*

# The Newborn

**KEY TERMS**

cold stress  
 jaundice  
 meconium  
 neonatal period  
 neurobehavioral  
 response  
 neutral thermal  
 environment  
 (NTE)  
 periodic breathing  
 reflex  
 surfactant  
 thermoregulation

# Newborn Transitioning

## Learning Objectives

*Upon completion of the chapter, you will be able to:*

1. Define the key terms used in this chapter.
2. Examine the major physiologic changes that occur as the newborn transitions to extrauterine life.
3. Determine the primary challenges faced by the newborn during the transition to extrauterine life.
4. Differentiate the three behavioral patterns that newborns progress through after birth.
5. Assess the five typical behavioral responses triggered by external stimuli of the newborn.

*The Healthy Start home care nurse reviewed the client's file in her car before she got out: 18-year-old primipara, 1 week postpartum with a term newborn girl weighing 7 pounds. The new mother, Maria, greeted the nurse at the door and let her inside the house. After performing a postpartum assessment on Maria and an assessment of her newborn daughter, the nurse asked Maria if she had any questions or concerns. Maria's eyes welled up with tears: she is worried that her daughter can't see.*

### Words of Wisdom

Newborns can't always be judged by their outer wrapping; rather, we should focus on the awesome gift inside.

**When** a child is born, the exhaustion and stress of labor are over for the parents, but now the newborn must begin the work of physiologically and behaviorally adapting to the new environment. The first 24 hours of life can be the most precarious (Gilbert, 2011).

The **neonatal period** is defined as the first 28 days of life. After birth, the newborn is exposed to a whole new world of sounds, colors, smells, and sensations. The newborn, previously confined to the warm, dark, wet intrauterine environment, is now thrust into an environment that is much brighter and cooler. As the newborn adapts to life after birth, numerous physiologic changes occur (Table 17.1).

Awareness of the adaptations that are occurring forms the foundation for providing support to the newborn during this crucial time. Physiologic and behavioral changes occur quickly during this transition period. Being aware of any deviations from the norm is crucial to ensure early identification and prompt intervention.

This chapter describes the physiologic changes of the newborn's major body systems. It also discusses the behavioral adaptations, including behavioral patterns and the newborn's behavioral responses, which occur during this transition period.

## PHYSIOLOGIC TRANSITIONING

The mechanics of birth require a change in the newborn for survival outside the uterus. Immediately at birth, respiratory gas exchange, along with circulatory modifications, must occur to sustain extrauterine life. During this

time, as newborns strive to attain homeostasis, they also experience complex changes in major organ systems. Although the transition usually takes place within the first 6 to 10 hours of life, many adaptations take weeks to attain full maturity.

## Cardiovascular System Adaptations

During fetal life, the heart relies on certain unique structures that assist it in providing adequate perfusion of vital body parts. The umbilical vein carries oxygenated blood from the placenta to the fetus. The ductus venosus allows the majority of the umbilical vein blood to bypass the liver and merge with blood moving through the vena cava, bringing it to the heart sooner. The foramen ovale allows more than half the blood entering the right atrium to cross immediately to the left atrium, bypassing the pulmonary circulation. The ductus arteriosus connects the pulmonary artery to the aorta, which allows bypassing of the pulmonary circuit. Only a small portion of blood passes through the pulmonary circuit for the main purpose of perfusion of the structure, rather than for oxygenation. The fetus depends on the placenta to provide oxygen and nutrients and to remove waste products.

At birth, the circulatory system must switch from fetal to newborn circulation and from placental to pulmonary gas exchange. The physical forces of the contractions of labor and birth, mild asphyxia, increased intracranial pressure as a result of cord compression and uterine contractions, and the cold stress experienced immediately

TABLE 17.1

ANATOMIC AND PHYSIOLOGIC COMPARISON OF THE FETUS AND NEWBORN

Comparison	Fetus	Newborn
Respiratory system	Fluid-filled, high-pressure system causes blood to be shunted from the lungs through the ductus arteriosus to the rest of the body.	Air-filled, low-pressure system encourages blood flow through the lungs for gas exchange; increased oxygen content of blood in the lungs contributes to the closing of the ductus arteriosus (becomes a ligament).
Site of gas exchange	Placenta	Lungs
Circulation through the heart	Pressures in the right atrium are greater than in the left, encouraging blood flow through the foramen ovale.	Pressures in the left atrium are greater than in the right, causing the foramen ovale to close.
Hepatic portal circulation	Ductus venosus bypasses; maternal liver performs filtering functions.	Ductus venosus closes (becomes a ligament); hepatic portal circulation begins.
Thermoregulation	Body temperature is maintained by maternal body temperature and the warmth of the intrauterine environment.	Body temperature is maintained through a flexed posture and brown fat.

Adapted from Blackburn, S. T. (2012). *Maternal, fetal, & neonatal physiology: A clinical perspective* (4th ed.). St. Louis, MO: Saunders Elsevier; Gardner, S. L., Carter, B. S., Enzman-Hines, M., & Hernandez, J. A. (2011). *Merenstein & Gardner's handbook of neonatal intensive care* (7th ed.). St. Louis, MO: Mosby Elsevier; and Mattson, S., & Smith, J. E. (2011). *Core curriculum for maternal-newborn nursing* (4th ed.). St. Louis, MO: Saunders Elsevier.

after birth lead to an increased release of catecholamines that is critical for the changes involved in the transition to extrauterine life. The increased levels of epinephrine and norepinephrine stimulate increased cardiac output and contractility, surfactant release, and promotion of pulmonary fluid clearance (Blackburn, 2012).

### Fetal to Neonatal Circulation Changes

Changes in circulation occur immediately at birth as the fetus separates from the placenta (Fig. 17.1). When the umbilical cord is clamped, the first breath is taken and the lungs begin to function. As a result, systemic vascular resistance increases and blood return to the heart via the inferior vena cava decreases. Concurrently with these changes, there is a rapid decrease in pulmonary vascular resistance and an increase in pulmonary blood flow (Warren, & Phillipi, 2012). The foramen ovale functionally closes with a decrease in pulmonary vascular resistance, which leads to a decrease in right-sided heart pressures. An increase in systemic pressure, after clamping of the cord, leads to an increase in left-sided heart pressures. The ductus arteriosus, ductus venosus, and umbilical vessels that were vital during fetal life are no longer needed. Over a period of months these fetal vessels form nonfunctional ligaments.

Before birth, the foramen ovale allowed most of the oxygenated blood entering the right atrium from the

inferior vena cava to pass into the left atrium of the heart. With the newborn's first breath, air pushes into the lungs, triggering an increase in pulmonary blood flow and pulmonary venous return to the left side of the heart. As a result, the pressure in the left atrium becomes higher than in the right atrium. The increased left atrial pressure causes the foramen ovale to close, thus allowing the output from the right ventricle to flow entirely to the lungs. With closure of this fetal shunt, oxygenated blood is now separated from nonoxygenated blood. The subsequent increase in tissue oxygenation further promotes the increase in systemic blood pressure and continuing blood flow to the lungs. The foramen ovale normally closes functionally at birth when left atrial pressure increases and right atrial pressure decreases. Permanent anatomic closure, though, really occurs throughout the next several weeks.

During fetal life, the ductus arteriosus, located between the aorta and the pulmonary artery, protected the lungs against circulatory overload by shunting blood (right to left) into the descending aorta, bypassing the pulmonary circulation. Its patency during fetal life is promoted by continual production of prostaglandin E2 (PGE2) by the ductus arteriosus (Gardner, Carter, Enzman-Hines, & Hernandez, 2011). The ductus arteriosus becomes functionally closed within the first few hours after birth. Oxygen is the most important factor in controlling its closure. Closure depends on the high oxygen content of

**FIGURE 17.1** Cardiovascular adaptations of the newborn. Note the changes in oxygenation between (A) prenatal circulation and (B) postnatal (pulmonary) circulation.

the aortic blood that results from aeration of the lungs at birth. At birth, pulmonary vascular resistance decreases, allowing pulmonary blood flow to increase and oxygen exchange to occur in the lungs. It occurs secondary to an increase in  $PO_2$  coincident with the first breath and umbilical cord occlusion when it is clamped.

The ductus venosus shunted blood from the left umbilical vein to the inferior vena cava during intrauterine life. It closes within a few days after birth, because this shunting is no longer needed as a result of activation of the liver. The activated liver now takes over the functions of the placenta (which was expelled at birth). The ductus venosus becomes a ligament in extrauterine life.

The two umbilical arteries and one umbilical vein begin to constrict at birth, because with placental expulsion, blood flow ceases. In addition, peripheral circulation increases. Thus, the vessels are no longer needed and they too become ligaments. Successful transition and closure of the three fetal shunts creates a neonatal circulation where deoxygenated blood returns to the heart through the inferior and superior vena cava. It enters the right atrium to the right ventricle and travels through the pulmonary artery to the pulmonary vascular bed. Oxygenated blood returns through pulmonary veins to the left atrium, the left ventricle, and through the aorta to the systemic circulation (Gardner, Carter, Enzman-Hines, & Hernandez, 2011). Box 17.1 provides a summary of fetal to neonatal circulation.

### BOX 17.1

#### SUMMARY OF FETAL TO NEONATAL CIRCULATION

- Clamping umbilical cord at birth eliminates the placenta as a reservoir for blood.
- Onset of respirations causes a rise in  $PO_2$  in the lungs and a decrease in pulmonary vascular resistance, *which...*
- Increases pulmonary blood flow and increases pressure in the left atrium, *which...*
- Decreases pressure in the right atrium of the heart, which causes closure of the foramen ovale (closes within minutes after birth secondary to a decreased pulmonary vascular resistance and increased left heart pressure)
- With an increase in oxygen levels after the first breath, an increase in systemic vascular resistance occurs, *which...*
- Decreases vena cava return, which reduces blood flow in the umbilical vein (constricts, becomes a ligament with functional closing).
- Closure of the ductus venosus (becomes a ligament) causes an increase in pressure in the aorta, which forces closure of the ductus arteriosus within 10 to 15 hours after birth.

## Heart Rate

During the first few minutes after birth, the newborn's heart rate is approximately 120 to 180 bpm. Thereafter, it begins to decrease to an average of 120 to 130 bpm (Donn, & Sinha, 2012). The newborn is highly dependent on heart rate for maintenance of cardiac output and blood pressure. Although the blood pressure is not taken routinely in the healthy term newborn, it is usually highest after birth and reaches a plateau within a week after birth. Cardiac defects may be identified in the newborn nursery by conducting a thorough and systematic physical assessment, including inspection, palpation, auscultation, and measurement of blood pressure and oxygen saturations. The ability of the nurse to identify irregular findings during physical assessment aids rapid identification and treatment.

### Take Note!

Transient functional cardiac murmurs may be heard during the neonatal period as a result of the changing dynamics of the cardiovascular system at birth (Buonocore, Bracci, & Weindling, 2012).

The fluctuations in both the heart rate and blood pressure tend to follow the changes in the newborn's behavioral state. An increase in activity, such as wakefulness, movement, or crying, corresponds to an increase in heart rate and blood pressure. In contrast, the compromised newborn demonstrates markedly less physiologic variability overall. Tachycardia may be found with volume depletion, cardiorespiratory disease, drug withdrawal, and hyperthyroidism. Bradycardia is often associated with apnea and is often seen with hypoxia.

## Blood Volume

The blood volume of the newborn depends on the amount of blood transferred from the placenta at birth. It is usually estimated to be 80 to 85 mL/kg of body weight in the term infant (Warren, & Phillippi, 2012). However, the volume may vary by as much as 25% to 40%, depending on when clamping of the umbilical cord occurs. Early (before 30 to 40 seconds) or late (after 3 minutes) clamping of the umbilical cord changes circulatory dynamics during transition. Recent studies indicate that the benefits of delayed cord clamping include improving the newborn's cardiopulmonary adaptation, preventing anemia in full-term newborns without increasing hypervolemia-related risks, increasing blood pressure, improving oxygen transport, and increasing red blood cell flow (van Rheenen, 2011). Although a tailored approach is required in the case of cord clamping, the balance of available data suggests that delayed cord clamping should be the method of choice (Gutierrez, Velasquez, & Iriarte, 2010). The standard of care currently is not

to rush cord clamping because of the preponderance of evidence that shows that it is better to wait a minute or two after birth. Cord blood has been described as “nature’s first stem cell transplant” because it possesses regenerative properties and can grow into different types of cells in the body (Tolosa et al., 2010). Further research is needed to explain the relationship among oxygen transport, red blood cell volume, and initiation of breathing, thereby validating whether early or delayed cord clamping is better.

### Blood Components

Fetal red blood cells are large, but few in number. After birth, the red cell count gradually increases as the cell size decreases, because the cells now live in an environment with much higher  $PO_2$ . A newborn’s red cells have a life span of 80 to 100 days, compared to 120 days in adults.

Hemoglobin initially declines as a result of a decrease in neonatal red cell mass (physiologic anemia of infancy). Leukocytosis (elevated white blood cells) is present as a result of birth trauma soon after birth. The newborn’s platelet count and aggregation ability are the same as those of adults.

The newborn’s hematologic values are affected by the site of the blood sample (capillary blood has higher levels of hemoglobin and hematocrit compared with venous blood), placental transfusion (delayed cord clamping and normal shift of plasma to extravascular spaces, which causes higher levels of hemoglobin and hematocrit), and gestational age (increased age is associated with increased numbers of red cells and hemoglobin) (Weindling, & Paize, 2010). Table 17.2 lists normal newborn blood values.

TABLE 17.2

NORMAL NEWBORN BLOOD VALUES

Lab Data	Normal Range
Hemoglobin	17–23 g/dL
Hematocrit	46–68%
Platelets	150,000–350,000/ $\mu$ L
Red blood cells	4.5–7.0 (1,000,000/ $\mu$ L)
White blood cells	10–30,000/ $mm^3$

## Respiratory System Adaptations

The first breath of life is a gasp that generates an increase in transpulmonary pressure and results in diaphragmatic descent. Hypercapnia, hypoxia, and acidosis resulting from normal labor become stimuli for initiating respirations. Inspiration of air and expansion of the lungs allow for an increase in tidal volume (amount of air brought into the lungs). **Surfactant** is a surface tension-reducing lipoprotein found in the newborn’s lungs that prevents alveolar collapse at the end of expiration and loss of lung volume. It lines the alveoli to enhance aeration of gas-free lungs, thus reducing surface tension and lowering the pressure required to open the alveoli. Normal lung function depends on surfactant, which permits a decrease in surface tension at end expiration (to prevent atelectasis) and an increase in surface tension during lung expansion (to facilitate elastic recoil on inspiration). Surfactant provides the lung stability needed for gas exchange. The newborn’s first breath, in conjunction with surfactant, overcomes the surface forces to permit aeration of the lungs. The chest wall of the newborn is floppy because of the high cartilage content and poorly developed musculature. Thus, accessory muscles to help in breathing are ineffective.

One of the most crucial adaptations that the newborn makes at birth is adjusting from a fluid-filled intrauterine environment to a gaseous extrauterine environment. During fetal life, the lungs are expanded with an ultrafiltrate of the amniotic fluid. During and after birth, this fluid must be removed and replaced with air. Passage through the birth canal allows intermittent compression of the thorax, which helps eliminate the fluid in the lungs. Pulmonary capillaries and the lymphatics remove the remaining fluid.

If fluid is removed too slowly or incompletely (e.g., with decreased thoracic squeezing during birth or diminished respiratory effort), transient tachypnea (respiratory rate above 60 bpm) of the newborn occurs. Examples of situations involving decreased thoracic compression and diminished respiratory effort include cesarean birth and sedation in newborns. Research findings support the need for thoracic compression because the absence of the neonate’s exposure to labor contractions, which may occur with cesarean births or heavy sedation during the labor process, is associated with an increased risk of transient tachypnea at term, with oxygen supplementation being needed for a longer duration (Donn, & Sinha, 2012).

### Take Note!

A baby born by cesarean delivery does not have the same benefit of the birth canal squeeze as does the newborn born by vaginal delivery. Closely observe the respirations of the newborn after cesarean delivery.

## Lungs

Before the newborn's lungs can maintain respiratory function, the following events must occur:

- Initiation of respiratory movement
- Expansion of the lungs
- Establishment of functional residual capacity (ability to retain some air in the lungs on expiration)
- Increased pulmonary blood flow
- Redistribution of cardiac output (Bope, & Kellerman, 2012)

Initial breathing is probably the result of a reflex triggered by pressure changes, noise, light, chilling, compression of the fetal chest during delivery, and high carbon dioxide and low oxygen concentrations of the newborn's blood. Many theories address the initiation of respiration in the newborn, but most are based on speculation from observations rather than on empirical research (Mattson, & Smith, 2011). Research continues to search for answers to these questions.

## Respirations

After respirations are established in the newborn, they are shallow and irregular, ranging from 30 to 60 breaths per minute, with short periods of apnea (less than 15 seconds). The newborn's respiratory rate varies according to his or her activity; the more active the newborn, the higher the respiratory rate, on average. Signs of respiratory distress to observe for include cyanosis, tachypnea, expiratory grunting, sternal retractions, and nasal flaring. Respirations should not be labored, and the chest movements should be symmetric. In some cases, **periodic breathing** may occur, which is the cessation of breathing that lasts 5 to 10 seconds without changes in color or heart rate (Blackburn, 2012). Periodic breathing may be observed in newborns within the first few days of life and requires close monitoring.

### Take Note!

Apneic periods lasting more than 15 seconds with cyanosis and heart rate changes require further evaluation (Gardner et al., 2011).

## Body Temperature Regulation

Newborns are dependent on their environment for the maintenance of body temperature, much more so immediately after birth than later in life. One of the most important elements in a newborn's survival is obtaining a stable body temperature to promote an optimal transition to extrauterine life. On average, a newborn's temperature ranges from 97.9° to 99.7° F (36.5° to 37.5° C).

**Thermoregulation** is the process of maintaining the balance between heat loss and heat production. It is a critical physiologic function that is closely related

FIGURE 17.2 Father and mother looking at their newborn after birth. Note the newborn's hat and warm blanket to preserve body heat.

to the transition and survival of the newborn. An appropriate thermal environment is essential for maintaining a normal body temperature. Compared with adults, newborns tolerate a narrower range of environmental temperatures and are extremely vulnerable to both underheating and overheating. Nurses play a key role in providing an appropriate environment to help newborns maintain thermal stability (Fig. 17.2).

## Heat Loss

Newborns have several characteristics that predispose them to heat loss:

- Thin skin with blood vessels close to the surface
- Lack of shivering ability to produce heat involuntarily
- Limited stores of metabolic substrates (glucose, glycogen, fat)
- Limited use of voluntary muscle activity or movement to produce heat
- Large body surface area relative to body weight
- Lack of subcutaneous fat, which provides insulation
- Little ability to conserve heat by changing posture (fetal position)
- No ability to adjust their own clothing or blankets to achieve warmth
- Inability to communicate that they are too cold or too warm

Every newborn struggles to maintain body temperature from the moment of birth, when the newborn's wet body is exposed to the much cooler environment of the birthing room. The amniotic fluid covering the newborn cools as it evaporates rapidly in the low humidity and air-conditioning of the room. The newborn's temperature may decrease 3 to 5 degrees within minutes after leaving the warmth of the mother's uterus (99.6° F [37.5° C]). The skin of newborns adjusts quickly to the challenging environmental conditions of extrauterine life. However,

certain functions, for example, microcirculation, continue to develop even beyond the neonatal period (Altimier, 2012).

The transfer of heat depends on the temperature of the environment, air speed, and water vapor pressure or humidity. Heat exchange between the environment and the newborn involves the same mechanisms as those with any physical object and its environment. These mechanisms are conduction, convection, evaporation, and radiation. Prevention of heat loss is a key nursing intervention (Fig. 17.3).

### Consider This

When I look down at my little miracle of life in my arms, I can't help but beam with pride at this great accomplishment. She seems so vulnerable and defenseless, and yet is equipped with everything she needs to survive at birth. When the nurse brought my daughter in for the first time after birth, I wanted to see and feel every part of her. Much to my dismay, she was wrapped up like a mummy in a blanket and she had a pink knit cap on her head. I asked the nurse why all the babies had to look like they were bound for the North Pole with all these layers on. Wasn't she aware it was summertime and probably at least 80 degrees outside?

The nurse explained that newborns lose body heat easily and need to be kept warm until their temperature stabilizes. Even though I wanted to get up close and personal with my baby, I decided to keep the pink polar bear outfit on her.

Thoughts: Newborns may be born with "everything they need to survive" on the outside, but they still experience temperature instability and lose heat through radiation, evaporation, convection, and conduction. Because the newborn's head is the largest body part, a great deal of heat can be lost if a cap is not kept on the head. What guidance can be given to this mother before discharge to stabilize her daughter's temperature while at home? What simple examples can be used to demonstrate your point?

### CONDUCTION

Conduction involves the transfer of heat from one object to another when the two objects are in direct contact with each other. Conduction refers to heat fluctuation between the newborn's body surface when in contact with other solid surfaces, such as a cold mattress, scale, or circumcision restraining board. Heat loss by conduction can also occur when touching a newborn with cold hands or when the newborn has direct contact with a colder object such as a metal scale. Using a warmed cloth diaper or blanket to cover any cold surface touching a newborn directly helps to prevent heat loss through

conduction. Placing the newborn skin-to-skin with the mother also helps prevent heat loss through conduction.

### CONVECTION

Convection involves the flow of heat from the body surface to cooler surrounding air or to air circulating over a body surface. An example of convection-related heat loss would be a cool breeze that flows over the newborn. To prevent heat loss by this mechanism, keep the newborn out of direct cool drafts (open doors, windows, fans, air conditioners) in the environment, work inside an isolette as much as possible and minimize opening portholes that allow cold air to flow inside, and warm any oxygen or humidified air that comes in contact with the newborn. Using clothing and blankets in isolettes is an effective means of reducing the newborn's exposed surface area and providing external insulation. Also, transporting the newborn to the nursery in a warmed isolette, rather than carrying him or her, helps to maintain warmth and reduce exposure to the cool air.

### EVAPORATION

Evaporation involves the loss of heat when a liquid is converted to a vapor. Evaporative loss may be insensible (such as from skin and respiration) or sensible (such as from sweating). Insensible loss occurs, but the individual is not aware of it. Sensible loss is objective and can be noticed. It depends on air speed and the absolute humidity of the air. For example, when the baby is born, the body is covered with amniotic fluid. The fluid evaporates into the air, leading to heat loss. Heat loss via evaporation also occurs when bathing a newborn. Drying newborns immediately after birth with warmed blankets and placing a cap on their head will help to prevent heat loss through evaporation. In addition, drying the newborn after bathing will help prevent heat loss through evaporation. Promptly changing wet linens, clothes, or diapers will also reduce heat loss and prevent chilling.

### RADIATION

Radiation involves the loss of body heat to cooler, solid surfaces that are in proximity but not in direct contact with the newborn. The amount of heat loss depends on the size of the cold surface area, the surface temperature of the newborn's body, and the temperature of the receiving surface area. For example, when a newborn is placed in a single-wall isolette next to a cold window, heat loss from radiation occurs. Newborns will become cold even though they are in a heated isolette. To reduce heat loss by radiation, keep cribs and isolettes away from outside walls, cold windows, and air conditioners. Also, using radiant warmers for transporting newborns and when performing procedures that may expose the newborn to the cooler environment will help reduce heat loss.

A warmed transporter is an enclosed isolette on wheels. A radiant warmer is an open bed with a radiant heat source above. This type of environment allows health

care professionals to reach the newborn to carry out procedures and treatments (see Evidence-Based Practice 17.1).

### Overheating

The newborn is also prone to overheating. Limited insulation and limited sweating ability can predispose any

newborn to overheating. Control of body temperature is achieved via a complex negative feedback system that creates a balance between heat production, heat gain, and heat loss. The primary heat regulator is located in the hypothalamus and the central nervous system. The immaturity of the newborn's central nervous system makes it difficult to create and maintain this balance.

## EVIDENCE-BASED PRACTICE 17.1

## RADIANT WARMERS VERSUS INCUBATORS FOR REGULATING BODY TEMPERATURE IN NEWBORNS

## STUDY

Providing a thermoneutral environment is an essential component of the immediate and longer-term care of the newborn. The methods currently used include incubators and open-care systems, with or without modifications such as heat shields and plastic wrap. The system used must allow ready access to the infant while minimizing alterations in the immediate environment. This study was performed to assess the effects of radiant warmers versus incubators on neonatal fluid and electrolyte balance, morbidity, and mortality. Eight studies were included in this review.

## Findings

Compared with incubators, radiant warmers caused a statistically significant increase in insensible water loss and a trend toward increased oxygen consumption that was not statistically significant. Due to small numbers, effects on important clinical outcomes could not be adequately assessed. A comparison of radiant warmers with heat shields versus incubators without heat shields showed a trend for increased insensible water loss in the

radiant warmer group, but the difference was not statistically significant. No difference was shown in terms of oxygen consumption. Therefore, at the present time, it is not clear which method of maintaining body temperature is best for newborn babies—radiant warmers or incubators. More research is necessary. Further randomized controlled trials are required to assess the effects of radiant warmers versus incubators in neonatal care on important short- and long-term outcomes.

## Nursing Implications

Preventing cold stress in newborns is essential in assisting them to make the physiologic transition to extra-uterine life. This study compared two heat sources but failed to reach a clear consensus as to which was better. Nurses can apply these results in caring for newborns by making sure that fluid intake is sufficient to make up for insensible water loss when the baby is under either heat source. In addition, they can assist in future research about heat sources that support thermoregulation in the newborn.

Adapted from Flenady, V., & Woodgate, P. G. (2009). Radiant warmers versus incubators for regulating body temperature in newborn infants. *Cochrane Database of Systematic Reviews* 2009(4). Art. No.: CD000435. DOI: 10.1002/14651858.CD000435.

Therefore, the newborn can become overheated easily. For example, an isolette that is too warm or one that is left too close to a sunny window may lead to hyperthermia. Although heat production can substantially increase in response to a cool environment, basal metabolic rate and the resultant heat produced cannot be reduced. Overheating increases fluid loss, the respiratory rate, and the metabolic rate considerably.

### Thermoregulation

Thermoregulation, the balance between heat loss and heat production, is related to the newborn's rate of metabolism and oxygen consumption. The newborn attempts to conserve heat and increase heat production by increasing the metabolic rate, increasing muscular activity through movement, increasing peripheral vasoconstriction, and assuming a fetal position to hold in heat and minimize exposed body surface area.

An environment in which body temperature is maintained without an increase in metabolic rate or oxygen use is called a **neutral thermal environment (NTE)**. Within an NTE, the rates of oxygen consumption and metabolism are minimal, and internal body temperature is maintained because of thermal balance. An NTE promotes growth and stability, conserves energy for basic bodily functions, and minimizes heat (energy) and water loss (Gardner et al., 2011). Because

newborns have difficulty maintaining their body heat through shivering or other mechanisms, they need a higher environmental temperature to maintain an NTE. If the environmental temperature decreases, the newborn responds by consuming more oxygen. The respiratory rate increases (tachypnea) in response to the increased need for oxygen. As a result, the newborn's metabolic rate increases.

The newborn's primary method of heat production is through nonshivering thermogenesis, a process in which brown fat (adipose tissue) is oxidized in response to cold exposure. Brown fat is a special kind of highly vascular fat found only in newborns. The brown coloring is derived from the fat's rich supply of blood vessels and nerve endings. These fat deposits, which are capable of intense metabolic activity—and thus can generate a great deal of heat—are found between the scapulae, axillae, at the nape of the neck, in the mediastinum, and in areas surrounding the kidneys and adrenal glands. Brown fat makes up about 2% to 6% of body weight in the full-term newborn (Altimier, 2012). When the newborn experiences a cold environment, the release of norepinephrine increases, which in turn stimulates brown fat metabolism by the breakdown of triglycerides. Cardiac output increases, increasing blood flow through the brown fat tissue. Subsequently, this blood becomes warmed as a result of the increased metabolic activity of the brown fat.

Newborns can experience heat loss through all four mechanisms, ultimately resulting in cold stress. **Cold stress** is excessive heat loss that requires a newborn to use compensatory mechanisms (such as nonshivering thermogenesis and tachypnea) to maintain core body temperature (Lissauer, & Fanaroff, 2011). The consequences of cold stress can be quite severe. As the body temperature decreases, the newborn becomes less active, lethargic, hypotonic, and weaker. All newborns are at risk for cold stress, particularly within the first 12 hours of life. However, preterm newborns are at the greatest risk for cold stress and experience more profound effects than full-term newborns because they have fewer fat stores, poorer vasomotor responses, and less insulation to cope with a hypothermic event.

Cold stress in the newborn can lead to the following problems if not reversed: depleted brown fat stores, increased oxygen needs, respiratory distress, increased glucose consumption leading to hypoglycemia, metabolic acidosis, jaundice, hypoxia, and decreased surfactant production (Blackburn, 2012).

### Take Note!

Nurses must be aware of the thermoregulatory needs of the newborn and must ensure that these needs are met to provide the newborn with the best start possible.

To minimize the effects of cold stress and maintain an NTE, the following interventions are helpful:

- Prewarming blankets and hats to reduce heat loss through conduction
- Keeping the infant transporter (warmed isolette) fully charged and heated at all times
- Drying the newborn completely after birth to prevent heat loss from evaporation
- Encouraging skin-to-skin contact with the mother if the newborn is stable
- Promoting early breast-feeding to provide fuels for nonshivering thermogenesis
- Using heated and humidified oxygen
- Always using radiant warmers and double-wall isolettes to prevent heat loss from radiation
- Deferring bathing until the newborn is medically stable, and using a radiant heat source while bathing (Fig. 17.4)
- Avoiding the placement of a skin temperature probe over a bony area or one with brown fat, because it does not give an accurate assessment of the whole body temperature (most temperature probes are placed over the liver when the newborn is supine or side-lying)

The interventions listed above allow the newborn to minimize his or her metabolic rate and oxygen consumption, thereby conserving vital energy stores required for optimum growth.

FIGURE 17.4 Bathing a newborn under a radiant warmer to prevent heat loss.

## Hepatic System Function

At birth, the newborn's liver assumes the functions that the placenta handled during fetal life. These functions include blood coagulation, and also iron storage, carbohydrate metabolism, and conjugation of bilirubin, as discussed next. Glycogen reserves provide energy and may become depleted if the metabolic needs of the newborn increase, such as during cold or respiratory stress.

### Iron Storage

As red blood cells are destroyed after birth, their iron is released and stored by the liver until new red cells need to be produced. Newborn iron stores are determined by total body hemoglobin content and length of gestation. If the mother's iron intake was adequate during pregnancy, sufficient iron has been stored in the newborn's liver for use during the first 6 months of age.

### Carbohydrate Metabolism

When the placenta is lost at birth, the maternal glucose supply is cut off. Initially, the newborn's serum glucose levels decline. Newborns must learn to regulate their

blood glucose concentration and adjust to an intermittent feeding schedule. Usually, a term newborn's blood glucose level is 70% to 80% of the maternal blood glucose level at birth (Warren, & Phillippi, 2012).

Glucose is the main source of energy for the first several hours after birth. With the newborn's increased energy needs after birth, the liver releases glucose from glycogen stores for the first 24 hours. Initiating feedings helps to stabilize the newborn's blood glucose levels. No evidence supports universal invasive routine measurement of glucose in healthy term newborns. Selective screening of at-risk newborns is more appropriate (Mattson, & Smith, 2011).

### Bilirubin Conjugation

The liver is also responsible for the conjugation of bilirubin—a yellow to orange bile pigment produced by the breakdown of red blood cells. In utero, elimination of bilirubin in the blood is handled by the placenta and the mother's liver. However, once the cord is cut, the newborn must now assume this function.

Bilirubin normally circulates in plasma, is taken up by liver cells, and is changed to a water-soluble pigment that is excreted in the bile. This conjugated form of bilirubin is excreted from liver cells as a constituent of bile.

The principal source of bilirubin in the newborn is the hemolysis of erythrocytes. This is a normal occurrence after birth, when fewer red blood cells are needed to maintain extrauterine life.

When red blood cells die after approximately 80 days of life, the heme in their hemoglobin is converted to bilirubin. Bilirubin is released in an unconjugated form called indirect bilirubin, which is fat soluble. Enzymes, proteins, and different cells in the reticuloendothelial system and liver process the unconjugated bilirubin into conjugated bilirubin or direct bilirubin. This form is water soluble and now enters the gastrointestinal system via the bile and is eventually excreted through feces. The kidneys also excrete a small amount.

Newborns produce bilirubin at a rate of approximately 6 to 8 mg/kg/day. This is more than twice the production rate in adults, primarily because of relative polycythemia and increased red blood cell turnover. Bilirubin production typically declines to the adult level within 10 to 14 days after birth (Hansen, 2012). In addition, the metabolic pathways of the liver are relatively immature and thus cannot conjugate bilirubin as quickly as needed.

Failure of the liver cells to break down and excrete bilirubin can cause an increased amount of bilirubin in the bloodstream, leading to jaundice (Punnoose, Schwartz, & Golub 2012). Bilirubin is toxic to the body and must be excreted. Blood tests ordered to determine bilirubin levels measure bilirubin in the serum. Total bilirubin is a combination of indirect (unconjugated) and direct (conjugated) bilirubin.

When unconjugated bilirubin pigment is deposited in the skin and mucous membranes, jaundice typically results. **Jaundice**, also known as icterus, refers to the yellowing of the skin, sclera, and mucous membranes that results from increased bilirubin blood levels. Visible jaundice as a result of increased blood bilirubin levels occurs in more than half of all healthy newborns. Even in healthy term newborns, extremely elevated blood levels of bilirubin during the first week of life can cause bilirubin encephalopathy, a permanent and devastating form of brain damage (Lauer, & Spector, 2011).

Common risk factors for the development of jaundice include fetal-maternal blood group incompatibility, prematurity, breast-feeding, drugs (such as diazepam [Valium], oxytocin [Pitocin], sulfisoxazole/erythromycin [Pediazole], and chloramphenicol [Chloromycetin]), maternal gestational diabetes, infrequent feedings, male gender, trauma during birth resulting in cephalhematoma, cutaneous bruising, polycythemia, previous sibling with hyperbilirubinemia, infections such as TORCH (toxoplasmosis, other viruses, rubella, cytomegalovirus, herpes simplex viruses), and ethnicity such as Asian or Native American (Hansen, 2012).

The causes of newborn jaundice can be classified into three groups based on the mechanism of accumulation:

1. Bilirubin overproduction, such as from blood incompatibility (Rh or ABO), drugs, trauma at birth, polycythemia, delayed cord clamping, and breast milk jaundice
2. Decreased bilirubin conjugation, as seen in physiologic jaundice, hypothyroidism, and breast-feeding
3. Impaired bilirubin excretion, as seen in biliary obstruction (biliary atresia, gallstones, neoplasm), sepsis, hepatitis, chromosomal abnormality (Turner syndrome, trisomies 18 and 21), and drugs (aspirin, acetaminophen, sulfa, alcohol, steroids, antibiotics) (Gardner et al., 2011).

Jaundice in the newborn is discussed in more detail in Chapter 24.

## Gastrointestinal System Adaptations

The full-term newborn has the capacity to swallow, digest, metabolize, and absorb food taken in soon after birth. At birth, the pH of the stomach contents is mildly acidic, reflecting the pH of the amniotic fluid. The once-sterile gut changes rapidly, depending on what feeding is received. Bowel sounds are normally heard shortly after birth, but may be hypoactive on the first day.

### Mucosal Barrier Protection

An important adaptation of the gastrointestinal system is the development of a mucosal barrier to prevent the penetration of harmful substances (bacteria, toxins, and

antigens) present within the intestinal lumen. At birth, the newborn must be prepared to deal with bacterial colonization of the gut. Colonization is dependent on oral intake. It usually occurs within 24 hours of age and is required for the production of vitamin K (Soll, 2010). After birth, environmental, oral, and cutaneous microbes from the mother will be mechanically transferred to the newborn by several processes including suckling, kissing, and caressing. Thus, the proximity of the birth canal and the anus, as well as parental expression of neonatal care, are effective methods of ensuring transmission of microbes from one generation to the next. If harmful substances are allowed to penetrate the mucosal epithelial barrier under pathologic conditions, they can cause inflammatory and allergic reactions (Anderson-Berry, & Bellig, 2012).

### Take Note!

Human breast milk provides a passive mechanism to protect the newborn against the dangers of a deficient intestinal defense system. It contains antibodies, viable leukocytes, and many other substances that can interfere with bacterial colonization and prevent harmful penetration.

## Stomach and Digestion

The physiologic capacity of the newborn stomach is considerably less than its anatomic capacity. There is a rapid gain in physiologic capacity during the first 4 days of life. After the first 4 days, the anatomic and physiologic capacities more closely approximate each other. Researchers have found that for the first 24 hours after birth, the newborn's small stomach does not stretch to hold more, as it will even a day or two later (Ellis, 2010). This explains the experience of countless hospital nurses who have learned the hard way that when newborns are fed an ounce or two by bottle during the first day of life, most of it tends to come right back up. The walls of the newborn stomach stay firm, expelling extra milk rather than stretching to hold it.

Small, frequent feedings set up a healthy eating pattern right from the start. Experts now advise adults that it is healthier to eat smaller amounts more often and the same is true for babies and children. Coaxing an infant to take more milk leads to overfeeding. If feeling overfull at feedings becomes the norm for a young infant, this may lead to unhealthy eating habits that contribute to childhood and adult obesity later (Plagemann, 2011).

The cardiac sphincter and nervous control of the stomach is immature, which may lead to uncoordinated peristaltic activity and frequent regurgitation. Immaturity of the pharyngoesophageal sphincter and absence of lower esophageal peristaltic waves also contribute to the reflux of gastric contents. Avoiding overfeeding and stimulating frequent burping may minimize regurgitation.

Most digestive enzymes are available at birth, allowing newborns to digest simple carbohydrates and protein. However, they have limited ability to digest complex carbohydrates and fats, because amylase and lipase levels are low at birth. As a result, newborns excrete a fair amount of lipids, resulting in fatty stools.

Adequate digestion and absorption are essential for newborn growth and development. Normally, term newborns lose 5% to 10% of their birth weight as a result of insufficient caloric intake within the first week after birth, shifting of intracellular water to extracellular space, and insensible water loss. To gain weight, the term newborn requires an intake of 108 kcal/kg/day from birth to 6 months of age (Lutz, & Przytulski, 2011).

## Bowel Elimination

The frequency, consistency, and type of stool passed by newborns vary widely. The evolution of a stool pattern begins with a newborn's first stool, which is meconium. **Meconium** is composed of amniotic fluid, shed mucosal cells, intestinal secretions, and blood. It is greenish black, has a tarry consistency, and is usually passed within 12 to 24 hours of birth. The first meconium stool passed is sterile, but this changes rapidly with ingestion of bacteria through feedings. After feedings are initiated, a transitional stool develops, which is greenish brown to yellowish brown, thinner in consistency, and seedy in appearance.

### Take Note!

Newborns who are fed early pass stools sooner, which helps to reduce bilirubin buildup (Simmons, 2011).

The last development in the stool pattern is the milk stool. Its characteristics differ in breast-fed and formula-fed newborns. The stools of the breast-fed newborn are yellow-gold, loose, and stringy to pasty in consistency, and typically sour-smelling. The stools of the formula-fed newborn vary depending on the type of formula ingested. They may be yellow, yellow-green, or greenish and loose, pasty, or formed in consistency, and they have an unpleasant odor.

## Renal System Changes

Frequently the newborn's kidneys are described as immature, but they are able to carry out their usual responsibilities and can handle the challenge of excretion and maintaining acid-base balance. Only when the newborn is faced with unexpected imbalances of water, electrolytes, or a disruption of acid-base status secondary to a preterm birth or illness does it lack the ability to handle the body's fluid homeostasis. A newborn infant's body mass is 75% water, the highest proportion of body water

at any stage of a person's life. The majority of term newborns void immediately after birth, indicating adequate renal function. Although the newborn's kidneys can produce urine, they are limited in their ability to concentrate it until about 3 months of age, when the kidneys mature more. Until that time, a newborn voids frequently and the urine has a low specific gravity (1.001 to 1.020). About six to eight voidings daily is average for most newborns; this indicates adequate fluid intake (Warren, & Phillippi, 2012).

The renal cortex is relatively underdeveloped at birth and does not reach maturity until 12 to 18 months of age. The glomerular filtration rate (GFR) is the amount of fluid filtered each minute by all the glomeruli of both kidneys and is one index of kidney function. At birth, the newborn's glomerular filtration rate is approximately 30% of normal adult values, reaching approximately 50% of normal adult values by the 10th day of life and full adult values by the first year of life (Gardner et al., 2011). The low GFR and the limited excretion and conservation capability of the kidney affect the newborn's ability to excrete salt, water loads, and drugs.

### Take Note!

The possibility of fluid overload is increased in newborns; keep this in mind when administering intravenous therapy to a newborn.

## Immune System Adaptations

Essential to the newborn's survival is the ability to respond effectively to hostile environmental forces. The newborn's immune system begins working early in gestation, but many of the responses do not function adequately during the early neonatal period. The risk of acquiring an infection is great because a newborn's immune system is immature and not able to respond for long periods of time to fight infections. The intra-uterine environment usually protects the fetus from harmful microorganisms and the need for defensive immunologic responses. With exposure to a wide variety of microorganisms at birth, the newborn must develop a balance between its host defenses and the hostile environmental organisms to ensure a safe transition to the outside world.

Responses of the immune system serve three purposes: defense (protection from invading organisms), homeostasis (elimination of worn-out host cells), and surveillance (recognition and removal of enemy cells). The newborn's immune system response involves recognition of the pathogen or other foreign material, followed by activation of mechanisms to react against and eliminate it. All immune responses primarily involve leukocytes (white blood cells).

The immune system's responses can be divided into two categories: natural and acquired immunity. These

mechanisms are interrelated and interdependent; both are required for immunocompetency.

## Natural Immunity

Natural immunity includes responses or mechanisms that do not require previous exposure to the microorganism or antigen to operate efficiently. Physical barriers (such as intact skin and mucous membranes), chemical barriers (such as gastric acids and digestive enzymes), and resident nonpathologic organisms make up the newborn's natural immune system. Natural immunity involves the most basic host defense responses: ingestion and killing of microorganisms by phagocytic cells.

## Acquired Immunity

Acquired immunity involves two primary processes: (1) the development of circulating antibodies or immunoglobulins capable of targeting specific invading agents (antigens) for destruction and (2) formation of activated lymphocytes designed to destroy foreign invaders. Acquired immunity is absent until after the first invasion by a foreign organism or toxin.

Immunologic ability depends heavily on immunoglobulins such as IgG, IgM, and IgA. The newborn depends largely on these three immunoglobulins for defense against microorganisms associated with illness. Newborns remain very susceptible to infections for months.

IgG is the major immunoglobulin and the most abundant, making up about 80% of all circulating antibodies (Blackburn, 2012). It is found in serum and interstitial fluid. It is the only class able to cross the placenta, with active placental transfer beginning at approximately 20 to 22 weeks' gestation. IgG produces antibodies against bacteria, bacterial toxins, and viral agents.

IgA is the second most abundant immunoglobulin in the serum. IgA does not cross the placenta, and maximum levels are reached during childhood. This immunoglobulin is believed to protect mucous membranes from viruses and bacteria. IgA is predominantly found in the gastrointestinal and respiratory tracts, tears, saliva, colostrum, and breast milk.

### Take Note!

A major source of IgA is human breast milk, so breast-feeding is believed to have significant immunologic advantages over formula feeding (Lutz, & Przytulski, 2011).

IgM is found in blood and lymph fluid and is the first immunoglobulin to respond to infection. It does not cross the placenta, and levels are generally low at birth unless a congenital intrauterine infection is present. IgM offers a major source of protection from

blood-borne infections. The predominant antibodies formed during neonatal or intrauterine infection are of this class.

## Integumentary System Adaptations

The newborn's skin is a large organ, making up approximately 13% of body weight in contrast to 3% of body weight in an adult (Gardner et al., 2011). The most important function of the skin is to provide a protective barrier between the body and the environment. It limits the loss of water, prevents absorption of harmful agents, protects thermoregulation and fat storage, and protects against physical trauma. The epidermal barrier begins to develop during midgestation and is fully formed by about 32 weeks' gestation. Although the neonatal epidermis is similar to the adult epidermis in thickness and lipid composition, skin development is not complete at birth (Fluhr, Darlenski, Lacjmann, & Baudouin et al., 2012). Although the basic structure is the same as that of an adult, the less mature the newborn, the less mature the skin functions. Fewer fibrils connect the dermis and epidermis in the newborn compared with the adult. Also in a newborn, the risk of injury producing a break in the skin from the use of tapes and monitors and from handling is greater than for an adult. Improper handling of the newborn during daily skin care practices, such as bathing, can cause damage, prevent healing, and interfere with the normal maturation process.

Newborns vary greatly in appearance. Many of the variations are temporary and reflect the physiologic adaptations that the newborn is experiencing. Skin coloring varies, depending on the newborn's age, race or ethnic group, temperature, and whether he or she is crying. Skin color changes with both the environment and health status. At birth, the newborn's skin is dark red to purple. As the newborn begins to breathe air his or her skin color changes to red. This redness normally begins to fade the first day.

## Neurologic System Adaptations

The nervous system consists of the brain, spinal cord, 12 cranial nerves, and a variety of spinal nerves that come from the spinal cord. Neurologic development follows cephalocaudal (head to toe) and proximal–distal (center to outside) patterns. Myelin develops early on in sensory impulse transmitters. Thus, the newborn has an acute sense of hearing, smell, and taste. The newborn's sensory capabilities include:

- Hearing—well developed at birth, responds to noise by turning to sound
- Taste—ability to distinguish between sweet and sour by 72 hours old
- Smell—ability to distinguish between mother's breast milk and breast milk from others
- Touch—sensitivity to pain, responds to tactile stimuli
- Vision—is incomplete at birth. Maturation is dependent on nutrition and visual stimulation. Newborns have ability to focus only on close objects (8 to 10 inches away) with a visual acuity of 20/140; they can track objects in midline or beyond (90 inches). This is the least mature sense at birth. The ability to fix, follow, and be alert is indicative of an intact CNS (Brémond-Gignac, Copin, Lapillonne, & Milazzo, 2011).

*Remember Maria, the new mother who is worried that her daughter can't see? What might the new mother notice about her daughter's behavior? What might be the new mother's expectations?*

Successful adaptations demonstrated by the respiratory, circulatory, thermoregulatory, and musculoskeletal systems indirectly indicate the central nervous system's (CNS's) successful transition from fetal to extrauterine life, because the CNS plays a major role in all these adaptations. In the newborn, congenital reflexes are the hallmarks of maturity of the CNS, viability, and adaptation to extrauterine life.

The presence and strength of a reflex is an important indication of neurologic development and function. A **reflex** is an involuntary muscular response to a sensory stimulus. It is built into the nervous system and does not need the intervention of conscious thought to take effect. The physical assessment of the neurologic system of the newborn includes evaluating the major reflexes (gag, Babinski, Moro, and Galant) and minor ones (finger grasp, toe grasp, rooting, sucking, head righting, stepping, and tonic neck). To assess each reflex, the nurse progresses methodically, taking care to document each finding (Jarvis, 2012). Many neonatal reflexes disappear with maturation, although some remain throughout adulthood.

The arcs of these reflexes end at different levels of the spine and brain stem, reflecting the function of the cranial nerves and motor systems. The ways newborns blink, move their limbs, focus on a caretaker's face, turn toward sound, suck, swallow, and respond to the environment are all indications of their neurologic abilities. Congenital defects within the CNS are frequently not overt but may be revealed in abnormalities in tone, posture, or behavior (Gilbert, 2011). Damage to the nervous system (birth trauma, perinatal hypoxia) during the birthing process can cause delays in the normal growth, development, and functioning of the newborn. Early identification may help to identify the cause and to start

early intervention to decrease long-term complications or permanent sequelae.

Newborn reflexes are assessed to evaluate neurologic function and development. Absent or abnormal reflexes in a newborn, persistence of a reflex past the age when it is normally lost, or redevelopment of an infantile reflex in an older child or adult may indicate neurologic pathology. (See Chapter 18 for a description of newborn reflex assessment.)

*The Healthy Start nurse explained to Maria that all newborns are born with some degree of myopia (inability to see distances) and that 20/20 vision is not generally achieved until 2 years of age. What developmental information should the nurse discuss with Maria?*

## BEHAVIORAL ADAPTATIONS

In addition to adapting physiologically, the newborn also adapts behaviorally. All newborns progress through a specific pattern of events after birth, regardless of their gestational age or the type of birth they experienced.

### Behavioral Patterns

The newborn usually demonstrates a predictable pattern of behavior during the first several hours after birth, characterized by two periods of reactivity separated by a sleep phase. Behavioral adaptation is a defined progression of events triggered by stimuli from the extrauterine environment after birth.

#### First Period of Reactivity

The first period of reactivity begins at birth and may last from 30 minutes up to 2 hours. The newborn is alert and moving and may appear hungry. This period is characterized by myoclonic movements of the eyes, spontaneous Moro reflexes, sucking motions, chewing, rooting, and fine tremors of the extremities. Muscle tone and motor activity are increased (Mattson, & Smith, 2011). Respiration and heart rate are elevated but gradually begin to slow as the next period begins.

This period of alertness allows parents to interact with their newborn and to enjoy close contact with their new baby (Fig. 17.5). The appearance of sucking and rooting behaviors provides a good opportunity for initiating breast-feeding. Many newborns latch on the nipple and suck well at this first experience.

**FIGURE 17.5** The first period of reactivity is an optimal time for interaction.

#### Period of Decreased Responsiveness

At 30 to 120 minutes of age, the newborn enters the second stage of transition—that of the *sleep period* or a decrease in activity. This phase is referred to as a period of decreased responsiveness. Movements are less jerky and less frequent. Heart and respiratory rates decline as the newborn enters the sleep phase. The muscles become relaxed, and responsiveness to outside stimuli diminishes. During this phase, it is difficult to arouse or interact with the newborn. No interest in sucking is shown. This quiet time can be used for both mother and newborn to remain close and rest together after labor and the birthing experience.

#### Second Period of Reactivity

The second period of reactivity begins as the newborn awakens and shows an interest in environmental stimuli. This period lasts 2 to 8 hours in the normal newborn (Buonocore, Bracci, & Weindling, 2012). Heart and respiratory rates increase. Peristalsis also increases. Thus, it is not uncommon for the newborn to pass meconium or void during this period. In addition, motor activity and muscle tone increase in conjunction with an increase in muscular coordination (Fig. 17.6).

Interaction between the mother and the newborn during this second period of reactivity is encouraged if the mother has rested and desires it. This period also provides a good opportunity for the parents to examine their newborn and ask questions.

#### Take Note!

Teaching about feeding, positioning for feeding, and diaper-changing techniques can be reinforced during this time.

**FIGURE 17.6** Newborn during the second period of reactivity. Note the newborn's wide-eyed interest.

## Newborn Behavioral Responses

Newborns demonstrate several predictable responses when interacting with their environment. How they react to the world around them is termed a **neurobehavioral response**. It comprises predictable periods that are probably triggered by external stimuli.

Expected newborn behaviors include orientation, habituation, motor maturity, self-quieting ability, and social behaviors. Any deviation in behavioral responses requires further assessment, because it may indicate a complex neurobehavioral problem.

### Orientation

The response of newborns to stimuli is called *orientation*. They become more alert when they sense a new stimulus in their environment. Orientation reflects newborns' response to auditory and visual stimuli, demonstrated by their movement of head and eyes to focus on that stimulus. Newborns prefer the human face and bright shiny objects. As the face or object comes into their line of vision, newborns respond by staring at the object intently. Newborns use this sensory capacity to become familiar with people and objects in their surroundings.

*Remember Maria, who was concerned about her newborn daughter's vision? She told the nurse that her daughter did not show any interest in her pastel-colored homemade mobile she had hung across the room from her crib. What suggestions can the nurse make to Maria regarding the placement of the mobile and the types and colors of objects used to promote orientation in her newborn daughter?*

### Habituation

Habituation is the newborn's ability to process and respond to visual and auditory stimuli. It is a measure of how well and appropriately an infant responds to the environment. Habituation is the ability to block out external stimuli after the newborn has become accustomed to the activity. During the first 24 hours after birth, newborns should increase their ability to habituate to environmental stimuli and sleep. Habituation provides a useful indicator of their neurobehavioral intactness.

### Motor Maturity

Motor maturity depends on gestational age and involves evaluation of posture, tone, coordination, and movements. These activities enable newborns to control and coordinate movement. When stimulated, newborns with good motor organization demonstrate movements that are rhythmic and spontaneous. Bringing the hand up to the mouth is an example of good motor organization. As newborns adapt to their new environment, smoother movements should be observed. Such motor behavior is a good indicator of the newborn's ability to respond and adapt accordingly; it indicates that the CNS is processing stimuli appropriately.

### Self-Quieting Ability

Self-quieting ability refers to newborns' ability to quiet and comfort themselves. Newborns vary in their ability to console themselves or to be consoled. "Consolability" is how newborns are able to change from the crying state to an active alert, quiet alert, drowsy, or sleep state. They console themselves by hand-to-mouth movements and sucking, alerting to external stimuli and motor activity (Kurth et al., 2010). Assisting parents to identify consoling behaviors to quiet their newborn if the newborn is not able to self-quiet is important. These behaviors include rocking, holding, gently patting, and softly singing to them.

### Social Behaviors

Social behaviors include cuddling and snuggling into the arms of the parent when the newborn is held. Usually newborns are very sensitive to being touched, cuddled, and held. Cuddliness is very important to parents, because they frequently gauge their ability to care for their newborn by the newborn's acceptance or positive response to their actions. This can be assessed by the degree to which the newborn nestles into the contours of the holder's arms. Most newborns cuddle, but some will resist. Assisting parents to assume comforting behaviors (e.g., by cooing while holding their newborn) and praising them for their efforts can help foster cuddling behaviors.

## KEY CONCEPTS

- The neonatal period is defined as the first 28 days of life. As the newborn adapts to life after birth, numerous physiologic changes occur.
- At birth, the cardiopulmonary system must switch from fetal to neonatal circulation and from placental to pulmonary gas exchange.
- One of the most crucial adaptations that the newborn makes at birth is the adjustment of a fluid medium exchange from the placenta to the lungs and that of a gaseous environment.
- Neonatal RBCs have a life span of 80 to 100 days in comparison with the adult RBC life span of 120 days. This difference in RBC life span causes several adjustment problems.
- Thermoregulation is the maintenance of balance between heat loss and heat production. It is a critical physiologic function that is closely related to the transition and survival of the newborn.
- The newborn's primary method of heat production is through nonshivering thermogenesis, a process in which brown fat (adipose tissue) is oxidized in response to cold exposure. Brown fat is a special kind of highly vascular fat found only in newborns.
- Heat loss in the newborn is the result of four mechanisms: conduction, convection, evaporation, and radiation.
- Responses of the immune system serve three purposes: defense (protection from invading organisms), homeostasis (elimination of worn-out host cells), and surveillance (recognition and removal of enemy cells).
- In the newborn, congenital reflexes are the hallmarks of maturity of the CNS, viability, and adaptation to extrauterine life.
- The newborn usually demonstrates a predictable pattern of behavior during the first several hours after birth, characterized by two periods of reactivity separated by a sleep phase.

## MULTIPLE-CHOICE QUESTIONS

- When assessing the term newborn, the following are observed: newborn is alert, heart and respiratory rates have stabilized, and meconium has been passed. The nurse determines that the newborn is exhibiting behaviors indicating:
  - Initial period of reactivity
  - Second period of reactivity
  - Decreased responsiveness period
  - Sleep period for newborns
- A nurse observes a 3-day-old term newborn who is starting to appear mildly jaundiced. What might explain this condition?
  - Physiologic jaundice secondary to breast-feeding
  - Hemolytic disease of the newborn due to blood incompatibility
  - Exposing the newborn to high levels of oxygen
  - Overfeeding the newborn with too much glucose water
- After teaching a group of nursing students about thermoregulation and appropriate measures to prevent heat loss by evaporation, which of the following student behaviors would indicate successful teaching?
  - Transporting the newborn in an isolette
  - Maintaining a warm room temperature
  - Placing the newborn on a warmed surface
  - Drying the newborn immediately after birth
- After birth, the nurse would expect which fetal structure to close as a result of increases in the pressure gradients on the left side of the heart?
  - Foramen ovale
  - Ductus arteriosus
  - Ductus venosus
  - Umbilical vein
- Which of the following newborns could be described as breathing normally?
  - Newborn A is breathing deeply, with a regular rhythm, at a rate of 20 bpm.
  - Newborn B is breathing diaphragmatically with sternal retractions, at a rate of 70 bpm.
  - Newborn C is breathing shallowly, with 40-second periods of apnea and cyanosis.
  - Newborn D is breathing shallowly, at a rate of 36 bpm, with short periods of apnea.
- When assessing a term newborn (6 hours old), the nurse auscultates bowel sounds and documents recent passing of meconium. These findings would indicate:
  - Abnormal gastrointestinal newborn transition and needs to be reported
  - An intestinal anomaly that needs immediate surgery

- A patent anus with no bowel obstruction and normal peristalsis
- A malabsorption syndrome resulting in fatty stools

## CRITICAL THINKING EXERCISES

- As the nurse manager, you have been orienting a new nurse in the nursery for the past few weeks. Although she has been demonstrating adequacy with most procedures, today you observe her bathing several newborns without covering them, weighing them on the scale without a cover, leaving the storage door open with the transporter nearby, and leaving the newborns' head covers and blankets off after showing them to family members through the nursery observation window.
  - What is your impression of this behavior?
  - What principles concerning thermoregulation need to be reinforced?
  - How will you evaluate whether your instructions have been effective?
- The most important adaptations for the newborn to make after birth are to establish respirations, make cardiovascular adjustments, and establish thermoregulation. Nursing care focuses on monitoring and supporting adjustments to extrauterine adaptation. Write appropriate nursing interventions to help achieve the following newborn adaptations:
  - Respiratory adaptation
  - Safety, including prevention of infection
  - Thermoregulation

## STUDY ACTIVITIES

- While in the nursery clinical setting, identify the period of behavioral reactivity (first, inactivity, or second period) for two newborns born at different times. Share your findings during the post conference for that clinical day.
- Dramatic changes occur in the cardiovascular system at birth. When the umbilical cord is clamped and the placenta is separated, there is a resultant increase in systemic blood pressure and changes to the three major fetal shunts (ductus venosus, foramen ovale, and ductus arteriosus) occur. Outline what happens to cause their functional closures during this period of transition.
- Find two web sites about the transition to extrauterine life that can be shared with other nursing students as well as nursery nurses. Critique the information presented in terms of how accurate and current it is.
- The most common mechanism of heat loss in the newborn is \_\_\_\_\_.

# Nursing Management of the Newborn

## Learning Objectives

*Upon completion of the chapter, you will be able to:*

1. Define the key terms used in this chapter.
2. Relate the assessments performed during the immediate newborn period.
3. Employ interventions that meet the immediate needs of the term newborn.
4. Demonstrate the components of a typical physical examination of a newborn.
5. Distinguish common variations that can be noted during a newborn's physical examination.
6. Characterize common concerns in the newborn and appropriate interventions.
7. Compare the importance of the newborn screening tests.
8. Plan for common interventions that are appropriate during the early newborn period.
9. Analyze the nurse's role in meeting the newborn's nutritional needs.
10. Outline discharge planning content and education needed for the family with a newborn.

*Kelly, a 16-year-old first-time mother, calls the hospital maternity unit 3 days after being discharged home. She tells the nurse that her newborn son “looks like a canary” and “isn't nursing well.” She wonders what is wrong.*

### Words of Wisdom

You can send a more powerful message with your actions and behavior than with words alone.

**Immediately** after the birth of a newborn, all parents are faced with the task of learning and understanding as much as possible about caring for this new family member, even if the parents already have other children. In their new or expanded role as parents, they will face many demands and challenges. For most, this is a wonderful, exciting time filled with many discoveries and much information.

Parents learn as they watch the nurse interacting with their newborn. Nurses play a major role in teaching parents about normal newborn characteristics and about ways to foster optimal growth and development. This role is even more important today because of limited hospital stays.

The newborn has come from a dark, small, enclosed space in the mother's uterus into the bright, cold extrauterine environment. Nurses can easily forget that they are caring for a small human being who is experiencing his or her first taste of human interaction outside the uterus. The newborn period is an extremely important one, and two national health goals have been developed to address this critical period (see the *Healthy People*

2020 feature; U.S. Department of Health and Human Services [USDHHS], 2010).

It is also easy to overlook the intensity with which parents and visitors observe the actions of nurses as they care for the new family member. Nurses need to serve as a model for giving nurturing care to newborns.

This chapter provides information about assessment and interventions in the period immediately following the birth of a newborn and during the early newborn period.

## NURSING MANAGEMENT DURING THE IMMEDIATE NEWBORN PERIOD

The period of transition from intrauterine to extrauterine life occurs during the first several hours after birth. During this time, the newborn is undergoing numerous adaptations, many of which are occurring simultaneously (see Chapter 17 for more information on the newborn's adaptation). The neonate's temperature, respiration, and cardiovascular dynamics stabilize during this period.

### HEALTHY PEOPLE 2020 • 18-1

#### Objective

- Increase the proportion of mothers who breast-feed their babies during the early postpartum period from a baseline of 74% to 81.9%.
- Increase the proportion of mothers who breast-feed at 6 months from a baseline of 43.5% to 60.6%.
- Increase the proportion of mothers who breast-feed at 1 year from a baseline of 22.7% to 34.1%.
- Ensure appropriate newborn bloodspot screening and follow-up testing.
- Increase the number of States and the District of Columbia that verify through linkage with vital records that all newborns are screened shortly after birth for conditions mandated by their state-sponsored screening program.
- Increase the proportion of screen-positive children who receive follow-up testing within the recommended time period.
- (Developmental) Increase the proportion of children with a diagnosed condition identified through newborn screening who have an annual assessment of services needed and received.
- Increase the proportion of newborns who are screened for hearing loss by no later than age 1 month, have audiologic evaluation by age 3 months, and are enrolled in appropriate intervention service no later than age 6 months.

*Healthy People* objectives based on data from <http://www.healthypeople.gov>.

#### Nursing Significance

- Will emphasize the importance of breast milk as the most complete form of nutrition for infants.
- Will help to promote infant health, growth, immunity, and development throughout the newborn and infant periods.
- Will help to foster early detection and prompt treatment for conditions, thereby lessening the incidence of illness, disability, and death associated with these conditions and their overall effects on the newborn, infant, and family.

Close observation of the newborn's status is essential. Careful examination of the newborn at birth allows for detection of anomalies, birth injuries, and disorders that can compromise adaptation to extrauterine life. Problems that occur during this critical time can have a life-long impact.

## Assessment

The initial newborn assessment is completed in the birthing area to determine whether the newborn is stable enough to stay with the parents or whether resuscitation or other immediate interventions are necessary. A second assessment is done within the first 2 to 4 hours, when the newborn is admitted to the nursery or the labor and delivery room (LDR) room where the parents are. A third assessment is completed before discharge. The purpose of these assessments is to determine the newborn's overall health status, to provide information to the parents about their newborn, and to identify apparent physical abnormalities (Baston & Durward, 2010).

During the initial newborn assessment, look for signs that might indicate a problem, including:

- Nasal flaring
- Chest retractions
- Grunting on exhalation
- Labored breathing
- Generalized cyanosis
- Abnormal breath sounds: rhonchi, crackles (rales), wheezing, and stridor
- Abnormal respiratory rates (tachypnea, more than 60 breaths/minute; bradypnea, less than 25 breaths/minute)
- Flaccid body posture
- Abnormal heart rates (tachycardia, more than 160 bpm; bradycardia, less than 100 bpm)
- Abnormal newborn size: small or large for gestational age

If any of these findings are noted, medical intervention may be necessary.

## Apgar Scoring

The **Apgar score**, introduced in 1952 by Dr. Virginia Apgar, is used to evaluate a newborn's physical condition at 1 minute and 5 minutes after birth. An additional Apgar assessment is done at 10 minutes if the 5-minute score is less than 7 points (Vahabi, Haidari, Akbari Torkamani, & Gorbani Vaghei, 2010). It can be used as a rapid method for assessing the survival of a neonate. Assessment of the newborn at 1 minute provides data about the newborn's initial adaptation to extrauterine life. Assessment at 5 minutes provides a clearer indication of the newborn's overall central nervous system status.

Five parameters are assessed with Apgar scoring. A quick way to remember the parameters of Apgar scoring is as follows:

- A = appearance (color)
- P = pulse (heart rate)
- G = grimace (reflex irritability)
- A = activity (muscle tone)
- R = respiratory (respiratory effort)

Each parameter is assigned a score ranging from 0 to 2 points. A score of 0 points indicates an absent or poor response; a score of 2 points indicates a normal response (Table 18.1). A normal newborn's score should be 8 to 10 points. The higher the score, the better the condition of the newborn. If the Apgar score is 8 points or higher, no intervention is needed other than supporting normal respiratory efforts and maintaining thermoregulation. Scores of 4 to 7 points signify moderate difficulty and scores of 0 to 3 points represent severe distress in adjusting to extrauterine life. The Apgar score is influenced by the presence of infection, congenital anomalies, physiologic immaturity, maternal sedation via medications, labor management, and neuromuscular disorders (Hegarty, & Craig, 2012).

When the newborn experiences physiologic depression, the Apgar score characteristics disappear in a predictable manner: first the pink coloration is lost, next the respiratory effort, and then the tone, followed by reflex irritability and finally heart rate (Wong, & MacLennan, 2011).

### Take Note!

Although Apgar scoring is done at 1 and 5 minutes, it also can be used as a guide during the immediate newborn period to evaluate the newborn's status for any changes because it focuses on critical parameters that must be assessed throughout the early transition period.

## Length and Weight

Parents are eager to know their newborn's length and weight. These measurements are taken soon after birth. A disposable tape measure or a built-in measurement board located on the side of some scales can be used. Length is measured from the head of the newborn to the heel with the newborn unclothed (Fig. 18.1). Because of the flexed position of the newborn after birth, place the newborn in a supine position and extend the leg completely when measuring the length. The expected length range of a full-term newborn is usually 44 to 55 cm (17 to 22 inches). Molding can affect measurement (Jarvis, 2012).

Most often, newborns are weighed using a digital scale that reads the weight in grams. Typically, the term newborn weighs 2,500 to 4,000 g (5 pounds, 8 ounces

**TABLE 18.1** APGAR SCORING FOR NEWBORNS

Parameter (Assessment Technique)	0 Point	1 Point	2 Points
Heart rate (auscultation of apical heart rate for 1 full minute)	Absent	Slow (<100 bpm)	>100 bpm
Respiratory effort (observation of the volume and vigor of the newborn's cry; auscultation of depth and rate of respirations)	Apneic	Slow, irregular, shallow	Regular respirations (usually 30–60 breaths/minute), strong, good cry
Muscle tone (observation of extent of flexion in the newborn's extremities and newborn's resistance when the extremities are pulled away from the body)	Limp, flaccid	Some flexion, limited resistance to extension	Tight flexion, good resistance to extension with quick return to flexed position after extension
Reflex irritability (flicking of the soles of the feet or suctioning of the nose with a bulb syringe)	No response	Grimace or frown when irritated	Sneeze, cough, or vigorous cry
Skin color (inspection of trunk and extremities with the appropriate color for ethnicity appearing within minutes after birth)	Cyanotic or pale	Appropriate body color; blue extremities (acrocyanosis)	Completely appropriate color (pink on both trunk and extremities)

Adapted from Gardner, S. L., Carter, B. S., Enzman-Hines, M., & Herndandez, J. A. (2011). *Merenstein & Gardner's handbook of neonatal intensive care* (7th ed.). St. Louis, MO: Mosby Elsevier; and Mattson, S., & Smith, J. E. (2011). *Core curriculum for maternal–newborn nursing* (4th ed.). St. Louis, MO: Saunders Elsevier.

to 8 pounds, 14 ounces; Fig. 18.2). Birth weights less than 10% or more than 90% on a growth chart are outside the normal range and need further investigation. Weights taken at later times are compared with previous weights and are documented with regard to gain or loss on a nursing flow sheet. Newborns typically lose approximately 10% of their initial birth weight by 3 to 4 days of age secondary to loss of meconium, extracellular fluid, and limited food intake. This weight loss is usually regained by the 10th day of life (Kliegman, Behrman, Jenson, & Stanton, 2011).

Newborns can be classified by their birth weight regardless of their gestational age (American Academy of Pediatrics [AAP], 2010c) as follows:

- Low birth weight: <2,500 g (<5.5 lb)
- Very low birth weight: <1,500 g (<3.5 lb)
- Extremely low birth weight: <1,000 g (<2.5 lb)

### Vital Signs

Heart rate and respiratory rate are assessed immediately after birth with Apgar scoring. Heart rate, obtained by

**FIGURE 18.1** Measuring a newborn's length.

**FIGURE 18.2** Weighing the newborn. Note how the nurse guards the newborn with her hand to prevent falling.

taking an apical pulse for 1 full minute, typically is 120 to 160 bpm. Newborns' respirations are assessed when they are quiet or sleeping. Place a stethoscope on the right side of the chest and count the breaths for 1 full minute to identify any irregularities. The newborn respiratory rate is 30 to 60 breaths/minute with symmetric chest movement. Heart and respiratory rates are usually assessed every 30 minutes until stable for 2 hours after birth. Once stable, the heart rate and respiratory rates are checked every 8 hours. These assessment time frames may vary per hospital protocols, so nurses should follow the facility's procedures (Warren, & Phillipi, 2012).

Axillary temperature is typically assessed not immediately after birth but on admission to the nursery or when the initial newborn assessment is carried out (e.g., the LDR room). In some health care agencies, temperatures are taken immediately after the Apgar score has been taken to allow for identification of hypothermia, which then requires a glucose check, but nurses need to follow their hospital protocols on this assessment timing. In term newborns, the normal axillary temperature range should be maintained at 97.7° to 99.5° F (36.5° to 37.5° C). Rectal temperatures are no longer taken because of the risk of perforation (Gardner, Carter, Enzman-Hines, & Hernandez, 2011; Mattson, & Smith, 2011). The thermometer or temperature probe is held in the midaxillary space according to manufacturer's directions and hospital protocol. Temperature is reassessed every 30 minutes until it has been stable for 2 hours, then every 8 hours until discharge (Kliegman et al., 2011).

Blood pressure is not usually assessed as part of a normal newborn examination unless there is a clinical indication or low Apgar scores. If assessed, an oscillometer (Dinamap) is used. The typical range is 50 to 75 mm Hg (systolic) and 30 to 45 mm Hg (diastolic). Crying, moving, and late clamping of the umbilical cord will increase systolic pressure (Jarvis, 2012).

Typical values for newborn vital signs are provided in Table 18.2.

### Gestational Age Assessment

To determine a newborn's **gestational age** (the stage of maturity), physical signs and neurologic characteristics are assessed. Typically, gestational age is determined by using a tool such as the Dubowitz/Ballard or New Ballard Score system (Fig. 18.3). This scoring system provides an objective estimate of gestational age by scoring the specific parameters of physical and neuromuscular maturity. Points are given for each assessment parameter, with a low score of –1 point or –2 points for extreme immaturity to 4 or 5 points for postmaturity. The scores from each section are added to correspond to a specific gestational age in weeks.

The physical maturity section of the examination is done during the first 2 hours after birth. The physical

**TABLE 18.2** NEWBORN VITAL SIGNS

Newborn Vital Signs	Ranges of values
Temperature	97.7–99.5° F (36.5–37.5° C)
Heart rate (pulse) to 180 during crying	120–160 bpm; can increase
Respirations	30–60 breaths/minute at rest; will increase with crying
Blood pressure	50–75 mm Hg systolic, 30–45 mm Hg diastolic

maturity assessment section of the Ballard examination evaluates physical characteristics that appear different at different stages depending on a newborn's gestational maturity. Newborns that are physically mature have higher scores than those who are not. The areas assessed on the physical maturity examination include:

- Skin texture—typically ranges from sticky and transparent to smooth, with varying degrees of peeling and cracking, to parchment-like or leathery with significant cracking and wrinkling
- Lanugo—soft downy hair on the newborn's body, which is absent in preterm newborns, appears with maturity, and then disappears again with postmaturity
- Plantar creases—creases on the soles of the feet, which range from absent to covering the entire foot, depending on maturity (the greater the number of creases, the greater the newborn's maturity)
- Breast tissue—the thickness and size of breast tissue and areola (the darkened ring around each nipple), which range from being imperceptible to full and budding
- Eyes and ears—eyelids can be fused or open and ear cartilage and stiffness determine the degree of maturity (the greater the amount of ear cartilage with stiffness, the greater the newborn's maturity)
- Genitals—in males, evidence of testicular descent and appearance of scrotum (which can range from smooth to covered with rugae) determine maturity; in females, appearance and size of clitoris and labia determine maturity (a prominent clitoris with flat labia suggests prematurity, whereas a clitoris covered by labia suggests greater maturity)

The neuromuscular maturity section typically is completed within 24 hours after birth. Six activities or

maneuvers that the newborn performs with various body parts are evaluated to determine the newborn's degree of maturity:

1. Posture—How does the newborn hold his or her extremities in relation to the trunk? The greater the degree of flexion, the greater the maturity. For example,

extension of arms and legs is scored as 0 points and full flexion of arms and legs is scored as 4 points.

2. Square window—How far can the newborn's hands be flexed toward the wrist? The angle is measured and scored from more than 90 degrees to 0 degrees to determine the maturity rating. As the angle decreases, the

newborn's maturity increases. For example, an angle of more than 90 degrees is scored as -1 point and an angle of 0 degrees is scored as 4 points.

3. Arm recoil—How far do the newborn's arms “spring back” to a flexed position? This measure evaluates the degree of arm flexion and the strength of recoil. The reaction of the arm is then scored from 0 to 4 points based on the degree of flexion as the arms are returned to their normal flexed position. The higher the points assigned, the greater the neuromuscular maturity (for example, recoil less than a 90-degree angle is scored as 4 points).
4. Popliteal angle—How far will the newborn's knees extend? The angle created when the knee is extended is measured. An angle of less than 90 degrees indicates greater maturity. For example, an angle of 180 degrees is scored as -1 point and an angle of less than 90 degrees is scored as 5 points.
5. Scarf sign—How far can the elbows be moved across the newborn's chest? An elbow that does not reach midline indicates greater maturity. For example, if the elbow reaches or nears the level of the opposite shoulder, this is scored as -1 point; if the elbow does not cross the proximate axillary line, it is scored as 4 points.
6. Heel to ear—How close can the newborn's feet be moved to the ears? This maneuver assesses hip flexibility: the lesser the flexibility, the greater the newborn's maturity. The heel-to-ear assessment is scored in the same manner as the scarf sign.

After the scoring is completed, the 12 scores are totaled and then compared with standardized values to determine the appropriate gestational age in weeks. Scores range from very low in preterm newborns to very high for mature and postmature newborns.

Typically newborns are also classified according to gestational age as:

- Preterm or premature—born prior to 37 completed weeks' gestation, regardless of birth weight
- Term—born between 38 and 42 weeks' gestation
- Post-term or postdates—born after completion of week 42 of gestation
- Postmature—born after 42 weeks and demonstrating signs of placental aging

Using the information about gestational age and then considering birth weight, newborns can also be classified as follows:

- Small for gestational age (SGA)—weight less than the 10th percentile on standard growth charts (usually <5.5 lb)
- Appropriate for gestational age (AGA)—weight between 10th and 90th percentiles
- Large for gestational age (LGA)—weight more than the 90th percentile on standard growth charts (usually >9 lb)

Chapter 23 describes these variations in birth weight and gestational age in greater detail.

### Take Note!

Gestational age assessment is important because it allows the nurse to plot growth parameters and to anticipate problems related to prematurity, postmaturity, and growth abnormalities.

## Nursing Interventions

During the immediate newborn period, care focuses on helping the newborn to make the transition to extrauterine life. The nursing interventions include maintaining airway patency, ensuring proper identification, administering prescribed medications, and maintaining thermoregulation.

### Maintaining Airway Patency

Immediately after birth, a newborn is suctioned to remove fluids and mucus from the mouth and nose (Fig. 18.4). Typically, the newborn's mouth is suctioned first with a bulb syringe to remove debris and then the nose is suctioned. Suctioning in this manner helps to prevent aspiration of fluid into the lungs by an unexpected gasp.

When suctioning a newborn with a bulb syringe, compress the bulb before placing it into the oral or nasal cavity. Release bulb compression slowly, making sure the tip is placed away from the mucous membranes to draw up the excess secretions. Remove the bulb syringe from the mouth or nose, and then, while holding the bulb syringe tip over an emesis basin lined with paper towel or tissue, compress the bulb to expel the secretions.

**FIGURE 18.4** A newborn is suctioned by means of a bulb syringe to remove mucus from the mouth and nose. The head-down-and-to-the-side position facilitates drainage. Care is given with the infant under a radiant heat source. (Copyright Caroline Brown, RNC, MS, DEd.)

Repeat the procedure several times until all secretions are removed.

### Take Note!

Always keep a bulb syringe near the newborn in case he or she develops sudden choking or a blockage in the nose.

## Ensuring Proper Identification

While not a crime of epidemic proportions, the abduction, by nonfamily members, of newborns from health care facilities has clearly become a subject of concern for parents, maternal–child care nurses, health care security and risk management administrators, law enforcement officials, and the National Center for Missing & Exploited Children (NCMEC). Proactive security measures must become everyone’s responsibility to ensure the safety of all newborns and their families in all hospital settings.

Before the newborn and family leave the birthing area, be sure that agency policy about identification has been followed. Typically, the mother, the newborn, and the father or any significant other or support person of the mother’s choosing receive identification (ID) bracelets. The newborn commonly receives two ID bracelets, one on a wrist and one on an ankle. The mother receives a matching one, usually on her wrist. The ID bands usually state name, gender, date and time of birth, and identification number. The same identification number is on the bracelets of all family members.

These ID bracelets provide for the safety of the newborn and must be secured before the mother and newborn leave the birthing area. The ID bracelets are checked by all nurses to validate that the correct newborn is brought to the right mother if they are separated for any period of time (Fig. 18.5). They also serve as the official newborn identification and should be checked before initiating any procedure on that newborn and

**FIGURE 18.5** The nurse checks the newborn’s identification band against the mother’s.

on discharge from the unit (NCMEC, 2011). Taking the newborn’s picture within 2 hours after birth with a color camera or color video/digital image also helps prevent mix-ups and abduction. Many facilities use electronic devices that sound an alarm if a newborn is removed from the area.

Newborns’ footprints may also be taken, using a form that includes the mother’s fingerprint, name, and date and time of the birth. Some states require footprints of the newborn, although many studies point out that birthing room staff members do not take consistently legible footprints suitable for identification purposes (Hiner, Kyka, Burks, Pisegna, & Gador, 2012). Many states have stopped requiring newborn footprints, and thus other means of identification are needed, such as collecting cord blood at the time of birth for DNA testing and live scans to capture digital forensic-quality prints that are suitable for identification purposes (Benz, 2011).

Prevention of infant abductions has been successful through a combination of increased security measures in hospitals, including video cameras and alarm devices, and education of staff and parents about precautions to take while in the hospital. It is critical not to allow anyone without identification to take an infant for any reason and to keep the infant within sight of the parent or nursery staff at all times. These measures should be largely invisible and create a sense of security rather than increasing parental fears about abduction.

## Administering Prescribed Medications

During the immediate newborn period, two medications are commonly ordered: vitamin K and eye prophylaxis with either erythromycin or tetracycline ophthalmic ointment (Drug Guide 18.1).

### VITAMIN K

Vitamin K, a fat-soluble vitamin, promotes blood clotting by increasing the synthesis of prothrombin by the liver. A deficiency of this vitamin delays clotting and might lead to hemorrhage.

Generally, the bacteria of the intestine produce vitamin K in adequate quantities. However, the newborn’s bowel is sterile, so vitamin K is not produced in the intestine until after microorganisms have been introduced, such as with the first feeding. Usually it takes about a week for the newborn to produce enough vitamin K to prevent vitamin K deficiency bleeding. An oral vitamin K preparation is also being given to newborns (Strehle, Howey, & Jones, 2010).

The efficacy of vitamin K in preventing early vitamin K deficiency bleeding is firmly established and has been the standard of care since the AAP recommended it in the early 1960s. The AAP (2010f) recommends that vitamin K be administered to all newborns soon after birth

## DRUG GUIDE 18.1 DRUGS FOR THE NEWBORN

Drug	Action/Indication	Nursing Implications
Phytonadione (vitamin K [Aqua-MEPHYTON, Kon-akion, Mephyton])	Provides the newborn with vitamin K (necessary for production of adequate clotting factors II, VII, IX, and X by the liver) during the first week of birth until newborn can manufacture it Prevents vitamin K deficiency bleeding (VKDB) of the newborn	<ul style="list-style-type: none"> <li>• Administer within 1 to 2 hr after birth.</li> <li>• Give as an IM injection at a 90-degree angle into the middle third of the vastus lateralis muscle.</li> <li>• Use a 25-gauge, 5/8-in. needle for injection.</li> <li>• Hold the leg firmly and inject medication slowly after aspirating.</li> <li>• Adhere to standard precautions.</li> <li>• Assess for bleeding at injection site after administration.</li> </ul>
Erythromycin ophthalmic ointment 0.5% or tetracycline ophthalmic ointment 1%	Provides bactericidal and bacteriostatic actions to prevent <i>Neisseria gonorrhoea</i> and <i>Chlamydia trachomatis</i> conjunctivitis Prevents ophthalmia neonatorum	<ul style="list-style-type: none"> <li>• Be alert for chemical conjunctivitis for 1–2 days.</li> <li>• Wear gloves, and open eyes by placing thumb and finger above and below the eye.</li> <li>• Gently squeeze the tube or ampoule to apply medication into the conjunctival sac from the inner canthus to the outer canthus of each eye.</li> <li>• Do not touch the tip to the eye.</li> <li>• Close the eye to make sure the medication permeates.</li> <li>• Wipe off excess ointment after 1 min.</li> </ul>

Adapted from King, T. L., & Brucker, M. C. (2011). *Pharmacology for women's health*. Sudbury, MA: Jones & Bartlett; and Skidmore-Roth, L. (2012). *Mosby's drug guide for nurses* (9th ed.). St. Louis, MO: Elsevier Health Sciences.

in a single intramuscular dose of 0.5 to 1 mg (Fig. 18.6). The AAP also suggests that additional research is needed to validate the efficacy and safety of oral forms of vitamin K, which have been used in many parts of the world but currently are not recommended in the United States.

**FIGURE 18.6** The nurse administers vitamin K IM to the newborn.

### EYE PROPHYLAXIS

All newborns in the United States, whether delivered vaginally or by cesarean birth, must receive an installation of a prophylactic agent in their eyes within an hour or two of birth. This is mandated in all 50 states to prevent **ophthalmia neonatorum**, which can cause neonatal blindness (Centers for Disease Control and Prevent [CDC], 2010). Ophthalmia neonatorum is a hyperacute purulent conjunctivitis occurring during the first 10 days of life. It is usually contracted during birth when the baby comes in contact with infected vaginal discharge of the mother (CDC, 2010). Most often both eyelids become swollen and red with purulent discharge.

Prophylactic agents that are currently recommended include erythromycin 0.5% ophthalmic ointment or tetracycline 1% ophthalmic ointment in a single application. Silver nitrate solution was formerly used but has little efficacy in preventing chlamydial eye disease (Crosswell, & Cheng 2012).

Regardless of which agent is used, instillation should be done as soon as possible after birth (Fig. 18.7). If

FIGURE 18.7 The nurse administers eye prophylaxis.

instillation is delayed to allow visualization and bonding, the nursery staff should make sure the agent is administered when the newborn reaches the nursery for observation and assessment.

Inform all parents about the eye treatment, including why it is recommended, what problems may arise if the treatment is not given, and possible adverse effects of the treatment.

#### Take Note!

Parents have the right to refuse this treatment, but if they received adequate teaching about the treatment and understand its importance, they usually will consent to it.

### Maintaining Thermoregulation

Newborns have trouble regulating their temperature; especially during the first few hours after birth (see Chapter 17 for a complete discussion). Therefore, maintaining body temperature is crucial.

Assess body temperature frequently during the immediate newborn period. The baby's temperature should be taken every 30 minutes for the first 2 hours or until the temperature has stabilized, and then every 8 hours until discharge (AAP, 2010e).

Commonly a thermistor probe (automatic sensor) is attached to the newborn to record body temperature on a monitoring device. The probe is taped to the newborn's abdomen, usually in the right upper quadrant, which allows for position changes without having to readjust the probe. The other end of the thermistor probe is inserted into the radiant heat control panel. Temperature parameters are set on an alarm system connected to the heat panel that will sound if the newborn's temperature falls out of the set range. Check the probe connection periodically to make sure that it remains secure. Remember the potential for heat loss in newborns, and perform all

nursing interventions in a way that minimizes heat loss and prevents hypothermia.

Axillary temperatures can also be used to assess the newborn's body temperature. At one time, rectal thermometers were routinely used to monitor body temperature, but their use is no longer recommended because of the risk of traumatizing the rectal lining (Mattson & Smith, 2011).

Nursing interventions to help maintain body temperature include:

- Dry the newborn immediately after birth to prevent heat loss through evaporation.
- Wrap the baby in warmed blankets to reduce heat loss via convection.
- Use a warmed cover on the scale to weigh the unclothed newborn.
- Warm stethoscopes and hands before examining the baby or providing care.
- Avoid placing newborns in drafts or near air vents to prevent heat loss through convection.
- Delay the initial bath until the baby's temperature has stabilized to prevent heat loss through evaporation.
- Avoid placing cribs near cold outer walls to prevent heat loss through radiation.
- Put a cap on the newborn's head after it is thoroughly dried after birth.
- Place the newborn under a temperature-controlled radiant warmer (Fig. 18.8).

## NURSING MANAGEMENT DURING THE EARLY NEWBORN PERIOD

The early newborn period is a time of great adjustment for both the mother and the newborn, both of whom are adapting to many physiologic and psychological changes. In the past, mothers and newborns remained in the health care facility while these dramatic changes were taking place, with nurses and doctors readily available. However, today shorter hospital stays are the norm, and new mothers can easily be overwhelmed by having to go through all of these changes in such a short time: the woman gives birth, experiences marked physiologic and psychological changes, and must adapt to her newborn and learn the skills needed to care for herself and the baby, all within 24 to 48 hours.

The nurse's role is to assist the mother and her newborn through this dramatic transition period. The newborn needs continued health assessment, and the mother needs to be taught to care for the new baby. At discharge, the new mother may panic and feel insecure about her role as primary caretaker. Nurses play a major role in promoting the newborn's transition by providing ongoing assessment and care and in promoting the woman's confidence by serving as a role model and teaching about proper newborn care.

FIGURE 18.8 Maintaining thermoregulation. (A) Radiant warmer. (B) Isolette.

## Assessment

The newborn requires ongoing assessment after leaving the birthing area to ensure that his or her transition to extrauterine life is progressing without problems. The nurse uses the data gathered during the initial assessment as a baseline for comparison.

## Perinatal History

Pertinent maternal and fetal data are vital to formulate a plan of care for the mother and her newborn. Historical information is obtained from the medical record and from interviewing the mother. Review the maternal history because it provides pertinent information, such as the presence of certain risk factors that could affect the newborn. Keep in mind that a comprehensive maternal history may not be available, especially if the mother has had limited or no prenatal care.

Historical information usually includes the following:

- Mother's name, medical record number, blood type, serology result, rubella and hepatitis status, and history of substance abuse
- Other maternal tests that are relevant to the newborn and care, such as HIV and group B streptococcus status
- Intrapartum maternal antibiotic therapy (type, dose, and duration)
- Maternal illness that can affect the pregnancy, evidence of chorioamnionitis, maternal use of medications such as steroids
- Prenatal care, including timing of first visit and subsequent visits
- Risk for blood group incompatibility, including Rh status and blood type

- Fetal distress or any nonreassuring fetal heart rate patterns during labor
- Known inherited conditions such as sickle cell anemia and phenylketonuria (PKU)
- Birth weights of previous live-born children, along with identification of any newborn problems
- Social history, including tobacco, alcohol, and recreational drug use
- History of depression or domestic violence
- Cultural factors, including primary language and educational level
- Pregnancy complications associated with abnormal fetal growth, fetal anomalies, or abnormal results from tests of fetal well-being
- Information on the progress of labor, birth, labor complications, duration of ruptured membranes, and presence of meconium in the amniotic fluid
- Medications given during labor, at birth, and immediately after birth
- Time and method of delivery, including presentation and the use of forceps or a vacuum extractor
- Status of the newborn at birth, including Apgar scores at 1 and 5 minutes, the need for suctioning, weight, gestational age, vital signs, and umbilical cord status
- Medications administered to the newborn
- Postbirth maternal information, including placental findings, positive cultures, and presence of fever

## Newborn Physical Examination

The initial newborn physical examination, which may demonstrate subtle differences related to the newborn's age, is carried out within the first 24 hours after birth. For example, a newborn who is 30 minutes old has not yet

completed the normal transition from intrauterine to extrauterine life, and thus variability may exist in vital signs and in respiratory, neurologic, gastrointestinal, skin, and cardiovascular systems. Therefore, a comprehensive examination should be delayed until after the newborn has completed the transition.

In a quiet newborn, begin the examination with the least invasive and noxious elements of the examination (auscultation of heart and lungs). Then examine the areas most likely to irritate the newborn (e.g., examining the hips and eliciting the Moro reflex). A general visual assessment provides an enormous amount of information about the well-being of a newborn. Initial observation gives an impression of a healthy (stable) versus an ill newborn and a term versus a preterm newborn.

A typical physical examination of a newborn includes a general survey of skin color, posture, state of alertness, head size, overall behavioral state, respiratory status, gender, and any obvious congenital anomalies. Check the overall appearance for anything unusual. Then complete the examination in a systematic fashion.

*Remember Kelly, who called the home health nurse and said her newborn son “looks like a canary”? What additional information is needed about the baby? What might be causing his yellow color?*

## ANTHROPOMETRIC MEASUREMENTS

Shortly after birth, after the gender of the child is revealed, most parents want to know the “vital statistics” of their newborn—length and weight—to report to their family and friends. Additional measurements, including head and chest circumference, are also taken and recorded. Abdominal measurements are not routinely obtained unless there is a suspicion of pathology that causes abdominal distention. The newborn’s progress from that point on will be validated based on these early measurements. These measurements will be compared with future serial measurements to determine growth patterns, which are plotted on growth charts to evaluate normalcy. Therefore, accuracy is paramount.

**Length.** The average length of most newborns is 50 cm (20 in), but it can range from 44 to 55 cm (17 to 22 inches). Measure length with the unclothed newborn lying on a warmed blanket placed on a flat surface with the knees held in an extended position. Then run a tape measure down the length of the newborn—from the head to the soles of the feet—and record this measurement in the newborn’s record (see Fig. 18.1).

**Weight.** At birth the average newborn weighs 3,400 g (7.5 lb), but normal birth weights can range from

2,500 to 4,000 g (5 lb, 8 oz to 8 lb, 14 oz). Newborns are weighed immediately after birth and then daily. Newborns usually lose up to 10% of their birth weight within the first few days of life, but regain it in approximately 10 days.

Newborns are weighed on admission to the nursery or are taken to a digital scale to be weighed and returned to the mother’s room. First, balance the scale if it is not balanced. Place a warmed protective cloth or paper as a barrier on the scale to prevent heat loss by conduction; recalibrate the scale to zero after applying the barrier. Next, place the unclothed newborn in the center of the scale. Keep a hand above the newborn for safety (see Fig. 18.2).

Weight is affected by racial origin, maternal age, size of the parents, maternal nutrition, maternal weight prenatally, and placental perfusion (Jarvis, 2012). Weight should be correlated with gestational age. A newborn who weighs more than normal might be LGA or an infant of a diabetic mother; a newborn who weighs less than normal might be SGA, preterm, or have a genetic syndrome. It is important to identify the cause for the deviation in size and to monitor the newborn for complications common to that etiology.

**Head Circumference.** The average newborn head circumference is 32 to 38 cm (13 to 15 inches). Measure the circumference at the head’s widest diameter (the occipitofrontal circumference). Wrap a flexible or paper measuring tape snugly around the newborn’s head and record the measurement (Fig. 18.9A).

### Take Note!

Head circumference may need to be remeasured at a later time if the shape of the head is altered from birth.

The head circumference should be approximately one fourth of the newborn’s length (Accardo & Jaworski, 2010). A small head might indicate microcephaly caused by rubella, toxoplasmosis, or SGA status; an enlarged head might indicate hydrocephalus or increased intracranial pressure. Both need to be documented and reported for further investigation.

**Chest Circumference.** The average chest circumference is 30 to 36 cm (12 to 14 inches). It is generally equal to or about 2 to 3 cm less than the head circumference (Jarvis, 2012). Place a flexible or paper tape measure around the unclothed newborn’s chest at the nipple line without pulling it taut (see Fig. 18.9B).

### Take Note!

The head and chest circumferences are usually equal by about 1 year of age.

A

B

**FIGURE 18.9** (A) Measuring head circumference. (B) Measuring chest circumference.

### VITAL SIGNS

In the newborn, temperature, pulse, and respirations are monitored frequently and compared with baseline data obtained immediately after birth. Generally, vital signs (excluding blood pressure) are taken:

- On admission to the nursery or in the LDR room after the parents are allowed to hold and bond with the newborn
- Once every 30 minutes until the newborn has been stable for 2 hours
- Then once every 4 to 8 hours until discharge (AAP, 2010e)

Blood pressure is not routinely assessed in a normal newborn unless the baby's clinical condition warrants it. This schedule can change depending on the baby's health status.

Obtain a newborn's temperature by placing an electronic temperature probe in the midaxillary area or by monitoring the electronic thermistor probe that has been taped to the abdominal skin (applied when the newborn was placed under a radiant heat source).

Monitor the newborn's temperature frequently per hospital protocol for changes until it stabilizes. If the temperature is higher, adjust the environment, such as removing some clothing or blankets. If the temperature is lower, check the radiant warmer setting or add a warmed blanket. Report any abnormalities to the primary health care provider if simple adjustments to the environment do not change the baby's temperature.

Obtain an apical pulse by placing the stethoscope over the fourth intercostal space on the chest. Listen for a full minute, noting rate, rhythm, and abnormal sounds such as murmurs. In the typical newborn, the heart rate is 120 to 160 bpm, with wide fluctuations with activity and sleep. Sinus arrhythmia is a normal finding. Murmurs detected during the newborn period do not necessarily indicate congenital heart disease, but they need to be assessed frequently over the next several months to see if they persist.

Also palpate the apical, femoral, and brachial pulses for presence and equality (Fig. 18.10). Report any abnormalities to the primary health care provider for evaluation.

Assess respirations by observing the rise and fall of the chest for 1 full minute. Respirations should be symmetric, slightly irregular, shallow, and unlabored at a rate of 30 to 60 breaths/minute. The newborn's respirations are predominantly diaphragmatic, but they are synchronous with abdominal movements. Also auscultate breath sounds. Note any abnormalities, such as tachypnea, bradypnea, grunting, gasping, periods of apnea lasting longer than 20 seconds, asymmetry or decreased chest expansion, abnormal breath sounds (rhonchi, crackles), or sternal retractions. Some variations might exist early after birth, but if the abnormal pattern persists, notify the primary health care provider.

### SKIN

Observe the overall appearance of the skin, including color, texture, turgor, and integrity. The newborn's skin should be smooth and flexible, and the color should be consistent with genetic background.

**Skin Condition and Color.** Check skin turgor by pinching a small area of skin over the chest or abdomen and note how quickly it returns to its original position. In a well-hydrated newborn, the skin should return to its normal position immediately. Skin that remains "tenting" after being pinched indicates dehydration. A small amount of lanugo (fine downy hair) may be observed over the shoulders and on the sides of the face and upper back. There may be some cracking and peeling of the skin. The skin should be warm to the touch and intact.

The newborn's skin often appears blotchy or mottled, especially in the extremities. Persistent cyanosis of fingers, hands, toes, and feet with mottled blue or

**FIGURE 18.10** Assessing the newborn's vital signs. **(A)** Assessing the apical pulse. **(B)** Palpating the femoral pulse. **(C)** Palpating the brachial pulse.

red discoloration and coldness is called **acrocyanosis** (Fig. 18.11). It may be seen in newborns during the first few weeks of life in response to exposure to cold. Acrocyanosis is normal and intermittent.

**Newborn Skin Variations.** While assessing the skin, make note of any rashes, ecchymoses or petechiae, nevi, or dark pigmentation. Skin lesions can be congenital or transient; they may be a result of infection or may result from the mode of birth. If any are present, observe the anatomic location, arrangement, type, and color. Bruising may result from the use of devices such as a vacuum extractor during delivery. Petechiae may be the

**FIGURE 18.11** Acrocyanosis. This commonly appears on the feet and hands of babies shortly after birth. This infant is a 32-week newborn. (From Fletcher M. [1998]. *Physical diagnosis in neonatology*. Philadelphia, PA: Lippincott-Raven Publishers.)

result of pressure on the skin during the birth process. Forceps marks may be observed over the cheeks and ears. A small puncture mark may be seen if internal fetal scalp electrode monitoring was used during labor.

Common skin variations include vernix caseosa, stork bites or salmon patches, milia, Mongolian spots, erythema toxicum, harlequin sign, nevus flammeus, and nevus vasculosus (Fig. 18.12).

**Vernix caseosa** is a thick white substance that protects the skin of the fetus. It is formed by secretions from the fetus's oil glands and is found during the first 2 or 3 days after birth in body creases and the hair. It does not need to be removed because it will be absorbed into the skin.

**Stork bites** or salmon patches are superficial vascular areas found on the nape of the neck, on the eyelids, and between the eyes and upper lip (see Fig. 18.12A). The name comes from the marks on the back of the neck where, as myth goes, a stork may have picked up the baby. They are caused by a concentration of immature blood vessels and are most visible when the newborn is crying. They are considered a normal variant, and most fade and disappear completely within the first year.

**Milia** are unopened sebaceous glands frequently found on a newborn's nose. They may also appear on the chin and forehead (see Fig. 18.12B). They form from oil glands and disappear on their own within 2 to 4 weeks. When they occur in a newborn's mouth and gums, they are termed **Epstein's pearls**. They occur in approximately 60% of newborns (Lewis, 2010).

**Mongolian spots** are blue or purple splotches that appear on the lower back and buttocks of newborns

**FIGURE 18.12** Common skin variations. (A) Stork bite. (B) Milia. (C) Mongolian spots. (D) Erythema toxicum. (E) Nevus flammeus (port-wine stain). (F) Strawberry hemangioma.

(see Fig. 18.12C). They tend to occur in African American, Asian, and Indian newborns but can occur in dark-skinned newborns of all races. The spots are caused by a concentration of pigmented cells and usually disappear within the first 4 years of life (Kliegman et al., 2011).

**Erythema toxicum** (newborn rash) is a benign, idiopathic, generalized, transient rash that occurs in up to 70% of all newborns during the first week of life. It consists of small papules or pustules on the skin resembling flea bites. The rash is common on the face, chest, and back (see Fig. 18.12D). One of the chief characteristics

of this rash is its lack of pattern. It is caused by the newborn's eosinophils reacting to the environment as the immune system matures. Histologically, erythema toxicum shows an abundance of eosinophils. Although it has been recognized and described for centuries, its etiology and pathogenesis remain unclear (Zagne, & Fernandes, 2011). It does not require any treatment and disappears in a few days.

**Harlequin sign** refers to the dilation of blood vessels on only one side of the body, giving the newborn the appearance of wearing a clown suit. It gives a

distinct midline demarcation, which is described as pale on the nondependent side and red on the opposite, dependent side. It results from immature autoregulation of blood flow and is commonly seen in low-birth-weight newborns when there is a positional change (Weber, & Kelley, 2010). It is transient, lasting as long as 20 minutes, and no intervention is needed.

**Nevus flammeus**, also called a port-wine stain, commonly appears on the newborn's face or other body areas (see Fig. 18.12E). It is a capillary angioma located directly below the dermis. It is flat with sharp demarcations and is purple-red. This skin lesion is made up of mature capillaries that are congested and dilated. It ranges in size from a few millimeters to large, occasionally involving as much as half the body surface. Although it does not grow in area or size, it is permanent and will not fade. Port-wine stains may be associated with structural malformations, bony or muscular overgrowth, and certain cancers. Recent studies have noted an association between port-wine birthmarks and childhood cancer, so newborns with these lesions should be monitored with periodic eye examinations, neurologic imaging, and extremity measurements. Lasers and intense pulsed light have been used to remove larger lesions with some success. The optimal timing of treatment is before 1 year of age (Melancon, Dohil, & Eichenfield, 2012).

**Nevus vasculosus**, also called a strawberry mark or strawberry hemangioma, is a benign capillary hemangioma in the dermal and subdermal layers. It is raised, rough, dark red, and sharply demarcated (see Fig. 18.12F). It is commonly found in the head region within a few weeks after birth and can increase in size or number. This type of hemangioma may be very subtle or even absent in the first few weeks of life, but they proliferate in the first few months of life. Commonly seen in premature infants weighing less than 1,500 g (Leonardi-Bee, Batta, O'Brien, & Bath-Hextall, 2011), these hemangiomas tend to resolve by age 3 without any treatment.

## HEAD

Head size varies with age, gender, and ethnicity and has a general correlation with body size. Inspect a newborn's head from all angles. The head should appear symmetric and round. As many as 90% of the congenital malformations present at birth are visible on the head and neck, so careful assessment is very important (Rollins, Collins, & Holden, 2010).

The newborn has two fontanelles at the juncture of the cranial bones. The anterior fontanelle is diamond shaped and closes by 18 to 24 months. Typically it measures 4 to 6 cm at the largest diameter (bone to bone). The posterior one is triangular, smaller than the anterior fontanelle (usually fingertip size or 0.5 to 1 cm), and closes by 6 to 12 weeks. Palpate both fontanelles, which should be soft, flat, and open. Then palpate the skull. It should

feel smooth and fused, except at the area of the fontanelles. Also assess the size of the head and the anterior and posterior fontanelles, and compare them with appropriate standards.

**Variations in Head Size and Appearance.** During inspection and palpation, be alert for common variations that may cause asymmetry. These include molding, caput succedaneum, and cephalhematoma.

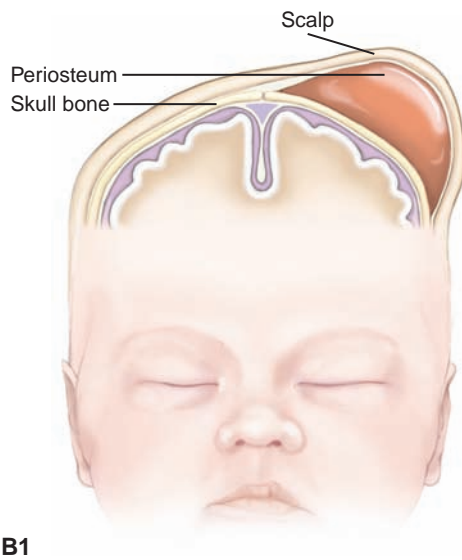

**Molding** is the elongated shaping of the fetal head to accommodate passage through the birth canal (Fig. 18.13). It occurs with a vaginal birth from a vertex position in which elongation of the fetal head occurs with prominence of the occiput and overriding sagittal suture line. It typically resolves within a week after birth without intervention.

**Caput succedaneum** describes localized edema on the scalp that occurs from the pressure of the birth process. It is commonly observed after prolonged labor. Clinically, it appears as a poorly demarcated soft tissue swelling that crosses suture lines. Pitting edema and overlying petechiae and ecchymosis are noted (Fig. 18.14A). The swelling will gradually dissipate in about 3 days without any treatment. Newborns who were delivered via vacuum extraction usually have a caput in the area where the cup was used.

**Cephalhematoma** is a localized effusion of blood beneath the periosteum of the skull. This condition is due to disruption of the vessels during birth. It occurs after prolonged labor and use of obstetric interventions

FIGURE 18.13 Molding in a newborn's head.

**FIGURE 18.14 (A, 1 and 2)** Caput succedaneum involves the collection of serous fluid and often crosses the suture line. **(B, 1 and 2)** Cephalhematoma involves the collection of blood and does not cross the suture line. (Photos from O'Doherty N. *Atlas of the newborn*. Philadelphia, PA: JB Lippincott, 1979:136, and 1979:117, 143, with permission.)

such as low forceps or vacuum extraction. The clinical features include a well-demarcated, often fluctuant swelling with no overlying skin discoloration. The swelling does not cross suture lines and is firmer to the touch than an edematous area (see Fig. 18.14B). Aspiration is not required for resolution and is likely to increase the risk of infection. Hyperbilirubinemia occurs following the breakdown of the RBCs within the hematoma. This type of hyperbilirubinemia occurs later than classic physiologic hyperbilirubinemia. Cephalhematoma usually appears on the second or third day after birth and disappears within weeks or months (Gardner et al., 2011).

**Common Abnormalities in Head or Fontanel Size.** Common abnormalities in head or fontanel size that may indicate a problem include:

- **Microcephaly**—a head circumference more than 2 standard deviations below average or less than 10% of normal parameters for gestational age, caused by failure of brain development. Microcephaly is common, affecting more than 25,000 infants in the United States each year. Children with severe microcephaly, defined as more than 3 standard deviations below the mean for age and sex, are more likely to have imaging abnormalities and more severe developmental impairments than those with milder microcephaly. About 40% of children with microcephaly also have epilepsy, 20% have cerebral palsy, 50% have intellectual disability, and 20% to 50% have ophthalmologic and hearing disorders (Sheth, 2012). It can be familial, with autosomal dominant or recessive inheritance, and it may be associated with infections (cytomegalovirus), rubella, toxoplasmosis, and syndromes such as trisomy 13, 18, or 21 and fetal alcohol syndrome. Genetic counseling and clinical management through carrier detection/prenatal diagnosis in families can help reduce the incidence of these disorders (Mahmood, Ahmad, & Hassan, 2011).
- **Macrocephaly**—a head circumference more than 90% of normal, typically related to hydrocephalus (Zeldin, 2012). It is often familial (with autosomal dominant inheritance) and can be either an isolated anomaly or a manifestation of other anomalies, including hydrocephalus and skeletal disorders (achondroplasia).
- **Large fontanels**—more than 6 cm in the anterior diameter bone to bone or more than a 1-cm diameter in the posterior fontanel; possibly associated with malnutrition, hydrocephaly, congenital hypothyroidism, trisomies 13, 18, and 21, and various bone disorders such as osteogenesis imperfecta.
- **Small or closed fontanels**—smaller-than-normal anterior and posterior diameters or fontanels that are closed at birth. Craniosynostosis and abnormal brain development are associated with a small fontanel or early fontanel closure associated with microcephaly (Sheth, 2012).

## FACE

Observe the newborn's face for fullness and symmetry. The face should have full cheeks and should be symmetric when the baby is resting and crying. If forceps were used during birth, the newborn may have bruising and reddened areas over both cheeks and parietal bones secondary to the pressure of the forceps blades. Reassure the parents that this resolves without treatment, and point out improvement each day.

Problems with the face can also involve facial nerve paralysis caused by trauma from the use of forceps. Paralysis is usually apparent on the first or second day of life. Typically, the newborn will demonstrate asymmetry of the face with an inability to close the eye and move the lips on the affected side. Newborns with facial nerve paralysis have difficulty making a seal around the nipple, and consequently milk or formula drools from the paralyzed side of the mouth. Most facial nerve palsies resolve spontaneously within days, although full recovery may require weeks to months. Attempt to determine the cause from the newborn's history.

**Nose.** Inspect the nose for size, symmetry, position, and lesions. The newborn's nose is small and narrow. The nose should have a midline placement, patent nares, and an intact septum. The nostrils should be of equal size and should be patent. A slight mucous discharge may be present, but there should be no actual drainage. The newborn is a preferential nose breather and will use sneezing to clear the nose if needed. The newborn can smell after the nasal passages are cleared of amniotic fluid and mucus (Jankowski, 2011).

**Mouth.** Inspect the newborn's mouth, lips, and interior structures. The lips should be intact with symmetric movement and positioned in the midline; there should not be any lesions. Inspect the lips for pink color, moisture, and cracking. The lips should encircle the examiner's finger to form a vacuum. Variations involving the lip might include cleft upper lip (separation extending up to the nose) or thin upper lip associated with fetal alcohol syndrome.

Assess the inside of the mouth for alignment of the mandible, intact soft and hard palate, sucking pads inside the cheeks, a midline uvula, a free-moving tongue, and working gag, swallow, and sucking reflexes. The mucous membranes lining the oral cavity should be pink and moist, with minimal saliva present.

Normal variations might include Epstein's pearls (small, white epidermal cysts on the gums and hard palate that disappear in weeks), erupted natal teeth that may need to be removed to prevent aspiration (Fig. 18.15), and thrush (white plaque inside the mouth caused by exposure to *Candida albicans* during birth), which cannot be wiped away with a cotton-tipped applicator.

**FIGURE 18.15** A natal tooth in a 16-day-old neonate. Natal teeth can be present at birth and are usually considered benign. No treatment is needed if they don't interfere with feeding.

**Eyes.** Inspect the external eye structures, including the eyelids, lashes, conjunctiva, sclera, iris, and pupils, for position, color, size, and movement. There may be marked edema of the eyelids and subconjunctival hemorrhages due to pressure during birth. The eyes should be clear and symmetrically placed. Test the blink reflex by bringing an object close to the eye; the newborn should respond quickly by blinking. Also test the newborn's pupillary reflex: pupils should be equal, round, and reactive to light bilaterally. Assess the newborn's gaze: he or she should be able to track objects to the midline. Movement may be uncoordinated during the first few weeks of life. Many newborns have transient strabismus (deviation or wandering of eyes independently) and searching nystagmus (involuntary repetitive eye movement), which is caused by immature muscular control. These are normal for the first 3 to 6 months of age.

Examine the internal eye structures. A red reflex (luminous red appearance seen on the retina) should be seen bilaterally on retinoscopy. The red reflex normally shows no dullness or irregularities.

Chemical conjunctivitis commonly occurs within 24 hours of instillation of eye prophylaxis after birth. There is lid edema with sterile discharge from both eyes. Usually it resolves within 48 hours without treatment.

**Ears.** Inspect the ears for size, shape, skin condition, placement, amount of cartilage, and patency of the auditory canal. The ears should be soft and pliable and should recoil quickly and easily when folded and released. Ears should be aligned with the outer canthi of the eyes. Low-set ears and abnormally shaped ears are characteristic of many syndromes and genetic abnormalities, such as trisomy 13 or 18, and internal organ abnormalities involving the renal system. Findings of sinuses or preauricular skin tags should prompt further evaluation for possible renal abnormalities since both systems develop at the same time.

An otoscopic examination is not typically done because the newborn's ear canals are filled with amniotic fluid and vernix caseosa, which would make visualization of the tympanic membrane difficult.

Newborn hearing screening is required by law in most states (discussed later in the chapter). Hearing loss is the most common birth defect in the United States: One in 1,000 newborns are profoundly deaf and 3 in 1,000 have some degree of hearing impairment (March of Dimes, 2011). Delays in identification and intervention may affect the child's cognitive, verbal, behavioral, and emotional development. Screening at birth has reduced the age at which newborns with hearing loss are identified and has improved early intervention rates dramatically. Available treatments include cochlear implantation, hearing augmentation, and follow-up by an audiologist, otolaryngologist, pediatrician, geneticist, and deaf education specialist (Drake & Gibson, 2010). Prior to universal newborn screening, children were usually older than 2 years before significant congenital hearing loss was detected; by this time it had already affected their speech and language skills (U.S. Preventive Services Task Force [USPSTF], 2009).

Causes of hearing loss can be conductive, sensorineural, or central. Risk factors for congenital hearing loss include cytomegalovirus infection and preterm birth necessitating a stay in the neonatal intensive care unit.

To assess for hearing ability generally, observe the newborn's response to noises and conversations. The newborn typically turns toward these noises and startles with loud ones.

## NECK

Inspect the newborn's neck for movement and ability to support the head. The newborn's neck will appear almost nonexistent because it is so short. Creases are usually noted. The neck should move freely in all directions and should be capable of holding the head in a midline position. The newborn should have enough head control to be able to hold it up briefly without support. Report any deviations such as restricted neck movement or absence of head control.

Also inspect the clavicles, which should be straight and intact. The clavicles are the bones most commonly broken in infants, especially large ones experiencing difficult births. In most cases, the fractured clavicle is asymptomatic, but edema, crepitus, and decreased or absent movement and pain or tenderness on movement of the arm on the affected side may be noted (Lurie, Wand, Golan, & Sadan, 2011). If the newborn with clavicular fracture is in pain, the affected arm should be immobilized, with the arm abducted more than 60 degrees and the elbow flexed more than 90 degrees. In addition to immobilization, treatment involves minimizing pain overall.

## CHEST

Inspect the newborn's chest for size, shape, and symmetry. The newborn's chest should be round, symmetric, and 2 to 3 cm smaller than the head circumference. The xiphoid process may be prominent at birth, but it usually becomes less apparent when adipose tissue accumulates. Nipples may be engorged and may secrete a white discharge. This discharge, which occurs in both boys and girls, is a result of exposure to high levels of maternal estrogen while in utero. This enlargement and milky discharge usually dissipates within a few weeks. Some newborns may have extra nipples, called supernumerary nipples. They are typically small, raised, pigmented areas vertical to the main nipple line, 5 to 6 cm below the normal nipple. Supernumerary nipples may be unilateral or bilateral, and they may include an areola, nipple, or both. They tend to be familial and do not contain glandular tissue. Supernumerary nipples are generally thought to be benign. Some studies have suggested an association with renal or urogenital anomalies, whereas other studies have failed to show this association. There is insufficient evidence to recommend imaging studies or removal in the absence of other clinical concerns or physical findings (Metzker, 2012). Reassure parents that these extra small nipples are harmless.

The newborn chest is usually barrel shaped, with equal anteroposterior and lateral diameters, and symmetric. Auscultate the lungs bilaterally for equal breath sounds. Normal breath sounds should be heard, with little difference between inspiration and expiration. Fine crackles can be heard on inspiration soon after birth as a result of amniotic fluid being cleared from the lungs. Diminished breath sounds might indicate atelectasis or pneumonia (Jarvis, 2012).

Listen to the heart when the newborn is quiet or sleeping. S1 and S2 heart sounds are accentuated at birth. The point of maximal impulse (PMI) is a lateral to midclavicular line located at the fourth intercostal space. A displaced PMI may indicate tension pneumothorax or cardiomegaly. Murmurs are often heard and are usually benign, but if present after the first 12 hours of life should be evaluated to rule out a cardiac disorder (Kliegman et al., 2011).

## ABDOMEN

Inspect the abdomen for shape and movement. Typically the newborn's abdomen is protuberant but not distended. This contour is a result of the immaturity of the abdominal muscles. Abdominal movements are synchronous with respirations because newborns are, at times, abdominal breathers.

Auscultate bowel sounds in all four quadrants and then palpate the abdomen for consistency, masses, and tenderness. Perform auscultation and palpation systematically in a clockwise fashion until all four quadrants have been assessed. Palpate gently to feel the liver, the kidneys, and any masses. The liver is normally palpable

1 to 3 cm below the costal margin in the midclavicular line. The kidneys are 1 to 2 cm above and to both sides of the umbilicus. Normal findings would include bowel sounds in all four quadrants and no masses or tenderness on palpation. Absent or hyperactive bowel sounds might indicate an intestinal obstruction. Abdominal distention might indicate ascites, obstruction, infection, masses, or an enlarged abdominal organ. The newborn may also show signs of abdominal tenderness (Springer, & Glasser, 2012). Imaging is a mainstay to diagnosis abdominal pathology and should be readily performed in a newborn with abdominal distention to determine the underlying etiology.

Inspect the umbilical cord area for the correct amount of blood vessels (two arteries and one vein). The umbilical vein is larger than the two umbilical arteries. Evidence of only a single umbilical artery is associated with renal and gastrointestinal anomalies. Also inspect the umbilical area for signs of bleeding, infection, granuloma, or abnormal communication with the intra-abdominal organs. Umbilical infections can occur because of an embryologic remnant or poor hygiene. Traditionally, gram-positive organisms, such as *Staphylococcus aureus* and *Streptococcus pyogenes*, were most commonly identified, but gram-negative and polymicrobial infections are seen today (Minkes, & Megison, 2012).

## GENITALIA

Inspect the penis and scrotum in the male. In the circumcised male newborn, the glans should be smooth, with the meatus centered at the tip of the penis. It will appear reddened until it heals. For the uncircumcised male, the foreskin should cover the glans. Check the position of the urinary meatus: it should be in the midline at the glans tip. If it is on the ventral surface of the penis, the condition is termed hypospadias; if it is on the dorsal surface of the penis, it is termed epispadias. In either case, circumcision should be avoided until further evaluation.

Inspect the scrotum for size, symmetry, color, presence of rugae, and location of testes. The scrotum usually appears relatively large with well formed rugae and that should cover the scrotal sac. There should not be bulging, edema, or discoloration (Fig. 18.16A).

Palpate the scrotum for evidence of the testes, which should be in the scrotal sac. The testes should feel firm and smooth and should be of equal size on both sides of the scrotal sac in the term newborn. Undescended testes (cryptorchidism) might be palpated in the inguinal canal in preterm infants; they can be unilateral or bilateral. If the testes are not palpable within the scrotal sac, further investigation is needed.

In the female newborn, inspect the external genitalia. The urethral meatus is located below the clitoris in the midline (Sawyer, 2011). In contrast to the male genitalia, the female genitalia will be engorged: the labia

**FIGURE 18.16** Newborn genitalia. **(A)** Male genitalia. Note the darkened color of the scrotum. **(B)** Female genitalia.

majora and minora may both be edematous. The labia majora is large and covers the labia minora. The clitoris is large and the hymen is thick. These findings are due to the maternal hormones estrogen and progesterone (see Fig. 18.16B). A vaginal discharge composed of mucus mixed with blood may also be present during the first few weeks of life. This discharge, called **pseudomenstruation**, requires no treatment. Explain this phenomenon to the parents.

Variations in female newborns may include a labial bulge, which might indicate an inguinal hernia, ambiguous genitalia, a rectovaginal fistula with feces present in the vagina, and an imperforate hymen.

Inspect the anus in both male and female newborns for position and patency. Passage of meconium indicates patency. If meconium is not passed, a lubricated rectal thermometer can be inserted or a digital examination can be performed to determine patency. Abnormal findings would include anal fissures or fistulas and no meconium passed within 24 hours after birth.

### EXTREMITIES AND BACK

Inspect the newborn's upper extremities for appearance and movement. Inspect the hands for shape, number,

and position of fingers and presence of palmar creases. The newborn's arms and hands should be symmetric and should move through range of motion without hesitation. Observe for spontaneous movement of the extremities. Each hand should have five digits. Note any extra digits (polydactyly) or fusing of two or more digits (syndactyly). Most newborns have three palmar creases on the hand. A single palmar crease, called a simian line, is frequently associated with Down syndrome.

A brachial plexus injury can occur during a difficult birth involving shoulder dystocia. Erb's palsy is an injury resulting from damage to the upper plexus, and palsies associated with the lower brachial plexus are termed Klumpke palsies. Factors associated with obstetric brachial plexus paralysis include large birth weight, breech delivery, and shoulder dystocia. Obstetric brachial plexus paralysis results from excessive lateral traction on the head away from the shoulder. This force on the brachial plexus can cause varying degrees of injury to the nerves. The affected arm hangs limp alongside the body, and the affected shoulder and arm are adducted, extended, and internally rotated with a pronated wrist. The Moro reflex is absent on the affected side in brachial palsy. Complete recovery may take 6 months or longer. Current research studies support endogenous labor forces as the etiology of this injury. Despite training in the management of shoulder dystocia and a rising institutional cesarean section rate, the incidence of brachial plexus injuries has remained unchanged compared with 10 years earlier (Walsh et al., 2011).

Assess the lower extremities in the same manner. They should be of equal length, with symmetric skinfolds. Inspect the feet for clubfoot (a turning-inward position), which is secondary to intrauterine positioning. This may be positional or structural. Perform the Ortolani and Barlow maneuvers to identify congenital hip dislocation, commonly termed developmental dysplasia of the hip (DDH). Nursing Procedure 18.1 highlights the steps for performing these maneuvers.

Inspect the back. The spine should appear straight and flat and should be easily flexed when the baby is held in a prone position. Observe for the presence of a tuft of hair, a pilonidal dimple in the midline, a cyst, or a mass along the spine. These abnormal findings should be documented and reported to the primary health care provider.

Table 18.3 summarizes the newborn assessment.

### NEUROLOGIC STATUS

Assess the newborn's state of alertness, posture, muscle tone, and reflexes.

**Newborn Alertness, Posture, and Muscle Tone.** The newborn should be alert and not persistently lethargic. The normal posture is hips abducted and partially flexed, with knees flexed. Arms are adducted and flexed at the

## NURSING PROCEDURE 18.1

## PERFORMING ORTOLANI AND BARLOW MANEUVERS

**Purpose: To Detect Congenital Developmental Dysplasia of the Hip****Ortolani Maneuver**

1. Place the newborn in the supine position and flex the hips and knees to 90 degrees at the hip.
2. Grasp the inner aspect of the thighs and abduct the hips (usually to approximately 180 degrees) while applying upward pressure.

3. Listen for any sounds during the maneuver. There should be no “cluck” or “click” heard when the legs are abducted. Such a sound indicates the femoral head hitting the acetabulum as the head reenters the area. This suggests developmental hip dysplasia.

Adapted from McCarthy, J. J. (2011). Developmental dysplasia of the hip. eMedicine. Retrieved from <http://emedicine.medscape.com/article/1248135-overview>; and Jarvis, C. (2012) Physical examination & health assessment. (6th ed.0, St. Louis, MO: Saunders Elsevier.

**Barlow Maneuver**

1. With the newborn still lying supine and grasping the inner aspect of the thighs (as just mentioned), adduct the thighs while applying outward and downward pressure to the thighs.

2. Feel for the femoral head slipping out of the acetabulum; also listen for a click.

elbow. Fists are often clenched, with fingers covering the thumb.

To assess for muscle tone, support the newborn with one hand under the chest. Observe how the neck muscles hold the head. The neck extensors should be able to hold the head in line briefly. There should be only slight head lag when pulling the newborn from a supine position to a sitting one.

**Newborn Reflexes.** Assess the newborn's reflexes to evaluate neurologic function and development. Absent or abnormal reflexes in a newborn, persistence of a reflex past the age when the reflex is normally lost, or return of an infantile reflex in an older child or adult may indicate neurologic pathology (Table 18.4). Reflexes commonly assessed in the newborn include sucking, Moro, stepping, tonic neck, rooting, Babinski, palmar grasp and plantar grasp reflexes. Spinal reflexes

tested include truncal incurvation (Galant reflex) and anocutaneous reflex (anal wink).

The sucking reflex is elicited by gently stimulating the newborn's lips by touching them. The newborn will typically open the mouth and begin a sucking motion. Placing a gloved finger in the newborn's mouth will also elicit a sucking motion (Fig. 18.17A).

The Moro reflex, also called the embrace reflex, occurs when the neonate is startled. To elicit this reflex, place the newborn on his or her back. Support the upper body weight of the supine newborn by the arms, using a lifting motion, without lifting the newborn off the surface. Then release the arms suddenly. The newborn will throw the arms outward and flex the knees; the arms then return to the chest. The fingers also spread to form a C. The newborn initially appears startled and then relaxes to a normal resting position (see Fig. 18.17B).

**TABLE 18.3** NEWBORN ASSESSMENT SUMMARY

Assessment	Usual Findings	Variations and Common Problems
Anthropometric measurements	Head circumference: 33–37 cm (13–14 in.) Chest circumference: 30–33 cm (12–13 in.) Weight: 2,500–4,000 g (5.5–8.5 lb) Length: 45–55 cm (19–21 in.)	SGA, LGA, preterm, post-term
Vital signs	Temperature: 97–99° F (36.5–37.5° C) Apical pulse: 110–160 bpm Respirations: 30–60 breaths/minute	
Skin	Normal: smooth, flexible, good skin turgor, warm	Jaundice, acrocyanosis, milia, Mongolian spots, stork bites
Head	Normal: varies with age, gender, ethnicity	Microcephaly, macrocephaly, enlarged fontanels
Face	Normal: full cheeks, facial features symmetric	Facial nerve paralysis, nevus flammeus, nevus vasculosus
Nose	Normal: small, placement in the midline and narrow, ability to smell	Malformation or blockage
Mouth	Normal: aligned in midline, symmetric, intact soft and hard palate	Epstein's pearls, erupted precocious teeth, thrush
Neck	Normal: short, creased, moves freely, baby holds head in midline	Restricted movement, clavicular fractures
Eyes	Normal: clear and symmetrically placed on face	Chemical conjunctivitis, subconjunctival hemorrhages
Ears	Normal: soft and pliable with quick recoil when folded and released	Low-set ears, hearing loss
Chest	Normal: round, symmetric, smaller than head	Nipple engorgement, whitish discharge
Abdomen	Normal: protuberant contour, soft, three vessels in umbilical cord	Distended, only two vessels in umbilical cord
Genitals	Normal male: smooth glans, meatus centered at tip of penis Normal female: swollen female genitals as a result of maternal estrogen	Edematous scrotum in males, vaginal discharge in females
Extremities and spine	Normal: extremities symmetric with free movement	Congenital hip dislocation; tuft or dimple on spine

Adapted from Baston, H., & Durward, H. (2010). *Examination of the newborn: A practical approach* (2nd ed.). Philadelphia, PA: Routledge Taylor & Francis Group; and Jarvis, C. (2012). *Physical examination & health assessment*. (6th ed.). St. Louis, MO: Saunders Elsevier.

Assess the stepping reflex by holding the newborn upright and inclined forward with the soles of the feet touching a flat surface. The baby should make a stepping motion or walking, alternating flexion and extension with the soles of the feet (see Fig. 18.17C).

The tonic neck reflex resembles the stance of a fencer and is often called the fencing reflex. Test this

reflex by having the newborn lie on the back. Turn the baby's head to one side. The arm toward which the baby is facing should extend straight away from the body with the hand partially open, whereas the arm on the side away from the face is flexed and the fist is clenched tightly. Reversing the direction to which the face is turned reverses the position (see Fig. 18.17D).

**TABLE 18.4** NEWBORN REFLEXES: APPEARANCE AND DISAPPEARANCE

Reflex	Appearance	Disappearance
Blinking	Newborn	Persists into adulthood
Moro	Newborn	3–6 mo
Grasp	Newborn	3–4 mo
Stepping	Birth	1–2 mo
Tonic neck	Newborn	3–4 mo
Sneeze	Newborn	Persists into adulthood
Rooting	Birth	4–6 mo
Gag reflex	Newborn	Persists into adulthood
Cough reflex	Newborn	Persists into adulthood
Babinski sign	Newborn	12 mo

Elicit the rooting reflex by stroking the newborn's cheek. The newborn should turn toward the side that was stroked and should begin to make sucking movements (see Fig. 18.17E).

The Babinski reflex should be present at birth and disappears at approximately 1 year of age. It is elicited by stroking the lateral sole of the newborn's foot from the heel toward and across the ball of the foot. The toes

should fan out. A diminished response indicates a neurologic problem and needs follow-up (see Fig. 18.17F).

The newborn exhibits two grasp reflexes: palmar grasp and plantar grasp. Elicit the palmar grasp reflex by placing a finger on the newborn's open palm. The baby's hand will close around the finger. Attempting to remove the finger causes the grip to tighten. Newborns have strong grasps and can almost be lifted from a flat surface if both hands are used. The grasp should be equal bilaterally (see Fig. 18.17G). The plantar grasp is similar to the palmar grasp. Place a finger just below the newborn's toes. The toes typically curl over the finger (see Fig. 18.17H).

Blinking, sneezing, gagging, and coughing are all protective reflexes and are elicited when an object or light is brought close to the eye (blinking), something irritating is swallowed or a bulb syringe is used for suctioning (gagging and coughing), or an irritant is brought close to the nose (sneezing).

The truncal incurvation reflex (Galant reflex) is present at birth and disappears in a few days to 4 weeks (Fig. 18.18). With the newborn in a prone position or held in ventral suspension, apply firm pressure and run a finger down either side of the spine. This stroking will cause the pelvis to flex toward the stimulated side. This indicates T2–S1 innervation. Lack of response indicates a neurologic or spinal cord problem.

The anocutaneous reflex (anal wink) is elicited by stimulating the perianal skin close to the anus. The external sphincter will constrict (wink) immediately with stimulation. This indicates S4–S5 innervations (Sawyer, 2011).

## Nursing Interventions

Developing confidence in caring for their newborn is challenging for most couples. It takes time and patience and a great deal of instruction provided by the nurse. “Showing and telling” parents about their newborn and all the procedures (e.g., feeding, bathing, changing, handling) involved in daily care are key nursing interventions.

### Providing General Newborn Care

Generally, newborn care involves bathing and hygiene, elimination and diaper area care, cord care, circumcision care, environmental safety measures, and prevention of infection. Nurses should teach these skills to parents and should serve as role models for appropriate and consistent interaction with newborns. Demonstrating respect for the newborn and family helps foster a positive atmosphere to promote the newborn’s growth and development.

## BATHING AND HYGIENE

Immediately after birth, drying the newborn and removing blood may minimize the risk of infection caused by hepatitis B, herpesvirus, and HIV, but the specific benefits of this practice remain unclear. Until the newborn has been thoroughly bathed, standard precautions should be used when handling the newborn.

Newborns are bathed primarily for aesthetic reasons, and bathing is postponed until thermal and cardiorespiratory stability is ensured. Traditional reasons why nurses bathe the newborn are so they can conduct a physical assessment, reduce the effect of hypothermia, and allow the mother to rest (Blume-Peytavi, Hauser, & Stamatas et al., 2012). However, recent research suggests that nurses do not need to give the newborn an initial bath to reduce heat loss; rather, the parents could be given this opportunity, supported by nurses. A study found that the amount of heat loss was similar in newborns bathed by parents versus newborns who were bathed by nurses (Blume-Peytavi, Hauser, & Stamatas et al., 2012).

Nursing Procedure 18.2 explains the steps for bathing the newborn. It is important for the nurse to wear gloves, because of potential exposure to maternal blood on the newborn, and perform the bath quickly, drying the baby thoroughly to prevent heat loss by evaporation.

After bathing, place the newborn under the radiant warmer and wrap him or her securely in blankets to prevent chilling. Check the baby’s temperature within an hour to make sure it is within normal limits. If it is low, place the newborn under a radiant heat source again.

After the initial bath, the newborn may not receive another full one during the stay in the birthing unit. The diaper area will be cleansed at each diaper change, and any milk spilled will be cleaned. Clear water and a mild soap are appropriate to cleanse the diaper area. The use of lotions, baby oil, and powders is not encouraged

## Bathing the Newborn

*It is important that the nurse wear gloves, because of potential exposure to maternal blood on the newborn, and perform the bath quickly, drying the baby thoroughly to prevent heat loss by evaporation. Keep the newborn covered to prevent heat loss during the bathing procedure.*

1. Begin the newborn bath starting from the cleanest area (the eyes) and proceeding to the most soiled area (the diaper area) to prevent cross-contamination. Use plain warm water on the face and eyes, adding a mild soap (e.g., Dove) to cleanse the remainder of the body. Wash, rinse, and dry each area before proceeding to the next one.

2. Wash the hair using running water so that the scalp can be thoroughly rinsed. A mild shampoo or soap can be used. Wash both fontanel areas. Frequently parents avoid these “soft spots” because they fear that they will “hurt the baby’s brain” if they rub too hard. Reassure parents that there is a strong membrane providing protection. Urge the parents to clean and rinse these areas well. If the anterior fontanel is not rinsed well after shampooing, cradle cap (dry flakes on the scalp) can develop.

3. Make sure to cleanse all body creases, especially the neck folds to remove any milk that may have dripped into these areas.

4. Continue downward washing the trunk and extremities ending up with the diaper area last.

because oils and lotions can lead to skin irritation and can cause rashes. Powders should not be used because they can be inhaled, causing respiratory distress. If the parents want to use oils and lotions, have them apply a small amount onto their hand first, away from the newborn; this warms the lotion. Then the parents should apply the lotion or oil sparingly.

Instruct parents that a bath two or three times weekly is sufficient for the first year; more frequent bathing may dry the skin. Parents should not fully immerse the newborn into water until the umbilical cord area is healed—up to 2 weeks after birth. Encourage parents to give the infant a sponge bath until the umbilical cord falls off and the navel area is healed completely. If the newborn has been circumcised, advise parents to wait until that area has also healed (usually 1 to 2 weeks). Until then, clean the penis with mild soap and water and apply a small amount of petroleum jelly to the tip to prevent the diaper from adhering to the penis. Instruct parents to apply the diaper loosely and place the newly circumcised male infant on his side or back to prevent pressure and irritation on the penis.

Encourage the parents to gather all items needed before starting the bath: a soft, clean washcloth; two cotton balls to clean the eyes; mild, unscented soap and shampoo; towels or blankets; a tub or basin with warm water; a clean diaper; and a change of clothes. Other guidelines for bathing newborns are given in Teaching Guidelines 18.1.

### ELIMINATION AND DIAPER AREA CARE

Newborn elimination patterns are highly individualized. Usually the urine is light amber in color. Soaking 6 to 12 diapers a day indicates adequate hydration. Stools can change in color, texture, and frequency without signaling a problem. Meconium is passed for the first 48 hours after birth; the stools appear thick, tarry, sticky, and dark green. Transitional stools (thin, brown to green, less sticky than meconium) typically appear by day 3 after initiation of feeding. The stool characteristics after transitional stool depend on whether the newborn is breast-fed or bottle-fed. Breast-fed newborns typically pass mustard-colored, soft stool with a seedy consistency; formula-fed newborns pass yellow to brown, formed stool with a pasty consistency. As long as the newborn seems content, is eating normally, and shows no signs of illness, minor changes in bowel movements should not be a concern.

The newborn needs to be checked frequently to see whether a diaper change is needed, especially after feeding. Adhere to standard precautions when providing diaper area care. Instruct parents to keep the top edge of the diaper below the umbilical cord area to prevent irritation and to allow air to help dry the cord.

Meconium can be difficult to remove from the skin. Use plain water or special cleansing wipes if necessary

## Teaching Guidelines 18.1 BATHING A NEWBORN

- Select a warm room with a flat surface at a comfortable working height.
- Before the bath, gather all supplies needed so they will be within reach.
- Never leave the newborn alone or unattended at any time during the bath.
- Undress the newborn down to shirt and diaper.
- Always support the newborn's head and neck when moving or positioning him or her.
- Place a blanket or towel underneath the newborn for warmth and comfort.
- In this order, progressing from the cleanest to the dirtiest areas:
  - Wipe eyes with plain water, using either cotton balls or a washcloth. Wipe from the inner corner of the eyes to the outer with separate wipes.
  - Wash the rest of the face, including ears, with plain water.
  - Using baby shampoo, gently wash the hair and rinse with water.
  - Pay special attention to body creases, and dry thoroughly.
  - Wash extremities, trunk, and back. Wash, rinse, dry, cover.
  - Wash diaper area last, using soap and water, and dry; observe for rash.
- Put on a clean diaper and clean clothes after the bath.

to clean the area. Teach parents how to clean the diaper area properly and how to prevent skin irritation. Encourage them to avoid products such as powder and fragranced items, which could irritate the newborn's skin.

Discuss the pros and cons of using cloth diapers versus disposable diapers so that the parents can make informed decisions. Regardless of the type of diapers used, up to 10 diapers a day, or about 70 a week, will be needed.

Additional information about diapering might include:

- Before diapering, make sure all supplies are within reach, including clean diaper, cleaning agent or wipes, and ointment.
- Lay the newborn on a changing table and remove the dirty diaper.
- Use water and mild soap or wipes to gently wipe the genital area clean; wipe from front to back for girls to avoid urinary tract infections.
- Wash your hands thoroughly before and after changing diapers.

While performing diaper area care, parents should observe the area closely for irritation or rash. Tips for preventing or healing a diaper rash include:

- Change diapers frequently, especially after bowel movements.
- Apply a “barrier” cream, such as A&D ointment, after cleaning with mild soap and water.
- Use dye- and fragrance-free detergents to wash cloth diapers.
- Avoid the use of plastic pants, because they tend to hold in moisture.
- Expose the newborn’s bottom to air several times a day.
- Place the newborn’s buttocks in warm water after he or she has had a diaper on all night.

### Take Note!

Advise parents that a rash that persists for more than 3 days may be fungal in origin and may require additional treatment. Encourage the parents to notify the health care provider.

## CORD CARE

The umbilical cord begins drying within hours after birth and is shriveled and blackened by the second or third day. Within 7 to 10 days, it sloughs off and the umbilicus heals. During this transition, frequent assessments of the area are necessary to detect any bleeding or signs of infection. Cord bleeding is abnormal and may occur if the cord clamp is loosened. Any cord drainage is also abnormal and is generally caused by infection, which requires immediate treatment.

To protect the cord area during each diaper change, apply the appropriate agent (e.g., triple dye, alcohol, or an antimicrobial agent), according to facility policy, to the cord stump to prevent any ascending infections. Single-use agents for cleaning are recommended to prevent cross-contamination with other newborns. Expect to remove the cord clamp approximately 24 hours after birth by using a cord-cutting clamp. However, if the cord is still moist, keep the clamp in place and ensure a referral to home health care so that the home care nurse can remove it after discharge. Always adhere to agency policies regarding cord care; changes in policy may be necessary based on new research findings.

Many parents avoid contact with the cord site to make sure they don’t “bother” it. Teach them how to care for the cord site when they go home to prevent complications (Teaching Guidelines 18.2).

## CIRCUMCISION CARE

**Circumcision** is the surgical removal of all or part of the foreskin (prepuce) of the penis (Tobian, & Gray, 2011). This has been traditionally done for hygiene and medical reasons and is the oldest known religious rite. In the Jewish faith, circumcision is a ritual that is

## Teaching Guidelines 18.2

### UMBILICAL CORD CARE

- Observe for bleeding, redness, drainage, or foul odor from the cord stump and report it to your newborn’s primary care provider immediately.
- Avoid tub baths until the cord has fallen off and the area has healed.
- Expose the cord stump to the air as much as possible throughout the day.
- Fold diapers below the level of the cord to prevent contamination of the site and to promote air-drying of the cord.
- Observe the cord stump, which will change color from yellow to brown to black. This is normal.
- Never pull the cord or attempt to loosen it; it will fall off naturally.

performed by a *mohel* (ordained circumciser) on the eighth day after birth if possible. The circumcision is followed by a religious ceremony during which the newborn is named.

There are three commonly used methods of circumcision: the Gomco clamp, the Plastibell device, and the Mogen clamp. During the circumcision procedure, part of the foreskin is removed by clamping and cutting with a scalpel (Gomco or Mogen clamp) or by using a Plastibell. The Plastibell is fitted over the glans, and the excess foreskin is pulled over the plastic ring. A suture is tied around the rim to apply pressure to the blood vessels, creating hemostasis. The excess foreskin is cut away. The plastic rim remains in place until healing occurs. The plastic ring typically loosens and falls off in approximately 1 week (Angel, & Maddox, 2012) (Fig. 18.19).

The debate over routine newborn circumcision continues in the United States. For many years, the purported benefits and harms of circumcision have been debated in the medical literature and society at large, with no clear consensus to date. Despite the controversy, circumcision is the most common surgical procedure performed on newborns, and almost two thirds (61%) of American male newborns are circumcised (CDC, 2011b).

A policy statement by the AAP indicates that newborn circumcision has potential disadvantages and risks as well as medical benefits and advantages. Risks to the newborn include infection, hemorrhage, skin dehiscence, adhesions, urethral fistula, and pain. Benefits to the newborn include the following:

- Urinary tract infections are slightly less common in circumcised boys. However, rates are low in both circumcised and uncircumcised boys and are easily treated without long-term sequelae.

**FIGURE 18.19** Circumcision. (A) Before the procedure. (B) Clamp applied and foreskin removed. (C) Appearance after circumcision.

- Sexually transmitted infections are less common in circumcised males, but the risk is believed to be related more to behavioral factors than to circumcision status. However, circumcised males have a 50% lower risk of acquiring HIV infection (Angel, & Maddox, 2012).
- There appears to be a slightly lower rate of penile cancer in circumcised males. However, penile cancer is rare and risk factors such as genital warts, infection with human papillomavirus, multiple sex partners, and cigarette smoking seem to play a much larger role in causing penile cancer than circumcision status (Kliegman et al., 2011).

The new AAP recommendations state that if parents decide to circumcise their newborn, pain relief must be provided. Research has found that newborns circumcised without analgesia experience pain and stress, indicated by changes in heart rate, blood pressure, oxygen saturation, and cortisol levels (Shockley, & Rickett, 2011). Analgesic methods may include EMLA cream (a topical mixture of local anesthetics), a dorsal penile nerve block with buffered lidocaine, acetaminophen, a sucrose pacifier, and swaddling (Cunningham et al., 2010).

The AAP (AAP, 2012). recommends that parents be given accurate and unbiased information about the risks and benefits of circumcision. As with other newborn procedures, research continues. Nurses must keep informed about current medical research to allow parents to make informed decisions. The absence of compelling medical evidence in favor of or against newborn circumcision makes informed consent of parents of paramount importance. The circumcision discussion involves cultural, religious, medical, and emotional considerations. Nurses may have difficulty remaining unbiased and unemotional as they present the facts to parents. Circumcision is a very personal decision for parents, and the nurse's major responsibility is to inform the parents of the risks and benefits of the procedure and to address concerns so that the parents can reach a fully informed decision.

### Take Note!

The decision to circumcise the male newborn is often a social one, with the strongest factor being whether the newborn's father is himself circumcised (Ahmed, & Ellsworth, 2012).

Immediately after circumcision, the tip of the penis is usually covered with petroleum jelly–coated gauze to keep the wound from sticking to the diaper. Continued care of this site includes:

- Assess for bleeding every 30 minutes for at least 2 hours.
- Document the first voiding to evaluate for urinary obstruction or edema.
- Squeeze soapy water over the area daily and then rinse with warm water. Pat dry.
- Apply a small amount of petroleum jelly with every diaper change if the Plastibell was used; clean with mild soap and water if other techniques were used.
- Fasten the diaper loosely over the penis and avoiding placing the newborn on his abdomen to prevent friction.

If a Plastibell has been used, it will fall off by itself in about a week. Inform parents of this and advise them not to pull it off sooner. Also instruct the parents to check daily for any foul-smelling drainage, bleeding, or unusual swelling.

If the newborn is uncircumcised, wash the penis with mild soap and water after each diaper change and do not force the foreskin back; it will retract normally over time.

### SAFETY

Newborns are completely dependent on those around them to ensure their safety. Their safety must be ensured while in the health care facility and after they are discharged. Parental education is key, especially as the newborn grows and develops and begins to respond to and explore his or her surroundings (Teaching Guidelines 18.3).

### Teaching Guidelines 18.3

#### GENERAL NEWBORN SAFETY

- Have emergency telephone numbers readily available, such as those for emergency medical assistance and the poison control center.
- Keep small or sharp objects out of reach to prevent them from being aspirated.
- Put safety plugs in wall sockets within the child's reach to prevent electrocution.
- Do not leave the infant alone in any room without a portable intercom on.
- Always supervise the newborn in the tub: a newborn can drown in 2 inches of water.
- Make sure the crib or changing table is sturdy, without any loose hardware, and is painted with lead-free paint.
- Avoid placing the crib or changing table near blinds or curtain cords.
- Provide a smoke-free environment for all infants.
- Place all infants on their backs to sleep to prevent sudden infant death syndrome.
- To prevent falls, do not leave the newborn alone on any elevated surface.
- Use sun shields on strollers and hats to avoid overexposing the newborn to the sun.
- To prevent infection, thoroughly wash your hands before preparing formula.
- Thoroughly investigate any infant care facility before using it.

Adapted from American Academy of Pediatrics. (2010c). *Bright futures guidelines for health supervision of infants, children, and adolescents*. Washington, DC: Author.

**Environmental Safety.** People who enter a health care facility for treatment expect to be safe there until they return home, but ensuring a safe environment can be a daunting challenge to a health care facility.

Consider this scenario: A woman dressed in nurse's clothing entered the hospital room of a new mother soon after she had given birth. This "nurse" told the mother she needed to take her newborn to the nursery to have him weighed. Sometime later, a staff nurse making her routine rounds realized something was wrong when she saw that the newborn's bassinet in the mother's room was empty and the mother was sound asleep in her bed. The staff nurse called security immediately because she suspected that a newborn abduction had taken place.

This is a typical abduction scenario that is repeated many times throughout the United States each year. In **infant abduction**, someone who is not a family member takes a child less than 1 year old (NCMEC, 2011). Infant abductions are traumatic for the parents, the community, and the health care facility. The facility may also

face huge financial liability if a lawsuit is filed by the parents.

Abductions typically occur during the day and are usually carried out by women who are not criminally sophisticated. Many of these women experienced a pregnancy loss in the past; they are often emotionally immature and compulsive, with low self-esteem. Most female abductors can play the role of a hospital employee convincingly. Infants usually are abducted when taken for testing, during return to the nursery, when left unattended in the nursery, or while a mother was napping or showering (Joint Commission, 2010).

Health care agencies are challenged to prevent infant abduction by instituting sound security practices and systems (Joint Commission, 2010). Such measures include the following:

- All newborns must be transported in cribs and not carried.
- Nurses must respond immediately to any security alarm that sounds on the unit.
- Newborns must never be unattended at any time, especially in hallways.
- All staff must wear appropriate identification at all times.
- Encourage mothers to keep their baby/bassinet on their far side, away from the door.
- Personnel should be wary of visitors who do not seem to be visiting a specific mother.
- The electronic security system should be checked to make sure it works.
- Footprint the newborn, take a color photograph, and record the newborn's physical examination within 2 hours of birth.
- Discontinue publication of birth notices in local newspapers.
- Develop and implement a proactive infant abduction prevention plan.
- Ensure the proper functioning and placement of any electronic sensors used on newborns.
- Parents should be taught what infant abduction is; why infant security is important; the schedule of nursery, feeding, and visiting hours; rules about visitor access; the facility's security policies and procedures; what parents can do to protect their infant in the hospital; which staff members are allowed to handle the newborn; and what a proper ID looks like.

Educating staff, educating mothers, and access control are the three key steps to preventing abductions from any health care facility. Providing a safe and secure environment is a shared responsibility of the facility, staff, and parents. Preventing abductions requires everyone to learn and follow the rules and policies.

**Car Safety.** Every state requires the use of car seats for infants and children, because motor vehicle accidents

are still the leading cause of unintentional injury and death in children under age 5. National Highway Traffic Safety Administration statistics show that nearly one half of deaths and injuries in infants occurred because they were not properly restrained. Child safety seats, when installed and used properly, can prevent injuries and save lives (AAP, 2011a).

Despite evidence that the use of car seats can reduce the morbidity and mortality of motor vehicle crashes, parents who lack knowledge about them may underuse or misuse them (Warren, & Phillippi, 2012). Make sure that both parents understand the importance of safely transporting their newborn in a federally approved safety car seat every time the infant rides in a car. Do not release any newborn unless the parents have a car seat in place for their newborn's ride home (Fig. 18.20). If they cannot afford one, many community organizations will provide one for them. According to the AAP's policy statement on child passenger safety issued in 2011, no one car seat is considered to be the "safest" or the "best," but rather consistent and proper use is the key to preventing injuries and deaths. Instruct parents in the following:

- Select a car seat that is appropriate for the child's size and weight.
- Caution caregivers against the placement of car seats on elevated or soft surfaces outside the car to prevent falling.
- Use the car seat correctly, every time the child is in the car.
- Use rear-facing car safety seats for most infants up to 2 years of age.
- Make sure the harness (most seats have a three- to five-point harness) is in the slots at or below the shoulders.

## INFECTION PREVENTION

The nurse plays a major role in preventing infection in the newborn environment. Ways to control infection are as follows:

FIGURE 18.20 Newborn in a properly secured car seat.

- Minimize exposure of newborns to organisms.
- Wash your hands before and after providing care, and insist that all personnel wash their hands before handling any newborn.
- Do not allow ill staff or visitors to visit or handle newborns.
- Monitor the umbilical cord stump and circumcision site for signs of infection.
- Provide eye prophylaxis by instilling prescribed medication soon after birth.
- Educate parents about appropriate home measures that will prevent infections, such as practicing good handwashing before and after diaper changes, keeping the newborn well hydrated, avoiding taking the infant into crowds (which may expose him or her to colds and flu viruses), observing for early signs of infection (fever, vomiting, loss of appetite, lethargy, labored breathing, green watery stools, drainage from umbilical cord site or eyes), and keeping pediatrician appointments for routine immunizations.

## Promoting Sleep

Although many parents feel their newborns need them every minute of the day, babies actually need to sleep much of the day initially. Usually newborns sleep up to 15 hours daily. They sleep for 2 to 4 hours at a time but do not sleep through the night because their stomach capacity is too small to go long periods without nourishment.

### Take Note!

All newborns develop their own sleep patterns and cycles, but it may take several months before the newborn sleeps through the night.

Parents should place the newborn on his or her back to sleep. To prevent suffocation, all fluffy bedding, quilts, sheepskins, stuffed animals, and pillows should be removed from the crib.

Parents should be informed that the practice of "co-sleeping" (sharing a bed) is not safe. For example, infants who sleep in adult beds are up to 40 times more likely to suffocate than those who sleep in cribs (AAP, 2011b). Suffocation can occur when the infant gets entangled in bedding or caught under pillows, or slips between the bed and the wall or the headboard and mattress. The parent may accidentally roll against or on top of the baby. The safest place for a newborn to sleep is in a crib, without any movable objects close by. Benefits vs. risks of co-bedding, bed sharing, or co-sleeping include:

- *Benefits*—Promotes breast-feeding practices; increases bonding time between infant and mother; promotes skin-to-skin contact; and increases maternal vigilance over infant.

- **Risks**—Increases risk for SIDS for infants younger than 4 months; risk of death if parent rolls over the infant; interrupts infant sleeping patterns; risk of asphyxia due to entrapment or airway obstruction; and unsafe design of adult beds for infants (Norton, & Grellner, 2011).

Teach parents to avoid other unsafe conditions, such as placing the newborn in the prone position, using a crib that does not meet federal safety guidelines, allowing window cords to hang loose and in proximity to the crib, placing blankets and pillows in the crib (can potentially smother infant), exposure to tobacco smoke, alcohol, and illicit drugs or setting the room temperature too high (can cause overheating) (AAP, 2011b). Recommendations for safe infant sleeping practices are an important aspect of education for new parents. It is important for nurses to assess families' cultural beliefs and their prior practices to fully understand how to make recommendations in a culturally sensitive manner.

### Enhancing Bonding

Encourage and enhance parent–newborn interaction by involving both parents with the baby and demonstrating appropriate nurturing behaviors:

- Say “hello” and introduce yourself to the newborn.
- Ask the parents' permission to care for and hold their newborn. This helps parents to realize that they are responsible for their child and reminds nurses of their role.
- Show parents the power of a soothing voice to calm the newborn (Fig. 18.21).

**FIGURE 18.21** The father uses a soothing voice to calm the newborn.

- Provide care to the newborn in the least stressful way.
- Demonstrate ways to gently wake up the newborn for better feeding.
- Tell parents what you are doing, why you are doing it, and how they can duplicate what you are doing at home.
- Offer the opportunity for parents to perform care while you observe them. Support their efforts to soothe the newborn throughout the care process.
- Help parents to interpret the communication cues the newborn uses.
- Point out the efforts the newborn is making to connect with the parents (e.g., alerting to the familiar voice, following the parents while they are speaking, quieting when held securely).

One of the most pleasurable aspects of newborn care is being close to them. Bonding begins soon after birth when parents cradle their newborn and gently stroke him or her with their fingers. Provide parents with opportunities for “skin-to-skin” contact with the newborn, holding the baby against their own skin when feeding or cradling. Many newborns respond very positively to gentle massage. If necessary, recommend books and videos that cover the subject.

For newborns, crying is their only way to communicate that something is wrong. Try to find out the reason why: Is the diaper wet? Is the room too hot or too cold? Is the baby uncomfortable (e.g., diaper rash or tight clothing)? Suggest the following ways in which parents can soothe an upset newborn:

- Try feeding or burping to relieve air or stomach gas.
- Lightly rub the newborn's back and speak softly to him or her.
- Gently sway side to side, or rock back and forth in a rocking chair.
- Talk with the newborn while making eye contact.
- Take the newborn for a walk in a stroller or carriage to get fresh air.
- Change the baby's position from back to side or vice versa.
- Try singing, reciting poetry and nursery rhymes, or reading to the baby.
- Turn on a musical mobile above the newborn's head.
- Give more physical contact by walking, rocking, or patting the newborn.
- Swaddle the newborn to provide a sense of security and comfort. To do this:
  - Spread out a receiving blanket, with one corner folded slightly.
  - Lay the newborn face up with head at the folded corner.
  - Wrap the left corner over the baby's body and tuck it beneath the baby.
  - Bring the bottom corner over the baby's feet.
  - Wrap the right corner around the baby, leaving only the head exposed.

## Assisting With Screening Tests

Screening newborns for problems is important because some potentially life-threatening metabolic diseases may not be obvious at birth. Newborn screening tests that are required in most states before discharge are used to check for certain genetic and inborn errors of metabolism and hearing. Early identification and initiation of treatment can prevent significant complications and can minimize the negative effects of untreated disease.

## GENETIC AND INBORN ERRORS OF METABOLISM SCREENING

Although each state mandates which conditions must be tested, the most common screening tests are for PKU, hypothyroidism, galactosemia, and sickle cell disease (Table 18.5).

The trend toward early discharge of newborns can affect the timing of screening and the accuracy of some test results. For example, the newborn needs to ingest enough breast milk or formula to elevate phenylalanine levels for the screening test to identify PKU accurately,

**TABLE 18.5** SELECTED CONDITIONS SCREENED FOR IN THE NEWBORN

Condition	Description	Clinical Picture/ Effect If Not Treated	Treatment	Timing of Screening
PKU	Autosomal recessive inherited deficiency in one of the enzymes necessary for the metabolism of phenylalanine to tyrosine—essential amino acids found in most foods	Irritability, vomiting of protein feedings, and a musty odor to the skin or body secretions of the newborn; if not treated, mental and motor retardation, seizures, microcephaly, and poor growth and development	Lifetime diet of foods low in phenylalanine (low protein) and monitoring of blood levels; special newborn formulas available: Phenex and Lofenalac	Universally screened for in the United States; testing is done 24–48 hours after protein feeding (PKU)
Congenital hypothyroidism	Deficiency of thyroid hormone necessary for normal brain growth, calorie metabolism, and development; may result from maternal hypothyroidism	Increased risk in newborns with birth weight <2,000 g or >4,500 g, and those of Hispanic and Asian ethnic groups; feeding problems, growth and breathing problems; if not treated, irreversible brain damage and intellectual disability	Lifelong thyroid replacement therapy	Testing (measures thyroxin [ $T_4$ ] and TSH) is done between days 4 and 6 of life
Galactosemia	Absence of the enzyme needed for the conversion of the milk sugar galactose to glucose	Poor weight gain, vomiting, jaundice, mood changes, loss of eyesight, seizures, and intellectual disability; if untreated, galactose buildup causing permanent damage to the brain, eyes, and liver, and eventually death	Eliminate milk from diet; substitute soy milk	First test done on discharge from the hospital with a follow-up test within 1 mo
Sickle cell anemia	Recessively inherited abnormality in hemoglobin structure, most commonly found in African American newborns	Anemia developing shortly after birth; increased risk for infection, growth restriction, vasoocclusive crisis	Maintenance of hydration and hemodilution, rest, electrolyte replacement, pain management, blood replacement, and antibiotics	Bloodspot obtained at same time of other newborn screening tests or prior to 3 months of age

Adapted from American Academy of Pediatrics. (2012). *Newborn screening tests*. Retrieved from <http://www.healthychildren.org/English/ages-stages/baby/Pages/Newborn-Screening-Tests.aspx>; Drake, E., & Gibson, M. (2010). Update on expanded newborn screening: Issues for consideration. *Nursing for Women's Health*, 14(3), 198–211.

so newborn screening for PKU testing should not be performed before 24 hours of age.

Screening tests for genetic and inborn errors of metabolism require a few drops of blood taken from the newborn's heel (Fig. 18.22). These tests are usually performed shortly before discharge. Newborns who are discharged before 24 hours of age need to have repeat tests done within a week in an outpatient facility.

Be aware of which conditions your state regularly screens for at birth to ensure that the parents are taught about the tests and the importance of early treatment. Also be familiar with the optimal time frame for screening and conditions that could affect the results. Ensure that a satisfactory specimen has been obtained at the appropriate time and that circumstances that could cause false results have been minimized. Send out specimens and completed forms within 24 hours of collection to the appropriate laboratory (Botkin, 2010).

### HEARING SCREENING

Hearing loss is the most common birth disorder in the United States: approximately 3 to 5 newborns out of every 1,000 live births have some degree of hearing loss. Unlike a physical deformity, hearing loss is not clinically

detectable at birth and thus remains difficult to assess (CDC, 2011a). Factors associated with an increased risk of hearing loss include:

- Family history of hereditary childhood sensory hearing loss
- Congenital infections such as cytomegalovirus, rubella, toxoplasmosis, or herpes
- Craniofacial anomalies involving the pinna or ear canal
- Low birth weight (less than 1,500 g)
- Postnatal infections such as bacterial meningitis
- Head trauma
- Hyperbilirubinemia requiring an exchange transfusion
- Exposure to ototoxic drugs, especially aminoglycosides
- Perinatal asphyxia (USPSTF, 2009)

Delays in identification and intervention may affect the child's language development, academic performance, and cognitive development. Detection before 3 months greatly improves outcomes. Because of this, auditory screening programs for all newborns are recommended by the AAP (2012) and are mandated by law in over 30 states. Screening only infants with risk factors is not enough, because as many as 50% of infants born with hearing loss have no known risk factors (USPSTF, 2009). Early identification and intervention can prevent severe psychosocial, educational, and language development delays.

The current goals of *Healthy People 2020* (USDHHS, 2010) are to screen all infants by 1 month of age, confirm hearing loss with an audiologic examination by 3 months of age, and treat with comprehensive early intervention services before 6 months of age (see the *Healthy People 2020* feature earlier in this chapter).

All newborns should be screened prior to discharge to ensure that any newborn with a hearing loss is not missed. Those with suspected hearing loss should be referred for follow-up assessment. Box 18.1 discusses screening methods. In addition, nurses should ensure that testing is accurate to facilitate early diagnosis and intervention services and to optimize the newborn's developmental potential.

### Dealing With Common Concerns

During the newborn period of transition, certain conditions can develop that require intervention. These conditions, although not typically life threatening, can be a source of anxiety for the parents. Common concerns include transient tachypnea of the newborn, physiologic jaundice, and hypoglycemia.

### TRANSIENT TACHYPNEA OF THE NEWBORN

Transient tachypnea of the newborn appears soon after birth. It is accompanied by retractions, expiratory grunting, or cyanosis and is relieved by low-dose oxygen

**FIGURE 18.22** Screening for PKU. (A) Performing a heel stick. (B) Applying the blood specimen to the card for screening.

## BOX 18.1

**NEWBORN HEARING SCREENING METHODS**

A newborn's hearing can be screened in one of two ways: otoacoustic emission (OAE) or automated auditory brain stem response (ABR). In OAE, an earphone is placed in the infant's ear canal and the sounds produced by the newborn's inner ear are measured in response to certain tones or clicks presented through the earphone. Preset parameters in the equipment decide whether the OAEs are sufficient for the newborn to pass or whether a referral is necessary for further evaluation.

In ABR, an earphone is placed in the ear canal or an earmuff is placed over the newborn's ear, and a soft, rapid tapping noise is presented. Electrodes placed around the newborn's head, neck, and shoulders record neural activity from the infant's brain stem in response to the tapping noises. The ABR tests how well the ear and the nerves leading to the brain work. Like OAEs, automated ABR screening is sensitive to more than mild degrees of hearing loss, but a "pass" does not guarantee normal hearing.

Adapted from Drake, E., & Gibson, M. (2010). Update on expanded newborn screening: Issues for consideration. *Nursing for Women's Health*, 14(3), 198–211; Lin, K., & Camp, M. (2010). Universal screening for hearing loss in newborns. *American Family Physician*, 81(2), 191–192; Russ, S., White, K., Dougherty, D., & Forsman, I. (2010). Preface: Newborn hearing screening in the United States: Historical perspective and future directions. *Pediatrics*, 126(Suppl 1), S3–S6; and Shulman, S., Besculides, M., Saltzman, A., Ireys, H., White, K., & Forsman, I. (2010). Evaluation of the universal newborn hearing screening and intervention program. *Pediatrics*, 126(Suppl 1), S19–S27.

therapy. Mild or moderate respiratory distress typically is present at birth or within 6 hours of birth. Transient tachypnea of the newborn is generally a self-limited disorder without significant morbidity. Transient tachypnea of the newborn resolves over a 24-hour to 72-hour period.

Transient tachypnea of the newborn occurs when the fetal liquid in the lungs is removed slowly or incompletely. This can be due to the lack of thoracic squeezing that occurs during a cesarean birth or diminished respiratory effort if the mother received central nervous system depressant medication. Prolonged labor, macrosomia of the fetus, and maternal asthma also have been associated with this condition. A vaginal birth appears to be protective against transient tachypnea of the newborn (Derbent et al., 2011).

Nursing interventions include providing supportive care: giving oxygen, ensuring warmth, observing respiratory status frequently, and allowing time for the pulmonary capillaries and the lymphatics to remove the remaining fluid. The clinical course is relatively benign, but any newborn respiratory issue can be very frightening

to the parents. Provide a thorough explanation and reassure them that the condition will resolve over time.

**PHYSIOLOGIC JAUNDICE**

Physiologic jaundice is very common in newborns, with the majority demonstrating yellowish skin, mucous membranes, and sclera within the first 3 days of life. In any given year, approximately 60% of the newborns in the United States will experience clinical jaundice (Lauer, & Spector, 2011). Jaundice is the visible manifestation of hyperbilirubinemia. It typically results from the deposition of unconjugated bilirubin pigment in the skin and mucous membranes.

Physiologic jaundice can be best understood as an imbalance between the production and elimination of bilirubin, with a multitude of factors and conditions affecting each of these processes. When an imbalance results because of an increase in circulating bilirubin (or the bilirubin load) to significantly high levels, it may go on to cause acute neurologic sequelae (acute bilirubin encephalopathy). In most infants, an increase in bilirubin production (e.g., due to hemolysis) is the primary cause of physiologic jaundice, and thus reducing bilirubin production is a rational approach for its management.

Factors that contribute to the development of physiologic jaundice in the newborn include an increased bilirubin load because of relative polycythemia, a shortened erythrocyte life span (80 days compared with the adult 120 days), and immature hepatic uptake and conjugation processes (Cohen, Wong, & Stevenson, 2010). Normally the liver removes bilirubin from the blood and changes it into a form that can be excreted. As the red blood cell breakdown continues at a fast pace, the newborn's liver cannot keep up with bilirubin removal. Thus, bilirubin accumulates in the blood, causing a yellowish discoloration on the skin.

The AAP has recently released guidelines for the prevention and management of hyperbilirubinemia in newborns:

- Promote and support successful breast-feeding practices to make sure the newborn is well hydrated and stooling frequently to promote elimination of bilirubin.
- Advise mothers to nurse their infants at least 8 to 12 times per day for the first several days.
- Avoid routine supplementation of nondehydrated breast-fed infants with water or dextrose water because that will not lower bilirubin levels.
- Ensure that all infants are routinely monitored for the development of jaundice and that nurseries have established protocols for the assessment of jaundice. Jaundice should be assessed whenever the infant's vital signs are measured but no less than every 8 to 12 hours.
- Before discharge, complete a systematic assessment for the risk of severe hyperbilirubinemia.

## EVIDENCE-BASED PRACTICE 18.1

## UNIVERSAL NEONATAL HEARING SCREENING VERSUS SELECTIVE SCREENING AS PART OF THE MANAGEMENT OF CHILDHOOD DEAFNESS

## STUDY

The principal factors that determine how deafness affects a child's development are the degree of hearing impairment and the age at which it is diagnosed. A number of factors are thought to increase the risk of hearing impairment, such as low birth weight, prematurity, and perinatal hypoxia and jaundice. The high incidence of deafness in children without risk factors and the introduction of simple new screening tests with high sensitivity and specificity have led many prestigious bodies to recommend universal early detection programs for deafness rather than screening that targets high-risk groups. A study was performed to compare the long-term effectiveness of a universal neonatal screening and early treatment program for hearing impairment versus screening and treatment of high-risk neonates only.

## Findings

This review found no randomized trials that compared the long-term results of these screening programs. Controlled trials and before-and-after studies are needed to address this issue.

## Nursing Implications

Although additional research is needed, nurses should encourage all parents to have their newborns screened. The AAP recommends hearing screening for all newborns so that early interventions can be provided to prevent speech, language, and cognitive development impairments. This information should be stressed during discharge planning activities and follow-up tests if warranted. Community follow-up is essential for all newborns who do not pass the hearing screening test in the hospital before discharge.

Adapted from Puig, T., Municio, A., & Medà, C. (2010). Universal neonatal hearing screening versus selective screening as part of the management of childhood deafness. *Cochrane Database of Systematic Reviews*, 2010(1). doi:10.1002/14651858.CD003731.pub3.

- Provide early and focused follow-up based on the risk assessment.
- When indicated, treat newborns with phototherapy or exchange transfusion to prevent acute bilirubin encephalopathy (AAP, 2010d).

In newborn infants, jaundice can be detected by blanching the skin with digital pressure on the bridge of the nose, sternum, or forehead, revealing the underlying color of the skin and subcutaneous tissue. If jaundice is present, the blanched area will appear yellow before the capillary refill. The assessment of jaundice must be performed in a well-lit room or, preferably, in daylight at a window. Jaundice is usually seen first in the face and progresses caudally to the trunk and extremities (AAP, 2010d).

Measures that parents can take to reduce the risk of jaundice include exposing the newborn to natural sunlight for short periods of time throughout the day to help oxidize the bilirubin deposits on the skin, providing breast-feeding on demand to promote elimination of bilirubin through urine and stooling, and avoiding glucose water supplementation, which hinders elimination.

If or when the levels of unconjugated serum bilirubin increase and do not return to normal levels with increased hydration, phototherapy is used. The serum level of bilirubin at which phototherapy is initiated is a matter of clinical judgment by the physician, but it is often begun when bilirubin levels reach 12 to 15 mg/dL in the first 48 hours of life in a term newborn (Hansen, 2010a). **Phototherapy** involves exposing the newborn to ultraviolet light, which converts unconjugated bilirubin into products that can be excreted through feces and urine. Phototherapy is the most common treatment for hyperbilirubinemia and has virtually eliminated the need for exchange transfusions in newborns now.

**Take Note!**

Exposure of newborns to sunlight represents the first documented use of phototherapy in the medical literature. Sister J. Ward, a charge nurse in Essex, England, recognized in 1956 that when jaundiced newborns were exposed to the sun they became less yellow. This observation changed the entire treatment of jaundice in newborns (Cashore, 2010).

Phototherapy reduces bilirubin levels in the blood by breaking down unconjugated bilirubin into colorless compounds. These compounds can then be excreted in the bile. Phototherapy aims to curtail the increase in bilirubin blood levels; thereby preventing kernicterus, a condition in which unconjugated bilirubin enters the brain. If not treated, kernicterus can lead to brain damage and death.

During the past several decades, phototherapy has generally been administered with either banks of fluorescent lights or spotlights. Factors that determine the dosage of phototherapy include spectrum of light emitted, irradiance of light source, design of light unit, surface area of newborn exposed to the light, and distance of the newborn from the light source (Hansen, 2010b). For phototherapy to be effective, the rays must penetrate as much of the skin as possible. Thus, the newborn must be naked and turned frequently to ensure maximum exposure of the skin. Several side effects of standard phototherapy have been identified: frequent loose stools, increased insensible water loss, transient rash, and potential retinal damage if the newborn's eyes are not covered sufficiently.

Recently, fiber-optic pads (Biliblanket or Bilivest) have been developed that can be wrapped around the newborn or on which the newborn can lie. The light is delivered from a tungsten-halogen bulb through a fiber-optic cable and is emitted from the sides and ends of the fibers inside a plastic pad (Mreihil, McDonagh, Nakstad, & Hansen, 2010). These products work on the premise that phototherapy can be improved by delivering higher-intensity therapeutic light to decrease bilirubin levels. The pads do not produce appreciable heat like the banks of lights or spotlights do, so insensible water loss is not increased. Eye patches also are not needed; thus, parents can feed and hold their newborns continuously to promote bonding.

When caring for newborns receiving phototherapy for jaundice, nurses must do the following:

- Closely monitor body temperature and fluid and electrolyte balance.
- Document frequency, character, and consistency of stools.
- Monitor hydration status (weight, specific gravity of urine and urine output).
- Turn frequently to increase the infant's skin exposure to phototherapy.
- Observe skin integrity (as a result of exposure to diarrhea and phototherapy lights).
- Provide eye protection to prevent corneal injury related to phototherapy exposure.
- Encourage parents to participate in their newborn's care to prevent parent–infant separation.

See Chapter 24 for a more detailed discussion of hyperbilirubinemia.

*The home health nurse made a postpartum visit to Kelly to assess the situation. Kelly's son was slightly jaundiced when the home health nurse pressed gently over his sternum, but Kelly said he was nursing better compared with the previous 2 days. What home suggestions can the nurse make to Kelly to reduce the jaundice? What specific education about physiologic jaundice is needed?*

## HYPOGLYCEMIA

Hypoglycemia affects as many as 40% of all full-term newborns (Cranmer, 2012). It is defined as a blood glucose level of less than 30 mg/dL or a plasma concentration of less than 40 mg/dL in the first 72 hours of life (Gardner et al., 2011). From a physiologic perspective, a newborn may be said to be hypoglycemic when glucose supply is inadequate to meet demand. In newborns, blood glucose levels fall to a low point during the first few hours of life because the source of maternal glucose is removed when the placenta is expelled. This period of transition is usually smooth, but certain newborns are at greater risk for hypoglycemia: infants of mothers who have diabetes, preterm newborns, and newborns with intrauterine growth restriction (IUGR), inadequate caloric intake, sepsis, asphyxia, hypothermia, polycythemia, glycogen storage disorders, and endocrine deficiencies (Kliegman et al., 2011).

Most newborns experience transient hypoglycemia and are asymptomatic. The symptoms, when present, are nonspecific and include jitteriness, lethargy, cyanosis, apnea, seizures, high-pitched or weak cry, hypothermia, and poor feeding. If hypoglycemia is prolonged or is left untreated, serious, long-term adverse neurologic sequelae such as learning disabilities and intellectual disabilities can occur (Halaby, & Steinkrauss, 2012). Treatment of hypoglycemia in the newborn includes administration of a rapid-acting source of glucose such as a sugar/water mixture or early formula-feeding. In acute, severe cases, IV administration of glucose may be required. Continuous monitoring of glucose levels is not only prudent but mandatory in high risk newborns. Although there is no specific means of preventing hypoglycemia in newborns, it is wise and cautious to monitor for symptoms and intervene as soon as symptoms are noted. Subsequently, early diagnosis and appropriate intervention are essential for all newborns.

Nursing care of the hypoglycemic newborn includes monitoring for signs of hypoglycemia or identifying high-risk newborns prone to this disorder based on their perinatal history, physical examination, body measurements, and gestational age. Glucose screening should be performed only on at-risk infants and those with clinical symptoms compatible with hypoglycemia (National Guideline Clearinghouse, 2010).

Prevent hypoglycemia in newborns at risk by initiating early feedings with breast milk or formula. If

hypoglycemia persists despite feeding, notify the primary health care provider for orders such as intravenous therapy with dextrose solutions. Anticipate hypoglycemia in certain high-risk newborns and begin assessments immediately on nursery admission.

### Promoting Nutrition

Several physiologic changes dictate the type and method of feeding throughout the newborn's first year. Some of these changes include the following:

- Stomach capacity is limited at birth. The emptying time is short (2 to 3 hours) and peristalsis is rapid. Therefore, small, frequent feedings are needed at first, with amounts progressively increasing with maturity.
- The immune system is immature at birth, so the baby is at a high risk for food allergies during the first 4 to 6 months of life. Introducing solid foods prior to this time increases the risk of developing food allergies.
- Pancreatic enzymes and bile to assist in digestion of fat and starch are in limited supply until about 3 to 6 months of age. Infants cannot digest cereal prior to this time.
- The kidneys are immature and unable to concentrate urine until about 4 to 6 weeks of age. Excess protein and mineral intake can place a strain on kidney function and can lead to dehydration. Infants need to consume more water per unit of body weight than adults do as a result of their high body weight from water.
- Immature muscular control at birth changes over time to assist in the feeding process by improving head and neck control, hand-eye coordination, swallowing, and ability to sit, grasp, and chew. At about 4 to 6 months, inborn reflexes disappear, head control develops, and the infant can sit to be fed, making spoon-feeding possible (Dudek, 2010).

### NEWBORN NUTRITIONAL NEEDS

As newborns grow, their energy and nutrient requirements change to meet their body's changing needs. During infancy, energy, protein, vitamin, and mineral requirements per pound of body weight are higher than at any other time of life. These high levels are needed to fuel the rapid growth and development during this stage of life. Generally, an infant's birth weight doubles in the first 4 to 6 months of life and triples within the first year (Lutz, & Przytulski, 2011).

A newborn's caloric needs range from 110 to 120 cal/kg body weight. Breast milk and formulas contain approximately 20 cal/oz, so the caloric needs of young infants can be met if several feedings are given throughout the day. Most term infants need a basic formula if the mother chooses not to breast-feed. These formulas are modeled after breast milk, which contains 20 calories per ounce. There is no evidence to recommend one brand over the other since all of them are nutritionally

interchangeable. All formulas are classified based on three parameters: caloric density, carbohydrate source, and protein composition (see Table 18.6).

Fluid requirements for the newborn and infant range from 100 to 150 mL/kg daily. This requirement can be met through breast- or bottle-feeding. Additional water supplementation is not necessary. Adequate carbohydrates, fats, protein, and vitamins are achieved through consumption of breast milk or formula. The AAP (2010g) recommends that bottle-fed infants be given iron supplementation, because iron levels are low in all types of formula milk. This can be achieved by giving iron-fortified formula from birth. The breast-fed infant draws on iron reserves for the first 6 months and then needs iron-rich foods or supplementation added at 6 months of age. The AAP (2010g) also has recommended that all infants (breast- and bottle-fed) receive a daily supplement of 400 IU of vitamin D starting within the first few days of life to prevent rickets and vitamin D deficiency. It is also recommended that fluoride supplementation be given to infants not receiving fluoridated water after the age of 6 months (AAP, 2010g).

### SUPPORTING THE CHOICE OF FEEDING METHOD

Parents typically decide about the method of feeding well before the infant is born. Prenatal and childbirth classes present information about breast-feeding versus bottle-feeding and allow the parents to make up their minds about which method is best for them. Various factors can influence their decision, including socioeconomic status, culture, sexual objectification, fear of a negative community reaction, personal inconvenience, dietary restrictions, lack of social support, employment, level of education, lack of access to breast pumps, lack of time, free formula provided by government programs, range of care interventions provided during pregnancy, childbirth, and the early postpartum period, and especially partner support (Brown, Raynor, & Lee, 2011; Haughton, Gregorio, & Pérez-Escamilla, 2010; Purdy, 2010). Nurses can provide evidence-based information to assist the couple in making their decision. Regardless of which method is chosen, the nurse needs to respect and support the couple's decision.

### FEEDING THE NEWBORN

The newborn can be fed at any time during the transition period if assessments are normal and a desire is demonstrated. Before the newborn can be fed, determine his or her ability to suck and swallow. Clear any mucus in the nares or mouth with a bulb syringe before initiating feeding. Auscultate bowel sounds, check for abdominal distention, and inspect the anus for patency. If these parameters are within normal limits, newborn feeding may be started. Most newborns are on demand feeding schedules and are allowed to feed when they awaken. When they go home, mothers are encouraged to feed their newborns every 2 to 4 hours during the day and

TABLE 18.6

COMPARISON OF BREAST MILK TO SELECTED FORMULA COMPOSITION

Type	Brand names	Calories/ ounce	Carbohydrate Source	Protein Source	Indications
Breast milk	None	20	Lactose	Human milk	Preferred for all infants
Term formula	Enfamil; Similac; Carnation Good Start	20	Lactose	Cow's milk	Appropriate for all term infants
Term formula with DHA and ARA	Enfamil Lipil; Good Start DHA & ARA; Similac Advance	20	Lactose	Cow's milk	Marketed to promote good vision and brain development
Preterm formula	Enfamil 24 Premature; Preemie SMA 24	24	Lactose	Cow's milk	Usually given to preterm infants <34 weeks' gestation
Soy formula	Enfamil Prosoabee; Good Start Soy	20	Corn based	Soy	For infants with galactosemia
Hypoallergenic formula	Similac Alimentum; Enfamil Nutramigen; Enfamil Pregestimil	20	Corn or sucrose	Extensively hydrolyzed	For infants with a milk protein allergy
Nonallergenic formula	Neocate; Nutramigen AA	20	Corn or sucrose	Amino acids	For infants with a milk protein allergy
Antireflux formula	Enfamil AR; Similac Sensitive RS	20	Lactose thickened with rice starch	Cow's milk	For infants with gastric reflux disorder

St. Louis, MO: Mosby Elsevier; Lutz, C. A., & Przytulski, K. R. (2011). *Nutrition & diet therapy* (5th ed.). Philadelphia, PA: F. A. Davis; Martinez, J., & Ballew, M. (2011). Infant formulas. *Pediatrics in Review*, 32(5), 179–189; and Mattson, S., & Smith, J. E. (2011) *Core curriculum for maternal-newborn nursing* (4th ed.), St. Louis, MO: Saunders Elsevier.

only when the newborn awakens during the night for the first few days after birth.

Parents often have many questions about feeding. Generally, newborns should be fed on demand whenever they seem hungry. Most newborns will give clues about their hunger status by crying, placing their fingers or fist in their mouth, rooting around, and sucking.

Newborns differ in their feeding needs and preferences, but most breast-fed ones need to be fed every 2 to 3 hours, nursing for 10 to 20 minutes on each breast. The length of feedings is up to the mother and newborn. Encourage the mother to respond to cues from her infant and not feed according to a standard or preset schedule.

Formula-fed newborns usually feed every 3 to 4 hours, finishing a bottle in 30 minutes or less. Daily formula intake for an infant should be 1.5 to 2 ounces per pound of body weight, but growth is a better measure of health than the amount of formula consumed (Lutz, & Przytulski, 2011). If the newborn seems satisfied, wets 6 to 10 diapers daily, produces several stools a day, sleeps well, and is gaining weight regularly, then he or she is probably receiving sufficient breast milk or formula.

Newborns swallow air during feedings, which causes discomfort and fussiness. Parents can prevent this by burping them frequently throughout the feeding. Tips about burping include:

- Hold the newborn upright with his or her head on the parent's shoulder (Fig. 18.23A).
- Support the head and neck while the parent gently pats or rubs the newborn's back (Fig. 18.23B).
- Have the newborn sit on the parent's lap, while supporting the baby's chest and head. Gently rub the newborn's back with the other hand.
- Lay the newborn on the parent's lap with the baby's back facing up.
- Support the newborn's head in the crook of the parent's arm and gently pat or rub the back.

#### Take Note!

It is the upright position, not the strength of the patting or rubbing that allows the newborn to release air accumulated in the stomach.

Stress to parents that feeding time is more than an opportunity to get nutrients into their newborn; it is also

**FIGURE 18.23** The nurse demonstrates (A) holding the newborn upright over the shoulder and (B) sitting the newborn upright, supporting the neck and chin.

a time for closeness and sharing. Feedings are as much for the baby's emotional pleasure as his or her physical well-being. Encourage parents to maintain eye contact with the newborn during the feeding, hold him or her comfortably close to them, and talk softly during the feeding to promote closeness and security.

## BREAST-FEEDING

There is consensus in the medical community that breast-feeding is optimal for all newborns. The AAP and the American Dietetic Association recommend breast-feeding exclusively for the first 6 months of life, continuing it in conjunction with other food at least until the newborn's first birthday (AAP, 2010a). Box 18.2 highlights the advantages of breast-feeding for the mother and newborn. In addition, breast-feeding is associated with lower incidence of necrotizing enterocolitis and

### BOX 18.2

#### ADVANTAGES OF BREAST-FEEDING

##### Advantages for the Newborn

- Contributes to the development of a strong immune system
- Stimulates growth of positive bacteria in digestive tract
- Reduces incidence of stomach upset, diarrhea, and colic
- Begins the immunization process at birth by providing passive immunity
- Promotes optimal mother–infant bonding
- Reduces risk of newborn constipation
- Promotes greater developmental gains in preterm infants
- Provides easily tolerated and digestible formula that is sterile, at proper temperature, and readily available with no artificial colorings, flavorings, or preservatives
- Is less likely to result in overfeeding, leading to obesity
- Promotes better tooth and jaw development as a result of sucking hard
- Provides protection against food allergies
- Is associated with avoidance of type 1 diabetes and heart disease

##### Advantages for the Mother

- Can facilitate postpartum weight loss
- Stimulates uterine contractions to control bleeding
- Lowers risk for ovarian and endometrial cancers
- Facilitates bonding with newborn infant
- Promotes uterine involution as a result of release of oxytocin
- Lowers risk of breast cancer and osteoporosis
- Affords some protection against conception, although it is not a reliable contraceptive method

Retrieved from <http://www.aap.org/breastfeeding/policyOnBreastfeedingAndUseOfHumanMilk.html>; Lutz, C. A., & Przytulski, K. R. (2011). *Nutrition & diet therapy* (5th ed.). Philadelphia, PA: F. A. Davis; and Walker, M. (2011). *Breastfeeding management for the clinician: Using the evidence* (2nd ed.). Sudbury, MA: Jones & Bartlett.

diarrhea during the early period of life and with lower incidence of inflammatory bowel diseases, type 2 diabetes, and obesity later in life (Le Huërou-Luron, Blat, & Boudry, 2010).

Mothers should continue to breast-feed during mild illnesses such as colds or the flu. However, in the United States mothers with HIV are advised not to breast-feed.

The composition of breast milk changes over time from colostrum, to transitional milk, and finally to mature milk. Colostrum is a thick, yellowish substance secreted during the first few days after birth. It is high in protein, minerals, and fat-soluble vitamins. It is rich in immunoglobulins (IgA), which help protect the newborn's gastrointestinal tract against infections. It is a natural laxative that helps rid the intestinal tract of meconium quickly (Santoro, Martinez, Ricco, & Jorge, 2010).

Transitional milk occurs between colostrum and mature milk and contains all the nutrients in colostrum, but it is thinner and less yellow than colostrum. This transitional milk is replaced by true or mature milk around day 10 after birth. Mature milk appears bluish and is not as thick as colostrum. It provides 20 cal/oz and contains:

- **Protein**—Although the content is lower than formula, it is ideal to support growth and development for the newborn. The majority of the protein is whey, which is easy to digest.
- **Fat**—Approximately 58% of total calories are fat, but they are easy to digest. Essential fatty acid content is high, as is the level of cholesterol, which helps develop enzyme systems capable of handling cholesterol later in life.
- **Carbohydrate**—Approximately 35% to 40% of total calories are in the form of lactose, which stimulates the growth of natural defense bacteria in the gastrointestinal system and promotes calcium absorption.
- **Water**—Water, the major nutrient in breast milk, makes up 85% to 95% of the total volume. Total milk volume varies with the age of the infant and demand.
- **Minerals**—Breast milk contains calcium, phosphorus, chlorine, potassium, and sodium, with trace amounts of iron, copper, and manganese. Iron absorption is about 50%, compared with about 4% for iron-fortified formulas.
- **Vitamins**—All vitamins are present in breast milk; vitamin D is the lowest in amount. Debate about the need for vitamin D supplementation is ongoing.
- **Enzymes**—Lipase and amylase are found in breast milk to assist with digestion (Dudek, 2010).

**Breast-Feeding Assistance.** Breast-feeding can be initiated immediately after birth. If the newborn is healthy and stable, wipe the newborn from head to toe with a dry cloth and place him or her skin-to-skin on the mother's abdomen. Then cover the newborn and mother with another warmed blanket to hold in the warmth. Immediate mother–newborn contact takes advantage

of the newborn's natural alertness after a vaginal birth and fosters bonding. This immediate contact also reduces maternal bleeding and stabilizes the newborn's temperature, blood glucose level, and respiratory rate (AAP, 2010a).

Left alone on the mother's abdomen, a healthy newborn scoots upward, pushing with the feet, pulling with the arms, and bobbing the head until finding and latching on to the mother's nipple. A newborn's sense of smell is highly developed, which also helps in finding the nipple. As the newborn moves to the nipple, the mother produces high levels of oxytocin, which contract the uterus, thereby minimizing bleeding. Oxytocin also causes the breasts to release colostrum when the newborn sucks on the nipple. Colostrum is rich in antibodies and thus provides the newborn with her "first immunization" against infection.

Keys to successful breast-feeding include:

- Initiating breast-feeding within the first hour of life if the newborn is stable
- Following the newborn's feeding schedule—8 to 12 times in 24 hours
- Providing unrestricted periods of breast-feeding
- Offering no supplement unless medically indicated
- Having a lactation consultant observe a feeding session
- Avoiding artificial nipples and pacifiers except during a painful procedure
- Feeding from both breasts over each 24-hour period
- Watching for indicators of sufficient intake from infant:
  - Six to ten wet diapers daily
  - Waking up hungry 8 to 12 times in 24 hours
  - Acting content and falling asleep after feeding
- Keeping the newborn with the mother throughout the hospital stay

Help position the newborn so that latching-on is effective and is not painful for the mother. Placing pillows or a folded blanket under the mother's head may help, or rolling her to one side and tucking the newborn next to her. Assess both the mother and newborn during this initial session to determine needs for assistance and education. One tool used frequently in this assessment is the LATCH scoring tool (Jenson, Wallace, & Kelsey, 1994). The LATCH scoring tool is a breast-feeding charting system that provides a systematic method for gathering information about individual breast-feeding sessions. The system assigns a numerical score of 0, 1, or 2 to five key components of breast-feeding. Each letter of the acronym LATCH denotes an area of assessment. "L" is for how well the infant latches onto the breast. "A" is for the amount of audible swallowing noted. "T" is for the mother's nipple type. "C" is for the mother's level of comfort. "H" is for the amount of help the mother needs to hold her infant to the breast. The system is visually represented in the same form as the Apgar scoring grid, and the numbers are handled in the same way. With the

**TABLE 18.7** THE LATCH SCORING TOOL

Parameters	0 Point	1 Point	2 Points
L: latch	Sleepy infant, no sustained latch achieved	Must hold nipple in infant's mouth to sustain latch and suck; must stimulate infant to continue to suck	Grasps nipple; tongue down; rhythmic sucking
A: audible swallowing	None	A few observed with stimulation	Spontaneous and intermittent both <24 hr old and afterward
T: type of nipple	Inverted (drawn inward into breast tissue)	Flat (not protruding)	Everted or protruding out after stimulation
C: comfort of nipple	Engorged, cracked bleeding; severe discomfort	Filling; reddened, small blisters or bruises; mild to moderate discomfort	Soft, nontender
H: hold (positioning)	Nurse must hold infant to breast	Minimal assistance; help with positioning, then mother takes over	No assistance needed by nurse

Adapted from Ahmed, A. (2010). Role of the pediatric nurse practitioner in promoting breastfeeding for late preterm infants in primary care settings. *Journal of Pediatric Healthcare*, 24(2), 116–122; American Academy of Pediatrics. (2010a). *AAP policy on breastfeeding and use of human milk*. Retrieved from <http://www.aap.org/breastfeeding/policyOnBreastfeedingAndUseOfHumanMilk.html>; Brodbeck, R. (2009). The big latch on. *Midwifery News* (54), 30–31; and Walker, M. (2011). *Breastfeeding management for the clinician: Using the evidence* (2nd ed.). Sudbury, MA: Jones & Bartlett.

LATCH system, the nurse can assess maternal and infant variables, define areas of needed intervention, and determine priorities in providing client care and teaching (Table 18.7). The higher the score, the less nursing intervention is needed by the mother and baby.

**Breast-Feeding Positioning.** The mother and infant must be in comfortable positions to ensure breast-feeding success. The four most common positions for breast-feeding are the football, cradle, across-the-lap, and side-lying holds. Each mother, on experimentation, can decide which positions feel most comfortable for her (Fig. 18.24).

In the football hold, the mother holds the infant's back and shoulders in her palm and tucks the infant under her arm. Remind the mother to keep the infant's ear, shoulder, and hip in a straight line. The mother supports the breast with her hand and brings it to the infant's lips to latch on. She continues to support the breast until the infant begins to nurse. This position allows the mother to see the infant's mouth as she guides her infant to the nipple. This is a good choice for mothers who have had a cesarean birth because it avoids pressure on the incision.

The cradling position is the one most commonly used. The mother holds the baby in the crook of her arm, with the infant facing the mother. The mother supports the breast with her opposite hand.

In the across-the-lap position, the mother places a pillow across her lap, with the infant facing the mother.

The mother supports the infant's back and shoulders with her palm and supports her breast from underneath. After the infant is in position, the infant is pulled forward to latch on.

In the side-lying position, the mother lies on her side with a pillow supporting her back and another pillow supporting the newborn in the front. To start, the mother props herself up on an elbow and supports the newborn with that arm, while holding her breast with the opposite hand. Once nursing is started, the mother lies down in a comfortable position.

To promote latching-on, instruct the mother to make a C or a V with her fingers. In the C hold, the mother places her thumb well above the areola and the other four fingers below the areola and under the breast. In the V hold, the mother places her index finger above the areola and her other three fingers below the areola and under the breast. Either method can be used as long as the mother's hand is well away from the nipple so the infant can latch on.

**Breast-Feeding Education.** Breast-feeding is not an innate skill in human mothers. Almost all women have the potential to breast-feed successfully, but many fail because of inadequate knowledge. Nursing Care Plan 18.1 gives typical nursing diagnoses, outcomes, and interventions. For many mothers and newborns, breast-feeding goes smoothly from the start, but for others it is a struggle. Nurses can help throughout the experience by

FIGURE 18.24 Breast-feeding positions.

demonstrating techniques and offering encouragement and praise for success. Correct positioning will enhance good attachment and will ensure effective milk transfer. Nurses should emphasize that the key to successful breast-feeding is correct positioning and latching-on.

Teaching by nurses has been shown to have a significant effect on both the ability to breast-feed successfully and the duration of lactation (Dudek, 2010). During the first few breast-feeding sessions, mothers want to know how often they should be nursing, whether breast-feeding is going well, if the newborn is getting enough nourishment, and what problems may ensue and how to cope with them. Education for the breast-feeding mother is highlighted in Teaching Guidelines 18.4.

*Remember Kelly, who was concerned about jaundice in her newborn son? At her son's 2-week well-baby checkup at the clinic, his bilirubin level came back within normal limits. Kelly still felt he was not getting enough to eat and stated that she might switch to formula-feeding her son. What information can the nurse present to promote and reinforce breast-feeding? Should the nurse make a referral to the lactation consultant?*

**Breast Milk Storage and Expression.** If the breast-feeding mother becomes separated from the newborn for any reason (e.g., work, travel, illness), she needs instruction on how to express and store milk safely. Expressing milk can be done manually (hand compression of breast) or by using a breast pump. Manual or handheld pumps are inexpensive and can be used by mothers who occasionally need an extra bottle if they are going out (Fig. 18.25). Electric breast pumps are used for mothers who experience a lengthy separation from their infants and need to pump their breasts regularly.

To ensure the safety of expressed breast milk, instruct the mother in the following:

- Wash your hands before expressing milk or handling breast milk.
- Use clean containers to store expressed milk.
- Use sealed and chilled milk within 24 hours.
- Discard any milk that has been refrigerated more than 24 hours.
- Use any frozen expressed milk within 3 months.
- Do not use microwave ovens to warm chilled milk.
- Discard any used milk; never refreeze it.
- Store milk in quantities to be used for each feeding (2 to 4 oz).
- Thaw milk in warm water before using (AAP, 2010a).

## NURSING CARE PLAN 18.1

## Overview of the Mother and Newborn Having Difficulty with Breast-Feeding

Baby boy James, weight 7 lb, 4 oz, was born a few hours ago. His mother, Jane, is a 19-year-old gravida 1, para 1. His Apgar scores were 9 points at both 1 and 5 minutes. Labor and birth were unremarkable, and James was admitted to the nursery for assessment. After stabilization, James was brought to his mother, who had said she wished to breast-feed. The postpartum nurse assisted Jane with positioning and latching-on and left the room for a few minutes. On returning, Jane was upset, James was crying, and Jane stated she wanted a bottle of formula to feed him since she didn't have milk and her nipples hurt.

Assessment reveals a young, inexperienced mother placed in an uncomfortable situation with limited knowledge of breast-feeding. Anxiety from the mother transferred to James, resulting in crying. The mother, apprehensive about breast-feeding, needs additional help.

**NURSING DIAGNOSIS:** Ineffective breast-feeding related to pain and limited skill

### Outcome Identification and Evaluation

The mother will demonstrate understanding of breast-feeding skills as evidenced by use of correct positioning and technique, and verbalization of appropriate information related to breast-feeding.

### Interventions: *Providing Education*

- Instruct mother on proper positioning for breast-feeding; suggest use of football hold, side-lying position, modified cradle, and across-the-lap position *to ensure comfort and to promote ease in breast-feeding.*
- Review breast anatomy and milk letdown reflex *to enhance mother's understanding of lactation.*
- Observe newborn's ability to suck and latch on to the nipple *to assess whether newborn has adequate ability.*
- Monitor sucking and newborn swallowing for several minutes *to ensure adequate latching on and to assess intake.*
- Reinforce nipple care with water and exposure to air *to maintain nipple integrity.*

**NURSING DIAGNOSIS:** Anxiety related to breast-feeding ability and irritable, crying newborn

### Outcome Identification and Evaluation

The mother will verbalize increased comfort with breast-feeding as evidenced by positive statements related to breast-feeding and verbalization of desire to continue to breast-feed newborn.

### Interventions: *Reducing Anxiety*

- Ensure that the environment is calm and soothing without distractions *to promote maternal and newborn relaxation.*
- Show mother correct latching-on technique *to promote breast-feeding.*
- Assist in calming newborn by holding and talking *to ensure that the newborn is relaxed prior to latching on.*
- Reassure mother she can be successful at breast-feeding *to enhance her self-esteem and confidence.*
- Encourage frequent trials and attempts *to enhance confidence.*
- Encourage the mother to verbalize her anxiety/fears *to reduce anxiety.*

(continued)

## NURSING CARE PLAN 18.1

## Overview of the Mother and Newborn Having Difficulty with Breast-Feeding (continued)

**NURSING DIAGNOSIS:** Pain related to breast-feeding and incorrect latching-on technique

### Outcome Identification and Evaluation

The mother will experience a decrease in pain during breast-feeding as evidenced by statements of less nipple pain.

### Interventions: *Reducing Pain*

- Suggest several alternate positions for breast-feeding to *increase comfort*.
- Demonstrate how to break suction before removing infant from breast to *minimize trauma to nipple*.
- Inspect nipple area to *promote early identification of trauma*.
- Reinforce correct latching-on technique to *prevent nipple trauma*.
- Administer pain medication if indicated to *relieve pain*.
- Instruct about nipple care between feedings to *maintain nipple integrity*.

### Teaching Guidelines 18.4

#### BREAST-FEEDING

- Set aside a quiet place where you can be relaxed and won't be disturbed. Relaxation promotes milk letdown.
- Sit in a comfortable chair or rocking chair or lie on a bed. Try to make each feeding calm, quiet, and leisurely. Avoid distractions.
- Listen to soothing music and sip a nutritious drink during feedings.
- Initially, nurse the newborn every few hours to stimulate milk production. Remember that the supply of milk is equal to the demand—the more sucking, the more milk.
- Watch for signals from the infant to indicate that he or she is hungry, such as:
  - Nuzzling against the mother's breasts
  - Demonstrating the rooting reflex by making sucking motions
  - Placing fist or hands in mouth to suck on
  - Crying and squirming
  - Smacking the lips
- Stimulate the rooting reflex by touching the newborn's cheek to initiate sucking.
- Look for signs indicating that the newborn has latched on correctly: wide-open mouth with the nipple and much of the areola in the mouth, lips rolled outward, and tongue over lower gum, visible jaw movement drawing milk out, rhythmic sucking with an audible swallowing (soft "ka" or "ah" sound indicates the infant is swallowing milk).
- Hold the newborn closely, facing the breast, with the newborn's ear, shoulder, and hip in direct alignment.
- Nurse the infant on demand, not on a rigid schedule. Feed every 2 to 3 hours within a 24-hour period for a total of 8 to 12 feedings.
- Alternate the breast you offer first; identify with a safety pin on bra.
- Vary your position for each feeding to empty breasts and reduce soreness.
- Look for signs that the newborn is getting enough milk:
  - At least six wet diapers and two to five loose yellow stools daily
  - Steady weight gain after the first week of age
  - Pale-yellow urine, not deep yellow or orange
  - Sleeping well, yet looks alert and healthy when awake
- Wake up the newborn if he or she has nursed less than 5 minutes by unwrapping him or her.
- Before removing the baby from the breast, break the infant's suction by inserting a finger.
- Burp the infant to release air when changing breasts and at the end of the breast-feeding session.
- Avoid supplemental formula-feedings to prevent "nipple confusion."
- Do not take drugs or medications unless approved by the health care provider.
- Avoid drinking alcohol or caffeinated drinks because they pass through milk.
- Do not smoke while breast-feeding; it increases the risk of sudden infant death syndrome.
- Always wash your hands before expressing or handling milk to store.
- Wear nursing bras and clothes that are easy to undo.

Adapted from American Academy of Pediatrics. (2010a). *AAP policy on breastfeeding and use of human milk*. Retrieved from <http://www.aap.org/breastfeeding/policyOnBreastfeedingAndUseOfHumanMilk.html>; and Walker, M. (2011). *Breastfeeding management for the clinician: Using the evidence* (2nd ed.). Sudbury, MA: Jones & Bartlett.

FIGURE 18.25 Hand-held breast pump.

**Common Breast-Feeding Concerns.** Breast-feeding women may experience problems such as cracked nipples, engorgement, or mastitis. Breast-feeding should not be painful for the mother. If she has sore, cracked nipples, the first step is to find the cause. Incorrect positioning or latching-on, removing the infant from the breast without first breaking the suction, or wearing a bra that is too tight can cause cracked or sore nipples. Cracked nipples can increase the risk of mastitis because a break in the skin may allow *Staphylococcus aureus* or other organisms to enter the body.

Sore nipples usually are caused by improper infant attachment, which traumatizes the tissue. The nurse should review techniques for proper positioning and latching-on. Recommend the following to the mother:

- Use only water, not soap, to clean the nipples to prevent dryness.
- Express some milk before feeding to stimulate the milk ejection reflex.
- Avoid using breast pads with plastic liners, and change pads when they are wet.
- Wear a comfortable bra that is not too tight.
- Apply a few drops of breast milk to the nipples after feeding.
- Rotate positions when feeding the infant to promote complete breast emptying.
- Leave the nursing bra flaps down after feeding to allow nipples to air-dry.
- Inspect the nipples daily for redness or cracks (Holmes & Howard, 2010).

To ease nipple pain and trauma, reinforce appropriate latching-on techniques and remind the woman

about the need to break the suction at the breast before removing the newborn from the breast. Additional measures may include applying cold compresses over the area and massaging breast milk onto the nipple after feeding.

Engorgement may occur as the milk comes in around day 3 or 4 after birth of the newborn. Explain to the mother that engorgement, though uncomfortable, is self-limited and will resolve as the newborn continues to nurse. The mother should continue to nurse during engorgement to avoid a plugged milk duct, which could lead to mastitis. Provide the following tips for relieving engorgement:

- Take warm to hot showers to encourage milk release.
- Express some milk manually before breast-feeding.
- Wear a supportive nursing bra 24 hours a day to provide support.
- Feed the newborn in a variety of positions—sitting up and then lying down.
- Massage the breasts from under the axillary area down toward the nipple.
- Increase the frequency of feedings.
- Apply warm compresses to the breasts prior to nursing.
- Stay relaxed while breast-feeding.
- Use a breast pump if nursing or manual expression is not effective.
- Remember that this condition is temporary and resolves quickly.

Mastitis, or inflammation of the breast, causes flu-like symptoms, chills, fever, and malaise. These symptoms may occur before the development of soreness, aching, swelling, and redness in the breast (usually the upper outer quadrant). This condition usually occurs in just one breast when a milk duct becomes blocked, causing inflammation, or through a cracked or damaged nipple, allowing bacteria to infect a portion of the breast. Treatment consists of rest, warm compresses, antibiotics, breast support, and continued breast-feeding (the infection will not pass into the breast milk). Explain to the mother that it is important to keep the milk flowing in the infected breast, whether it is through nursing or manual expression or with a breast pump.

#### FORMULA-FEEDING

Despite the general acknowledgment that breast-feeding is the most desirable means of feeding infants, about 40% of mothers choose formula-feeding and need education about this procedure. Formula-fed infants grow more rapidly than breast-fed infants not only in weight but also in length.

Formula-feeding requires more than just opening, pouring, and feeding. Parents need information about the types of formula available, preparation and storage of formula, equipment, feeding positions, and the amount to feed their newborn. The mother also needs to know how to prevent lactation (see Chapter 16 for more information).

Commercially prepared formulas are regulated by the Food and Drug Administration, which sets minimum and maximum levels of nutrients. Formulas are manufactured by numerous manufacturers in the United States. Normal full-term infants usually receive conventional cow's milk-based formula, but the health care provider makes this decision. If the infant shows signs of a reaction or lactose intolerance, a switch to another formula type is recommended. The general recommendation is for all infants to receive iron-fortified formula until the age of 1 year. The latest generation of infant formulas includes some fortification with docosahexaenoic acid (DHA) and arachidonic acid (ARA), two natural components of breast milk. Researchers have found that formulas with DHA and ARA can enhance visual and cognitive development and delay onset and reduced incidence of upper respiratory infections (URIs) and common allergic diseases up to 3 years of age in children (Birch et al., 2010).

Commercial formulas come in three forms: powder, concentrate, and easy to feed or ready to use. All are similar in terms of nutritional content but differ in expense. Powdered formula is the least expensive, with concentrated formula the next most expensive. Both must be mixed with water before using. Ready-to-feed formula is the most expensive; it can be opened and poured into a bottle and fed directly to the infant.

Parents need information about the equipment needed for formula-feeding. Basic supplies are four to six 4-oz bottles, eight to ten 8-oz bottles, eight to ten nipple units, a bottle brush, and a nipple brush. A key area of instruction is assessing for flow of formula through the nipple and checking for any nipple damage. When the bottle is filled and turned upside down, the flow from the nipple should be approximately one drop per second. If the parents are using bottles with disposable bags, instruct them to make sure they have a tight-fitting nipple to prevent leaks. Frequent observation of the flow rate from the nipple and the condition of the nipple will prevent choking and aspiration associated with too fast a rate of delivery. Ask the parents to fill a bottle with formula and then turn it upside down and observe the rate at which the formula drips from the bottle. If it is too fast (more than one drop/second), then the nipple should be replaced.

Correct formula preparation is critical to the newborn's health and development. Mistakes in dilution may result if the parents do not understand how to prepare the formula or make measurement errors. The safety of the water supply should be considered. If well water is used, parents should sterilize the water by boiling it or should use bottled water. Many health care providers still recommend that all water used in formula preparation be brought to a rolling boil for 1 to 2 minutes and then cooled to room temperature before use.

Opened cans of ready-made or concentrated formula should be covered and refrigerated after being prepared for the day (24 hours). Instruct parents to discard any unused portions after 48 hours.

### Take Note!

Any formula left in the bottle after feeding should also be discarded, because the infant's saliva has been mixed with it.

To warm refrigerated formula, advise the parents to place the bottle in a pan of hot water or an electric bottle warmer and test the temperature by letting a few drops fall on the inside of the wrist. If it is comfortably warm to the mother, it is the correct temperature.

**Formula-Feeding Assistance.** The process of feeding a newborn formula from a bottle should mirror breast-feeding as closely as possible. Although nutrition is important, so are the emotional and interactive components of feeding. Encourage parents to cuddle their newborn closely and position him or her so that the head is in a comfortable position, not too far back or turned, which makes swallowing difficult (Fig. 18.26). Also urge parents to communicate with their newborn during the feedings by talking and singing to him or her.

Although it may seem that bottle-feeding is not a difficult task, many new parents find it awkward. At first glance, holding an infant and a bottle appears simple enough, but both the position of the baby and the angle of the bottle must be correct.

**FIGURE 18.26** Father holding his newborn securely while feeding.

**Formula-Feeding Positions.** Advise mothers to feed their newborns in a relaxed and quiet setting to create a sense of calm for themselves and the baby. Make sure that comfort is a priority for both mother and newborn. The mother can sit in a comfortable chair, using a pillow to support the arm in which she is holding the baby. The mother can cradle the newborn in a semi-upright position, supporting the newborn's head in the crook of her arm. Holding the newborn close during feeding provides stimulation and helps prevent choking. Holding the newborn's head raised slightly will help prevent formula from washing backward into the eustachian tubes in the ears, which can lead to an ear infection.

**Formula-Feeding Education.** Parents require teaching about the correct preparation and storage of formula as well as the techniques for feeding. See Teaching Guidelines 18.5.

### Teaching Guidelines 18.5

#### FORMULA-FEEDING

- Wash your hands with soap and water before preparing formula.
- Mix the formula and water amounts exactly as the label specifies.
- Always hold the newborn and bottle during feedings; never prop the bottle.
- Never freeze formula or warm it in the microwave.
- Place refrigerated formula in a pan of hot water for a few minutes to warm.
- Test the temperature of the formula by shaking a few drops on the wrist.
- Hold the bottle like a pencil, keeping it tipped to prevent air from entering. Position the bottle so that the nipple remains filled with milk.
- Burp the infant after every few ounces to allow air swallowed to escape.
- Move the nipple around in the infant's mouth to stimulate sucking.
- Always keep a bulb syringe close by to use if choking occurs.
- Avoid putting the infant to bed with a bottle to prevent "baby bottle tooth decay."
- Feed the newborn approximately every 3 to 4 hours.
- Use an iron-fortified formula for the first year.
- Prepare enough formula for the next 24 hours.
- Check nipples regularly and discard any that are sticky, cracked, or leaking.
- Store unmixed, open liquid formula in the refrigerator for up to 48 hours.
- Throw away any formula left in the bottle after each feeding.

Proper positioning makes bottle-feeding easier and more enjoyable for both mother and newborn. As in breast-feeding, frequent burping is key. Advise the parents to hold the bottle so that formula fills the nipple, thus allowing less air to enter. Infants get fussy when they swallow air during feedings and need to be relieved of it every 2 to 3 oz.

Emphasize to parents that an electrolyte imbalance can occur in infants who are fed formula that has been incorrectly mixed. Hyponatremia can result from formula that is mixed too thickly; the high concentration of sodium is too much for the baby's immature kidneys to handle. As a result, sodium is excreted along with water, leading to dehydration. Mixing the formula with too much water in an effort to save money can lead to failure to thrive and lack of weight gain (Hormann, 2010).

### Preparing for Discharge

Preparing the parents for discharge is an essential task for the nurse. Because of today's shorter hospital stays, the nurse must identify the major teaching topics that need to be covered. Nurses should assess the parents' baseline knowledge and learning needs and plan how to meet them. Using the following principles fosters a learner-centered approach:

- Make the environment conducive to learning. Encourage the parents to feel comfortable during this intense time by using support and praise.
- Allow the parents to provide input about the content and the process of learning. What do they want and need to learn?
- Build the parents' self-esteem by confirming that their responses to the entire birthing process and aftercare are legitimate, and others have felt the same way.
- Ensure that what the parents learn is relevant to their day-to-day home situation.
- Encourage responsibility by reinforcing that their emotional and physical responses are within the normal range.
- Respect cultural beliefs and practices that are important to the family by taking into account their heritage and health beliefs regarding newborn care. Examples include placing a bellyband over the newborn's navel (Hispanics and African Americans), delaying naming the newborn (Asian Americans and Haitians), and delaying breast-feeding (Native Americans; they regard colostrum as "bad") (Bowers, 2012).

While in the hospital, women have ready access to support and hands-on instruction regarding feeding and newborn care. When the new mother is discharged, this close supervision and support by nurses should not end abruptly. Providing the new parents with the phone number of the mother-baby unit will help them

through this stressful transitional period. Giving the new family information and offering backup support via the telephone will increase parenting success.

### Consider This

I have always prided myself on being very organized and in control in most situations, but survival at home after childbirth wasn't one of them. I left the hospital 24 hours after giving birth to my son because my doctor said I could. The postpartum nurse encouraged me to stay longer, but wanting to be in control and sleeping in my own bed again won out. I thought my baby would be sleeping while I sent out birth announcements to my friends and family—wrong! What happened instead was my son didn't sleep as I imagined and my nipples became sore after breast-feeding every few hours. I was weary and tired and wanted to sleep, but I couldn't. Somehow I thought I would be getting a full night's sleep because I was up throughout the day, but that was a fantasy too. At 2 o'clock in the morning when you are up feeding your baby, you feel you are the only one in the world up at that time and feel very much alone. My feelings of being organized and in control all the time have changed dramatically since I left the hospital. I have learned to yield to the important needs of my son and derive satisfaction from being able to bring comfort to him and to let go of my control.

Thoughts: It is interesting to see how a newborn changed this woman's need to organize and control her environment. What "tips of survival" could the nurse offer this woman to help in her transition to home with her newborn? How can friends and family help when women arrive home from the hospital with their newborns?

### ENSURING FOLLOW-UP CARE

Most newborns are scheduled for their first health follow-up appointment within 2 to 4 days after discharge so they can have additional laboratory work done as part of the newborn screening series, especially if they were discharged within 48 hours. After this first visit, the typical schedule of health care visits is as follows: 2 to 4 weeks of age; 2, 4, and 6 months of age for checkups and vaccines; 9 months of age for a checkup; 12 months for a checkup and tuberculosis testing; 15 and 18 months for checkups and vaccines; and 2 years of age for a checkup. These appointments provide an opportunity for parents to ask questions and receive anticipatory guidance as their newborn grows and develops.

In addition to encouraging parents to keep follow-up appointments, advise parents to call their health care provider if they notice signs of illness in their newborn. They should know which over-the-counter medicines

should be kept on hand. Review the following warning signs of illness with parents:

- Temperature of 101° F (38.3° C) or higher
- Forceful, persistent vomiting, not just spitting up
- Refusal to take feedings
- Two or more green, watery diarrheal stools
- Infrequent wet diapers and change in bowel movements from normal pattern
- Lethargy or excessive sleepiness
- Inconsolable crying and extreme fussiness
- Abdominal distention
- Difficult or labored breathing

### PROVIDING IMMUNIZATION INFORMATION

Parents also need instructions about immunizations for their newborn. **Immunization** is the process of rendering an individual immune or of becoming immune to certain communicable diseases (WebMD, 2011). The purpose of the immune system is to identify unknown (nonself) substances in the body and develop a defense against these invaders. Disease prevention by immunization is a public health priority and is one of the leading health indicators as part of *Healthy People 2020*. Despite many advances in vaccine delivery, the goal of universal immunization has not been reached (AAP, 2010b). Nurses can help to meet this national goal by educating new parents about the importance of disease prevention through immunizations.

Immunity can be provided either passively or actively. Passive immunity is protection transferred via already formed antibodies from one person to another. Passive immunity includes transplacental passage of antibodies from a mother to her newborn, immunity passed through breast milk, and immunity from immunoglobulins. Passive immunity provides limited protection and decreases over a period of weeks or months (Jana & Shu, 2010). Active immunity is protection produced by an individual's own immune system. It can be obtained by having the actual disease or by receiving a vaccine that produces an immunologic response by that person's body. Active immunity may be lifelong either way.

The newborn's first immunization (hepatitis B) is received in the hospital soon after birth. The first dose can also be given by age 2 months if the mother is HbsAg negative. If the mother is HbsAg positive, then the newborn should receive hepatitis B vaccine and hepatitis B immunoglobulin within 12 hours of birth (Cunningham et al., 2010).

Education for the parents should include the risks and benefits for each vaccine and possible adverse effects. Federal law requires a consent form to be signed before administering a vaccine. Parents have the right to refuse immunizations based on their religious beliefs and can sign a waiver noting their decision. When consent has been received, the nurse administering the

vaccine must document the date and time it was given, name and manufacturer, lot number and expiration date of the vaccine given, site and route of administration, and the name and title of the nurse who administered the vaccine.

### KEY CONCEPTS

- The period of transition from intrauterine to extrauterine life occurs during the first several hours after birth. It is a time of stabilization for the newborn's temperature, respiration, and cardiovascular dynamics.
- The newborn's bowel is sterile at birth. It usually takes about a week for the newborn to produce vitamin K in sufficient quantities to prevent VKDB.
- It is recommended that all newborns in the United States receive an installation of a prophylactic agent (erythromycin or tetracycline ophthalmic ointment) in their eyes within an hour or two of being born.
- Nursing measures to maintain newborns' body temperature include drying them immediately after birth to prevent heat loss through evaporation, wrapping them in prewarmed blankets, putting a hat on their head, and placing them under a temperature-controlled radiant warmer.
- The specific components of a typical newborn examination include a general survey of skin color, posture, state of alertness, head size, overall behavioral state, respiratory status, gender, and any obvious congenital anomalies.
- Gestational age assessment is pertinent because it allows the nurse to plot growth parameters and to anticipate potential problems related to prematurity/postmaturity and growth abnormalities such as SGA/LGA.
- After the newborn has passed the transitional period and stabilized, the nurse needs to complete ongoing assessments, vital signs, weight and measurements, cord care, hygiene measures, newborn screening tests, and various other tasks until the newborn is discharged home from the birthing unit.
- Important topics about which to educate parents include environmental safety, newborn characteristics, feeding and bathing, circumcision and cord care, sleep and elimination patterns of newborns, safe infant car seats, holding/positioning, and follow-up care.
- Newborn screening tests consist of hearing and certain genetic and inborn errors of metabolism tests required in most states for newborns before discharge from the birth facility.
- The AAP and the American Dietetic Association recommend breast-feeding exclusively for the first 6 months of life and that it continue along with other food at least until the first birthday.
- Parents who choose not to breast-feed need to know what types of formula are available, preparation and storage of formula, equipment, feeding positions, and how much to feed their infant.
- Common problems associated with the newborn include transient tachypnea, physiologic jaundice, and hypoglycemia.
- Transient tachypnea of the newborn appears soon after birth; is accompanied by retractions, expiratory grunting, or cyanosis; and is relieved by low-dose oxygen.
- Physiologic jaundice is a very common condition in newborns, with the majority demonstrating yellowish skin, mucous membranes, and sclera within the first 3 days of life. Newborns undergoing phototherapy in the treatment of jaundice require close monitoring of their body temperature and fluid and electrolyte balance; observation of skin integrity; eye protection; and parental participation in their care.
- The newborn with hypoglycemia requires close monitoring for signs and symptoms of hypoglycemia if present. In addition, newborns at high risk need to be identified based on their perinatal history, physical examination, body measurements, and gestational age. Blood glucose levels of all newborns are checked within the first few hours after birth and every 4 hours thereafter.
- The schedule for immunizations should be reviewed with parents, stressing the importance of continual follow-up health care to preserve their infant's health.

## MULTIPLE-CHOICE QUESTIONS

- At birth, a newborn's assessment reveals the following: heart rate of 140 bpm, loud crying, some flexion of extremities, crying when bulb syringe is introduced into the nares, and a pink body with blue extremities. The nurse would document the newborn's Apgar score as:
  - 5 points
  - 6 points
  - 7 points
  - 8 points
- The nurse is explaining phototherapy to the parents of a newborn. The nurse would include which of the following as the purpose?
  - Increase surfactant levels
  - Stabilize the newborn's temperature
  - Destroy Rh-negative antibodies
  - Oxidize bilirubin on the skin
- The nurse administers a single dose of vitamin K intramuscularly to a newborn after birth to promote:
  - Conjugation of bilirubin
  - Blood clotting
  - Foreman ovale closure
  - Digestion of complex proteins
- A prophylactic agent is instilled in both eyes of all newborns to prevent which of the following conditions?
  - Gonorrhea and chlamydia
  - Thrush and Enterobacter
  - Staphylococcus* and syphilis
  - Hepatitis B and herpes
- The AAP recommends that all newborns be placed on their backs to sleep to reduce the risk of:
  - Respiratory distress syndrome
  - Bottle mouth syndrome
  - Sudden infant death syndrome
  - GI regurgitation syndrome
- Which one of the following immunizations is most commonly received by newborns before hospital discharge?
  - Pneumococcus
  - Varicella
  - Hepatitis A
  - Hepatitis B
- Which condition would be missed if a newborn were screened before he had tolerated protein feedings for at least 48 hours?
  - Hypothyroidism
  - Cystic fibrosis
  - Phenylketonuria
  - Sickle cell disease

## CRITICAL THINKING EXERCISES

- Linda Scott, an African American mother who delivered her first baby and is on the mother–baby unit, calls the nursery nurse into her room and expresses concern about how her daughter looks. Ms. Scott tells the nurse that her baby's head looks like a “banana” and is mushy to the touch, and she has “white spots” all over her nose. In addition, there appear to be “big bluish bruises” all over her baby's buttocks. She wants to know what is wrong with her baby and whether these problems will go away.
  - How should the nurse respond to Ms. Scott's questions?
  - What additional newborn instruction might be appropriate at this time?
  - What reassurance can be given to Ms. Scott regarding her daughter's appearance?
- At approximately 12:30 AM on a Friday, a woman enters a hospital through a busy emergency department. She is wearing a white uniform and a lab coat with a stethoscope around her neck. She identifies herself as a new nurse coming back to check on something she had left on the unit on an earlier shift. She enters a postpartum client's room containing the mother's newborn, pushes the open crib down a hallway, and escapes through an exit. The security cameras aren't working. The infant isn't discovered missing until the 2 AM check by the nurse.
  - What impact does an infant abduction have on the family and the hospital?
  - What security measure was the weak link in the chain of security?
  - What can hospitals do to prevent infant abduction?

## STUDY ACTIVITIES

- Obtain a set of vital signs (temperature, pulse, respiration) of a newborn on admission to the nursery. Repeat this procedure and compare changes in the values several hours later. Discuss what changes in the vital signs you would expect during this transitional period.
- Interview a new mother on the postpartum unit on her second day about the changes she has noticed in her newborn's appearance and behavior within the past 24 hours. Discuss your interview findings at post conference.
- Demonstrate a newborn bath to a new mother in her room, using the principle of bathing from the cleanest to the dirtiest body part. Discuss the questions asked by the mother and her reaction to the demonstration in post conference.

4. Go to the La Leche League web site (refer to [thePoint](#)). Review the information it provides on breast-feeding. How helpful would it be to a new mother?
5. Debate the risks and benefits of neonatal circumcision within your nursing group at postconference. Did either side present a stronger position? What is your opinion, and why?

## Nursing Management of Pregnancy at Risk: Pregnancy-Related Complications

### Learning Objectives

Upon completion of the chapter, you will be able to:

1. Define the key terms used in this chapter.
2. Evaluate the term “high-risk pregnancy.”
3. Determine the common factors that might place a pregnancy at high risk.
4. Detect the causes of vaginal bleeding during early and late pregnancy.
5. Outline nursing assessment and management for the pregnant woman experiencing vaginal bleeding.
6. Develop a plan of care for the woman experiencing preeclampsia, eclampsia, and HELLP syndrome.
7. Examine the pathophysiology of hydramnios and subsequent management.
8. Evaluate factors in a woman’s prenatal history that place her at risk for premature rupture of membranes (PROM).
9. Formulate a teaching plan for maintaining the health of pregnant women experiencing a high-risk pregnancy.

*Helen, a 35-year-old G5 P4, presented to the labor and birth suite with severe abdominal pain. She reports that the pain began suddenly about an hour ago while she was resting. She has had two prior cesarean births and thus far has had an uneventful past 32 weeks. Helen appears distressed and is moaning. What additional assessments do you need to do to care for Helen? What might be your immediate nursing action?*

### Words of Wisdom

Detours and bumps along the road of life can be managed, but many cannot be entirely cured.

**Most** people view pregnancy as a natural process with a positive outcome—the birth of a healthy newborn. Unfortunately, conditions can occur that may result in negative outcomes for the fetus, mother, or both. A **high-risk pregnancy** is one in which a condition exists that jeopardizes the health of the mother, her fetus, or both. The condition may result from the pregnancy, or it may be a condition that was present before the woman became pregnant.

Approximately one in four pregnant women is considered to be at high risk or diagnosed with complications (Gilbert, 2011). Women who are considered to be at high risk have a higher morbidity and mortality compared with mothers in the general population. The risk status of a woman and her fetus can change during the pregnancy, with a number of problems occurring during labor, birth, or afterward, even in women without any known previous antepartal risk. Examples of high-risk conditions include gestational diabetes and ectopic pregnancy. Many obstetric complications and conditions are life-threatening emergencies with high morbidity and mortality rates. It is essential that these be identified early to ensure the best possible outcome for the mother and infant. These conditions are specifically addressed in *Healthy People 2020* (U.S. Department of Health and Human Services, 2010). Early identification of the woman at risk is essential to ensure that appropriate interventions are instituted promptly, increasing the opportunity to change the course of events and provide a positive outcome.

The term *risk* may mean different things to different groups. For example, health care professionals may focus on the disease processes and treatments to

prevent complications. Nurses may focus on nursing care and on the psychosocial impact on the woman and her family. Insurance companies may concentrate on the economic issues related to the high-risk status. The woman's attention may be focused on her own needs and those of her family. Together, working as a collaborative team, the ultimate goal of care is to ensure the best possible outcome for the woman, her fetus, and her family.

Risk assessment begins at the first antepartal visit and continues with each subsequent visit because factors may be identified in later visits that were not apparent during earlier visits. For example, as the nurse and client develop a trusting relationship, previously unidentified or unsuspected factors (such as drug abuse or intimate partner violence) may be revealed. Through education and support, the nurse can encourage the client to inform her health care provider of these concerns, and necessary interventions or referrals can be made.

Various factors must be considered when determining a woman's risk for adverse pregnancy outcomes, and a comprehensive approach to high-risk pregnancy is needed. For example, prenatal stress and distress have been shown to have significant consequences for the mother, child, and family (Dunkel, & Tanner, 2012). Risks are grouped into broad categories based on threats to health and pregnancy outcome. Current categories of risk are biophysical, psychosocial, sociodemographic, and environmental (Gilbert, 2011) (Box 19.1).

This chapter describes the major conditions directly related to pregnancy that can complicate a pregnancy, possibly affecting maternal and fetal outcomes. These include bleeding during pregnancy (spontaneous abortion, ectopic pregnancy, gestational trophoblastic disease, cervical insufficiency, placenta previa, abruptio placentae, and placenta accreta), hyperemesis gravidarum, gestational hypertension, HELLP syndrome, gestational diabetes, blood incompatibility, amniotic fluid imbalances (hydramnios and oligohydramnios), multiple gestation, and premature rupture of membranes. Chapter 20 addresses preexisting conditions that can complicate a woman's pregnancy as well as populations that are considered to be at high risk.

## HEALTHY PEOPLE 2020 • 19-1

### Objective

**MICH-6** Reduce maternal illness and complications due to pregnancy (complications during hospitalized labor and delivery).

**MICH-9** Reduce preterm births.

### Nursing Significance

Will reduce perinatal morbidity and mortality and optimize pregnancy outcomes.

Will help to preserve the health and well-being of the growing fetus if the pregnancy goes to term.

*Healthy People* objectives based on data from <http://www.healthypeople.gov>.

## BLEEDING DURING PREGNANCY

Bleeding at any time during pregnancy is potentially life threatening. Every minute of every day, a woman dies in pregnancy or childbirth. The biggest killer is obstetric hemorrhage, the successful treatment of which is a challenge for both the developed and developing worlds.

## BOX 19.1

**FACTORS PLACING A WOMAN AT RISK DURING PREGNANCY****Biophysical Factors**

- Genetic conditions
- Chromosomal abnormalities
- Multiple pregnancy
- Defective genes
- Inherited disorders
- ABO incompatibility
- Large fetal size
- Medical and obstetric conditions
- Preterm labor and birth
- Cardiovascular disease
- Chronic hypertension
- Incompetent cervix
- Placental abnormalities
- Infection
- Diabetes
- Maternal collagen diseases
- Thyroid disease
- Asthma
- Post-term pregnancy
- Hemoglobinopathies
- Nutritional status
- Inadequate dietary intake
- Food fads
- Excessive food intake
- Under- or overweight status
- Hematocrit value less than 33%
- Eating disorder

**Psychosocial Factors**

- Smoking
- Caffeine
- Alcohol and substance abuse
- Maternal obesity
- Inadequate support system
- Situational crisis
- History of violence
- Emotional distress
- Unsafe cultural practices

**Sociodemographic Factors**

- Poverty status
- Lack of prenatal care
- Age younger than 15 years or older than 35 years
- Parity—all first pregnancies and more than five pregnancies
- Marital status—increased risk for unmarried women

- Accessibility to health care
- Ethnicity—increased risk in nonwhite women

**Environmental Factors**

- Infections
- Radiation
- Pesticides
- Illicit drugs
- Industrial pollutants
- Second-hand cigarette smoke
- Personal stress

Adapted from Gilbert, E. S. (2011). *Manual of high-risk pregnancy and delivery* (5th ed.). St. Louis, MO: Mosby Elsevier; and Gardner, S. L., Carter, B. S., Enzman-Hines, M., & Hernandez, J. A. (2011). *Merenstein & Gardner's handbook of neonatal intensive care* (7th ed.). St. Louis, MO: Mosby Elsevier.

The presence of an attendant at every birth and access to emergency obstetric care are strategic to reducing maternal morbidity and mortality (Murthy & Smith, 2010). Management of obstetric hemorrhage involves early recognition, assessment, and resuscitation. Various methods are available to try to stop the bleeding, ranging from pharmacologic methods to aid uterine contraction (e.g., oxytocin, ergometrine, and prostaglandins) to surgical methods to stem the bleeding (e.g., balloon tamponade, compression sutures, or arterial ligation). Bleeding can occur early or late in the pregnancy and may result from numerous conditions. Conditions commonly associated with early bleeding (first half of pregnancy) include spontaneous abortion, ectopic pregnancy, gestational trophoblastic disease, and cervical insufficiency. Conditions associated with late bleeding include placenta previa, abruptio placentae, and placenta accreta, which usually occur after the 20th week of gestation.

**Spontaneous Abortion**

An **abortion** is the loss of an early pregnancy, usually before week 20 of gestation. Abortion can be spontaneous or induced. A spontaneous abortion refers to the loss of a fetus resulting from natural causes—that is, not elective or therapeutically induced by a procedure. Nonmedical people often use the term *miscarriage* to denote an abortion that has occurred spontaneously. A miscarriage can occur during early pregnancy, and many women who miscarry may not even be aware that they are pregnant. About 80% of spontaneous abortions occur within the first trimester. The terms *stillbirth* and *miscarriage* can sometimes be confusing. Both refer to the loss of an early pregnancy; however, stillbirth occurs later in pregnancy.

A stillbirth is the loss of a fetus after the 20th week of development, whereas a miscarriage refers to a loss before the 20th week. Some stillbirths can occur right up to the time of labor and delivery. Stillbirths are much less common than miscarriages, occurring in only 1 out of every 160 pregnancies (March of Dimes, 2011g).

The overall rate for spontaneous abortion in the United States is reported to be 15% to 20% of recognized pregnancies in the United States. However, with the development of highly sensitive assays for human chorionic gonadotropin (hCG) levels that detect pregnancies prior to the expected next menses, the incidence of pregnancy loss increases significantly—to about 60% to 70% (Puscheck, 2012). The frequency of spontaneous abortion increases further with maternal age.

## Pathophysiology

The causes of spontaneous abortion are varied and often unknown. The most common cause for first-trimester abortions is fetal genetic abnormalities, usually unrelated to the mother. Chromosomal abnormalities are more likely causes in the first trimester and maternal disease is more likely in the second trimester. Those occurring during the second trimester are more likely related to maternal conditions, such as cervical insufficiency, congenital or acquired anomaly of the uterine cavity (uterine septum or fibroids), hypothyroidism, diabetes mellitus, chronic nephritis, use of crack cocaine, inherited and acquired thrombophilias, lupus, polycystic ovary syndrome, severe hypertension, and acute infection such as rubella virus, cytomegalovirus, herpes simplex virus, bacterial vaginosis, and toxoplasmosis (Silver, Branch, Goldenberg, Iams, & Klebanoff, 2011).

Women experiencing a first-trimester abortion at home without a dilation and curettage (D&C) to resolve it require frequent monitoring of hCG levels to validate that all the conceptus tissues have been expelled. Women going through a second-trimester abortion are admitted to the hospital to have an augmented labor and delivery. Nursing care would focus on care of the laboring women with tremendous attention paid to providing emotional support to the woman and her family.

## Nursing Assessment

When a pregnant woman calls and reports vaginal bleeding, she must be seen as soon as possible by a health care professional to ascertain the etiology. Varying degrees of vaginal bleeding, low back pain, abdominal cramping, and passage of products of

conception tissue may be reported. Ask the woman about the color of the vaginal bleeding (bright red is significant) and the amount—for example, question her about the frequency with which she is changing her peripads (saturation of one peripad hourly is significant) and the passage of any clots or tissue. Instruct her to save any tissue or clots passed and bring them with her to the health care facility. Also, obtain a description of any other signs and symptoms the woman may be experiencing, along with a description of their severity and duration. It is important to remain calm and listen to the woman's description.

When the woman arrives at the health care facility, assess her vital signs and observe the amount, color, and characteristics of the bleeding. Ask her to rate her current pain level, using an appropriate pain assessment tool. Also, evaluate the amount and intensity of the woman's abdominal cramping or contractions, and assess the woman's level of understanding about what is happening to her. A thorough assessment helps in determining the type of spontaneous abortion, such as threatened abortion, inevitable abortion, incomplete abortion, complete abortion, missed abortion, and habitual abortion, that the woman may be experiencing (Table 19.1).

## Nursing Management

Nursing management of the woman with a spontaneous abortion focuses on providing continued monitoring and psychological support, for the family is experiencing acute loss and grief. An important component of this support is reassuring the woman that spontaneous abortions usually result from an abnormality and that her actions did not cause the abortion.

### Providing Continued Monitoring

Continued monitoring and ongoing assessments are essential for the woman experiencing a spontaneous abortion. Monitor the amount of vaginal bleeding through pad counts and observe for passage of products of conception tissue. Assess the woman's pain and provide appropriate pain management to address the cramping discomfort.

Assist in preparing the woman for procedures and treatments such as surgery to evacuate the uterus or medications such as misoprostol or PGE<sub>2</sub>. If the woman is Rh negative and not sensitized, expect to administer RhoGAM within 72 hours after the abortion is complete. Drug Guide 19.1 gives more information about these medications.

TABLE 19.1

## CATEGORIES OF ABORTION

Category	Assessment Findings	Diagnosis	Therapeutic Management
Threatened abortion	Vaginal bleeding (often slight) early in a pregnancy No cervical dilation or change in cervical consistency Mild abdominal cramping Closed cervical os No passage of fetal tissue	Vaginal ultrasound to confirm if sac is empty Declining maternal serum hCG and progesterone levels to provide additional information about viability of pregnancy	Conservative supportive treatment Possible reduction in activity in conjunction with nutritious diet and adequate hydration
Inevitable abortion	Vaginal bleeding (greater than that associated with threatened abortion) Rupture of membranes Cervical dilation Strong abdominal cramping Possible passage of products of conception	Ultrasound and hCG levels to indicate pregnancy loss	Vacuum curettage if products of conception are not passed, to reduce risk of excessive bleeding and infection Prostaglandin analogs such as misoprostol to empty uterus of retained tissue (only used if fragments are not completely passed)
Incomplete abortion (passage of some of the products of conception)	Intense abdominal cramping Heavy vaginal bleeding Cervical dilation	Ultrasound confirmation that products of conception still in uterus	Client stabilization Evacuation of uterus via D&C or prostaglandin analog
Complete abortion (passage of all products of conception)	History of vaginal bleeding and abdominal pain Passage of tissue with subsequent decrease in pain and significant decrease in vaginal bleeding	Ultrasound demonstrating an empty uterus	No medical or surgical intervention necessary Follow-up appointment to discuss family planning
Missed abortion (nonviable embryo retained in utero for at least 6 weeks)	Absent uterine contractions Irregular spotting Possible progression to inevitable abortion	Ultrasound to identify products of conception in uterus	Evacuation of uterus (if inevitable abortion does not occur): suction curettage during first trimester, dilation and evacuation during second trimester Induction of labor with intravaginal PGE2 suppository to empty uterus without surgical intervention
Habitual abortion	History of three or more consecutive spontaneous abortions Not carrying the pregnancy to viability or term	Validation via client's history	Identification and treatment of underlying cause (possible causes such as genetic or chromosomal abnormalities, reproductive tract abnormalities, chronic diseases or immunologic problems) Cervical cerclage in second trimester if incompetent cervix is the cause

## DRUG GUIDE 19.1 MEDICATIONS USED WITH SPONTANEOUS ABORTIONS

Medication	Action/Indications	Nursing Implications
Misoprostol (Cytotec)	Stimulates uterine contractions to terminate a pregnancy; to evacuate the uterus after abortion to ensure passage of all the products of conception	<ul style="list-style-type: none"> <li>• Monitor for side effects such as diarrhea, abdominal pain, nausea, vomiting, dyspepsia.</li> <li>• Assess vaginal bleeding and report any increased bleeding, pain, or fever.</li> <li>• Monitor for signs and symptoms of shock, such as tachycardia, hypotension, and anxiety.</li> </ul>
Mifepristone (RU-486)	Acts as progesterone antagonist, allowing prostaglandins to stimulate uterine contractions; causes the endometrium to slough; may be followed by administration of misoprostol within 48 hours	<ul style="list-style-type: none"> <li>• Monitor for headache, vomiting, diarrhea, and heavy bleeding.</li> <li>• Anticipate administration of antiemetic prior to use to reduce nausea and vomiting.</li> <li>• Encourage client to use acetaminophen to reduce discomfort from cramping.</li> </ul>
PGE <sub>2</sub> , dinoprostone (Cervidil, Prepidil Gel, Prostin E2)	Stimulates uterine contractions, causing expulsion of uterine contents; to expel uterine contents in fetal death or missed abortion during second trimester, or to efface and dilate the cervix in pregnancy at term	<ul style="list-style-type: none"> <li>• Bring gel to room temperature before administering.</li> <li>• Avoid contact with skin.</li> <li>• Use sterile technique to administer.</li> <li>• Keep client supine for 30 min after administering.</li> <li>• Document time of insertion and dosing intervals.</li> <li>• Remove insert with retrieval system after 12 hr or at the onset of labor.</li> <li>• Explain purpose and expected response to client.</li> </ul>
Rh(D) immunoglobulin (Gamulin, HydroRho-D, RhoGAM, MICRhoGAM)	Suppresses immune response of nonsensitized Rh-negative clients who are exposed to Rh-positive blood; to prevent isoimmunization in Rh-negative women exposed to Rh-positive blood after abortions, miscarriages, and pregnancies	<ul style="list-style-type: none"> <li>• Administer intramuscularly in deltoid area.</li> <li>• Give only MICRhoGAM for abortions and miscarriages &lt;12 wk unless fetus or father is Rh negative (unless client is Rh positive, Rh antibodies are present).</li> <li>• Educate woman that she will need this after subsequent deliveries if newborns are Rh positive; also check lab study results prior to administering the drug.</li> </ul>

Adapted from King, T. L., & Brucker, M. C. (2011). *Pharmacology for women's health*. Sudbury, MA: Jones & Bartlett; and Skidmore-Roth, L. (2012). *Mosby's 2012 nursing drug reference* (25th ed.), Philadelphia, PA: Elsevier Health Science.

### Providing Support

A woman's emotional reaction may vary depending on her desire for this pregnancy and her available support network. Provide both physical and emotional support. In addition, prepare the woman and her family for the assessment process, and answer their questions about what is happening.

Explaining some of the causes of spontaneous abortions can help the woman to understand what is happening and may allay her fears and guilt that she did something to cause this pregnancy loss. Most women experience an acute sense of loss and go through a

grieving process with a spontaneous abortion. Providing sensitive listening, counseling, and anticipatory guidance to the woman and her family will allow them to verbalize their feelings and ask questions about future pregnancies.

The grieving period may last as long as 2 years after a pregnancy loss, with each person grieving in his or her own way. Encourage friends and family to be supportive but give the couple space and time to work through their loss. Referral to a community support group for parents who have experienced a miscarriage can be very helpful during this grief process.

## Ectopic Pregnancy

An **ectopic pregnancy** is any pregnancy in which the fertilized ovum implants outside the uterine cavity. The term *ectopic* is derived from the Greek word *ektōpos*, meaning “out of place,” and it refers to the implantation of a fertilized egg in a location outside of the uterine cavity, including the fallopian tubes, cervix, ovary, and the abdominal cavity. This abnormally implanted gestation grows and draws its blood supply from the site of abnormal implantation. As the gestation enlarges, it creates the potential for organ rupture because only the uterine cavity is designed to expand and accommodate fetal development. Ectopic pregnancy can lead to massive hemorrhage, infertility, or death. Ectopic pregnancies occur in 1 in every 50 pregnancies in the United States or roughly 2% of all pregnancies are diagnosed as ectopic; this rate has increased during the past 30 years (March of Dimes, 2011b). Their discovery prior to rupture has increased dramatically in the past few decades as a result of improved diagnostic techniques such as the development of sensitive and specific radioimmunoassays for hCG, high-resolution ultrasonography, and the widespread availability of laparoscopy (Kirk 2012).

With an ectopic pregnancy, rupture and hemorrhage may occur due to the growth of the embryo. A ruptured ectopic pregnancy is a medical emergency. It is a potentially life-threatening condition and involves pregnancy loss. Even in the United States, women can and do still die from ectopic pregnancy. Although recent data are lacking, the last comprehensive report from the Centers for Disease Control and Prevention (CDC) showed ectopic pregnancy to be the third most common pregnancy-related cause of death in the United States, accounting for 9% of all pregnancy-related deaths (Marion, & Rodney Meeks, 2012).

## Pathophysiology

Normally, the fertilized ovum implants in the uterus. In ectopic pregnancy the journey along the fallopian tube is arrested or altered in some way. With an ectopic pregnancy, the ovum implants outside the uterus. The most common site for implantation is the fallopian tubes, but some ova may implant in the ovary, the intestine, the cervix, or the abdominal cavity (Fig. 19.1) (Sepilian & Wood, 2012). None of these anatomic sites can accommodate placental attachment or a growing embryo.

Ectopic pregnancies usually result from conditions that obstruct or slow the passage of the fertilized ovum through the fallopian tube to the uterus. This may be a physical blockage in the tube, or failure of the tubal epithelium to move the zygote (the cell formed after the egg is fertilized) down the tube into the uterus. In the general population, most cases are the result of tubal scarring

**FIGURE 19.1** Possible sites for implantation with an ectopic pregnancy.

secondary to pelvic inflammatory disease. Organisms such as *Neisseria gonorrhoea* and *Chlamydia trachomatis* preferentially attack the fallopian tubes, producing silent infections. A recent study reported a twofold-increased risk for ectopic pregnancy in women with a history of a chlamydia infection, secondly to tubal damage (Shaw & Horne 2012). Other associated risk factors for ectopic pregnancy include previous tubal surgery, infertility, genital or pelvic inflammatory disease, previous pregnancy loss (induced or spontaneous), use of an intrauterine contraceptive device, previous ectopic pregnancy, uterine fibroids, sterilization, smoking, douching, and exposure to diethylstilbestrol (McQueen, 2011).

## Therapeutic Management

The diagnosis of ectopic pregnancy can be challenging because many women are asymptomatic before tubal rupture. Diagnostic procedures used for a suspected ectopic pregnancy include a urine pregnancy test to confirm the pregnancy, beta-hCG concentrations to exclude false negative urine test, and a transvaginal ultrasound to visualize the out-of-place pregnancy (Givens, & Lipscomb, 2012).

The therapeutic management of ectopic pregnancy depends on whether the tube is intact or has ruptured. Historically, the treatment of ectopic pregnancy was limited to surgery, but medical therapy is currently available.

If the fallopian tube is still intact, medical management becomes an option. To be eligible for medical therapy, the client must be hemodynamically stable, with no signs of active bleeding in the peritoneal cavity, and the mass (which must measure less than 4 cm as determined by ultrasound) must be unruptured (Marion, & Rodney,

Meeks, 2012). The potential advantages include avoidance of surgery, the preservation of tubal patency and function, and a lower cost. Methotrexate, prostaglandins, misoprostol, and actinomycin have all been used in the medical (nonsurgical) management of ectopic pregnancy, with a reported success rate of approximately 90%. Medical management with methotrexate, though not approved by the Food and Drug Administration for this purpose, has been endorsed by the American College of Obstetricians and Gynecologists.

Methotrexate in many cases is considered the treatment of choice over surgical intervention, especially in clients who are hemodynamically stable, and is the agent most commonly used. It is a folic acid antagonist that inhibits cell division in the developing embryo. It typically has been used as a chemotherapeutic agent in the treatment of leukemias, lymphomas, and carcinomas. It has been shown to produce results similar to that for surgical therapy in terms of high success rate, low complication rate, and good reproductive potential (Stika, 2012). Adverse effects associated with methotrexate include nausea, vomiting, stomatitis, diarrhea, gastric upset, increased abdominal pain, and dizziness. Methotrexate for an ectopic pregnancy is ordered based on the client's body surface area. The standard single dose is 50 mg/m<sup>2</sup> given intramuscularly. The administration of methotrexate should be limited to people who have had education and training in the handling and administration of hazardous drugs. In some facilities internal policies require that only nurses who have completed a chemotherapy certification and/or hazardous drug competency program can administer this product (Shastay & Paparella, 2010). Prior to receiving the single-dose intramuscular injection to treat unruptured pregnancies, the woman needs to be counseled on the risks, benefits, adverse effects, and the possibility of failure of medical therapy, which would result in tubal rupture, necessitating surgery (Shastay, & Paparella, 2010). The woman is then instructed to return weekly for follow-up laboratory studies for the next several weeks until beta-hCG titers decrease. Beta-hCG level changes between days 0 and 4 after methotrexate therapy have clinical significance and predictive value. A decreasing beta-hCG level is highly predictive of treatment success (Sagiv, Debbie, Feit, Cohen-Sacher et al., 2012).

Surgical management for the unruptured fallopian tube might involve a linear salpingostomy to preserve the tube—an important consideration for the woman wanting to preserve her future fertility. It may also be considered when medical treatment is considered unsuitable.

With a ruptured ectopic pregnancy, surgery is necessary as a result of possible uncontrolled hemorrhage. A laparotomy with a removal of the tube (salpingectomy) may be necessary. With earlier diagnosis and medical management, the focus has changed from preventing maternal death to facilitating rapid recovery and preserving fertility.

Regardless of the treatment approach (medical or surgical), the woman's beta-hCG level is monitored until it is undetectable to ensure that any residual trophoblastic tissue that forms the placenta is gone. Also, all Rh-negative unsensitized clients are given Rh immunoglobulin to prevent isoimmunization in future pregnancies.

## Nursing Assessment

Nursing assessment focuses on determining the existence of an ectopic pregnancy and whether or not it has ruptured. A woman with a suspected ectopic pregnancy may have to undergo several diagnostic tests, some of which are invasive. Consider how she might feel during all of these tests, anticipate her questions, and offer her thorough explanations and reassurances.

## Health History and Physical Examination

Assess the client thoroughly for signs and symptoms that may suggest an ectopic pregnancy. The onset of signs and symptoms varies, but they usually begin at about the seventh or eighth week of gestation. A missed menstrual period, adnexal fullness, and tenderness may indicate an unruptured tubal pregnancy. As the tube stretches, the pain increases. Pain may be unilateral, bilateral, or diffuse over the abdomen.

### Take Note!

The hallmark of ectopic pregnancy is abdominal pain with spotting within 6 to 8 weeks after a missed menstrual period. Although this is the classic triad, all three of these signs and symptoms occur in only about 50% of cases. Many women have symptoms typical of early pregnancy, such as breast tenderness, nausea, fatigue, shoulder pain, and low back pain.

In addition, review the client's history for possible contributing factors. These may include:

- Previous ectopic pregnancy
- History of sexually transmitted infections (STIs)
- Fallopian tube scarring from pelvic inflammatory disease
- In utero exposure to diethylstilbestrol
- Endometriosis
- Previous tubal or pelvic surgery
- Infertility and infertility treatments, including use of fertility drugs
- Uterine abnormalities such as fibroids
- Presence of intrauterine contraception
- Use of progestin-only mini-pill (slows ovum transport)
- Postpartum or postabortion infection
- Altered estrogen and progesterone levels (interferes with tubal motility)
- Increasing age (older than 35 years)
- Cigarette smoking (Marion, & Rodney Meeks, 2012)

If rupture or hemorrhage occurs before treatment begins, symptoms may worsen and include severe, sharp, and sudden pain in the lower abdomen as the tube tears open and the embryo is expelled into the pelvic cavity; feelings of faintness; referred pain to the shoulder area, indicating bleeding into the abdomen, caused by phrenic nerve irritation; hypotension; marked abdominal tenderness with distention; and hypovolemic shock (Young, 2010).

### **Laboratory and Diagnostic Testing**

The use of transvaginal ultrasound to visualize the misplaced pregnancy and low levels of serum beta-hCG assist in diagnosing an ectopic pregnancy. The ultrasound determines whether the pregnancy is intrauterine, assesses the size of the uterus, and provides evidence of fetal viability. The visualization of an adnexal mass and the absence of an intrauterine gestational sac are diagnostic of ectopic pregnancy (Kirk, 2012). In a normal intrauterine pregnancy, beta-hCG levels typically double every 2 to 4 days until peak values are reached 60 to 90 days after conception. Concentrations of hCG decrease after 10 to 11 weeks and reach a plateau at low levels by 100 to 130 days (Wang, Zhao, Teng, Lu, & Tong, 2010). Therefore, low beta-hCG levels are suggestive of an ectopic pregnancy or impending abortion. Additional tests may be done to rule out other conditions such as spontaneous abortion, ruptured ovarian cyst, appendicitis, and salpingitis.

## **Nursing Management**

Nursing management for the woman with an ectopic pregnancy focuses on preparing the woman for treatment, providing support, and providing education about preventive measures.

### **Preparing the Woman for Treatment**

Administer analgesics as ordered to promote comfort and relieve discomfort from abdominal pain. Although the intensity of the pain can vary, women often report a great deal of pain. If the woman is treated medically, explain the medication that will be used and what she can expect. Also review signs and symptoms of possible adverse effects. If treatment will occur on an outpatient basis, outline the signs and symptoms of ectopic rupture (severe, sharp, stabbing, unilateral abdominal pain; vertigo/fainting; hypotension; and increased pulse) and advise the woman to seek medical help immediately if they occur.

If surgery is needed, close assessment and monitoring of the client's vital signs, bleeding (peritoneal or vaginal), and pain status are critical to identify

hypovolemic shock, which may occur with tubal rupture. Prepare the client physiologically and psychologically for surgery or any procedure. Provide a clear explanation of the expected outcome. Astute vigilance and early referral will help reduce short- and long-term morbidity.

### **Providing Emotional Support**

The woman with an ectopic pregnancy requires support throughout diagnosis, treatment, and aftercare. A woman's psychological reaction to an ectopic pregnancy is unpredictable. However, it is important to recognize she has experienced a pregnancy loss in addition to undergoing treatment for a potentially life-threatening condition. The woman may find it difficult to comprehend what has happened to her because events occur so quickly. In the woman's mind, she had just started a pregnancy and now it has ended abruptly. Bleeding during any pregnancy is traumatic because of the uncertainty of the outcome. Help her to make this experience "more real" by encouraging her and her family to express their feelings and concerns openly, and validating that this is a loss of pregnancy and it is okay to grieve over the loss. Although the woman may have physically recovered following an ectopic pregnancy, she may still experience significant emotional distress for a long period of time.

Provide emotional support, spiritual care, client education, and information about community support groups (such as Resolve through Sharing) as the client grieves for the loss of her unborn child and comes to terms with the medical complications of the situation. Acknowledge the client's pregnancy and allow her to discuss her feelings about what the pregnancy means. Also, stress the need for follow-up blood testing for several weeks to monitor hCG titers until they return to zero, indicating resolution of the ectopic pregnancy. Ask about her feelings and concerns about her future fertility, and provide teaching about the need to use contraceptives for at least three menstrual cycles to allow her reproductive tract to heal and the tissue to be repaired. Include the woman's partner in this discussion to make sure both parties understand what has happened, what intervention is needed, and what the future holds regarding childbearing.

### **Educating the Client**

Preventing ectopic pregnancies through screening and client education is essential. Many can be prevented by avoiding conditions that might cause scarring of the fallopian tubes. In addition, a contributing factor to the development of ectopic pregnancy is a previous ectopic pregnancy. Therefore, educating the woman is crucial.

Prevention education may include the following:

- Reduce risk factors such as sexual intercourse with multiple partners or intercourse without a condom.
- Avoid contracting STIs that lead to pelvic inflammatory disease (PID).
- Obtain early diagnosis and adequate treatment of STIs.
- If an intrauterine contraceptive system is chosen, descriptions of the signs of PID should be included to reduce the risk of repeat ascending infections, which can be responsible for tubal scarring.
- Avoid smoking during childbearing years since a correlation and increase in risk exists.
- Use condoms to decrease the risk of infections that cause tubal scarring.
- Seek prenatal care early to confirm the location of pregnancy.

## Gestational Trophoblastic Disease

**Gestational trophoblastic disease (GTD)** comprises a spectrum of neoplastic disorders that originate in the placenta. Gestational tissue is present, but the pregnancy is not viable. The incidence is about 1 in 1,500 pregnancies in the United States; in Asian countries, the rate is 1 of every 120 pregnancies (Moore & Hernandez, 2012). The two most common types of GTD are hydatidiform mole (partial or complete) and choriocarcinoma.

### Pathophysiology

Hydatidiform mole is a benign neoplasm of the chorion in which the chorionic villi degenerate and become transparent vesicles containing clear, viscid fluid. Hydatidiform mole is classified as complete or partial, distinguished by differences in clinical presentation, pathology, genetics, and epidemiology (Digiulio, Wiedaseck, & Monchek, 2012). The complete mole contains no fetal tissue and develops from an “empty egg,” which is fertilized by a normal sperm (the paternal chromosomes replicate, resulting in 46 all-paternal chromosomes) (Fig. 19.2). The embryo is not viable and dies. No circulation is established, and no embryonic tissue is found. The complete mole is associated with the development of choriocarcinoma. Most women with a classic complete mole present with vaginal bleeding, anemia, excessively enlarged uterus, preeclampsia, and hyperemesis.

The partial mole has a triploid karyotype (69 chromosomes), because two sperm have provided a double contribution by fertilizing the ovum. Women with a partial mole usually present with the clinical features of a missed or incomplete abortion, including vaginal bleeding and a small- or normal-size for date uterus (Digiulio, Wiedaseck, & Monchek, 2012).

**FIGURE 19.2** Complete hydatiform mole. The chorionic villi degenerate and become filled with a viscid fluid, forming transparent vesicles.

The exact cause of molar pregnancy is unknown, but researchers are looking into a genetic basis. Other theories include an ovular defect, stress, or a nutritional deficiency (carotene). Although the etiology remains uncertain, at some point in the pregnancy, trophoblastic cells that normally would form the placenta proliferate and the chorionic villi becomes edematous. The latter changes become the grapelike clusters that characterize the molar pregnancy (King & Brucker, 2011). Studies have revealed some remarkable features about molar pregnancies, including:

- Ability to invade into the wall of the uterus
- Tendency to recur in subsequent pregnancies
- Possible development into choriocarcinoma, a virulent cancer with metastasis to other organs
- Influence of nutritional factors, such as protein deficiency
- Tendency to affect older women more often than younger women

Having a molar pregnancy (partial or complete) results in the loss of the pregnancy and the possibility of developing choriocarcinoma, a chorionic malignancy from the trophoblastic tissue. The most frequent sites of metastases are the lungs, lower genital tract, brain, and liver (Gilbert, 2011). Partial moles rarely transform into choriocarcinoma.

### Therapeutic Management

Treatment consists of immediate evacuation of the uterine contents as soon as the diagnosis is made and long-term follow-up of the client to detect any remaining trophoblastic tissue that might become malignant. D&C is used to empty the uterus. The tissue obtained is sent to the laboratory for analysis to evaluate for choriocarcinoma.

Serial levels of hCG are used to detect residual trophoblastic tissue for 1 year. If any tissue remains, hCG levels will not regress. In 80% of women with a benign hydatidiform mole, serum hCG titers steadily drop to normal within 8 to 12 weeks after evacuation of the molar pregnancy. In the other 20% of women with a malignant hydatidiform mole, serum hCG levels begin to rise (Goldstein, & Berkowitz, 2012).

Due to the increased risk for cancer, the client is advised to receive extensive follow-up therapy for the next 12 months. The follow-up protocol may include:

- Baseline hCG level, chest radiograph, and pelvic ultrasound
- Quantitative hCG levels every week until undetectable for 3 consecutive weeks; then serial hCG levels monthly for 1 year
- Chest radiograph every 6 months to detect pulmonary metastasis
- Regular pelvic examinations to assess uterine and ovarian regression
- Systemic assessments for symptoms indicative of lung, brain, liver, or vaginal metastasis
- Strong recommendation to avoid pregnancy for 1 year because the pregnancy can interfere with the monitoring of hCG levels
- Use of a reliable contraceptive for at least 1 year (Gilbert, 2011)

## Nursing Assessment

The nurse plays a crucial role in identifying and bringing this condition to the attention of the health care provider based on sound knowledge of the typical clinical manifestations and through astute antepartal assessments.

Clinical manifestations of GTD are very similar to those of spontaneous abortion at about 12 weeks of pregnancy. Assess the woman for potential clinical manifestations at each antepartal visit. Be alert for the following:

- Report of early signs of pregnancy, such as amenorrhea, breast tenderness, fatigue
- Brownish vaginal bleeding/spotting
- Anemia
- Inability to detect a fetal heart rate after 10 to 12 weeks' gestation
- Bilateral ovarian enlargement caused by cysts and elevated levels of hCG
- Severe morning sickness (due to high hCG levels)
- Fluid retention and swelling
- Uterine size larger than expected for pregnancy dates
- Extremely high hCG levels present; no single value considered diagnostic
- Early development of preeclampsia (usually not present until after 24 weeks)
- Absence of fetal heart rate or fetal activity
- Expulsion of grapelike vesicles (possible in some women)

The diagnosis is made by high hCG levels and the characteristic appearance of the vesicular molar pattern in the uterus via transvaginal ultrasound.

## Nursing Management

Nursing management of the woman with GTD focuses on preparing her for a D&C, providing emotional support to deal with the loss and potential risks, and educating her about the risk that cancer may develop after a molar pregnancy and the strict adherence needed with the follow-up program. The woman must understand the need for the continued follow-up care regimen to improve her chances of future pregnancies and to ensure her continued quality of life.

### Preparing the Client

Upon diagnosis, the client will need an immediate evacuation of the uterus. Perform preoperative care, preparing the client physically and psychologically for the procedure.

### Providing Emotional Support

To aid the client and her family in coping with the loss of the pregnancy and the possibility of a cancer diagnosis, use the following interventions:

- Listen to their concerns and fears.
- Allow them time to grieve for the pregnancy loss.
- Acknowledge their loss and sad feelings (say you are sorry for their loss).
- Encourage them to express their grief; allow them to cry.
- Provide them with as much factual information as possible to help them make sense of what is happening.
- Enlist support from additional family and friends as appropriate and with the client's permission.

### Educating the Client

After GTD is diagnosed, teach the client about the condition and appropriate interventions that may be necessary to save her life. Explain each phase of treatment accurately and provide support for the woman and her family as they go through the grieving process.

As with any facet of health care, be aware of the latest research and new therapies. Inform the client about her follow-up care, which will probably involve close clinical surveillance for approximately 1 year, and reinforce its importance in monitoring the client's condition. Tell the client that serial serum beta-hCG levels are used to detect residual trophoblastic tissue. Continued high or increasing hCG titers are abnormal and need further evaluation.

Inform the client about the possible use of chemotherapy, such as methotrexate, which may be started as prophylaxis. Strongly urge the client to use a reliable contraceptive to prevent pregnancy for 1 year, because a pregnancy would interfere with tracking the serial beta-hCG levels used to identify a potential malignancy. Stress the need for the client to cooperate and adhere to the plan of therapy throughout this yearlong follow-up period.

### Consider This

We had lived across the dorm hall from each other during nursing school but really didn't get to know each other except for a casual hello in passing. When we graduated, Rose went to work in the emergency room and I in OB. We saw each other occasionally in the employee cafeteria, but a quick hello was all that we usually exchanged. I heard she married one of the paramedics who worked in the ER and was soon pregnant. I finally got to say more than hello when she was admitted to the OB unit bleeding during her fourth month of pregnancy. Gestational trophoblastic disease was discovered instead of a normal pregnancy. I remember holding her in my arms as she wept. She was told she had a complete molar pregnancy after surgery, and she would need extensive follow-up for the next year. I lost track of her that summer as my life became busier. Around Thanksgiving time, I heard she had died from choriocarcinoma. I attended her funeral, finally, to get the time to say a final hello and good-bye, but this time with sadness and tears.

Thoughts: Rose was only 26 years old when she succumbed to this very virulent cancer. I think back and realize I missed knowing this brave young woman and wished that I had taken the time to say more than hello. Could her outcome have been different? Why wasn't it recognized earlier? Did she not follow up after her diagnosis? I can only speculate regarding the whom, what, and where. She lived a short but purposeful life, and hopefully continued research will change other women's outcomes in the future.

## Cervical Insufficiency

Cervical insufficiency, also called premature dilation of the cervix, describes a weak, structurally defective cervix that spontaneously dilates in the absence of contractions in the second trimester or in the early third trimester, resulting in the loss of the pregnancy. Since this typically occurs in the fourth or fifth month of gestation before the point of fetal viability, the fetus dies unless the dilation can be arrested. The incidence of cervical insufficiency is less than 1%; estimates range from 1 in 500 to 1 in

2,000 pregnancies, accounting for approximately 20% to 25% of second- and third-trimester losses (March of Dimes, 2011a).

## Pathophysiology

The exact mechanism contributing to cervical insufficiency is not known. The cervix may have less elastin, less collagen, and greater amounts of smooth muscle than the normal cervix, and thus results in loss of sphincter tone (Mattson & Smith, 2011). Several theories have been proposed that focus on damage to the cervix as a key component of hormonal factors, such as increased amounts of relaxin. When the pressure of the expanding uterine contents becomes greater than the ability of the cervical sphincter to remain closed, the cervix suddenly relaxes, allowing effacement and dilation to proceed. The cervical dilation is typically rapid, relatively painless, and accompanied by minimal bleeding (March of Dimes, 2011a).

Cervical insufficiency is likely to be the clinical end point of many pathologic processes, such as congenital cervical hypoplasia, in utero diethylstilbestrol exposure that caused cervical hypoplasia, or trauma to the cervix (conization, amputation, obstetric laceration, or forced cervical dilation [may occur during elective pregnancy termination]). Other conditions such as previous precipitous birth, a prolonged second stage of labor, increased amounts of relaxin and progesterone, or increased uterine volume (multiple gestation, hydramnios) are associated with cervical insufficiency (Gilbert, 2011). However, the exact etiology of cervical insufficiency is not known.

Cervical length also has been associated with cervical insufficiency and subsequently preterm birth. Recent studies have examined the association between a short cervical length and the risk of preterm birth. Some have demonstrated a continuum of risk between a shorter cervix on ultrasound and a higher risk of preterm birth, leading to the hypothetical argument that women with a short cervix on ultrasound might benefit from cervical cerclage, but there have been conflicting results (Owen, & Mancuso, 2012).

## Therapeutic Management

Cervical insufficiency may be treated in a variety of ways: bed rest; pelvic rest; avoidance of heavy lifting; or surgically, via a cervical cerclage procedure in the second trimester. Cerclage was devised more than 50 years ago based on the hypothesis that for some women, weakness or malfunction of the cervix has a causative role in the pathway to preterm birth. Cervical cerclage involves using a heavy purse-string suture to secure and reinforce the internal os of the cervix (Fig. 19.3).

FIGURE 19.3 (A) Cervical cerclage. (B) Suturing the cervix for cervical insufficiency.

According to the American College of Obstetricians and Gynecologists (ACOG) (2011), if a short cervix is identified at or after 20 weeks and no infection (chorioamnionitis) is present, the decision to proceed with cerclage should be made with caution. There have been limited numbers of well-designed randomized studies to support its efficacy. Suture displacement, rupture of membranes, and chorioamnionitis are the most common complications associated with cerclage placement, and their incidence varies widely in relation to the timing and indications for the cerclage (Jazayeri, 2012). The optimal timing for cerclage removal is unclear, but ACOG (2011) supports cerclage placement up to 28 weeks' gestation.

## Nursing Assessment

Nursing assessment focuses on obtaining a thorough history to determine any risk factors that might have a bearing on this pregnancy: previous cervical trauma, preterm labor, fetal loss in the second trimester, or previous surgeries or procedures involving the cervix. History may reveal a previous loss of pregnancy around 20 weeks.

Also be alert for complaints of vaginal discharge or pelvic pressure. Commonly with cervical insufficiency the woman will report a pink-tinged vaginal discharge or an increase in low pelvic pressure, cramping to vaginal bleeding, and loss of amniotic fluid. Cervical dilation also occurs. If this continues, rupture of the membranes, release of amniotic fluid, and uterine contractions occur, subsequently resulting in delivery of the fetus, often before it is viable.

### Take Note!

The diagnosis of cervical insufficiency remains difficult in many circumstances. The cornerstone of diagnosis is a history of a pregnancy loss during the second or third trimester associated with painless cervical dilation without evidence of uterine activity.

Transvaginal ultrasound typically is done between 16 and 24 weeks' gestation to determine cervical length, evaluate for shortening, and attempt to predict an early

preterm birth. Cervical shortening occurs from the internal os outward and can be viewed on ultrasound as funneling. The amount of funneling can be determined by dividing funnel length by cervical length. The most common time at which a short cervix or funneling develops is 16 to 24 weeks, so ultrasound screening should be performed during this interval (Ross & Eden, 2011). A cervical length of less than 25 mm is abnormal between 16 and 24 weeks and may increase the risk of preterm labor. Among clients with a short cervix, provide education concerning the signs and symptoms of preterm labor, especially as the pregnancy approaches potential viability. Prenatal visits/contacts may be scheduled at more frequent intervals to increase client interaction with the care provider, especially between 20 and 34 weeks' gestation, which may decrease the rate of extremely early preterm births.

Expect the woman (particularly a woman with pelvic pressure, backache, or increased mucoid discharge) to undergo serial transvaginal ultrasound evaluations every few days to avoid missing rapid changes in cervical dilation or until the trend in cervical length can be characterized (Petrozza & Berin, 2011).

For a woman at risk for preterm birth, home uterine activity monitoring can be used to screen for prelabor uterine contractility so that escalating contractility can be identified, allowing earlier intervention to prevent preterm birth. The home uterine activity monitor consists of a pressure sensor attached to a belt that is held against the abdomen and a recording/storage device that is carried on a belt or hung from the shoulder. Uterine activity is typically recorded by the woman for 1 hour twice daily, while she is performing routine activities. The stored data are transmitted via telephone to a perinatal nurse, and a receiving device prints out the data. The woman is contacted if there are any problems.

Although in theory identifying early contractions to initiate interventions to arrest the labor sounds reasonable, research shows that uterine activity monitoring in asymptomatic high-risk women is inadequate for predicting preterm birth (Genc & Ford, 2010). This practice

continues even though numerous randomized trials have found no relationship between monitoring and actual reduction of preterm labor. In more recent research findings, cervical length is predictive of preterm birth in all populations studied. A cervical length of less than 25 mm warrants intervention to improve the health outcomes of pregnant women and their infants (Larma, & Iams, 2012).

## Nursing Management

Nursing management focuses on monitoring the woman very closely for signs of preterm labor: backache, increase in vaginal discharge, rupture of membranes, and uterine contractions. Provide emotional support and education to allay the couple's anxiety about the well-being of their fetus. Provide preoperative care and teaching as indicated if the woman will be undergoing cerclage. Teach the client and her family about the signs and symptoms of preterm labor and the need to report any changes immediately. Also reinforce the need for activity restrictions (if appropriate) and continued regular follow-up. Continuing surveillance throughout the pregnancy is important to promote a positive outcome for the family.

### Placenta Previa

**Placenta previa** is a bleeding condition that occurs during the last two trimesters of pregnancy. In placenta previa (literally, “afterbirth first”), the placenta implants over the cervical os. It may cause serious morbidity and mortality to the fetus and mother. The risk of placenta previa in a first pregnancy is 1 in 400, but it rises to 1 in 160 after one cesarean section; 1 in 60 after two; 1 in 30 after three; and 1 in 10 after four cesarean sections and is associated with potentially serious consequences from

hemorrhage, abruption (separation) of the placenta, or emergency cesarean birth (Joy, Lyon, & Stone, 2012). With the rising incidence of cesarean section operations combined with increasing maternal age and more infertility treatments, the number of cases of placenta previa is increasing dramatically (Rosenberg, Pariente, Sergienko, Wiznitzer, & Sheiner, 2011).

## Pathophysiology

The exact cause of placenta previa is unknown. It is initiated by implantation of the embryo in the lower uterus perhaps due to uterine endometrial scarring or damage in the upper segment, which may incite placental growth in the unscarred lower uterine segment. Uteroplacental underperfusion may also be present, which may increase the surface area required for placental attachment and may cause the placenta to encroach on the lower uterine segment. With placental attachment and growth, the cervical os may become covered by the developing placenta. Placental vascularization is defective, allowing the placenta to attach directly to the myometrium (accreta), deeply attach to the myometrium (increta), or infiltrate the myometrium (percreta).

Placenta previa is generally classified according to the degree of coverage or proximity to the internal os, as follows (Fig. 19.4):

- Total placenta previa: the internal cervical os is completely covered by the placenta
- Partial placenta previa: the internal os is partially covered by the placenta
- Marginal placenta previa: the placenta is at the margin or edge of the internal os
- Low-lying placenta previa: the placenta is implanted in the lower uterine segment and is near the internal os but does not reach it

**FIGURE 19.4** Classification of placenta previa. **(A)** Marginal. **(B)** Partial. **(C)** Complete.

## Therapeutic Management

Therapeutic management depends on the extent of bleeding, the amount of placenta over the cervical os, whether the fetus is developed enough to survive outside the uterus, the position of the fetus, the mother's parity, and the presence or absence of labor (Allahdin, Voigt, & Htwe, 2011). With the rising rate of previous cesarean sections, the frequency of placenta previa has increased. Most women continue to present in emergency departments, therefore the associated morbidity due to hemorrhage remains high. Efforts should be made to avoid primary cesarean section where possible. In addition antenatal care and timely diagnosis of placenta previa on ultrasound can decrease the associated morbidity.

If the mother and fetus are both stable, therapeutic management may involve expectant (“wait-and-see”) care. This care can be carried out at home or on an antepartal unit in the health care facility. If there is no active bleeding and the client has ready access to reliable transportation, can maintain bed rest at home, and can comprehend instructions, expectant care at home is appropriate. However, if the client requires continuous care and monitoring and cannot meet the home care requirements, the antepartal unit is the best environment.

## Nursing Assessment

Nursing assessment involves a thorough history, including possible risk factors, and physical examination. Evaluate the client closely for these risk factors:

- Advancing maternal age (more than 35 years)
- Previous cesarean birth
- Multiparity
- Uterine insult or injury
- Cocaine use
- Prior placenta previa
- Infertility treatment
- Asian ethnic background (incidence is increased in Asian cultural groups)
- Multiple gestations
- Previous induced surgical abortion
- Smoking
- Previous myomectomy to remove fibroids
- Short interval between pregnancies
- Hypertension or diabetes (Gilbert, 2011)

## Health History and Physical Examination

Ask the client if she has any problems associated with bleeding, now or in the recent past. The classical clinical presentation is painless, bright-red vaginal bleeding occurring during the second or third trimester. The initial bleeding usually is not profuse and it ceases spontaneously, only to recur again. The first episode of bleeding occurs (on average) at 27 to 32 weeks' gestation. The

bleeding is thought to arise secondary to the thinning of the lower uterine segment in preparation for the onset of labor. When the bleeding occurs at the implantation site in the lower uterus, the uterus cannot contract adequately and stop the flow of blood from the open vessels. Typically with normal placental implantation in the upper uterus, minor disruptive placental attachment is not a problem, because there is a larger volume of myometrial tissue able to contract and constrict bleeding vessels.

Assess the client for uterine contractions, which may or may not occur with the bleeding. Palpate the uterus; typically it is soft and nontender on examination. Auscultate the fetal heart rate; it commonly is within normal parameters. Fetal distress is usually absent but may occur when cord problems arise, such as umbilical cord prolapse or cord compression, or when the client has experienced blood loss to the extent that maternal shock or placental abruption has occurred (Paterson & Wilson, 2010).

## Laboratory and Diagnostic Testing

To validate the position of the placenta, a transvaginal ultrasound is done. In addition, magnetic resonance imaging may be ordered when preparing for delivery because it allows identification of placenta accreta (placenta abnormally adherent to the myometrium), increta (placenta accreta with penetration of the myometrium), or percreta (placenta accreta with invasion of the myometrium to the peritoneal covering, causing rupture of the uterus) in addition to placenta previa. These placental abnormalities, although rare, carry a very high morbidity and mortality rate, possibly necessitating a hysterectomy at delivery.

## Nursing Management

Whether the care setting is in the client's home or in the health care facility, the nurse focuses on monitoring the maternal–fetal status, including assessing for signs and symptoms of vaginal bleeding and fetal distress, and providing support and education to the client and her family, including what events and diagnostic studies are being performed. For the majority of women, a cesarean birth will be planned. Nursing Care Plan 19.1 discusses the nursing process for the woman with placenta previa.

## Monitoring Maternal–Fetal Status

Assess the degree of vaginal bleeding; inspect the perineal area for blood that may be pooled underneath the woman. Estimate and document the amount of bleeding. Perform a peripad count on an ongoing basis, making sure to report any changes in amount or frequency to the health care provider. If the woman is experiencing active

## NURSING CARE PLAN 19.1

## Overview of the Woman with Placenta Previa

Sandy, a 39-year-old G5, P4, multigravida client at 32 weeks' gestation, was admitted to the labor and birth suite with sudden vaginal bleeding. Sandy had no further active bleeding and did not complain of any abdominal discomfort or tenderness. She did complain of occasional "tightening" in her stomach. Her abdomen palpated soft. Fetal heart rates were in the 140s with accelerations with movement. She was placed on bed rest with bathroom privileges. Ultrasound identified a low-lying placenta with a viable, normal-growth fetus. She was diagnosed with placenta previa and admitted for observation and surveillance of fetal well-being. Her history revealed two previous cesarean births, smoking half a pack of cigarettes per day, and endometritis infection after birth of her last newborn. Additional assessment findings included painless, bright-red vaginal bleeding with initial bleeding ceasing spontaneously; irregular, mild, and sporadic uterine contractions; fetal heart rate and maternal vital signs within normal range; fetus in transverse lie; anxiety related to the outcome of pregnancy; and expression of feelings of helplessness.

**NURSING DIAGNOSIS:** Risk for injury (fetal and maternal) related to threat to uteroplacental perfusion and hemorrhage

## Outcome Identification and Evaluation

The client will maintain adequate tissue perfusion as evidenced by stable vital signs, decreased blood loss, few or no uterine contractions, normal fetal heart rate patterns and variability, and positive fetal movement.

Interventions: *Maintaining Adequate Tissue Perfusion*

- Establish IV access *to allow for administration of fluids, blood, and medications as necessary.*
- Obtain type and cross-match for at least 2 units blood products *to ensure availability should bleeding continue.*
- Obtain specimens as ordered for blood studies, such as CBC and clotting studies, *to establish a baseline and use for future comparison.*
- Monitor output *to evaluate adequacy of renal perfusion.*
- Administer IV fluid replacement therapy as ordered *to maintain blood pressure and blood volume.*
- Palpate for abdominal tenderness and rigidity *to determine bleeding and evidence of uterine contractions.*
- Institute bed rest *to reduce oxygen demands.*
- Assess for rupture of membranes *to evaluate for possible onset of labor.*
- Avoid vaginal examinations *to prevent further bleeding episodes.*
- Complete an Rh titer *to identify need for RhoGAM.*
- Avoid nipple stimulation *to prevent uterine contractions.*
- Continuously monitor for contractions or PROM *to allow for prompt intervention.*
- Administer tocolytic agents as ordered *to stall pre-term labor.*
- Monitor vital signs frequently *to identify possible hypovolemia and infection.*
- Assess frequently for active vaginal bleeding *to minimize risk of hemorrhage.*
- Continuously monitor fetal heart rate with electronic fetal monitor *to evaluate fetal status.*
- Assist with fetal surveillance tests as ordered *to aid in determining fetal well-being.*
- Observe for abnormal fetal heart rate patterns, such as loss of variability, decelerations, tachycardia, *to identify fetal distress.*
- Position client in side-lying position with wedge for support *to maximize placental perfusion.*
- Assess fetal movement *to evaluate for possible fetal hypoxia.*
- Teach woman to monitor fetal movement *to evaluate well-being.*
- Administer oxygen as ordered *to increase oxygenation to mother and fetus.*

## NURSING CARE PLAN 19.1

## Overview of the Woman with Placenta Previa (continued)

**NURSING DIAGNOSIS:** Anxiety related to threat to self and fetus, unknown future

### Outcome Identification and Evaluation

The client will experience a decrease in anxiety as evidenced by verbal reports of less anxiety, use of effective coping measures, and calm demeanor.

### Interventions: *Minimizing Anxiety*

- Provide factual information about diagnosis and treatment, and explain interventions and the rationale behind them *to provide client with understanding of her condition.*
- Answer questions about health status honestly *to establish a trusting relationship.*
- Speak calmly to client and family members *to minimize environmental stress.*
- Encourage the use of past effective techniques for coping *to promote relaxation and feelings of control.*
- Acknowledge and facilitate the woman's spiritual needs *to promote effective coping.*
- Involve the woman and family in the decision-making process *to foster self-confidence and control over situation.*
- Maintain a presence during stressful periods *to allay anxiety.*
- Use the sense of touch if appropriate *to convey caring and concern.*
- Encourage talking as a means *to release tension.*

bleeding, prepare for blood typing and cross-matching in the event a blood transfusion is needed.

#### Take Note!

Avoid doing vaginal examinations in the woman with placenta previa. They may disrupt the placenta and cause hemorrhage.

Monitor maternal vital signs and uterine contractility frequently for changes. Have the client rate her level of pain using an appropriate pain rating scale.

Assess fetal heart rates via Doppler or electronic monitoring to detect fetal distress. Monitor the woman's cardiopulmonary status, reporting any difficulties in respirations, changes in skin color, or complaints of difficulty breathing. Have oxygen equipment readily available should fetal or maternal distress develop. Encourage the client to lie on her side to enhance placental perfusion.

If the woman has an intravenous (IV) line inserted, inspect the IV site frequently. Alternately, anticipate the insertion of an intermittent IV access device such as a saline lock, which can be used if quick access is needed for fluid restoration and infusion of blood products. Obtain laboratory tests as ordered, including complete blood count (CBC), coagulation studies, and Rh status if appropriate.

Administer pharmacologic agents as necessary. Give Rh immunoglobulin if the client is Rh negative at 28 weeks' gestation. Monitor tocolytic medication if prevention of preterm labor is needed.

### Providing Support and Education

Determine the woman's level of understanding about placenta previa and the associated procedures and treatment plan. Doing so is important to prevent confusion and gain her cooperation. Provide information about the condition and make sure that all information related is consistent with information from the primary care provider. Explain all assessments and treatment measures as needed. Act as a client advocate in obtaining information for the family.

Teach the woman how to perform and record daily fetal movement. This action serves two purposes. One, it provides valuable information about the fetus. Two, it is an activity that the client can participate in, thereby fostering some feeling of control over the situation.

If the woman will require prolonged hospitalization or home bed rest, assess the physical and emotional impact that this may have on her. Evaluate her coping mechanisms to help determine how well she will be able to adjust to and cooperate with the treatment plan. Allow the client to verbalize her feelings and fears and provide emotional support. Also, provide opportunities for distraction—educational videos, arts and crafts, computer games, reading books—and evaluate the client's response.

In addition to the emotional impact of prolonged bed rest, thoroughly assess the woman's skin to prevent skin breakdown and to help alleviate her discomfort secondary

to limited physical activity. Instruct the woman in appropriate skin care measures. Encourage her to eat a balanced diet with adequate fluid intake to ensure adequate nutrition and hydration and prevent complications associated with urinary and bowel elimination secondary to bed rest.

Teach the client and family about any signs and symptoms that should be reported immediately. In addition, prepare the woman for the possibility of a cesarean birth. The woman must notify her health care provider about any bleeding episodes or backaches (may indicate preterm labor contractions) and must adhere to the prescribed bed rest regimen. To ensure compliance and a positive outcome, she needs to be aware of the purpose of all of the observations that need to be made.

## Abruptio Placentae

**Abruptio placentae** is the separation of a normally located placenta after the 20th week of gestation and prior to birth that leads to hemorrhage. It is a significant cause of third-trimester bleeding, with a high mortality rate. It occurs in about 1% of all pregnancies throughout the world, or 1 in 100 pregnancies. There is a 10 to 20 times greater risk of reoccurrence in a subsequent pregnancy. Maternal risks include obstetric hemorrhage, need for blood transfusions, emergency hysterectomy, disseminated intravascular coagulopathy and renal failure. Maternal death is rare but seven times higher than the overall maternal mortality rate. Perinatal consequences include low birth weight, preterm delivery, asphyxia, stillbirth, and perinatal death. In developed countries, approximately 10% of all preterm births and 10% to 20% of all perinatal deaths are caused by placental abruption (Tikkanen, 2011). The overall fetal mortality rate for placental abruption is 20% to 40%, depending on the extent of the abruption. Maternal mortality is approximately 6% in abruptio placentae and is related to cesarean birth and/or hemorrhage/coagulopathy (March of Dimes, 2011e).

## Pathophysiology

The etiology of this condition is unknown; however, it has been proposed that abruption starts with degenerative changes in the small maternal arterioles, resulting in thrombosis, degeneration of the decidua, and possible rupture of a vessel. Bleeding from the vessel forms a retroplacental clot. The bleeding causes increased pressure behind the placenta and results in separation (Deering 2012).

Fetal blood supply is compromised and fetal distress develops in proportion to the degree of placental separation. This is caused by the insult of the abruption itself

and by issues related to prematurity when early birth is required to alleviate maternal or fetal distress.

Abruptio placentae is classified according to the extent of separation and the amount of blood loss from the maternal circulation. Classifications include:

- Mild (grade 1): minimal bleeding (less than 500 mL), marginal separation (10% to 20%), tender uterus, no coagulopathy, no signs of shock, no fetal distress
- Moderate (grade 2): moderate bleeding (1,000 to 1,500 mL), moderate separation (20% to 50%), continuous abdominal pain, mild shock, normal maternal blood pressure, maternal tachycardia
- Severe (grade 3): absent to moderate bleeding (more than 1,500 mL), severe separation (more than 50%), profound shock, dark vaginal bleeding, agonizing abdominal pain, decreased maternal blood pressure, significant maternal tachycardia and development of disseminated intravascular coagulopathy (DIC) (Gilbert, 2011)

Abruptio placentae also may be classified as partial or complete, depending on the degree of separation. Alternately, it can be classified as concealed or apparent, by the type of bleeding (Fig. 19.5).

*Remember Helen, the pregnant woman with severe abdominal pain? Electronic fetal monitoring revealed uterine hypertonicity with absent fetal heart sounds. Palpation of her abdomen revealed rigidity and extreme tenderness in all four quadrants. Her vital signs were as follows: temperature, afebrile; pulse, 94; respirations, 22; blood pressure, 130/90 mm Hg. What might you suspect as the cause of Helen's abdominal pain? What course of action would you anticipate for Helen?*

## Therapeutic Management

Treatment of abruptio placentae is designed to assess, control, and restore the amount of blood lost; to provide a positive outcome for both mother and newborn; and to prevent coagulation disorders, such as DIC (Box 19.2). Emergency measures include starting two large-bore IV lines with normal saline or lactated Ringer's solution to combat hypovolemia, obtaining blood specimens for evaluating hemodynamic status values and for typing and cross-matching, and frequently monitoring fetal and maternal well-being. After the severity of abruption is determined and appropriate blood and fluid replacement is given, cesarean birth is done immediately if fetal distress is evident. If the fetus is not in distress, close monitoring continues, with delivery planned at the earliest signs of fetal distress. Because of the possibility of fetal blood loss through the placenta, a neonatal intensive care team should be available during the birth process to assess

**FIGURE 19.5** Classifications of abruptio placentae. **(A)** Partial abruption with concealed hemorrhage. **(B)** Partial abruption with apparent hemorrhage. **(C)** Complete abruption with concealed hemorrhage.

and treat the newborn immediately for shock, blood loss, and hypoxia.

If the woman develops DIC, treatment focuses on determining the underlying cause of DIC and correcting it.

#### BOX 19.2

### DISSEMINATED INTRAVASCULAR COAGULATION

DIC is a bleeding disorder characterized by an abnormal reduction in the elements involved in blood clotting resulting from their widespread intravascular clotting (Gilbert, 2011). This disorder can occur secondary to abruptio placentae, amniotic fluid embolism, endotoxin sepsis, retained dead fetus, post-hemorrhagic shock, hydatidiform mole, and gynecologic malignancies.

Simply put, the clinical and pathologic manifestations of DIC can be described as a loss of balance between the clot-forming activity of thrombin and the clot-lysing activity of plasmin. Therefore, too much thrombin tips the balance toward the prothrombic state and the client develops clots. Alternately, too much clot lysis (fibrinolysis) results from plasmin formation and the client hemorrhages. Small clots form throughout the body, and eventually the blood-clotting factors are used up, rendering them unavailable to form clots at sites of tissue injury. Clot-dissolving mechanisms are also increased, which results in bleeding (possibly severe).

DIC is usually associated with high mortality and morbidity rates. No single laboratory test is sensitive or specific enough to diagnose DIC definitively, but it can be diagnosed by using a combination of multiple

clinical and laboratory tests that reflect the pathophysiology of the syndrome.

Laboratory studies that assist in the diagnosis include:

- Decreased fibrinogen and platelets
- Prolonged PT and aPTT
- Positive D-dimer tests and fibrin (split) degradation products (objective evidence of the simultaneous formation of thrombin and plasmin) (Martina, 2010)

Adapted from Gilbert, E. S. (2011). *Manual of high-risk pregnancy and delivery* (5th ed.). St. Louis, MO: Mosby Elsevier; and Martina, M. (2010). Disseminated intravascular coagulation in obstetric and gynecologic disorders. *Seminars in Thrombosis & Hemostasis*, 36(4), 404–418.

Replacement therapy of the coagulation factors is achieved by transfusion of fresh-frozen plasma along with cryoprecipitate to maintain the circulating volume and provide oxygen to the cells of the body. Anticoagulant therapy (low-molecular-weight heparin), packed red cells, platelet concentrates, antithrombin concentrates, and nonclotting protein-containing volume expanders, such as plasma protein fraction or albumin, are also used to combat this serious condition (Su, & Chong, 2012). Prompt identification and early intervention are essential for a woman with acute DIC associated with abruptio placentae to treat DIC and possibly save her life.

### Nursing Assessment

Abruptio placentae is a medical emergency. The nurse plays a critical role in assessing the pregnant woman presenting with abdominal pain and/or experiencing

## COMPARISON CHART 19.1

## PLACENTA PREVIA VERSUS ABRUPTIO PLACENTAE

Manifestation	Placenta Previa	Abruptio Placentae
<i>Onset</i>	Insidious	Sudden
<i>Type of bleeding</i>	Always visible; slight, then more profuse	Can be concealed or visible
<i>Blood description</i>	Bright red	Dark
<i>Discomfort/pain</i>	None (painless)	Constant; uterine tenderness on palpation
<i>Uterine tone</i>	Soft and relaxed	Firm to rigid
<i>Fetal heart rate</i>	Usually in normal range	Fetal distress or absent
<i>Fetal presentation</i>	May be breech or transverse lie; engagement is absent	No relationship

vaginal bleeding, especially in a concealed hemorrhage, in which the extent of bleeding is not recognized. Rapid assessment is essential to ensure prompt, effective interventions to prevent maternal and fetal morbidity and mortality. Comparison Chart 19.1 compares placenta previa with abruptio placentae.

### Health History and Physical Examination

Abruptio placentae produces a wide range of clinical effects, depending on the extent of placental separation and the amount of maternal blood loss. Begin the health history by assessing the woman for risk factors that may predispose her to abruptio placentae, such as advanced maternal age (over 35 years old), poor nutrition, multiple gestation, excessive intrauterine pressure caused by hydramnios, chronic hypertension, cigarette smoking, severe trauma (e.g., auto accident, intimate partner violence), cocaine or methamphetamine abuse, thrombophilia, alcohol ingestion, and multiparity (Deering, 2012). Ask the woman about her previous pregnancies to determine if she has experienced a prior abruptio. In addition, be alert for other notable risk factors, such as male fetal gender, chorioamnionitis, prolonged premature ruptured membranes (more than 24 hours), oligohydramnios, preeclampsia, and low socioeconomic status (Mattson & Smith, 2011).

Assess the woman for bleeding. As the placenta separates from the uterus, hemorrhage ensues. It can be apparent, appearing as vaginal bleeding, or it can be concealed. Vaginal bleeding is present in 80% of women diagnosed with abruptio placentae and may be significant enough to jeopardize both maternal and fetal health within a short time frame. The remaining 20% of abruptions are associated with a concealed hemorrhage and the absence of vaginal bleeding. Monitor the woman's

level of consciousness, noting any signs or symptoms that may suggest shock.

#### Take Note!

Vital signs can be within normal range, even with significant blood loss, because a pregnant woman can lose up to 40% of her total blood volume without showing signs of shock (Gilbert, 2011).

Assess the woman for complaints of pain, including the type, onset, and location. Ask if she has had any contractions. Palpate the abdomen, noting any contractions, uterine tenderness, tenseness, or rigidity. Ask if she has noticed any changes in fetal movement and activity. Decreased fetal movement may be the presenting complaint, resulting from fetal jeopardy or fetal death (Crowl, Colwell, & Mattered, 2011). Assess fetal heart rate and continue to monitor it electronically.

#### Take Note!

Classic manifestations of abruptio placentae include painful, dark-red vaginal bleeding (port-wine color) because the bleeding comes from the clot that was formed behind the placenta; “knife-like” abdominal pain; uterine tenderness; contractions; and decreased fetal movement. Rapid assessment is essential to ensure prompt, effective interventions to prevent maternal and fetal morbidity and mortality.

### Laboratory and Diagnostic Testing

Laboratory and diagnostic tests may be helpful in diagnosing the condition and guiding management. These studies may include:

- CBC—determines the current hemodynamic status; however, it is not reliable for estimating acute blood loss

- Fibrinogen levels—typically are increased in pregnancy (hyperfibrinogenemia); thus, a moderate dip in fibrinogen levels might suggest coagulopathy (DIC) and, if profuse bleeding occurs, the clotting cascade might be compromised
- Prothrombin time (PT)/activated partial thromboplastin time (aPTT)—determines the client's coagulation status, especially if surgery is planned
- Type and cross-match—determines blood type if a transfusion is needed
- Kleihauer–Betke test—detects fetal red blood cells (RBCs) in the maternal circulation, determines the degree of fetal–maternal hemorrhage, and helps calculate the appropriate dosage of RhoGAM to give to Rh-negative clients
- Nonstress test—demonstrates findings of fetal jeopardy manifested by late decelerations or bradycardia
- Biophysical profile—aids in evaluating clients with chronic abruption; a low score (less than 6 points) suggests possible fetal compromise (Krishna & Chandrarahan, 2011)

Ultrasound is not useful for making a definitive diagnosis because the clot is sonographically visible in less than 50% of the cases. A CT scan is a more reliable method for evaluation of placental abruption (Manriquez, Srinivas, Bollepalli, Britt, & Drachman, 2010).

## Nursing Management

Nursing management of the woman with abruptio placentae warrants immediate care to provide the best outcome for both mother and fetus.

### Ensuring Adequate Tissue Perfusion

On arrival at the facility, place the woman on strict bed rest and in a left lateral position to prevent pressure on the vena cava. This position provides uninterrupted perfusion to the fetus. Expect to administer oxygen therapy via nasal cannula to ensure adequate tissue perfusion. Monitor oxygen saturation levels via pulse oximetry to evaluate the effectiveness of interventions.

Obtain maternal vital signs frequently, as often as every 15 minutes as indicated, depending on the woman's status and amount of blood loss. Observe for changes in vital signs suggesting hypovolemic shock and report them immediately. Also expect to insert an indwelling urinary (Foley) catheter to assess hourly urine output and initiate an IV infusion for fluid replacement using a large-bore catheter.

Assess fundal height for changes. An increase in size would indicate bleeding. Monitor the amount and characteristics of any vaginal bleeding as frequently as every

15 to 30 minutes. Be alert for signs and symptoms of DIC, such as bleeding gums, tachycardia, oozing from the IV insertion site, and petechiae, and administer blood products as ordered if DIC occurs.

Institute continuous electronic fetal monitoring. Assess uterine contractions and report any increased uterine tenseness or rigidity. Also observe the tracing for tetanic uterine contractions or changes in fetal heart rate patterns suggesting fetal compromise.

### Providing Support and Education

A woman diagnosed with abruptio placentae may be filled with a sense of heightened anxiety and apprehension—for her own health as well as that of her fetus. Communicate empathy and understanding of the client's experience, and provide emotional support throughout this frightening time. Remain with the couple, acknowledge their emotions and fears, and address their spiritual and cultural needs. Answer their questions about the status of their fetus openly and honestly, being sure to explain indicators of fetal well-being. Provide information about the various diagnostic tests, treatments, and procedures that may be done, including the possible need for a cesarean birth.

Depending on the client's status, extent of bleeding, and length of gestation, the fetus may not survive. If the fetus does survive, he or she most likely will require neonatal intensive care. Assist the client and family to deal with the loss or with the birth of a newborn in the neonatal intensive care unit.

Although abruptio placentae is not a preventable condition, client education is important to help reduce the risk for a recurrence of this condition. Encourage the woman to avoid drinking, smoking, or using drugs during pregnancy. Urge her to seek early and continuous prenatal care and to receive prompt health care if any signs and symptoms occur in future pregnancies.

*Think back to Helen, the pregnant woman described at the beginning of the chapter. She was diagnosed with abruptio placentae and was prepared for an emergency cesarean birth. On exploration, there was almost a 75% abruption, with approximately 800 mL of concealed blood between the uterus and the placenta. In addition, she lost an additional 500 mL during surgery. What in Helen's history may have placed her at increased risk for abruption? What assessments and interventions would be essential during her postpartum recovery secondary to her large blood loss? What psychosocial interventions would be necessary due to her fetal loss?*

## Placenta Accreta

**Placenta accreta** is a condition in which the placenta attaches itself too deeply into the wall of the uterus but does not penetrate the uterine muscle. A common risk of placenta accreta during the birthing process is the possibility of hemorrhaging during manual attempts to detach the placenta. According to the March of Dimes (2011e), 1 in 2,500 pregnancies results in this condition. The specific cause of placenta accreta is unknown, but it can be related to placenta previa, advanced maternal age, smoking, and previous cesarean births. According to the literature, a cesarean birth increases the possibility of a future placenta accreta; the more cesarean births that are done, the greater the incidence.

According to ACOG (2010a), postpartum hemorrhage is a complication associated with placenta accreta. Ninety percent of accretas have postpartum hemorrhage, and 50% of these will result in a hysterectomy (ACOG, 2010a). Women at highest risk of emergency hysterectomy are those who are multiparous, had a cesarean birth in either a previous or the present pregnancy, or had abnormal placentation. The essential management issues are early detection and immediate and appropriate intervention. If a placenta accreta diagnosis is made, the client should be counseled that a cesarean section and possible hysterectomy may be necessary interventions (Resnik, 2011).

Placenta accreta is typically diagnosed after birth when the placenta fails to normally separate from the uterine wall. A profuse hemorrhage may result because the uterus cannot contract to close off the open blood vessels. Management will depend on the severity of the bleeding and frequently necessitates a prompt hysterectomy (Gilbert, 2011). Nurses need to be prepared to assist in this emergency situation as dictated by the health care provider.

## HYPEREMESIS GRAVIDARUM

At least 70% to 85% of women experience nausea and vomiting during their pregnancy (Lutz & Przytulski, 2011). The term *morning sickness* is often used to describe this condition when symptoms are relatively mild. Such symptoms usually disappear after the first trimester. This mild form mostly affects the quality of life of the woman and her family, whereas the severe form—**hyperemesis gravidarum**—results in dehydration, electrolyte imbalance, and the need for hospitalization (Wilcox, 2012).

Unlike morning sickness, hyperemesis gravidarum is a complication of pregnancy characterized by persistent, uncontrollable nausea and vomiting that begins in the first trimester and causes dehydration, ketosis, and weight loss of more than 5% of prepregnancy body weight (King & Brucker, 2011).

Hyperemesis is estimated to occur in approximately 5 out of 1,000 pregnancies. The prevalence increases in molar pregnancies and multiple gestations. The peak incidence is at 8 to 12 weeks of pregnancy, and symptoms usually resolve by week 20 (Ogunyemi & Fong, 2012; Wilcox, 2012).

### Take Note!

Every pregnant woman needs to be instructed to report any episodes of severe nausea and vomiting or episodes that extend beyond the first trimester.

## Pathophysiology

Although the exact cause of nausea and vomiting is unknown, its effects—decreased placental blood flow, decreased maternal blood flow, and acidosis—can threaten the health of the mother and fetus. Dehydration can also lead to preterm labor (Garcia, 2012). Numerous theories abound, but few studies have produced scientific evidence to identify the etiology of this condition. It is likely that multiple factors contribute to it.

Elevated levels of hCG are present in all pregnant women during early pregnancy, usually declining after 12 weeks. This corresponds to the usual duration of morning sickness. In hyperemesis gravidarum, the hCG levels are often higher and extend beyond the first trimester. Symptoms exacerbate the disease. Decreased fluid intake and prolonged vomiting cause dehydration; dehydration increases the serum concentration of hCG, which in turn exacerbates the nausea and vomiting—a vicious cycle. A few other theories that have been proposed to explain its etiology include:

- Endocrine theory—high levels of hCG and estrogen during pregnancy
- Metabolic theory—vitamin B<sub>6</sub> deficiency
- Psychological theory—psychological stress increases the symptoms

## Therapeutic Management

Hyperemesis gravidarum is a diagnosis of exclusion. Careful consideration of other conditions must be assessed when a client experiences nausea and vomiting for the first time after 9 weeks' gestation.

Conservative management in the home is the first line of treatment for the woman with hyperemesis gravidarum. This usually focuses on dietary and lifestyle changes.

If conservative management fails to alleviate the client's symptoms and nausea and vomiting continue, hospitalization is necessary to reverse the effects of severe nausea and vomiting.

On admission to the hospital, blood tests are ordered to assess the severity of the client's dehydration, electrolyte imbalance, ketosis, and malnutrition. Parenteral fluids and

drugs are ordered to rehydrate the woman and reduce the symptoms. The first choice for fluid replacement is generally 5% dextrose in lactated Ringer's solution with vitamins (pyridoxine [B<sub>6</sub>]) and electrolytes added. Oral food and fluids are withheld for the first 24 to 36 hours to allow the GI tract to rest. Antiemetics may be administered rectally or intravenously to control the nausea and vomiting initially because the woman is considered NPO. Once her condition stabilizes and she is allowed oral intake, medications may be administered orally.

If the client does not improve after several days of bed rest, "gut rest," IV fluids, and antiemetics, total parenteral nutrition or feeding through a percutaneous endoscopic gastrostomy tube is instituted to prevent malnutrition.

The U.S. Food and Drug Administration has not approved any drugs for the treatment of nausea and vomiting in pregnancy, but the risk of administration must be balanced against the sequelae of prolonged starvation and dehydration. Finding a drug that works for any given client is largely a matter of trial and error. If one drug is ineffective, another class of drugs with a different mechanism of action may help. Promethazine

(Phenergan) and prochlorperazine (Compazine) are among the older preparations usually tried first. If they fail to relieve symptoms, newer drugs such as ondansetron (Zofran) may be tried. Most drugs are given parenterally or rectally. There is no evidence that any antiemetic class is superior to another with respect to effectiveness (King & Brucker, 2011) (Drug Guide 19.2).

Few women receive complete relief of symptoms from any one therapy. Complementary and alternative medicine therapies appeal to many to help supplement traditional ones. Some popular therapies include acupressure, massage, therapeutic touch, ginger, and the wearing of Sea-bands to prevent nausea and vomiting. Recent research has reported a positive effect of using acupressure (provided by Sea-bands) over the Neiguan point on the wrist to control nausea and vomiting associated with pregnancy (Garcia, 2012).

## Nursing Assessment

Nursing assessment of the woman with hyperemesis gravidarum requires a thorough history and physical examination

### DRUG GUIDE 19.2 MEDICATIONS USED FOR HYPEREMESIS GRAVIDARUM

Medication	Action/Indications	Nursing Implications
Promethazine (Phenergan)	Diminishes vestibular stimulation and acts on the chemoreceptor trigger zone (CTZ) Symptomatic relief of nausea and vomit(ing), and motion sickness	Be alert for urinary retention, dizziness, hypotension, and involuntary movements. Institute safety measures to prevent injury secondary to sedative effects. Offer hard candy and frequent rinsing of mouth for dryness.
Prochlorperazine (Compazine)	Acts centrally to inhibit dopamine receptors in the CTZ and peripherally to block vagus nerve stimulation in the GI tract Controls severe nausea and vomiting	Be alert for abnormal movements and for neuroleptic malignant syndrome such as seizures, hyper/hypotension, tachycardia, and dyspnea. Assess mental status, intake/output. Caution client not to drive as a result of drowsiness or dizziness. Advise to change position slowly to minimize effects of orthostatic hypotension.
Ondansetron (Zofran)	Blocks serotonin release, which stimulates the vagal afferent nerves, thus stimulating the vomiting reflex	Monitor for possible side effects such as diarrhea, constipation, abdominal pain, headache, dizziness, drowsiness, and fatigue. Monitor liver function studies as ordered.

Adapted from King, T. L., & Brucker, M. C. (2011). *Pharmacology for women's health*. Sudbury, MA: Jones & Bartlett; and Wilcox, S. R. (2012). Pregnancy, hyperemesis gravidarum. *eMedicine*. Retrieved from <http://emedicine.medscape.com/article/796564-overview>.

to identify signs and symptoms associated with this disorder. The client is extremely uncomfortable. She may experience many hours of lost work productivity and sleep, and hyperemesis may damage family relationships. If hyperemesis progresses untreated, it may cause neurologic disturbances, renal damage, retinal hemorrhage, or death (Jarvis & Nelson-Piercy, 2011). Laboratory and diagnostic tests aid in determining the severity of the disorder.

### Health History and Physical Examination

Begin the history by asking the client about the onset, duration, and course of her nausea and vomiting. Ask her about any medications or treatments she used and how effective they were in relieving her nausea and vomiting. Obtain a diet history from the client, including a dietary recall for the past week. Note the client's knowledge of nutrition and need for appropriate nutritional intake. Be alert for patterns that may contribute to or trigger her distress. Also ask about any complaints of ptyalism (excessive salivation), anorexia, indigestion, and abdominal pain or distention. Ask if she has noticed any blood or mucus in her stool.

Review the client's history for possible risk factors, such as young age, nausea and vomiting with previous pregnancy, history of intolerance of oral contraceptives, nulliparity, trophoblastic disease, multiple gestation, emotional or psychological stress, gastroesophageal reflux disease, primigravida status, obesity, hyperthyroidism, and *Helicobacter pylori* seropositivity (Ogunyemi & Fong, 2012). Weigh the client and compare this weight to her weight before she began experiencing symptoms and to her prepregnancy weight to estimate the degree of loss. With hyperemesis, weight loss usually exceeds 5% of body mass.

Inspect the mucous membranes for dryness and check skin turgor for evidence of fluid loss and dehydration. Assess blood pressure for changes, such as hypotension, that may suggest a fluid volume deficit. Also note any complaints of weakness, fatigue, activity intolerance, dizziness, or sleep disturbances.

Assess the client's perception of the situation. Note any evidence of depression, anxiety, irritability, mood changes, and decreased ability to concentrate, which can add to her emotional distress (Wilcox, 2012). Determine the woman's support systems that are available for help.

### Laboratory and Diagnostic Testing

The results of laboratory and diagnostic tests may provide clues to the severity or etiology of the disorder. These may include:

- Liver enzymes—elevations of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are usually present
- CBC—elevated levels of RBCs and hematocrit, indicating dehydration
- Urine ketones—positive when the body breaks down fat to provide energy in the absence of adequate intake
- Blood urea nitrogen (BUN)—increased in the presence of salt and water depletion
- Urine specific gravity—greater than 1.025, possibly indicating concentrated urine linked to inadequate fluid intake or excessive fluid loss; ketonuria
- Serum electrolytes—decreased levels of potassium, sodium, and chloride resulting from excessive vomiting and loss of hydrochloric acid in stomach
- Ultrasound—evaluation for molar pregnancy or multiple gestation (Sonkusare, 2011)

## Nursing Management

Nursing management for the client with hyperemesis gravidarum focuses on promoting comfort by controlling the client's nausea and vomiting and promoting adequate nutrition. In addition, the nurse plays a major role in supporting and educating the client and her family.

### Promoting Comfort and Nutrition

During the initial period, expect to withhold all oral food and fluids, maintaining NPO status to allow the GI tract to rest. In addition, administer prescribed antiemetics to relieve the nausea and vomiting and IV fluids to replace fluid losses. Monitor the rate of infusion to prevent overload and assess the IV insertion site to prevent infiltration or infection. Also administer electrolyte replacement therapy as ordered to correct any imbalances, and periodically check serum electrolyte levels to evaluate the effectiveness of therapy.

Provide physical comfort measures such as hygiene measures and oral care. Pay special attention to the environment, making sure to keep the area free of pungent odors. As the client's nausea and vomiting subside, gradually introduce oral fluids and foods in small amounts. Monitor intake and output and assess the client's tolerance to the increase in intake.

### Providing Support and Education

Women with hyperemesis gravidarum commonly are fatigued physically and emotionally. Many are exhausted, frustrated, and anxious. Offer reassurance that all interventions are directed toward promoting positive pregnancy outcomes for both the woman and her fetus. Providing information about the expected plan of care may help to alleviate the client's anxiety. Listen to her concerns and feelings, answering all questions honestly. Educate the woman and her family about the condition and its treatment options (Teaching Guidelines 19.1). Teach the client about therapeutic lifestyle changes,

such as avoiding stressors and fatigue that may trigger nausea and vomiting. Offer ongoing support and encouragement and promote active participation in care decisions, thereby empowering the client and her family. Attempting to provide the client with a sense of control may help her overcome the feeling that she has lost control. If necessary, refer the client to a spiritual advisor or counseling. Also suggest possible local or national support groups that the client may contact for additional information.

### Teaching Guidelines 19.1

#### TEACHING TO MINIMIZE NAUSEA AND VOMITING

- Avoid noxious stimuli—such as strong flavors, perfumes, or strong odors such as frying bacon—that might trigger nausea and vomiting.
- Avoid tight waistbands to minimize pressure on abdomen.
- Eat small, frequent meals throughout the day—six small meals.
- Separate fluids from solids by consuming fluids in between meals.
- Avoid lying down or reclining for at least 2 hours after eating.
- Use high-protein supplement drinks.
- Avoid foods high in fat.
- Increase your intake of carbonated beverages.
- Increase your exposure to fresh air to improve symptoms.
- Eat when you are hungry, regardless of normal mealtimes.
- Drink herbal teas containing peppermint or ginger.
- Avoid fatigue and learn how to manage stress in life.
- Schedule daily rest periods to avoid becoming overtired.
- Eat foods that settle the stomach, such as dry crackers, toast, or soda.

Arrange for possible home care follow-up for the client and reinforce discharge instructions to promote understanding. Collaborate with community resources to ensure continuity of care.

## HYPERTENSIVE DISORDERS OF PREGNANCY

Hypertension remains the most commonly encountered medical condition in pregnant women, complicating up to 15% of all pregnancies. It results in frequent hospital admissions, maternal morbidity and mortality, and preterm births with concomitant neonatal morbidity and

mortality. Hypertensive disorders of pregnancy comprise a spectrum of severity ranging from a mild elevation of blood pressure to severe preeclampsia and hemolysis (Chandiramani, Joash, & Shennan, 2010).

Hypertensive disorders of pregnancy include chronic hypertension, gestational hypertension, preeclampsia, eclampsia, and chronic hypertension with superimposed preeclampsia. Preeclampsia complicates about 3% of pregnancies, and all hypertensive disorders affect up to 15% of pregnancies and are on the rise. Hypertensive disorders are associated with higher rates of maternal, fetal, and infant mortality and with severe morbidity, especially in cases of severe preeclampsia, eclampsia, and HELLP syndrome (Hutcheon, Lisonkova, & Joseph, 2011).

ACOG (2010b) and the National High Blood Pressure Education Program (2002) have identified a classification system for hypertensive disorders. Hypertension may be a preexisting condition (chronic hypertension) or it may present for the first time during pregnancy (gestational hypertension). Both chronic hypertension and preeclampsia can be subclassified as either mild or severe. For chronic hypertension, subclassification is dependent on systolic and diastolic values. For preeclampsia, subclassification is dependent on the severity of end organ involvement (Gilbert, 2011). Regardless of its onset or subclassification, hypertension jeopardizes the well-being of the mother as well as the fetus. The classification of hypertensive disorders in pregnancy currently consists of five categories:

- *Chronic hypertension*: hypertension that exists prior to pregnancy or that develops before 20 weeks' gestation
- *Gestational hypertension*: blood pressure elevation (140/90 mm Hg) identified after 20 weeks' gestation without proteinuria. Blood pressure returns to normal by 12 weeks' postpartum
- *Preeclampsia*: most common hypertensive disorder of pregnancy, which develops with proteinuria after 20 weeks' gestation. It is a multisystem disease process, which is classified as mild or severe, depending on the severity of the organ dysfunction.
- *Eclampsia*: Onset of seizure activity in a woman with preeclampsia
- *Chronic hypertension with superimposed preeclampsia*: occurs in approximately 20% of pregnant women with increased maternal and fetal morbidity rates (Mattson & Smith, 2011).

Population-based data indicate that approximately 1% of pregnancies are complicated by chronic hypertension, 5% to 6% by gestational hypertension (without proteinuria), and 1% to 2% by preeclampsia (Gibson & Carson, 2011).

### Chronic Hypertension

Chronic hypertension is defined as blood pressure exceeding 140/90 mm Hg before pregnancy or before

20 weeks' gestation. When hypertension is first identified during a woman's pregnancy and she is less than 20 weeks' gestation, blood pressure elevations usually represent chronic hypertension. Chronic hypertension occurs in about 20% of women of childbearing age, with the prevalence varying according to age, race, and body mass index. As our nation's obesity rate rises, more women will start pregnancies with elevated blood pressures. About 25% of women with chronic hypertension develop preeclampsia during pregnancy (Gibson & Carson, 2011). Women with chronic hypertension in pregnancy should be monitored for the development of worsening hypertension and/or the development of superimposed preeclampsia.

Women with mild chronic hypertension often do not require antihypertensive therapy during most of pregnancy. Pharmacologic treatment of mild hypertension does not reduce the likelihood of developing preeclampsia later in gestation and increases the likelihood of intrauterine growth restriction. If maternal blood pressure exceeds 160/100 mm Hg, however, drug treatment is recommended (Gilbert, 2011). Nurses can play a large role in educating their hypertensive clients to help them understand potential complications and how simple changes in their lifestyles might be helpful in influencing the pregnancy outcome positively.

## Gestational Hypertension

**Gestational hypertension** is characterized by hypertension without proteinuria after 20 weeks' gestation resolving by 12 weeks' postpartum (Mattson & Smith, 2011). Previously, gestational hypertension was known as pregnancy-induced hypertension or toxemia of pregnancy, but these terms are no longer used. Gestational hypertension is defined as systolic blood pressure  $> 140$  mm Hg and/or diastolic  $> 90$  mm Hg on at least two occasions at least 6 hours apart after the 20th week of gestation, in women known to be normotensive prior to this time and prior to pregnancy (Gibson & Carson, 2011). Gestational hypertension can be differentiated from chronic hypertension, which appears before the 20th week of gestation; or hypertension before the current pregnancy, which continues after the woman gives birth. The gestational hypertension category is used in women with nonproteinuric hypertension of pregnancy, in which the pathophysiologic disturbances of the preeclampsia syndrome do not develop before giving birth. Gestational hypertension is a temporary diagnosis for hypertensive pregnant women who do not meet the criteria for preeclampsia (both hypertension and proteinuria) or chronic hypertension (hypertension first detected before the 20th week of pregnancy).

## Preeclampsia and Eclampsia

Normal physiologic adaptations to pregnancy are altered in the woman who develops preeclampsia. Preeclampsia can be described as a multisystem, vasopressive disorder that targets the cardiovascular, hepatic, renal, and central nervous systems. Preeclampsia can be classified as mild or severe with a potential progression to eclampsia. Each is associated with specific criteria. Comparison Chart 19.2 highlights these classifications.

## Pathophysiology

Preeclampsia remains an enigma. The condition can be devastating to both the mother and fetus, and yet the etiology still remains a mystery to medical science despite decades of research. Many theories exist, but none have truly explained the widespread pathologic changes that result in pulmonary edema, oliguria, seizures, thrombocytopenia, and abnormal liver enzymes (Lindheimer, Taler, & Cunningham, 2010). Despite the results of several research studies, the use of aspirin or supplementation with calcium, magnesium, zinc, or antioxidant therapy (vitamin C and E), salt restriction, diuretic therapy, or fish oils has not proved to prevent this destructive condition.

The underlying mechanisms involved with this disorder are vasospasm and hypoperfusion. In addition, endothelial injury occurs, leading to platelet adherence, fibrin deposition, and the presence of schistocytes (fragment of an erythrocyte).

Generalized vasospasm results in elevation of blood pressure and reduced blood flow to the brain, liver, kidneys, placenta, and lungs. Decreased liver perfusion leads to impaired liver function and subcapsular hemorrhage. This is demonstrated by epigastric pain and elevated liver enzymes in the maternal serum. Decreased brain perfusion leads to small cerebral hemorrhages and symptoms of arterial vasospasm such as headaches, visual disturbances, blurred vision, and hyperactive deep tendon reflexes (DTRs). A thromboxane/prostacyclin imbalance leads to increased thromboxane (potent vasoconstrictor and stimulator of platelet aggregation) and decreased prostacyclin (potent vasodilator and inhibitor of platelet aggregation), which contribute to the hypertensive state. Decreased kidney perfusion reduces the glomerular filtration rate, resulting in decreased urine output and increased serum levels of sodium, BUN, uric acid, and creatinine, further increasing extracellular fluid and edema. Increased capillary permeability in the kidneys allows albumin to escape, which reduces plasma colloid osmotic pressure and moves more fluid into extracellular spaces; this leads to pulmonary edema and generalized edema. Poor placental perfusion resulting from prolonged vasoconstriction helps to contribute to intrauterine growth restriction, premature separation of the

## COMPARISON CHART 19.2

## PREECLAMPSIA VERSUS ECLAMPSIA

	Mild Preeclampsia	Severe Preeclampsia	Eclampsia
Blood pressure	>140/90 mm Hg after 20 weeks' gestation	>160/110 mm Hg	>160/110 mm Hg
Proteinuria	300 mg/24 hr or greater than 1+ protein on a random dipstick urine sample	>500 mg/24 hr; greater than 3+ on random dipstick urine sample	Marked proteinuria
Seizures/coma	No	No	Yes
Hyperreflexia	No	Yes	Yes
Other signs and symptoms	Mild facial or hand edema Weight gain	Headache Oliguria Blurred vision, scotomata (blind spots) Pulmonary edema Thrombocytopenia (platelet count <100,000 platelets/mm <sup>3</sup> ) Cerebral disturbances Epigastric or RUQ pain HELLP	Severe headache Generalized edema RUQ or epigastric pain Visual disturbances Cerebral hemorrhage Renal failure HELLP

placenta (abruptio placentae), persistent fetal hypoxia, and acidosis. In addition, hemoconcentration (resulting from decreased intravascular volume) causes increased blood viscosity and elevated hematocrit (ACOG, 2010b).

## Therapeutic Management

Management of the woman with preeclampsia varies depending on the severity of her condition and its effects on the fetus. Typically the woman is managed conservatively if she is experiencing mild symptoms. However, if the condition progresses, management becomes more aggressive.

### Management for Mild Preeclampsia

Conservative strategies for mild preeclampsia are used if the woman exhibits no signs of renal or hepatic dysfunction or coagulopathy. A woman with mild elevations in blood pressure may be placed on bed rest at home. She is encouraged to rest as much as possible in the lateral recumbent position to improve uteroplacental blood flow, reduce her blood pressure, and promote diuresis. In addition, antepartal visits and diagnostic testing—such as CBC, clotting studies, liver enzymes, and platelet levels—increase in frequency. The woman will be asked to monitor her blood pressure daily (every 4 to 6 hours

while awake) and report any increased readings; she will also measure the amount of protein found in urine using a dipstick and will weigh herself for any weight gain. Daily fetal movement counts also are implemented. If there is any decrease in movement, the woman needs to be evaluated by her health care provider that day. A balanced, nutritional diet with no sodium restriction is advised. In addition, she is encouraged to drink six to eight 8-oz glasses of water daily.

If home management fails to reduce the blood pressure, admission to the hospital is warranted and the treatment strategy is individualized based on the severity of the condition and the gestational age at the time of diagnosis. During the hospitalization, the woman with mild preeclampsia is monitored closely for signs and symptoms of severe preeclampsia or impending eclampsia (e.g., persistent headache, hyperreflexia). Blood pressure measurements are frequently recorded along with daily weights to detect excessive weight gain resulting from edema. Fetal surveillance is instituted in the form of daily fetal movement counts, nonstress testing, and serial ultrasounds to evaluate fetal growth and amniotic fluid volume to confirm fetal well-being. Expectant management usually continues until the pregnancy reaches term, fetal lung maturity is documented, or complications develop that warrant immediate birth. Women with mild preeclampsia are at greatest risk for postpartum hypertension (Cruz, Gao, & Hibbard, 2011).

Prevention of disease progression is the focus of treatment during labor. Blood pressure is monitored frequently and a quiet environment is important to minimize the risk of stimulation and to promote rest. IV magnesium sulfate is infused to prevent any seizure activity, along with antihypertensives if blood pressure values begin to rise. Calcium gluconate is kept at the bedside in case the magnesium level becomes toxic. Continued close monitoring of neurologic status is warranted to detect any signs or symptoms of hypoxemia, impending seizure activity, or increased intracranial pressure. An indwelling urinary (Foley) catheter usually is inserted to allow for accurate measurement of urine output.

### Management for Severe Preeclampsia

Severe preeclampsia may develop suddenly and bring with it high blood pressure of more than 160/110 mm Hg, proteinuria of more than 5 g in 24 hours, oliguria of less than 400 mL in 24 hours, cerebral and visual symptoms, and rapid weight gain. This clinical picture signals severe preeclampsia, and immediate hospitalization is needed.

Treatment is highly individualized and based on disease severity and fetal age. Birth of the infant is the only cure, because preeclampsia depends on the presence of trophoblastic tissue. Therefore, the exact age of the fetus is assessed to determine viability.

Severe preeclampsia is treated aggressively because hypertension poses a serious threat to mother and fetus. The goal of care is to stabilize the mother–fetus dyad and prepare for birth. Therapy focuses on controlling hypertension, preventing seizures, preventing long-term morbidity, and preventing maternal, fetal, or newborn death (Lim & Erogul, 2011). Intense maternal and fetal surveillance starts when the mother enters the hospital and continues throughout her stay.

The woman in labor with severe preeclampsia typically receives oxytocin to stimulate uterine contractions and magnesium sulfate to prevent seizure activity. Oxytocin and magnesium sulfate can be given simultaneously via infusion pumps to ensure both are administered at the prescribed rate. Magnesium sulfate is given IV via an infusion pump. A loading dose of 4 to 6 g is given over 5 minutes. Then, a maintenance dose of 2 g/hour is given.

The client is evaluated closely for magnesium toxicity. If at all possible, a vaginal delivery is preferable to a cesarean birth for better maternal outcomes and less risk associated with a surgical birth. PGE2 gel may be used to ripen the cervix. A cesarean birth may be performed if the client is seriously ill. A pediatrician/neonatologist or neonatal nurse practitioner should be available in the birthing room to care for the newborn. A newborn whose mother received high doses of magnesium sulfate

needs to be monitored for respiratory depression, hypocalcemia, and hypotonia. Decreased fetal heart rate variability may occur but, in general, magnesium sulfate does not pose a risk to the fetus. The newborn may exhibit respiratory depression, loss of reflexes, muscle weakness, and neurologic depression (Cruz et al., 2011).

### Management of Eclampsia

In the woman who develops an eclamptic seizure, the convulsive activity begins with facial twitching, followed by generalized muscle rigidity. Respirations cease for the duration of the seizure, resulting from muscle spasms, thus compromising fetal oxygenation. Coma usually follows the seizure activity, with respiration resuming. Eclamptic seizures are life-threatening emergencies and require immediate treatment to decrease maternal morbidity and mortality.

As with any seizure, the initial management is to clear the airway and administer adequate oxygen. Positioning the woman on her left side and protecting her from injury during the seizure are key. Suction equipment must be readily available to remove secretions from her mouth after the seizure is over. IV fluids are administered after the seizure at a rate to replace urine output and additional insensible losses. Fetal heart rate is monitored closely. Magnesium sulfate is administered IV to prevent further seizures. Serum magnesium levels, respiratory rate, reflexes, and urine output in women receiving magnesium sulfate are closely monitored to avoid magnesium toxicity and prevent cardiac arrest. Calcium gluconate (1 g IV) is typically ordered to counteract magnesium toxicity. Hypertension is controlled with antihypertensive medications. After the seizures are controlled, the woman's stability is assessed and birth via induction or cesarean birth is performed (Schub, 2011).

If the woman's condition remains stable, she will be transferred to the postpartum unit for care. If she becomes unstable after giving birth, she may be transferred to the critical care unit for closer observation.

### Nursing Assessment

Preventing complications related to preeclampsia requires the use of assessment, advocacy, and counseling skills. Assessment begins with the accurate measurement of the client's blood pressure at each encounter. In addition, nurses need to assess for subjective complaints that may indicate progression of the disease—visual changes, severe headaches, unusual bleeding or bruising, or epigastric pain (Schub, 2011). The significant signs of preeclampsia—proteinuria and hypertension—occur without the woman's awareness. Unfortunately, by the time symptoms are noticed, gestational hypertension can be severe.

**Take Note!**

The absolute blood pressure (value that validates elevation) of 140/90 mm Hg should be obtained on two occasions 6 hours apart to be diagnostic of preeclampsia. Proteinuria is defined as 300 mg or more of urinary protein per 24 hours or more than 1+ protein by chemical reagent strip or dipstick of at least two random urine samples collected at least 6 hours apart with no evidence of UTI (ACOG, 2010b).

### Health History and Physical Examination

Take a thorough history during the first antepartal visit to identify whether the woman is at risk for preeclampsia.

Risk factors include:

- Primigravida status
- Chromosomal abnormalities
- Structural congenital anomalies
- Multifetal pregnancy
- History of preeclampsia in a previous pregnancy
- Excessive placental tissue, as is seen in women with GTD
- Chronic stress
- Use of ovulation drugs
- Family history of preeclampsia (mother or sister)
- Lower socioeconomic group
- History of diabetes, hypertension, or renal disease
- Poor nutrition
- African American ethnicity
- Age extremes (younger than 20 or older than 40)
- Obesity (Tharpe, Farley, & Jordan, 2013)

In addition, complete a nutritional assessment that includes the woman's usual intake of protein, calcium, daily calories, and fluids.

Women at risk for preeclampsia require more frequent prenatal visits throughout their pregnancy, and they require teaching about problems so that they can report them promptly.

Blood pressure must be measured carefully and consistently. Obtain all measurements with the woman in the same position (blood pressure is highest in the sitting position and lowest in the side-lying position) and by using the same technique (automated vs. manual). This standardization in position and technique will yield the most accurate readings (Macdonald-Wallis, Lawlor, Fraser, May et al., 2012).

Obtain the client's weight (noting gain since last visit), and assess for amount and location of edema. Asking questions such as "Do your rings still fit on your fingers?" or "Is your face puffy when you get up in the morning?" will help to determine whether fluid retention is present or if the woman's status has changed since her last visit.

**Take Note!**

Although edema is not a cardinal sign of preeclampsia, weight should be monitored frequently to identify sudden gains in a short time span. Current research relies less

on the classic triad of symptoms (hypertension, proteinuria, and edema or weight gain) and more on decreased organ perfusion, endothelial dysfunction (capillary leaking and proteinuria), and elevated blood pressure as key indicators (Gibson & Carson, 2011).

If edema is present, assess the distribution, degree, and pitting. Document your findings and identify whether the edema is dependent or pitting. Dependent edema is present on the lower half of the body if the client is ambulatory, where hydrostatic pressure is greatest. It is usually observed in the feet and ankles or in the sacral area if the client is on bed rest.

Pitting edema is edema that leaves a small depression or pit after finger pressure is applied to a swollen area (Gibson & Carson, 2011). Record the depth of pitting demonstrated when pressure is applied. Although subjective, the following is used to record relative degrees:

- 1+ pitting edema = 2-mm depression into skin; disappears rapidly
- 2+ pitting edema = 4-mm skin depression; disappears in 10 to 15 seconds
- 3+ pitting edema = 6-mm depression into skin; lasts more than 1 minute
- 4+ pitting edema = 8-mm depression into skin; lasts 2 to 3 minutes

At every antepartal visit, assess the fetal heart rate with a Doppler device. Also check a clean-catch urine specimen for protein using a dipstick.

### Laboratory and Diagnostic Testing

Various laboratory tests may be performed to evaluate the woman's status. Typically these include a CBC, serum electrolytes, BUN, creatinine, and hepatic enzyme levels. Urine specimens are checked for protein; if levels are 1 to 2+ or greater, a 24-hour urine collection is completed.

### Nursing Management

Nursing management of the woman with preeclampsia focuses on close monitoring of blood pressure and ongoing assessment for evidence of disease progression. Throughout the client's pregnancy, fetal surveillance is key.

### Intervening With Preeclampsia

The woman with mild preeclampsia requires frequent monitoring to detect changes because preeclampsia can progress rapidly. Instruct all women in the signs and symptoms of preeclampsia and urge them to contact their health care professional for immediate evaluation should any occur.

Typically women with mild preeclampsia can be managed at home if they have a good understanding

of the disease process, blood pressure and vital signs are stable, have no abnormal laboratory test results, and demonstrate good fetal movement (Teaching Guidelines 19.2). The home care nurse makes frequent visits and follow-up phone calls to assess the woman's condition, to assist with scheduling periodic evaluations of the fetus (such as nonstress tests), and to evaluate any changes that might suggest a worsening of the woman's condition.

### Teaching Guidelines 19.2

#### TEACHING FOR THE WOMAN WITH MILD PREECLAMPSIA

- Rest in a quiet environment to prevent cerebral disturbances.
- Drink 8 to 10 glasses of water daily.
- Consume a balanced, high-protein diet including high-fiber foods.
- Obtain intermittent bed rest to improve circulation to the heart and uterus.
- Limit your physical activity to promote urination and subsequent decrease in blood pressure.
- Enlist the aid of your family so that you can obtain appropriate rest time.
- Perform self-monitoring as instructed, including:
  - Taking your own blood pressure twice daily
  - Checking and recording weight daily
  - Performing urine dipstick twice daily
  - Recording the number of fetal kicks daily
- Contact the home health nurse if any of the following occurs:
  - Increase in blood pressure
  - Protein present in urine
  - Gain of more than 1 pound in 1 week
  - Burning or frequency when urinating
  - Decrease in fetal activity or movement
  - Headache (forehead or posterior neck region)
  - Dizziness or visual disturbances
  - Increase in swelling in hands, feet, legs, and face
  - Stomach pain, excessive heartburn, or epigastric pain
  - Decreased or infrequent urination
  - Contractions or low back pain
  - Easy or excessive bruising
  - Sudden onset of abdominal pain
  - Nausea and vomiting

Early detection and management of mild preeclampsia is associated with the greatest success in reducing progression of this condition. As long as the client carries out the guidelines of care as outlined by the health care provider and remains stable, home care can continue

to maintain the pregnancy until the fetus is mature. If disease progression occurs, hospitalization is required.

### Intervening With Severe Preeclampsia

The woman with severe preeclampsia requires hospitalization. Maintain the client on complete bed rest in the left lateral lying position. Ensure that the room is dark and quiet to reduce stimulation. Give sedatives as ordered to encourage quiet bed rest. The client is at risk for seizures if the condition progresses. Therefore, institute and maintain seizure precautions, such as padding the side rails and having oxygen, suction equipment, and call light readily available to protect the client from injury.

#### Take Note!

Preeclampsia increases the risk of placental abruption, preterm birth, intrauterine growth restriction, and fetal distress during childbirth. Be prepared!

Closely monitor the client's blood pressure. Administer antihypertensives as ordered to reduce blood pressure (Drug Guide 19.3). Assess the client's vision and level of consciousness. Report any changes and any complaints of headache or visual disturbances. Offer a high-protein diet with 8 to 10 glasses of water daily. Monitor the client's intake and output every hour and administer fluid and electrolyte replacements as ordered. Assess the woman for signs and symptoms of pulmonary edema, such as crackles and wheezing heard on auscultation, dyspnea, decreased oxygen saturation levels, cough, neck vein distention, anxiety, and restlessness. The treatment of acute pulmonary edema is symptomatic and includes the administration of vasodilating agents and of diuretics. The development of acute pulmonary edema in women with hypertension during pregnancy is associated with high levels of IV fluid administration (Thornton et al., 2011).

To achieve a safe outcome for the fetus, prepare the woman for possible testing to evaluate fetal status as preeclampsia progresses. Testing may include the nonstress test, serial ultrasounds to track fetal growth, amniocentesis to determine fetal lung maturity, Doppler velocimetry to screen for fetal compromise, and biophysical profile to evaluate ongoing fetal well-being (Lindheimer et al., 2010).

Other laboratory tests may be performed to monitor the disease process and to determine if it is progressing into HELLP syndrome. These include liver enzymes such as lactic dehydrogenase (LDH), ALT, and AST; chemistry panel, such as creatinine, BUN, uric acid, and glucose; CBC, including platelet count; coagulation studies, such as PT, PTT, fibrinogen, and bleeding time; and a 24-hour urine collection for protein and creatinine clearance.

**DRUG GUIDE 19.3 MEDICATIONS USED WITH PREECLAMPSIA AND ECLAMPSIA**

Medication	Action/Indications	Nursing Implications
Magnesium sulfate	Blockage of neuromuscular transmission, vasodilation Prevention and treatment of eclamptic seizures	Loading dose of 4 to 6 grams by IV in 100 ml of fluid administered over 15 to 20 minutes, followed by a maintenance dose of 2 grams as a continuous IV infusion. Monitor serum magnesium levels closely. Assess DTRs and check for ankle clonus. Have calcium gluconate readily available in case of toxicity. Monitor for signs and symptoms of toxicity, such as flushing, sweating, hypotension, and cardiac and CNS depression.
Hydralazine hydrochloride (Apresoline)	Vascular smooth muscle relaxant, thus improving perfusion to renal, uterine, and cerebral areas Reduction in blood pressure	Administer 5–10 mg by slow IV bolus every 20 min as needed. Use parenteral form immediately after opening ampule. Withdraw drug slowly to prevent possible rebound hypertension. Monitor for adverse effects such as palpitations, headache, tachycardia, anorexia, nausea, vomiting, and diarrhea.
Labetalol hydrochloride (Normodyne)	Alpha-1 and beta blocker Reduction in blood pressure	Be aware that drug lowers blood pressure without decreasing maternal heart rate or cardiac output. Administer IV dose of 20–40 mg every 15 min as needed and then administer IV infusion of 2 mg/min until desired blood pressure value achieved. Monitor for possible adverse effects such as gastric pain, flatulence, constipation, dizziness, vertigo, and fatigue.
Nifedipine (Procardia)	Calcium channel blocker/dilation of coronary arteries, arterioles, and peripheral arterioles Reduction in blood pressure, stoppage of preterm labor	Administer 10–20 mg orally for three doses and then every 4–8 hr. Monitor for possible adverse effects such as dizziness, peripheral edema, angina, diarrhea, nasal congestions, cough.
Sodium nitroprusside	Rapid vasodilation (arterial and venous) Severe hypertension requiring rapid reduction in blood pressure	Administer via continuous IV infusion with dose titrated according to blood pressure levels. Wrap IV infusion solution in foil or opaque material to protect from light. Monitor for possible adverse effects, such as apprehension, restlessness, retrosternal pressure, palpitations, diaphoresis, abdominal pain.
Furosemide (Lasix)	Diuretic action, inhibiting the reabsorption of sodium and chloride from the ascending loop of Henle Pulmonary edema (used only if condition is present)	Administer via slow IV bolus at a dose of 10–40 mg over 1–2 min. Monitor urine output hourly. Assess for possible adverse effects such as dizziness, vertigo, orthostatic hypotension, anorexia, vomiting, electrolyte imbalances, muscle cramps, and muscle spasms.

Adapted from Gilbert, E. S. (2011). *Manual of high-risk pregnancy and delivery* (5th ed.). St. Louis, MO: Mosby Elsevier; and King, T. L., & Brucker, M. C. (2011). *Pharmacology for women's health*. Sudbury, MA: Jones & Bartlett.

Administer parenteral magnesium sulfate as ordered to prevent seizures. Assess DTRs to evaluate the effectiveness of therapy. Clients with preeclampsia commonly present with hyperreflexia. Severe preeclampsia causes changes in the cortex, which disrupts the equilibrium of impulses between the cerebral cortex and the spinal cord. Brisk reflexes (hyperreflexia) are the result of an irritable cortex and indicate central nervous system (CNS) involvement (Choi, Lee, Oh, Kim et al., 2012).

Diminished or absent reflexes occur when the client develops magnesium toxicity. Because magnesium is a potent neuromuscular blockade, the afferent and efferent nerve pathways do not relay messages properly and hyporeflexia develops. Common sites used to assess DTRs are biceps reflex, triceps reflex, patellar reflex, Achilles reflex, and plantar reflex. Nursing Procedure 19.1 highlights the steps for assessing the patellar reflex.

The National Institute of Neurological Disorders and Stroke, a division of the National Institutes of Health, published a scale in the early 1990s that, although subjective, is used widely today. It grades reflexes from 0 to 4+. Grades 2+ and 3+ are considered normal, whereas grades 0 and 4 may indicate pathology (Table 19.2). Because these are subjective assessments, to improve communication of reflex results, condensed descriptor categories such as absent, average, brisk, or clonus should be used rather than numeric codes (Gilbert, 2011).

Clonus is the presence of rhythmic involuntary contractions, most often at the foot or ankle. Sustained clonus confirms CNS involvement. Nursing Procedure 19.2 highlights the steps when testing for ankle clonus.

With magnesium sulfate administration, the client is at risk for magnesium toxicity. Closely assess the client for signs of toxicity, which include a respiratory rate of less than 12 breaths per minute, absence of DTRs, and a decrease in urinary output (<30 mL/hour). Also monitor serum magnesium levels. Although exact levels may vary among agencies, serum magnesium levels ranging from 4 to 7 mEq/L are considered therapeutic, whereas levels more than 8 mEq/dL are generally considered toxic. As levels increase, the woman is at risk for severe problems:

- 10 mEq/L: possible loss of DTRs
- 15 mEq/L: possible respiratory depression
- 25 mEq/L: possible cardiac arrest (Mattson & Smith, 2011)

If signs and symptoms of magnesium toxicity develop, expect to administer calcium gluconate as the antidote.

Throughout the client's stay, closely monitor her for signs and symptoms of labor. Perform continuous electronic fetal monitoring to assess fetal well-being. Note trends in baseline rate and presence or absence of accelerations or decelerations. Also observe for signs of fetal distress and report them immediately. Administer glucocorticoid treatment as ordered to enhance fetal lung maturity and prepare for labor induction if the mother's condition warrants.

## NURSING PROCEDURE 19.1

### Assessing the Patellar Reflex

#### Purpose: To Evaluate for Nervous System Irritability Related to Preeclampsia

1. Place the woman in the supine position (or sitting upright with the legs dangling freely over the side of the bed or examination table).
2. If lying supine, have the woman flex her knee slightly.
3. Place a hand under the knee to support the leg and locate the patellar tendon. It should be midline just below the knee cap.
4. Using a reflex hammer or the side of your hand, strike the area of the patellar tendon firmly and quickly.
5. Note the movement of the leg and foot. A patellar reflex occurs when the leg and foot move (documented as 2+).
6. Repeat the procedure on the opposite leg.

Keep the client and family informed of the woman's condition and educate them about the course of treatment. Provide emotional support for the client and family. Severe preeclampsia is very frightening for the client and her family, and most expectant mothers are very anxious about their own health as well as that of the fetus. To allay anxiety, use light touch to comfort and reassure her that the necessary actions are being taken.

**TABLE 19.2** GRADING DEEP TENDON REFLEXES

Description of Finding	Grade
Reflex absent, none elicited	0
Hypoactive response, sluggish	1
Reflex in lower half of normal range	2
Reflex in upper half of normal range	3
Hyperactive, brisk, clonus present	4

Adapted from Gilbert, E. S. (2011). *Manual of high-risk pregnancy and delivery* (5th ed.). St. Louis, MO: Mosby Elsevier; and Mattson, S., & Smith, J. E. (2011). *Core curriculum for maternal–newborn nursing* (4th ed.). St. Louis, MO: Saunders Elsevier.

Actively listening to her concerns and fears and communicating them to the health care provider are important in keeping lines of communication open. Offering praise for small accomplishments can provide positive reinforcement for behaviors that should be continued.

### Intervening for Eclampsia

The onset of seizure activity identifies eclampsia. Typically, eclamptic seizures are generalized and start with

facial twitching. The body then becomes rigid, in a state of tonic muscular contraction. The clonic phase of the seizure involves alternating contraction and relaxation of all body muscles. Respirations stop during seizure activity and resume shortly after it ends. Client safety is the primary concern during eclamptic seizures. If possible, turn the client to her side and remain with her. Make sure that the side rails are up and padded. Dim the lights and keep the room quiet.

Document the time and sequence of events as soon as possible. After the seizure activity has ceased, suction the nasopharynx as necessary and administer oxygen. Continue the magnesium sulfate infusion to prevent further seizures. Ensure continuous electronic fetal monitoring, evaluating fetal status for changes. Also assess the client for uterine contractions. After the client is stabilized, prepare her for the birthing process as soon as possible to reduce the risk of perinatal mortality.

### Providing Follow-Up Care

After delivery of the newborn, continue to monitor the client for signs and symptoms of preeclampsia/eclampsia for at least 48 hours. Expect to continue to administer magnesium sulfate infusion for 24 hours to prevent seizure activity, and monitor serum magnesium levels for toxicity.

## NURSING PROCEDURE 19.2

### Testing for Ankle Clonus

#### Purpose: To Evaluate for Nervous System Irritability Related to Preeclampsia

1. Place the woman in the supine position.
2. Have the client slightly bend her knee and place a hand under the knee to support it.
3. Dorsiflex the foot briskly and then quickly release it.
4. Watch for the foot to rebound smoothly against your hand. If the movement is smooth without any rapid contractions of the ankle or calf muscle, then clonus is not present; if the movement is jerky and rapid, clonus is present.
5. Repeat on the opposite side.

Assess vital signs at least every 4 hours, along with routine postpartum assessments: fundus, lochia, breasts, bladder, bowels, and the woman's emotional state. Monitor urine output closely. Diuresis is a positive sign that, along with a decrease in proteinuria, signals resolution of the disease.

## HELLP SYNDROME

The HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count) is a variant of the preeclampsia/eclampsia syndrome that occurs in 10% to 20% of clients whose diseases are labeled as severe (Moodley & Khedun, 2011). It is a life-threatening obstetric complication considered by many to be a severe form of preeclampsia involving hemolysis, thrombocytopenia, and liver dysfunction. Both HELLP and preeclampsia occur during the later stages of pregnancy, and sometimes after childbirth. HELLP syndrome is a clinically progressive condition. Early diagnosis is critical to prevent liver distention, rupture, and hemorrhage and the onset of DIC. If the condition presents prenatally, morbidity and mortality can affect both mother and baby.

HELLP syndrome occurs in up to 20% of pregnant women diagnosed with severe preeclampsia. It is unique, as it is a laboratory-value specific diagnosis. Women with HELLP usually have fewer signs of abnormalities consistent with the metabolic syndrome and a lower prevalence of thrombophilia as compared with preeclampsia women without HELLP (Sep et al., 2010). Although it has been reported as early as 17 weeks' gestation, most of the time it is diagnosed between 22 and 36 weeks' gestation (Pawelec, Palczynski, & Karmowski, 2012). It can present prior to the presence of an elevated blood pressure. HELLP syndrome leads to an increased maternal risk for developing liver hematoma or rupture, stroke, cardiac arrest, seizure, pulmonary edema, DIC, subendocardial hemorrhage, adult respiratory distress syndrome, renal damage, sepsis, hypoxic encephalopathy, and maternal or fetal death (Pridjian, 2011). The recognition of HELLP syndrome and an aggressive multidisciplinary approach and prompt transfer of these women to obstetric centers with expertise in this field are required for the improvement of maternal–fetal prognosis.

## Pathophysiology

The hemolysis that occurs is termed microangiopathic hemolytic anemia. This cascade of events is thought to happen when RBCs become fragmented as they pass through small, damaged blood vessels. Elevated liver enzymes are the result of reduced blood flow to the liver secondary to obstruction from fibrin deposits. At the same time, endothelial damage and fibrin deposition in the liver may lead

to liver impairment and can result in hemorrhagic necrosis, indicated by right upper quadrant (RUQ) tenderness, nausea, and vomiting. Hyperbilirubinemia and jaundice result from liver impairment. Low platelets result from vascular damage, the result of vasospasm, and platelets aggregate at sites of damage, resulting in thrombocytopenia in multiple sites (Ciantar & Walker, 2011).

## Therapeutic Management

The treatment for HELLP syndrome is based on the severity of the disease, the gestational age of the fetus, and the condition of the mother and fetus. The mainstay of treatment is lowering of high blood pressure with rapid-acting antihypertensive agents, prevention of convulsions or further seizures with magnesium sulfate, and use of steroids for fetal lung maturity if necessary, followed by the birth of the infant (Onyangunga & Moodley, 2012). The client should be admitted or transferred to a tertiary center with a neonatal intensive care unit. Additional treatment includes correction of the coagulopathies that accompany HELLP syndrome. After this syndrome is diagnosed and the woman's condition is stable, birth of the infant is indicated.

Magnesium sulfate is used prophylactically to prevent seizures. Antihypertensives such as hydralazine or labetalol are given to control blood pressure. Blood component therapy—such as fresh-frozen plasma, packed red blood cells, or platelets—is transfused to address the microangiopathic hemolytic anemia. Birth may be delayed up to 96 hours so that betamethasone or dexamethasone can be given to stimulate lung maturation in the preterm fetus.

## Nursing Assessment

Nursing assessment of the woman with HELLP is similar to that for the woman with severe preeclampsia. Be alert for complaints of nausea (with or without vomiting), malaise, epigastric or RUQ pain, and demonstrable edema. Perform systematic assessments frequently, as indicated by the woman's condition and response to therapy.

A diagnosis of HELLP syndrome is made based on laboratory test results, including:

- Low hematocrit that is not explained by any blood loss
- Elevated LDH (liver impairment)
- Elevated AST (liver impairment)
- Elevated ALT (liver impairment)
- Elevated BUN
- Elevated bilirubin level
- Elevated uric acid and creatinine levels (renal involvement)
- Low platelet count (less than 100,000 cells/mm<sup>3</sup>)

## Nursing Management

Nursing management of the woman diagnosed with HELLP syndrome is the same as that for the woman with severe preeclampsia. If possible, the woman with HELLP syndrome should be transferred to a tertiary care center once she has been assessed and stabilized. Closely monitor the client for changes and provide ongoing support throughout this experience.

## GESTATIONAL DIABETES

Gestational diabetes is a condition involving glucose intolerance that occurs during pregnancy. It is discussed in greater detail in Chapter 20.

## BLOOD INCOMPATIBILITY

Blood incompatibility most commonly involves one of two issues: blood type or the Rh factor. *Blood type incompatibility*, also known as ABO incompatibility, arises when a mother with blood type O becomes pregnant with a fetus with a different blood type (type A, B, or AB). The mother's serum contains naturally occurring anti-A and anti-B, which can cross the placenta and hemolyze fetal RBCs. It is usually less severe than Rh incompatibility. One reason is that fetal RBCs express less of the ABO blood group antigens compared with adult levels. In addition, in contrast to the Rh antigens, the ABO blood group antigens are expressed by a variety of fetal (and adult) tissues, reducing the chances of anti-A and anti-B binding their target antigens on the fetal RBCs. ABO incompatibility rarely causes significant hemolysis, and prenatal treatment is not warranted.

*Rh factor incompatibility* occurs when a pregnant woman's immune system creates antibodies against fetal Rh blood factors. Although the mother will exhibit no symptoms of Rh incompatibility, Rh antibodies adversely affect fetal health. Rh antibodies can cause fetal heart problems, breathing difficulties, jaundice, and a form of anemia known as hemolytic disease of the newborn. Rh sensitization occurs in approximately 1 in 1,000 births to Rh-negative women (March of Dimes, 2011f). According to the CDC (2011), Rh disease affected 16,000 newborns in the United States annually before RhoGAM administration was used to prevent it. Despite prevention measures, approximately 4,000 infants are still annually affected with Rh disease.

## Pathophysiology

Hemolysis associated with *ABO incompatibility* is limited to type O mothers with fetuses who have type A or B blood. In mothers with type A and B blood, naturally occurring antibodies are of the IgM class, which

do not cross the placenta, whereas in type O mothers, the antibodies are predominantly IgG in nature. Because A and B antigens are widely expressed in a variety of tissues besides RBCs, only a small portion of the antibodies crossing the placenta is available to bind to fetal red cells. In addition, fetal red cells appear to have less surface expression of A or B antigen, resulting in few reactive sites—hence the low incidence of significant hemolysis in affected neonates.

With ABO incompatibility, usually the mother is blood type O, with anti-A and anti-B antibodies in her serum; the infant is blood type A, B, or AB. The incompatibility arises as a result of the interaction of antibodies present in maternal serum and the antigen sites on the fetal red cells.

*Rh incompatibility* is a condition that develops when a woman with Rh-negative blood type is exposed to Rh-positive blood cells and subsequently develops circulating titers of Rh antibodies. Individuals with Rh-positive blood type have the D antigen present on their red cells, whereas individuals with an Rh-negative blood type do not. The presence or absence of the Rh antigen on the RBC membrane is genetically controlled.

In the United States, about 15% of the Caucasian population, 5% to 8% of the African American and Hispanic populations, and 1% to 2% of the Asian and Native American populations are Rh negative. The vast majority (85%) of individuals is considered Rh positive (March of Dimes, 2011f).

Rh incompatibility most commonly arises with exposure of an Rh-negative mother to Rh-positive fetal blood during pregnancy or birth, during which time erythrocytes from the fetal circulation leak into the maternal circulation. Isoimmunization can also occur during an amniocentesis, ectopic pregnancy, placenta previa, placenta abruption, in utero fetal death, spontaneous abortion, or abdominal/pelvic trauma. After a significant exposure, alloimmunization or sensitization occurs. As a result, maternal antibodies are produced against the foreign Rh antigen.

Theoretically, fetal blood and maternal blood do not mix during pregnancy. In reality, however, small placental accidents (transplacental bleeds secondary to minor separation), abortions, ectopic pregnancy, abdominal trauma, trophoblastic disease, amniocentesis, placenta previa, and abruptio placentae allow fetal blood to enter the maternal circulation and initiate the production of antibodies to destroy Rh-positive blood. The amount of fetal blood necessary to produce Rh incompatibility varies. In one study, less than 1 mL of Rh-positive blood was shown to result in sensitization of women who are Rh negative (Salem & Singer, 2012).

Once sensitized, it takes approximately a month for Rh antibodies in the maternal circulation to cross over into the fetal circulation. In 90% of cases, sensitization occurs during delivery (Kim, & Makar, 2012). Thus, most firstborn

infants with Rh-positive blood type are not affected because the short period from first exposure of Rh-positive fetal erythrocytes to the birth of the infant is insufficient to produce a significant maternal IgG antibody response.

The risk and severity of alloimmune response increase with each subsequent pregnancy involving a fetus with Rh-positive blood. A second pregnancy with an Rh-positive fetus often produces a mildly anemic infant, whereas succeeding pregnancies produce infants with more serious hemolytic anemia.

## Nursing Assessment

At the first prenatal visit, determine the woman's blood type and Rh status. Also obtain a thorough health history, noting any reports of previous events involving hemorrhage to delineate the risk for prior sensitization. When the client's history reveals an Rh-negative mother who may be pregnant with an Rh-positive fetus, prepare the client for an antibody screen (indirect Coombs test) to determine whether she has developed isoimmunity to the Rh antigen. This test detects unexpected circulating antibodies in a woman's serum that could be harmful to the fetus (Gilbert, 2011).

## Nursing Management

If the indirect Coombs test is negative (meaning no antibodies are present), then the woman is a candidate for RhoGAM. If the test is positive, RhoGAM is of no value because isoimmunization has occurred. In this case, the fetus is carefully monitored for hemolytic disease.

The incidence of isoimmunization has declined dramatically as a result of prenatal and postnatal RhoGAM administration after any event in which blood transfer may occur. The standard dose is 300 mcg, which is effective for 15 mL of fetal blood cells. Rh immunoglobulin helps to destroy any fetal cells in the maternal circulation before sensitization occurs, thus inhibiting maternal antibody production. This provides temporary passive immunity, thereby preventing maternal sensitization.

The current recommendation is for every Rh-negative nonimmunized woman to receive RhoGAM at some point between 28 and 32 weeks' gestation and again within 72 hours after giving birth. Other indications for RhoGAM include:

- Ectopic pregnancy
- Chorionic villus sampling
- Amniocentesis
- Prenatal hemorrhage
- Molar pregnancy
- Maternal trauma
- Percutaneous umbilical sampling
- Therapeutic or spontaneous abortion
- Fetal death
- Fetal surgery (King & Brucker, 2011)

Despite the availability of RhoGAM and laboratory tests to identify women and newborns at risk, isoimmunization remains a serious clinical reality that continues to contribute to perinatal and neonatal mortality. Nurses, as client advocates, are in a unique position to make sure test results are brought to the health care provider's attention so appropriate interventions can be initiated. In addition, nurses must stay abreast of current literature and research regarding isoimmunization and its management. Stress to all women that early prenatal care can help identify and prevent this condition. Because Rh incompatibility is preventable with the use of RhoGAM, prevention remains the best treatment. Nurses can make a tremendous impact to ensure positive outcomes for the greatest possible number of pregnancies through education.

## AMNIOTIC FLUID IMBALANCES

Amniotic fluid develops from several maternal and fetal structures, including the amnion, chorion, maternal blood, fetal lungs, GI tract, kidneys, and skin. Any alteration in one or more of the various sources will alter the amount of amniotic fluid. Hydramnios and oligohydramnios are two imbalances associated with amniotic fluid.

### Hydramnios

**Hydramnios**, formerly called polyhydramnios, is a condition in which there is too much amniotic fluid (more than 2,000 mL) surrounding the fetus between 32 and 36 weeks. It occurs in approximately 3% of all pregnancies and is associated with fetal anomalies of development. Approximately 18% of all women with diabetes will develop hydramnios during their pregnancy. There is an increase in cesarean births for fetal labor intolerance, low 5-min Apgar scores, increased neonatal birth weight, congenital anomalies, and newborn intensive care unit admissions for women with too much amniotic fluid at term (Moore, 2011). Overall, it is associated with poorer fetal outcomes because of the increased incidence of preterm births, fetal malpresentation, and cord prolapse.

There are several causes of hydramnios. Generally, too much fluid is being produced, there is a problem with the fluid being taken up, or both. It can be associated with maternal disease and fetal anomalies, but it can also be idiopathic in nature.

## Therapeutic Management

Treatment may include close monitoring and frequent follow-up visits with the health care provider if the hydramnios is mild to moderate. In severe cases in which the woman is in pain and experiencing shortness of

breath, an amniocentesis or artificial rupture of the membranes is done to reduce the fluid and the pressure. Removal of fluid by amniocentesis is only transiently effective. A noninvasive treatment may involve the use of a prostaglandin synthesis inhibitor (indomethacin) to decrease amniotic fluid volume by decreasing fetal urinary output, but this may cause premature closure of the fetal ductus arteriosus (Boyd & Carter, 2011).

## Nursing Assessment

Begin the assessment with a thorough history, being alert to risk factors such as maternal diabetes or multiple gestations. Review the maternal history for information about possible fetal anomalies, including fetal esophageal or intestinal atresia, neural tube defects, chromosomal deviations, fetal hydrops, CNS or cardiovascular anomalies, and hydrocephaly.

Determine the gestational age of the fetus and measure the woman's fundal height. With hydramnios, there is a discrepancy between fundal height and gestational age, or a rapid growth of the uterus is noted. Assess the woman for complaints of discomfort in her abdomen, such as being severely stretched and tight. Also note any reports of uterine contractions, which may result from overstretching of the uterus. Assess for shortness of breath resulting from pressure on her diaphragm and inspect her lower extremities for edema, which results from increased pressure on the vena cava.

Palpate the abdomen and obtain fetal heart rate. Often the fetal parts and heart rate are difficult to obtain because of the excess fluid present.

Prepare the woman for possible diagnostic testing to evaluate for the presence of possible fetal anomalies. An ultrasound usually is done to measure the pockets of amniotic fluid to estimate the total volume. In some cases, ultrasound also is helpful in finding the etiology of hydramnios, such as multiple pregnancy or a fetal structural anomaly.

## Nursing Management

Nursing management of the woman with hydramnios focuses on ongoing assessment and monitoring for symptoms of abdominal pain, dyspnea, uterine contractions, and edema of the lower extremities. Explain to the woman and her family that this condition can cause her uterus to become overdistended and may lead to preterm labor and preterm rupture of membranes. Outline the signs and symptoms of both conditions and instruct the woman to contact her health care provider if they occur. If a therapeutic amniocentesis is performed, assist the health care provider and monitor maternal and fetal status throughout for any changes.

## Oligohydramnios

**Oligohydramnios** is a decreased amount of amniotic fluid (less than 500 mL) between 32 and 36 weeks' gestation. It occurs in 5% to 8% of all pregnancies. Oligohydramnios may result from any condition that prevents the fetus from making urine or blocks it from going into the amniotic sac. Oligohydramnios occurs in about 4 out of every 100 pregnancies. It is most common in the last trimester of pregnancy, but it can develop at any time in the pregnancy. About one out of eight women whose pregnancies last 2 weeks past the due date develops oligohydramnios. This happens as amniotic fluid levels naturally decline.

This condition puts the fetus at an increased risk of perinatal morbidity and mortality (March of Dimes, 2011c). Reduction in amniotic fluid reduces the ability of the fetus to move freely without risk of cord compression, which increases the risk for fetal death and intrapartum hypoxia.

## Therapeutic Management

The woman with oligohydramnios can be managed on an outpatient basis with serial ultrasounds and fetal surveillance through nonstress testing and biophysical profiles. As long as fetal well-being is demonstrated with frequent testing, no intervention is necessary. If fetal well-being is compromised, however, birth is planned along with amnioinfusion (the transvaginal infusion of crystalloid fluid to compensate for the lost amniotic fluid). The fluid is introduced into the uterus through an intrauterine pressure catheter. The infusion is administered in a controlled fashion to prevent overdistention of the uterus. Amnioinfusion is thought to improve abnormal fetal heart rate patterns, decrease cesarean births, and possibly minimize the risk of neonatal meconium aspiration syndrome, but more studies need to be done to validate this (Butt & Ahmed, 2011).

## Nursing Assessment

Review the maternal history for factors associated with oligohydramnios, including:

- Uteroplacental insufficiency
- Premature rupture of membranes prior to labor onset
- Hypertension of pregnancy
- Maternal diabetes
- Intrauterine growth restriction
- Post-term pregnancy
- Fetal renal agenesis
- Polycystic kidneys
- Urinary tract obstructions

Assess the client for complaints of fluid leaking from the vagina. Leaking of amniotic fluid from the vagina

occurs with rupture of the amniotic sac. Leaking in conjunction with a uterus that is small for expected dates of gestation also suggests oligohydramnios. Unfortunately, the woman may not present with any symptoms. Typically, the reduced volume of amniotic fluid is identified on ultrasound.

## Nursing Management

Nursing management of the woman with oligohydramnios involves continuous monitoring of fetal well-being during nonstress testing or during labor and birth by identifying category II and III patterns on the fetal monitor. Variable decelerations indicating cord compression are common. Changing the woman's position might be therapeutic in altering this fetal heart rate pattern. After the birth, evaluate the newborn for signs of postmaturity, congenital anomalies, and respiratory difficulty.

Assist with amnioinfusion as indicated and continue to assess the woman's vital signs and contraction status and the fetal heart rate throughout the procedure. Provide comfort measures such as changing the bed linens and the woman's bed clothes frequently because of the constant leakage of fluid from the vagina. Also provide frequent perineal care during the infusion.

## MULTIPLE GESTATION

**Multiple gestation** is defined as more than one fetus being born to a pregnant woman. This includes twins, triplets, and higher-order multiples such as quadruplets. In the past two decades, the number of multiple gestations in the United States has jumped dramatically because of the widespread use of fertility drugs, older women having babies, and assisted reproductive technologies to treat infertility. About one third of live births from assisted reproductive technology result in more than one

infant, and twins represent 85% of those multiple-birth children (Miro, Vidal, & Balasch, 2012). In the United States, the overall prevalence of twins is approximately 12 per 1,000, and two thirds are dizygotic (Fletcher, Zach, Pramanik, & Ford, 2012). The increasing number of multiple gestations is a concern because women who are expecting more than one infant are at high risk for preterm labor, hydramnios, hyperemesis gravidarum, anemia, preeclampsia, and antepartum hemorrhage. Fetal/newborn risks or complications include prematurity, respiratory distress syndrome, birth asphyxia/perinatal depression, congenital anomalies (CNS, cardiovascular, and GI defects), twin-to-twin transfusion syndrome (transfusion of blood from one twin [i.e., donor] to the other twin [i.e., recipient]), intrauterine growth restriction, and becoming conjoined twins (Fletcher et al., 2012).

The two types of twins are monozygotic and dizygotic (Fig. 19.6). Monozygotic twins develop when a single, fertilized ovum splits during the first 2 weeks after conception. Monozygotic twins also are called identical twins. Two sperm fertilizing two ova produce dizygotic twins, which are called fraternal twins. Separate amnions, chorions, and placentas are formed in dizygotic twins. Triplets can be monozygotic, dizygotic, or trizygotic.

## Therapeutic Management

When a multiple gestation is confirmed, the woman is followed with serial ultrasounds to assess fetal growth patterns and development. Biophysical profiles along with nonstress tests are ordered to determine fetal well-being. Many women are hospitalized in late pregnancy to prevent preterm labor and receive closer surveillance. During the intrapartum period the woman is closely monitored, with a perinatal team available to assist after birth. Operative delivery is frequently needed due to fetal malpresentation.

**FIGURE 19.6** Multiple gestation with twins. **(A)** Dizygotic twins, where each fetus has its own placenta, amnion, and chorion. **(B)** Monozygotic twins, where the fetuses share one placenta, two amnions, and one chorion.

## Nursing Assessment

Obtain a health history and physical examination. Be alert for complaints of fatigue and severe nausea and vomiting. Assess the woman's abdomen and fundal height. Typically with a multiple gestation the uterus is larger than expected based on the estimated date of birth. Laboratory test results may reveal anemia. Prepare the woman for ultrasound, which typically confirms the diagnosis of a multiple gestation.

## Nursing Management

During the prenatal period, care focuses on providing education and support for the woman in areas of nutrition, increased rest periods, and close observation for pregnancy complications: anemia, excessive weight gain, proteinuria, edema, vaginal bleeding, and hypertension. Instruct the woman to be alert for and report immediately any signs and symptoms of preterm labor: contractions, uterine cramping, low back ache, increase in vaginal discharge, loss of mucus plug, pelvic pain, and pressure.

With the onset of labor, expect to monitor fetal heart rates continuously. Prepare the woman for an ultrasound to assess the presentation of each fetus to determine the best delivery approach. Ensure that extra nursing staff and the perinatal team are available for any birth or newborn complications.

After the babies are born, closely assess the woman for hemorrhage by frequently assessing uterine involution. Palpate the uterine fundus and monitor the amount and characteristics of lochia.

Throughout the entire pregnancy, birth, and hospital stay, inform and support the woman and her family. Encourage them to ask questions and verbalize any fears and concerns.

## PREMATURE RUPTURE OF MEMBRANES

**Premature rupture of membranes (PROM)** is the rupture of the bag of waters before the onset of true labor. There are a number of associated conditions and complications, such as infection, prolapsed cord, abruption placenta, and preterm labor. High-risk factors associated with preterm PROM include low socioeconomic status, multiple gestation, low body mass index, tobacco use, preterm labor history, placenta previa, abruption placenta, urinary tract infection, vaginal bleeding at any time in pregnancy, cerclage, and amniocentesis (Jazayeri, 2010).

If prolonged (greater than 24 hours), the woman's risk for infection (chorioamnionitis, endometritis, sepsis, and neonatal infections) increases and this risk continues

to increase as the duration of rupture time increases. The time interval from rupture of membranes to the onset of regular contractions is termed the latent period.

Women with PROM present with leakage of fluid, vaginal discharge, vaginal bleeding, and pelvic pressure, but they are not having contractions. PROM is diagnosed by speculum vaginal examination of the cervix and vaginal cavity. Pooling of fluid in the vagina or leakage of fluid from the cervix, ferning of the dried fluid under microscopic examination, and alkalinity of the fluid as determined by Nitrazine paper confirm the diagnosis.

The terminology pertaining to PROM can be confusing. PROM is rupture of the membranes prior to the onset of labor and is used appropriately when referring to a woman who is beyond 37 weeks' gestation, has presented with spontaneous rupture of the membranes, and is not in labor. Related terms include **preterm premature rupture of membranes (PPROM)**, which is defined as rupture of membranes prior to the onset of labor in a woman who is *less* than 37 weeks' gestation. Perinatal risks associated with PPRM may stem from immaturity, including respiratory distress syndrome, intraventricular hemorrhage, patent ductus arteriosus, and necrotizing enterocolitis. Eighty-five percent of neonatal morbidity and mortality is a result of prematurity. PPRM is associated with 30% to 40% of preterm deliveries and is the leading identifiable cause of preterm delivery. PPRM complicates 3% of all pregnancies and occurs in approximately 150,000 pregnancies yearly in the United States (Jazayeri, 2011).

The exact cause of PROM is not known, but many are associated with vaginal bleeding, placental abruption, microbial invasion of the amniotic cavity, and defective placentation. In many cases, PROM occurs spontaneously. Increasing evidence associates abnormalities in vaginal flora during pregnancy with preterm labor and birth with potential neonatal sequelae due to prematurity and poor perinatal outcome (Rutanen 2012). A recent study found that women with previous PPRM are at increased risk for recurrence, and a short interval between pregnancies is associated with increased risk (Getahun et al., 2010).

## Therapeutic Management

Treatment of PROM typically depends on the gestational age. Under no circumstances is an unsterile digital cervical examination done until the woman enters active labor, to minimize infection exposure. If the fetal lungs are mature, induction of labor is initiated. PROM is not a lone indicator for surgical birth. If the fetal lungs are immature, expectant management is carried out with adequate hydration, reduced physical activity, pelvic rest, and close observation for possible infection, such as with frequent monitoring of vital signs and laboratory

test results (e.g., the white blood cell count). Corticosteroids may be given to enhance fetal lung maturity if lungs are immature, although this remains controversial. Recent studies have shown clear benefits of antibiotics to decrease neonatal morbidity associated with PPRM (Cousens, Blencowe, Gravett, & Lawn, 2010).

## Nursing Assessment

Nursing assessment focuses on obtaining a complete health history and performing a physical examination to determine maternal and fetal status. An accurate assessment of the gestational age and knowledge of the maternal, fetal, and neonatal risks are essential to appropriate evaluation, counseling, and management of women with PROM and PPRM. Nurses need to be aware that the risk of infection increases with the duration of PPRM.

### Health History and Physical Examination

Review the maternal history for risk factors such as infection, increased uterine size (hydramnios, macrosomia, multifetal gestation), uterine and fetal anomalies, lower socioeconomic status, STIs, cervical insufficiency, vaginal bleeding, and cigarette smoking during pregnancy. Ask about any history or current symptoms of urinary tract infection (UTI) (frequency, urgency, dysuria, or flank pain) or pelvic or vaginal infection (pain or vaginal discharge).

Assess for signs and symptoms of labor, such as cramping, pelvic pressure, or back pain. Also assess her vital signs, noting any signs indicative of infection such as fever and elevated white blood cell count (more than 18,000 cells/mm<sup>3</sup>) (Waters & Mercer, 2011).

Institute continuous electronic fetal heart rate monitoring to evaluate fetal well-being. Conduct a vaginal examination to ascertain the cervical status in PROM. If PPRM exists, a sterile speculum examination (where the examiner inspects the cervix but does not palpate it) is done rather than a digital cervical examination because it may diminish latency (period of time from rupture of membranes to birth) and increase newborn morbidity (Cunningham et al., 2010).

Observe the characteristics of the amniotic fluid. Note any evidence of meconium, or a foul odor. When meconium is present in the amniotic fluid, it typically indicates fetal distress related to hypoxia. Meconium stains the fluid yellow to greenish brown, depending on the amount present. A foul odor of amniotic fluid indicates infection. Also observe the amount of fluid. A decreased amount of amniotic fluid reduces the cushioning effect, thereby making cord compression a possibility. Some research shows that restoring the volume of lost amniotic fluid will help to reduce the risk of infection and reduce cord compression. See Evidence-Based Practice 19.1. Key assessments are summarized in Box 19.3.

### BOX 19.3

#### KEY ASSESSMENTS WITH PREMATURE RUPTURE OF MEMBRANES

For the woman with PROM, the following assessments are essential:

- Determining the date, time, and duration of membrane rupture by client interview
- Ascertaining gestational age of the fetus based on date of mother's last menstrual period, fundal height, and ultrasound dating
- Questioning the woman about possible history of or recent UTI or vaginal infection that might have contributed to PROM
- Assessing for any associated labor symptoms, such as back pain or pelvic pressure
- Assisting with or performing diagnostic tests to validate leakage of fluid, such as Nitrazine test, "ferning" on slide, and ultrasound. Contamination of Nitrazine tape with lubricant or insufficient fluid will render the assessment unreliable.
- Continually assessing for signs of infection including:
  - Elevation of maternal temperature and pulse rate
  - Abdominal/uterine tenderness
  - Fetal tachycardia more than 160 bpm
  - Elevated white blood cell count and C-reactive protein
  - Cloudy, foul-smelling amniotic fluid

St. Louis, MO: Saunders Elsevier; and Melamed, N., Ben-Haroush, A., Pardo, J., Chen, R., Hadar, E., Hod, M., & Yogev, Y. (2011). Expectant management of preterm premature rupture of membranes: Is it all about gestational age? *American Journal of Obstetrics and Gynecology*, 204(1), 48.e1–e8.

### Laboratory and Diagnostic Testing

To diagnose PROM or PPRM, several procedures may be used: the Nitrazine test, fern test, or ultrasound. After the insertion of a sterile speculum, a sample of the fluid in the vaginal area is obtained. With a Nitrazine test, the pH of the fluid is tested; amniotic fluid is more basic (7.0) than normal vaginal secretions (4.5). Nitrazine paper turns blue in the presence of amniotic fluid. However, false-positive results can occur if blood, urine, semen, or antiseptic chemicals are also present; all will increase the pH.

For the fern test, a sample of vaginal fluid is placed on a slide to be viewed directly under a microscope. Amniotic fluid will develop a fern-like pattern when it dries because of sodium chloride crystallization. If both of these tests are inconclusive, a transvaginal ultrasound can also be used to determine whether membranes have ruptured by demonstrating a decreased amount of

**EVIDENCE-BASED PRACTICE 19.1****AMNIOINFUSION FOR PRETERM PREMATURE RUPTURE OF MEMBRANES****BACKGROUND AND OBJECTIVE**

Preterm premature rupture of membranes (PPROM) is the single most identifiable cause of preterm labor. The sac (membranes) surrounding the fetus and fluid in the uterus usually ruptures during labor. If the membranes rupture before labor and preterm (before 37 weeks) the fetus has an increased risk of infection. Reduced fluid around the fetus also increases the chance of the umbilical cord being compressed, which can reduce the fetus's supply of nutrients and oxygen. In addition, insufficient fluid in the uterus may interfere with normal lung development in very small fetuses and can cause fetal distress, with changes in heart rate. Extra fluid can be injected through the woman's vagina (transcervical amnioinfusion) or abdomen (transabdominal amnioinfusion) into the uterus, providing more liquid to surround the fetus.

Some evidence shows that restoring amniotic fluid volume with saline or a similar fluid (amnioinfusion) following PPRM may be beneficial for preterm infants (by preventing infection, lung damage, and death) and mothers (by preventing infection of the uterus after childbirth). The objective of this study was to assess the effects of amnioinfusion for PPRM on perinatal and maternal morbidity and mortality.

**Study**

Five trials were selected, but only data from four studies were analyzed (with a total of 241 participants). One trial did not contribute any data to the review. Transcervical amnioinfusion improved fetal umbilical artery pH at delivery (mean difference, 0.11; 95% confidence interval [CI], 0.08 to 0.14; one trial, 61 participants) and reduced persistent variable decelerations during labor (risk ratio [RR], 0.52; 95% CI, 0.30 to 0.91; one trial, 86 participants). Transabdominal amnioinfusion was associated with a reduction in neonatal death (RR, 0.30; 95% CI, 0.14 to 0.66; two trials, 94 participants), neonatal sepsis (RR, 0.26, 95% CI, 0.11 to 0.61; one trial, 60 participants), pulmonary hypoplasia (RR, 0.22; 95% CI, 0.06 to 0.88; one trial, 34 participants) and puerperal sepsis (RR, 0.20; 95% CI, 0.05 to 0.84; one trial, 60 participants). Women in the amnioinfusion group were also less likely to deliver within 7 days of membrane rupture (RR, 0.18; 95% CI, 0.05 to 0.70; one trial, 34 participants).

**Findings**

The review of four randomized controlled trials (with data from a total of 241 participants analyzed) found some evidence to show that amnioinfusion with a saline solution may improve health outcomes and be beneficial for babies and mothers following PPRM. However, the evidence is currently insufficient to recommend its routine use because of the limited number of trials and low numbers of women in the trials. These results are encouraging but are limited by the sparse data and unclear methodological robustness; therefore, further evidence is required before amnioinfusion for PPRM can be recommended for routine clinical practice.

**Nursing Implications**

Although this study's findings were inconclusive, nurses can educate their clients about the potential of this procedure when they are admitted to the obstetrical unit with PPRM. A thorough understanding of the rationale behind it and the procedure itself is needed for the woman to make an informed decision. This education would fall under the nurse's role.

Adapted from Hofmeyr, G. J., Essilfie-Appiah, G., & Lawrie, T. A. (2012). Amnioinfusion for preterm premature rupture of membranes. *Cochrane Database of Systematic Reviews*, 2012(1). doi:10.1002/14651858.CD000942.pub2.

amniotic fluid (oligohydramnios) in the uterus (Jazayeri, 2011).

Other laboratory and diagnostic tests that may be used include:

- Urinalysis and urine culture for UTI or asymptomatic bacteriuria
- Cervical test or culture for chlamydia or gonorrhea
- Vaginal culture for bacterial vaginosis and trichomoniasis
- Vaginal introital/rectal culture for group B streptococcus

**Nursing Management**

Nursing management for the woman with PROM or PPRM focuses on preventing infection and identifying uterine contractions. The risk for infection is great because of the break in the amniotic fluid membrane and its proximity to vaginal bacteria. Therefore, monitor maternal vital signs closely. Be alert for a temperature elevation or an increase in pulse, which could indicate infection. Also monitor the fetal heart rate continuously, reporting any fetal

tachycardia (which could indicate a maternal infection) or variable decelerations (suggesting cord compression). If variable decelerations are present, anticipate amnioinfusion based on agency policy. Evaluate the results of laboratory tests such as a CBC. An elevation in white blood cells would suggest infection. Administer antibiotics if ordered.

Encourage the woman and her partner to verbalize their feelings and concerns. Educate them about the purpose of the protective membranes and the implications of early rupture. Keep them informed about planned interventions, including potential complications and required therapy. As appropriate, prepare the woman for induction or augmentation of labor as appropriate if she is near term.

If labor does not start within 48 hours, the woman with PPROM may be discharged home on expectant management, which may include:

- Antibiotics if cervicovaginal cultures are positive
- Activity restrictions
- Education about signs and symptoms of infection and when to call with problems or concerns (Teaching Guidelines 19.3)
- Frequent fetal testing for well-being
- Ultrasound every 3 to 4 weeks to assess amniotic fluid levels
- Possible corticosteroid treatment depending on gestational age
- Daily kick counts to assess fetal well-being

### Teaching Guidelines 19.3

#### TEACHING FOR THE WOMAN WITH PPROM

- Monitor your baby's activity by performing fetal kick counts daily.
- Check your temperature daily and report any temperature increases to your health care provider.
- Watch for signs related to the beginning of labor. Report any tightening of the abdomen or contractions.
- Avoid any touching or manipulating of your breasts, which could stimulate labor.
- Do not insert anything into your vagina or vaginal area—no tampons, avoid vaginal intercourse
- Do not swim in pools or in the ocean or sit in a hot tub or Jacuzzi.
- Take showers for daily hygiene needs; avoid sitting in a tub bath.
- Maintain any specific activity restrictions as recommended.
- Wash your hands thoroughly after using the bathroom and make sure to wipe from front to back each time.
- Keep your perineal area clean and dry.
- Take your antibiotics as directed if your health care provider has prescribed them.
- Call your health care provider with changes in your condition, including fever, uterine tenderness, feeling like your heart is racing, and foul-smelling vaginal discharge.

#### KEY CONCEPTS

- Identifying risk factors early on and throughout the pregnancy is important to ensure the best outcome for every pregnancy. Risk assessment should start with the first prenatal visit and continue with subsequent visits.
- The three most common causes of hemorrhage early in pregnancy (first half of pregnancy) are spontaneous abortion, ectopic pregnancy, and GTD.
- Ectopic pregnancies occur in about 1 in 50 pregnancies and have increased dramatically during the past few decades.
- Having a molar pregnancy results in the loss of the pregnancy and the possibility of developing choriocarcinoma, a chronic malignancy from the trophoblastic tissue.
- The classic clinical picture presentation for placenta previa is painless, bright-red vaginal bleeding occurring during the third trimester.
- Treatment of abruptio placentae is designed to assess, control, and restore the amount of blood lost; to provide a positive outcome for both mother and infant; and to prevent coagulation disorders.
- DIC can be described in simplest terms as a loss of balance between the clot-forming activity of thrombin and the clot-lysing activity of plasmin.
- Hyperemesis gravidarum is a complication of pregnancy characterized by persistent, uncontrollable nausea and vomiting before the 20th week of gestation.
- Gestational hypertension is the leading cause of maternal death in the United States and the most common complication reported during pregnancy.
- HELLP is an acronym for hemolysis, elevated liver enzymes, and low platelets.
- Rh incompatibility is a condition that develops when a woman of Rh-negative blood type is exposed to Rh-positive fetal blood cells and subsequently develops circulating titers of Rh antibodies.
- Hydramnios occurs in approximately 3% to 4% of all pregnancies and is associated with fetal anomalies of development.
- Nursing care related to the woman with oligohydramnios involves continuous monitoring of fetal well-being during nonstress testing or during labor and birth by identifying category II and III patterns on the fetal monitor.

- The increasing number of multiple gestations is a concern because women who are expecting more than one infant are at high risk for preterm labor, hydramnios, hyperemesis gravidarum, anemia, pre-eclampsia, and antepartum hemorrhage.
- Nursing care related to PROM centers on infection prevention and identification of preterm labor contractions.
- Monitoring maternal vital signs for changes and the fetal health rate once PPRM occurs is essential to increasing the changes of a good outcome.
- It is essential that nurses educate all pregnant women how to detect the early signs of PROM and what action is needed if it happens.

## MULTIPLE-CHOICE QUESTIONS

1. A woman diagnosed with preeclampsia is to receive magnesium sulfate. The rationale for this drug is to:
  - a. Reduce CNS irritability to prevent seizures
  - b. Provide supplementation of an important mineral she needs
  - c. Prevent constipation during and after the birthing process
  - d. Decrease musculoskeletal tone to augment labor
2. A woman is suspected of having abruptio placentae. Which of the following would the nurse expect to assess as a classic symptom?
  - a. Painless, bright-red bleeding
  - b. "Knife-like" abdominal pain
  - c. Excessive nausea and vomiting
  - d. Hypertension and headache
3. RhoGAM is given to Rh-negative women to prevent maternal sensitization. In addition to pregnancy, Rh-negative women would also receive this medication after which of the following?
  - a. Therapeutic or spontaneous abortion
  - b. Head injury from a car accident
  - c. Blood transfusion after a hemorrhage
  - d. Unsuccessful artificial insemination procedure
4. After teaching a woman about hyperemesis gravidarum and how it differs from the typical nausea and vomiting of pregnancy, which statement by the woman indicates that the teaching was successful?
  - a. "I can expect the nausea to last through my second trimester."
  - b. "I should drink fluids with my meals instead of in between them."
  - c. "I need to avoid strong odors, perfumes, or flavors."
  - d. "I should lie down after I eat for about 2 hours."
5. A pregnant woman, approximately 12 weeks' gestation, comes to the emergency department after calling her health care provider's office and reporting moderate vaginal bleeding. Assessment reveals cervical dilation and moderately strong abdominal cramps. She reports that she has passed some tissue with the bleeding. The nurse interprets these findings to suggest which of the following?
  - a. Threatened abortion
  - b. Inevitable abortion
  - c. Incomplete abortion
  - d. Missed abortion

## CRITICAL THINKING EXERCISES

1. Suzanne, a 16-year-old primigravida, presents to the maternity clinic complaining of continual nausea and vomiting for the past 3 days. She states she is approximately 15 weeks pregnant and has been unable to hold anything down or take any fluids in without throwing up for the past 3 days. She reports she is dizzy and weak. On examination, Suzanne appears pale and anxious. Her mucous membranes are dry, skin turgor is poor, and her lips are dry and cracked.
  - a. What is your impression of this condition?
  - b. What risk factors does Suzanne have?
  - c. What intervention is appropriate for this woman?
2. Gloria is an obese 39-year-old primigravida of African American descent who is diagnosed with gestational hypertension. Her history reveals that her sister developed preeclampsia during her pregnancy. When describing her diet to the nurse, Gloria mentions that she tends to eat a lot of fast food.
  - a. What risk factors does Gloria have that increase her risk for gestational hypertension?
  - b. When assessing Gloria, what assessment findings would lead the nurse to suspect that Gloria has developed severe preeclampsia?

## STUDY ACTIVITIES

1. Ask a community health maternity nurse how the signs and symptoms of gestational hypertension (including preeclampsia and eclampsia) are taught, and how effective efforts have been to reduce the incidence in the area.
2. Find a website designed to help parents who have suffered a pregnancy loss secondary to a spontaneous abortion. What is its audience level? Is the information up to date?
3. A pregnancy in which the blastocyst implants outside the uterus is an \_\_\_\_\_ pregnancy.
4. The most serious complication of hydatidiform mole is the development of \_\_\_\_\_ afterward.
5. Discuss various activities a woman with a multiple gestation could engage in to help pass the time when ordered to be on bed rest at home for 2 months.

### KEY TERMS

acquired  
immunodeficiency  
syndrome (AIDS)  
adolescence  
anemia  
fetal alcohol spectrum  
disorder (FASD)  
gestational diabetes  
mellitus  
glycosylated hemoglobin  
(HbA1C) level  
human immunodeficiency  
virus (HIV)  
impaired fasting glucose  
impaired glucose  
tolerance  
multiple sclerosis (MS)  
neonatal abstinence  
syndrome  
perinatal drug abuse  
pica  
pregestational diabetes  
rheumatoid arthritis (RA)  
systemic lupus  
erythematosus (SLE)  
teratogen  
type 1 diabetes  
type 2 diabetes

# Nursing Management of the Pregnancy at Risk: Selected Health Conditions and Vulnerable Populations

## Learning Objectives

*Upon completion of the chapter, you will be able to:*

1. Define the key terms used in this chapter.
2. Select at least two conditions present before pregnancy that can have a negative effect on a pregnancy.
3. Examine how a condition present before pregnancy can affect the woman physiologically and psychologically when she becomes pregnant.
4. Evaluate the nursing assessment and management for a pregnant woman with diabetes from that of a pregnant woman without diabetes.
5. Explore how congenital and acquired heart conditions can affect a woman's pregnancy.
6. Design the nursing assessment and management of a pregnant woman with cardiovascular disorders and respiratory conditions.
7. Differentiate among the types of anemia affecting pregnant women in terms of prevention and management.
8. Relate the nursing care needed for the pregnant woman with an autoimmune disorder.
9. Compare the most common infections that can jeopardize a pregnancy, and propose possible preventive strategies.
10. Develop a plan of care for the pregnant woman who is HIV positive.
11. Outline the nurse's role in the prevention and management of adolescent pregnancy.
12. Determine the impact of pregnancy on a woman over the age of 35.
13. Analyze the effects of substance abuse during pregnancy.

*Rose, a thin 16-year-old appearing very pregnant, came into the clinic wheezing and having difficulty catching her breath. She had missed several previous prenatal visits but arrived at the clinic today in distress. Rose has a history of asthma since she was 5 years old. How might Rose's current condition affect her pregnancy? Is this picture typical of the pregnant woman with asthma?*

### Words of Wisdom

As the sun sets each day, nurses should make sure they have done something for others, and should try to be understanding even under the most difficult of conditions.

**Pregnancy** and childbirth are exciting yet complex facets within the continuum of women's health. Ideally the pregnant woman is free of any conditions that can affect a pregnancy, but in reality many women enter pregnancy with a multitude of health-related or psychosocial issues that can have a negative impact on the outcome.

Many pregnant women express the wish "I hope my baby is born healthy." Nurses can play a major role in helping this become a reality by educating women before they become pregnant. Conditions such as diabetes, cardiac and respiratory disorders, anemia, autoimmune disorders, and specific infections frequently can be controlled through close prenatal management so that their impact on pregnancy is minimized. Nurses can provide pregnancy prevention strategies when counseling teenagers. Meeting the developmental needs of pregnant adolescents is a challenge. Finally, lifestyle choices can place many women at risk during pregnancy, and nurses need to remain nonjudgmental when working with these special populations. Lifestyle choices such as use of alcohol, nicotine, and illicit substances during pregnancy are addressed in a *Healthy People 2020* goal.

Chapter 19 described pregnancy-related conditions that place the woman at risk. This chapter addresses common conditions that can have a negative impact on the pregnancy and special populations at risk, outlining appropriate nursing assessment and management for each condition or situation. The unique skills of nurses, in conjunction with the other members of the health care team, can increase the potential for a positive outcome in many high-risk pregnancies.

### HEALTHY PEOPLE 2020 • 20-1

#### Objective

Increase abstinence from alcohol, cigarettes, and illicit drugs among pregnant women  
 Increase in reported abstinence in the past month from substances by pregnant women  
 Alcohol from a baseline of 89.4% to 98.3%  
 Binge drinking from a baseline of 95% to 100%  
 Cigarette smoking from a baseline of 89.6% to 98.6%  
 Illicit drugs from a baseline of 94.9% to 100%

#### Nursing Significance

Will help to focus attention on measures for reducing substance exposure and use, thereby minimizing the effects of these substances on the fetus and newborn

*Healthy People* objectives based on data from <http://www.healthy-people.gov>.

## DIABETES MELLITUS

Diabetes mellitus is a chronic disease characterized by a relative lack of insulin or absence of the hormone that is necessary for glucose metabolism. The chronic hyperglycemia of diabetes is associated with long-term damage, dysfunction, and failure of the eyes, kidneys, nerves, heart, and blood vessels. The prevalence of diabetes in the United States is increasing at an alarming rate, already reaching epidemic proportions. Contributing factors to these increasing rates are more sedentary lifestyles, dietary changes, continued immigration by high-risk populations, and the epidemic of childhood and adolescent obesity that is presently evolving in our nation. Currently, an estimated 20% of people over the age of 20 have undiagnosed prediabetes. This group of people is the pool from which childbearing women are drawn (Backholer, Chen, & Shaw, 2012).

Diabetes commonly is classified based on disease etiology (American Diabetes Association [ADA], 2012a). These groups include:

- **Type 1 diabetes:** absolute insulin deficiency (due to an autoimmune process); usually appears before the age of 30 years; approximately 10% of those diagnosed have type 1 diabetes.
- **Type 2 diabetes:** insulin resistance or deficiency (related to obesity, sedentary lifestyle); diagnosed primarily in adults older than 30 years of age but is now being seen in children; accounts for 90% of all diagnosed cases.
- **Impaired fasting glucose and impaired glucose tolerance:** characterized by hyperglycemia at a level lower than what qualifies as a diagnosis of diabetes (fasting blood glucose level between 100 and 125 mg/dL; blood glucose level between 140 and 199 mg/dL after a 2-hour glucose tolerance test, respectively); symptoms of diabetes are absent; newborns are at risk for being large for gestational age (LGA).
- **Gestational diabetes mellitus:** glucose intolerance with its onset during pregnancy or first detected in pregnancy.

During pregnancy, diabetes typically is categorized into two groups: **pregestational diabetes** (alteration in carbohydrate metabolism identified before conception), which includes women with type 1 or type 2 disease; and gestational diabetes, which develops during pregnancy.

The International Association of Diabetes and Pregnancy Study Group has issued new recommendations for diagnosing and classifying hyperglycemia in pregnancy (see Table 20.1).

Gestational diabetes is associated with either neonatal complications such as macrosomia, hypoglycemia, and birth trauma or maternal complications such as preeclampsia and cesarean birth. Gestational diabetes affects about 18% of all pregnant women (ADA, 2012e).

TABLE 20.1

## RECOMMENDATIONS FOR DIAGNOSING AND CLASSIFYING HYPERGLYCEMIA IN PREGNANCY

When	Diagnosis	Test	Cutoff for Diagnosis
First prenatal visit	Overt (pregestational) diabetes	Fasting HbA1C Random	126 mg/dL <7% 200 mg/dL
24–28 weeks	Gestational diabetes	Fasting 75 g OGTT–1 hr 75 g OGTT–2 hr	92 mg/dL 180 mg/dL 153 mg/dL

OGTT = oral glucose tolerance test.

Adapted from International Association of Diabetes and Pregnancy Study Group. (2012). Screening for gestational diabetes mellitus. *Diabetes Care*, 35(2). Retrieved from <http://care.diabetesjournals.org/content/early/2012/01/23/dc11-1643>; Kendrick, J. (2011). Screening and diagnosing gestational diabetes mellitus revisited: Implications from HAPO. *Journal of Perinatal & Neonatal Nursing*, 25(3), 226–232; and Moore, T. R. (2012). Diabetes mellitus and pregnancy. *eMedicine*. Retrieved from <http://emedicine.medscape.com/article/127547>.

Before the discovery of insulin in 1922, most women with diabetes were infertile or experienced spontaneous abortion (March of Dimes, 2012). During the past several decades, great strides have been made in improving the outcomes of pregnancy in women with diabetes, but this chronic metabolic disorder remains a high-risk condition during pregnancy. A favorable outcome requires commitment on the woman's part to comply with frequent prenatal visits, dietary restrictions, self-monitoring of blood glucose levels, frequent laboratory tests, intensive fetal surveillance, and perhaps hospitalization.

The prevalence of gestational diabetes is strongly related to the woman's race and culture. Prevalence rates are higher in African American, Hispanic, Native American, and Asian women than in Caucasian women (Moore, 2012).

## Pathophysiology

Normal pregnancy is characterized by increasing peripheral resistance to insulin and a compensatory increase in insulin secretion. Therefore, pregnancy might be viewed as a stress test for the glucose homeostasis mechanisms. That is, women who have some degree of chronic insulin resistance and compensatory increased insulin production resulting in beta-cell dysfunction before pregnancy may be unable to mount a sufficiently robust beta-cell response to pregnancy-mediated insulin resistance.

With diabetes, there is a deficiency of or resistance to insulin. This alteration interferes with the body's ability to obtain essential nutrients for fuel and storage. If a pregnant woman has pregestational diabetes or develops gestational diabetes, the profound metabolic alterations that occur during pregnancy and that are necessary to support the growth and development of the fetus are greatly affected.

Maternal metabolism is directed toward supplying adequate nutrition for the fetus. In pregnancy, placental hormones cause insulin resistance at a level that tends to parallel the growth of the fetoplacental unit. As the placenta grows, more placental hormones are secreted. Human placental lactogen (hPL) and growth hormone (somatotropin) increase in direct correlation with the growth of placental tissue, rising throughout the last 20 weeks of pregnancy and causing insulin resistance. Subsequently, insulin secretion increases to overcome the resistance of these two hormones. In the pregnant woman without diabetes, the pancreas can respond to the demands for increased insulin production to maintain normal glucose levels throughout the pregnancy (Tharpe, Farley, & Jordan, 2013). However, the woman with glucose intolerance or diabetes during pregnancy cannot cope with changes in metabolism resulting from insufficient insulin to meet the needs during gestation.

Over the course of pregnancy, insulin resistance changes. It peaks in the last trimester to provide more nutrients to the fetus. The insulin resistance typically results in postprandial hyperglycemia, although some women also have an elevated fasting blood glucose level (Skvarca, Tomazic, Krhin, Blagus et al., 2012). With this increased demand on the pancreas in late pregnancy, women with diabetes or glucose intolerance cannot accommodate the increased insulin demand; glucose levels rise as a result of insulin deficiency, leading to hyperglycemia. Subsequently, the mother and her fetus can experience major problems (Table 20.2).

## Screening

The American College of Obstetricians and Gynecologists (ACOG) and ADA currently recommend a risk analysis of all pregnant women at their first prenatal

TABLE 20.2

## DIABETES AND PREGNANCY: EFFECTS ON THE MOTHER AND FETUS

## Effects on the Mother

- Hydramnios due to fetal diuresis caused by hyperglycemia
- Gestational hypertension of unknown etiology
- Ketoacidosis due to uncontrolled hyperglycemia
- Preterm labor secondary to premature membrane rupture
- Stillbirth in pregnancies complicated by ketoacidosis and poor glucose control
- Hypoglycemia as glucose is diverted to the fetus (occurring in first trimester)
- Urinary tract infections resulting from excess glucose in the urine (glucosuria), which promotes bacterial growth
- Chronic monilial vaginitis due to glucosuria, which promotes growth of yeast
- Difficult labor, cesarean birth, postpartum hemorrhage secondary to an overdistended uterus to accommodate a macrosomic infant

## Effects on the Fetus/Neonate

- Cord prolapse secondary to hydramnios and abnormal fetal presentation
- Congenital anomaly due to hyperglycemia in the first trimester (cardiac problems, neural tube defects, skeletal deformities, and genitourinary problems)
- Macrosomia resulting from hyperinsulinemia stimulated by fetal hyperglycemia
- Birth trauma due to increased size of fetus, which complicates the birthing process (shoulder dystocia)
- Preterm birth secondary to hydramnios and an aging placenta, which places the fetus in jeopardy if the pregnancy continues
- Fetal asphyxia secondary to fetal hyperglycemia and hyperinsulinemia
- Intrauterine growth restriction secondary to maternal vascular impairment and decreased placental perfusion, which restricts growth
- Perinatal death due to poor placental perfusion and hypoxia
- Respiratory distress syndrome resulting from poor surfactant production secondary to hyperinsulinemia inhibiting the production of phospholipids, which make up surfactant
- Polycythemia due to excessive red blood cell (RBC) production in response to hypoxia
- Hyperbilirubinemia due to excessive RBC breakdown from hypoxia and an immature liver unable to break down bilirubin
- Neonatal hypoglycemia resulting from ongoing hyperinsulinemia after the placenta is removed
- Subsequent childhood obesity and carbohydrate intolerance

Adapted from Gilbert, E. S. (2011). *Manual of high risk pregnancy and delivery* (5th ed.). St. Louis, MO: Mosby Elsevier; and March of Dimes. (2012). *Diabetes in pregnancy*. Retrieved from [http://marchofdimes.com/professionals/14332\\_1197.asp](http://marchofdimes.com/professionals/14332_1197.asp).

visit and additional screening of all high-risk pregnant women again at 24 to 28 weeks, or earlier if risk factors are present. If the initial screening risk assessment is low, additional screening may not be necessary. Pregnant women who fulfill all of the following criteria need not be screened at their first prenatal visit:

- No history of glucose intolerance
- Less than 25 years old
- Normal body weight
- No family history (first-degree relative) of diabetes
- No history of poor obstetric outcome
- Not from an ethnic/racial group with a high prevalence of diabetes (ADA, 2012e)

If the initial risk assessment is high, rescreening should take place between 24 and 28 weeks. A woman with abnormal early results may have had diabetes before the pregnancy, and her fetus is at great risk for congenital anomalies. An elevated glycosylated hemoglobin supports the likelihood of gestational diabetes. Combining the use of HbA1c and plasma glucose measurements for the diagnosis of diabetes offers the benefits of each test and reduces the risk of systematic bias inherent in HbA1c testing alone (Balaji & Seshiah, 2011).

There is little consensus regarding the appropriate screening method. Typically, screening is based on a 75-g 1-hour glucose challenge test, usually performed between week 24 and 28 of gestation (ADA, 2012c). A 75-g oral glucose load is given, without regard to the timing or content of the last meal. Blood glucose is measured 1 hour later; a level above 140 mg/dL is abnormal. If the result is abnormal, a 3-hour glucose tolerance test is done. Normal values are:

- Fasting blood glucose level: less than 92 mg/dL
- At 1 hour: less than 180 mg/dL
- At 2 hours: less than 153 mg/dL
- At 3 hours: less than 140 mg/dL

A diagnosis of gestational diabetes can be made only after an abnormal result is obtained on the glucose tolerance test. One or more abnormal values confirm a diagnosis of gestational diabetes (ADA, 2012e). A newer, more controlled screening is currently being considered for adoption by ADA and ACOG because of mounting evidence that diagnosing and treating even mild gestational diabetes reduces morbidity for both mother and infant (ADA, 2012c). If adopted, the new guidelines are expected to have immediate, widespread clinical implications.

## Therapeutic Management

Preconception counseling is key for the woman with pregestational diabetes (the alteration in carbohydrate metabolism is identified before conception) to ensure that her disease state is stable. The problem though is that as many as half of all pregnancies in the United States are unplanned. Thus women with chronic medical conditions such as diabetes might not have the opportunity to take steps to optimize management of their diabetes before becoming pregnant. When preconception care is possible, women with pregestational diabetes should be taught how to improve their metabolic control prior to conception to reduce the risk of birth defects. Nurses caring for women of reproductive age can contribute to preconception care by helping to counsel someone who is prediabetic to avoid progression to diabetes and its attendant risks during pregnancy. The goals of preconception care are to:

- Integrate the woman into the management of her diabetes
- Achieve the lowest glycosylated hemoglobin A1C test results without excessive hypoglycemia
- Ensure effective contraception until stable glycemia is achieved
- Identify and evaluate long-term diabetic complications such as retinopathy, nephropathy, neuropathy, cardiovascular disease, and hypertension (ADA, 2012a)

Excellent control of blood glucose, as evidenced by normal fasting blood glucose levels and a **glycosylated hemoglobin (HbA1C) level** (a measurement of the average glucose levels during the past 100 to 120 days), is crucial to achieve the best pregnancy outcome. A glycosylated hemoglobin level of less than 7% indicates good control; a value of more than 8% indicates poor control and warrants intervention (ADA, 2012c).

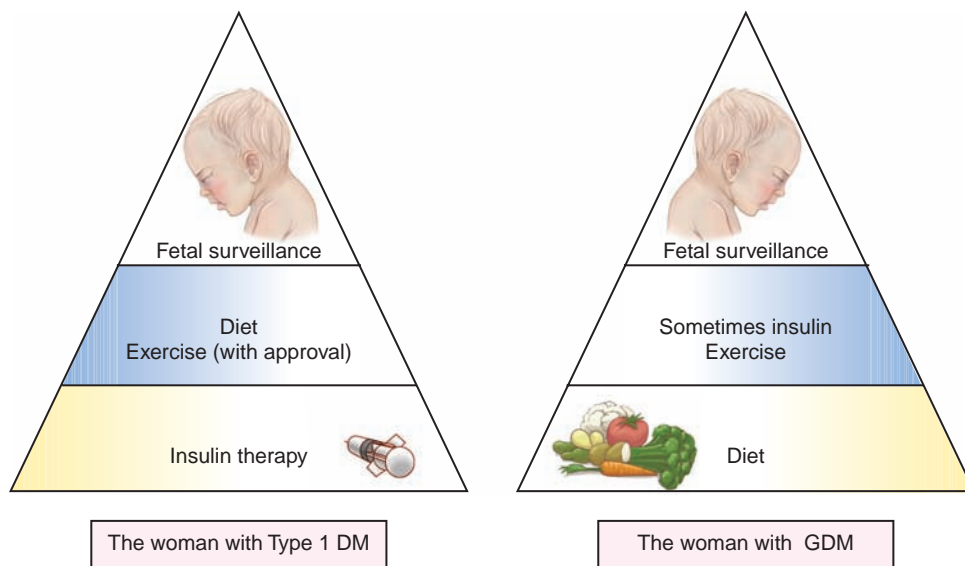

Preconception counseling is also important in helping to reduce the risk of congenital malformation. The

most common malformations associated with diabetes occur in the renal, cardiac, skeletal, and central nervous systems. Since these defects occur by the eighth week of gestation, preconception counseling is critical. The rate of congenital anomalies in women with pregestational diabetes can be reduced if excellent glycemic control is achieved at the time of conception (Moore, 2012). This information needs to be stressed with all women with diabetes who are contemplating a pregnancy.

In addition, the woman with pregestational diabetes needs to be evaluated for complications of diabetes. This evaluation should be part of baseline screening and continuing assessment during pregnancy.

Therapeutic management for the woman with gestational diabetes mellitus (defined as glucose intolerance with its onset during pregnancy or first detected during pregnancy) focuses on tight glucose control. The ADA (2012e) recommends maintaining a fasting blood glucose level below 92 mg/dL, with postprandial levels below 180 mg/dL at 1-hour and 2-hour postprandial levels below 153 mg/dL. In comparison, for pregnant women without diabetes, near-normal glucose values include a fasting value between 60 and 90 mg/dL, a 1-hour postprandial value of 100 to 120 mg/dL, and a 2-hour postprandial value of 60 to 120 mg/dL. Such tight control has been advocated because it is associated with a reduction in macrosomia. In addition, maternal prepregnancy weight and weight gain during pregnancy appear to be significant and independent risk factors for macrosomia in women with gestational diabetes also (Ouzounian et al., 2011).

Women with diabetes need comprehensive prenatal care. The primary goals of care are to maintain glycemic control and minimize the risks of the disease on the fetus. Key aspects of treatment include nutritional management, exercise, insulin regimens, and close maternal and fetal surveillance (Fig. 20.1).

**FIGURE 20.1** Treatment overview for diabetes in pregnancy. For women with pregestational type 1 DM, the foundation of glycemic management is insulin therapy along with dietary management, exercise, and fetal surveillance. For the woman who develops gestational diabetes, dietary modification is generally the foundation of treatment. Some women may require insulin along with dietary modifications, whereas others will not require insulin therapy, and others do not. Exercise and fetal surveillance are also important facets of care.

Nutritional management focuses on maintaining balanced glucose levels and providing enough energy and nutrients for the pregnant woman, while avoiding ketosis, and minimizing the risk of hypoglycemia in women treated with insulin. Nutrition therapy is the cornerstone of therapy for women with gestational diabetes (Magon & Seshiah, 2011). Eating for two in pregnancy with diabetes means eating not volume for two, but rather quality and timing to support both mother and fetus. Women who receive dietary instruction and follow it have been shown to have a better pregnancy outcome than those who don't receive dietary advice (Lutz & Przytulski, 2011). For the woman with gestational diabetes, nutritional management and exercise may be all that is necessary. Pharmacologic therapy is considered if nutrition and exercise fail to maintain target glucose levels.

Insulin, which doesn't cross the placenta, historically has been the medication of choice for treating hyperglycemia in pregnancy. Insulin is calculated based on the woman's weight. Combining intermediate and short-acting insulin yields the best result for most women. Two insulin doses are given daily with two thirds of the total insulin in the morning to cover energy needs of the active day and one third at night (King & Brucker, 2011). Recent studies have examined the use of oral hypoglycemic medications in pregnancy with much success. Several studies have used glyburide (DiaBeta) with promising results. Many health care providers are using glyburide and metformin as an alternative to insulin therapy because they do not cross the placenta and therefore do not cause fetal/neonatal hypoglycemia. Some oral hypoglycemic medications are considered safe and may be used if nutrition and exercise are not adequate alone. Maternal and newborn outcomes are similar to those seen in women who are treated with insulin. Oral hypoglycemic agents, however, must be further investigated to determine their safety with confidence and provide better treatment options for diabetes in pregnancy. Currently, there is a growing acceptance of glyburide (glibenclamide) use as a primary therapy for gestational diabetes. Glyburide and metformin have also been found to be safe, effective, and economical for the treatment of gestational diabetes. Insulin, however, still has an important role to play in gestational diabetes (Moore, 2012). Gestational diabetes offers a window of opportunity, which needs to be seized, for prevention of diabetes in future life (Refuerzo, 2011).

The ADA (2012b) recommends that women diagnosed with gestational diabetes by a 3-hour glucose tolerance test receive nutritional counseling from a registered dietitian. The ADA also recommends insulin therapy if diet is unsuccessful in achieving a fasting glucose level below 92 mg/dL, a 1-hour postprandial level below 180 mg/dL, or 2-hour postprandial level below 153 mg/dL (ADA, 2012b).

The ACOG (2010b) recommends the use of diet or insulin to achieve a 1-hour postprandial blood glucose level of 130 mg/dL. Both ADA and ACOG believe that further studies are needed to establish the safety of oral antidiabetic agents. Glycemic control—regardless of whether it involves diet, insulin, or oral agents—leads to fewer cases of shoulder dystocia, hyperbilirubinemia requiring phototherapy, nerve palsy, bone fracture, LGA status, and fetal macrosomia (ACOG, 2010b).

Exercise is another important component of comprehensive prenatal care for the pregnant woman with glucose intolerance. Regular exercise helps maintain glucose control by increasing the uptake of glucose into the cells and decreasing central obesity, hypertension, and dyslipidemia, which will ultimately decrease the woman's insulin requirements (Gilbert, 2011). Regular physical activity has been proven to result in marked benefits for mother and fetus. Maternal benefits include improved cardiovascular function, limited pregnancy weight gain, decreased musculoskeletal discomfort, reduced incidence of muscle cramps and lower limb edema, mood stability, and reduction of gestational diabetes mellitus and gestational hypertension. Fetal benefits include decreased fat mass, improved stress tolerance, and advanced neurobehavioral maturation. Research also suggests the role of physical activity in prevention of gestational diabetes (Redden, LaMonte, Freudenheim, & Rudra, 2011).

Insulin remains the medication of choice for glycemic control in pregnant and lactating women with any type of diabetes (Moore, 2012). Generally, insulin doses are reduced in the first trimester to prevent hypoglycemia resulting from increased insulin sensitivity as well as from nausea and vomiting. Newer short-acting insulins such as lispro (Humalog) and aspart (NovoLog), which do not cross the placenta, may help reduce postprandial hyperglycemia, episodes of hypoglycemia between meals. Target fasting glucose values of 60 to 90 mg/dL and 1-hour postprandial values less than 120 mg/dL are necessary to provide good glycemic control and good pregnancy outcomes (Moore, 2012). Changes in diet and activity level add to the need for changes in insulin dosages throughout pregnancy.

Insulin regimens vary, and controversy remains over the best strategy for insulin delivery in pregnancy. Many health care providers use a split-dose therapy (two thirds of the daily dose in the morning and the remaining one third in the evening). Others advocate the use of an insulin pump to deliver a continuous subcutaneous insulin infusion. Regardless of which protocol is used, frequent blood glucose measurements are necessary, and the insulin dosage is adjusted on the basis of daily glucose levels. See Evidence-Based Practice 20.1 feature.

## EVIDENCE-BASED PRACTICE 20.1

## SELECTING METHODS OF INSULIN ADMINISTRATION FOR PREGNANT WOMEN WITH DIABETES

## STUDY

Diabetes results in a rise in blood glucose above normal physiologic levels; if untreated this may cause damage to many systems including the cardiovascular and renal systems. Pregnancy leads to a physiologic resistance to insulin action; for those women who have pregestational diabetes, this results in an increasing insulin requirement.

A woman who has diabetes and becomes pregnant is at risk for various problems, both for herself and her fetus. The goal during pregnancy is to maintain optimal glucose control. For these women, insulin is the mainstay of treatment. Unfortunately, blood glucose levels are not static and insulin requirements change throughout pregnancy.

Insulin typically is administered subcutaneously, commonly in multiple doses throughout the day. However, it also may be administered via a continuous subcutaneous infusion. The question arises as to which method of insulin administration affords the best control of blood glucose levels. The belief is that the continuous infusions would provide better blood glucose control and thus reduce the risks of problems for the mother and fetus.

A study was conducted comparing the effects of continuous subcutaneous insulin infusions with multiple daily doses of insulin therapy. The study involved a search of randomized controlled trials comparing these two methods of administration and their effect on neonatal birthweight, perinatal mortality, fetal anomalies, and maternal hypo- and hyperglycemia. Five trials involving 153 women and 154 pregnancies were included.

Adapted from Farrar, D., Tuffnell, D. J., & West, J. (2011). Continuous subcutaneous insulin infusion versus multiple daily injections of insulin for pregnant women with diabetes. *Cochrane Database of Systematic Reviews*, 2011(10). doi:10.1002/14651858.CD005542.pub2.

## Findings

Women receiving continuous insulin infusions experienced an increase in birth weight of their infants compared to mothers receiving multiple daily doses of insulin. However, the researchers did not identify this difference as clinically significant. The researchers found no significant differences in perinatal mortality, fetal anomalies, or maternal hypo- and hyperglycemia between the two groups. The researchers attributed this to the small number of trials reviewed and the limited sample size of participants in the study. They concluded that there was insufficient evidence to support one method being better than the other. Continuous insulin infusion is safe in pregnancy, but it has not yet been associated with any improved pregnancy outcome. The researchers recommended additional research using a more vigorous approach and larger samples of women.

## Nursing Implications

This study, although inconclusive, does underscore the need for glucose control in women with pregestational diabetes. Nurses need to be aware of these findings so that they can integrate knowledge of adequate blood glucose control when teaching pregnant women with diabetes about its potential effects, regardless of the method for insulin administration. Nurses also need to be cognizant of the various methods for insulin administration so that they can incorporate the information from this study to provide individualized care to the pregnant woman with diabetes, thereby promoting the best possible outcomes for the mother and her fetus.

Close maternal and fetal surveillance is also essential. Frequent laboratory tests are done during pregnancy to monitor the woman's status and glucose control. Fetal surveillance via diagnostic testing aids in evaluating fetal well-being and assisting in determining the best time for birth.

For the laboring woman with diabetes, intravenous saline or lactated Ringer's is given and blood glucose levels are monitored every 1 to 2 hours. Glucose levels are maintained below 110 mg/dL throughout labor to reduce the likelihood of neonatal hypoglycemia. If necessary, an infusion of regular insulin may be given to maintain this level (ADA, 2012b). If the woman was receiving insulin during her pregnancy, adjustments in dosage may be necessary after birth since glucose diversion across the placenta to supply the growing fetus is no longer present and insulin resistance is now removed. Frequently, the woman with gestational diabetes can remain controlled through diet and weight management; the woman with type 1 diabetes usually returns

to prepregnant levels of insulin administration (Scott & Flanagan, 2010).

After giving birth, the overt glycemic abnormalities of gestational diabetes usually resolve. This phenomenon suggests that the diabetes is transient and that the consequences of gestational diabetes end with the birth of the infant. However, for the woman, childbirth is not the end of the story. The diagnosis of gestational diabetes heralds future health risks. Knowledge of this "failed" stress test conveys new information about her future risk for type 2 diabetes, which warrants further screening and prevention efforts during the postpartum period and beyond.

## Nursing Assessment

Nursing assessment begins at the first prenatal visit. A thorough history and physical examination in conjunction with specific laboratory and diagnostic testing aids in developing an individualized plan of care for the woman with diabetes.

## Health History and Physical Examination

For the woman with pregestational diabetes, obtain a thorough history of the preexisting diabetic condition. Ask about her duration of disease, management of glucose levels (insulin injections, insulin pump, or oral hypoglycemic agents), dietary adjustments, presence of vascular complications and current vascular status, current insulin regimen, and technique used for glucose testing. Review any information that she may have received as part of her preconception counseling and measures that were implemented during this time.

Be knowledgeable about the woman's nutritional requirements and assess the adequacy and pattern of her dietary intake. Assess her blood glucose self-monitoring in terms of technique, frequency, and her ability to adjust the insulin dose based on the changing patterns. Ask about the frequency of episodes of hypoglycemia or hyperglycemia to ascertain the woman's ability to recognize and treat them. Continue to assess her for signs and symptoms of hypo- and hyperglycemia.

During antepartum visits, assess the client's knowledge about her disease, including the signs and symptoms of hypoglycemia, hyperglycemia, and diabetic ketoacidosis, insulin administration techniques, and the impact of pregnancy on her chronic condition. If possible have the woman demonstrate her technique for blood glucose monitoring and insulin administration if appropriate. It is essential that the nurse keeps in mind that there is a huge learning curve for women with diabetes concerning the need for dietary changes, frequency of blood glucose monitoring, exercise, and insulin or oral medication administration. All of a sudden, the woman is expected to make rapid changes in her life and this can be overwhelming for many. The nurse can help facilitate these changes by exercising patience and understanding and reinforcing all verbal instructions with written material. Frequent encouragement is also needed to assist the woman in her lifestyle changes. Although the client may have had diabetes for some time, do not assume that she has a firm knowledge base about her disease process or management of it (Fig. 20.2).

Assess the woman's risk for gestational diabetes at the first prenatal visit. The ADA (2012e) recommends assessing all women for risk factors and then determining the need for additional testing in the high-risk group only. Factors that place a woman at high risk include:

- Previous infant with congenital anomaly (skeletal, renal, central nervous system [CNS], cardiac)
- History of gestational diabetes or hydramnios in a previous pregnancy
- Family history of diabetes
- Age 35 years or older
- Previous infant weighing more than 9 pounds (4,000 g)
- Previous unexplained fetal demise or neonatal death

**FIGURE 20.2** The nurse is demonstrating the technique for self-blood glucose monitoring with a pregnant client who has diabetes.

- Maternal obesity (body mass index [BMI] >30)
- Hypertension before pregnancy or in early pregnancy
- Hispanic, Native American, Pacific Islander, or African American ethnicity
- Recurrent monilia infections that do not respond to treatment
- Signs and symptoms of glucose intolerance (polyuria, polyphagia, polydipsia, fatigue)
- Presence of glycosuria or proteinuria (Moore, 2012)

Women with clinical characteristics consistent with a high risk for gestational diabetes should undergo glucose testing as soon as feasible.

Provide close ongoing assessment throughout the antepartal period. Women with gestational diabetes mellitus are at increased risk for preeclampsia and glucose control–related complications such as hypoglycemia, hyperglycemia, and ketoacidosis. Gestational diabetes of any severity increases the risk of fetal macrosomia. It is also associated with an increased frequency of maternal hypertensive disorders and operative births. This may be the result of fetal growth disorders (ADA, 2012e). Even though gestational diabetes is diagnosed during pregnancy, the woman may have had glucose intolerance before the pregnancy. Therefore, monitor the woman closely for signs and symptoms of possible complications.

Also assess the woman's psychosocial adaptation to her condition. This assessment is critical to gain her cooperation for a change in regimen or the addition of a new regimen throughout pregnancy. Identify her support systems and note any financial constraints, because she will need intense monitoring and frequent fetal surveillance.

## Laboratory and Diagnostic Testing

The results of laboratory and diagnostic tests provide valuable information about maternal and fetal well-being. Women with pregestational diabetes and those

discovered to have gestational diabetes require ongoing maternal and fetal surveillance to promote the best outcome.

## SURVEILLANCE

Maternal surveillance may include the following:

- Urine check for protein (may indicate the need for further evaluation for preeclampsia) and for nitrates and leukocyte esterase (may indicate a urinary tract infection)
- Urine check for ketones (may indicate the need for evaluation of eating habits)
- Kidney function evaluation every trimester for creatinine clearance and protein levels
- Eye examination in the first trimester to evaluate the retina for vascular changes
- HbA1c every 4 to 6 weeks to monitor glucose trends (Kendrick, 2011)

Fetal surveillance may include ultrasound to provide information about fetal growth, activity, and amniotic fluid volume and to validate gestational age. Alpha-fetoprotein levels may be obtained to detect congenital anomalies such as an open neural tube or ventral wall defects of omphalocele or gastroschisis, and a fetal echocardiogram may be necessary to rule out cardiac anomalies. A biophysical profile helps to monitor fetal well-being and uteroplacental perfusion, and nonstress tests commonly are performed weekly after 28 weeks' gestation to evaluate fetal well-being. As the pregnancy progresses, an amniocentesis may be done to determine the lecithin/sphingomyelin (L/S) ratio and the presence of phosphatidyl glycerol (PG) to evaluate whether the fetal lung is mature enough for birth (Moore, 2012).

## Nursing Management

The ideal outcome of every pregnancy is a healthy newborn and mother. Nurses can be pivotal in realizing this positive outcome for women with pregestational or gestational diabetes by implementing measures to minimize risks and complications. Since the woman with diabetes is considered to be at high risk, antepartal visits occur more frequently (every 2 weeks up to 28 weeks and then twice a week until birth), providing the nurse with numerous opportunities for ongoing assessment, education, and counseling (Nursing Care Plan 20.1).

### Promoting Optimal Glucose Control

At each visit, review the mother's blood glucose levels, including any laboratory tests and self-monitoring results. Reinforce with the woman the need to perform blood glucose monitoring (usually four times a day: before meals and at bedtime) and to keep a record of the results. If appropriate, obtain a fingerstick blood glucose level to evaluate the accuracy of self-monitoring results.

Also assess the woman's techniques for monitoring blood glucose levels and for administering insulin if ordered, and offer support and guidance. If the woman is receiving insulin therapy, assist with any changes needed if glucose levels are not controlled.

Obtain a urine specimen and check for glucose, protein, and ketones. Ask the woman if she has had any episodes of hypoglycemia and what she did to alleviate them.

Discuss dietary measures related to blood glucose control (Fig. 20.3). In addition, recommend the following:

- Avoid weight loss and dieting during pregnancy.
- Ensure that food intake is adequate to prevent ketone formation and promote weight gain.
- Eat three meals a day plus three snacks to promote glycemic control:
  - 40% of calories from good-quality complex carbohydrates
  - 35% of calories from protein sources
  - 25% of calories from unsaturated fats.
- Small frequent feedings throughout the day are recommended.
- Bedtime snacks are recommended for all women.
- Include protein and fat at each meal (National Diabetes Information Clearing House, 2011).

### Take Note!

Nutrient requirements and recommendations for weight gain for the pregnant woman with diabetes are the same as those for the pregnant nondiabetic woman.

If necessary, arrange for consultation with a dietitian or nutritionist to individualize the dietary plan. Also encourage the women to participate in an exercise program that includes at least three sessions lasting longer than 15 minutes per week. Exercise may lessen the need for insulin or dosage adjustments.

When caring for the laboring woman with pregestational or gestational diabetes, adjust the intravenous flow rate and the rate of supplemental regular insulin based on the blood glucose levels as ordered. Monitor blood glucose levels every 1 to 2 hours or more frequently if necessary. Keep a syringe with 50% dextrose solution Retrieved from the bedside to treat profound hypoglycemia. Monitor fetal heart rate patterns throughout labor to detect category II and III patterns. Assess maternal vital signs every hour, in addition to assessing the woman's urinary output with an indwelling catheter. If a cesarean birth is scheduled, monitor the woman's blood glucose levels hourly and administer short-acting insulin or glucose based on the blood glucose levels as ordered.

After birth, monitor blood glucose levels every 2 to 4 hours for the first 48 hours to determine the woman's insulin need and continue intravenous fluid administration as ordered. Encourage breast-feeding to assist in

## NURSING CARE PLAN 20.1

## Overview of the Pregnant Woman with Type 1 Diabetes

Donna, a 30-year-old woman with type 1 diabetes, presents to the maternity clinic for pre-conception care. She has had diabetes for 8 years and takes insulin twice daily by injection. She does blood glucose self-monitoring four times daily. She reports that her disease is fairly well controlled, but “I’m worried about how my diabetes will affect a pregnancy and my baby. Will I need to make changes in my routine? Will my baby be normal?” She reports that she recently had a foot infection and needed to go to the emergency department because it led to an episode of ketoacidosis. She states that her last glycosylated hemoglobin A1c test results were abnormal.

**NURSING DIAGNOSIS:** Ineffective health maintenance: maternal related to deficient knowledge regarding care in diabetic condition in pregnancy as evidenced by questions about effect on pregnancy, possible changes in regimen, and pregnancy outcome

**Outcome Identification and Evaluation**

The client will demonstrate increased knowledge of type 1 diabetes and effects on pregnancy as evidenced by proper techniques for blood glucose monitoring and insulin administration, ability to modify insulin doses and dietary intake to achieve control, and verbalization of need for glycemic control prior to pregnancy, with blood glucose levels remaining within normal range.

**Interventions: Providing Client Teaching**

- Assess client’s knowledge of diabetes and pregnancy *to establish a baseline from which to develop an individualized teaching plan.*
- Review the underlying problems associated with diabetes and how pregnancy affects glucose control *to provide client with a firm knowledge base for decision making.*
- Review signs and symptoms of hypoglycemia and hyperglycemia and prevention and management measures *to ensure client can deal with them should they occur.*
- Provide written materials describing diabetes and care needed for control *to provide opportunity for client’s review and promote retention of learning.*
- Observe client administering insulin and self-glucose testing for technique and offer suggestions for improvement if needed *to ensure adequate self-care ability.*
- Discuss proper foot care *to prevent future infections.*
- Teach home treatment for symptomatic hypoglycemia *to minimize risk to client and fetus.*
- Outline acute and chronic diabetic complications *to reinforce the importance of glucose control.*
- Discuss use of contraceptives until blood glucose levels can be optimized before conception occurs *to promote best possible health status before conception.*
- Explain the rationale for good glucose control and the importance of achieving excellent glyce-mic control before pregnancy *to promote a positive pregnancy outcome.*
- Review self-care practices (blood glucose monitoring and frequency of testing; insulin administration; adjustment of insulin dosages based on blood glucose levels) *to foster independence in self-care and feelings of control over the situation.*
- Refer client for dietary counseling *to ensure optimal diet for glycemic control.*
- Outline obstetric management and fetal surveillance needed for pregnancy *to provide client with information on what to expect.*
- Discuss strategies for maintaining optimal glyce-mic control during pregnancy *to minimize risks to client and fetus.*

**NURSING DIAGNOSIS:** Anxiety related to threat to self and fetus as evidenced by questions about her condition’s effect on the baby and baby being normal

(continued)

## NURSING CARE PLAN 20.1

## Overview of the Pregnant Woman with Type 1 Diabetes (continued)

## Outcome Identification and Evaluation

The client will openly express her feelings related to her diabetes and pregnancy as evidenced by statements of feeling better about her preexisting condition and pregnancy outlook, and statements of understanding related to future childbearing by linking good glucose control with positive outcomes for both her and offspring.

Interventions: *Minimizing Anxiety*

- Review the need for a physical examination to evaluate for any effects of diabetes on the client's health status.
- Explain the rationale for assessing client's blood pressure, vision, and peripheral pulses at each visit to provide information related to possible effects of diabetes on health status.
- Identify any alterations in present diabetic condition that need intervention to aid in minimizing risks that may increase client's anxiety level.
- Review potential effects of diabetes on pregnancy to promote client understanding of risks and ways to control or minimize them.
- Encourage active participation in decision making and planning pregnancy to promote feelings of control over the situation and foster self-confidence.
- Discuss feelings about future childbearing and managing pregnancy to help reduce anxiety related to uncertainties.
- Encourage client to ask questions or voice concerns to help decrease anxiety related to the unknown.
- Emphasize the use of frequent and continued surveillance of client and fetal status during pregnancy to reduce the risk of complications and aid in alleviating anxieties related to the unknown.
- Provide positive reinforcement for healthy behaviors and actions to foster continued use and enhancement of self-esteem.

FIGURE 20.3 The pregnant client with diabetes eating a nutritious meal to ensure adequate glucose control.

maintaining good glucose control. For the woman with pregestational diabetes and type 1 or 2 diabetes, expect insulin needs to decrease rapidly after birth: they may be reduced by half of the antepartum dose as meals are started (King & Brucker, 2011). Some women may return to their prepregnancy insulin dosage.

The therapy plan after childbirth is individualized for each woman. If recommended dietary modifications are carried out along with weight loss, the woman with gestational diabetes may return to her normal glucose levels. This is also true for the woman with pregestational diabetes, except that she will return to her prepregnancy insulin administration levels. This provides the nurse with a wonderful opportunity to reinforce healthy lifestyle interventions on the postpartum unit. Nurses can also become involved with community-based education to continue to offer their expertise.

## Preventing Complications

Assess the woman closely for signs and symptoms of complications at each visit. Anticipate possible complications and plan appropriate interventions or referrals.

Check the woman's blood pressure for changes and evaluate for proteinuria when obtaining a urine specimen. These might suggest the development of preeclampsia. Measure fundal height and review gestational age. Note any discrepancies between fundal height and gestational age or a sudden increase in uterine growth. These may suggest hydramnios.

Encourage the woman to perform daily fetal movement counts to monitor fetal well-being. Tell her specifically when she should notify her health care provider. Also prepare the woman for the need for frequent laboratory and diagnostic testing to evaluate fetal status. Assist with serial ultrasounds to monitor fetal growth and with nonstress tests and biophysical profiles to assess fetal well-being.

### Consider This

Scott and I had been busy all day setting up the new crib in our nursery, and we finally sat down to rest. I was due any day, and we had been putting this off until we had a long weekend to complete the task. I was excited to think about all the frilly pinks that decorated her room. I was sure that my new daughter would love it as much as I loved her already. A few days later I barely noticed any fetal movement, but I thought that she must be as tired as I was by this point.

That night I went into labor and kept looking at the worried faces of the nurses and the midwife in attendance. I had been diagnosed with gestational diabetes a few months ago and had tried to follow the instructions regarding diet and exercise, but old habits are hard to change when you are 38 years old. I was finally told after a short time in the labor unit that they couldn't pick up a fetal heartbeat and an ultrasound was to be done—still no heartbeat was detected. Scott and I were finally told that our daughter was a stillborn. All I could think about was that she would never get to see all the pink colors in the nursery.

### Providing Client Education and Counseling

The pregnant woman with diabetes requires counseling and education about the need for strict glucose monitoring, diet and exercise, and signs and symptoms of complications. Encourage the client and her family to make any lifestyle changes needed to optimize the pregnancy outcome. Providing dietary education, weight control measures, and lifestyle advice that extends beyond pregnancy may lower the risk that the woman will have

gestational diabetes in subsequent pregnancies as well as type 2 diabetes (Ferrera, Hedderson, Ching, Kim et al., 2012). At each visit stress the importance of performing blood glucose screening and documenting the results. With proper instruction, the client and her family will be able to cope with all the changes in her body during pregnancy (Teaching Guidelines 20.1).

### Teaching Guidelines 20.1

#### TEACHING FOR THE PREGNANT WOMAN WITH DIABETES

- Be sure to keep your appointments for frequent prenatal visits and tests for fetal well-being.
- Perform blood glucose self-monitoring as directed, usually before each meal and at bedtime. Keep a record of your results and call your health care provider with any levels outside the established range. Bring your results to each prenatal visit.
- Perform daily “fetal kick counts.” Document them and report any decrease in activity.
- Drink eight to ten 8-ounce glasses of water each day to prevent bladder infections and maintain hydration.
- Wear proper, well-fitted footwear when walking to prevent injury.
- Engage in a regular exercise program such as walking to aid in glucose control, but avoid exercising in temperature extremes.
- Consider breast-feeding your infant to lower your blood glucose levels.
- If you are taking insulin:
  - Administer the correct dose of insulin at the correct time every day.
  - Eat breakfast within 30 minutes after injecting regular insulin to prevent a reaction.
  - Plan meals at a fixed time and snacks to prevent extremes in glucose levels.
- Avoid simple sugars (cake, candy, cookies), which raise blood glucose levels.
- Know the signs and symptoms of hypoglycemia and treatment needed:
  - Sweating, tremors, cold, clammy skin, headache
  - Feeling hungry, blurred vision, disorientation, irritability
  - Treatment: Drink 8 ounces of milk and eat two crackers or glucose tablets
- Carry “glucose boosters” (such as Life Savers) to treat hypoglycemia.
- Know the signs and symptoms of hyperglycemia and treatment needed:
  - Dry mouth, frequent urination, excessive thirst, rapid breathing

- Feeling tired, flushed, hot skin, headache, drowsiness
- Treatment: Notify health care provider, because hospitalization may be needed
- Wear a diabetic identification bracelet at all times.
- Wash your hands frequently to prevent infections.
- Report any signs and symptoms of illness, infection, and dehydration to your health care provider, because these can affect blood glucose control.

Review discussions about the timing of birth and the rationale. Counsel the client about the possibility of cesarean birth for an LGA infant, or inform the woman who will be giving birth vaginally about the possible need for augmentation with oxytocin (Pitocin).

### Take Note!

*In the woman with well-controlled diabetes, birth is typically not induced before term unless complications arise, such as preeclampsia or fetal compromise. An early delivery date might be set for the woman with poorly controlled diabetes who is having complications.*

Instruct the client about the benefits of breast-feeding related to blood glucose control. Breast-feeding helps to normalize blood glucose levels. Therefore, encourage the woman to breast-feed her newborn. Also teach the woman receiving insulin for her diabetes that her insulin needs after birth will drastically decrease. Inform her that she will need a repeat glucose challenge test at a postpartum visit (ADA, 2012d).

For the woman with gestational diabetes, the focus is on lifestyle education. Women with gestational diabetes have a greater than 50% increased risk of developing type 2 diabetes (ADA, 2012d). Inform the woman that screening most likely will be done at the postpartum follow-up appointment in 6 weeks. Women with normal results at that visit typically are screened every 3 years thereafter (ADA, 2012d). Teach her how to maintain an optimal weight to reduce her risk of developing diabetes. If necessary, refer the woman to a dietitian to help outline a balanced nutritious diet.

## CARDIOVASCULAR DISORDERS

Every minute, an American woman dies of cardiovascular disease and more than one in three women is living with a cardiovascular disorder, including nearly half of all African American women and 34% of Caucasian women (American Heart Association [AHA], 2012). Cardiovascular disease (CVD) is the leading cause of death for men and women in the United States. It kills nearly

500,000 women each year. Despite the prominent reduction in cardiovascular mortality among men, the rate has not declined for women. Cardiovascular disease has killed more women than men since 1984 (AHA, 2012). In addition to being the number-one killer of women, at the time of diagnosis women have both a poorer overall prognosis and a higher risk of death than men diagnosed with heart disease. Women represent 53% of CVD deaths (Kim, Draska, Hess, Wilson & Richardson 2012; Herman 2012). In both men and women risk factors such as hypertension, high blood cholesterol level, smoking, lack of physical activity, and obesity increase the probability of developing CVD. Menopause, oral contraceptive use, and bilateral oophorectomy in premenopausal women also affect the risk of CVD in women (Hauk, 2012).

More women die of heart disease, stroke, and other cardiovascular diseases than men, yet many women do not realize they are at risk. These diseases kill more women each year than the next three causes of death combined, including all types of cancer (AHA, 2012).

Approximately 3% of pregnant women have cardiac disease, which is responsible for 10% to 25% of maternal deaths (Cunningham et al., 2010). The prevalence of cardiac disease is increasing as a result of lifestyle patterns, including cigarette smoking, diabetes, and stress. As women are delaying childbearing, the incidence of cardiac disease in pregnancy will continue to increase. The cardiovascular adaptations during pregnancy are well tolerated by the normal heart, but may unveil undiagnosed underlying heart disease, or tip the hemodynamic balance and lead to decompensation in those with existing heart disease (Brooks, 2011).

Rheumatic heart disease used to represent the majority of cardiac conditions during pregnancy, but congenital heart disease now constitutes nearly half of all cases of heart disease encountered during pregnancy. Classic symptoms of heart disease mimic common symptoms of late pregnancy, such as palpitations, shortness of breath with exertion, and occasional chest pain. Few women with heart disease die during pregnancy, but they are at risk for other complications, such as heart failure, arrhythmias, and stroke. Their offspring are also at risk of complications, such as premature birth, low birth weight for gestational age, respiratory distress syndrome, intraventricular hemorrhage, and death (Simpson, 2012).

### Congenital and Acquired Heart Disease

Congenital heart disease often involves structural defects that are present at birth but may not be discovered at that time (Table 20.3). Until recently women with congenital heart disease did not live long enough to bear children.

**TABLE 20.3** SELECTED HEART CONDITIONS AFFECTING PREGNANCY

Condition	Description	Management
<i>Congenital</i>		
Tetralogy of Fallot	Congenital defect involving four structural anomalies: obstruction to pulmonary flow; ventricular septal defect (abnormal opening between the right and left ventricles); dextroposition of the aorta (aortic opening overriding the septum and receiving blood from both ventricles); and right ventricular hypertrophy (increase in volume of the myocardium of the right ventricle)	Hospitalization and bed rest possible after the 20th week with hemodynamic monitoring via a pulmonary artery catheter to monitor volume status Oxygen therapy may be necessary during labor and birth.
Atrial septal defect (ASD)	Congenital heart defect involving a communication or opening between the atria with left-to-right shunting due to greater left-sided pressure Arrhythmias present in some women.	Treatment with atrioventricular nodal blocking agents, and at times with electrical cardioversion
Ventricular septal defect (VSD)	Congenital heart defect involving an opening in the ventricular septum, permitting blood flow from the left to the right ventricle. Complications include arrhythmias, heart failure, and pulmonary hypertension.	Rest with limited activity if symptomatic
Patent ductus arteriosus	Abnormal persistence of an open lumen in the ductus arteriosus between the aorta and the pulmonary artery after birth; results in increased pulmonary blood flow and redistribution of flow to other organs.	Surgical ligation of the open ductus during infancy; subsequent problems minimal after surgical correction
<i>Acquired</i>		
Mitral valve prolapse	Very common in the general population, occurring most often in younger women Leaflets of the mitral valve prolapse into the left atrium during ventricular contraction. The most common cause of mitral valve regurgitation if present during pregnancy Usually improvements in mitral valve function due to increased blood volume and decreased systemic vascular resistance of pregnancy; most women are able to tolerate pregnancy well.	Most women are asymptomatic; diagnosis is made incidentally. Occasional palpitations, chest pain, or arrhythmias in some women, possibly requiring beta blockers Usually no special precautions are necessary during pregnancy.
Mitral valve stenosis	Most common chronic rheumatic valvular lesion in pregnancy Causes obstruction of blood flow from the atria to the ventricle, thereby decreasing ventricular filling and causing a fixed cardiac output Resultant pulmonary edema, pulmonary hypertension, and right ventricular failure Most pregnant women with this condition can be managed medically.	General symptomatic improvement with medical management involving diuretics, beta blockers, and anticoagulant therapy Activity restriction, reduction in sodium, and potentially bed rest if condition severe
Aortic stenosis	Narrowing of the opening of the aortic valve, leading to an obstruction to left ventricular ejection Women with mild disease can tolerate hypervolemia of pregnancy; with progressive narrowing of the opening, cardiac output becomes fixed. Diagnosis can be confirmed with echocardiography. Most women can be managed with medical therapy, bed rest, and close monitoring.	Diagnosis confirmed with echocardiography Pharmacologic treatment with beta blockers and/or antiarrhythmic agents to reduce risk of heart failure and/or dysrhythmias Bed rest/limited activity and close monitoring

(continued)

**TABLE 20.3** SELECTED HEART CONDITIONS AFFECTING PREGNANCY (continued)

Condition	Description	Management
Peripartum cardiomyopathy	Rare congestive cardiomyopathy that may arise during pregnancy. Multiparity, age, multiple fetuses, hypertension, an infectious agent, autoimmune disease, or cocaine use may contribute to its presence. Development of heart failure in the last month of pregnancy or within 5 months of giving birth without any preexisting heart disease or any identifiable cause	Preload reduction with diuretic therapy Afterload reduction with vasodilators Improvement in contractility with inotropic agents Nonpharmacologic approaches include salt restriction and daily exercise such as walking or biking. The question of whether another pregnancy should be attempted is controversial due to the high risk of repeat complications.
Myocardial infarction (MI)	Rare during pregnancy but incidence is expected to increase as older women are becoming pregnant and the risk factors for coronary artery disease become more prevalent. Factors contributing to MI include family history, stress, smoking, age, obesity, multiple fetuses, hypercholesterolemia, and cocaine use. Increased plasma volume and cardiac output during pregnancy increase the cardiac workload as well as the myocardial oxygen demands; imbalance in supply and demand may contribute to myocardial ischemia.	Usual treatment modalities for any acute MI along with consideration for the fetus Anticoagulant therapy, rest, and lifestyle changes to preserve the health of both parties

Adapted from Gardner, S. L., Carter, B. S., Enzman-Hines, M., & Hernandez, J. A. (2011). *Merenstein & Gardner's handbook of neonatal intensive care* (7th ed.). St. Louis, MO: Mosby Elsevier; Gilbert, E. S. (2011). *Manual of high risk pregnancy and delivery* (5th ed.). St. Louis, MO: Mosby Elsevier; and Mattson, S., & Smith, J.E. (2011). *Core curriculum for maternal–newborn nursing* (4th ed.). St. Louis, MO: Saunders Elsevier.

Today, due to new surgical techniques to correct these defects, many of these women can complete a successful pregnancy at relatively low risk when appropriate counseling and optimal care are provided. Increasing numbers of women with complex congenital heart disease are reaching childbearing age. Complications such as growth restriction, preterm and premature birth, and fetal and neonatal mortality are more common among children of women with congenital heart disease. The risk of complications is determined by the severity of the cardiac lesion, the presence of cyanosis, the maternal functional class, and the use of anticoagulation therapy (Simpson 2012).

Women with certain congenital conditions should avoid pregnancy. These include uncorrected tetralogy of Fallot or transposition of the great arteries, and Eisenmenger's syndrome, a defect with both cyanosis and pulmonary hypertension (Opatowsky, Siddiqi, D' Souza, Webb et al., 2012).

Acquired heart diseases are conditions affecting the heart and its associated blood vessels that develop during a person's lifetime, in contrast to congenital heart diseases, which are present at birth. Acquired heart diseases include coronary artery disease, coronary heart disease, rheumatic heart disease, diseases of the pulmonary

vessels and the aorta, diseases of the tissues of the heart, and diseases of the heart valves. The incidence of rheumatic heart disease has declined dramatically in the past several decades because of prompt identification of streptococcal throat infections and treatment with antibiotics. When the heart is involved, valvular lesions, such as mitral stenosis, prolapse, or aortic stenosis, are common (see Table 20.3).

Many women are postponing childbearing until their 30s and 40s. With advancing maternal age, underlying medical conditions such as hypertension, diabetes, and hypercholesterolemia contributing to ischemic heart disease become more common and increase the incidence of acquired heart disease complicating pregnancy. Coronary artery disease and myocardial infarction may result.

A woman's ability to function during the pregnancy is often more important than the actual diagnosis of the cardiac condition. The following is a functional classification system developed by the Criteria Committee of the New York Heart Association (1994) based on past and present disability and physical signs:

- *Class I:* asymptomatic with no limitation of physical activity; no objective evidence of cardiac disease.

- *Class II:* symptomatic (dyspnea, chest pain) with increased activity resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain.
- *Class III:* symptomatic (fatigue, palpitations) with normal activity resulting in marked limitation of physical activity. They are comfortable at rest. Less than ordinary activity causes fatigue, palpitation, dyspnea, or anginal pain.
- *Class IV:* symptomatic at rest or with any physical activity resulting in inability to carry on any physical activity without discomfort. Symptoms of heart failure or the anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.

The classification may change as the pregnancy progresses and the woman's body must cope with the increasing stress on the cardiovascular system resulting from the numerous physiologic changes taking place. Typically, a woman with class I or II cardiac disease can go through a pregnancy without major complications. A woman with class III disease usually has to maintain bed rest during pregnancy. A woman with class IV disease should avoid pregnancy (Pieper, 2011). Women with cardiac disease may benefit from preconception counseling so that they know the risks before deciding to become pregnant.

Maternal mortality varies directly with the functional class at pregnancy onset. ACOG has adopted a three-tiered classification according to the risk of death during pregnancy (Box 20.1).

## Pathophysiology

Numerous hemodynamic changes occur in all pregnant women. These normal physiologic changes can over-stress the woman's cardiovascular system, increasing her risk for problems. Increased cardiac workload and greater myocardial oxygen demand during pregnancy place the woman's cardiovascular system at high risk for morbidity and mortality.

Pregnancy causes cardiac output to rise as early as the first trimester, reaching peak values at 20 to 24 weeks, and continues to increase until it plateaus between 28 and 34 weeks' gestation. This rise in cardiac output is due to a 30% to 50% increase in blood volume (stroke volume) and a 30% increase in heart rate. A normal resting heart rate for any pregnant woman can be on average 20 beats per minute above her normal values.

### Take Note!

Uterine blood flow increases by at least 1 liter per minute, requiring the body to produce more blood

### BOX 20.1

#### CLASSIFICATION OF MATERNAL MORTALITY RISK

Group I (minimal risk) has a mortality rate of 1% and comprises women with:

- Patent ductus arteriosus
- Tetralogy of Fallot, corrected
- Atrial septal defect
- Ventricular septal defect
- Mitral stenosis, class I and II

Group II (moderate risk) has a mortality rate of 5% to 15% and comprises women with:

- Tetralogy of Fallot, uncorrected
- Mitral stenosis with atrial fibrillation
- Aortic stenosis, class III and IV
- Aortic coarctation without valvular involvement
- Artificial valve replacement

Group III (major risk) has a 25% to 50% mortality rate and comprises women with:

- Pulmonary hypertension
- Complicated aortic coarctation
- Previous myocardial infarction

Adapted from American Heart Association. (2012). *Women and heart disease*. Retrieved from [http://www.heart.org/HEARTORG/Advocate/IssuesandCampaigns/QualityCare/Women-and-Heart-Disease\\_UCM\\_430484\\_Article.jsp](http://www.heart.org/HEARTORG/Advocate/IssuesandCampaigns/QualityCare/Women-and-Heart-Disease_UCM_430484_Article.jsp); Brooks, R. (2011). Pregnancy and heart disease: An introduction. *British Journal of Midwifery*, 19(12), 763–772; and Gilbert, E. S. (2011). *Manual of high risk pregnancy and delivery* (5th ed.). St. Louis, MO: Mosby Elsevier.

during pregnancy. This results in a 25% increase in red blood cells, a 50% expansion of plasma volume during pregnancy, and an overall hemodilution. In addition, the increase in total red blood cellular volume includes an increase in clotting factors and platelets, defining the hypercoagulable state of pregnancy (Mohamad, Fakhri, & Bernal, 2012). These changes start as early as the second month of gestation.

Similarly, cardiac output increases steadily during pregnancy by 30% to 50% over prepregnancy levels. Stroke volume increases 20% to 30% from prepregnant levels, and the maternal heart rate increases by 10 to 20 beats per minute (bpm). The increase is due to both the expansion in blood volume and the augmentation of stroke volume and heart rate. Other hemodynamic changes associated with pregnancy include a decrease in both the systemic vascular resistance and pulmonary vascular resistance, thereby lowering the systolic and diastolic blood pressure. In addition, the hypercoagulability associated with pregnancy might increase the risk of arterial thrombosis and embolization. These normal physiologic changes are important for a successful adaptation

## COMPARISON CHART 20.1

## CARDIOVASCULAR CHANGES: PREPREGNANCY VS. PREGNANCY

Measurement	Prepregnancy	Pregnancy
Heart rate	72 ( $\pm$ 10 bpm)	+10–20%
Cardiac output	4.3 ( $\pm$ 0.9 L/min)	+30–50%
Blood volume	5 L	+20–50%
Stroke volume	73.3 ( $\pm$ 9 mL)	+30%
Systemic vascular resistance	1,530 ( $\pm$ 520 dyne/cm/sec)	–20%
Oxygen consumption	250 mL/min	+20–30%

Adapted from American Heart Association [AHA]. (2012). *Women and heart disease*. Retrieved from [http://www.heart.org/HEARTORG/Advocate/IssuesandCampaigns/QualityCare/Women-and-Heart-Disease\\_UCM\\_430484\\_Article.jsp](http://www.heart.org/HEARTORG/Advocate/IssuesandCampaigns/QualityCare/Women-and-Heart-Disease_UCM_430484_Article.jsp); Brooks, R. (2011). Pregnancy and heart disease: An introduction. *British Journal of Midwifery*, 19(12), 763-772; Franklin, W. J., Benton, M., & Parekh, D. R. (2011). Cardiac disease in pregnancy. *Texas Heart Institute Journal*, 38(2), 151–153; and Mattson, S., & Smith, J.E. (2011). *Core curriculum for maternal–newborn nursing* (4th ed.). St. Louis, MO: Saunders Elsevier.

to pregnancy but create unique physiologic challenges for the woman with cardiac disease (Comparison Chart 20.1).

## Therapeutic Management

Ideally, a woman with a history of congenital or acquired heart disease should consult her health care provider before becoming pregnant and should undergo a risk assessment. This risk assessment must consider the woman's functional capacity, exercise tolerance, degree of cyanosis, medication needs, and history of arrhythmias. Data needed for risk assessment can be acquired from a thorough cardiovascular history and examination, a 12-lead electrocardiogram (ECG), and evaluation of oxygen saturation levels by pulse oximetry. The impact of heart disease on a woman's childbearing potential needs to be clearly explained, and providing information on how pregnancy may affect her and the fetus is important. This allows women to make an informed choice about whether they wish to accept the risks associated with pregnancy. When possible, any surgical procedures, such as valve replacement, should be done before pregnancy to improve fetal and maternal outcomes (De Santo, Romano, Della Corte, D'Oria et al., 2012).

If the woman presents for care after she has become pregnant, prenatal counseling focuses on the impact of the hemodynamic changes of pregnancy, the signs and symptoms of cardiac compromise, and dietary and lifestyle changes needed. More frequent prenatal visits (every 2 weeks until the last month and then weekly) are usually needed to ensure the health and safety of the mother and fetus.

## Nursing Assessment

Frequent and thorough assessments are crucial during the antepartum period to ensure early detection of and prompt intervention for problems. Assess the woman's vital signs, noting any changes. Auscultate the apical heart rate and heart sounds, being especially alert for abnormalities, including irregularities in rhythm or murmurs. Check the client's weight and compare to baseline and weights obtained on previous visits. Report any weight gain outside recommended parameters. Inspect the extremities for edema and note any pitting.

Question the woman about fetal activity, and ask if she has noticed any changes. Report any changes such as a decrease in fetal movements. Ask the woman about any symptoms of preterm labor, such as low back pain, uterine contractions, and increased pelvic pressure and vaginal discharge, and report them immediately. Assess the fetal heart rate and review serial ultrasound results to monitor fetal growth.

Assess the client's lifestyle and her ability to cope with the changes of pregnancy and its effect on her cardiac status and ability to function. Evaluate the client's understanding of her condition and what restrictions and lifestyle changes may be needed to provide the best outcome for her and her fetus. A healthy infant and mother at the end of pregnancy is the ultimate goal. As the client's pregnancy advances, expect her functional class to be revised based on her level of disability. Suggest realistic modifications.

The nurse plays a major role in recognizing the signs and symptoms of cardiac decompensation.

Decompensation refers to the heart's inability to maintain adequate circulation. As a result, tissue perfusion in the mother and the fetus is impaired. The pregnant woman is most vulnerable for this complication from 28 to 32 weeks of gestation and in the first 48 hours postpartum (Simpson, 2012). Assess the woman for the following signs and symptoms:

- Shortness of breath on exertion, dyspnea
- Cyanosis of lips and nail beds
- Swelling of face, hands, and feet
- Jugular vein engorgement
- Rapid respirations
- Abnormal heartbeats, reports of heart racing or palpitations
- Chest pain with effort or emotion
- Syncope with exertion
- Increasing fatigue
- Moist, frequent cough

### Take Note!

Assessing the pregnant woman with heart disease for cardiac decompensation is vital because the mother's hemodynamic status determines the health of the fetus.

## Nursing Management

Nursing management of the pregnant woman with heart disease focuses on assisting with measures to stabilize the mother's hemodynamic status, because a decrease in maternal blood pressure or volume will cause blood to be shunted away from the uterus, thus reducing placental perfusion. Pregnant women with cardiac disease also need assistance in reducing risks that would lead to complications or further cardiac compromise. Therefore, education and counseling are critical. Collaboration between the cardiologist, obstetrician, perinatologist, and nurse is needed to promote the best possible outcome.

Drug therapy may be indicated for the pregnant woman with a cardiac disorder. Possible drugs include diuretics, such as Lasix, to prevent heart failure; digitalis to increase contractility and decrease heart rates; antiarrhythmic agents (lidocaine); beta blockers (labetalol); calcium channel blockers (nifedipine) to treat hypertension; and anticoagulants (low-molecular-weight heparin). Warfarin (Coumadin) is not recommended because it crosses the placenta and may have teratogenic effects. Warfarin is a U.S. Food and Drug Administration (FDA) Pregnancy Category X drug. It has been associated with spontaneous abortion, multiple birth defects, fetal growth restriction, and stillbirth (King & Brucker, 2011). The FDA's risk categories are as follows:

- Category A: Controlled human studies show no risk
- Category B: No evidence of risk in humans, but no controlled human studies are documented

- Category C: Risk to humans has not been excluded
- Category D: Positive evidence of risk to humans from human and/or animal studies
- Category X: Contraindicated in pregnancy

Encourage the woman to continue taking her cardiac medications as prescribed. Review the indications, actions, and potential side effects of the medications. Reinforce the importance of frequent antepartal visits and close medical supervision throughout the pregnancy.

Discuss the need to conserve energy. Help the client to prioritize household chores and child care to allow rest periods. Encourage the client to rest in the side-lying position, which enhances placental perfusion.

Encourage the client to eat nutritious foods and consume a high-fiber diet to prevent straining and constipation. Discuss limiting sodium intake if indicated to reduce fluid retention. Contact a dietitian to assist the woman in planning nutritionally appropriate meals.

Assist the woman in preparing for diagnostic tests to evaluate fetal well-being. Describe the tests that may be done, such as ECG and echocardiogram, and explain the need for serial nonstress testing, usually beginning at approximately 32 weeks' gestation.

Instruct the woman in how to monitor fetal activity and movements. Urge her to do this daily and report any changes in activity immediately.

Although the morbidity and mortality rates of pregnant women with cardiac disease have decreased greatly, hemodynamic changes during pregnancy (increased heart rate, stroke volume, cardiac output and blood volume) have a profound effect, which may increase cardiac work and might exceed the functional capacity of the diseased heart. These changes may result in pulmonary hypertension, pulmonary edema, heart failure, or maternal death (Mattson & Smith, 2011). Explain the signs and symptoms of these complications and review the sign and symptoms of cardiac decompensation, encouraging the woman to notify her health care provider if any occur.

Provide support and encouragement throughout the antepartal period. Assess the support systems available to the client and her family, and encourage her to use them. If necessary, assist with referrals to community services for additional support.

During labor, anticipate the need for invasive hemodynamic monitoring, and make sure the woman has been prepared for this beforehand. Monitor her fluid volume carefully to prevent overload. Anticipate the use of epidural anesthesia if a vaginal birth is planned. After birth, assess the client for fluid overload as peripheral fluids mobilize. This fluid shift from the periphery to the central circulation taxes the heart, and signs of heart failure such as cough, progressive dyspnea, edema, palpitations, and crackles in the lung bases may ensue before postpartum diuresis begins.

Because hemodynamics do not return to baseline for several days after childbirth, women at intermediate or high risk require monitoring for at least 48 hours postpartum (Tharpe, Farley, & Joedan, 2013).

## Chronic Hypertension

Chronic hypertension exists when the woman has high blood pressure before pregnancy or before the 20th week of gestation, or when hypertension persists for more than 12 weeks postpartum. The *Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure* (Joint National Committee, 2003) has classified blood pressure as follows:

- Normal: systolic less than 120 mm Hg, diastolic less than 80 mm Hg
- Prehypertension: systolic 120 to 139 mm Hg, diastolic 80 to 89 mm Hg
- Mild hypertension: systolic 140 to 159 mm Hg, diastolic 90 to 99 mm Hg
- Severe hypertension: systolic 160 mm Hg or higher, diastolic 100 mm Hg or higher

Chronic hypertension occurs in up to 22% of women of childbearing age, with the prevalence varying according to age, race, and BMI. It complicates at least 5% of pregnancies, with one in four women developing preeclampsia during pregnancy (Czeizel & Bánhidly, 2011). Chronic hypertension is typically seen in older, obese women with glucose intolerance. The most common complication is preeclampsia, which is seen in approximately 25% of women who enter the pregnancy with hypertension (Gilbert, 2011). (See Chapter 19 for more information about preeclampsia.)

## Therapeutic Management

Preconception counseling is important in fostering positive outcomes. Typically, it involves lifestyle changes such as diet, exercise, weight loss, and smoking cessation.

Treatment for women with chronic hypertension focuses on maintaining normal blood pressure, preventing superimposed preeclampsia/eclampsia, and ensuring normal fetal development. Once the woman is pregnant, antihypertensive agents are typically reserved for severe hypertension >160 mm Hg systolic and >100 mm Hg diastolic. Methyldopa (Aldomet) is commonly prescribed because of its safety record during pregnancy. This slow-acting antihypertensive agent helps to improve uterine perfusion. Other antihypertensive agents that can be used include labetalol (Trandate), atenolol (Tenormin), and nifedipine (Procardia) (Gilbert, 2011).

Lifestyle changes are needed and should continue throughout gestation. The woman with chronic

hypertension will be seen more frequently (every 2 weeks until 28 weeks and then weekly until birth) to monitor her blood pressure and to assess for any signs of preeclampsia. At approximately 24 weeks' gestation, the woman will be instructed to document fetal movement. At this same time, serial ultrasounds will be ordered to monitor fetal growth and amniotic fluid volume. Additional tests will be included if the client's status changes.

## Nursing Assessment

Nursing assessment of the woman with chronic hypertension involves a thorough history and physical examination. Review the woman's history closely for risk factors. The pathogenesis of hypertension is multifactorial and includes many modifiable risk factors such as smoking, obesity, caffeine intake, excessive alcohol intake, excessive salt intake, and use of nonsteroidal anti-inflammatory drugs. Also be alert for nonmodifiable risk factors such as increasing age and African American race (Seely & Ecker, 2011). Ask if the woman has received any preconception counseling and what measures have been used to prevent or control hypertension.

Assess the woman's vital signs, in particular her blood pressure. Evaluate her blood pressure in all three positions (sitting, lying, and standing) and note any major differences in the readings. Assess her for orthostatic hypertension when she changes her position from sitting to standing. Document your findings.

Ask the woman if she monitors her blood pressure at home; if so, inquire about the typical readings. Ask the woman if she uses any medications for blood pressure control, including the drug, dosage, and frequency of administration, as well as any side effects. Ask the woman about lifestyle modifications that she has used to address any modifiable risk factors, and their effectiveness.

Hypertension during pregnancy decreases uteroplacental perfusion. Therefore, fetal well-being must be assessed and closely monitored. Anticipate serial ultrasounds to assess fetal growth and amniotic fluid volume. Question the woman about fetal movement and evaluate her report of daily "kick counts." Assess fetal heart rate at every visit.

## Nursing Management

Preconception counseling is the ideal time to discuss lifestyle changes to prevent or control hypertension. One area to cover during this visit would be the Dietary Approaches to Stop Hypertension (DASH) diet, which contains an adequate intake of potassium, magnesium, and calcium. Sodium is usually limited to 2.4 g. Suggest aerobic exercise as tolerated. Encourage smoking cessation and avoidance of alcohol. If the woman is overweight,

encourage her to lose weight before becoming pregnant, not during the pregnancy (Dudek, 2010). Stressing the positive benefits of a healthy lifestyle might help motivate the woman to make the necessary modifications and change unhealthy habits.

Assist the woman in scheduling appointments for antepartum visits every 2 weeks until 28 weeks' gestation and then weekly. Prepare the woman for frequent fetal assessments. Explaining the rationale for the need to monitor fetal growth is important to gain the woman's cooperation. Carefully monitor the woman for signs and symptoms of abruptio placenta (abdominal pain, rigid abdomen, vaginal bleeding), as well as superimposed preeclampsia (elevation in blood pressure, weight gain, edema, proteinuria). Alerting the woman to these risks allows early identification and prompt intervention.

Stress the importance of daily periods of rest (1 hour) in the left lateral recumbent position to maximize placental perfusion. Encourage women with chronic hypertension to use home blood pressure monitoring devices. Urge the woman to report any elevations. As necessary, instruct the woman and her family how to take and record a daily blood pressure, and reinforce the need for her to take her medications as prescribed to control her blood pressure and to ensure the well-being of her unborn child. Praising her for her efforts at each prenatal visit may motivate her to continue the regimen throughout her pregnancy.

The close monitoring of the woman with chronic hypertension continues during labor and birth and during the postpartum period to prevent or identify the onset of preeclampsia. Accurate and frequent blood pressure readings and careful administration of antihypertensive medications, if prescribed, are essential components of care. Stressing the need for continued medical supervision after childbirth is vital to motivate the woman to maintain or initiate lifestyle changes and dietary habits and stay compliant with her medication regimen.

## RESPIRATORY CONDITIONS

During pregnancy, the respiratory system is affected by hormonal changes, mechanical changes, and prior respiratory conditions. These changes can cause a woman with a history of compromised respiration to decompensate during pregnancy. Although upper respiratory infections are typically self-limiting, chronic respiratory conditions, such as asthma or tuberculosis, can have a negative effect on the growing fetus when alterations in oxygenation occur in the mother. The outcome of pregnancy in a woman with a respiratory condition depends on the severity of the oxygen alteration as well as the degree and duration of hypoxia on the fetus.

## Asthma

Worldwide the prevalence of asthma among pregnant women is on the rise, and pregnancy leads to a worsening of asthma for many women (Murphy & Gibson, 2011). Asthma affects approximately 4% to 8% of pregnancies, ranging between 200,000 and 376,000 women annually in the United States. It affects over 20 million Americans and is one of the most common and potentially serious medical conditions to complicate pregnancy (Little, & Sinert, 2012). Maternal asthma is associated with an increased risk of infant death, preeclampsia, intrauterine growth restriction (IUGR), preterm birth, and low birth weight. These risks are linked to the severity of asthma: more severe asthma increases the risk (National Asthma Education and Prevention Program [NAEPP], 2012).

*Remember Rose, the pregnant teenager with asthma in acute distress described at the beginning of the chapter? What therapies might be offered to control her symptoms? Should she be treated differently than someone who is not pregnant? Why or why not?*

## Pathophysiology

Asthma, an allergic-type inflammatory response of the respiratory tract to various stimuli, is also known as reactive airway disease because the bronchioles constrict in response to allergens, irritants, and infections. Asthma is characterized by paroxysmal or persistent symptoms of bronchoconstriction including breathlessness, chest tightness, cough, and sputum production. In addition to bronchoconstriction, inflammation of the airways produces thick mucus that further limits the movement of air and makes breathing difficult.

The normal physiologic changes of pregnancy affect the respiratory system. Although the respiratory rate does not change, hyperventilation increases at term by 48% due to high progesterone levels. Diaphragmatic elevation and a decrease in functional lung residual capacity occur late in pregnancy, which may reduce the woman's ability to inspire deeply to take in more oxygen. Oxygen consumption and the metabolic rate both increase, placing additional stress on the woman's respiratory system (American Academy of Allergy, Asthma, & Immunology [AAAAI], 2012).

Both the woman and her fetus are at risk if asthma is not well managed during pregnancy. When a pregnant woman has trouble breathing, her fetus also has trouble getting the oxygen it needs for adequate growth and development. Severe persistent asthma has been

linked to the development of maternal hypertension, preeclampsia, placenta previa, uterine hemorrhage, and oligohydramnios. Women whose asthma is poorly controlled during pregnancy are at increased risk of preterm birth, low birth weight, and stillbirth (Little, & Sinert, 2012).

The severity of the condition improves in one third of pregnant women, remains unchanged in one third, and worsens in one third (Gilbert, 2011). However, the effect of pregnancy on asthma is unpredictable. The greatest increase in asthma attacks usually occurs between 24 and 36 weeks' gestation; flare-ups are rare during the last 4 weeks of pregnancy and during labor (AAAAI, 2012).

## Therapeutic Management

Asthma should be treated as aggressively in pregnant women as in nonpregnant women because the benefits of averting an asthma attack outweigh the risks of medications. The ultimate goal of asthma therapy is to prevent hypoxic episodes to preserve continuous fetal oxygenation; improved maternal and perinatal outcomes are achieved with optimal control of asthma. One third of women with asthma develop worsening of control during pregnancy, therefore close monitoring and reevaluation are essential. Four important aspects of asthma treatment ensure optimal control: close monitoring, education of clients, avoidance of asthma triggers, and pharmacologic therapy.

Many women with asthma have positive skin tests to allergens, the most common being animal dander, dust mites, cockroach antigens, pollens, and molds. There are nonimmune triggers as well, including strong odors, tobacco smoke, air pollutants, and drugs such as aspirin and beta blockers. For exercise-triggered asthma, the use of a bronchodilator 5 to 60 minutes before exercise may reduce symptoms. Avoidance of these allergens and triggers can significantly reduce the need for medication and the occurrence of exacerbations during and after pregnancy. All women should be strongly encouraged to stop smoking, but especially those with asthma because they are at increased risk for worsening chronic and acute asthma sequelae.

Allergy injections may benefit those with allergies and asthma, called allergic asthma. Also called immunotherapy, allergy shots do not "cure" asthma in the manner in which an injection of, say, antibiotics might cure an infection. Instead, allergy shots work a bit more like a vaccine. Allergy injections for asthma actually contain a very small amount of an allergen (substance causing allergy). Over time, the dosage is increased. Exposure to progressive amounts of the allergen is likely to help the body develop a tolerance to it. If the allergen buildup is effective, the allergic reaction will become much less

severe. Allergy injections can reduce the symptoms of allergies and prevent the development of asthma.

Medical therapy includes a stepwise approach in an attempt to use the least amount of medication necessary to control a woman's asthma and keep her severity in the mild range. Goals of therapy include having normal or near-normal pulmonary function and minimal or no chronic symptoms, exacerbations, or limitations on activities. The final goal is to minimize the adverse effects of treatment.

Inhaled corticosteroids are preferred for the management of all levels of persistent asthma in pregnancy. Corticosteroids are the most effective treatment for the airway inflammation of asthma and reduce the hyperresponsiveness of airways to allergens and triggers.

NAEPP (2012) recommends three specific drugs to be used during pregnancy to control asthma:

- Budesonide (inhaled corticosteroid)
- Albuterol (short-acting beta<sub>2</sub> agonist)
- Salmeterol (long-acting beta<sub>2</sub> agonist)

Oral corticosteroids are not recommended for the treatment of asthma during pregnancy, but they can be used to treat severe asthma attacks during pregnancy (AAAAI, 2012). In addition, two prostaglandins (Hemabate and misoprostol [Cytotec]) used for treating postpartum hemorrhage and cervical ripening are contraindicated for clients with asthma due to the risk of bronchial spasm and bronchoconstriction (King & Brucker, 2011).

## Nursing Assessment

Obtain a thorough history of the disease, including the woman's usual therapy and control measures. Question the woman about asthma triggers and strategies used to reduce exposure to them (Box 20.2). Review the client's medication therapy regimen.

Auscultate the lungs and assess respiratory and heart rates. Include the rate, rhythm, and depth of respirations; skin color; blood pressure and pulse rate; and signs of fatigue. Clients with an acute asthma attack often present with wheezing, chest tightness, tachypnea, nonproductive coughing, shortness of breath, and dyspnea. Lung auscultation findings might include diffuse wheezes and rhonchi, bronchovesicular sounds, and a more prominent expiratory phase of respiration compared to the inspiratory phase (Mattson & Smith, 2011). If the pregnancy is far enough along, the fetal heart rate is measured and routine prenatal assessments (weight, blood pressure, fundal height, urine for protein) are completed.

Laboratory studies usually include a complete blood count with differential (to assess the degree of nonspecific inflammation and identify anemia) and pulmonary function tests (to assess the severity of an attack and to

## BOX 20.2

**COMMON ASTHMA TRIGGERS**

- Smoke and chemical irritants
- Air pollution
- Dust mites
- Animal dander
- Seasonal changes with pollen, molds, and spores
- Upper respiratory infections
- Esophageal reflux
- Medications, such as aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs)
- Exercise
- Cold air
- Emotional stress

provide a baseline to evaluate the client's response to treatment).

## Nursing Management

Nursing management focuses on client education about the condition and the skills necessary to manage it: self-monitoring, correct use of inhalers, identifying and limiting exposure to asthma triggers, and following a long-term plan for managing asthma and for promptly handling signs and symptoms of worsening asthma. Client education fosters adherence to the treatment regimen, thereby promoting an optimal environment for fetal growth and development.

Client education should begin at the first prenatal visit. The importance of optimal asthma control and the risks of poor control for the woman and her fetus should be discussed early in pregnancy. Clients should be taught signs and symptoms, and which should be of concern, as well as who to contact in emergent situations. Women should be observed using their inhalers and correct use reinforced. Frank discussion about the importance of continuing asthma medications and the possible severe consequences for the woman and her fetus with discontinuation is vital.

Ensure that the woman understands drug actions and interactions, the uses and potential abuses of asthma medications, and the signs and symptoms that require medical evaluation. Reviewing potential perinatal

complications with the woman is helpful in motivating her to adhere to the prescribed regimen. At each antepartum visit, reassess the efficacy of the treatment plan to determine whether adjustments are needed.

Taking control of asthma in pregnancy is the responsibility of the client along with her health care team. Providing the client with the knowledge and tools to monitor her condition, control triggers and her environment (Teaching Guidelines 20.2), and use medications to prevent acute exacerbations assist the client in taking control. Facilitating a partnership with the woman will improve perinatal outcomes.

### Teaching Guidelines 20.2

#### TEACHING TO CONTROL ASTHMA LINKED TO ENVIRONMENTAL TRIGGERS

- Remove any carpeting in the house, especially the bedroom, to reduce dust mites.
- Use allergen-proof encasing on the mattress, box spring, and pillows.
- Wash all bedding in hot water.
- Remove dust collectors in house, such as stuffed animals, books, knickknacks.
- Avoid pets in the house to reduce exposure to pet dander.
- Use a high-efficiency particulate air-filtering system in the bedroom.
- Do not smoke, and avoid places where you can be exposed to passive cigarette smoke from others.
- Stay indoors and use air conditioning when the pollen or mold count is high or air quality is poor.
- Wear a covering over your nose and mouth when going outside in the cold weather.
- Avoid exposure to persons with colds, flu, or viruses.

When teaching the pregnant woman with asthma, cover the following topics:

- Signs and symptoms of asthma progression and exacerbation
- Importance and safety of medication to the fetus and to herself
- Warning signs that indicate the need to contact the health care provider
- Potential harm to the fetus and to herself by under-treatment or delay in seeking help
- Prevention and avoidance of known triggers
- Home use of metered-dose inhalers
- Adverse effects of medications

During labor, monitor the client's oxygenation saturation by pulse oximetry and provide pain management through epidural analgesia to reduce stress, which may trigger an acute attack. Continuously monitor the fetus

for distress during labor and assess fetal heart rate patterns for hypoxia. Assess the newborn for signs and symptoms of hypoxia.

Nurses should instruct and strongly urge women to remain on asthma medications during pregnancy because one third of clients have worsening of their asthma, including those women with mild asthma. There are proven negative effects from exacerbations and poor control on pregnancy outcome, whereas there are clear benefits of good control. Client education about the importance of good asthma control is essential for improving pregnancy outcomes.

*Rose, the pregnant teenager described earlier, is concerned about passing her asthma on to her baby. What should the nurse discuss with her? What questions should the nurse ask to help in identifying triggers in Rose's environment to prevent future asthma attacks?*

#### Take Note!

Successful asthma management can reduce adverse perinatal outcomes: preeclampsia, preterm birth, and low birth weight.

## Tuberculosis

Tuberculosis (TB) is known as the great masquerader and manifestation of the disease can be vague and widespread. It is a disease that has been around for years but never seems to go away completely. Globally, TB is second only to HIV/AIDS as a cause of illness and death in adults, accounting for over 9 million cases of active disease and 2 million deaths each year. Someone in the world is newly infected with TB every second. Overall, one third of the world's population is currently infected with TB (World Health Organization [WHO], 2012). Although it is not prevalent in the United States, a resurgence was noted starting in the mid-1980s secondary to the AIDS epidemic and immigration. Left undiagnosed and untreated, each person with active TB will infect on average between 10 and 15 people each year (WHO, 2012). The link between poverty and TB is strong. With the large numbers of immigrants coming to the United States, all nurses must be skilled in screening for and managing this condition.

In many cultures the social consequences associated with the diagnosis of TB fall most heavily on women. Difficulties finding a marriage partner and divorce or abandonment among those already married are significant consequences for women from Pakistan, Vietnam, and India. Fear of social consequences can translate into

delayed or absent health-seeking behavior. In pregnancy, TB that is treated early and adequately has outcomes equivalent to those in nonpregnant women. By contrast, studies have reported a fourfold increase in obstetrical mortality with increased incidence of spontaneous abortion and preeclampsia, and a ninefold increase in preterm labor in cases where TB was diagnosed late (Murthy & Smith, 2010).

A person becomes infected by inhaling the infectious organism *Mycobacterium tuberculosis*, which is carried on droplet nuclei and spread by airborne transmission. The lung is the major site of involvement, but the lymph glands, meninges, bones, joints, and kidneys can become infected. Women can remain asymptomatic for long periods of time as the organism lies dormant. Pregnant women with untreated TB are more likely to have an underweight infant, an infant with a low Apgar score, and perinatal death (Mnyani & McIntyre, 2011). The newborn is at risk of postnatally acquired TB if the mother still has active TB at the time of birth. Therefore, prenatal diagnosis and effective treatment of the mother are essential.

## Therapeutic Management

WHO recommends that the treatment of TB in pregnant women should be the same as that in nonpregnant women, and the rest of the general population the only exception being that streptomycin should be avoided in pregnancy because it is ototoxic to the fetus. The standard treatment is ethambutol, isoniazid, rifampicin, and pyrazinamide for 2 months—the intensive phase—followed by 4 months of isoniazid and rifampicin—the continuation phase (Mnyani & McIntyre, 2011). Medications are the cornerstone of treatment to prevent infection from progressing. The FDA developed five pregnancy categories that rank the risk of teratogenic effects of drugs to be used in drug labeling (see the list earlier in the chapter in the discussion of heart disease). The safety of the first-line drugs for the management of active TB in pregnancy has been established, and therapy improves both maternal and neonatal outcomes.

## Nursing Assessment

Review the woman's history for risk factors such as immunocompromised status, recent immigration status, homelessness or overcrowded living conditions, and injectable drug use. Women emigrating from developing countries such as Latin America, Asia, the Indian subcontinent, Eastern Europe, Russia, China, Mexico, Haiti, and Africa with high rates of TB also are at risk.

At antepartum visits, be alert for clinical manifestations of TB, including fatigue, fever or night sweats,

nonproductive cough, weakness, slow weight loss, anemia, hemoptysis, and anorexia (Nhan-Chang & Jones, 2010). If TB is suspected or the woman is at risk for developing TB, anticipate screening with purified protein derivative (PPD) administered by intradermal injection. If the client has been exposed to TB, a reddened induration will appear within 72 hours. If the test is positive, anticipate a follow-up chest x-ray with lead shielding over the abdomen and sputum cultures to confirm the diagnosis.

## Nursing Management

Compliance with the multidrug therapy is critical to protect the woman and her fetus from progression of TB. Provide education about the disease process, the mode of transmission, prevention, potential complications, and the importance of adhering to the treatment regimen.

Stressing the importance of health promotion activities throughout the pregnancy is important. Some suggestions might include avoiding crowded living conditions, avoiding sick people, maintaining adequate hydration, eating a nutritious, well-balanced diet, keeping all prenatal appointments to evaluate fetal growth and well-being, and getting plenty of fresh air by going outside frequently. Determining the woman's understanding of her condition and treatment plan is important for compliance. A language interpreter may be needed to validate and reinforce her understanding if she does not speak English.

Breast-feeding is not contraindicated during the medication regimen and should in fact be encouraged. Management of the newborn of a mother with TB involves preventing transmission by teaching the parents not to cough, sneeze, or talk directly into the newborn's face. Nurses need to stay current about new therapies and screening techniques to treat this centuries-old disease.

## HEMATOLOGIC CONDITIONS

**Anemia**, a reduction in red blood cell volume, is measured by hematocrit (Hct) or a decrease in the concentration of hemoglobin (Hgb) in the peripheral blood. This results in reduced capacity of the blood to carry oxygen to the vital organs of the mother and fetus. Anemia is a sign of an underlying problem but does not indicate its origin.

### Iron-Deficiency Anemia

Iron-deficiency anemia affects one in four pregnancies and is usually related to an inadequate dietary intake of iron (Curran, 2011). Iron-deficiency anemia accounts for 75% to 95% of the cases of anemia in pregnant women.

A woman who is pregnant often has insufficient iron stores to meet the demands of pregnancy. A recent study found that it was also strongly associated with low socioeconomic status, which affected women's knowledge and health-seeking behaviors. The study concluded that empowering women in terms of education and economic status was the key factor in combating anemia in pregnancy to prevent the vicious cycle of associated problems (Noronha, Bhaduri, Bhat, & Kamath, 2010). The clinical consequences of iron-deficiency anemia include preterm delivery, perinatal mortality, and postpartum depression. Fetal and neonatal consequences include low birth weight and poor mental and psychomotor performance (Gilbert, 2011). With significant maternal iron depletion, the fetus will attempt to store iron, but at the cost to the mother. Anemia at term increases the perinatal risk for both the mother and newborn. The risks of hemorrhage (impaired platelet function) and infection during and after birth also are increased. Clinical symptoms of iron-deficiency anemia include fatigue, headache, restless legs syndrome, and pica eating behaviors.

## Therapeutic Management

The goals of treatment for iron-deficiency anemia in pregnancy are to eliminate symptoms, correct the deficiency, and replenish iron stores. The Centers for Disease Control and Prevention (CDC), Institute of Medicine, and ACOG recommend routine iron supplementation for all pregnant women starting at a low dose of 30 mg/day beginning at the first prenatal visit (Goonewardene, Shehata, & Hamad 2012). Attempting to meet maternal iron requirements solely through diet in the face of diminished iron stores is difficult.

## Nursing Assessment

Review the mother's history for factors that may contribute to the development of iron-deficiency anemia, including poor nutrition, hemolysis, **pica** (consuming nonfood substances), multiple gestation, limited intervals between pregnancies, and blood loss. Assess the woman's dietary intake as well as the quantity and timing of ingestion of substances that interfere with iron absorption, such as tea, coffee, chocolate, and high-fiber foods. Ask the woman if she has fatigue, weakness, malaise, anorexia, or increased susceptibility to infection, such as frequent colds. Inspect the skin and mucous membranes, noting any pallor. Obtain vital signs and report any tachycardia.

Prepare the woman for laboratory testing. Laboratory tests usually reveal low Hgb (<11 g/dL), low Hct (<35%), low serum iron (<30 mcg/dL), microcytic and hypochromic cells, and low serum ferritin (<100 mg/dL).

**Take Note!**

Hemoglobin and hematocrit decrease normally during pregnancy in response to an increase in blood plasma in comparison to red blood cells. This hemodilution can lead to physiologic anemia of pregnancy, which does not indicate a decrease in oxygen-carrying capacity or true anemia.

## Nursing Management

Nursing management of the woman with iron-deficiency anemia focuses on encouraging compliance with drug therapy and providing dietary instruction about the intake of foods high in iron. Although iron constitutes a minimal percentage of the body's total weight, it has several major roles: it assists in the transport of oxygen and carbon dioxide throughout the body, it aids in the production of red blood cells, and it plays a role in the body's immune response.

Stress the importance of taking the prenatal vitamin and iron supplement consistently. Encourage the woman to take the iron supplement with vitamin C-containing fluids such as orange juice, which will promote absorption, rather than milk, which can inhibit iron absorption. Taking iron on an empty stomach improves its absorption, but many women cannot tolerate the gastrointestinal discomfort it causes. In such cases, advise the woman to take it with meals. Instruct the woman about adverse effects, which are predominantly gastrointestinal and include gastric discomfort, nausea, vomiting, anorexia, diarrhea, metallic taste, and constipation. Suggest that the woman take the iron supplement with meals and increase her intake of fiber and fluids to help overcome the most common side effects.

Provide dietary counseling. Recommend foods high in iron, such as dried fruits, whole grains, green leafy vegetables, meats, peanut butter, and iron-fortified cereals (Dudek, 2010). Anticipate the need for a referral to a dietitian. Teaching Guidelines 20.3 highlights instructions for the pregnant woman with iron-deficiency anemia.

### Teaching Guidelines 20.3

#### TEACHING FOR THE WOMAN WITH IRON-DEFICIENCY ANEMIA

- Take your prenatal vitamin daily; if you miss a dose, take it as soon as you remember.
- For best absorption, take iron supplements between meals.
- Avoid taking iron supplements with coffee, tea, chocolate, and high-fiber food.
- Eat foods rich in iron, such as:
  - Meats, green leafy vegetables, legumes, dried fruits, whole grains

- Peanut butter, bean dip, whole-wheat fortified breads and cereals
- For best iron absorption from foods, consume the food along with a food high in vitamin C.
- Increase your exercise, fluids, and high-fiber foods to reduce constipation.
- Plan frequent rest periods during the day.

## Thalassemia

Thalassemia is a group of hereditary anemias in which synthesis of one or both chains of the hemoglobin molecule (alpha and beta) is defective. Inheritance is autosomal recessive. A low Hgb and a microcytic, hypochromic anemia results. The prevalence and severity of thalassemia depend on the woman's racial background: persons of Mediterranean, Asian, Italian, or Greek heritage and African Americans are most frequently affected. Beta-thalassemia is the most common form found in the United States (Curran, 2011).

Thalassemia occurs in two forms: alpha-thalassemia and beta-thalassemia. Alpha-thalassemia (minor), the heterozygous form, results from the inheritance of one abnormal gene from either parent, placing the offspring in a carrier trait state. These women have little or no hematologic disease and are clinically asymptomatic (silent carrier state). Beta-thalassemia (major) is the form involving inheritance of the gene from both parents. Beta-thalassemia major can be very severe. Genetic counseling might be necessary when decisions about childbearing are being made.

Thalassemia minor has little effect on the pregnancy, although the woman will have mild, persistent anemia. This anemia does not respond to iron therapy, and iron supplements should not be prescribed. Women with thalassemia major do not usually become pregnant because of lifelong severe hemolysis, anemia, and premature death (Leung, & Lao, 2012).

Management of thalassemia during pregnancy depends on the severity of the disease. Identification and screening are important to plan care. The woman's ethnic background, medical history, and blood studies are analyzed. If the woman is determined to be a carrier, screening of the father of the child is indicated. Knowledge of the carrier state of each parent provides the genetic counselor with knowledge about the risk that the fetus will be a carrier or will have the disease (Curran, 2011).

Mild anemia may be present, and instructions to rest and avoid infections are helpful. Nurses should provide supportive care and expectant management throughout the pregnancy.

## Sickle Cell Anemia

Sickle cell anemia is an autosomal recessive inherited condition that results from a defective hemoglobin molecule (hemoglobin S). It is found most commonly in African Americans, Southeast Asians, and Middle Eastern populations. Sickle cell disease affects millions of people across the globe. In the United States, approximately 70,000 to 100,000 people have the disease, and 2 million have the sickle cell trait. Sickle cell disease occurs once in every 500 African American births, and once in 36,000 Hispanic American births. One in 12 African Americans has the sickle cell trait. Women with sickle cell disease can have more adverse maternal outcomes such as preeclampsia, eclampsia, preterm labor, placental abruption, intrauterine growth restriction, and low birth weight (Macmullen, & Dulski, 2011). The gene offers protection against malaria, but can be a cause of chronic pain and early death. Life expectancy is 48 years for females (Malowany, & Butany, 2012). People with only one gene for the trait (heterozygous) will have sickle cell trait without obvious symptoms of the disease and with little effect on the pregnancy.

### Pathophysiology

In the human body, the hemoglobin molecule serves as the oxygen-carrying component of the red blood cells. Most people have several types of circulating hemoglobin (HbA and HbA2) that make up the majority of their circulatory system. In sickle cell disease, the abnormal hemoglobin S (HbS) replaces HbA and HbA2. This abnormal hemoglobin (HbS) becomes sickle shaped as a result of any stress or trauma such as infection, fever, acidosis, dehydration, physical exertion, excessive cold exposure, or hypoxia. Significant anemia results.

Sickle cell anemia during pregnancy is associated with more severe anemia and frequent vaso-occlusive crises, with increased maternal and perinatal morbidity and mortality. In pregnant women with sickle cell anemia, complications can occur at any time during gestation, labor and birth, or postpartum. This is believed to be secondary to hormonal modifications, hypercoagulable state, and increased susceptibility to infection. Microvascular sickling in the placental circulation is associated with miscarriages, placental abruption, preeclampsia, preterm labor, intrauterine growth restriction, fetal distress, and low birth weight (Malowany, & Butany, 2012).

### Therapeutic Management

Ideally, women with hemoglobinopathies are screened before conception and are made aware of the risks of sickle cell anemia to themselves and to the fetus. A blood

hemoglobin electrophoresis is done for all women from high-risk ancestry at their first prenatal visit to determine the types and percentages of hemoglobin present. This information should help them in making reproductive decisions.

Treatment depends on the health status of the woman. The effect of sickle cell disease on pregnancy depends on which manifestations the woman is experiencing. For example, sickle cell anemia combined with the increased blood volume in pregnancy increases the risks for heart failure should fluid overload occur in therapy for the anemia (Macmullen & Dulski, 2011). Early and continuous prenatal care is needed to safeguard the fetus/infant from potential complications during the antepartum, intrapartum, and postpartum periods. Toward this end, prenatal visits for the first and second trimester should be scheduled more frequently. During pregnancy, only supportive therapy is used: blood transfusions for severe anemia, analgesics for pain, and antibiotics for infection.

### Nursing Assessment

Assess the woman for signs and symptoms of sickle cell anemia. Ask the woman if she has anorexia, dyspnea, or malaise. Inspect the color of the skin and mucous membranes, noting any pallor. Be alert for indicators of sickle cell crisis, including severe abdominal pain, muscle spasms, leg pains, joint pain, fever, stiff neck, nausea and vomiting, and seizures (Curran, 2011).

### Nursing Management

Clients require emotional support, education, and follow-up care to deal with this chronic condition, which can have a great impact on the woman and her family. Monitor vital signs, fetal heart rate, weight gain, and fetal growth. Assess hydration status at each visit and urge the client to drink 8 to 10 glasses of fluid daily to prevent dehydration. Teach the client about the need to avoid infections (including meticulous handwashing), cigarette smoking, alcohol consumption, and temperature extremes.

Assist the woman in scheduling frequent fetal well-being assessments, such as biophysical profiles, nonstress tests, and contraction stress tests, and monitor laboratory test results for changes. Throughout the antepartal period, be alert for early signs and symptoms of crisis.

During labor, encourage rest and provide pain management. Oxygen supplementation is typically used throughout labor, along with intravenous fluids to maintain hydration. The fetal heart rate is monitored closely. After giving birth, the woman is fitted with antiembolism stockings to prevent blood clot formation. Before discharge from the facility after birth of the newborn, discuss family planning options.

The ability to predict the clinical course of sickle cell anemia during pregnancy is difficult. Outcomes have improved for pregnant women with the disease, and nowadays the majority can achieve a successful live birth. However, pregnancy is associated with an increased incidence of morbidity and mortality. Optimal management during pregnancy should be directed at preventing pain crises, chronic organ damage, and early mortality using a multidisciplinary team approach and prompt, effective, and safe relief of acute pain episodes. Although these measures do not remove the risk of maternal and fetal complications, they are thought to minimize them, promoting a successful pregnancy outcome. As part of the OB health care team, the nurse provides nursing interventions for the labor and postpartum client aimed at pain management, maternal/fetal safety, and client education. The overall objective is a healthy outcome for the childbearing family. The nurse has a vital role in making this happen.

## AUTOIMMUNE DISORDERS

Autoimmune disorders are a group of more than 80 distinct diseases that emerge when the immune system launches an immune response against its own cells and tissues. Two distinct types of autoimmune disease occur:

1. Localized disorders target specific organs such as the thyroid gland in Hashimoto's thyroiditis and Graves' disease.
2. Systemic disorders affect multiple organs. For example, in systemic lupus erythematosus (SLE), the immune system can target the lungs, hearts, joints, kidneys, brain, and red blood cells.

Autoimmune disorders may cause mild insidious symptoms that come and go or debilitating conditions with high mortality.

Women suffer from autoimmune disease more than men. According to the CDC (2011h), autoimmune diseases affect approximately 8% of the population, 78% of whom are women. Autoimmune diseases are the third most common category of disease in the United States after cancer and heart disease; they affect approximately 5% to 8% of the population or 14 to 22 million people (CDC, 2011h). Years ago, the general advice to women with autoimmune diseases, especially SLE, multiple sclerosis, or rheumatoid syndromes, was to avoid pregnancy because there was a high risk of maternal and fetal morbidity and mortality. However, it is now clear that these risks can be reduced in general by avoiding pregnancy when the diseases are active and continuing appropriate medication to reduce the chances of disease flare during pregnancy.

### Systemic Lupus Erythematosus

Lupus disease, also referred to as **systemic lupus erythematosus (SLE)**, is a chronic, relapsing autoimmune

disease of the connective tissues that can affect various organs, such as the skin, joints, kidneys, and serosal membranes. Lupus disease is of unknown etiology, but it is thought to be a failure of the regulatory mechanisms of the autoimmune system. Several triggers that cause the disease to activate include estrogen; cigarette smoking; infections, especially Epstein-Barr virus; physical or psychological stress; exposure to ultraviolet light; and pregnancy. Lupus symptoms may include swollen joints, extreme fatigue, oral ulcers, skin rashes, and sensitivity to sunlight (Madazli, Bulut, Erenel, Gezer, & Guralp, 2010). Lupus is a complex disorder characterized by periods of relative inactivity and periods of disease exacerbation (flare-ups).

The overall incidence of lupus in the United States is 125 per 100,000 people. The peak onset occurs between ages 15 and 45 with over 80% of the cases being diagnosed in women who are in their childbearing years. SLE is more common among those of African American, Afro-Caribbean, Asian, Native American, and Hispanic descent (Schur & Bermas, 2010).

## Pathophysiology

The autoimmune responses in SLE cause the body not to recognize "self" from "nonself," thus allowing antibodies to be formed that attack the body's own cells and proteins. This activity causes suppression of the body's normal immunity and damage to the body tissue. The autoimmune response may initially involve one organ or several. The most common organ systems involved are the cardiovascular, integumentary, musculoskeletal, and nervous systems and the kidneys and lungs. In pregnancy, inflammation of the connective tissue of the deciduas can result in placental implantation problems and poor functioning (Cohen, Berger, Steup-Beekman, Bloemenkamp, & Bajema, 2010).

A pregnancy with lupus is prone to complications, including flares of disease activity during pregnancy or in the postpartum period, preeclampsia, miscarriage, stillbirth, IUGR, and preterm birth. Active lupus nephritis poses the greatest risk. The recognition of a lupus flare during pregnancy may be difficult because the signs and symptoms may mimic those of normal pregnancy (Baer, Witter, & Petri, 2011).

## Therapeutic Management

The focus of therapy is to control disease flare-ups, suppress symptoms, and prevent organ damage. Treatment decisions are based on severity of the condition and organ involvement. Treatment of SLE in pregnancy is generally limited to NSAIDs (e.g., ibuprofen [Advil]), prednisone (Deltasone), and an antimalarial agent, hydroxychloroquine (Plaquenil). During pregnancy in the woman with SLE, the goal is to keep drug therapy to a minimum (King & Brucker, 2011).

## Nursing Assessment

The time at which the nurse comes in contact with the woman in her childbearing life cycle will determine the focus of the assessment. If the woman is considering pregnancy, it is recommended that she postpone conception until the disease has been stable or in remission for 6 months. Active disease at time of conception and history of renal disease increase the likelihood of a poor pregnancy outcome (Gilbert, 2011). In particular, if pregnancy is planned during periods of inactive or stable disease, the result often is giving birth to healthy full-term babies without increased risks of pregnancy complications. Nonetheless, pregnancies in most autoimmune diseases are still classified as high risk because of the potential for major complications. Preconception counseling should include the medical and obstetric risks of spontaneous abortion, stillbirth, fetal death, fetal growth restriction, preeclampsia, preterm labor, and neonatal death and the need for more frequent visits for monitoring her condition (Borchers, Naguwa, Keen, & Gershwin, 2010).

If the woman is already pregnant when the nurse encounters her, the nurse needs to assess for the following:

- Duration and presence of SLE signs and symptoms (fatigue, fever, malaise, polyarthritis, skin rashes, and multiorgan involvement)
- Evidence of anemia, thrombocytopenia, and thrombophilias
- Underlying renal disease (check the urine for protein and specific gravity)
- Signs of flare-ups
- Abnormalities in laboratory tests
- Signs of infection (check at each prenatal visit especially UTIs and URIs since prednisone can mask signs of infection and lower resistance)
- Fetal well-being and growth (check using ultrasound, fundal height measurements, nonstress tests, and biophysical profiles)

## Nursing Management

The nurse should discuss with the woman the importance of having good control over her SLE condition throughout the pregnancy. Discussions should focus on the effects of SLE during the pregnancy and possible risk for exacerbations. Emphasize the importance of frequent prenatal visits to detect early preeclampsia, preterm labor, or infections. Instruction should cover the implications and potential side effects of all drug therapies prescribed. Teach energy conservation techniques to prevent fatigue, signs and symptoms to report (extreme fatigue, edema, confusion, abdominal pain, weight loss, leg pain, anorexia), and the need for frequent and close monitoring for fetal well-being. After childbirth, a discussion of birth control and the effects of the various methods on the disease is essential. Referral to self-help groups and local and national SLE

organizations is important for further education of the woman and her family.

SLE can greatly complicate a pregnancy if close supervision is not maintained. The keys to a successful outcome for the mother and her infant include an accurate assessment of the disease, the various systems involved, and vigilance during the pregnancy for disease progression, effects on the fetus, and development of complications. Nursing care should be directed at early detection of problematic signs and symptoms, education of the mother and family, careful evaluation of the fetal status, and providing support to assist the mother in strengthening her coping strategies.

## Multiple Sclerosis

**Multiple sclerosis (MS)** is a chronic inflammatory, demyelinating autoimmune disorder of the central nervous system. The National Multiple Sclerosis Society (2011) estimates that approximately 400,000 people in the United States have MS. It is more commonly seen in women than in men, and the mean age of onset is 30 years. Globally, approximately 2.1 million are affected. There is no cure for the disease, and the disease usually becomes a chronic condition.

In the early, inflammatory course of MS, autoreactive T cells cross the blood-brain barrier, attacking myelin proteins and leading to inflammation and demyelination. As the inflammatory process continues, repeated injury results of the myelin membrane with progressive neurodegeneration. The pathologic hallmark of MS can be described as multicentric, multiphasic CNS inflammation with resultant demyelination (Desmazieres, Sol-Foulon & Lubetzki 2012).

Uncomplicated MS does not have adverse effects on fertility, labor, or birth. Rates of spontaneous abortion, congenital anomalies, and fetal mortality are no higher among women with MS when compared to women in the general population (Jalkanen, Alanen, & Airas, 2010). There is no indication that women with MS require different care or management during the labor and birth process. Pregnant women with MS tend to have fewer relapses during gestation with a subsequent increase in disease activity in the first 3 months postpartum. Breast-feeding does not seem to have an influence on severity or frequency of exacerbations (Moots, 2010). Breast-feeding should be encouraged as long as the woman is not being treated with disease-modifying agents.

The clinical presentation of MS can be similar to common pregnancy-related symptoms, especially fatigue, weakness, constipation, urinary frequency, balance problems, back pain, and visual changes. The similarity of the symptoms makes it difficult to attribute any symptoms that may develop during an established pregnancy to the disease process. These symptoms should be assessed carefully to assess MS exacerbations (Stuart & Bergstrom, 2011).

The focus of MS therapy is to prevent clinical relapse and postpone neurodegeneration and the subsequent disability. Current medications include anti-inflammatories, immunosuppressants, immunomodulators/biologic agents, and a variety of complementary alternative therapies such as vitamin/mineral supplementation, homeopathy, botanical products, and antioxidants. The complementary or alternative therapies have not been proven to reduce relapse rates or disease progression, but many MS sufferers turn to them (King & Brucker, 2011). Most medications used in MS treatment are not FDA approved during pregnancy, but many have been used and have not shown to have adverse effects.

Nursing care is similar to that outlined under SLE previously. The need for support at this life-changing time is crucial. Continuity of care, access to tailored information when requested by the woman or her family, and having a point of contact are all important aspects of nursing care.

## Rheumatoid Arthritis

**Rheumatoid arthritis (RA)** is characterized by joint inflammation and progressive disability and is one of the most common chronic autoimmune disorders. It predominates in women, commonly affecting women of childbearing age and may complicate pregnancy. RA primarily affects synovial joints and tissues of the hands and feet, but any joint can be involved. Over time, bone and cartilage are damaged by the chronic inflammation process, resulting in joint deformity and loss of function. Progression of the disease and ensuing disability is unpredictable.

Rheumatoid arthritis affects approximately 1% of adults worldwide. It is present in nearly all geographic areas and impacts all ethnic groups. The disease typically presents between 30 and 50 years of age and affects twice as many women as men (Temprano, & Smith, 2012). The course of RA during pregnancy is usually benign. In about three fourths of pregnancies, the symptoms of the disease lessen. In these cases, most women experience relief in the first trimester that continues throughout the pregnancy. For many women with RA, pregnancy can provide a reprieve from long-term joint pain and inflammation, but others will not experience remission and will continue to need medication. RA does not adversely affect pregnancy outcome. With occasional exceptions, RA returns after the third to fourth month postpartum (Mitchell, Kaul, & Clowse, 2010).

Individuals with RA typically present with pain, swelling, and tenderness in joints; decreased mobility; and stiffness after periods of inactivity. Treatment of RA focuses on reducing joint inflammation, managing pain, and preventing joint destruction. The categories of medications used to accomplish this are NSAIDs, glucocorticoids, hydroxychloroquine, methotrexate,

immunomodulators/biologic agents and complementary alternative therapies such as physical therapy, exercise, acupuncture, and joint splinting for pain relief. During pregnancy, medications are limited to hydroxychloroquine, glucocorticoids, and NSAIDs. Methotrexate is a FDA Pregnancy Category X drug and, therefore, is contraindicated during pregnancy (King & Brucker, 2011).

Nursing care should address the teratogenicity and adverse effects of some of the medications used to treat rheumatoid arthritis. Women with RA must be monitored closely following childbirth because most are likely to have arthritis flare-ups during the postpartum period. The general nursing care is similar to that outlined for the low-risk pregnant woman.

Nurses caring for women with any disability (physical or cognitive) in general need to provide level-appropriate education on all reproductive health issues and improved access to health care. The woman's specific disability, her resources, and her approach to pregnancy and childbirth all help shape her experience. The nurse can play a role in making her experience a positive, memorable time in her life. Care for the woman with a disability should be well planned and coordinated by ensuring all documentation of the woman's needs and concerns is readily available to all personnel involved in her care. All members of the health care team should be involved in the plan of care and kept up to date of any changes. It is essential that the nurse facilitate care to ensure continuity of care throughout the woman's pregnancy and childbirth experience (Lawler, 2011).

## INFECTIONS

A wide variety of infections can affect the progression of pregnancy, possibly having a negative impact on the outcome. The effect of the infection depends on the timing and severity of the infection and the body systems involved. Common viral infections include cytomegalovirus, rubella, herpes simplex, hepatitis B, varicella, parvovirus B19, and several sexually transmitted infections (STIs; Table 20.4). Toxoplasmosis and group B streptococcus are common nonviral infections. Only the most common infections will be discussed here.

## Cytomegalovirus

Cytomegalovirus (CMV) is the most common congenital and perinatal viral infection in the world (Fig. 20.4). CMV is the leading cause of congenital infection, with morbidity and mortality at birth and sequelae. Each year approximately 1% to 7% of pregnant women acquire a primary CMV infection (Johnson, Anderson, & Pass, 2012). Of these, about 30% to 40% transmit the infection

**TABLE 20.4** SEXUALLY TRANSMITTED INFECTIONS AFFECTING PREGNANCY

Infection/Organism	Effect on Pregnancy and Fetus/Newborn	Implications
Syphilis ( <i>Treponema pallidum</i> )	Maternal infection increases risk of premature labor and birth. Newborn may be born with congenital syphilis—jaundice, rhinitis, anemia, IUGR, and CNS involvement.	All pregnant women should be screened for this STI and treated with benzathine penicillin G 2.4 million units IM to prevent placental transmission.
Gonorrhea ( <i>Neisseria gonorrhoea</i> )	Majority of women are asymptomatic. It causes ophthalmia neonatorum in the newborn from birth through infected birth canal.	All pregnant women should be screened at first prenatal visit, with repeat screening in the third trimester. All newborns receive mandatory eye prophylaxis with tetracycline or erythromycin within the first hour of life. Mother is treated with ceftriaxone (Rocephin) 125 mg IM in single dose before going home.
Chlamydia ( <i>Chlamydia trachomatis</i> )	Majority of women are asymptomatic. Infection is associated with infertility and ectopic pregnancy, spontaneous abortions, preterm labor, premature rupture of membranes, low birth weight, stillbirth, and neonatal mortality. Infection is transmitted to newborn through vaginal birth. Neonate may develop conjunctivitis or pneumonia.	All pregnant women should be screened at first prenatal visit and treated with erythromycin.
Human papillomavirus (HPV)	Infection causes warts in the anogenital area, known as condylomata acuminata. These warts may grow large enough to block a vaginal birth. Fetal exposure to HPV during birth is associated with laryngeal papillomas.	Warts are treated with trichloroacetic acid, liquid nitrogen, or laser therapy under colposcopy. Two HPV vaccines have been FDA approved (Gardasil and Cervarix) against the viral types most likely to cause cervical cancer (types 16 and 18) and genital warts (types 6 and 11) has been licensed in the United States for girls and women 9 to 26 years old. The vaccines are 95% to 100% effective. The vaccines are now recommended for young boys also.
Trichomonas ( <i>Trichomonas vaginalis</i> )	Infection produces itching and burning, dysuria, strawberry patches on cervix, and vaginal discharge. Infection is associated with premature rupture of membranes and preterm birth.	Treatment is with a single 2-g dose of metronidazole (Flagyl).

Adapted from Centers for Disease Control and prevention [CDC]. (2012a). *Sexually transmitted diseases*. Retrieved from <http://www.cdc.gov/std>; and King, T. L., & Brucker, M. C. (2011). *Pharmacology for women's health*. Sudbury, MA: Jones & Bartlett.

to their fetuses. The risk of serious fetal injury is greatest when maternal infection develops in the first trimester or early in the second trimester. Between 10% and 15% of congenitally infected infants are acutely symptomatic at birth and most of the survivors have serious long-term complications (Lazzarotto, Guerra, Gabrielli,

Lanari, & Landini, 2011). It is a leading cause of hearing loss and intellectual disability in the United States. As a result of its substantial disease burden, congenital CMV is associated with an estimated \$1 billion to \$2 billion in direct economic costs each year. However, there has been limited progress in developing interventions to

**FIGURE 20.4** Clinical appearance of infant with congenital CMV with stigmata of disease, including petechial rash, microcephaly, jaundice, and abnormal posture of upper extremities secondary to CNS damage.

prevent or treat CMV infection (Johnson, Anderson, & Pass, 2012). Pregnant women acquire active disease primarily from sexual contact, blood transfusions, kissing, and contact with children in daycare centers. It can also be spread through vertical transmission from mother to child in utero (causing congenital CMV), during birth, or through breast-feeding. The virus can be found in virtually all body fluids. Prevalence rates in women in the United States range from 50% to 85% (Hoerst & Samson, 2012). In the United States, approximately 1 in 60 people undergo seroconversion each year. Although prevalent in the U.S. population, CMV is not easily transmitted from host to recipient. The incidence of primary CMV infection in pregnant women in the United States ranges from 1% to 3% (Hoerst & Samson, 2012). CMV infection during pregnancy may result in abortion, stillbirth, low birth weight, IUGR, microcephaly, deafness, blindness, intellectual disability, jaundice, or congenital or neonatal infection. The first or primary infection, if it occurs during pregnancy, is the most dangerous to the fetus: the fetus has a 30% to 40% chance of being infected.

There are three time periods during which mother-to-child transmission can occur: in utero, during birth, and after birth. However, permanent disability only occurs in association with in utero infection. Such disability can result from maternal infection during any point in the pregnancy, but more severe disabilities are usually associated with maternal infection during the first trimester.

Most women are asymptomatic and don't know they have been exposed to CMV. Symptoms of CMV in the fetus and newborn, known as cytomegalovirus inclusion disease, include hepatomegaly, thrombocytopenia, IUGR, jaundice, microcephaly, hearing loss, chorioretinitis, and intellectual disability (Hoerst & Samson, 2012). Prenatal screening for CMV infection is not routinely performed. Since there is no therapy to prevent or treat CMV

infections, nurses are responsible for educating and supporting childbearing-age women at risk for CMV infection. Stressing the importance of good handwashing and the use of sound hygiene practices can help to reduce transmission of the virus. A few specific hygiene guidelines for pregnant women include the following:

- Wash hands frequently with soap and water, especially after diaper changes, feeding, wiping nose or drool, and handling children's toys.
- Do not share cups, plates, utensils, food, or toothbrushes.
- Do not share towels or washcloths.
- Do not put a child's pacifier in your mouth.
- Clean toys, countertops, and other surfaces that come in contact with children's urine or saliva.

## Rubella

Rubella, commonly called German measles, is spread by droplets or through direct contact with a contaminated object. The risk of a pregnant woman transmitting this virus through the placenta to her fetus increases with earlier exposure to the virus. When infection occurs within the first month after conception, 50% of fetuses show signs of infection; in the second month following conception, 25% of fetuses will be infected; and in the third month, 10% of fetuses will be affected (White, Boldt, Holditch, Poland, & Jacobson, 2012).

Preconception care has been defined as a set of interventions designed to identify and modify risks to a woman's health or pregnancy outcome through prevention and management. This care should be provided any time any health care provider sees a reproductive age woman. Personal and family history, physical exam, laboratory screening, reproductive plan, nutrition, supplements, weight, exercise, vaccinations, and injury prevention should be reviewed in all women. Folic acid 400 micrograms per day, as well as proper diet and exercise, should be encouraged. Women should receive the influenza vaccine if planning pregnancy during flu season; the rubella and varicella vaccines if there is no evidence of immunity to these viruses; and tetanus/diphtheria/pertussis if lacking adult vaccination (Berghella, Buchanan, Pereira, & Baxter, 2010).

Education for primary prevention is key. Ideally, all women have been vaccinated and have adequate immunity against rubella. However, all women are still screened at their first prenatal visit to determine their status. A rubella antibody titer of 1:8 or greater proves evidence of immunity. Women who are not immune should be vaccinated during the immediate postpartum period so they will be immune before becoming pregnant again (CDC, 2011c). Nurses need to check the rubella immune status of all new mothers and should make sure all mothers with a titer of less than 1:8 are immunized prior to discharge after birth of the newborn.

## Herpes Simplex Virus

Approximately 50 million people are infected with genital herpes in the United States, and 1.5 million new cases are diagnosed annually, including 1,500 newborns (Roett, Mayor, Uduhiri 2012). Despite strategies designed to prevent perinatal transmission, the number of cases of newborn herpes simplex virus (HSV) infection continues to rise, mirroring the rising prevalence of genital herpes infection in women of childbearing age (Fig. 20.5) (Urah, 2011).

HSV is a DNA virus with two subtypes: HSV-1 and HSV-2. HSV-1 infections were traditionally associated with oral lesions (fever blisters), whereas HSV-2 infections occurred in the genital region. Currently, either type can be found in either location (Urah, 2011).

Infection occurs by direct contact of the skin or mucous membranes with an active lesion through such activities as kissing, sexual (vaginal, oral, anal) contact, or routine skin-to-skin contact. HSV is associated with infections of the genital tract that when acquired during pregnancy can result in severe systemic symptoms in the mother and significant morbidity and mortality in the newborn. In addition, it may cause spontaneous abortion, birth anomalies, IUGR, or preterm labor. A 50% mortality rate may occur if the neonatal exposure is with an active primary infection (Mattson & Smith, 2011). Once the virus enters the body, it never leaves.

Infants born to mothers with a primary HSV infection have a 30% to 50% risk of acquiring the infection via perinatal transmission near or during birth. Recurrent genital herpes simplex infections carry a 1% to 3% risk of neonatal infection if the recurrence occurs around the time of vaginal birth (March of Dimes, 2011b). About one in four pregnant women is infected with genital herpes, although most do not know it. Fortunately, only a small

number pass the infection on to their newborns (March of Dimes, 2011b).

The greatest risk of transmission is when the mother develops a primary infection near term and it is not recognized. Most neonatal infections are acquired at or around the time of birth through either ascending infection after ruptured membranes or contact with the virus at the time of birth. The method and timing of birth in a woman with genital herpes are controversial. The CDC (2012b) recommends that in the absence of active lesions, a vaginal birth is acceptable, but if the woman has active herpetic lesions near or at term, a cesarean birth should be planned. All invasive procedures that might cause a break in the infant's skin should be avoided, such as artificial rupture of membranes, fetal scalp electrode, or forceps and vacuum extraction (Gilbert, 2011).

Management for the woman with genital herpes during pregnancy involves caring for her as well as reducing the risk of newborn herpes. No therapy can eradicate HSV, and this chronic infection is noted for its frequent asymptomatic viral shedding. Because the majority of newborn herpes cases result from perinatal transmission of the virus during vaginal birth, and because transmission can result in severe neurologic impairment or death, treatment of the mother with an antiviral agent such as acyclovir (Zovirax) must be started as soon as the culture comes back positive. Since the introduction of acyclovir, newer second-generation antivirals have been introduced (e.g., valacyclovir [Valtrex] and famciclovir [Famvir]) and are available (King & Brucker, 2011). Universal screening for herpes is not economically sound, so nurses need to remain knowledgeable about current practice to provide accurate and sensitive care to all women.

## Hepatitis B Virus

Hepatitis B virus (HBV) is one of the most prevalent chronic diseases in the world. It has infected approximately 2 billion people worldwide, of whom more than 350 million are chronically infected. Life-threatening liver disease (cirrhosis, liver failure, and hepatocellular carcinoma) occurs in as many as 40% of people with hepatitis B. HBV infection causes about 5,000 deaths annually in the United States (Tran, 2012). HBV can be transmitted through contaminated blood, illicit drug use, and sexual contact. The virus is 100 times more infectious than HIV and, unlike HIV, it can live outside the body in dried blood for more than a week (Hoerst & Samson, 2012).

Sexual transmission accounts for most adult HBV infections in the United States. Acutely infected women develop hepatitis with anorexia, nausea, vomiting, fever, abdominal pain, and jaundice. In women with acute hepatitis B, vertical transmission occurs in approximately

**FIGURE 20.5** Newborn with disseminated herpes simplex virus infection. Note the healing ulcerations on the abdomen of the infant. From Sweet RL, Gibbs RS. *Atlas of Infectious Diseases of the Female Genital Tract*. Philadelphia, PA: Lippincott Williams & Wilkins, 2005.

10% of newborns when infection occurs in the first trimester and in 80% to 90% of newborns when acute infection occurs in the third trimester. Without intervention, 70% to 90% of infants born to women who are positive for hepatitis B will have chronic hepatitis B by 6 months of age (Tran, 2012).

In addition, hepatitis B infection during pregnancy is associated with an increased risk of preterm birth, fetal distress during labor, meconium peritonitis, low birth weight, and neonatal death. Newborns infected with HBV are likely to become chronic carriers of the virus, becoming reservoirs for continued infection in the population (CDC, 2011d). The fetus is at particular risk during birth because of the possible contact with contaminated blood at this time.

The CDC (2011d) recommends that all pregnant women should be tested for hepatitis B surface antigen (HBsAg) regardless of previous HBV vaccine or screening. Infants born to HBsAg-positive mothers should receive single-antigen HBV vaccine and hepatitis B immunoglobulin (HBIG) within 12 hours after birth. Completion of the vaccine schedule is recommended by HBV vaccination at 1 and 6 months (CDC, 2011d).

## Nursing Assessment

Review the woman's history for factors placing her at high risk:

- History of sexually transmitted infections
- Household contacts with HBV-infected persons
- Employment as a health care worker
- Abuse of intravenous drugs
- Sex worker (prostitute)
- Foreign born
- Multiple sexual partners
- Chinese, Southeast Asian, or African heritage
- Sexual partners who are HBV infected (CDC, 2011d)

At the first prenatal visit, all pregnant women should be screened for HbsAg via blood studies. Expect to repeat this screening later in pregnancy for women in high-risk groups (Hoerst & Samson, 2012).

## Nursing Management

If a woman tests positive for HBV, expect to administer HBV immune globulin (HBIG, Hep-B-Gammagee). The newborn will also receive HBV vaccine (Recombivax-HB, Engerix-B) within 12 hours of birth. The second and third doses of the vaccine are given at 1 and 6 months of age (CDC, 2011d). The CDC recommends routine vaccination of all newborns.

Women who are HbsAg negative may be vaccinated safely during pregnancy. No current research supports the use of surgical births to reduce vertical transmission

of HBV. Breast-feeding by mothers with chronic HBV infection does not increase the risk of viral transmission to their newborns. It is not a contraindication to breast-feeding (Jonas, 2010).

Client education related to prevention of HBV is essential. Teach the woman about safer sex practices, good handwashing techniques, and the use of standard precautions (Teaching Guidelines 20.4). Protection can be afforded with the highly effective hepatitis B vaccine.

### Teaching Guidelines 20.4

#### TEACHING TO PREVENT HEPATITIS B VIRUS

- Abstain from alcohol.
- Avoid intravenous drug exposure or sharing of needles.
- Encourage all household contacts and sexual partners to be vaccinated.
- Receive immediate treatment for any STI.
- Know that your newborn will receive the hepatitis B vaccine soon after birth.
- Use good handwashing techniques at all times.
- Avoid contact with blood or body fluids.
- Use barrier methods such as condoms during sexual intercourse.
- Avoid sharing any personal items, such as razors, toothbrushes, or eating utensils.

Permanent remission of the disease even with treatment rarely occurs. Therefore, therapy is directed at long-term suppression of viral replication and prevention of end-stage liver disease. Urge the woman to consume a high-protein diet and avoid fatigue. A healthy lifestyle can help delay disease progression. Initiate an open discussion about the modes of transmission and use of condoms to prevent spread.

## Varicella Zoster Virus

Varicella zoster virus (VZV), a member of the herpesvirus family, is the virus that causes both varicella (chickenpox) and herpes zoster (shingles). Pregnant women are at risk for developing varicella when they come in close contact with children who have active infection. Maternal varicella can be transmitted to the fetus through the placenta, leading to congenital varicella syndrome, if the mother is infected during the first half of pregnancy, via an ascending infection during birth, or by direct contact with infectious lesions, leading to infection after birth. Varicella occurs in approximately 1 to 7 of 10,000 pregnancies (Anderson, 2011).

Congenital varicella syndrome can occur in newborns of mothers infected during early pregnancy. The

vertical transmission rate is estimated to be between 2% and 10%. It is characterized by low birth weight, skin lesions in a dermatomal distribution, spontaneous abortion, chorioretinitis, cataracts, cutaneous scarring, limb hypoplasia, microcephaly, ocular abnormalities, intellectual disability, and early death (Marino et al., 2011).

Preconception counseling is important for preventing this condition. A major component of counseling involves determining the woman's varicella immunity. The vaccine is administered if needed. Varicella vaccine is a live attenuated viral vaccine. It should be administered to all adolescents and adults 13 years of age and older who do not have evidence of varicella immunity (King & Brucker, 2011). Provide education to women who work in occupations that increase the risk of exposure to the virus, such as daycare workers, teachers of young children, and staff caring for children in institutional settings.

Varicella during pregnancy can be associated with severe illnesses for both the mother and her newborn. If contracted in the first half of pregnancy, some pregnant women are at risk for developing varicella pneumonia, which may put them at risk of life-threatening ventilatory compromise and death. Risk of varicella pneumonia appears to increase during pregnancy (Lamont et al., 2011). If the mother develops varicella rashes close to her due date, generalized neonatal varicella leading to death in about 20% of cases can be expected (Anderson, 2011). Maternal infection is preventable by preconception vaccination.

## Parvovirus B19

Parvovirus B19 infection occurs worldwide and is extremely common. The incidence of acute B19 infection in pregnancy is about 3%. Approximately 30% to 50% of pregnant women are not immune, and vertical transmission is common following maternal infection in pregnancy. Fetal infection may be associated with a normal outcome, but fetal death may also occur without ultrasound evidence of infectious sequelae (Dijkmans, de Jong, Dijkmans, Lopriore et al., 2012). Parvovirus B19 is a common, self-limiting benign childhood virus that causes erythema infectiosum, also known as fifth disease (referring to its "fifth place" in a list of common childhood infections). Approximately 65% of women of reproductive age have developed immunity to parvovirus B19 (Mattson & Smith, 2011).

## Pathophysiology

The infection is spread transplacentally, by the oropharyngeal route in casual contact, and through infected blood. Infection of the fetus occurs through transplacental passage of the virus. Acute infection in pregnancy

can cause B19 infection in the fetus, leading to nonimmune fetal hydrops secondary to severe anemia or fetal loss, depending on the gestational age at the time of infection. The risk to the fetus is greatest when the woman is exposed and infected within the first 20 weeks of gestation. In addition to hydrops, other fetal effects of parvovirus include spontaneous abortion, congenital anomalies (CNS, craniofacial, and eye), and long-term effects such as hepatic insufficiency, myocarditis, and learning disabilities (Marino et al., 2011). Fetal infection with B19V is also associated with intrauterine fetal death, nonimmune hydrops fetalis, thrombocytopenia, myocarditis, and neurologic manifestations. Fetal infection can also remain clinically unrecognized (de Jong, Walther, Kroes, & Oepkes, 2011).

## Therapeutic Management

Generally, a diagnosis of parvovirus is based on clinical symptoms and serologic antibody testing for parvovirus immunoglobulin G (IgG) and parvovirus immunoglobulin M (IgM). Parvovirus B19 infection is followed by life-long immunity, which is shown by positive serum B19 IgG. Pregnant women who have been exposed to or who develop symptoms of parvovirus B19 require assessment to determine whether they are susceptible to infection (nonimmune). If the woman is immune, she can be reassured that she will not develop infection and that the virus will not adversely affect her pregnancy. If she is nonimmune, then referral to a perinatologist is recommended and counseling regarding the risks of fetal transmission, fetal loss, and hydrops is necessary. Knowledge of how best to manage this infection during pregnancy lags behind our understanding of the potential adverse consequences.

Intrauterine B19 infection is a cause of fetal anemia, hydrops, and demise, and perhaps also of congenital anomalies. The best strategy for surveillance of the infected pregnant woman is serial ultrasounds for detection of hydropic changes and fetal anemia, and treatment for severe fetal anemia. Serial ultrasounds are advocated because the rates of fetal death and complications peak 4 to 6 weeks after exposure, but they can occur as late as 3 months following onset of symptoms. The infected newborn is assessed for any anomaly and followed for up to 6 years to identify any sequelae (Cennimo & Dieudonne, 2011).

## Nursing Assessment

Review the mother's history for any risk factors. Schoolteachers, daycare workers, and women living with school-aged children are at highest risk for being seropositive for parvovirus B19, especially if a recent outbreak has occurred in those settings. Also assess the

woman for specific signs and symptoms. The characteristic rash starts on the face with a “slapped-cheeks” appearance and is followed by a generalized maculopapular rash. Fever, arthralgia, and generalized malaise are usually present in the mother. Prepare the mother for antibody testing.

## Nursing Management

Prevention is the best strategy. Stress the need for hand-washing after handling children; cleaning toys and surfaces that children have been in contact with; and avoiding the sharing of food and drinks. Screening for parvovirus B19 during early pregnancy may help in early diagnosis, but the cost effectiveness of a national screening program has not been accepted to date. The nurse can provide information regarding risk factors and potential complications if exposed and support the parent’s decision.

### Group B Streptococcus

Group B streptococcus (GBS) is a naturally occurring bacterium found in approximately 50% of healthy adults. Women who test positive for the GBS bacteria are considered carriers. Carrier status is transient and doesn’t indicate illness. Approximately 25% of pregnant women carry GBS in the rectum or vagina, thus introducing the risk of colonization of the fetus during birth. GBS affects about 1 in every 2,000 newborns in the United States (March of Dimes, 2011c). Approximately 1 out of every 100 to 200 newborns born to mothers who carry GBS will develop signs and symptoms of GBS disease. Although GBS is rarely serious in adults, it can be life threatening to newborns. GBS is the most common cause of sepsis and meningitis in newborns and is a frequent cause of newborn pneumonia (Yun & Humza, 2011). Newborns with early-onset (within a week after birth) GBS infections may have pneumonia or sepsis, whereas late-onset (after the first week) infections often manifest with meningitis (CDC, 2011c).

Genital tract colonization poses the most serious threat to the newborn because of exposure during birth and to the mother because of ascending infection after the membranes rupture. GBS colonization in the mother is thought to cause chorioamnionitis, endometritis, and postpartum wound infection.

## Therapeutic Management

Antibiotic therapy usually is effective in treating women with GBS infections of the urinary tract or uterus, or chorioamnionitis without any sequelae. According to the 2012c CDC guidelines, all pregnant women should be screened for GBS at 35 to 37 weeks’ gestation and treated. Vaginal

and rectal specimens are cultured for the presence of the bacterium. Women with positive cultures are treated with a penicillin-based anti-infective agent and also during labor.

Penicillin G is the treatment of choice for GBS infection because of its narrow spectrum. Alternative antibiotics can be prescribed for clients with a penicillin allergy. The drug is usually administered intravenously at least 4 hours before birth so that it can reach adequate levels in the serum and amniotic fluid to reduce the risk of newborn colonization. Close monitoring is required during the administration of intravenous antibiotics because severe allergic reactions can occur rapidly.

## Nursing Assessment

Review the woman’s prenatal history, asking about any previous infection. Determine if the woman’s membranes have ruptured and the time of rupture. Rupture of amniotic membranes greater than 18 hours increases the risk for infection. Monitor the mother’s vital signs, reporting any maternal fever greater than 100.4° F (38° C). Assess the woman for other risk factors for perinatal transmission of GBS, including previous colonization with GBS, low socioeconomic status, African American race, age less than 20 years, positive colonization at 35 to 37 weeks’ gestation, GBS in urine sample, previous birth of GBS-positive newborn, preterm birth, and use of invasive obstetric procedures (March of Dimes, 2011c). Document this information to help prevent vertical transmission to the newborn.

Many women with GBS infection are asymptomatic, but they may have urinary tract infections, uterine infections, and chorioamnionitis.

## Nursing Management

Nurses play major roles as educators and advocates for all women and newborns to reduce the incidence of GBS infections. Ensure that pregnant women between 35 and 37 weeks’ gestation are screened for GBS infection during a prenatal visit. Record the results and notify the birth attendant if the woman has tested positive for GBS. During labor, be prepared to administer intravenous antibiotics to all women who are GBS positive.

### Toxoplasmosis

Toxoplasmosis is a relatively widespread parasitic infection caused by a one-celled organism, *Toxoplasma gondii*. When a pregnant woman is exposed to this protozoan, the infection can pose serious risks to her fetus. Between 1 in 1,000 and 8,000 newborns are born infected with toxoplasmosis in the United States (Hokelek, 2011). It is transferred by hand to mouth after touching cat feces while changing the cat litter box or through gardening in

contaminated soil. Consuming undercooked meat, such as pork, lamb, or venison, can also transmit this organism.

A pregnant woman who contracts toxoplasmosis for the first time has an approximately 40% chance of passing the infection to her fetus (March of Dimes, 2011h). Although the woman typically remains asymptomatic, transmission to her fetus can occur throughout pregnancy. A fetus that contracts congenital toxoplasmosis typically has a low birth weight, enlarged liver and spleen, chorioretinitis, jaundice, IUGR, hydrocephalus, microcephaly, neurologic damage, and anemia. Severity varies with gestational age; usually, the earlier the infection, the more severe the effects (Kuehn, 2012).

Treatment of the woman during pregnancy to reduce the risk of congenital infection is a combination of pyrimethamine and sulfadiazine. Treatment with sulfonamides during pregnancy has been shown to reduce the risk of congenital infection.

Prevention is the key to managing this infection. Nurses play a key role in educating the woman about measures to prevent toxoplasmosis (Teaching Guidelines 20.5).

### Teaching Guidelines 20.5

#### TEACHING TO PREVENT TOXOPLASMOSES

- Avoid eating raw or undercooked meat, especially lamb or pork. Cook all meat to an internal temperature of 160° F (71° C) throughout.
- Clean cutting boards, work surfaces, and utensils with hot soapy water after contact with raw meat or unwashed fruits and vegetables.
- Peel or thoroughly wash all raw fruits and vegetables before eating them.
- Wash hands thoroughly with warm water and soap after handling raw meat.
- Avoid feeding the cat raw or undercooked meats.
- Avoid emptying or cleaning the cat's litter box. Have someone else do it daily.
- Keep the cat indoors to prevent it from hunting and eating birds or rodents.
- Avoid uncooked eggs and unpasteurized milk.
- Wear gardening gloves when in contact with outdoor soil.
- Avoid contact with children's sandboxes, because cats can use them as litter boxes.

## Women Who Are HIV Positive

**Human immunodeficiency virus (HIV)** is a retrovirus that is transmitted by blood and body fluids. The number of people living with HIV infection in 2010 was estimated

at nearly 50 million, including approximately 20 million women of childbearing age and 2.5 million children, most of whom acquired HIV from mother-to-child transmission. According to the most recent incidence estimates, approximately 56,000 persons have been infected with HIV annually during the past decade (CDC, 2011f).

Despite the revolutionary strides that have been made in treatment and detection and recent clinical advances and cautious optimism associated with combination therapies and vaccines, the number of individuals who are HIV positive continues to climb worldwide. Intensive efforts notwithstanding, no real “cure” can be seen on the horizon (Bennett, & Gilroy, 2012). Also, despite dramatic reductions in perinatal transmission of HIV in the United States, barriers to prevention still exist and perinatal HIV infections continue.

Historically, HIV/AIDS was associated with the male homosexual community and intravenous drug users, but currently the prevalence of HIV/AIDS is now increasing more rapidly among women than men. Women are the fastest-growing segment of persons becoming infected with HIV; transmission in women occurs most frequently from sexual contact (64%) and from intravenous drug use (33%) (CDC, 2011f). Most women, a large number of whom are mothers, have acquired the disease through heterosexual contact. The risk of acquiring HIV through heterosexual contact is greater for women due to exposure to the higher viral concentration in semen. In addition, sexual intercourse may cause breaks in the vaginal lining, increasing the chances that the virus will enter the woman's body. Fifty percent of all HIV/AIDS cases worldwide occur in women. AIDS is the third leading cause of death among all U.S. women aged 25 to 44 years and the leading cause of death among African American women in this age group (CDC, 2011f).

## Pathophysiology

The three recognized modes of HIV transmission are unprotected sexual intercourse with an infected partner, contact with infected blood or blood products, and perinatal transmission.

### Take Note!

HIV is not transmitted by doorknobs, faucets, toilets, dirty dishes, mosquitoes, wet towels, coughing or sneezing, shaking hands, or being hugged or by any other indirect method.

The virus attacks the T4 cells, decreases the CD4 cell count, and disables the immune system. The HIV condition can progress to a severe immunosuppressed state termed **acquired immunodeficiency syndrome (AIDS)**. AIDS is a progressive, debilitating disease that suppresses cellular immunity, predisposing the infected

person to opportunistic infections and malignancies. The CDC defines AIDS as an HIV-infected person with a specific opportunistic infection or a CD4 count of less than 200. Eventually, death occurs. The time from infection with HIV to development of AIDS is a median of 11 years but varies depending on whether the client is taking current antiretroviral therapy (Johnsen, 2012). Research indicates that pregnancy does not accelerate the progression of HIV to AIDS or death (Anderson 2012).

Once infected with HIV, the woman develops antibodies that can be detected with the enzyme-linked immunosorbent assay (ELISA) and confirmed with the Western blot test. Antibodies develop within 6 to 12 weeks after exposure, although this latent period is much longer in some women. Table 20.5 highlights the four stages of HIV infection according to the CDC (2011f).

## Impact of HIV on Pregnancy

When a woman who is infected with HIV becomes pregnant, the risks to herself, her fetus, and the newborn are great. The risks are compounded by problems such as drug abuse, lack of access to prenatal care, poverty, poor nutrition, and high-risk behaviors such as unsafe sex practices and multiple sex partners, which can predispose the woman to additional STIs such as herpes, syphilis, or human papillomavirus (HPV). Additional risk factors to assess for include women who exchange sex for money or drugs or have sex partners who do; a woman whose past or present sex partners were HIV infected; and women who had a blood transfusion between 1978 and 1985. Early identification of

maternal HIV seropositivity allows early antiretroviral treatment to prevent mother-to-child transmission, allows a provider to avoid obstetric practices that may increase the risk for transmission, and allows an opportunity to counsel the mother against breast-feeding (also known to increase the risk for transmission) (U.S. Preventive Services Task Force [USPSTF], 2011). Subsequently, pregnant women who are HIV positive are at risk for preterm delivery, premature rupture of membranes, intrapartum or postpartum hemorrhage, postpartum infection, poor wound healing, and genitourinary tract infections (CDC, 2011f).

Perinatal transmission of HIV (from the mother to the fetus or child) also can occur. However, such cases have decreased in the past several years in the United States, primarily due to the use of zidovudine (ZDV) therapy in pregnant women infected with HIV. This has not been the case in poor countries without similar resources. The Joint United Nations programs on HIV/AIDS (UNAIDS) estimates that over 700,000 new infections due to mother-to-child transmission occur annually. This number is expected to increase rapidly as the prevalence rises in Southeast Asia (Johnsen, 2012). Perinatal transmission rates are as high as 35% when there is no intervention (antiretroviral therapy) and below 2% when antiretroviral treatment and appropriate care are available. A recent Cochran meta-analysis review found that ZDV, nevirapine, and birth by elective cesarean section appear to be effective in decreasing the risk of mother-to-child transmission of HIV infection (Brocklehurst, 2011).

African American and Hispanic women make up 80% of HIV/AIDS cases among women and according to

**TABLE 20.5** STAGES OF HIV INFECTION OUTLINED BY THE CDC

Stages	Description	Clinical Picture
I	Acute infection	Early stage with pervasive viral production Flu-like symptoms 2–4 wks after exposure Signs and symptoms: weight loss, low-grade fever, fatigue, sore throat, night sweats, and myalgia
II	Asymptomatic infection	Viral replication continues within lymphatics Usually free of symptoms; lymphadenopathy
III	Persistent generalized lymphadenopathy	Possibly remaining in this stage for years; AIDS develops in most within 7–10 yr Opportunistic infections occur
IV	End-stage disease (AIDS)	Severe immune deficiency High viral load and low CD4 counts Signs and symptoms: bacterial, viral, or fungal opportunistic infections, fever, wasting syndrome, fatigue, neoplasms, and cognitive changes

Adapted from Centers for Disease Control and Prevention. (2011a). *Basic information about HIV and AIDS*. Retrieved from <http://www.cdc.gov/hiv/topics/basic/index.htm>.

CDC data (2012b), at the end of 2009, 86% of prenatally infected children were African American or Hispanic. Lack of timely HIV testing during pregnancy is a major contributor to this outcome. Interventions are needed that will address knowledge barriers to HIV testing among African American and Hispanic women. Research has found that women who have information about methods to prevent perinatal HIV transmission and the importance of testing for the baby's or mother's health are more likely to be HIV tested. Media campaigns addressing the benefits of HIV testing may be a significant intervention. Media campaigns are not only successful in promoting HIV testing but, in populations with high HIV prevalence, they also are cost effective (Arya, Levison, & Giordano, 2010).

With perinatal transmission, approximately 25% to 50% of children manifest AIDS within the first year of life, and about 80% have clinical symptoms of the disease within 3 to 5 years (Johnsen, 2012). Breast-feeding is a major contributing factor for mother-to-child transmission, and the infected mother must be informed about this (March of Dimes, 2011d). The U.S. Public Health Service recommends that women who are HIV positive should avoid breast-feeding to prevent HIV transmission to the newborn. Given the devastating effects of HIV infection on children, preventing its transmission is critical (Bennett, & Gilroy, 2012).

In addition to perinatal transmission, the fetus and newborn also are at risk for prematurity, IUGR, low birth weight, and infection. Prompt treatment with antiretroviral medications for the infant with an HIV infection may slow the progression of the disease.

## Therapeutic Management

Women who are seropositive for HIV require counseling about the risk of perinatal transmission and the potential for obstetric complications. The risk of perinatal transmission directly correlates with the viral load (Johnsen, 2012). A discussion of the options on continuing the pregnancy, medication therapy, risks, perinatal outcomes, and treatment is warranted. Women who elect to continue with the pregnancy should be treated with antiretroviral therapy regardless of their CD4 count or viral load.

Drug therapy is the mainstay of treatment for pregnant women infected with HIV. The standard treatment is oral antiretroviral drugs given twice daily from 14 weeks' gestation until giving birth, intravenous administration during labor, and oral syrup for the newborn in the first 6 weeks of life (Davis, & Yawetz, 2012). The goal of therapy is to reduce the viral load as much as possible, which reduces the risk of transmission to the fetus.

Decisions about the birthing method to be used are made on an individual basis based on several factors involving the woman's health. Some reports suggest

that cesarean birth may reduce the risk of HIV infection (Johnsen, 2012). Efforts to reduce instrumentation, such as avoiding the use of an episiotomy, fetal scalp electrodes, and fetal scalp sampling, will reduce the newborn's exposure to body fluids.

With appropriate therapies, the prognosis for pregnant women with HIV infection has improved significantly. In addition, the newborns of women with HIV infection who have received treatment usually do not become infected. Unfortunately, therapy is complicated and medications are expensive. Moreover, the medications are associated with numerous adverse effects and possible toxic reactions. These therapies offer a dual purpose: reduce the likelihood of mother-to-infant transmission and provide optimal suppression of the viral load in the mother. The core goal of all medical therapy is to bring the client's viral load to an undetectable level, thus minimizing the risk of transmission to the fetus and newborn.

## Nursing Assessment

Nursing assessment begins with a thorough history and physical examination. In addition, the woman is offered screening for HIV antibodies. Screening and effective intervention for women who are HIV positive are essential components of prenatal services, which also include education, counseling, testing, treatment, and continued care.

### Health History and Physical Examination

Review the woman's history for risk factors, such as unsafe sex practices, multiple sex partners, and injectable drug use. Also have the woman complete a risk assessment survey. In addition, question the woman about any flu-like symptoms such as a low-grade fever, fatigue, sore throat, night sweats, diarrhea, cough, skin lesions, or muscle pain.

Perform a complete physical examination. Obtain the woman's weight and determine if she has lost weight recently. Assess for signs and symptoms of STIs, such as vulvovaginal candidiasis, bacterial vaginosis, HSV, chancroid, CMV, or chlamydia because of the increased risk for STIs.

#### Take Note!

Women who request an HIV test despite reporting no individual risk factors should be considered at risk, since many are not likely to disclose their high-risk behaviors.

### Laboratory and Diagnostic Testing

The USPSTF (2011) recommends that all pregnant women be offered HIV antibody testing, regardless of their risk of infection, and that testing be done during the initial prenatal evaluation. Testing is essential because treatments

are available that can reduce the likelihood of perinatal transmission and maintain the health of the woman.

### Take Note!

Screening only women who are identified as high risk based on their histories is inadequate due to the prolonged latency period that can exist after exposure. Also, research indicating that treatment with antiretroviral agents could reduce vertical transmission from the infected mother to the newborn has dramatically increased the importance of HIV antibody screening in pregnancy.

Offer all women who are pregnant or planning a pregnancy HIV testing using ELISA. Prepare the woman with a reactive screening test for an additional test, such as the Western blot or an immunofluorescence assay. The Western blot is the confirmatory diagnostic test. A positive antibody test confirmed by a supplemental test indicates that the woman has been infected with HIV and can pass it on to others. HIV antibodies are detectable in at least 95% of women within 3 months after infection (Tung, Sangi-Haghpeykar, & Levison, 2010).

In addition to the usual screening tests done in normal pregnancy, additional testing for STIs may be necessary. Women infected with HIV have high rates of STIs, especially HPV, vulvovaginal candidiasis, bacterial vaginosis, syphilis, HSV, chancroid, CMV, gonorrhea, chlamydia, and hepatitis B (March of Dimes, 2011d).

## Nursing Management

Women infected with HIV should have comprehensive prenatal care, which starts with pretest and post-test counseling. In pretest counseling, the client completes a risk assessment survey and the nurse explains the meaning of positive versus negative test results, obtains informed consent for HIV testing, and educates the woman on how to prevent HIV infection by changing lifestyle behaviors if needed. Post-test counseling includes informing the client of the test results, reviewing the meaning of the results again, and reinforcing safer sex guidelines. All pretest and post-test counseling should be documented in the client's chart.

### Educating the Client

Pregnant clients are dealing with many issues at their first prenatal visit. The confirmation of pregnancy may be accompanied by feelings of joy, anxiety, depression, or other emotions. Simultaneously, the client is given many pamphlets and receives advice and counseling about many important health issues (e.g., nutrition, prenatal development, appointment schedules). This health teaching may be done while the woman feels excited, tired, and anxious. To expect women to understand detailed explanations of a complex disease entity (HIV/

AIDS) too may be unrealistic. Determine the client's readiness for this discussion.

Identify the client's individual needs for teaching, emotional support, and physical care. Nurses need to approach education and counseling of HIV-positive pregnant women in a caring, sensitive manner. Address the following information:

- Infection control issues at home
- Safer sex precautions
- Stages of the HIV disease process and treatment for each stage
- Symptoms of opportunistic infections
- Preventive drug therapies for her unborn infant
- Avoidance of breast-feeding
- Referrals to community support, counseling, and financial aid
- Client's support system and potential caretaker
- Importance of continual prenatal care
- Need for a well-balanced diet
- Measures to reduce exposure to infections

Be knowledgeable about HIV infection and how HIV is transmitted and share this knowledge with all women. Nurses also can work to influence legislators, public health officials, and the entire health establishment toward policies to address the HIV epidemic. Research toward treatment and cure is tremendously important, but the major key to prevention of the spread of the virus is education. Nurses play a major role in this education.

### Supporting the Client

Be aware of the psychosocial sequelae of HIV/AIDS. A diagnosis of HIV can put a woman into an emotional tailspin, where she is worried about her own health and that of her unborn infant. She may experience grief, fear, or anxiety about the future of her children. Along with the medications that are so important to her health maintenance, address the woman's mental health needs, family dynamics, capacity to work, and social concerns and provide appropriate support and guidance.

Be aware of your personal beliefs and attitudes toward women who are HIV positive or have AIDS. Incorporate this awareness in your actions as you help the woman face the reality of the diagnosis and treatment options. Empathy, understanding, caring, and assistance are key to helping the client and her family.

### Preparing for Labor, Birth, and Afterward

Current evidence suggests that cesarean birth performed before the onset of labor and before the rupture of membranes significantly reduces the rate of perinatal transmission. ACOG recommends that HIV-positive women be offered elective cesarean birth to reduce the rate of transmission beyond that which may be achieved through antiretroviral therapy. They further suggest that

operative births be performed at 38 weeks' gestation and that amniocentesis be avoided to prevent contamination of the amniotic fluid with maternal blood. Decisions concerning the method of delivery should be based on the woman's viral load, the duration of ruptured membranes, the progress of labor, and other pertinent clinical factors (USPSTF, 2011).

Prepare the woman physically and emotionally for the possibility of cesarean birth and assist as necessary. Ensure that she understands the rationale for the surgical birth.

After the birth of the newborn, the motivation for taking antiretroviral medications may be lower, thus affecting the woman's compliance with therapy. Encourage the woman to continue therapy for her own sake as well as that of the newborn. Nurses can make a difference in helping women to adhere to their complex drug regimens.

Reinforce family planning methods during this time, incorporating a realistic view of her disease status. It is clear that hormonal contraceptives are not protective against HIV infection and that dual protection with condoms should be the goal for women using hormonal contraception (Blish & Baeten, 2011). Advise the woman that breast-feeding is not recommended. Instruct the woman who is HIV positive in self-care measures, including the proper method for disposing of perineal pads to reduce the risk of exposing others to infected body fluids. Finally, teach her the signs and symptoms of infection in newborns and infants, encouraging her to report any to the health care provider.

The evolution of HIV infection into a chronic disease has implications across all clinical care settings. Every nurse should be knowledgeable about the prevention, testing, treatment, and chronicity of the disease in order to provide high-quality care to people with or at risk for HIV. Nurses, therefore, need to have an understanding of the changing epidemiology of the disease, the most recent testing recommendations, developments in screening technology, the implications of aging with HIV infection, and the nursing implications of this ongoing epidemic.

### Take Note!

When providing direct care, **ALWAYS** follow standard precautions.

## VULNERABLE POPULATIONS

Every year there are an estimated 208 million pregnancies worldwide, with about 6.7 million of them in the United States (Alan Guttmacher Institute, 2012b). Each pregnancy runs the risk of an adverse outcome for the mother and the baby, but risks are dramatically increased for certain vulnerable populations: adolescents, women over the age of 35, women who are obese, and women

who abuse substances. Although risks cannot be totally eliminated once pregnancy has begun, they can be reduced through appropriate and timely interventions.

Every woman's experience with pregnancy is unique and personal. The circumstances each one faces and what pregnancy means to her involve emotions and experiences that belong solely to her. Many women in these special population groups go through this experience in confusion and isolation, feeling desperately in need of help but not knowing where to go. Although all pregnant women experience these emotions to a certain extent, they are heightened in women who have numerous psychosocial issues. Pregnancy is a stressful time. Pregnant women face wide-ranging changes in their lives, relationships, and bodies as they move toward parenthood. These changes can be challenging for a woman without any additional stresses but are even more so in the face of age extremes, illness, or substance abuse.

Skilled nursing interventions are essential to promote the best outcome for the client and her baby. Timely support and appropriate interventions during the perinatal period can have long-standing implications for the mother and her newborn, ultimately with the goal of stability and integration of the family as a unit.

## Pregnant Adolescent

**Adolescence** lasts from the onset of puberty to the cessation of physical growth, roughly from 11 to 19 years of age. Adolescents vacillate between being children and being adults. They need to adjust to the physiologic changes their bodies are undergoing and establish a sexual identity during this time. They search for personal identity and desire freedom and independence of thought and action. However, they continue to have a strong dependence on their parents (Feldman, 2012).

Each year, almost 750,000 U.S. women aged 15 to 19 become pregnant. Two thirds of all teen pregnancies occur among 18- to 19-year-olds. These pregnancies, which account for 10% of all births, are typically unintended and occur outside of marriage. Eighty-two percent of teen pregnancies are unplanned; teens account for about one fifth of all unintended pregnancies annually (Alan Guttmacher Institute, 2012a). In addition, about half of all teen pregnancies occur within 6 months of first having sexual intercourse. About one in four teen mothers under age 18 have a second baby within 2 years after the birth of their first baby. Most of these girls are unmarried, and many are not ready for the emotional, psychological, and financial responsibilities of parenthood. Teens are least likely of all maternal age groups to get early and regular prenatal care (March of Dimes, 2011g). Adolescent pregnancy is further complicated by the adolescent's lack of financial resources: the income of teen mothers is half that of women who have given birth in their 20s (March of Dimes, 2011g).

Although the incidence of teenage pregnancy has steadily declined since the early 1990s, it continues to be higher in the United States than in any other industrialized country (Alan Guttmacher Institute, 2012a). Even this reduced incidence represents what is considered an unacceptably high level of pregnancy in an age group that is likely to suffer the social consequences of early pregnancy most. Even though teen birth rates in the United States have declined, they remain high, especially among Black and Hispanic teens and in southern states. The Latina teen birth rate is the highest of any ethnic group in the United States.

Currently, fewer high school students are having sexual intercourse, and more sexually active students are using some method of contraception. However, many teens who have had sexual intercourse have not spoken with their parents about sex, and use of contraceptives remains rare (CDC, 2011g). Subsequently, adolescent

pregnancy is considered a major health problem and is addressed in *Healthy People 2020*.

## Impact of Pregnancy in Adolescence

The impact of adolescent pregnancy is evident in maternal and perinatal morbidity and mortality. Nonetheless, in addition to the age involved in precocious pregnancy, it also reflects previous conditions such as malnutrition, infectious diseases, and deficiencies in the health care given to pregnant adolescents. The most important impact lies in the psychosocial area: it contributes to a loss of self-esteem, a destruction of life projects, and the maintenance of the circle of poverty (Molina, Roca, Zamorano, & Araya, 2010).

Adolescents are a unique group with special needs related to their stage of development. Adolescent

### HEALTHY PEOPLE 2020 • 20-2

#### Objective

**FP-8** Reduce pregnancy rates among adolescent females by 10 percent by 2020.

**FP-9** Increase the proportion of adolescents ages 17 years and under who have never had sexual intercourse by 10 percent by 2020.

**FP-10** Increase the proportion of sexually active persons ages 15 to 19 years who use condoms to both effectively prevent pregnancy and provide barrier protection against disease by 10 percent by 2020.

**FP-11** Increase the proportion of sexually active persons ages 15 to 19 years who use condoms and hormonal or intrauterine contraception to both effectively prevent pregnancy and provide barrier protection against disease by 10 percent by 2020.

**FP-12** Increase the proportion of adolescents who received formal instruction on reproductive health topics before they were 18 years old by 10 percent by 2020.

**FP-13** Increase the proportion of adolescents who talked to a parent or guardian about reproductive health topics before they were 18 years old by 10 percent by 2020.

**HIV-8** Reduce the number of perinatally acquired HIV and AIDS cases by 10 percent by 2020.

**MICH-11** Increase abstinence from alcohol, cigarettes, and illicit drugs among pregnant women by 10 percent by 2020.

**MICH-25** Reduce the occurrence of fetal alcohol syndrome (FAS) by 10 percent by 2020.

**NWS-22** Reduce iron deficiency among pregnant females.

#### Nursing Significance

Will help to foster a continued decline in adolescent pregnancy rates by focusing on interventions related to pregnancy prevention, including safe sex practices and teaching about the complications associated with adolescent pregnancy.

Education for the pregnant mothers about the need and rationale for antiretroviral drug therapy to prevent vertical transmission of HIV to their fetus will help reduce this incidence.

Education and support offered to pregnant women regarding the hazards of alcohol, cigarettes, and illicit drugs will reduce the abuse of these substances to enhance the perinatal outcomes.

Providing nutritional instruction on iron-rich foods will help reduce the incidence of iron deficiency anemia during pregnancy.

pregnancy can be an emotionally charged situation, laden with ethical dilemmas and decisions. Topics such as abstinence, safer sex, abortion, and the decision to have a child are sensitive issues.

Adolescent pregnancy is an area when a nurse's moral convictions may influence the care that he or she provides to clients. Nurses need to examine their own beliefs about teen sexuality to identify personal assumptions. Putting aside one's moral convictions may be difficult, but it is necessary when working with pregnant adolescents. To be effective, health care providers must be able to communicate with adolescents in a manner they can understand and respect them as individuals.

The idea of it taking “a village to raise a child,” as suggested by former First Lady Hillary Clinton in 1996, is perhaps even more valid than previously thought regarding teen pregnancy. The evidence suggests that it's not enough to teach teens to “just say no,” nor is it enough to give them information about contraceptive methods; teens need to be connected to their parents, their peers, and their community (Katz, 2011). Nurses should feel that there is always hope and the chance of positive outcomes; nurses see that each and every day, often in the faces of their youngest clients. Nurses have to believe in that and work toward ‘connecting’ with their teen clients.

## Developmental Issues

An adolescent must accomplish certain developmental tasks to advance to the next stage of maturity. These developmental tasks include:

- Seeking economic and social stability
- Developing a personal value system
- Building meaningful relationships with others (Fig. 20.6)
- Becoming comfortable with their changing bodies
- Working to become independent from their parents
- Learning to verbalize conceptually (Herrman, 2010)

FIGURE 20.6 Adolescent girls sharing time together.

Adolescents have special needs when working to accomplish their developmental tasks and making a smooth transition to young adulthood. One of the biggest areas of need is sexual health. Adolescents commonly lack the information, skills, and services necessary to make informed choices related to their sexual and reproductive health. Developmentally, adolescents are trying to figure out who they are and how they fit into society. As adolescents mature, their parents become less influential and peers become more influential. Peer pressure can lead adolescents to participate in sexual activity, as can the typical adolescent's belief that “it won't happen to me” (Box 20.3).

As a result, unplanned pregnancies occur. Work on the developmental tasks of adolescence, especially identity, can be interrupted as the adolescent attempts to integrate the tasks of pregnancy, bonding, and preparing to care for another with the tasks of developing self-identity and independence. A pregnant adolescent must try to meet her own needs along with those of her fetus. The process of learning how to separate from the parents while learning how to bond and attach to a newborn brings conflict and stress. A pregnancy can exacerbate an adolescent's feeling of loss of control and helplessness (Riesch, Anderson, Pridham, Lutz, & Becker, 2010).

### BOX 20.3

#### POSSIBLE FACTORS CONTRIBUTING TO ADOLESCENT PREGNANCY

- Early menarche
- Peer pressure to become sexually active
- Sexual or other abuse as a child
- Lack of accurate contraceptive information
- Fear of telling parents about sexual activity
- Feelings of invulnerability
- Poverty (85% of births occur in poor families)
- Culture or ethnicity (high incidence in Hispanic and African American girls)
- Unprotected sex
- Low self-esteem and inability to negotiate
- Lack of appropriate role models
- Strong need for someone to love
- Drug use, truancy from school, or other behavioral problems
- Wish to escape a bad home situation
- Early dating without supervision

Adolescent pregnancy. *Nursing for Women's Health*, 15(2), 149–152; and March of Dimes (2011g). *Teenage pregnancy*. Retrieved from [http://www.marchofdimes.com/professionals/14332\\_1159.asp](http://www.marchofdimes.com/professionals/14332_1159.asp).

## Health and Social Issues

Adolescent pregnancy has a negative impact in terms of both health and social consequences. For example, 7 out of 10 adolescents will drop out of school. More than 75% will receive public assistance within 5 years of having their first child. In addition, children of adolescent mothers are at greater risk of preterm birth, low birth weight, child abuse, neglect, poverty, and death. The younger the adolescent is at the time of the first pregnancy, the more likely it is that she will have another pregnancy during her teens (March of Dimes, 2011g). Adolescent pregnancy also places them at high risk for obstetric complications such as preterm labor and births; low-birth-weight infants; sexually transmitted infections; preeclampsia, iron-deficiency anemia, poor eating habits, and inadequate nutrition and postpartum depression (Aruda, Waddicor, Frese, Cole, & Burke, 2010).

The psychosocial risks associated with early childbearing often have an even greater impact on mothers, families, and society than the obstetric or medical risks (Whiteley & Brown, 2010). Pregnant adolescents experience higher rates of domestic violence and substance abuse. Those experiencing abuse are more likely to abuse substances, receive inadequate prenatal care, and have lower pregnancy weight compared with those who are not (Mander, 2010). Moreover, substance abuse (cigarettes, alcohol, or illicit drugs) can contribute to low birth weight, IUGR, preterm births, newborn addiction, and sepsis (March of Dimes, 2011g).

Although early childbearing (12 to 19 years of age) occurs in all socioeconomic groups, it is more prevalent among poor women and those from minority backgrounds, who face more obstetric and newborn risks than their more affluent counterparts (March of Dimes, 2011g). Poverty often contributes to delayed prenatal care and medical complications related to poor nutrition, such as anemia.

The financial burden of adolescent pregnancy is high and costs taxpayers an estimated \$11 billion annually in the United States (Alan Guttmacher Institute, 2012a). Much of the expense stems from Medicaid, food stamps, state health department maternity clinics, the federal Aid to Families with Dependent Children program, and direct payments to health care providers. However, this amount does not address the costs to society in terms of the loss of human resources and the far-reaching intergenerational effects of adolescent parenting.

For some adolescents, pregnancy may be seen as a hopeless situation: a grim story of poverty and lost dreams, of being trapped in a life that was never wanted. Health-related behaviors, such as smoking, diet, sexual behavior, and help-seeking behaviors, which are developed during adolescence often endure into later life (Herrman, 2010). The consequences associated with an adolescent's less-than-optimal health status at this age

due to pregnancy can ultimately affect her long-term health and that of her children.

However, some adolescents can create a happy, stable life for themselves and their children by facing their challenges and working hard to beat the odds.

*Recall Rose, the pregnant teenager with asthma. What issues would be important for the nurse to discuss with her related to her pregnancy, her asthma, and her age?*

## Nursing Assessment

Assessment of the pregnant adolescent is the same as that for any pregnant woman. However, when dealing with pregnant teens, the nurse also needs to ask:

- How does the girl see herself in the future?
- Are realistic role models available to her?
- How much does she know about child development?
- What financial resources are available to her?
- Does she work? Does she go to school?
- What emotional support is available to her?
- Can she resolve conflicts and manage anger?
- What does she know about health and nutrition for herself and her child?
- Will she need help dealing with the challenges of the new parenting role?
- Does she need information about community resources?

Having an honest regard for adolescents requires getting to know them and being able to appreciate the important aspects of their life. Doing so forms a basis for the nurse's clinical judgment and promotes care that takes into account the concerns and practical circumstances of the teen and her family. Skillful practice includes knowing how and when to advise a teen and when to listen and refrain from giving advice. Giving advice can be misinterpreted as "preaching," and the adolescent will probably ignore the information. The nurse must be perceptive, flexible, and sensitive and must work to establish a therapeutic relationship.

## Nursing Management

For adolescents, as for all women, pregnancy can be a physically, emotionally, and socially stressful time. The pregnancy is often both the result of and cause of social problems and stressors that can be overwhelming to them. Nurses must support adolescents during the transition from childhood into adulthood, which is complicated by their emergence into motherhood. Assist the adolescent in identifying family and friends who want to be involved and provide support throughout the pregnancy.

Help the adolescent identify the options for this pregnancy, such as abortion, self-parenting of the child, temporary foster care for the baby or herself, or placement of the child for adoption. Explore with the adolescent why she became pregnant. Becoming aware of why she decided to have a child is necessary to help with the development of the adolescent and her ability to parent. Identify barriers to seeking prenatal care, such as lack of transportation, too many problems at home, financial concerns, the long wait for an appointment, and lack of sensitivity on the part of the health care system. Encourage the girl to set goals and work toward them. Assist her in returning to school and furthering her education. As appropriate, initiate a referral for career or job counseling.

Stress that the girl's physical well-being is important for both her and her developing fetus, which depends on her for its own health-related needs. Assist with arrangements for care, including stress management and self-care.

Having a healthy newborn eases the transition to motherhood somewhat, rather than having to deal with the added stress of caring for an unhealthy baby (Heavey, 2010). Monitor weight gain, sleep and rest patterns, and nutritional status to promote positive outcomes for both mother and child. Stress the importance of attending prenatal education classes. Provide appropriate teaching based on the adolescent's developmental level and emphasize the importance of continued prenatal and follow-up care. Monitor maternal and fetal well-being throughout pregnancy and labor (Fig. 20.7).

Nurses can also play a major role in preventing adolescent pregnancies, perhaps by volunteering to talk to teen groups. Teaching Guidelines 20.6 highlights the key areas for teaching adolescents about pregnancy prevention.

Tackling the many issues surrounding adolescent pregnancy is difficult. Making connections with clients

**FIGURE 20.7** A pregnant adolescent receiving care during labor.

### Teaching Guidelines 20.6

#### TOPICS FOR TEACHING ADOLESCENTS TO PREVENT PREGNANCY

- High-risk behaviors that lead to pregnancy
- Involvement in programs such as Free Teens, Teen Advisors, or Postponing Sexual Involvement
- Planning and goal setting to visualize their futures in terms of career, college, travel, and education
- Choice of abstinence or taking a step back to become a “second-time virgin”
- Discussions about sexuality with a wiser adult—someone they respect can help put things in perspective
- Protection against sexually transmitted infections and pregnancy if they choose to remain sexually active
- Critical observation and review of peers and friends to make sure they are creating the right atmosphere for friendship
- Empowerment to make choices that will shape their life for years to come, including getting control of their own lives now
- Appropriate use of recreational time, such as sports, drama, volunteer work, music, jobs, church activities, and school clubs

Adapted from Katz, A. (2011). Adolescent pregnancy. *Nursing for Women's Health*, 15(2), 149–152; and March of Dimes (2011g). *Teenage pregnancy*. Retrieved from [http://www.marchofdimes.com/professionals/14332\\_1159.asp](http://www.marchofdimes.com/professionals/14332_1159.asp).

is crucial regardless of how complex their situation is. The future challenges nurses to find solutions to teenage pregnancies. Nurses must take proactive positions while working with adolescents, parents, schools, and communities to reduce the problems associated with early childbearing.

Nurses who provide care to adolescents have an opportunity to discuss future pregnancies and to use health care visits to teach about preconception health. Teaching adolescents who both express a desire for pregnancy and those who do not express such a desire is an important part of comprehensive nursing care. Teens require thorough teaching about health care risks such as smoking cessation, body weight control, interpersonal violence, and the need for folic acid. Adolescents should be prime recipients of preconception education at every health care visit.

Teen childbearing is associated with adverse consequences for mothers and their children and imposes high public sector costs. Prevention of teen pregnancy requires evidence-based sex education, support for parents in talking with their children about pregnancy prevention and other aspects of sexual and reproductive health, and ready access to effective and

affordable contraception for teens who are sexually active (CDC, 2011g).

### The Pregnant Woman Over Age 35

The term *elderly primip* is used to describe women aged 35 or older who are pregnant for the first time. A few decades ago, a woman having a baby after the age of 35 probably was giving birth to the last of several children, but today she may be having her first. With advances in technology and the tendency of women to seek career advancement prior to childbearing, the dramatic increase in women having first pregnancies after the age of 35 will likely continue.

### Impact of Pregnancy on the Older Woman

Whether childbearing is delayed by choice or by chance, women starting a family at age 35 or older are not doing so without risk. Women in this age group may already have chronic health conditions that can put the pregnancy at risk. In addition, numerous studies have shown that increasing maternal age is a risk factor for infertility and spontaneous abortions, gestational diabetes, chronic hypertension, preeclampsia, preterm labor and birth, multiple pregnancy, genetic disorders and chromosomal abnormalities, placenta previa, IUGR, low Apgar scores, and surgical births (Schmidt, Sobotka, Bentzen, & Nyboe Andersen, 2012). However, even though increased age implies increased complications, most women today who become pregnant after age 35 have healthy pregnancies and healthy newborns. Today, one in five women in the United States has her first child after age 35 (March of Dimes, 2011f).

### Nursing Assessment

Nursing assessment of the pregnant woman over age 35 is the same as that for any pregnant woman. For a woman of this age, a preconception visit is important to identify chronic health problems that might affect the pregnancy and also to address lifestyle issues that may take time to modify. Encourage the older woman to plan for the pregnancy by seeing her health care provider before getting pregnant to discuss preexisting medical conditions, medications, and lifestyle choices. Assess the woman for risk factors such as cigarette smoking, poor nutrition, overweight or underweight, alcohol use, or illicit drug use.

A preconception visit also provides the opportunity to educate the woman about risk factors and provide information on how to modify her lifestyle habits to improve the pregnancy outcome. Assist the woman with lifestyle changes so that she can begin pregnancy in an

optimal state of health. For example, if the woman is overweight, educate her about weight loss so that she can start the pregnancy at a healthy weight. If the woman smokes, encourage smoking cessation to reduce the effects of nicotine on herself and her fetus.

Prepare the woman for laboratory and diagnostic testing to establish a baseline for future comparisons. The risk of having a baby with Down syndrome increases with age, especially over age 35. Amniocentesis is routinely offered to all older women to allow the early detection of numerous chromosomal abnormalities, including Down syndrome. Additionally, a quadruple blood test screen (alpha fetoprotein [AFP], human chorionic gonadotropin [hCG], unconjugated estriol [UE], and inhibin A [placental hormone]) drawn between 15 and 20 weeks of pregnancy can be helpful in screening for Down syndrome and neural tube defects.

### Nursing Management

During routine prenatal visits, the nurse can play a key role in promoting a healthy pregnancy. Consider social, genetic, and environmental factors that are unique to the older pregnant women and prepare to address these factors when providing care. In a study by Kort and colleagues (2011), compared with the younger women, older women had statistically similar rates of gestational hypertension, gestational diabetes, preterm premature rupture of membranes/preterm labor, and abnormal placentation. Cesarean birth was higher in older women versus younger ones. Neonatal outcomes of gestational age and birth weight were excellent and similar between groups.

Assess the woman's knowledge about risk factors and measures to reduce them. Educate her about measures to promote a positive outcome. Encourage her to get early and regular prenatal care. Advise her to eat a variety of nutritious foods, especially fortified cereals, enriched grain products, and fresh fruits and vegetables, and drink at least six to eight glasses of water daily and to take the prescribed vitamin containing 400 mcg of folic acid daily. Also stress the need for her to avoid alcohol intake during pregnancy, avoid exposure to secondhand smoke, and take no drugs unless they are prescribed. Provide continued surveillance of the mother and fetus throughout the pregnancy.

### The Obese Pregnant Woman

Obese pregnant women are a particularly vulnerable group because their disability (obesity) is highly visible. In the United States, nearly 36% of adults are obese, including one out of three women (WHO, 2011). Excess weight and obesity have gained attention as serious health care threats globally. Obesity contributes to

social, psychological, and economic problems throughout a woman's lifetime. Negative attitudes and discrimination by society can have negative consequences for the woman's quality of life. The number of women who are overweight or obese during pregnancy has also increased. During pregnancy, excess weight increases both obstetric and neonatal risks, including:

- Gestational diabetes
- Hypertension
- Thromboembolism
- Fetal macrosomia (birth weight. >4000 grams)
- Difficulty fighting postpartum infections
- Tendency to remain overweight/obesity between pregnancies
- Prolongation of pregnancy/increased likelihood of post-term infant
- Increased risk of stillbirth
- Higher rate of cesarean births
- Increased risk of maternal mortality
- High risk for postpartum hemorrhage (Hull, Montgomery, Vireday, & Kendall-Tackett, 2011).

Negative or judgmental attitudes toward overweight or obese individuals can be encountered within the health care community and its providers, including nurses (Phillips, 2012).

Individualized nursing care for obese pregnant women is obvious. Extra time may be needed to promote healthful practices, which should include dealing with issues of weight, diet, and exercise. This care must be done with honesty and respect for all of the woman's needs. There is an opportunity for health promotion aimed at disseminating information about the risks of obesity in pregnancy to overweight and obese women of childbearing age.

### The Pregnant Woman with Substance Abuse

The epidemic of substance abuse continues to pose a significant challenge to all nations. Although there is a tendency to simply associate drug abuse with poverty, the problem affects every social stratum, gender, and race; and pregnant women are no exception. **Perinatal drug abuse** is the use of alcohol and other drugs by pregnant women. The incidence of substance abuse during pregnancy is highly variable because most pregnant women are reluctant to reveal the extent of their use. The National Institute on Drug Abuse (NIDA) (2011b) estimates that 7% of the women in the United States have used illicit drugs while pregnant. These include cocaine, marijuana, heroin, and psychotherapeutic drugs that were not prescribed by a health care professional. More than 20% used alcohol and 19% smoked cigarettes during their pregnancy (2011b).

## Impact of Substance Abuse on Pregnancy

Substance use can be viewed along a continuum between social recreational drug use and addiction. Substance abuse is very prevalent remains and continues to remain undetected and underdiagnosed in many pregnant women.

The positive overall impact of adequate prenatal care on birth outcomes is well documented. For pregnant substance users, the receipt of adequate prenatal care is especially critical. Several studies have reported that increasing the adequacy of prenatal care utilization in pregnant substance users reduces risks for prematurity, low birth weight, and perinatal mortality. However, many pregnant women who are substance users do not seek prenatal care for fear of being reported to Child Protective Services (Roberts & Pies, 2011).

The use of drugs, legal or not, increases the risk of medical complications in the mother and poor birth outcomes in the newborn. The placenta acts as an active transport mechanism, not as a barrier, and substances pass from a mother to her fetus through the placenta. Thus, along with the mother, the fetus experiences substance use, abuse, and addiction. Additionally, fetal vulnerability to drugs is much greater because the fetus has not developed the enzymatic system needed to metabolize drugs (Gilbert, 2011).

### Effects of Addiction

Addiction is a multifaceted process that is affected by environmental, psychological, family, and physical factors. Women who use drugs, alcohol, or tobacco come from all socioeconomic backgrounds, cultures, and lifestyles. Factors associated with substance abuse during a pregnancy may include low self-esteem, inadequate support systems, low self-expectations, high levels of anxiety, socioeconomic barriers, involvement in abusive relationships, chaotic familial and social systems, and a history of psychiatric illness or depression. Women often become substance abusers to relieve their anxieties, depression, and feelings of worthlessness (Bennett et al., 2010).

Societal attitudes regarding women and substance abuse may prohibit them from admitting the problem and seeking treatment. Society sanctions women for failing to live up to expectations of how a pregnant woman "should" behave, thereby possibly driving them further away from the treatment they so desperately need. For many reasons, pregnant women who abuse substances feel unwelcome in prenatal clinics or medical settings. Often they seek prenatal care late or not at all. They may fear being shamed or reported to legal or child protection authorities. A nonjudgmental atmosphere and unbiased teaching to all pregnant women regardless of their lifestyle is crucial. A caring, concerned manner is critical

to help these women feel safe and respond honestly to assessment questions.

Pregnancy can be a motivator for some who want to try treatment. The goal of therapy is to help the client deal with pregnancy by developing a trusting relationship. Providing a full spectrum of medical, social, and emotional care is needed.

### Effects of Commonly Abused Substances

Substance abuse in pregnancy has increased during the past three decades in the United States, resulting in approximately 250,000 infants being born yearly with prenatal exposure to illicit substances (CDC, 2011e). Routine screening and education of women of childbearing age remain the most important ways to reduce addiction in pregnancy.

Substance abuse during pregnancy, particularly in the first trimester, has a negative effect on the health of the mother and the growth and development of the fetus. The fetus experiences the same systemic effects as the mother, but often more severely. The fetus cannot metabolize drugs as efficiently as the expectant mother and will experience the effects long after the drugs have left the women's system. Substance abuse during pregnancy is associated with preterm labor, abortion, IUGR, abruptio placenta, low birth weight, neurobehavioral abnormalities, and long-term childhood developmental consequences (Pinto et al., 2010). Table 20.6 summarizes

the effects of selected drugs during pregnancy. *Healthy People 2020* also addresses goals for perinatal substance abuse.

### ALCOHOL

Alcohol abuse is a major public health issue in the United States. Alcohol is a teratogen, a substance known to be toxic to human development. Approximately 10% of pregnant women report alcohol consumption (CDC, 2011e). Theoretically, no mother would give a glass of wine, beer, or hard liquor to her newborn, but when she drinks, her embryo or fetus is exposed to the same blood alcohol concentration as she is.

The teratogenic effects of heavy maternal drinking have been recognized since 1973, when fetal alcohol syndrome was first described. Fetal alcohol syndrome is now a classification under the broader term of **fetal alcohol spectrum disorder (FASD)**; this disorder includes the full range of birth defects, such as structural anomalies and behavioral and neurocognitive disabilities caused by prenatal exposure to alcohol (Economidoy, Klimi, & Vivilaki, 2012). FASD affects 1 in 100 infants each year, more than autism, and Down syndrome, cerebral palsy, cystic fibrosis, spina bifida, and sudden infant death syndrome (SIDS) combined (National Organization on Fetal Alcohol Syndrome [NOFAS], 2011). Each year in the United States, up to 50,000 infants are born with FASD. It is the leading cause of nongenetic intellectual disability in the United States, possibly exceeding

**TABLE 20.6** EFFECTS OF SELECTED DRUGS ON PREGNANCY

Substance	Effect on Pregnancy
Alcohol	Spontaneous abortion, inadequate weight gain, IUGR, fetal alcohol spectrum disorder, the leading cause of intellectual disability
Caffeine	Vasoconstriction and mild diuresis in mother; fetal stimulation, but teratogenic effects not documented via research
Nicotine	Vasoconstriction, reduced uteroplacental blood flow, decreased birth weight, abortion, prematurity, abruptio placentae, fetal demise
Cocaine	Vasoconstriction, gestational hypertension, abruptio placentae, abortion, "snow baby syndrome," CNS defects, IUGR
Marijuana	Anemia, inadequate weight gain, "amotivational syndrome," hyperactive startle reflex, newborn tremors, prematurity, IUGR
Opiates and Narcotics	Maternal and fetal withdrawal, abruptio placentae, preterm labor, premature rupture of membranes, perinatal asphyxia, newborn sepsis and death, intellectual impairment, malnutrition
Sedatives	CNS depression, newborn withdrawal, maternal seizures in labor, newborn abstinence syndrome, delayed lung maturity

Adapted from Centers for Disease Control and Prevention. (2011e). *Illegal drug use in the United States*. Retrieved from <http://www.cdc.gov/nchs/fastats/druguse.htm>; Gilbert, E. S. (2011). *Manual of high risk pregnancy and delivery* (5th ed.). St. Louis, MO: Mosby Elsevier; and March of Dimes (2011e). *Illicit drug use during pregnancy*. Retrieved from [http://www.marchofdimes.com/professionals/14332\\_1169.asp](http://www.marchofdimes.com/professionals/14332_1169.asp).

even Down syndrome, which is currently approaching 1 in 500 live births. Alcohol consumption during pregnancy results in brain, craniofacial, and heart defects, neurotoxicity, and immune systems dysfunction. The preferred action taken to prevent alcohol consumption during pregnancy is abstinence. However, the detection, diagnosis, and treatment of FASD remain major public health needs in this country and throughout the world.

Not every woman who drinks during pregnancy will give birth to an affected child. Based on the best research available, the following is known about alcohol consumption during pregnancy:

- Intake increases the risk of alcohol-related birth defects, including growth deficiencies, facial abnormalities, CNS impairment, behavioral disorders, and intellectual development.
- No amount of alcohol consumption is considered safe during pregnancy.
- Damage to the fetus can occur at any stage of pregnancy, even before a woman knows she is pregnant.
- Cognitive defects and behavioral problems resulting from prenatal exposure are lifelong.
- Alcohol-related birth defects are completely preventable (U.S. Department of Health and Human Services, 2011).

Risk factors for giving birth to an alcohol-affected newborn include maternal age, socioeconomic status, ethnicity, genetic factors, poor nutrition, depression, family disorganization, unplanned pregnancy, and late prenatal care (CDC, 2011b). Identification of risk factors strongly associated with alcohol-related birth outcomes could help identify high-risk pregnancies requiring intervention.

Characteristics of FASD include craniofacial dysmorphism (thin upper lip, small head circumference, and small eyes), IUGR, microcephaly, and congenital anomalies such as limb abnormalities and cardiac defects. Long-term sequelae include postnatal growth restriction, attention deficits, delayed reaction time, and poor scholastic performance (NOFAS, 2011). The complex neurobehavioral problems typically manifest themselves insidiously. Children with prenatal alcohol exposure struggle with cognitive, academic, social, emotional, and behavioral challenges. These challenges reduce the child's ability to learn and function successfully in many structured environments (Blakemore 2012). Common cognitive and behavioral problems are listed in Box 20.4, and Figure 20.8 illustrates the characteristic facial features. See Chapter 24 for a more detailed discussion of the newborn with FASD.

One of the biggest challenges in determining the true prevalence of FASD is how to recognize the syndrome, which depends in part on the age and physical features of the person being assessed. Difficulty identifying alcohol abuse results from the client's denial of alcohol use, unwillingness to report alcohol consumption,

#### BOX 20.4

#### COMMON COGNITIVE AND BEHAVIORAL PROBLEMS ASSOCIATED WITH FASD

- Attention deficit/hyperactivity disorder (ADHD)
- Inability to foresee consequences
- Inability to learn from previous experience
- Lack of organization
- Learning difficulties
- Poor abstract thinking
- Poor reasoning and judgment skills
- Poor memory
- Poor impulse control
- Speech and language problems
- Poor judgment

Adapted from Centers for Disease Control and Prevention. (2011b). *Fetal alcohol spectrum disorders*. Retrieved from <http://www.cdc.gov/ncbddd/fasd/alcohol-use.html>.

underreporting, and limited ability to recollect the frequency, quantity, and type of alcohol consumed. This makes it difficult to identify women who are drinking during pregnancy, institute preventive measures, or refer them for treatment.

Women who drink excessively while pregnant are at high risk for giving birth to children with birth defects. To prevent these defects, women should stop drinking during all phases of a pregnancy. Unfortunately, many women continue to drink during their pregnancy despite warnings from professionals.

Currently, it is not known whether there is a minimal amount of alcohol safe to drink during pregnancy;

FIGURE 20.8 Typical facial characteristics of a newborn with FASD.

an occasional glass of wine might be harmless or might not be. Therefore, eliminating alcohol consumption during pregnancy is the ultimate goal to prevent FASD. Most women know they shouldn't drink during pregnancy, but the "window of vulnerability"—the time lag between conception and the discovery of pregnancy—may put substantial numbers of children at risk. Additionally, traditional alcohol-screening questionnaires, such as the Michigan Alcoholism Screening Test (MAST) and the CAGE Questionnaire, are not sensitive enough to detect low levels of alcohol consumption among women.

Several challenges remain in preventing birth defects due to alcohol consumption:

- Ways to improve clinical recognition of high-risk women who drink alcohol
- Ways to intervene more effectively to modify drinking behaviors
- In utero approaches to prevent or minimize fetal injury
- Strategies to address the neurodevelopmental problems of children affected by maternal alcohol ingestion

### NONMEDICAL USE OF PRESCRIPTION DRUGS

In addition to alcohol and illicit drug use, a new worldwide trend has emerged and may soon exceed illicit drug use. That is, the nonmedical use of prescription drugs found in many home medicine cabinets. Common drugs of choice include analgesics, stimulants, sedatives, and tranquilizers. A frequent belief among abusers is that prescribed medications are less dangerous than street drugs and using a friend's medication is safe. Unfortunately, unintentional poisoning deaths occur frequently. In addition, the development of a counterfeit market has developed utilizing the Internet, thereby creating a global counterfeit drug market (Wong, Ordean, & Kahan, 2011).

Early detection through a comprehensive evaluation is essential to improve overall treatment outcomes. A major role of the nurse is to focus on prevention in the first place through education of all women about the dangers associated with misuse of prescription medications. Community education is vital to manage risks to prevent problems from developing.

### CAFFEINE

Caffeine is a widely used and accepted pharmacologically active substance. The effect of caffeine intake during pregnancy on fetal growth and development is still unclear. A recent study found that caffeine intake of no more than 300 mg/day during pregnancy does not affect pregnancy duration and the condition of the newborn (Jarosz, Wierzejska, & Siuba, 2012). Caffeine, a CNS stimulant, is present in varying amounts in such common products as coffee, tea, colas, and chocolate. It is also in cold remedies and analgesics. Birth defects have not been linked to caffeine consumption, but maternal coffee consumption decreases iron absorption and may increase the risk of anemia during pregnancy.

Moderate caffeine consumption (less than 300 mg/day) does not appear to be a major contributing factor in miscarriage or preterm birth. The relationship of caffeine to growth restriction remains undetermined. A final conclusion cannot be made at this time as to whether there is a correlation between high caffeine intake and miscarriage due to lack of sufficient studies (ACOG, 2010a).

### NICOTINE

Cigarette smoking during pregnancy is associated with numerous obstetric, fetal, and developmental complications, as well as an increased risk of adverse health consequences in the adult offspring. Nicotine replacement therapy (NRT) has been developed as a pharmacotherapy for smoking cessation and is considered to be a safer alternative for women to smoking during pregnancy. The safety of NRT (transdermal patches and bupropion) use during pregnancy has been evaluated in a limited number of short-term human trials, but there is currently no information on the long-term effects of developmental nicotine exposure in humans (Clark & Nakad, 2011).

Nicotine is found in cigarettes, and is another substance that is harmful to the pregnant women and her fetus. Nicotine, which causes vasoconstriction, transfers across the placenta and reduces blood flow to the fetus, contributing to fetal hypoxia. When compared with alcohol, marijuana, and other illicit drug use, tobacco use is less likely to decline as the pregnancy progresses (McGowen et al., 2010). Smoking is associated with adverse pregnancy outcomes. However, these adverse outcomes can be avoided if the woman stops smoking before becoming pregnant.

Smoking increases the risk of spontaneous abortion, preterm labor and birth, maternal hypertension, placenta previa, and abruptio placentae. The perinatal death rate among infants of smoking mothers is 20% to 35% higher than that of nonsmoking mothers (Galloway, 2012).

Smoking has also been considered an important risk factor for low birth weight, SIDS, and cognitive deficits, especially in language, reading, and vocabulary, as well as poorer performances on tests of reasoning and memory. Researchers have also reported behavior problems, such as increased activity, inattention, impulsivity, opposition, and aggression (Blood-Siegfried & Rende, 2010).

Women who smoke during the pregnancy often continue to smoke after giving birth, and thus the infant will be exposed to nicotine after birth. This environmental or passive exposure affects the child's development and increases the risk of childhood respiratory disorders.

### COCAINE

Cocaine use is second only to marijuana use in women who abuse drugs during pregnancy. The incidence of cocaine exposure in utero is 1 to 10 per 1,000 live births (Strathearn & Mayes, 2010). There is evidence that

cocaine affects infant development both directly, via in utero exposure, and indirectly via alterations in maternal care after birth.

Cocaine is a psychoactive drug derived from the leaves of the coca plant, which grows in the Andes Mountains of Peru, Ecuador, and Bolivia. The freebase form, called “crack” because of the cracking or popping noise made in its preparation, is less expensive, easily made, and smokable. Cocaine is a powerful vasoconstrictor. When sniffed into the mucous membranes of the nose, it produces an intense “rush” that some have compared to an orgasmic experience. Smoked crack is absorbed rapidly by the pulmonary vasculature and reaches the brain’s circulation in 6 to 8 seconds (NIDA, 2011a).

Cocaine use produces vasoconstriction, tachycardia, and hypertension in both the mother and the fetus (Irner, Teasdale, Nielsen, Vedal, & Olofsson, 2012). Uteroplacental insufficiency may result from reduced blood flow and placental perfusion. Chronic use can result in low birth weight, the most common effect of cocaine use in pregnancy (NIDA, 2011a).

Studies suggest that perinatal cocaine use increases the risk of preterm labor, abortion, abruptio placentae, IUGR, intrauterine fetal distress and demise, seizures, withdrawal, and cerebral infarcts. Cocaine may increase the risk of uterine rupture and congenital anomalies (NIDA, 2011a). Fetal anomalies associated with cocaine use in early pregnancy involve neurologic problems such as neural tube defects and microcephaly; cardiovascular anomalies such as congenital heart defects; genitourinary conditions such as prune belly syndrome, hydronephrosis, and ambiguous genitalia; and gastrointestinal system problems such as necrotizing enterocolitis (Prentice, 2010). Some infants exposed to cocaine in utero show increased irritability and are difficult to calm and soothe to sleep.

## MARIJUANA

Marijuana is the most commonly used illicit drug in America, with over 90 million people having tried it at least once. It is often called pot, reefer, herb, widow, hash, grass, weed, Mary Jane, or MJ (NIDA, 2011c). Marijuana is a preparation of the leaves and flowering tops of *Cannabis sativa*, the hemp plant, which contains a number of pharmacologically active agents. Tetrahydrocannabinol (THC) is the most active ingredient of marijuana. With heavy smoking, THC narrows the bronchi and bronchioles and produces inflammation of the mucous membranes. Smoking marijuana causes tachycardia and a reduction in blood pressure, resulting in orthostatic hypotension.

The effects of marijuana smoking on pregnancy are not yet fully understood because there are very few studies on its long-term effects on child development. One can speculate that the effects of marijuana on the immature nervous system may be subtle and not detected

until more complex functions are required, usually in a formal educational setting. There is some evidence that marijuana increases the risk of spontaneous abortion and preterm delivery (van Gelder et al., 2010). Although marijuana is not considered teratogenic, many newborns display altered responses to visual stimuli, increased tremulousness, and a high-pitched cry, which might indicate CNS insults (Prentice, 2010). A strong correlation exists between the use of marijuana and the use of alcohol and cigarettes.

## OPIATES AND NARCOTICS

Opiates and narcotics include opium, heroin (known as horse, junk, smack, downtown), morphine, codeine, hydromorphone (Dilaudid; little D), oxycodone (Percodan, perkins), meperidine (Demerol, demise), and methadone (meth, dollies). These drugs are CNS depressants that soothe and lull. They may be used medically for pain, but all have a high potential for abuse. Most cause an intense addiction in both mother and newborn.

Narcotic dependence is particularly problematic in pregnant women. It leads to medical, nutritional, and social neglect by the woman due to the long-term risks of physical dependence, malnutrition, compromised immunity, hepatitis, and fatal overdose (Alexander, LaRosa, Bader, & Garfield, 2010). Taking opiates or narcotics during pregnancy places the woman at increased risk for preterm labor, IUGR, and preeclampsia (Wang, 2012).

Heroin is the most common illicitly used opioid. It is derived from the seeds of the poppy plant and can be sniffed, smoked, or injected. It crosses the placenta via simple diffusion within 1 hour of maternal consumption (Bandstra, Morrow, Mansoor, & Accornero, 2010). Use of heroin during pregnancy is believed to affect the developing brain of the fetus and may cause behavioral abnormalities in childhood (Alexander et al., 2010).

The most common harmful effect of heroin and other narcotics on newborns is withdrawal, or **neonatal abstinence syndrome** (see Chapter 24). This collection of symptoms may include irritability, hypertonicity, excessive and often high-pitched cry, vomiting, diarrhea, feeding disturbances, respiratory distress, disturbed sleeping, excessive sneezing and yawning, nasal stuffiness, diaphoresis, fever, poor sucking, tremors, and seizures (Wang, 2012).

Withdrawal from opiates during pregnancy is extremely dangerous for the fetus, so a prescribed oral methadone maintenance program combined with psychotherapy is recommended for the pregnant woman. This closely supervised treatment program reduces withdrawal symptoms in the newborn, reduces drug cravings, and blocks the euphoric effects of narcotic drugs in order to reduce illicit drug use. Methadone maintenance provides a steady state of opiate levels, thus reducing the risk of withdrawal to the fetus and exposure to HIV and other STIs because the mother is no longer injecting

drugs. However, methadone has the same withdrawal consequences for women and newborns as heroin does (Kreek, Borg, Ducat, & Ray, 2010).

### SEDATIVES

Sedatives relax the central nervous system and are used medically for inducing relaxation and sleep, relieving tension, and treating seizures. Sedatives easily cross the placenta and can cause birth defects and behavioral problems. Infants born to mothers who abuse sedatives during pregnancy may be physically dependent on the drugs themselves and are more prone to respiratory problems, feeding difficulties, disturbed sleep, sweating, irritability, and fever (Alexander et al., 2010).

### METHAMPHETAMINES

Methamphetamine use is now more common than cocaine use in pregnancy, and its use by women of childbearing age is increasing in the United States. This highly addictive stimulant is commonly known as speed, meth, or chalk. In its smoked form, it is often referred to as ice, crystal, crank, and glass. It is a white, odorless, bitter-tasting powder that was developed from its parent drug, amphetamine, and was used originally in nasal decongestants and bronchial inhalers. The maternal effects include increased energy and alertness, an intense rush, decreased appetite, tachycardia, and tachypnea. Chronic use can lead to psychosis, including paranoia, hallucinations, memory loss, and aggressive or violent behavior. Signs of methamphetamine use include track marks from intravenous injection, malnutrition, severe dental decay (meth mouth), and skin abscesses from skin picking (LaGasse et al., 2011). Few studies have been done on the effects of methamphetamine abuse during pregnancy, but the few done indicate an increased risk for preterm births, placental abruption, fetal growth restriction, and congenital anomalies (NIDA, 2011d). These findings are hard to interpret, however, due to small sample size and polydrug use of the participants.

## Nursing Assessment

Complete a thorough history and physical examination to evaluate a client for substance use and abuse. Substance abuse screening in pregnancy is done to detect the use of any substance known or suspected to exert a deleterious effect on the client or her fetus. Routinely ask about substance abuse with all women of childbearing age, inform them of the risks involved, and advise them against continuing. Screening questionnaires are helpful in identifying potential users, may reduce the stigma of asking clients about substance abuse, and may result in a more accurate and consistent evaluation. The questions in Box 20.5 may be helpful in assessing a client who is at risk for substance abuse during pregnancy. Using “accepting” terminology may encourage the woman to give honest answers without fear of reproach.

### BOX 20.5

#### SAMPLE QUESTIONS FOR ASSESSING SUBSTANCE USE

- Have you ever used recreational drugs? If so, when and what?
- Have you ever taken a prescription drug other than as intended?
- What are your feelings about drug use during pregnancy?
- How often do you smoke cigarettes? How many per day?
- How often do you drink alcohol?
- Have you ever felt guilty about drinking or drug use?

If the assessment reveals substance use, obtain additional information by using the RAFFT questionnaire, which is a sensitive screening instrument for identifying substance abuse (Muhrer, 2010):

- R:** Do you drink or take drugs to **R**elax, improve your self-image, or fit in?
- A:** Do you ever drink or take drugs while **A**lone?
- F:** Do you have any close **F**riends who drink or take drugs?
- F:** Does a close **F**amily member have a problem with alcohol or drugs?
- T:** Have you ever gotten in **T**rouble from drinking or taking drugs?

A woman who claims to have taken no drugs while pregnant may be unaware that substances such as hair dye, diet cola, paint, or over-the-counter medications for colds or headaches are still considered drugs. Thus, it is very difficult to get a true picture of the real use of drugs by pregnant women.

Many drugs are considered to have a teratogenic effect on growing fetuses. A **teratogen** is any environmental substance that can cause physical defects in the developing embryo and fetus. Pregnant women with substance abuse commonly present with polysubstance abuse, which is likely to be more damaging than the use of any single substance. Thus, it is inherently difficult to ascribe a specific perinatal effect to any one substance (Gilbert, 2011).

A urine toxicology screen may also be helpful in determining drug use, although a urine screen identifies only recent or heavy use of drugs. The length of time a drug is present in urine is as follows:

- Cocaine: 24 to 48 hours in an adult, 72 to 96 hours in an infant
- Heroin: 24 hours in an adult, 24 to 48 hours in an infant
- Marijuana: 1 week to 1 month in an adult, up to a month or longer in an infant
- Methadone: up to 10 days in an infant (Wang, 2012)

## Nursing Management

If the woman's drug screen is positive, use this as an opportunity to discuss prenatal exposure to substances that may be harmful. The discussion may lead the nurse to refer the client for a diagnostic assessment or identify an intervention such as counseling that may be helpful. Being nonjudgmental is a key to success; a client is more apt to trust and reveal patterns of abuse if the nurse does not judge her and her lifestyle choices.

A positive drug screen in a newborn warrants an investigation by the state protection agency. In the interim, institute measures to reduce stress and stimuli to promote the newborn's comfort (see Chapter 24 for a more in-depth discussion).

Be proactive, supportive, and accepting when caring for the client. Assure women with substance abuse problems that sharing information of a confidential nature with health care providers will not render them liable to criminal prosecution. Provide counseling and education, emphasizing the following:

- Effects of substance exposure on the fetus
- Interventions to improve mother-child attachment and improve parenting
- Psychosocial support if treatment is needed to reduce substance abuse
- Referral to outreach programs to improve access to treatment facilities
- Hazardous legal substances to avoid during pregnancy
- Follow-up of children born to substance-dependent mothers
- Dietary counseling to improve the pregnancy outcome for both mother and child
- Drug screening to identify all drugs a client is using
- More frequent prenatal visits to monitor fetal well-being
- Maternal and fetal benefits of remaining drug free
- Cultural sensitivity
- Coping skills, support systems, and vocational assistance

There is nothing categorically different about addiction in pregnancy compared with addiction in general. Pregnant women who use drugs are women who use drugs, get pregnant, and cannot stop using drugs. The fact that they are condemned in society leads to their further marginalization, which does nothing to improve their lives or the lives of their children.

Substance abuse is a complex problem that requires sensitivity to each woman's unique situation and contributing factors. Be sure to address individual psychological and sociocultural factors to help the woman regain control of her life. Treatment must combine different approaches and provide ongoing support for women learning to live drug free. Developing personal strengths, such as communication skills, assertiveness,

and self-confidence, will help the woman to resist drug use. Encourage the use of appropriate coping skills. Enhancing self-esteem also helps provide a foundation to avoid drugs.

### KEY CONCEPTS

- Preconception counseling for the woman with diabetes is helpful in promoting blood glucose control to prevent congenital anomalies.
- The classification system for diabetes is based on disease etiology and not pharmacology management; the classification includes type 1 diabetes, type 2 diabetes, gestational diabetes, and impaired fasting glucose and impaired glucose tolerance.
- A functional classification for heart disease during pregnancy is based on past and present disability: class I, asymptomatic with no limitation of physical activity; class II, symptomatic (dyspnea, chest pain) with increased activity; class III, symptomatic (fatigue, palpitation) with normal activity; and class IV, symptomatic at rest or with any physical activity.
- Chronic hypertension exists when the woman has a blood pressure of 140/90 mm Hg or higher before pregnancy or before the 20th week of gestation or when hypertension persists for more than 12 weeks' postpartum.
- Successful management of asthma in pregnancy involves elimination of environmental triggers, drug therapy, and client education.
- Ideally, women with hematologic conditions are screened before conception and are made aware of the risks to themselves and to a pregnancy.
- A wide variety of infections, such as cytomegalovirus, rubella, herpes simplex, hepatitis B, varicella, parvovirus B19, and many sexually transmitted infections can affect a pregnancy, having a negative impact on its outcome.
- The prevalence of HIV/AIDS is increasing more rapidly among women than men: half of all the HIV/AIDS cases worldwide now occur in women. There are only three recognized modes of HIV transmission: unprotected sexual intercourse with an infected partner, contact with infected blood or blood products, and perinatal transmission. Breast-feeding is a major contributing factor in mother-to-child transmission of HIV.
- Cases of perinatal AIDS have decreased in the past several years in the United States, primarily because of the use of zidovudine (ZDV) therapy in pregnant women with HIV. The U.S. Preventive Services Task Force recommends that all pregnant women should

be offered HIV antibody testing regardless of their risk of infection, and that testing should be done during the initial prenatal evaluation.

- The younger an adolescent is at the time of her first pregnancy, the more likely it is that she will have another pregnancy during her teens. About 1 million teenagers between the ages of 15 and 19 become pregnant each year; about half give birth and keep their infants.
- The nurse's role in caring for the pregnant adolescent is to assist her in identifying the options for this pregnancy, including abortion, self-parenting of the child, temporary foster care for the baby or herself, or placement for adoption.
- Pregnant women with substance abuse problems commonly abuse several substances, making it difficult to ascribe a specific perinatal effect to any one substance. Societal attitudes regarding pregnant women and substance abuse may prohibit them from admitting the problem and seeking treatment.
- Substance abuse during pregnancy is associated with preterm labor, abortion, low birth weight, CNS and fetal anomalies, and long-term childhood developmental consequences.
- Fetal alcohol spectrum disorder is a lifelong yet completely preventable set of physical, mental, and neurobehavioral birth defects; it is the leading cause of intellectual disability in the United States.
- Nursing management for the woman with substance abuse focuses on screening and preventing substance abuse to reduce the high incidence of obstetric and medical complications as well as the morbidity and mortality among passively addicted newborns.

## MULTIPLE-CHOICE QUESTIONS

- Which of the following would the nurse include when teaching a pregnant woman about the pathophysiologic mechanisms associated with gestational diabetes?
  - Pregnancy fosters the development of carbohydrate cravings.
  - There is progressive resistance to the effects of insulin.
  - Hypoinsulinemia develops early in the first trimester.
  - Glucose levels decrease to accommodate fetal growth.
- When providing prenatal education to a pregnant woman with asthma, which of the following would be important for the nurse to do?
  - Explain that she should avoid steroids during her pregnancy.
  - Demonstrate how to assess her blood glucose levels.
  - Teach correct administration of subcutaneous bronchodilators.
  - Ensure she seeks treatment for any acute exacerbation.
- Which of the following conditions would most likely cause a pregnant woman with type 1 diabetes the greatest difficulty during her pregnancy?
  - Placenta previa
  - Hyperemesis gravidarum
  - Abruptio placentae
  - Rh incompatibility
- Women who drink alcohol during pregnancy:
  - Often produce more alcohol dehydrogenase
  - Usually become intoxicated faster than before
  - Can give birth to an infant with fetal alcohol spectrum disorder
  - Gain fewer pounds throughout the gestation
- When explaining to a pregnant woman about HIV infection and transmission, which of the following would the nurse include?
  - It primarily occurs when there is a large viral load in the blood.
  - HIV is most commonly transmitted via sexual contact.
  - It affects the majority of infants of mothers with HIV infection.
  - Nurses are most frequently affected due to needlesticks.

## CRITICAL THINKING EXERCISE

- A client at 26 weeks' gestation came to the clinic to follow up on her previous 1-hour glucose screening. Her results had come back outside the accepted screening range, and a 3-hour glucose tolerance test (GTT) had been ordered. It resulted in three abnormal values, confirming a diagnosis of gestational diabetes. As the nurse in the prenatal clinic you are seeing her for the first time.
  - What additional information will you need to provide care for her?
  - What education will she need to address this new diagnosis?
  - How will you evaluate the effectiveness of your interventions?
- A 14-year-old girl comes to the public health clinic with her mother. The mother tells you that her daughter has been "out messing around and has gotten herself pregnant." The girl is crying quietly in the corner and avoids eye contact with you. The mother reports that her daughter "must be following in my footsteps" because she became pregnant when she was only 15 years old. The client's mother goes back out into the waiting room and leaves the client with you.
  - What is your first approach with the client to gain her trust?
  - List the client's educational needs during this pregnancy.
  - What prevention strategies are needed to prevent a second pregnancy?
- Linda, a 27-year-old G3P2, is admitted to the labor and birth suite because of preterm rupture of membranes at an estimated 35 weeks' gestation. She has received no prenatal care and reports this was an unplanned pregnancy. Linda appears distracted and very thin. She reports that her two previous children have been in foster care since birth because the child welfare authorities "didn't think I was an adequate mother." She denies any recent use of alcohol or drugs, but you smell alcohol on her breath. She has a spontaneous vaginal birth a few hours later, producing a 4-lb baby boy with Apgar scores of 8 at 1 minute and 9 at 5 minutes.
  - What aspects of this woman's history may lead the nurse to suspect that this infant may be at risk for fetal alcohol spectrum disorder?
  - What additional screening or laboratory tests might validate your suspicion?
  - What physical and neurodevelopmental deficits might present later in life if the infant has fetal alcohol spectrum disorder?

## STUDY ACTIVITIES

1. In the maternity clinic or hospital setting, interview a pregnant woman with a preexisting medical condition (e.g., diabetes, asthma, sickle cell anemia) and find out how this condition affects her life and this pregnancy, especially her lifestyle choices.
2. You have a close friend who has a problem with alcohol but denies it. She now admits to you that she thinks she is pregnant because she missed her period. What specific information and advice should you give her concerning alcohol use during pregnancy?
3. Should marijuana be legalized in the United States? What impact might your view (pro or con) have on pregnant women and their offspring?
4. Outline a discussion you might have with an HIV-positive pregnant woman who doesn't see the need to take antiretroviral agents to prevent perinatal transmission.
5. The nurse is preparing a teaching session about breastfeeding for a group of pregnant women who have various infections listed below. The nurse would include women with which of the following conditions? Select all that apply.
  - a. Hepatitis B
  - b. Parvovirus B19
  - c. Herpesvirus type 2
  - d. HIV-positive status
  - e. Cytomegalovirus
  - f. Varicella-zoster virus

**KEY TERMS**

amnioinfusion  
 arrest disorders  
 cesarean birth  
 dystocia  
 forceps  
 hypertonic uterine  
 dysfunction  
 hypotonic uterine  
 dysfunction  
 labor induction  
 macrosomia  
 multifetal pregnancy  
 precipitate labor  
 preterm labor  
 prolonged  
 pregnancy  
 protracted disorders  
 shoulder dystocia  
 tocolytic  
 umbilical cord  
 prolapse  
 vacuum extractor  
 vaginal birth after  
 cesarean (VBAC)

# Nursing Management of Labor and Birth at Risk

## Learning Objectives

*Upon completion of the chapter, you will be able to:*

1. Define the key terms used in this chapter.
2. Propose at least five risk factors associated with dystocia.
3. Differentiate the four major abnormalities or problems associated with dysfunctional labor patterns, giving examples of each problem.
4. Examine the nursing management for the woman with dysfunctional labor experiencing a problem with the powers, passenger, passageway, or psyche.
5. Devise a plan of care for the woman experiencing preterm labor.
6. Relate the nursing assessment and management of the woman experiencing a prolonged pregnancy.
7. Assess four obstetric emergencies that can complicate labor and birth, including appropriate management for each.
8. Compare and contrast the nursing management for the woman undergoing labor induction or augmentation, forceps- and vacuum-assisted birth.
9. Summarize the plan of care for a woman who is to undergo a cesarean birth.
10. Evaluate the key areas to be addressed when caring for a woman who is to undergo vaginal birth after cesarean (VBAC).

*Jennifer, a 29 year-old G1P0, is at 41 weeks' gestation. Her health care provider has recommended that she come in for induction. She is very anxious about doing this since she has heard "horror stories" about the "hard painful contractions" that can result. What can the nurse do to calm her fears?*

## Words of Wisdom

In the face of a crisis or a potentially bad outcome, add a mixture of warmth and serenity to your technical abilities.

**Most** women describe pregnancy as an exciting time in their life, but the development of an unexpected problem can suddenly change this description dramatically. Consider the woman who has had a problem-free pregnancy and then suddenly develops a condition during labor, changing a routine situation into a possible crisis. Many complications occur with little or no warning and present challenges for the perinatal health care team as well as the family. The nurse plays a major role in identifying the problem quickly and coordinating immediate intervention, ultimately achieving a positive outcome.

National health goals address maternal and newborn outcomes involving complications of labor and birth and cesarean birth (U.S. Department of Health and Human Services, 2010). These goals are highlighted in *Healthy People 2020*.

This chapter will address several conditions occurring during labor and birth that may increase the risk of an adverse outcome for the mother and fetus. It also describes birth-related procedures that may be necessary for the woman who develops a condition that increases her risk or that may be needed to reduce the woman's risk for developing a condition, thus promoting optimal maternal and fetal outcomes. Nursing management of the woman and her family focuses on professional support and compassionate care.

## DYSTOCIA

**Dystocia**, defined as abnormal or difficult labor, can be influenced by a vast number of maternal and fetal factors. Dystocia is said to exist when the progress of

labor deviates from normal; it is characterized by a slow and abnormal progression of labor. It occurs in approximately 8% to 11% of all labors and is the leading indicator for primary cesarean birth in the United States (Joy, Scott, & Lyon, 2011).

To characterize a labor as abnormal, a basic understanding of normal labor is essential. Normal labor starts with regular uterine contractions that are strong enough to result in cervical effacement and dilation. Early in labor, uterine contractions are irregular and cervical effacement and dilation occur gradually. When cervical dilation reaches 4 cm and uterine contractions become more powerful, the active phase of labor begins. It is usually during the active phase that dystocia becomes apparent. Because dystocia cannot be predicted or diagnosed with certainty, the term “failure to progress” is often used. This term includes lack of progressive cervical dilation, lack of descent of the fetal head, or both. An adequate trial of labor is needed to declare with confidence that dystocia or “failure to progress” exists.

Early identification of and prompt interventions for dystocia are essential to minimize risk to the woman and fetus. According to the American College of Obstetricians and Gynecologists (ACOG) (2009c), factors associated with an increased risk for dystocia include epidural analgesia, excessive analgesia, multifetal pregnancy, hydramnios, maternal exhaustion, ineffective maternal pushing technique, occiput posterior position, longer first stage of labor, nulliparity, short maternal stature (less than 5 feet tall), fetal birth weight (more than 8.8 lb), shoulder dystocia, abnormal fetal presentation or position (breech), fetal anomalies (hydrocephalus), maternal age older than 35 years, high caffeine intake, overweight, gestational age more than 41 weeks, chorioamnionitis, ineffective uterine contractions, and high fetal station at complete cervical dilation.

Dystocia can result from problems or abnormalities involving the expulsive forces (known as the “powers”); presentation, position, and fetal development (the “passenger”); the maternal bony pelvis or birth canal (the “passageway”); and maternal stress (the “psyche”). Table 21.1 summarizes the diagnosis, therapeutic management, and nursing management of the common problems associated with dystocia.

### HEALTHY PEOPLE 2020 • 21-1

Objective	Nursing Significance
<b>MICH-9</b> Reduce preterm births	<ul style="list-style-type: none"> <li>Will help to focus attention on the need for close antepartum surveillance and identification of risks factors for preterm labor/births and provide appropriate interventions to reduce it.</li> </ul>
<b>MICH-7</b> Reduce cesarean births among low-risk (full-term, singleton, vertex presentation) women	<ul style="list-style-type: none"> <li>Will help to reduce the number of surgical births with accompanying risk factors and costs by appropriate labor management, continual labor support, and practice patterns, while helping to ensure positive maternal and newborn outcomes.</li> </ul>

*Healthy People* objectives based on data from <http://www.healthypeople.gov>.

### Problems with the Powers

When the expulsive forces of the uterus become dysfunctional, the uterus may either never fully relax (hypertonic contractions), placing the fetus in jeopardy, or relax too much (hypotonic contractions), causing ineffective contractions. Still another dysfunction can occur when the uterus contracts so frequently and with such intensity that a very rapid birth will take place (precipitate labor).

	Description	Diagnosis	Therapeutic Management	Nursing Management
Problems with the Powers				
Hypertonic uterine dysfunction	<p>Occurring in the latent phase of the first stage of labor (cervical dilation of &lt;4 cm); uncoordinated.</p> <p>Force of contraction typically in the midsection of uterus at the junction of the active upper and passive lower segments of the uterus rather than in the fundus.</p> <p>Loss of downward pressure to push the presenting part against the cervix</p> <p>Woman commonly becomes discouraged due to lack of progress; also has increased pain secondary to uterine anoxia.</p>	<p>Characteristic hypertonicity of the contractions and the lack of labor progress</p>	<p>Therapeutic rest with the use of sedatives to promote relaxation and stop the abnormal activity of the uterus.</p> <p>Identification and intervention of any contributing factors.</p> <p>Ruling out abruptio placentae (also associated with high resting tone and persistent pain).</p> <p>Onset of a normal labor pattern occurs in many women after a 4- to 6-hr rest period.</p>	<p>Institute bed rest and sedation to promote relaxation and reduce pain.</p> <p>Assist with measures to rule out fetopelvic disproportion and fetal malpresentation.</p> <p>Evaluate fetal tolerance to labor pattern, such as monitoring of FHR patterns.</p> <p>Assess for signs of maternal infection.</p> <p>Promote adequate hydration through IV therapy.</p> <p>Provide pain management via epidural or IV analgesics.</p> <p>Assist with amniotomy to augment labor.</p> <p>Explain to woman and family about dysfunctional pattern.</p> <p>Plan for operative birth if normal labor pattern is not achieved.</p>
Hypotonic uterine dysfunction	<p>Often termed secondary uterine inertia because the labor begins normally and then the frequency and intensity of contractions decrease. Possible contributing factors: overdistended uterus with multifetal pregnancy or large single fetus, too much pain medicine given too early in labor, fetal malposition, and regional anesthesia</p>	<p>Evaluation of the woman's labor to confirm that she is having hypotonic active labor rather than a long latent phase.</p> <p>Evaluation of maternal pelvis and fetal presentation and position to ensure that they are not contributing to the prolonged labor without noticeable progress.</p>	<p>Identification of possible cause of inefficient uterine action (a malpositioned fetus, a too small maternal pelvis, overdistention of the uterus with fluid or a macrosomic fetus).</p> <p>Rupture of amniotic sac (amniotomy) if all causes ruled out.</p> <p>Possible augmentation with oxytocin (Pitocin) to stimulate effective uterine contractions.</p> <p>Cesarean birth if amniotomy and augmentation ineffective.</p>	<p>Administer oxytocin as ordered once fetopelvic disproportion is ruled out.</p> <p>Assist with amniotomy if membranes are intact.</p> <p>Provide continuous electronic fetal monitoring.</p> <p>Monitor vital signs, contractions, and cervix continually.</p> <p>Assess for signs of maternal and fetal infection.</p> <p>Explain to woman and family about dysfunctional pattern.</p> <p>Plan for surgical birth if normal labor pattern is not achieved or fetal distress occurs.</p>

Precipitate labor	Abrupt onset of higher-intensity contractions occurring in a shorter period of time instead of the more gradual increase in frequency, duration, and intensity that typifies most spontaneous labors	Identification based on the rapidity of progress through the stages of labor	Vaginal delivery if maternal pelvis is adequate	Closely monitor woman with previous history. Anticipate use of scheduled induction to control labor rate. Administer pharmacologic agents, such as tocolytics, to slow labor. Stay in constant attendance to monitor progress.
Problems with the Passenger	Engagement of fetal head in the left or right occipito-transverse position with the occiput rotating posteriorly rather than into the more favorable occiput anterior position (fetus born facing upward instead of the normal downward position) Labor usually much longer and more uncomfortable (causing increased back pain during labor) if fetus remains in this position. Possible extensive caput succedaneum and molding from the sustained occiput posterior position.	Leopold maneuvers and vaginal examination to determine position of fetal head in conjunction with the mother's complaints of severe back pain (back of fetal head pressing on mother's sacrum and coccyx).	Labor to proceed, preparing the woman for a long labor (spontaneous resolution possible). Comfort measures and maternal positioning to help promote fetal head rotation.	Assess for complaints of intense back pain in first stage of labor. Anticipate possible use of forceps to rotate to anterior position at birth or manual rotation to anterior position at end of second stage. Assess for prolonged second stage of labor with arrest of descent (common with this malposition). Encourage maternal position changes to promote fetal head rotation: hands and knees and rocking pelvis back and forth; side-lying position; side lunges during contractions; sitting, kneeling, or standing while leaning forward; squatting position to give birth and enlarge pelvic outlet. Prepare for possible cesarean birth if rotation is not achieved. Administer agents as ordered for pain relief (effective pain relief crucial to help the woman to tolerate the back discomfort). Apply low back counter pressure during contractions to ease the discomfort. Use other helpful measures to attempt to rotate the fetal head, including lateral abdominal stroking in the direction that the fetal head should rotate; assisting the client into a hands-and-knees position (all fours); and squatting, pelvic rocking, stair climbing, assuming a side-lying position toward the side that the fetus should rotate, and side lunges. Provide measures to reduce anxiety. Continuously reinforce the woman's progress. Teach woman about measures to facilitate fetal head rotation.

TABLE 21.1

## DIAGNOSIS AND MANAGEMENT OF COMMON PROBLEMS ASSOCIATED WITH DYSTOCIA (continued)

	<b>Description</b>	<b>Diagnosis</b>	<b>Therapeutic Management</b>	<b>Nursing Management</b>
Face and brow presentation	Face presentation with complete extension of the fetal head. Brow presentation: fetal head between full extension and full flexion so that the largest fetal skull diameter presents to the pelvis.	Diagnosis only once labor is well established via vaginal examination; palpation of facial features as the presenting part rather than the fetal head	Vaginal birth possible with face presentation with an adequate maternal pelvis and fetal head rotation; cesarean birth if head rotates backward. Cesarean birth for brow presentation unless head flexes.	Assist with evaluating for fetopelvic disproportion. Anticipate cesarean birth if vertex position is not achieved. Explain fetal malposition to the woman and her partner. Provide close observation for any signs of fetal hypoxia, as evidenced by late decelerations on the fetal monitor.
Breech presentation	Fetal buttocks, or breech, presenting first rather than the head. 1. Frank breech: buttock as the presenting part, with hips flexed and legs and knees extended upward 2. Complete breech (or full breech): buttock as presenting part, with hips flexed and knees flexed in a “cannonball” position 3. Footling or incomplete breech: One or two feet as the presenting part, with one or both hips extended	Vaginal examination to determine breech presentation. Ideally, ultrasound to confirm a clinically suspected presentation and to identify any fetal anomalies.	The optimal method of birth is controversial: cesarean birth by some providers unless the fetus is small and the mother has a large pelvis; vaginal birth by others with each occurrence treated individually and labor monitored very closely. Regardless of the birth method selected, the risk for trauma is high. Breech vaginal births are not recommended by ACOG and come with a higher risk to the mother and infant than a planned surgical birth. Vaginal delivery: fetus allowed to spontaneously deliver up to the umbilicus; then maneuvers to assist in the delivery of the remainder of the body, arms, and head; fetal membranes left intact as long as possible and to prevent cord prolapse; anesthesiologist and pediatrician present.	Assess for associated conditions such as placenta previa, hydramnios, fetal anomalies, and multifetal pregnancy. Arrange for ultrasound to confirm fetal presentation. Assist with external cephalic version possible after 36 weeks and administer tocolytics to assist with external cephalic version. Anticipate trial labor for 4 to 6 hr to evaluate progress if version is unsuccessful. Plan for cesarean birth if no progress is seen or fetal distress occurs. After external cephalic version, administer RhoGAM to the Rh-negative woman to prevent a sensitization reaction if trauma has occurred and the potential for mixing of blood exists.

Cesarean birth; use of external cephalic version to reduce the chance of breech presentation at birth; attempted after the 36th week of gestation but before the start of labor (some fetuses spontaneously turn to a cephalic presentation on their own toward term, and some will return to the breech presentation if external cephalic version is attempted too early; variable success rates, with risk for fractured bones, ruptured viscera, abruptio placentae, fetomaternal hemorrhage, and umbilical cord entanglement. Tocolytic drugs to relax the uterus, as well as other methods, to facilitate external cephalic version at term. Individual evaluation of each woman for all factors before any interventions are initiated.

Shoulder dystocia

Delivery of fetal head with neck not appearing; retraction of chin against the perineum; shoulders remaining wedged behind the mother's pubic bone, causing a difficult birth with potential for injury to both mother and baby.  
If shoulders still above the brim at this stage, no advancement. Newborn's chest trapped within the vaginal vault; chest unable to expand with respiration (although nose and mouth are outside).

Emergency, often unexpected complication. Diagnosis made when newborn's head delivers without delivery of neck and remaining body structures.

If anticipated, preparatory tasks instituted: alerting of key personnel; education of woman and family regarding steps to be taken in the event of a difficult birth; emptying of woman's bladder to allow additional room for possible maneuvers needed for the birth. McRobert's maneuver. Suprapubic pressure (not fundal) (see Fig. 21.1).

Intervene immediately due to cord compression.  
Perform McRobert's maneuver and application of suprapubic pressure. Assist with positioning the woman in squatting position, hands-and-knees position, or lateral recumbent position for birth to free shoulder.  
Anticipate cesarean birth if no success in dislodging shoulders.

(continued)

TABLE 21.1

## DIAGNOSIS AND MANAGEMENT OF COMMON PROBLEMS ASSOCIATED WITH DYSTOCIA (continued)

Description	Diagnosis	Therapeutic Management	Nursing Management
Risk of umbilical cord compression between the fetal body and the maternal pelvis.	Primary risk factors, including suspected infant macrosomia (weight >4,500 g), maternal diabetes mellitus, excessive maternal weight gain, abnormal maternal pelvic anatomy, maternal obesity, postdated pregnancy, short stature, a history of previous shoulder dystocia, and use of epidural analgesia	Combination of maneuvers effective in more than 50% of cases of shoulder dystocia Newborn resuscitation team readily available.	Clear room of unnecessary clutter to make room for additional personnel and equipment. After the birth, assess newborn for crepitus, deformity, Erb's palsy, or bruising, which might suggest neurologic damage or a fracture.
Multifetal pregnancy  More than one fetus, leading to uterine overdistention and possibly resulting in hypotonic contractions and abnormal presentations of the fetuses. Fetal hypoxia during labor a significant threat due to placenta providing oxygen and nutrients to more than one fetus.	Nearly all multiples are now diagnosed early by ultrasound. Most women go into labor before 37 weeks.	Admission to facility with specialized care unit if woman goes into labor. Spontaneous progression of labor if woman has no complicating factors and first fetus is in longitudinal lie. Separate monitoring of each FHR during labor and birth. After birth of first fetus, clamping of cord and lie of the second twin assessed. Possible external cephalic version necessary to assist in providing a longitudinal lie. Second and subsequent fetuses at greater risk for birth-related complications, such as umbilical cord prolapse, malpresentation, and abruptio placentae. Cesarean birth if risk factors high.	Assess for hypotonic labor pattern due to overdistention. Evaluate for fetal presentation, maternal pelvic size, and gestational age to determine mode of delivery. Ensure presence of neonatal team for birth of multiples. Anticipate need for cesarean birth, which is common in multifetal pregnancy.

<p>Excessive fetal size and abnormalities</p>	<p>Macrosomia leading to fetopelvic disproportion (fetus unable to fit through the maternal pelvis to be born vaginally). Reduced contraction strength due to overdistention by large fetus leading to a prolonged labor and the potential for birth injury and trauma. Fetal abnormalities possibly interfering with fetal descent, leading to prolonged labor and difficult birth.</p>	<p>A diagnosis of fetal macrosomia can be confirmed by measuring the birth weight after birth. Suspicion of macrosomia based on the findings of an ultrasound examination before onset of labor (if suspected due to conditions such as maternal diabetes or obesity, estimation of fetal weight via ultrasound). Leopold's maneuvers to estimate fetal weight and position on admission to labor and birth unit.</p>	<p>Scheduled cesarean birth if diagnosis is made before the onset of labor to reduce the risk of injury to both the newborn and the mother. If identified by Leopold's maneuvers, possible trial of labor to evaluate progress; however, providers usually opt to proceed with a cesarean birth in a primigravida with a macrosomic fetus.</p>	<p>Assess for inability of fetus to descend. Anticipate need for vacuum and forceps-assisted births (common). Plan for cesarean birth if maternal parameters are inadequate to give birth to large fetus.</p>
<p>Problems with the Passageway</p>	<p>Contraction of one or more of the three planes of the pelvis. Poorer prognosis for vaginal birth in women with android and platypelloid types of pelvis. Contracted pelvis involving reduction in one or more of the pelvic diameters interfering with progress of labor: inlet, midpelvis, and outlet contraction. Obstruction in the birth canal, such as placenta previa that partially or completely obstructs the internal os of the cervix, fibroids in the lower uterine segment, a full bladder or rectum, an edematous cervix caused by premature bearing-down efforts, and human papillomavirus (HPV) warts.</p>	<p>Shortest A-P diameter &lt;10 cm or greatest transverse diameter &lt;12 cm. (Approximation of A-P diameter via measurement of diagonal conjugate, which in the contracted pelvis is &lt;11.5 cm.) X-ray pelvimetry to determine the smallest A-P diameter through which the fetal head must pass. Interschial tuberosity diameter of &lt;8 cm possibly compromising outlet contraction (outlet and midpelvic contractures frequently occur together).</p>	<p>Focus on allowing natural forces of labor contractions to push the largest diameter (biparietal) of the fetal head beyond the obstruction or narrow passage. Possible forceps and vacuum extraction to assist navigation through this passageway.</p>	<p>Assess for poor contractions, slow dilation, prolonged labor. Evaluate bowel and bladder status to reduce soft tissue obstruction and allow increased pelvic space. Anticipate trial of labor; if no labor progression after an adequate trial, plan for cesarean birth.</p>

(continued)

## DIAGNOSIS AND MANAGEMENT OF COMMON PROBLEMS ASSOCIATED WITH DYSTOCIA (continued)

Description	Diagnosis	Therapeutic Management	Nursing Management
Problems with the Psyche	Ruling out of other possible causes of dystocia	<p>Treatment dependent on woman's responses such as anxiety, fear, anger, frustration, or denial (highly variable due to woman's understanding of the condition itself, past experiences, previous coping mechanisms, and the amount of family and nursing support received).</p> <p>Appropriate medical or surgical interventions depending on the underlying condition.</p>	<p>Provide comfortable environment—dim lighting, music.</p> <p>Encourage partner to participate.</p> <p>Provide pain management to reduce anxiety and stress.</p> <p>Ensure continuous presence of staff to allay anxiety.</p> <p>Provide frequent updates concerning fetal status and progress.</p> <p>Provide ongoing encouragement to minimize the woman's stress and help her to cope with labor and to promote a positive, timely outcome.</p> <p>Assist in relaxation and comfort measures to help her body work more effectively with the forces of labor.</p>
<p>Release of stress-related hormones (catecholamines, cortisol, epinephrine, beta-endorphin), which act on smooth muscle (uterus) and reduce uterine contractility. Excessive release of catecholamines and other stress-related hormones not therapeutic.</p> <p>Release also results in decreased uteroplacental perfusion and increased risk for poor newborn adjustment.</p>			<p>Engage the woman in conversation about her emotional well-being; offer anticipatory guidance and reassurance to increase her self-esteem and ability to cope, decrease frustration, and encourage cooperation.</p>

**Hypertonic uterine dysfunction** occurs when the uterus never fully relaxes between contractions. Subsequently, contractions are erratic and poorly coordinated because more than one uterine pacemaker is sending signals for contraction. Contractions are ineffectual, erratic, uncoordinated, and involve only a portion of the uterus. Women in this situation experience a prolonged latent phase, stay at 2 to 3 cm, and do not dilate as they should. Placental perfusion becomes compromised, thereby reducing oxygen to the fetus. These hypertonic contractions exhaust the mother, who is experiencing frequent, intense, and painful contractions with little progression. This dysfunctional pattern occurs in early labor and affects nulliparous women more than multiparous women (Walsh, Foley, & O'herlihy, 2011).

**Hypotonic uterine dysfunction** occurs during active labor (dilation more than 4 cm) when contractions become poor in quality and lack sufficient intensity to dilate and efface the cervix. Factors associated with this abnormal labor pattern include overstretching of the uterus, a large fetus, multiple fetuses, hydramnios, multiple parity, bowel or bladder distention preventing descent, and excessive use of analgesia. Clinical manifestations of hypotonic uterine dysfunction include weak contractions that become milder, a uterine fundus that can be easily indented with fingertip pressure at the peak of each contraction, and contractions that become more infrequent and briefer (Joy et al., 2011). The major risk with this complication is hemorrhage after giving birth because the uterus cannot contract effectively to compress blood vessels.

*Labor* refers to uterine contractions resulting in progressive dilation and effacement of the cervix, and accompanied by descent and expulsion of the fetus. *Abnormal labor*, *dystocia*, and *failure to progress* are imprecise terms that have been used to describe a difficult labor pattern that deviates from that observed in the majority of women who have spontaneous vaginal deliveries. A better classification is to characterize labor abnormalities as protraction disorders (i.e., slower than normal progress) or arrest disorders (i.e., complete cessation of progress).

The term **protracted disorders** refers to a series of events including protracted active phase dilation (slower than normal rate of cervical dilation) and protracted descent (delayed descent of the fetal head in the active phase). A laboring woman who has a slower than normal rate of cervical dilation is said to have a protraction labor pattern disorder. In terms of time, it describes a labor lasting more than 18 to 24 hours. Diagnostic criteria are 1.2 cm per hour for primips and 1.5 cm per hour for multips. For protracted descent, the criteria are less than 1.0 cm per hour in primips and less than 2.0 cm per hour for multips (Tharpe, Farley, & Jordan, 2013). A slow progress may be the result of cephalopelvic disproportion (CPD). Most women, however, benefit greatly from adequate hydration and some nutrition, emotional reassurance,

and position changes—these women may go on and give birth vaginally.

**Arrest disorders** include secondary arrest of dilation (no progress in cervical dilation in more than 2 hours), arrest of descent (fetal head does not descend for more than 1 hour in primip and more than 0.5 hour in multip), and failure of descent (no descent). About 20% of labors involve either protraction or arrest disorders (Satin, 2010).

**Precipitate labor** is labor that is completed in less than 3 hours from the start of contractions to birth. A nullipara's cervix dilates faster than 5 cm per hour or the fetal head descends faster than 1 cm per 12 minutes. A multipara's cervix dilates faster than 10 cm per hour or the fetal head descends faster than 1 cm per 6 minutes (Gilbert, 2011). Women experiencing precipitate labor typically have soft perineal tissues that stretch readily, permitting the fetus to pass through the pelvis quickly, or abnormally strong uterine contractions. Maternal complications are rare if the maternal pelvis is adequate and the soft tissues yield to a fast fetal descent. However, if the fetus delivers too fast, it does not allow the cervix to dilate and efface, which leads to cervical lacerations and the potential for uterine rupture. Potential fetal complications may include head trauma, such as intracranial hemorrhage or nerve damage, and hypoxia due to the rapid progression of labor (Barss, 2011).

Precipitate labor is an anxiety-producing situation and frequently very painful with little rest between contractions. Continuous monitoring, frequent updates on her labor progress, pain management and reassurance about her condition can assist in reducing the mother's anxious state of mind. Management includes readiness of the health care team for this rapid birth.

## Problems with the Passenger

Any presentation other than occiput anterior or a slight variation of the fetal position or size increases the probability of dystocia. These variations can affect the contractions or fetal descent through the maternal pelvis. Common problems involving the fetus include occiput posterior position, breech presentation, multifetal pregnancy, excessive size (macrosomia) as it relates to CPD, and structural anomalies.

Persistent occiput posterior is the most common malposition, occurring in about 15% of laboring women. The reasons for this malposition are often unclear. This position presents slightly larger diameters to the maternal pelvis, thus slowing fetal descent. A fetal head that is poorly flexed may be responsible. In addition, poor uterine contractions may not push the fetal head down into the pelvic floor to the extent that the fetal occiput sinks into it rather than being pushed to rotate in an anterior direction.

Face and brow presentations are rare and are associated with fetal abnormalities (anencephaly), pelvic contractures, high parity, placenta previa, hydramnios, low birth weight, or a large fetus (World Health Organization [WHO], 2010).

Breech presentation, which occurs in 3% to 4% of labors, is frequently associated with multifetal pregnancies, grand multiparity (more than five births), advanced maternal age, placenta previa, hydramnios, preterm births, uterine malformations or fibroids, and fetal anomalies such as hydrocephaly (Fischer, 2011). In a persistent breech presentation, an increased frequency of prolapsed cord, placenta previa, low birth weight from preterm birth, fetal or uterine anomalies, and perinatal morbidity and mortality from a difficult birth may occur (Cunningham et al., 2010). Perinatal mortality is increased two- to fourfold with a breech presentation, regardless of the mode of delivery. Recent research has found that a planned surgical birth versus a vaginal birth does improve perinatal outcomes (Hofmeyer, Hannah, & Lawrie, 2011).

**Shoulder dystocia** is defined as the obstruction of fetal descent and birth by the axis of the fetal shoulders after the fetal head has been delivered. The incidence of shoulder dystocia is increasing due to increasing birth weight, with reports of it in up to 2% of vaginal births. It is one of the most anxiety-provoking emergencies encountered in labor. Failure of the shoulders to deliver spontaneously places both the woman and the fetus at risk for injury. Postpartum hemorrhage, secondary to uterine atony or vaginal lacerations, is the major complication to the mother. Transient Erb's or Duchenne's brachial plexus palsies and clavicular or humeral fractures are the most common fetal injuries encountered with shoulder dystocia

(WHO, 2010). Newborns experiencing shoulder dystocia typically have greater shoulder-to-head and chest-to-head disproportions compared with those delivered without dystocia (Cunningham et al., 2010). Prompt recognition and appropriate management, such as with McRobert's maneuver or suprapubic pressure, can reduce the severity of injuries to the mother and newborn (Fig. 21.1).

### Take Note!

Prompt recognition and appropriate management of shoulder dystocia can reduce the severity of injuries to the mother and infant. Immediately assess the infant for signs of trauma such as a fractured clavicle, Erb's palsy, or neonatal asphyxia. Assess the mother for excessive vaginal bleeding and blood in the urine from bladder trauma.

**Multifetal pregnancy** refers to twins, triplets, or more infants within a single pregnancy (Box 21.1). The incidence is increasing, primarily as a result of infertility treatment (both ovarian stimulation and in vitro fertilization) and an increased number of women giving birth at older ages (March of Dimes, 2011a). The incidence of twins is approximately 1 in 30 conceptions, with about two thirds of them due to the fertilization of two ova (dizygotic or fraternal) and about one third occurring from the splitting of one fertilized ovum (monozygotic or identical twins). One in approximately 8,100 pregnancies results in triplets (March of Dimes, 2011a). The most common maternal complication is postpartum hemorrhage resulting from uterine atony.

Excessive fetal size and abnormalities can also contribute to labor and birth dysfunctions. **Macrosomia**, in which a newborn weighs 4,000 to 4,500 g (8.13 to 9.15 lb)

**FIGURE 21.1** Maneuvers to relieve shoulder dystocia. **(A)** McRobert's maneuver. The mother's thighs are flexed and abducted as much as possible to straighten the pelvic curve. **(B)** Suprapubic pressure. Light pressure is applied just above the pubic bone, pushing the fetal anterior shoulder downward to displace it from above the mother's symphysis pubis. The newborn's head is depressed toward the mother's anus while light suprapubic pressure is applied.

## BOX 21.1

**MULTIFETAL PREGNANCY**

As the name implies, a multifetal pregnancy involves more than one fetus. These fetuses can result from fertilization of a single ovum or multiple ova. Monozygotic (identical) twins develop from one single ovum that divides into equal halves during early cleavage phase. Monozygotic twins are genetically identical, always the same gender, and look very similar in appearance. The number of amnions and chorions depends on the timing of division (cleavage). One fertilized ovum splitting into two separate individuals is termed *natural clones*. This type of twinning occurs in approximately 1 of 250 live births (March of Dimes, 2011a).

Twin pregnancies that are multiple-ova conceptions (dizygotic twins) result from two ova fertilized by two sperm. They are referred to as fraternal twins. Genetically, dizygotic twins are as alike (or unlike) as any other pair or siblings. There are separate amnions and chorions although the chorions and placentas may be fused. The incidence of dizygotic twinning is approximately 1 in 500 Asians, 1 in 125 Caucasians, and as high as 1 in 20 in African populations (March of Dimes, 2011a). Fraternal twins account for two thirds of all twins and there is a tendency to repeat within families. Currently the incidence of fraternal twins is increasing secondary to advancing maternal age when pregnancy occurs and an increase in use of fertility drugs and procedures being done.

Multiple births other than twins can be of the identical type, the fraternal type, or combinations of the two. Triplets can occur from the division of one zygote into two, with one dividing again, producing identical triplets, or they can come from two zygotes, one dividing into a set of identical twins, and the second zygote developing as a single fraternal sibling, or from three separate zygotes. Triplets are said to occur once in 7,000 births and quadruplets once in 660,000 births (March of Dimes, 2011a). In recent years, fertility drugs used to induce ovulation have resulted in a greater frequency of quadruplets, quintuplets, sextuplets, and even octuplets.

or more at birth, complicates approximately 10% of all pregnancies (Jazayeri, 2012). Fetal abnormalities may include hydrocephalus, ascites, or a large mass on the neck or head. Complications associated with dystocia related to excessive fetal size and anomalies include an increased risk for postpartum hemorrhage, dysfunctional labor, fetopelvic disproportion, soft tissue laceration during vaginal birth, fetal injuries or fractures, and asphyxia (Joy et al., 2011).

**Problems with the Passageway**

Problems with the passageway (pelvis and birth canal) are related to a contraction of one or more of the three planes of the maternal pelvis: inlet, midpelvis, and outlet.

The female pelvis can be classified into four types based on the shape of the pelvic inlet, which is bounded anteriorly by the posterior border of the symphysis pubis, posteriorly by the sacral promontory, and laterally by the linea terminalis. The four basic types are gynecoid, anthropoid, android, and platypelloid (see Chapter 12 for additional information). Contraction of the midpelvis is more common than inlet contraction and typically causes an arrest of fetal descent. Obstructions in the maternal birth canal, such as swelling of the soft maternal tissue and cervix, termed soft tissue dystocia, also can hamper fetal descent and impede labor progression outside the maternal bony pelvis.

**Problems with the Psyche**

Many women experience an array of emotions during labor, which may include fear, anxiety, helplessness, being alone, and weariness. These emotions can lead to psychological stress, which indirectly can cause dystocia. Hormones released in response to anxiety can cause dystocia.

Intense anxiety stimulates the sympathetic nervous system, which releases catecholamines that can lead to myometrial dysfunction. Norepinephrine and epinephrine then lead to uncoordinated or increased uterine activity (Cheng & Caughey, 2012).

**Nursing Assessment**

Begin the assessment by reviewing the client's history to look for risk factors for dystocia. Include in the assessment the mother's frame of mind to identify fear, anxiety, stress, lack of support, and pain, which can interfere with uterine contractions and impede labor progress. Helping the woman to relax will promote normal labor progress.

Assess the woman's vital signs. Note any elevation in temperature (might suggest an infection) or changes in heart rate or blood pressure (might signal hypovolemia). Evaluate the uterine contractions for frequency and intensity. Question the woman about any changes in her contraction pattern, such as a decrease or increase in frequency or intensity, and report these. Assess fetal heart rate (FHR) and pattern, reporting any abnormal patterns immediately.

Assess fetal position via Leopold's maneuvers to identify any deviations in presentation or position, and report any deviations. Assist with or perform a vaginal examination to determine cervical dilation, effacement, and engagement of the fetal presenting part. Evaluate for evidence of membrane rupture. Report any malodorous fluid.

**Nursing Management**

Nursing management of the woman with dystocia, regardless of the etiology, requires patience. The nurse should provide physical and emotional support to the client and

her family. The final outcome of any labor depends on the size and shape of the maternal pelvis, the quality of the uterine contractions, and the size, presentation, and position of the fetus. Thus, dystocia is diagnosed not at the start of labor but rather after it has progressed for a time.

### Promoting the Progress of Labor

The nurse plays a major role in determining the progress of labor. Continue to assess the woman, frequently monitoring cervical dilation and effacement, uterine contractions, and fetal descent, and document that all assessed parameters are progressing. Evaluate progress in active labor by using the simple rule of 1 cm per hour for cervical dilation. When the woman's membranes rupture, if they have not already ruptured, observe for visible cord prolapse.

#### Take Note!

If a dysfunctional labor occurs, contractions will slow or fail to advance in frequency, duration, or intensity; the cervix will fail to respond to uterine contractions by dilating and effacing; and the fetus will fail to descend.

Throughout labor, assess the woman's fluid balance status. Check skin turgor and mucous membranes. Monitor intake and output. Also monitor the client's bladder for distention at least every 2 hours and encourage her to empty her bladder often. In addition, monitor her bowel status. A full bladder or rectum can impede descent.

Continue to monitor fetal well-being. If the fetus is in the breech position, be especially observant for visible cord prolapse and note any variable decelerations in heart rate. If either occurs, report it immediately.

Be prepared to administer a labor stimulant such as oxytocin (Pitocin) if ordered to treat hypotonic labor contractions. Anticipate the need to assist with manipulations if shoulder dystocia is diagnosed. Prepare the woman and her family for the possibility of a cesarean birth if labor does not progress.

### Providing Physical and Emotional Comfort

Employ physical comfort measures to promote relaxation and reduce stress. Offer blankets for warmth and a back-rub, if the client wishes, to reduce muscle tension. Provide an environment conducive to rest so the woman can conserve her energy. Lower the lights and reduce external noise by closing the hallway door. Offer a warm shower to promote relaxation (if not contraindicated). Use pillows to support the woman in a comfortable position, changing her position every 30 minutes to reduce tension and to enhance uterine activity and efficiency. Offer her fluids/food as appropriate to moisten her mouth and replenish her energy (Fig. 21.2).

**FIGURE 21.2** The nurse applies a cool, moist washcloth to the client's forehead and offers her ice chips to combat thirst and provide comfort to the woman experiencing dystocia.

Assist with providing counterpressure along with backrubs if the fetus is in the occiput posterior position. Encourage the woman to assume different positions to promote fetal rotation. Upright positions are helpful in facilitating fetal rotation and descent. Also encourage the woman to visualize the descent and birth of the fetus.

Assess the woman's level of pain and degree of distress. Administer analgesics as ordered or according to the facility's protocol.

Evaluate the mother's level of fatigue throughout labor, such as verbal expressions of feeling exhausted, inability to cope in early labor, or inability to rest or calm down between contractions. Praise the woman and her partner for their efforts. Provide empathetic listening to increase the client's coping ability, and remain with the client to demonstrate caring.

### Promoting Empowerment

Educate the client and family about dysfunctional labor and its causes and therapies. Explain therapeutic interventions that may be needed to assist with the labor process. Encourage the client and her partner to participate in decision making about interventions.

Assist the woman and partner in expressing their fears and anxieties. Provide encouragement to help them to maintain control. Support the client and her partner in their coping efforts. Keep the woman and her partner informed of progress and advocate for them.

## PRETERM LABOR

**Preterm labor** is defined as the occurrence of regular uterine contractions accompanied by cervical effacement and dilation before the end of the 37th week of gestation. If not halted, it leads to preterm birth.

Preterm births remain one of the biggest contributors to perinatal morbidity and mortality in the world. According to the March of Dimes (2011c), about 12% of births (one in eight infants) in the United States are premature.

Preterm birth is one of the most common obstetric complications, and its sequelae have a profound effect on the survival and health of the newborn. The rate of preterm births in the United States has increased 35% in the past 20 years. Preterm births account for 75% of neurodevelopmental disorders and other serious morbidities, as well as behavioral and social problems. They account for 85% of all perinatal morbidity and mortality. In addition, up to \$30 billion is spent on maternal and infant care related to prematurity annually (March of Dimes, 2011c). Infants born prematurely also are at risk for serious sequelae such as respiratory distress syndrome, infections, congenital heart defects, thermoregulation problems that can lead to acidosis and weight loss, intraventricular hemorrhage, jaundice, hypoglycemia, feeding difficulties resulting from diminished stomach capacity and an underdeveloped suck reflex, and neurologic disorders related to hypoxia and trauma at birth (Clark & Varner, 2011). Although great strides have been made in neonatal intensive care, prematurity remains the leading cause of death within the first month of life and is the second leading cause of all infant deaths (March of Dimes, 2011c).

The exact cause of preterm labor is not known. Currently, prevention is the goal.

## Therapeutic Management

Predicting the risk of preterm labor is valuable only if there is an available intervention that is likely to improve the situation. According to ACOG, many factors must be considered before selecting an intervention. Many factors influence the decision to intervene when women present with symptoms of preterm labor, including the probability of progressive labor, gestational age, and the risks of treatment. ACOG (2009a) recommends the following as guidelines:

- There are no clear first-line **tocolytic** drugs (drugs that promote uterine relaxation by interfering with uterine contractions) to manage preterm labor. Clinical circumstances and the health care provider's preference should dictate treatment.
- Antibiotics do not appear to prolong gestation and should be reserved for group B streptococcal prophylaxis in women in whom birth is imminent.
- Tocolytic drugs may prolong pregnancy for 2 to 7 days; during this time, steroids can be given to improve fetal lung maturity and the woman can be transported to a tertiary care center.

**FIGURE 21.3** The mother with preterm labor resting in bed at home.

Despite these recommendations, health care providers continue to prescribe pharmacologic treatment for preterm labor at home and in the hospital setting. This treatment often includes oral or intravenous tocolytics and varying degrees of activity restriction (Fig. 21.3). Antibiotics may also be prescribed to treat presumed or confirmed infections. Steroids may be given to enhance fetal lung maturity between 24 and 34 weeks' gestation.

## Tocolytic Therapy

The decision to stop preterm labor is individualized based on risk factors, extent of cervical dilation, membrane status, fetal gestational age, and presence or absence of infection. Tocolytic therapy is most likely ordered if preterm labor occurs before the 34th week of gestation in an attempt to delay birth and thereby to reduce the severity of respiratory distress syndrome and other complications associated with prematurity. Tocolytic therapy does not typically prevent preterm birth, but it may delay it. It is contraindicated for abruptio placentae, acute fetal distress or death, eclampsia or severe preeclampsia, active vaginal bleeding, dilation of more than 6 cm, chorioamnionitis, and maternal hemodynamic instability (Kenyon & Peebles, 2011).

Medications most commonly used for tocolysis include magnesium sulfate (which reduces the muscle's ability to contract), indomethacin (Indocin, a prostaglandin synthetase inhibitor), and nifedipine (Procardia, a calcium channel blocker). These drugs are used "off label," which means that they are effective for this purpose but have not been officially tested and developed for this purpose by the U.S. Food and Drug Administration (FDA) (King & Brucker, 2011). In a recent Cochrane review study, calcium channel blockers were found to be better in preventing preterm labor when compared to beta-mimetics (King, Flenady, Papatsonis, Dekker, & Carbonne, 2011). All of these medications have serious side effects, and the woman needs close supervision when they are being administered (Drug Guide 21.1).

**DRUG GUIDE 21.1 MEDICATIONS USED WITH PRETERM LABOR**

Drug	Action/Indication	Nursing Implications
Magnesium sulfate	<p>Relaxes uterine muscles to stop irritability and contractions, to arrest uterine contractions for preterm labor (off-label use).</p> <p>Has been used in seizure prophylaxis and treatment of seizures in preeclamptic and eclamptic clients for almost 100 yr</p>	<p>Administer IV with a loading dose of 4–6 g over 15–30 min initially, and then maintain infusion at 1–4 g/hr.</p> <p>Assess vital signs and deep tendon reflexes (DTRs) hourly; report any hypotension or depressed or absent DTRs.</p> <p>Monitor level of consciousness; report any headache, blurred vision, dizziness, or altered level of consciousness.</p> <p>Perform continuous electronic fetal monitoring; report any decreased FHR variability, hypotonia, or respiratory depression.</p> <p>Monitor intake and output hourly; report any decrease in output (&lt;30 mL/hr).</p> <p>Assess respiratory rate; report respiratory rate &lt;12 breaths/min; auscultate lung sounds for evidence of pulmonary edema.</p> <p>Monitor for common maternal side effects, including flushing, nausea and vomiting, dry mouth, lethargy, blurred vision, and headache.</p> <p>Assess for nausea, vomiting, transient hypotension, lethargy.</p> <p>Assess for signs and symptoms of magnesium toxicity, such as decreased level of consciousness, depressed respirations and DTRs, slurred speech, weakness, and respiratory and/or cardiac arrest.</p> <p>Have calcium gluconate readily available at the bedside to reverse magnesium toxicity.</p>
Indomethacin (Indocin)	<p>Inhibits prostaglandins, which stimulate contractions; inhibits uterine activity to arrest preterm labor</p>	<p>Continuously assess vital signs, uterine activity, and FHR.</p> <p>Administer oral form with food to reduce GI irritation.</p> <p>Do not give to women with peptic ulcer disease.</p> <p>Schedule ultrasound to assess amniotic fluid volume and function of ductus arteriosus before initiating therapy; monitor for signs of maternal hemorrhage.</p> <p>Be alert for maternal adverse effects such as nausea and vomiting, heartburn, rash, prolonged bleeding time, oligohydramnios, and hypertension.</p> <p>Monitor for neonatal adverse effects, including constriction of ductus arteriosus, premature ductus closure, necrotizing enterocolitis, oligohydramnios, and pulmonary hypertension.</p> <p>Contraindicated in &gt;32 weeks' gestations, intrauterine growth restriction, history of asthma, urticaria, or allergic type reactions to aspirin or NSAIDs.</p>
Nifedipine (Procardia)	<p>Blocks calcium movement into muscle cells, inhibits uterine activity to arrest preterm labor</p>	<p>Use caution if giving this drug with magnesium sulfate because of increased risk for hypotension.</p> <p>Monitor blood pressure hourly if giving with magnesium sulfate; report a pulse rate &gt;110 bpm.</p> <p>Monitor for fetal effects such as decreased uteroplacental blood flow manifested by fetal bradycardia, which can lead to fetal hypoxia.</p>

**DRUG GUIDE 21.1 MEDICATIONS USED WITH PRETERM LABOR** (continued)

Drug	Action/Indication	Nursing Implications
		<p>Monitor for adverse effects, such as flushing of the skin, headache, transient tachycardia, palpitations, postural hypertension, peripheral edema, and transient fetal tachycardia.</p> <p>Contraindicated in women with cardiovascular disease or hemodynamic instability.</p>
Betamethasone (Celestone)	Promotes fetal lung maturity by stimulating surfactant production; prevents or reduces risk of respiratory distress syndrome and intraventricular hemorrhage in the preterm neonate less than 34 weeks' gestation	<p>Administer two doses intramuscularly 24 hr apart.</p> <p>Monitor for maternal infection or pulmonary edema.</p> <p>Educate parents about potential benefits of drug to preterm infant.</p> <p>Assess maternal lung sounds and monitor for signs of infection.</p>

### Corticosteroids

Corticosteroids given to the mother in preterm labor can help prevent or reduce the frequency and severity of respiratory distress syndrome in premature infants delivered between 24 and 34 weeks' gestation. The beneficial effects of corticosteroids on fetal lung maturation have been reported within 48 hours of initial administration. A recent Cochrane review found that corticosteroids repeatedly administered to the woman in preterm labor provided short-term benefits to the preterm infant of less respiratory distress and fewer serious health problems in the first few weeks after birth. They supported the use of repeat dose(s) of prenatal corticosteroids for women still at risk of preterm birth 7 days or more after an initial course. These benefits were associated with a small reduction in size at birth. The current available evidence reassuringly shows no significant harm in early childhood, although no benefit. Further research is needed on the long-term benefits and risks for the woman and baby. Individual client data meta-analysis may clarify how to maximize benefit and minimize harm (Crowther, McKinlay, Middleton, & Harding, 2011). These drugs require at least 24 hours to become effective, so timely administration is crucial.

### Nursing Assessment

The preterm birth rate cannot be reduced until there are ways to predict the risk for preterm birth. Because the etiology is often multifactorial, an individualized approach is needed.

### Health History and Physical Examination

The signs of preterm labor are subtle and may be overlooked by the client as well as the health care professional. Obtain a thorough health history and be alert for risk factors associated with preterm labor and birth (Box 21.2).

Frequently, women are unaware that uterine contractions, effacement, and dilation are occurring, thus making early intervention ineffective in arresting preterm labor and preventing the birth of a premature newborn. Ask the woman about any complaints, being alert for the subtle symptoms of preterm labor, which may include:

- Change or increase in vaginal discharge with mucous, water, or blood in it
- Pelvic pressure (pushing-down sensation)
- Low, dull backache
- Menstrual-like cramps
- Feeling of pelvic pressure or fullness
- GI upset: nausea, vomiting, and diarrhea
- General sense of discomfort or unease
- Heaviness or aching in the thighs
- Uterine contractions, with or without pain
- More than six contractions per hour
- Intestinal cramping, with or without diarrhea (Gilbert, 2011; Waters & Mercer, 2011)

Assess the pattern of the contractions: the contractions must be persistent, such that four contractions occur every 20 minutes or eight contractions occur in 1 hour. Evaluate cervical dilation and effacement: cervical effacement is 80% or greater and cervical dilation is greater than 1 cm (American Academy of Pediatrics [AAP] &

## EVIDENCE-BASED PRACTICE 21.1

## LABOR INDUCTION AND OUTCOMES FOR WOMEN BEYOND TERM

## STUDY

Births after 42 weeks seem to carry a slightly increased risk for the newborn, and this review sought to find out if induction of labor at a prespecified time could reduce this increased risk or not. Placental perfusion decreases as the placenta ages and becomes less efficient at delivering oxygen and nutrients to the fetus. Amniotic fluid volume also begins to decline by 40 weeks of gestation, increasing the fetus's risk for oligohydramnios, meconium aspiration, and cord compression. However, questions arise: What is the best time for inducing labor in a prolonged pregnancy? Does labor induction improve maternal and fetal outcomes, or would it be better to wait for spontaneous labor to begin? A study was conducted to compare the effects of inducing labor in women at or beyond term with those of waiting for spontaneous labor to begin. A search was conducted for randomized controlled trials that compared labor induction with waiting for spontaneous labor to begin in women who were at term or prolonged pregnancy. Two review authors collected the data and analyzed the trials. A total of 19 trials involving almost 8,000 women were evaluated.

## Findings

Based on the trials analyzed, fewer perinatal deaths occurred in women who underwent labor induction at 41 completed weeks of gestation or later. Fewer newborns experienced meconium aspiration syndrome with induction at 41 weeks or more. Women at 37 to 40 weeks' gestation who received expectant management were more likely to undergo a cesarean birth compared to those in the same gestational week range who received induction. Statistical analysis, however, showed that these differences were not significant.

## Nursing Implications

Although the study did not reveal results that were statistically significant, nurses need to be aware of the potential benefits and limitations associated with labor induction so that they can provide women and their families with the most appropriate information about options for a prolonged pregnancy. Nurses can integrate information from this study in their teaching about the risks associated with prolonged pregnancy. They can also use this information to help answer the couple's questions about induction and its effectiveness as well as provide anticipatory guidance about the procedure. Doing so fosters empowerment of the woman and her family, promoting optimal informed decision making.

## BOX 21.2

## RISK FACTORS ASSOCIATED WITH PRETERM LABOR AND BIRTH

- African American race (double the risk)
- Maternal age extremes (<16 years and >40 years old)
- Low socioeconomic status
- Alcohol or other drug use, especially cocaine
- Poor maternal nutrition
- Maternal periodontal disease
- Cigarette smoking
- Low level of education
- History of prior preterm birth (triples the risk)
- Uterine abnormalities, such as fibroids
- Low pregnancy weight for height
- Preexisting diabetes or hypertension
- Multifetal pregnancy
- Premature rupture of membranes
- Late or no prenatal care
- Short cervical length
- STIs: gonorrhea, *Chlamydia*, trichomoniasis
- Bacterial vaginosis (50% increased risk)
- Chorioamnionitis
- Hydramnios
- Gestational hypertension
- Cervical insufficiency
- Short interpregnancy interval (<1 year between births)
- Placental problems, such as placenta previa and abruption placenta
- Maternal anemia
- UTI
- Domestic violence
- Stress, acute and chronic

Adapted from March of Dimes. (2011c). *Preterm labor and birth: A serious pregnancy complication*. Retrieved from [http://www.marchofdimes.com/pregnancy/preterm\\_indepth.html](http://www.marchofdimes.com/pregnancy/preterm_indepth.html).

ACOG, 2010). On examination, engagement of the fetal presenting part will be noted.

### Laboratory and Diagnostic Testing

Commonly used diagnostic testing for preterm labor risk assessment includes a complete blood count to detect infection, which may be a contributing factor to preterm labor; urinalysis to detect bacteria and nitrites, which are indicative of a urinary tract infection (UTI); and an amniotic fluid analysis to determine fetal lung maturity and the presence of subclinical chorioamnionitis.

Four other tests may be used for preterm labor prediction: fetal fibronectin testing, cervical length evaluation by transvaginal ultrasound, salivary estriol, and home monitoring of uterine activity to recognize preterm contractions. Fetal fibronectin and cervical length examinations have a high negative predictive value and are thus better at predicting which pregnant women are unlikely to have a preterm birth as opposed to predicting those who will (Ross & Eden, 2011).

#### FETAL FIBRONECTIN

Fetal fibronectin, a glycoprotein produced by the chorion, is found at the junction of the chorion and decidua (fetal membranes and uterus). It acts as biologic glue, attaching the fetal sac to the uterine lining. It normally is present in cervicovaginal secretions up to 22 weeks of pregnancy and again at the end of the last trimester (1 to 3 weeks before labor). It usually cannot be detected between 24 and 34 weeks of pregnancy (5½ to 8½ months) unless there has been a disruption between the chorion and deciduas. It is present in cervicovaginal fluid prior to delivery, regardless of gestational age. The test is a useful marker for impending membrane rupture within 7 to 14 days if the level increases to greater than 0.05 mcg/mL. Conversely, a negative fetal fibronectin test is a strong predictor that preterm labor in the next 2 weeks is unlikely (Moroz & Simhan 2012).

A sterile applicator is used to collect a cervicovaginal sample during a speculum examination. The result is either positive (fetal fibronectin is present) or negative (fetal fibronectin is not present). Interpretation of fetal fibronectin results must always be viewed in conjunction with the clinical findings; it is not used as a lone indicator for predicting preterm labor. The primary importance of cervicovaginal fetal fibronectin lies in the high negative predictive values of the test for reducing preterm birth risk. Fibronectin testing can be a useful tool in the triaging of women symptomatic for preterm labor.

#### TRANSVAGINAL ULTRASOUND

Transvaginal ultrasound of the cervix has been used as a tool to predict preterm labor in high-risk pregnancies and to differentiate between true and false preterm labor. Three parameters are evaluated during the transvaginal ultrasound: cervical length and width, funnel width and

length, and percentage of funneling. Measurement of the closed portion of the cervix visualized during the transvaginal ultrasound is the single most reliable parameter for prediction of preterm delivery in high-risk women (Gilbert, 2011).

Cervical length varies during pregnancy and can be measured fairly reliably after 16 weeks' gestation using an ultrasound probe inserted in the vagina. A cervical length of 3 cm or more indicates that delivery within 14 days is unlikely. Women with a short cervical length of 2.5 cm during the mid-trimester have a substantially greater risk of preterm birth prior to 35 weeks' gestation. As with fetal fibronectin testing, negative results can be reassuring and prevent unnecessary interventions (Greco, Gupta, Syngelaki, Poon, & Nicolaidis, 2012).

### Nursing Management

Nurses play a key role in reducing preterm labor and births to improve pregnancy outcomes for both mothers and their infants. Early detection of preterm labor is currently the best strategy to improve outcomes. Because of the numerous factors associated with preterm labor, it is challenging to identify and address all of them, especially when women experiencing contractions are frequently falsely reassured and not assessed thoroughly to determine the cause. This delay impedes initiation of interventions to reduce infant death and morbidity.

Preterm birth prevention programs for women at high risk have used self-monitoring of symptoms and patterns, weekly cervical examinations, clinical markers, telephone monitoring, home visiting, alone or in combination, with disappointing results. Preterm labor is currently thought to be a chronic, long-term multifactorial process with a genetic component. Despite technologic and pharmacologic advances in the identification and treatment of preterm labor, the incidence remains high and is growing in the United States (Rattihalli, Smith, & Field, 2012).

Nursing management of the woman with preterm labor involves administering tocolytic therapy if indicated, thoroughly educating the client, and providing psychological support during the process.

### Administering Tocolytic Therapy

Tocolysis is the use of drugs to inhibit uterine contractions. The primary goals of tocolytic therapy are to arrest labor and delay birth long enough to initiate prophylactic corticosteroid therapy when indicated for stimulation of fetal lung maturity and to arrange for maternal-fetal transport to a perinatal tertiary care hospital. A firm diagnosis of preterm labor is necessary before treatment is considered. Diagnosis requires the presence of both uterine contractions and cervical change (or an initial cervical examination of more than 2 cm and/or more than 80% effacement in a nulliparous client). A cause for preterm labor should always be sought. Absolute

contraindications to administering tocolytic agents to stop labor include intrauterine infection, active hemorrhage, fetal distress, fetal abnormality incompatible with life, intrauterine growth restriction (IUGR), severe preeclampsia, heart disease, prolonged premature rupture of the membranes (PPROM), and intrauterine demise (Ross & Eden, 2011). Bed rest and hydration are commonly recommended, but without proven efficacy.

Prevention of preterm labor remains an elusive goal. Presently, women at high risk for preterm labor are offered progesterone therapy at the start of their second trimester. Although progesterone therapy is recommended by ACOG, it has not been FDA approved for this purpose and has mixed results (King & Brucker, 2011).

Short-term pharmacologic therapy remains the cornerstone of management. However, there are no studies to suggest that any tocolytic agent can delay birth for longer than 48 hours (Abramovici, Cantu, & Jenkins, 2012). No single agent has a clear therapeutic advantage. Tocolytics include magnesium sulfate, calcium channel blockers (nifedipine).

Magnesium sulfate may be ordered. This agent acts as a physiologic calcium antagonist and a general inhibitor of neurotransmission. Expect to administer it intravenously. Monitor the woman for nausea, vomiting, headache, weakness, hypotension, and cardiopulmonary arrest. Frequent monitoring of maternal respiratory effort and deep tendon reflexes is essential for early recognition of overdose. Because magnesium is exclusively excreted by the kidneys, adequate renal function is essential for safe administration. Assess the fetus for decreased FHR variability, drowsiness, and hypotonia. Magnesium has a wide margin of safety and is commonly used as a first-line drug.

Calcium channel blockers promote uterine relaxation by decreasing the influx of calcium ions into myometrium cells to inhibit contractions. Although calcium channel blockers may be prescribed to manage preterm labor, available literature provides little evidence that they have better efficacy in treating preterm labor than magnesium sulfate (King et al., 2011). Administer calcium channel blockers (nifedipine) orally or sublingually every 4 to 8 hours as ordered. Monitor the woman for hypotension, reflex tachycardia, headache, nausea, and facial flushing.

If beta-adrenergic agonists (terbutaline) are ordered, expect to administer the agent as a single subcutaneous injection. It may be repeated if the maternal heart rate remains less than 130 bpm. Closely assess the woman for side effects, including jitteriness, flushing, hypotension, nervousness, anxiety, restlessness, nausea, and tachycardia. Assess the fetus for tachycardia, hypotension, and hypoglycemia. The FDA issued an advisory warning about terbutaline as a tocolytic agent in the early 2000s and since then its use has waned in the United States (King & Brucker, 2011).

Supportive nursing care is needed for the woman in preterm labor whether the contractions are stopped with tocolytic therapy or not. Nursing tasks include monitoring vital signs, measuring intake and output, encouraging bed rest on the woman's left side to enhance placental perfusion, monitoring the fetal heart rate via an external monitor continuously, limiting vaginal examinations to prevent an ascending infection, and monitoring the mother and fetus closely for any adverse effects from the tocolytic agents. Offering the couple ongoing explanations will help prepare them for the birth.

## Educating the Client

Ensure that every pregnant woman receives basic education about preterm labor, including information about harmful lifestyles, the signs of genitourinary infections and preterm labor, and the appropriate response to these symptoms. Teach the client how to palpate for and time uterine contractions. Provide written materials to support this education at a level and in a language appropriate for the client. Also educate clients about the importance of prenatal care, risk reduction, and recognizing the signs and symptoms of preterm labor. Teaching Guidelines 21.1 highlights important instructions related to preventing preterm labor.

### Teaching Guidelines 21.1

#### TEACHING TO PREVENT PRETERM LABOR

- Avoid traveling for long distances in cars, trains, planes, or buses.
- Avoid lifting heavy objects, such as laundry, groceries, or a young child.
- Avoid performing hard, physical work, such as yard work, moving of furniture, or construction.
- Visit a dentist in early pregnancy to evaluate and treat periodontal disease.
- Enroll in a smoking cessation program if you are unable to quit on your own.
- Curtail sexual activity until after 37 weeks if experiencing preterm labor symptoms.
- Consume a well-balanced nutritional diet to gain appropriate weight.
- Avoid the use of substances such as marijuana, cocaine, and heroin.
- Identify factors and areas of stress in your life, and use stress management techniques to reduce them.
- If you are experiencing intimate partner violence, seek resources to modify the situation.

Recognize the signs and symptoms of preterm labor and notify your birth attendant if any occur:

- Uterine contractions, cramping, or low back pain

- Feeling of pelvic pressure or fullness
- Increase in vaginal discharge
- Nausea, vomiting, and diarrhea
- Leaking of fluid from vagina

If you are experiencing any of these signs or symptoms, do the following:

- Stop what you are doing and rest for 1 hour.
- Empty your bladder.
- Lie down on your side.
- Drink two to three glasses of water.
- Feel your abdomen and make note of the hardness of the contraction. Call your health care provider and describe the contraction as
  - Mild if it feels like the tip of the nose
  - Moderate if it feels like the tip of the chin
  - Strong if it feels like your forehead

Adapted from American College of Obstetricians and Gynecologists. (2009a). ACOG practice bulletin no. 43: Management of preterm labor. *Obstetrics and Gynecology*, 101, 1039–1047; and Ross, M. G., & Eden, R. D. (2011). Preterm labor. *eMedicine*. Retrieved from <http://emedicine.medscape.com/article/260998-overview>.

Explaining to the couple what is happening in terms of labor progress, the treatment regimen, and the status of the fetus is important to reduce the anxiety associated with the risk of giving birth to a preterm infant. Educate them about the importance of promotion of fetal lung maturity with corticosteroids. Include supportive family members in all education. Allow time for the woman and her family to express their concerns about the possible outcome for the infant and the possible side effects of the tocolytic therapy. Encourage them to vent any feelings, fears, and anger they may experience. Provide the woman and her family with an honest appraisal of the situation and plan of treatment throughout her care.

### Providing Psychological Support

Preterm labor and birth present multifactorial challenges for everyone involved. If the woman's activities are restricted, additional stresses may be placed on the family, contributing to the crisis. Assess the stress levels of the client and family, and make appropriate referrals. Emphasize the need for more frequent supervision and office visits, and encourage clients to talk to their health care provider for reassurance.

Every case of spontaneous preterm labor is unique. Care must take into account the clinical circumstances, and the full and informed consent of the woman and her partner is needed. Half of all women who ultimately give birth prematurely have no identifiable risk factors. Nurses should be sensitive to any complaint and should provide appropriate assessment, information, and

follow-up. Sensitivity to the subtle differences between normal pregnancy sensations and the prodromal symptoms of preterm labor is a key factor in ensuring timely care. Offer clarification and validation of the woman's symptoms.

If tocolytic therapy is not successful in stopping uterine contractions, support the couple through this stressful period to prepare them for the birth. Keep them informed of all progress and changes; for example, continuously monitor maternal and fetal vital signs, especially the maternal temperature to detect signs of early infection. Offer one-on-one contact and be available throughout this difficult and anxiety-producing period.

## PROLONGED PREGNANCY

A term pregnancy usually lasts 38 to 42 weeks. A **prolonged pregnancy** is one that continues past the end of the 42nd week of gestation, or 294 days from the first day of the last menstrual period. A post-term or prolonged pregnancy is defined as a pregnancy that extends to 42 0/7 weeks and beyond. Within the United States, about 18% of singleton pregnancies extend beyond 41 weeks (Gilbert, 2011). Incorrect dates account for the majority of these cases: many women have irregular menses and thus cannot identify the date of their last menstrual period accurately.

*Recall Jennifer described at the beginning of the chapter, who was at 41 weeks' gestation. What information would be most important to determine on admission to the facility? What interventions might the nurse anticipate when she arrives?*

The exact etiology of a prolonged pregnancy is unknown because the mechanism for the initiation of labor is not completely understood. Theories suggest there may be a deficiency of estrogen and continued secretion of progesterone that prohibits the uterus from contracting, but no evidence has validated this. A woman who has one prolonged pregnancy is at greater risk for another in subsequent pregnancies.

Prolonged pregnancies may adversely affect both the mother and fetus or newborn. Maternal risk is related to the large size of the fetus at birth, which increases the chances that a cesarean birth will be needed. Other issues might include dystocia, birth trauma, postpartum hemorrhage, and infection. Mechanical or artificial interventions such as forceps or vacuum-assisted birth and labor induction with oxytocin may be necessary. In addition, maternal exhaustion and feelings of despair over

this prolonged gestation can add to the woman's anxiety level and reduce her coping ability. Women often blame themselves for prolonging the pregnancy, and a woman's negative feelings about herself can bring about strained relationships with the people closest to her.

Fetal risks associated with a prolonged pregnancy include macrosomia, shoulder dystocia, brachial plexus injuries, low Apgar scores, postmaturity syndrome (loss of subcutaneous fat and muscle and meconium staining), and CPD. All of these conditions predispose this fetus to birth trauma or a surgical birth. The perinatal mortality rate at more than 42 weeks of gestation is twice that at term and increases sixfold and higher at 43 weeks of gestation and beyond. Uteroplacental insufficiency, meconium aspiration, and intrauterine infection contribute to the increased rate of perinatal deaths (Beacock, 2011). As the placenta ages, its perfusion decreases and it becomes less efficient at delivering oxygen and nutrients to the fetus. Amniotic fluid volume also begins to decline by 40 weeks of gestation, possibly leading to oligohydramnios, subsequently resulting in fetal hypoxia and an increased risk of cord compression because the cushioning effect offered by adequate fluid is no longer present. Hypoxia and oligohydramnios predispose the fetus to aspiration of meconium, which is released by the fetus in response to a hypoxic insult (Caughey & Butler, 2011). All of these issues can compromise fetal well-being and lead to fetal distress.

## Nursing Assessment

Obtain a thorough history to determine the estimated date of birth. Many women are unsure of the date of their last menstrual period, so the date given may be unreliable. Despite numerous methods used to date pregnancies, many are still miscalculated. Accurate gestational dating via ultrasound is essential.

Antepartum assessment for a prolonged pregnancy typically includes daily fetal movement counts done by the woman, nonstress tests done twice weekly, amniotic fluid assessments as part of the biophysical profile, and weekly cervical examinations to evaluate for ripening. In addition, assess the following:

- Client's understanding of the various fetal well-being tests
- Client's stress and anxiety concerning her lateness
- Client's coping ability and support network

## Nursing Management

Once the dates have been established and postdate status is confirmed, monitoring fetal well-being becomes critical. When determining the plan of care for a woman with a prolonged pregnancy, the first decision is whether to deliver the baby or wait. If the decision is to wait, then fetal surveillance is key. If the decision is to have the

woman deliver, labor induction is initiated. Both decisions remain controversial, and there is no clear answer about which option is more appropriate. Therefore, the plan must be individualized.

*Think back to Jennifer, who is scheduled for labor induction. What ongoing nursing assessments would be important when providing care for her?*

## Providing Support

The intense surveillance is time consuming and intrusive, adding to the anxiety and worry already being experienced by the woman about her overdue status. Be alert to the woman's anxiety and allow her to discuss her feelings. Provide reassurance about the expected time range for birth and the well-being of the fetus based on the assessment tests. Validating the woman's stressful state due to the prolonged pregnancy provides an opportunity for her to verbalize her feelings openly.

## Educating the Woman and Her Partner

Teach the woman and her partner about the testing required and the reasons for each test. Also describe the methods that may be used for cervical ripening if indicated. Explain about the possibility of induction if the woman's labor is not spontaneous or if a dysfunctional labor pattern occurs. Also prepare the woman for the possibility of a surgical delivery if fetal distress occurs.

## Providing Care During the Intrapartum Period

During the intrapartum period, continuously assess and monitor FHR to identify potential fetal distress early (e.g., late or variable decelerations) so that interventions can be initiated. Also monitor the woman's hydration status to ensure maximal placental perfusion. When the membranes rupture, assess amniotic fluid characteristics (color, amount, and odor) to identify previous fetal hypoxia and prepare for prevention of meconium aspiration. Report meconium-stained amniotic fluid immediately when the membranes rupture. Anticipate the need for amnioinfusion to minimize the risk of meconium aspiration by diluting the meconium in the amniotic fluid expelled by the hypoxic fetus. In addition, monitor the woman's labor pattern closely because dysfunctional patterns are common (Gilbert, 2011).

Encourage the woman to verbalize her feelings and concerns, and answer all her questions. Provide support, presence, information, and encouragement throughout this time.

## WOMEN REQUIRING LABOR INDUCTION AND AUGMENTATION

Ideally, all pregnancies go to term, with labor beginning spontaneously. However, many women need help to initiate or sustain the labor process. **Labor induction** involves the stimulation of uterine contractions by medical or surgical means before the onset of spontaneous labor. The labor induction rate is at an all-time high in the United States. The widespread use of artificial induction of labor for convenience has contributed to the recent increase in the number of cesarean births. Evidence is compelling that elective induction of labor significantly increases the risk of cesarean birth, instrumented delivery, use of epidural analgesia, and neonatal intensive care unit admission, especially for nulliparous women (Carter 2012).

Labor induction is not an isolated event: it brings about a cascade of other interventions that may or may not produce a favorable outcome. Labor induction also involves intravenous therapy, bed rest, continuous electronic fetal monitoring, significant discomfort from stimulating uterine contractions, epidural analgesia/anesthesia, and a prolonged stay on the labor and birth unit (Grivell, Reilly, Oakey, Chan, & Dodd, 2012). Labor augmentation enhances ineffective contractions after labor has begun. Continuous electronic FHR monitoring is necessary.

There are multiple medical and obstetric reasons for inducing labor, the most common being prolonged gestation. Other indications for inductions include PPRM, gestational hypertension, cardiac disease, renal disease, chorioamnionitis, dystocia, intrauterine fetal demise, isoimmunization, and diabetes (Goldberg, 2012). Contraindications to labor induction include complete placenta previa, abruptio placentae, transverse fetal lie, prolapsed umbilical cord, a prior classic uterine incision that entered the uterine cavity, pelvic structure abnormality, previous myomectomy, vaginal bleeding with unknown cause, invasive cervical cancer, active genital herpes infection, and abnormal FHR patterns (ACOG, 2009b). In general, labor induction is indicated when the benefits of birth outweigh the risks to the mother or fetus for continuing the pregnancy. However, the balance between risk and benefit remains controversial.

### Take Note!

Before labor induction is started, fetal maturity (dating, ultrasound, amniotic fluid studies) and cervical readiness (vaginal examination, Bishop scoring; see Table 21.2) must be assessed. Both need to be favorable for a successful induction.

## Therapeutic Management

The decision to induce labor is based on a thorough evaluation of maternal and fetal status. Typically, this includes an ultrasound to evaluate fetal size, position, and

gestational age and to locate the placenta; engaged presenting fetal part; pelvimetry to rule out fetopelvic disproportion; a nonstress test to evaluate fetal well-being; a phosphatidylglycerol (PG) level to assess fetal lung maturity; Nitrazine paper and/or fern test to confirm ruptured membranes; complete blood count and urinalysis to rule out infection; and a vaginal examination to evaluate the cervix for inducibility (ACOG, 2009b). Accurate dating of the pregnancy also is essential before cervical ripening and induction are initiated to prevent a preterm birth.

## Cervical Ripening

Cervical ripening is a process by which the cervix softens via the breakdown of collagen fibrils. It is the first step in the process of cervical effacement and dilation so that, on average, the cervix is approximately 50% effaced and 2 cm dilated at the onset of labor, although wide differences do exist. There has been increasing awareness that if the cervix is unfavorable or unripe, a successful vaginal birth is unlikely. Cervical ripeness is an important variable when labor induction is being considered. A ripe cervix is shortened, centered (anterior), softened, and partially dilated. An unripe cervix is long, closed, posterior, and firm. Cervical ripening usually begins prior to the onset of labor contractions and is necessary for cervical dilation and the passage of the fetus.

Various scoring systems to assess cervical ripeness have been introduced, but the Bishop score is most commonly used today. The Bishop score helps identify women who would be most likely to achieve a successful induction (Table 21.2). The duration of labor is inversely correlated with the Bishop score: a score over 8 indicates a successful vaginal birth. Bishop scores of less than 6 usually indicate that a cervical ripening method should be used prior to induction (Goldberg, 2012). Medical induction of labor has two components: cervical ripening and induction of contractions. When induction of labor is indicated, cervical readiness for labor is evaluated by pelvic exam and determination of a Bishop score is documented.

## NONPHARMACOLOGIC METHODS

Nonpharmacologic methods for cervical ripening are less frequently used today, but nurses need to be aware of them and question clients about their use. Methods may include herbal agents such as evening primrose oil, black haw, black and blue cohosh, and red raspberry leaves. In addition, castor oil, hot baths, and enemas are used for cervical ripening and labor induction. The risks and benefits of these agents are unknown. None have been evaluated scientifically, and thus, none can be recommended regarding their efficacy or safety.

Another nonpharmacologic method suggested for labor induction is sexual intercourse along with breast stimulation. This promotes the release of oxytocin, which stimulates uterine contractions. In addition, human semen

**TABLE 21.2** BISHOP SCORING SYSTEM

Score	Dilation (cm)	Effacement (%)	Station	Cervical Consistency	Position of Cervix
0	Closed	0–30	–3	Firm	Posterior
1	1–2	40–50	–2	Medium	Midposition
2	3–4	60–70	–1 or 0	Soft	Anterior
3	5–6	80	+1 or +2	Very soft	Anterior

Modified from Bishop, E. H. (1964). Pelvic scoring for elective induction. *Obstetrics & Gynecology*, 24(2), 267.

is a biologic source of prostaglandins used for cervical ripening. According to a Cochrane review, sexual intercourse with breast stimulation would appear beneficial, but safety issues have not been fully evaluated, nor can this activity be standardized. It appears to shorten the latent phase of labor (Tharpe, Farley, & Jordan, 2013). Therefore, its use as a method for labor induction is not validated by research.

### MECHANICAL METHODS

Mechanical methods are used to open the cervix and stimulate the progression of labor. All share a similar mechanism of action: application of local pressure stimulates the release of prostaglandins to ripen the cervix. Potential advantages of mechanical methods, compared with pharmacologic methods, may include simplicity or preservation of the cervical tissue or structure, lower cost, and fewer side effects. The risks associated with these methods include infection, bleeding, membrane rupture, and placental disruption (Jozwiak, Bloemenkamp, Kelly, Mol, et al., 2012).

For example, an indwelling (Foley) catheter (e.g., 26 French) can be inserted into the endocervical canal to ripen and dilate the cervix. The catheter is placed in the uterus, and the balloon is filled. Direct pressure is then applied to the lower segment of the uterus and the cervix. This direct pressure causes stress in the lower uterine segment and probably the local production of prostaglandins (Jozwiak, Rengerink, Benthem et al., 2012).

Hygroscopic dilators absorb endocervical and local tissue fluids; as they enlarge, they expand the endocervix and provide controlled mechanical pressure. The products available include natural osmotic dilators (laminaria, a type of dried seaweed) and synthetic dilators containing magnesium sulfate (Lamicel, Dilapan). Hygroscopic dilators are advantageous because they can be inserted on an outpatient basis and no fetal monitoring is needed. As many dilators are inserted in the cervix as will fit, and they expand over 12 to 24 hours as they absorb water. Absorption of water leads to expansion of the dilators and opening of the cervix. They are a reliable alternative when prostaglandins are contraindicated or unavailable (Gilbert, 2011).

Recently there has been a reduction in the use of hygroscopic and osmotic dilators for the induction of labor in favor of pharmacologic agents. The increased risk of maternal and fetal infections with hygroscopic and osmotic dilators when compared with that associated with the use of other pharmacologic agents and the ease of pharmacologic administration may be reasons for the decline. Placement of dilators also requires additional training and may be associated with rupture of membranes, vaginal bleeding, and client discomfort or pain (Ramirez, 2011).

Recent systematic review of randomized trials that compared cervical ripening with mechanical methods versus alternative pharmacologic agents or placebo demonstrated that maternal infection was increased in clients who underwent cervical ripening with mechanical methods. Thus, mechanical methods for cervical ripening have fallen into disfavor and are used infrequently today when compared to pharmacologic or surgical methods for induction (Ramirez, 2011).

### SURGICAL METHODS

Surgical methods used to ripen the cervix and induce labor include stripping of the membranes and performing an amniotomy. Stripping of the membranes is accomplished by inserting a finger through the internal cervical os and moving it in a circular direction. This motion causes the membranes to detach. Manual separation of the amniotic membranes from the cervix is thought to induce cervical ripening and the onset of labor (Goldberg, 2012). However, there is no strong evidence at this time that membrane stripping significantly shortens the duration of pregnancy.

An amniotomy involves inserting a cervical hook (Amniohook) through the cervical os to deliberately rupture the membranes. This promotes pressure of the presenting part on the cervix and stimulates an increase in the activity of prostaglandins locally. Risks associated with these procedures include umbilical cord prolapse or compression, maternal or neonatal infection, FHR deceleration, bleeding, and client discomfort (Mozurkewich et al., 2011).

When either of these techniques is used, amniotic fluid characteristics (such as whether it is clear or bloody, or meconium is present) and the FHR pattern must be monitored closely.

**PHARMACOLOGIC AGENTS**

The use of pharmacologic agents has revolutionized cervical ripening. The use of prostaglandins to attain cervical ripening has been found to be highly effective in producing cervical changes independent of uterine contractions (King & Brucker, 2011). In some cases, women will go into labor, requiring no additional stimulants for induction. Induction of labor with prostaglandins offers the advantage of promoting both cervical ripening and uterine contractility. A drawback of prostaglandins is their ability to induce excessive uterine contractions, which can increase maternal and perinatal morbidity (Kelly, Malik, Smith, Kavanagh, & Thomas, 2012).

Prostaglandin analogs commonly used for cervical ripening include dinoprostone gel (Prepidil), dinoprostone inserts (Cervidil), and misoprostol (Cytotec). Misoprostol (Cytotec), a synthetic PGE1 analog, is a gastric cytoprotective agent used in the treatment and prevention of peptic ulcers. It can be administered intravaginally or orally to ripen the cervix or induce labor. It is available in 100-mcg or 200-mcg tablets, but doses of 25 to 50 mcg are typically used. It is important to note that only dinoprostone is approved by the FDA for use as a cervical ripening agent, although ACOG acknowledges the apparent safety and effectiveness of misoprostol for this purpose (King & Brucker, 2011). A major adverse effect of the obstetric use of Cytotec is hyperstimulation of the uterus, which may progress to uterine tetany with marked impairment of uteroplacental blood flow, uterine rupture (requiring surgical repair, hysterectomy, and/or salpingo-oophorectomy), or amniotic fluid embolism

**DRUG GUIDE 21.2 DRUGS USED FOR CERVICAL RIPENING AND LABOR INDUCTION**

Drug	Action/Indication	Nursing Implications
Dinoprostone (Cervidil insert; Prepidil gel)	Directly softens and dilates the cervix/to ripen cervix and induce labor  FDA approved for cervical ripening	Provide emotional support. Administer pain medications as needed. Frequently assess degree of effacement and dilation. Monitor uterine contractions for frequency, duration, and strength. Assess maternal vital signs and FHR pattern frequently. Monitor woman for possible adverse effects such as headache, nausea and vomiting, and diarrhea.
Misoprostol (Cytotec)	Ripens cervix/to induce labor	Instruct client about purpose and possible adverse effects of medication. Ensure informed consent is signed per hospital policy. Assess vital signs and FHR patterns frequently. Monitor client's reaction to drug. Initiate oxytocin for labor induction at least 4 hours after last dose was administered. Monitor for possible adverse effects such as nausea and vomiting, diarrhea, uterine hyperstimulation, and category II and III FHR patterns.
Oxytocin (Pitocin)	Acts on uterine myofibrils to contract/to initiate or reinforce labor	Administer as an IV infusion via pump, increasing dose based on protocol until adequate labor progress is achieved. Assess baseline vital signs and FHR and then frequently after initiating oxytocin infusion. Determine frequency, duration, and strength of contractions frequently. Notify health care provider of any uterine hypertonicity or abnormal FHR patterns. Maintain careful I&O, being alert for water intoxication. Keep client informed of labor progress. Monitor for possible adverse effects such as hyperstimulation of the uterus, impaired uterine blood flow leading to fetal hypoxia, rapid labor leading to cervical lacerations or uterine rupture, water intoxication (if oxytocin is given in electrolyte-free solution or at a rate exceeding 20 mU/min), and hypotension.

(2011). *Pharmacology for women's health*. Sudbury, MA: Jones & Bartlett; and Mattson, S., & Smith, J. E. (2011). *Core curriculum for maternal–newborn nursing* (4th ed.). St. Louis, MO: Saunders Elsevier.

(Ramirez, 2011) (see Drug Guide 21.2). Furthermore, it is contraindicated for women with prior uterine scars and therefore should not be used for cervical ripening in women attempting a vaginal birth after cesarean.

## Oxytocin

Oxytocin is a potent endogenous uterotonic agent used for both artificial induction and augmentation of labor. It is produced naturally by the posterior pituitary gland and stimulates contractions of the uterus. For women with low Bishop scores, cervical ripening is typically initiated before oxytocin is used. Once the cervix is ripe, oxytocin is the most popular pharmacologic agent used for inducing or augmenting labor. Frequently a woman with an unfavorable cervix is admitted the evening before induction to ripen her cervix with one of the prostaglandin agents. Then induction begins with oxytocin the next morning if she has not already gone into labor. Doing so markedly enhances the success of induction.

Response to oxytocin varies widely: some women are very sensitive to even small amounts. The most common adverse effect of oxytocin is uterine hyperstimulation, leading to fetal compromise and impaired oxygenation (King & Brucker, 2011). The response of the uterus to the drug is closely monitored throughout labor so that the oxytocin infusion can be titrated appropriately. In addition, oxytocin has an antidiuretic effect, resulting in decreased urine flow that may lead to water intoxication. Symptoms to watch for include headache and vomiting.

Oxytocin is administered via an intravenous infusion pump piggybacked into the main intravenous line at the port most proximal to the insertion site. Typically 10 units of oxytocin is added to 1 L of isotonic solution. The dose is titrated according to protocol to achieve stable contractions every 2 to 3 minutes lasting 40 to 60 seconds (Gittinger & Abbott, 2011). The uterus should relax between contractions. If the resting uterine tone remains above 20 mm Hg, uteroplacental insufficiency and fetal hypoxia can result. This underscores the importance of continuous FHR monitoring. Unfortunately, neither the optimal oxytocin administration regimen nor the maximum oxytocin dose has been established through research or agreed-on expert opinion. Nurses assisting with labor inductions need to become familiar with their hospital protocols concerning dosage, infusion rates, and frequency of change.

Oxytocin has many advantages: it is potent and easy to titrate, it has a short half-life (1 to 5 minutes), and it is generally well tolerated. Induction using oxytocin has side effects (water intoxication, hypotension, and uterine hypertonicity), but because the drug does not cross the placental barrier, no direct fetal problems have been observed (Simpson, 2011) (Fig. 21.4).

**FIGURE 21.4** The nurse monitors an intravenous infusion of oxytocin being administered to a woman in labor who is being induced.

*Remember Jennifer, the young woman described at the beginning of the chapter? After her cervix is ripened, an oxytocin infusion is started and her progress is slow. What encouragement can the nurse offer? After a few hours, her contractions begin to increase in intensity and frequency. What typical pain management measures can the nurse implement, and how would the nurse evaluate the effectiveness of these measures?*

## Nursing Assessment

Nursing assessment of the woman who is undergoing labor induction or augmentation involves a thorough history and physical examination. Review the woman's history for relative indications for induction or augmentation, such as diabetes, hypertension, post-term status, dysfunctional labor pattern, prolonged ruptured membranes, and maternal or fetal infection, and for contraindications such as placenta previa, overdistended uterus, active genital herpes, fetopelvic disproportion, fetal malposition, or severe fetal distress.

Assist with determining the gestational age of the fetus to prevent a preterm birth. Assess fetal well-being to validate the client's and fetus's ability to withstand labor contractions. Evaluate the woman's cervical status, including cervical dilation and effacement, and station via vaginal examination as appropriate before cervical

ripening or induction is started. Determine the Bishop score to determine the probable success of induction.

### Take Note!

Nurses working with women in labor play an important role acting as the “eyes” and “ears” for the birth attendant because they remain at the client’s bedside throughout the entire experience. Close, frequent assessment and follow-up interventions are essential to ensure the safety of the mother and her unborn child during cervical ripening and labor induction or augmentation.

## Nursing Management

Explain to the woman and her partner about the induction or augmentation procedure clearly, using simple terms (Teaching Guidelines 21.2). Ensure that an informed consent has been signed after the client and her partner have received complete information about the procedure, including its advantages, disadvantages, and potential risks. Ensure that the Bishop score has been determined before proceeding. Nursing Care Plan 21.1

### Teaching Guidelines 21.2

#### TEACHING IN PREPARATION FOR LABOR INDUCTION

- Your health care provider may recommend that you have your labor induced. This may be necessary for a variety of reasons, such as elevated blood pressure, a medical condition, prolonged pregnancy over 41 weeks, or problems with fetal heart rate patterns or fetal growth.
- Your health care provider may use one or more methods to induce labor, such as stripping the membranes, breaking the amniotic sac to release the fluid, administering medication close to or in the cervix to soften it, or administering a medication called oxytocin (Pitocin) to stimulate contractions.
- Labor induction is associated with some risks and disadvantages, such as overactivity of the uterus; nausea, vomiting, or diarrhea; and changes in fetal heart rate.
- Prior to inducing your labor, your health care provider may perform a procedure to ripen your cervix to help ensure a successful induction.
- Medication may be placed around your cervix the day before you are scheduled to be induced.
- During the induction, your contractions may feel stronger than normal. However, the length of your labor may be reduced with induction.
- Medications for pain relief and comfort measures will be readily available.
- Health care staff will be present throughout labor.

presents an overview of the nursing care for a woman undergoing labor induction.

## Administering Oxytocin

If not already done, prepare the oxytocin infusion by diluting 10 units of oxytocin in 1,000 mL of lactated Ringer’s solution or ordered isotonic solution. Use an infusion pump on a secondary line connected to the primary infusion. Start the oxytocin infusion in mU/min or milliliters per hour as ordered. Each hospital has its own standards/protocols for oxytocin infusion and dilution. The nurse needs to follow that procedure when administering this medication. Maintain the rate once the desired contraction frequency has been reached. To ensure adequate maternal and fetal surveillance during induction or augmentation, the nurse-to-client ratio should not exceed 1:2 (Simpson, 2011).

During induction or augmentation, monitoring of the maternal and fetal status is essential. Apply an external electronic fetal monitor or assist with placement of an internal device. Obtain the mother’s vital signs and the FHR every 15 minutes during the first stage. Evaluate the contractions (frequency, duration, and intensity) and resting tone, and adjust the oxytocin infusion rate accordingly. Monitor the FHR, including baseline rate, baseline variability, and decelerations, to determine whether the oxytocin rate needs adjustment. Discontinue the oxytocin and notify the birth attendant if uterine hyperstimulation or a nonreassuring FHR pattern occurs. Perform or assist with periodic vaginal examinations to determine cervical dilation and fetal descent: cervical dilation of 1 cm per hour typically indicates satisfactory progress.

Continue to monitor the FHR continuously and document it every 15 minutes during the active phase of labor and every 5 minutes during the second stage. Assist with pushing efforts during the second stage.

Measure and record intake and output to prevent excess fluid volume. Encourage the client to empty her bladder every 2 hours to prevent soft tissue obstruction.

## Providing Pain Relief and Support

Assess the woman’s level of pain. Ask her frequently to rate her pain and provide pain management as needed. Offer position changes and other nonpharmacologic measures. Note her reaction to any medication given, and document its effect. Monitor her need for comfort measures as contractions increase.

Throughout induction and augmentation, frequently reassure the woman and her partner about the fetal status and labor progress. Provide them with frequent updates on the condition of the woman and the fetus. Assess the woman’s ability to cope with stronger contractions (Simpson, 2010). Provide support and encouragement as indicated.

## NURSING CARE PLAN 21.1

## Overview of the Women Undergoing Labor Induction

Rose, a 29-year-old primipara, is admitted to the labor and birth suite at 40 weeks' gestation for induction of labor. Assessment reveals that her cervix is ripe and 80% effaced, and dilated to 2 cm. Rose says, "I'm a bit nervous about being induced. I've never been through labor before and I'm afraid that I'll have a lot of pain from the medicine used to start the contractions." She consents to being induced but wants reassurance that this procedure won't harm the baby. Upon examination, the fetus is engaged and in a cephalic presentation, with the vertex as the presenting part. Her partner is at her side. Induction is initiated with oxytocin. Rose reports that contractions have started and are beginning to get stronger.

**NURSING DIAGNOSIS:** Anxiety related to induction of labor and associated medical interventions needed as evidenced by statements about being nervous, not having gone through labor before, fear of pain and potential harm to fetus

**Outcome Identification and Evaluation**

The client will experience decrease in anxiety as evidenced by ability to verbalize understanding of procedures involved and use of positive coping skills to reduce anxious state.

**Interventions: Minimizing Anxiety**

- Provide a clear explanation of the labor induction process *to provide client and partner with a knowledge base.*
- Maintain continuous physical presence *to provide physical and emotional support and demonstrate concern for maternal and fetal well-being.*
- Explain each procedure before carrying it out and answer questions *to promote understanding of procedure and rationale for use and decrease fear of the unknown.*
- Review with client measures used in the past to deal with stressful situations *to determine effectiveness; encourage use of past effective coping strategies to aid in controlling anxiety.*
- Instruct client's partner in helpful measures to assist client in coping and encourage their use *to foster joint participation in the process and feelings of being in control and to provide support to the client.*
- Offer frequent reassurance of fetal status and labor progress *to help alleviate client's concerns and foster continued participation in the labor process.*

**NURSING DIAGNOSIS:** Risk for injury (maternal or fetal) related to induction procedure risk factors: hypertonic uterine contractions, potential preterm birth as evidenced by client's concerns about fetal well-being and possible adverse effects of oxytocin administration

**Outcome Identification and Evaluation**

The client will remain free of complications associated with induction as evidenced by progression of labor as expected, delivery of healthy newborn, and absence of signs and symptoms of maternal and fetal adverse effects.

**Interventions: Promoting Maternal and Fetal Safety**

- Follow agency's protocol for medication use and infusion rate *to ensure accurate, safe drug administration.*
- Set up oxytocin IV infusion to piggyback into the primary IV infusion line *to allow for prompt discontinuation should adverse effects occur.*
- Use an infusion pump *to deliver accurate dose as ordered.*
- Gradually increase oxytocin dose in increments based on assessment findings and protocol *to promote effective uterine contractions.*
- Maintain oxytocin rate once desired frequency of contractions has been reached *to ensure continued progress in labor.*

## NURSING CARE PLAN 21.1

**Overview of the Women Undergoing Labor Induction** (continued)

- Accurately monitor contractions for frequency, duration, and intensity and resting tone *to prevent development of hypertonic contractions.*
- Maintain a nurse-to-client ratio of 1:2 *to ensure maternal and fetal safety.*
- Monitor FHR via electronic fetal monitoring during induction and continuously observe the FHR response to titrated medication rate *to ensure fetal well-being and identify adverse effects immediately.*
- Obtain maternal vital signs every 1 to 2 hours or as indicated by agency's protocol, reporting any deviations, *to promote maternal well-being and allow for prompt detection of problems.*
- Communicate with birth attendant frequently concerning progress *to ensure continuity of care.*
- Discontinue oxytocin infusion if tetanic contractions (>90 seconds), uterine hyperstimulation (<2 minutes apart), elevated uterine resting tone, or a distressed FHR pattern occurs *to minimize risk of drug's adverse effects.*
- Provide client with frequent reassurance of maternal and fetal status *to minimize anxiety.*

**NURSING DIAGNOSIS:** Pain related to uterine contractions as evidenced by client's statements about contractions increasing in intensity and expected effect of oxytocin administration

**Outcome Identification and Evaluation**

The client will report a decrease in pain as evidenced by statements of increased comfort and pain rating of 3 or less on numeric pain rating scale.

**Interventions: Promoting Maternal and Fetal Safety**

- Explain to the client that she will experience discomfort sooner than with naturally occurring labor *to promote client's awareness of events and prepare client for the experience.*
- Frequently assess client's pain using a pain rating scale *to quantify client's level of pain and evaluate effectiveness of pain relief measures.*
- Provide comfort measures, such as hygiene, backrubs, music, and distraction, and encourage the use of breathing and relaxation techniques *to help promote relaxation.*
- Provide support for her partner *to aid in alleviating stress and concerns.*
- Employ nonpharmacologic methods, such as position changes, birthing ball, hydrotherapy, visual imagery, and effleurage, *to help in managing pain and foster feelings of control over situation.*
- Administer pharmacologic agents such as analgesia or anesthesia as appropriate and as ordered *to control pain.*
- Continuously reassess client's pain level *to evaluate effectiveness of pain management techniques used.*

*After a very long day, Jennifer gives birth to a healthy baby boy with Apgar scores of 9 at 1 minute and 10 at 5 minutes. When transferring her to the postpartum unit, what information is essential to include for the accepting nurse? What specific nursing information should be given to the nursery nurse regarding the laboring experience? With such a lengthy labor, what assessments might the postpartum nurse have focused on for the first few hours after birth?*

**VAGINAL BIRTH AFTER CESAREAN**

**Vaginal birth after cesarean (VBAC)** describes a woman who gives birth vaginally after having at least one previous cesarean birth. Despite evidence that some women who have had a cesarean birth are candidates for vaginal birth, most women who have had a cesarean birth once undergo another for subsequent pregnancies (Macdorman, Declercq, & Menacker, 2011).

The choice of a vaginal or a repeat cesarean birth can be offered to women who had a lower abdominal

incision. However, controversy remains. The argument against VBAC focuses on the risk of uterine rupture and hemorrhage. Although the risk of uterine rupture is relatively low, the rate of fetal mortality in the event of a uterine rupture is extremely high.

Contraindications to VBAC include a prior classic uterine incision, prior transfundal uterine surgery (myomectomy), uterine scar other than low-transverse cesarean scar, contracted pelvis, and inadequate staff or facility if an emergency cesarean birth in the event of uterine rupture is required (Caughey, 2011). Most women go through a trial of labor to see how they progress, but this must be performed in an environment capable of handling the emergency of uterine rupture. The use of cervical ripening agents increases the risk of uterine rupture and thus is contraindicated in VBAC clients. The woman considering induction of labor after a previous cesarean birth needs to be informed of the increased risk of uterine rupture with an induction than with spontaneous labor (Ouzounian, Miller, Hiebert, Battista, & Lee, 2011).

Women are the primary decision makers about the choice of birth method, but they need education about VBAC during their prenatal course. Management is similar for any women experiencing labor, but certain areas require special focus:

- **Consent:** Fully informed consent is essential for the woman who wants to have a trial of labor after cesarean birth. The client must be advised about the risks as well as the benefits. She must understand the ramifications of uterine rupture, even though the risk is small.
- **Documentation:** Record keeping is an important component of safe client care. If and when an emergency occurs, it is imperative to take care of the client, but also to keep track of the plan of care, interventions and their timing, and the client's response. Events and activities can be written right on the fetal monitoring tracing to correlate with the change in fetal status.
- **Surveillance:** A distressed fetal monitor tracing in a woman undergoing a trial of labor after a cesarean birth should alert the nurse to the possibility of uterine rupture. Terminal bradycardia must be considered an emergency situation, and the nurse should prepare the team for an emergency delivery.
- **Readiness for emergency:** According to ACOG (2010) criteria for a safe trial of labor for a woman who has had a previous cesarean birth, the physician, anesthesia provider, and operating room team must be immediately available. Anything less would place the woman and fetus at risk.

Women and their health care providers are advised to consider VBAC in the context of potential risk, available resources, and the health care system. The ACOG (2010) guidelines emphasize the need for thorough counseling, shared decision making, and client autonomy.

Nurses must act as advocates, giving input on the appropriate selection of women who wish to undergo

VBAC. Nurses also need to become experts at reading fetal monitoring tracings to identify fetal distress and set in motion an emergency birth. Including all of these nursing strategies will make VBAC safer for all.

## INTRAUTERINE FETAL DEMISE

Pregnancy and childbirth are associated with hopes, expectations, joy, and happiness for the future. When an unborn life suddenly ends with fetal loss, the family members are profoundly affected. The sudden loss of an expected child is tragic and the family's grief can be very intense: it can last for years and can cause extreme psychological stress and emotional problems (Gardner, Carter, Enzman-Hines, & Hernandez, 2011). Regardless of race, only female parents experience intrauterine death or the birth of a dead fetus inside the uterus. To women who have gone through this harrowing experience, culturally appropriate and sensitive care is crucial. Particularly for the mother, fetal death in the last trimester of pregnancy, when she feels very close to the fetus due to its frequent movement in the uterus, must be similar to losing a part of her body.

Grief, the typical response to the loss of a valued object, is not an intellectual response. Rather, it is personally experienced as a deep emotion of sadness and sorrow. Feelings such as helplessness, disbelief, unreality, and powerlessness are common. Emotional recovery from the pain of perinatal loss occurs with time, but it varies with each couple.

Fetal death can be due to numerous conditions, such as prolonged pregnancy, infection, hypertension, advanced maternal age, Rh disease, uterine rupture, diabetes, congenital anomalies, cord accident, abruption, blunt trauma, premature rupture of membranes, or hemorrhage—or it may go unexplained (Gilbert, 2011). Trauma in pregnancy remains one of the major contributors to maternal and fetal morbidity and mortality. Potential complications include maternal injury or death, shock, internal hemorrhage, intrauterine fetal demise, direct fetal injury, abruptio placentae, and uterine rupture. The leading causes of obstetric trauma are motor vehicle accidents, falls, assaults, and gunshots, and ensuing injuries are classified as blunt abdominal trauma, pelvic fractures, or penetrating trauma. In view of the significant impact of trauma on the pregnant woman and her fetus, preventive strategies are paramount (Romero & Pearlman, 2012).

Early pregnancy loss may be through a spontaneous abortion (miscarriage), an induced abortion (therapeutic abortion), or a ruptured ectopic pregnancy. A wide spectrum of feelings may be expressed, from relief to sadness and despair. A fetal death can occur at any gestational age, and typically there is little or no warning other than reduced fetal movement.

The moment that fetal death is diagnosed can frequently be described very clearly and in detail by most women. In many cases, the death was sudden, and women have no chance to prepare for the impending grief. With

the death of a fetus or neonate, a couple's dreams and hopes for their expected child suddenly dissolve. To women who have experienced a sudden fetal death, the following processes may take place: experiencing a quiet birth without the infant, eclipsed by emptiness, anger, anxiety, loneliness, and sorrow; living without their infant, making it very difficult to see others with young infants; and experiencing differences with their partner over the loss (Gardner et al., 2011). Grief is an individual process of coping with the stressful change in relationships that is created by a death. The process of grieving a death is not completed within a specific time frame, and for some, it is never complete. In general, the grief accompanying the loss of a fetus proceeds in the following order:

1. Accepting the reality of the loss
2. Getting over suffering from the loss
3. Adapting to the new environment without the deceased
4. Emotionally relocating the deceased and getting on with life (Moore, Parrish, & Black, 2011)

The period following a fetal death is extremely difficult for the family. For many women, emotional healing takes much longer than physical healing. The feelings of loss can be intense. The grief response in some women may be so great that their relationships become strained, and healing can become hampered unless appropriate interventions and support are provided.

Fetal death also affects the health care staff. Despite the trauma that the loss of a fetus causes, some staff members avoid dealing with the bereaved family, never talking about or acknowledging their grief. This seems to imply that not discussing the problem will allow the grief to dissolve and vanish. As a result, the family's needs go unrecognized. Failing to keep the lines of communication open with a bereaved client and her family closes off some of the channels to recovery and healing that may be desperately needed. Subsequently, the bereaved family members may feel isolated.

## Nursing Assessment

History and physical examination are of limited value in the diagnosis of fetal death, since the only history tends to be recent absence of fetal movement. An inability to obtain fetal heart sounds on examination suggests fetal demise, but an ultrasound is necessary to confirm the absence of fetal cardiac activity. Once fetal demise is confirmed, induction of labor is indicated.

## Nursing Management

The nurse can play a major role in assisting the grieving family. Nurses who can deal honestly with their own feelings regarding loss will be better able to help others cope with theirs. By working with couples who have suffered a significant loss, the nurse can grow personally and professionally and gain a deeper perspective about

life. With skillful intervention, the bereaved family may be better prepared to resolve their grief and move forward. To assist families in the grieving process, include the following measures:

- Provide accurate, understandable information to the family.
- Be knowledgeable about the grief process and comfortable in sharing another's grief.
- Utilize active listening to provide needed encouragement to the family members to open up to their feelings.
- Create a warm, receptive, accepting, and caring environment conducive to dialogue.
- Encourage discussion of the loss and venting of feelings of grief and guilt.
- Provide the family with baby mementos and pictures to validate the reality of death.
- Allow unlimited time with the stillborn infant after birth to validate the death; provide time for the family members to be together and grieve; offer the family the opportunity to see, touch, and hold the infant.
- Use appropriate touch, such as holding a hand or touching a shoulder.
- Inform the chaplain or the religious leader of the family's denomination about the death and request his or her presence.
- Assist the parents with the funeral arrangements or disposition of the body.
- Provide the parents with brochures offering advice about how to talk to other siblings about the loss.
- Refer the family to the support group SHARE Pregnancy and Infant Loss Support, Inc., which is designed for those who have lost an infant through abortion, miscarriage, fetal death, stillbirth, or other tragic circumstances.
- Make community referrals to promote a continuum of care after discharge.

Support provided by nurses can have a positive influence on the long-term adjustment of couples and families coping with perinatal loss. Openness to talking with couples about their loss and grief is foundational. A sensitive nurse who is comfortable talking about loss and is able to assist couples in navigating the process of grief provides a starting point for preparation for future pregnancy. Couples need to talk about their loss, its meaning, and the emotions that accompany it while the nurse listens. Nurses play a significant role in linking women and men to appropriate professional support. As couples move through their grief and begin to consider another pregnancy, sensitive nursing care may mediate the understandable anxiety and concern that accompany this process (Moore et al., 2011).

## WOMEN EXPERIENCING AN OBSTETRIC EMERGENCY

Obstetric emergencies are challenging to all labor and birth personnel because of the increased risk of adverse outcomes for the mother and fetus. Quick clinical

judgment and good critical decision making will increase the odds of a positive outcome for both mother and fetus. This section discusses a few of these emergencies: umbilical cord prolapse, placenta previa, placental abruption, uterine rupture, and amniotic fluid embolism.

### Umbilical Cord Prolapse

An **umbilical cord prolapse** is the protrusion of the umbilical cord alongside (occult) or ahead of the presenting part of the fetus (Fig. 21.5). This condition occurs in 1 out of every 300 births and requires prompt recognition and intervention for a positive outcome (March of Dimes, 2011d). Cord prolapse occurs in 3% of deliveries when the fetus is in the vertex position and in 3.7% of deliveries when the fetus is in the breech position. The risk is increased further when the presenting part does not fill the lower uterine segment, as is the case with incomplete breech presentations (5% to 10%), premature infants, and multiparous women (Brailovschi, Sheiner, Wiznitzer, Shahaf, & Levy, 2012). With a 50% perinatal mortality rate, it is one of the most catastrophic events in the intrapartum period (Beall & Ross, 2012).

### Pathophysiology

Prolapse usually leads to total or partial occlusion of the cord. Since this is the fetus's only lifeline, fetal perfusion deteriorates rapidly. Complete occlusion renders the fetus helpless and oxygen deprived. The fetus will die if the cord compression is not relieved.

### Nursing Assessment

Prevention is the key to managing cord prolapse by identifying clients at risk for this condition. Carefully assess

each client to help predict her risk status. Be aware that cord prolapse is more common in pregnancies involving malpresentation, growth restriction, prematurity, ruptured membranes with a fetus at a high station, hydramnios, grandmultiparity, and multifetal gestation (Cunningham et al., 2010). Continuously assess the client and fetus to detect changes and to evaluate the effectiveness of any interventions performed.

#### Take Note!

When the presenting part does not fully occupy the pelvic inlet, prolapse is more likely to occur.

### Nursing Management

Prompt recognition of a prolapsed cord is essential to reduce the risk of fetal hypoxia resulting from prolonged cord compression. When membranes are artificially ruptured, assist with verifying that the presenting part is well applied to the cervix and engaged into the pelvis. If pressure or compression of the cord occurs, assist with measures to relieve the compression. Typically, the examiner places a sterile gloved hand into the vagina and holds the presenting part off the umbilical cord until delivery. Changing the woman's position to a modified Sims, Trendelenburg, or knee-chest position also helps relieve cord pressure. Monitor fetal heart rate, maintain bed rest, and administer oxygen if ordered. Provide emotional support and explanations as to what is going on to allay the woman's fears and anxiety. If the mother's cervix is not fully dilated, prepare the woman for an emergency cesarean birth to save the fetus's life.

### Placenta Previa

Placenta previa is placental implantation in the lower uterine segment over or near the internal os of the

**FIGURE 21.5** Prolapsed cord. (A) Prolapse within the uterus. (B) Prolapse with the cord visible at the vulva.

cervix, typically during the second or third trimester of pregnancy. With uterine segment formation and cervical dilation, placental implantation over or near the cervical os, instead of along the uterine wall, inevitably results in spontaneous placental separation—and subsequent hemorrhage. This position can create a barrier for the fetus from the uterus during the birthing process. As the cervix begins to thin and dilate (open up) in preparation for labor, blood vessels that connect the placenta to the uterus may tear and cause bleeding. It is the most common cause of bleeding in the second half of pregnancy and should be suspected in any woman beyond 24 weeks' gestation presenting with vaginal bleeding; ultrasonography (e.g., transvaginal) is used to diagnose it. During labor and birth, bleeding can be severe, which can place the mother and fetus at risk. Reported incidence is approximately 1 in 200 births (March of Dimes, 2011b). There is a direct relationship between the number of previous cesarean births and the risk of placenta previa, probably due to uterine scarring. The degree of occlusion of the internal cervical os may depend on the degree of cervical dilation, so what may appear to be a low-lying or marginal placenta previa prior to the onset of labor can progress to become more serious as the cervix effaces and opens up (Mattson & Smith, 2011).

The incidence of maternal mortality is less than 1%, but common morbidities include septicemia, renal failure, hemorrhage and hypovolemic shock, invasive placenta (accrete, increta, and percreta), and postpartum anemia. The risk for perinatal mortality is less than 10%, but common neonatal morbidities include stillbirth, prematurity, malpresentation, IUGR, and fetal anemia (Gilbert, 2011).

Maternal signs and symptoms of placenta previa include sudden, painless bleeding (that may be heavy enough to be considered hemorrhaging), anemia, pallor, hypoxia, low blood pressure, tachycardia, soft and nontender uterus, and rapid, weak pulse. Bleeding may be episodic, with spontaneous initiation and cessation; in some cases, it is asymptomatic.

Management of placenta previa varies by type and gestational age, and frequent medical surveillance may be sufficient in marginal cases; prompt treatment with bed rest, close monitoring, and control/replacement of blood loss greatly reduces risk for maternal and fetal complications and death. Vaginal delivery is possible when bleeding is minimal, placenta previa is marginal, or labor is rapid. Pregnancy termination, early birth by cesarean section, or a hysterectomy may be necessary in order to control severe bleeding, especially for clients with complete placenta previa. The overall maternal prognosis is good if hemorrhage is controlled and sepsis or other complications are prevented. Fetal prognosis is directly related to the amount of blood loss. The U.S. perinatal mortality rate associated with placenta previa is 2% to 3%, and the maternal mortality rate is 0.03%. Risk for placenta previa recurrence in subsequent pregnancies is 4% to 8% (Buckley & Schub, 2011).

Nursing management includes the following: monitor maternal vital signs, intake and output, vaginal bleeding, and physiologic status for signs of hemorrhage, shock, or infection; closely monitor fetal heart tones for distress (e.g., bradycardia, tachycardia, baseline changes); and treat fetal distress, as ordered. Administer prescribed IV fluids, packed RBCs, platelets, and frozen plasma for transfusion, if ordered; Rho(D) immune globulin, if the client is Rh negative; IV augmented oxytocin (Pitocin) to induce labor, if needed; and in cases of preterm labor, tocolytics (e.g., magnesium sulfate) to inhibit uterine contractions and corticosteroids (e.g., betamethasone) to enhance fetal lung maturity. Follow facility pre- and postsurgical protocols if woman becomes a surgical candidate (e.g., for cesarean section); reinforce pre- and postsurgical education and ensure completion of facility's informed consent documents; closely monitor postsurgically for bleeding, infection, and other complications; assess client's anxiety level and coping ability; and provide emotional support and reassurance.

### Placental Abruption

Placental abruption refers to premature separation of a normally implanted placenta from the maternal myometrium. Abruption placenta occurs in about 1% of all pregnancies throughout the world (March of Dimes, 2011b). Risk factors include preeclampsia, gestational hypertension, seizure activity, uterine rupture, trauma, smoking, cocaine use, coagulation defects, previous history of abruption, domestic violence, and placental pathology. These conditions may force blood into the underlayer of the placenta and cause it to detach (Deering, 2011).

Management of placental abruption depends on the gestational age, the extent of the hemorrhage, and maternal–fetal oxygenation perfusion/reserve status (see Chapter 19 for additional information on abruption placenta). Treatment is based on the circumstances. Typically once the diagnosis is established, the focus is on maintaining the cardiovascular status of the mother and developing a plan to deliver the fetus quickly. A cesarean birth may take place quickly if the fetus is still alive with only a partial abruption. A vaginal birth may take place if there is fetal demise secondary to a complete abruption.

### Uterine Rupture

Uterine rupture is a catastrophic tearing of the uterus at the site of a previous scar into the abdominal cavity. Its onset is often marked only by sudden fetal bradycardia, and treatment requires rapid surgery for good outcomes. From the time of diagnosis to delivery, only 10 to 30 minutes are available before clinically significant fetal morbidity occurs. Fetal morbidity occurs secondary to catastrophic hemorrhage, fetal anoxia, or both.

## Nursing Assessment

Review the mother's history for risk conditions such as uterine scars, prior cesarean births, prior rupture, trauma, prior invasive molar pregnancy, history of placenta percreta or increta, congenital uterine anomalies, multiparity, previous uterine myomectomy, malpresentation, labor induction with excessive uterine stimulation, and crack cocaine use (Nahum & Pham, 2011). Reviewing a client's history for risk factors might prove to be lifesaving for both mother and fetus.

Generally, the first and most reliable symptom of uterine rupture is sudden fetal distress. Other signs may include acute and continuous abdominal pain with or without an epidural, vaginal bleeding, hematuria, irregular abdominal wall contour, loss of station in the fetal presenting part, and hypovolemic shock in the woman, fetus, or both (Nahum & Pham, 2011).

Timely management of uterine rupture depends on prompt detection. Because many women desire a trial of labor after a previous cesarean birth, the nurse must be familiar with the signs and symptoms of uterine rupture. It is difficult to prevent uterine rupture or to predict which women will experience rupture, so constant preparedness is necessary.

Screening all women with previous uterine surgical scars is important, and continuous electronic fetal monitoring should be used during labor because this may provide the only indication of an impending rupture.

## Nursing Management

Because the presenting signs may be nonspecific, the initial management will be the same as that for any other cause of acute fetal distress. Urgent delivery by cesarean birth is usually indicated. Monitor maternal vital signs and observe for hypotension and tachycardia, which might indicate hypovolemic shock. Assist in preparing for an emergency cesarean birth by alerting the operating room staff, anesthesia provider, and neonatal team. Insert an indwelling urinary (Foley) catheter if one is not in place already. Inform the woman of the seriousness of this event and remind her that the health care staff will be working quickly to ensure her health and that of her fetus. Remain calm and provide reassurance that everything is being done to ensure a safe outcome for both.

The life-threatening nature of uterine rupture is underscored by the fact that the maternal circulatory system delivers approximately 500 mL of blood to the term uterus every minute (Gupta & Nanda, 2011). Maternal death is a real possibility without rapid intervention. Newborn outcome after rupture depends largely on the speed with which surgical rescue is carried out. As in any case of acute obstetric emergency, preparation and timely mobilization of all necessary personnel is key to optimizing outcome.

### Take Note!

When excessive bleeding occurs during the childbirth process and it persists or signs such as bruising or petechiae appear, disseminated intravascular coagulation (DIC) should be suspected.

## Amniotic Fluid Embolism

Amniotic fluid embolism remains an enigmatic, but devastating obstetric condition associated with significant maternal and newborn morbidity and mortality. It is a rare and often fatal event characterized by the sudden onset of hypotension, hypoxia, and coagulopathy. Amniotic fluid containing particles of debris (e.g., hair, skin, vernix, or meconium) enters the maternal circulation and obstructs the pulmonary vessels, causing respiratory distress and circulatory collapse (Ketchem & Rimbos, 2011). Prediction and diagnosis of the event are nearly impossible. However, timely recognition and response is critical in saving a woman's life. Although estimates vary, amniotic fluid embolism, also referred to as anaphylactoid syndrome of pregnancy, occurs in from 1 in 40,000 to 1 in 60,000 births, with a reported mortality rate reaching 86% (Moore, 2012).

## Pathophysiology

Normally, amniotic fluid does not enter the maternal circulation because it is contained within the uterus, sealed off by the amniotic sac. An embolus occurs when the barrier between the maternal circulation and the amniotic fluid is broken and amniotic fluid enters the maternal venous system via the endocervical veins, the placental site (if the placenta is separated), or a site of uterine trauma. This condition has a high mortality rate: as many as 50% of women die within the first hour after the onset of symptoms, and about 85% of survivors have permanent hypoxia-induced neurologic damage (Moore, 2012).

Although medical science has supplied many answers to questions about this condition, health care providers remain largely unable to predict or prevent an amniotic fluid embolism or to decrease its mortality rate.

## Nursing Assessment

Nurses must have a high degree of suspicion with this disorder and not waste time; a team response is essential because every person will be needed. Nurses must stay a step ahead and be prepared at all times in this OB emergency. No test can diagnose an amniotic fluid embolism. Therefore, the nurse's assessment skills are critical. Immediate recognition and diagnosis of this condition are essential to improve maternal and fetal outcomes. Until recently, the diagnosis could be made only after an

autopsy of the mother revealed squamous cells, lanugo hair, or other fetal and amniotic material in the pulmonary arterial vasculature (Gilbert, 2011).

The clinical appearance is varied, but most women report difficulty breathing. Other symptoms include hypotension, cyanosis, seizures, tachycardia, coagulation failure, DIC, pulmonary edema, uterine atony with subsequent hemorrhage, adult respiratory distress syndrome, and cardiac arrest (Abdel-Razeq, 2011).

### Take Note!

Amniotic fluid embolism should be suspected in any pregnant women with an acute onset of dyspnea, hypotension, and DIC. By knowing how to intervene, the nurse can promote a better chance of survival for both the mother and her newborn.

## Nursing Management

Upon recognizing the signs and symptoms of this life-threatening diagnosis, institute supportive measures: oxygenation (resuscitation and 100% oxygen), circulation (IV fluids, inotropic agents to maintain cardiac output and blood pressure), control of hemorrhage and coagulopathy (oxytocic agents to control uterine atony and bleeding), seizure precautions, and administration of steroids to control the inflammatory response. Monitor vital signs, pulse oximetry, skin color, and temperature and observe for clinical signs of coagulopathy (vaginal bleeding, bleeding from IV site, bleeding from gums) (Gilbert, 2011).

Care is largely supportive and aimed at maintaining oxygenation and hemodynamic function and correcting coagulopathy. There is no specific therapy that is life-saving once this condition starts. Adequate oxygenation is necessary, with endotracheal intubation and mechanical ventilation for most women. Vasopressors are used to maintain hemodynamic stability. Management of DIC may involve replacement with packed red blood cells or fresh-frozen plasma as necessary. Oxytocin infusions and prostaglandin analogs can be used to address uterine atony.

Explain to the client and family what is happening and what therapies are being instituted. The woman is usually transferred to a critical care unit for intensive observation and care. Assist the family to express their feelings and provide support as needed. Inform and reassure the woman and family as much as possible during this crisis.

## WOMEN REQUIRING BIRTH-RELATED PROCEDURES

Many women can give birth without the need for any operative obstetric interventions. Most do not anticipate the need for any medical intervention. However, in some situations interventions are necessary to safeguard the

health of the mother and fetus. The most common birth-related procedures are amnioinfusion, episiotomy (see Chapter 14), forceps-assisted or vacuum-assisted birth, cesarean birth, and vaginal birth following a previous cesarean birth (see section earlier in this chapter). Nurses play a major role in helping couples to cope with any unanticipated procedures by offering thorough explanations of the procedure, its anticipated benefits and risks, and any other options available.

## Amnioinfusion

**Amnioinfusion** is a technique in which a volume of warmed, sterile, normal saline or Ringer's lactate solution is introduced into the uterus through an intrauterine pressure catheter to increase the volume of fluid when oligohydramnios is present. It is used to change the relationship of the uterus, placenta, cord, and fetus to improve placental and fetal oxygenation. Instilling an isotonic glucose-free solution into the uterus helps to cushion the umbilical cord to prevent compression or dilute thick meconium (Hofmeyr & Lawrie, 2012).

This procedure is commonly indicated for severe variable decelerations due to cord compression, oligohydramnios due to placental insufficiency, postmaturity or rupture of membranes, preterm labor with premature rupture of membranes, and thick meconium fluid. However, it does not prevent meconium aspiration syndrome (Baxter, Sehdev, & Breckenridge, 2010). Contraindications to amnioinfusion include vaginal bleeding of unknown origin, umbilical cord prolapse, amnionitis, uterine hypertonicity, and severe fetal distress (Wrich & Whiteside, 2010).

There is no standard protocol for amnioinfusion; nurses should follow their own hospital protocols. After obtaining informed consent, a vaginal examination is performed to evaluate for cord prolapse, establish dilation, and confirm presentation. Next, 250 to 500 mL of warmed normal saline or lactated Ringer's solution is administered using an infusion pump over 20 to 30 minutes. Overdistention of the uterus is a risk, so the amount of fluid infused must be monitored closely. Amnioinfusion should reach therapeutic result or increase the amniotic fluid volume in approximately 30 minutes (Mattson & Smith, 2011).

When caring for the woman who is receiving an amnioinfusion, include the following:

- Explain the need for the procedure, what it involves, and how it may solve the problem.
- Inform the mother that she will need to remain on bed rest during the procedure.
- Assess the mother's vital signs and associated discomfort level.
- Maintain intake and output records.
- Assess the duration and intensity of uterine contractions frequently to identify overdistention or increased uterine tone.

- Assess for fluid leakage by evaluating the chuck or pad under the woman to determine that it is not being retained in the uterus, which could lead to increased uterine pressure.
- Monitor the FHR pattern to determine whether the amnioinfusion is improving the fetal status.
- Prepare the mother for a possible cesarean birth if the FHR does not improve after the amnioinfusion.

### Forceps- or Vacuum-Assisted Birth

Forceps or a vacuum extractor may be used to apply traction to the fetal head or to provide a method of rotating the fetal head during birth. **Forceps** are stainless-steel instruments, similar to tongs, with rounded edges that fit around the fetus's head. Some forceps have open blades and some have solid blades. Outlet forceps are used when the fetal head is crowning and low forceps are used when the fetal head is at a +2 station or lower but not yet crowning. The forceps are applied to the sides of the fetal head. The type of forceps used is determined by the birth attendant. All forceps have a locking mechanism that prevents the blades from compressing the fetal skull. Use of forceps has declined in popularity recently because many obstetricians are not trained to use them in their residency (Fig. 21.6).

A **vacuum extractor** is a cup-shaped instrument attached to a suction pump used for extraction of the fetal head (Fig. 21.7). The suction cup is placed against the occiput of the fetal head. The pump is used to create negative pressure (suction) of approximately 50 to 60 mm Hg. The birth attendant then applies traction until the fetal head emerges from the vagina.

The indications for the use of either method are similar and include a prolonged second stage of labor, a distressed FHR pattern, failure of the presenting part to fully rotate and descend in the pelvis, limited sensation and inability to push effectively due to the effects of regional

anesthesia, presumed fetal jeopardy or fetal distress, maternal heart disease, acute pulmonary edema, intrapartum infection, maternal fatigue, or infection. There is a clear trend to choose vacuum extraction over forceps to assist delivery, but the evidence supporting that trend is unconvincing. Recent literature confirms some advantages for forceps (e.g., a lower failure rate) and some disadvantages for vacuum extraction (e.g., increased neonatal injury), depending on the clinical circumstances (Lacker 2012).

The use of forceps or a vacuum extractor poses the risk of tissue trauma to the mother and the newborn. Maternal trauma may include lacerations of the cervix, vagina, or perineum; hematoma; extension of the episiotomy incision into the anus; hemorrhage; and infection. Potential newborn trauma includes ecchymoses, facial and scalp lacerations, facial nerve injury, cephalhematoma, and caput succedaneum (Cunningham et al., 2010).

Prevention is key to reducing the use of these techniques. Preventive measures include frequently changing the client's position, encouraging ambulation if permitted, frequently reminding the client to empty her bladder to allow maximum space for birth, and providing adequate hydration throughout labor. Additional measures include assessing maternal vital signs, the contraction pattern, the fetal status, and the maternal response to the procedure. Provide a thorough explanation of the procedure and the rationale for its use. Reassure the mother that any marks or swelling on the newborn's head or face will disappear without treatment within 2 to 3 days. Alert the postpartum nursing staff about the use of the technique so that they can observe for any bleeding or infection related to genital lacerations.

### Cesarean Birth

A **cesarean birth** is the delivery of the fetus through an incision in the abdomen and uterus. A classic (vertical)

**FIGURE 21.6** Forceps delivery (uncommon). **(A)** Example of forceps. **(B)** Forceps being applied to the fetus. **(C)** Forceps marks are commonly found in newborns delivered by forceps. Such marks are transient and disappear in a day or two.

**FIGURE 21.7** Vacuum extractor for delivery. **(A)** Example of a vacuum extractor. **(B)** Vacuum extractor applied to the fetal head to assist in delivery.

or low transverse incision may be used; today, the low transverse incision is more common (Fig. 21.8).

High cesarean birth rates are an international concern. The cesarean birth rate in the United States is on the rise at an alarming rate. Today approximately 33% or one in three births occurs this way. This is the 12th consecutive year the cesarean birth rate has risen, despite a number of medical organizations, including the WHO and ACOG, urging medical care providers to work on lowering the cesarean birth rate (Centers for Disease Control and Prevention, 2010). Several factors may explain this increased incidence of cesarean deliveries: the use of electronic fetal monitoring, which identifies fetal distress early; the reduced number of forceps-assisted births; older maternal age and reduced parity; increasing maternal obesity, with more nulliparous women having infants; convenience to the client and doctor; and an increase in malpractice suits (Declercq, Young, Cabral, & Ecker, 2011).

Cesarean birth is a major surgical procedure with increased risks compared to a vaginal birth. The client is at risk for complications such as infection, hemorrhage, aspiration, pulmonary embolism, urinary tract trauma, thrombophlebitis, paralytic ileus, and atelectasis. Fetal injury and transient tachypnea of the newborn also may occur (Hyde, Mostyn, Modi, & Kemp, 2012).

Spinal, epidural, or general anesthesia is used for cesarean births. Epidural anesthesia is most commonly used today because it is associated with less risk and most women wish to be awake and aware of the birth experience.

## Nursing Assessment

Review the woman's history for indications associated with cesarean birth and complete a physical examination. Any condition that prevents the safe passage of the fetus through the birth canal or that seriously compromises

maternal or fetal well-being may be an indication for a cesarean birth. A cesarean birth is performed for maternal indications or fetal indications, or both. The leading indications for cesarean birth are previous cesarean birth, breech presentation, dystocia, and fetal distress. These indications are responsible for the majority of all cesarean births. Recently, debate has ensued over the option of elective cesarean birth on maternal request. Evidence shows that informing the pregnant woman requesting a surgical birth of the associated risks and benefits for the current and any subsequent pregnancies is reasonable. The clinician's role should be to provide the best evidence-based counseling possible to the woman and to respect her autonomy and decision-making capabilities when considering route of birth.

**FIGURE 21.8** Low transverse incision for cesarean birth.

Examples of specific indications include active genital herpes, fetal macrosomia, fetopelvic disproportion, prolapsed umbilical cord, placental abnormality (placenta previa or abruptio placentae), previous classic uterine incision or scar, gestational hypertension, diabetes, positive HIV status, and dystocia. Fetal indications include malpresentation (nonvertex presentation), congenital anomalies (fetal neural tube defects, hydrocephalus, abdominal wall defects), and fetal distress (Joy & Contag, 2011).

## Nursing Management

Once the decision has been made to proceed with a cesarean birth, assess the woman's knowledge of the procedure and necessary preparation. Assist with obtaining diagnostic tests as ordered. These tests are usually ordered to ensure the well-being of both parties and may include a complete blood count; urinalysis to rule out infection; blood type and cross-match so that blood is available for transfusion if needed; an ultrasound to determine fetal position and placental location; and an amniocentesis to determine fetal lung maturity if needed.

Although the nurse's role in a cesarean birth can be very technical and skill oriented at times, the focus must remain on the woman, not the equipment surrounding the bed. Care should be centered on the family, not the surgery. Provide education and minimize separation of the mother, father, and newborn. Remember that the client is anxious and concerned about her welfare as well as that of her child. Use touch, eye contact, therapeutic communication, and genuine caring to provide couples with a positive birth experience, regardless of the type of delivery.

### Providing Preoperative Care

Client preparation varies depending on whether the cesarean birth is planned or unplanned. The major difference is the time allotted for preparation and teaching. In an unplanned cesarean birth, institute measures quickly to ensure the best outcomes for the mother and fetus. Ensure that the woman has signed an informed consent, and allow for discussion of fears and expectations. Provide essential teaching and explanations to reduce the woman's fears and anxieties.

Ascertain the client's and family's understanding of the surgical procedure. Reinforce the reasons for surgery given by the surgeon. Outline the procedure and expectations of the surgical experience. Ensure that all diagnostic tests ordered have been completed, and evaluate the results. Explain to the woman and her family about what to expect postoperatively. Reassure the woman that pain management will be provided throughout the procedure and afterward. Encourage the woman to report any pain.

Ask the woman about the time she last had anything to eat or drink. Document the time and what was consumed. Throughout the preparations, assess maternal and fetal status frequently.

Provide preoperative teaching to reduce the risk of postoperative complications. Demonstrate the use of the incentive spirometer and deep-breathing and leg exercises. Instruct the woman on how to splint her incision.

Complete the preoperative procedures, which may include:

- Preparing the surgical site as ordered
- Starting an intravenous infusion for fluid replacement therapy as ordered
- Inserting an indwelling (Foley) catheter and informing the client about how long it will remain in place (usually 24 hours)
- Administering any preoperative medications as ordered; documenting the time administered and the client's reaction

Maintain a calm, confident manner in all interactions with the client and family. Help transport the client and her partner to the operative area.

### Providing Postoperative Care

Postoperative care for the mother who has had a cesarean delivery is similar to that for one who has had a vaginal birth, with a few additional measures. Assess vital signs and lochia flow every 15 minutes for the first hour, then every 30 minutes for the next hour, and then every 4 hours if stable. Assist with perineal care and instruct the client in the same. Inspect the abdominal dressing and document description, including any evidence of drainage. Assess uterine tone to determine fundal firmness. Check the patency of the intravenous line, making sure the infusion is flowing at the correct rate. Inspect the infusion site frequently for redness.

Assess the woman's level of consciousness if sedative drugs were administered. Institute safety precautions until the woman is fully alert and responsive. If a regional anesthetic was used, monitor for the return of sensation to the legs.

Assess for evidence of abdominal distention and auscultate bowel sounds. Assist with early ambulation to prevent respiratory and cardiovascular problems and to promote peristalsis. Monitor intake and output at least every 4 hours initially and then every 8 hours as indicated.

Encourage the woman to cough, perform deep-breathing exercises, and use the incentive spirometer every 2 hours. Administer analgesics as ordered and provide comfort measures, such as splinting the incision and pillows for positioning. Assist the client to move in bed and turn side to side to improve circulation. Also encourage the woman to ambulate to promote venous return from the extremities.

Encourage early touching and holding of the newborn to promote bonding. Assist with breast-feeding initiation and offer continued support. Suggest alternate positioning techniques to reduce incisional discomfort while breast-feeding.

Review with the couple their perception of the surgical birth experience. Allow them to verbalize their feelings and assist them in positive coping measures. Prior to discharge, teach the woman about the need for adequate rest, activity restrictions such as lifting, and signs and symptoms of infection.

- Generally, the first and most reliable symptom of uterine rupture is fetal distress.
- Amniotic fluid embolism is a rare but often fatal event characterized by the sudden onset of hypotension, hypoxia, and coagulopathy.
- Cesarean births have steadily risen in the United States; today, approximately one in three births occurs this way. Cesarean birth is a major surgical procedure and has increased risks over vaginal birth.

## KEY CONCEPTS

- Risk factors for dystocia include epidural analgesia, occiput posterior position, longer first stage of labor, nulliparity, short maternal stature (<5 feet tall), high birth weight, maternal age older than 35 years, gestational age more than 41 weeks, chorioamnionitis, pelvic contractions, macrosomia, and high station at complete cervical dilation.
- Dystocia may result from problems in the powers, passenger, passageway, or psyche.
- Problems involving the powers that lead to dystocia include hypertonic uterine dysfunction, hypotonic uterine dysfunction, and precipitate labor.
- Management of hypertonic labor pattern involves therapeutic rest with the use of sedatives to promote relaxation and stop the abnormal activity of the uterus.
- Any presentation other than occiput or a slight variation of the fetal position or size increases the probability of dystocia.
- Multifetal pregnancy may result in dysfunctional labor due to uterine overdistention, which may lead to hypotonic dystocia and abnormal presentations of the fetuses.
- During labor, evaluation of fetal descent, cervical effacement and dilation, and characteristics of uterine contractions are paramount to determine progress or lack thereof.
- Antepartum assessment for a prolonged pregnancy typically includes daily fetal movement counts done by the woman, nonstress tests done twice weekly, amniotic fluid assessments as part of the biophysical profile, and weekly cervical examinations to check for ripening for induction.
- Once the cervix is ripe, oxytocin is the most popular pharmacologic agent used for inducing or augmenting labor.

## MULTIPLE-CHOICE QUESTIONS

- When reviewing the medical record of a client, the nurse notes that the woman has a condition in which the fetus cannot physically pass through the maternal pelvis. The nurse interprets this as:
  - Cervical insufficiency
  - Contracted pelvis
  - Maternal disproportion
  - Fetopelvic disproportion
- The nurse would anticipate a cesarean birth for a client who has which active infection present at the onset of labor?
  - Hepatitis
  - Herpes simplex virus
  - Toxoplasmosis
  - Human papillomavirus
- After a vaginal examination, the nurse determines that the client's fetus is in an occiput posterior position. The nurse would anticipate that the client will have:
  - Intense back pain
  - Frequent leg cramps
  - Nausea and vomiting
  - A precipitous birth
- When assessing the following women, which would the nurse identify as being at the greatest risk for preterm labor?
  - Woman who had twins in a previous pregnancy
  - Client living in a large city
  - Woman working full time as a computer programmer
  - Client with a history of a previous preterm birth
- The rationale for using a prostaglandin gel for a client prior to the induction of labor is to:
  - Stimulate uterine contractions
  - Numb cervical pain receptors
  - Prevent cervical lacerations
  - Soften and efface the cervix

- A client who was in active labor and whose cervix had dilated to 4 cm experiences a weakening in the intensity and frequency of her contractions and exhibits no further progress in labor. The nurse interprets this as a sign of:
  - Hypertonic labor
  - Precipitate labor
  - Hypotonic labor
  - Dysfunctional labor

## CRITICAL THINKING EXERCISES

- Marsha, a 26-year-old multipara, is admitted to the labor and birth suite in active labor. After a few hours, the nurse notices a change in her contraction pattern—poor contraction intensity and no progression of cervical dilatation beyond 5 cm. Marsha keeps asking about her labor progress and appears anxious about “how long this labor is taking.”
  - Based on the nurse's findings, what might you suspect is going on?
  - How can the nurse address Marsha's anxiety?
  - What are the appropriate interventions to change this labor pattern?
- Marsha activates her call light and states, “I feel increased wetness down below.”
  - What might be occurring?
  - How will the nurse confirm the suspicions?
  - What interventions are appropriate for this finding?

## STUDY ACTIVITIES

 thrombophlebitis  
 uterine atony  
 uterine inversion

# Nursing Management of the Postpartum Woman at Risk

## Learning Objectives

*Upon completion of the chapter, you will be able to:*

1. Define the key terms used in this chapter.
2. Examine the major conditions that place the postpartum woman at risk.
3. Analyze the risk factors, assessment, preventive measures, and nursing management of common postpartum complications.
4. Differentiate the causes of postpartum hemorrhage based on the underlying pathophysiologic mechanisms.
5. Outline the nurse's role in assessing and managing the care of a woman with a thromboembolic condition.
6. Characterize the nursing management of a woman who develops a postpartum infection.
7. Compare and contrast at least two affective disorders that can occur in women after birth, describing specific therapeutic management for each.

*Joan gave birth about an hour ago to her fifth baby boy, who weighed 10 pounds, and she is resting in bed when the nurse comes in to assess her. She tells the nurse that she feels like there is “something really wet” between her legs. She also feels a bit light-headed. What would the nurse suspect is happening? What findings would support the nurse’s suspicion? What should the nurse do first?*

## Words of Wisdom

After holding their breath during the childbirth experience, nurses shouldn't let it out fully and relax until the woman and baby are discharged.

**Typically**, recovery from childbirth proceeds normally both physiologically and psychologically. It is a time filled with many changes and wide-ranging emotions, and the new mother commonly experiences a great sense of accomplishment. However, the woman can experience deviations from the norm, developing a postpartum condition that places her at risk. These high-risk conditions or complications can become life threatening. *Healthy People 2020* addresses these risks in two national health goals that were retained from the 2010 edition.

This chapter addresses the nursing management of the most common conditions that place the postpartum woman at risk: hemorrhage, thromboembolic disease, infections, and postpartum affective disorders.

## POSTPARTUM HEMORRHAGE

**Postpartum hemorrhage** is a potentially life-threatening complication that can occur after both vaginal and cesarean births. It is the leading cause of maternal death worldwide, with an estimated mortality rate of 358,000 per year, or 1 maternal death every 4 minutes. A hemorrhage occurs in 5% of all births and is responsible for a major part of maternal mortality. The majority of these deaths occur within 4 hours of childbirth, which indicates that they are a consequence of the third stage of labor management (Rath, 2011).

### HEALTHY PEOPLE 2020 • 22-1

#### Objective

#### Nursing Significance

##### BDBS-15

Increase the proportion of women with von Willebrand disease (vWD) who are timely and accurately diagnosed by 10% by 2020.

- Will help foster the need for early identification of problems and prompt intervention to reduce the potential negative outcomes of pregnancy and birth.

##### MHMD-4

Reduce the proportion of persons who experience major depressive episode by 10% by 2020.

- Will help to contribute to lower rates of rehospitalization, morbidity, and mortality by focusing on thorough assessments in the postpartum period.
- Will help to minimize the devastating effects of complications during the postpartum period and the woman's ability to care for her newborn.

*Healthy People* objectives based on data from <http://www.healthypeople.gov>.

Postpartum hemorrhage is defined as a blood loss greater than 500 mL after vaginal birth or more than 1,000 mL after a cesarean birth. However, this definition is arbitrary, because estimates of blood loss at birth are subjective and generally inaccurate. Studies have suggested that health care providers consistently underestimate actual blood loss. A major obstetric hemorrhage is defined as a blood loss of more than 2,500 mL or bleeding that required more than 5 units of transfused blood (McLintock & James, 2011). Blood loss that occurs within 24 hours of birth is termed *early postpartum hemorrhage*; blood loss that occurs 24 hours to 6 weeks after birth is termed *late postpartum hemorrhage*. A more objective definition of postpartum hemorrhage (PPH) would be any amount of bleeding that places the mother in hemodynamic jeopardy.

## Pathophysiology

Excessive bleeding can occur at any time between the separation of the placenta and its expulsion or removal. The most common cause of postpartum hemorrhage is **uterine atony**, failure of the uterus to contract and retract after birth. The uterus must remain contracted after birth to control bleeding from the placental site. Any factor that causes the uterus to relax after birth will cause bleeding—even a full bladder that displaces the uterus.

During the third stage of labor the muscles of the uterus contract downward, causing constriction of the blood vessels that pass through the uterine wall to the placental surface and stopping the flow of blood. This action also causes the placenta to separate from the uterine wall. The absence of uterine contractions may result in excessive blood loss. Uterotonic medications promote uterine contractions to prevent atony and speed delivery of the placenta.

Over the course of pregnancy, maternal blood volume increases as much as 50% (from 4 to 6 L). The plasma volume increases twice as much in comparison to the total red blood cell volume. As a result, hemoglobin and hematocrit fall. The increase in blood volume meets the perfusion demands of the low-resistance uteroplacental unit and provides a reserve for the blood loss that occurs at delivery (Cunningham et al., 2010). Given this increase, the typical signs of hemorrhage (e.g., falling blood pressure, increasing pulse rate, and decreasing urinary output) do not appear until as much as 1,800 to 2,100 mL of blood has been lost (Gilbert, 2011). Clinical manifestations of shock resulting from blood loss are seen in Table 22.1.

In addition, accurate determination of actual blood loss is difficult because of blood pooling inside the uterus, on peripads, mattresses, and the floor. Because no universal clinical standard exists, nurses must remain vigilant, assessing for risk factors and checking clients carefully before the birth attendant leaves the birthing area.

**TABLE 22.1** CLINICAL MANIFESTATIONS OF SHOCK DUE TO BLOOD LOSS

Degree of Shock	Blood Loss	Signs and Symptoms
Mild	<20%	Diaphoresis Increased capillary refilling Cool extremities Maternal anxiety
Moderate	20–40%	Tachycardia Postural hypotension Oliguria
Severe	>40%	Hypotension Agitation/confusion Hemodynamic instability

Adapted from Gilbert, E. S. (2011). *Manual of high-risk pregnancy and delivery* (5th ed.). St. Louis, MO: Mosby Elsevier; McIntock, C., & James, A. (2011). Obstetric hemorrhage. *Journal of Thrombosis and Hemostasis*, 9(8), 1441-1451; and Udeani, J. (2011). Hemorrhagic shock. *eMedicine*. Retrieved from <http://emedicine.medscape.com/article/432650-overview>.

Other causes of PPH include lacerations of the genital tract, episiotomy, retained placental fragments, uterine inversion, coagulation disorders, large for gestational age newborn, failure to progress during the second stage of labor, placenta accreta, induction or augmentation of labor with oxytocin, surgical birth, and hematomas of the vulva, vagina, or subperitoneal areas (Smith & Brennan, 2012). A helpful way to remember the causes of postpartum hemorrhage is by using the “5 T’s”:

1. **Tone:** uterine atony, distended bladder
2. **Tissue:** retained placenta and clots
3. **Trauma:** vaginal, cervical, or uterine injury
4. **Thrombin:** coagulopathy (preexisting or acquired)
5. **Traction:** causing uterine inversion

## Tone

Altered uterine muscle tone most commonly results from overdistention of the uterus. Overdistention can be caused by multifetal gestation, fetal macrosomia, hydramnios, fetal abnormality, or placental fragments. Other causes might include prolonged or rapid, forceful labor, especially if stimulated by oxytocin; bacterial toxins (e.g., chorioamnionitis, endomyometritis, septicemia); use of anesthesia, especially halothane; and magnesium sulfate used in the treatment of preeclampsia (Tharpe, Farley, & Jordan, 2013). Overdistention of the uterus is a major risk factor for uterine atony, the most common cause of early postpartum hemorrhage, which can lead to hypovolemic shock. A distended bladder can also displace the uterus

from the midline to either side, which impedes its ability to contract to reduce bleeding.

## Tissue

Uterine contraction and retraction lead to detachment and expulsion of the placenta after birth. Classic signs of placental separation include a small gush of blood with lengthening of the umbilical cord and a slight rise of the uterus in the pelvis. Complete detachment and expulsion of the placenta permit continued contraction and optimal occlusion of blood vessels. Failure of complete placental separation and expulsion leads to retained fragments, which occupy space and prevent the uterus from contracting fully to clamp down on blood vessels; this can lead to hemorrhage. After the placenta has been expelled, a thorough inspection is necessary to confirm its intactness; tears or fragments left inside may indicate an accessory lobe or placenta accreta (an uncommon condition in which the chorionic villi adhere to the myometrium, causing the placenta to adhere abnormally to the uterus and not separate and deliver spontaneously). Profuse hemorrhage results because the uterus cannot contract fully.

A prolapse of the uterine fundus to or through the cervix so that the uterus is turned inside out after birth is called **uterine inversion**. This condition is associated with grand multiparity, abnormal adherence of the placenta, excessive traction on the umbilical cord, vigorous fundal pressure, precipitous labor, or vigorous manual removal of the placenta. Occurring in about 1 in 6,000 births, uterine inversion is a rare occurrence in obstetrics, but the event has serious consequences. Immediate life-threatening hemorrhage occurs within minutes, and, in cases in which the diagnosis is not rapidly made, maternal death often results (Ogah & Munjuluri, 2011). Prompt recognition and rapid treatment to replace the inverted uterus will avoid morbidity and mortality for this serious complication (Stevens & Wittich, 2011). (Uterine inversion is discussed in more detail in the “Traction” section below.)

**Subinvolution** refers to incomplete involution of the uterus or failure to return to its normal size and condition after birth (Dorland, 2011). Complications of subinvolution include hemorrhage, pelvic peritonitis, salpingitis, and abscess formation (Chelmow, O’Grady, & Guzman, 2011). Causes of subinvolution include retained placental fragments, distended bladder, uterine myoma, and infection. All of these conditions contribute to delayed postpartum bleeding. The clinical picture includes a postpartum fundal height that is higher than expected, with a boggy uterus; the lochia fails to change colors from red to serosa to alba within a few weeks. This condition is usually identified at the woman’s postpartum examination 4 to 6 weeks after birth with a bimanual vaginal examination or ultrasound. Treatment is directed toward stimulating the uterus to expel fragments with a uterine stimulant, and antibiotics are given to prevent infection.

## Trauma

Damage to the genital tract may occur spontaneously or through the manipulations used during birth. Lacerations and hematomas resulting from birth trauma can cause significant blood loss. Hematomas can present as pain or as a change in vital signs disproportionate to the amount of blood loss. Uterine inversion can occur secondary to pressure or pulling on the umbilical cord when the placenta is still firmly attached to the fundus after the infant has been born. Additionally, uterine rupture can cause damage to the genital tract and is more common in women with previous cesarean incisions or those who have undergone any procedure resulting in disruption of the uterine wall, including myomectomy, perforation of the uterus during a dilation and curettage (D&C), biopsy, or intrauterine device (IUD) insertion (Smith & Brennan, 2012).

Trauma can also occur after prolonged or vigorous labor, especially if the uterus has been stimulated with oxytocin or prostaglandins. Trauma can also occur after extrauterine or intrauterine manipulation of the fetus.

Cervical lacerations commonly occur during a forceps delivery or in mothers who have not been able to resist bearing down before the cervix is fully dilated. Vaginal sidewall lacerations are associated with operative vaginal births but may occur spontaneously, especially if the fetal hand presents with the head. Lacerations can arise during manipulations to resolve shoulder dystocia. Lacerations should always be suspected in the face of a contracted uterus with bright-red blood continuing to trickle out of the vagina.

## Thrombin

Thrombosis (blood clots) helps to prevent postpartum hemorrhage immediately after birth by providing hemostasis. Fibrin deposits and clots in supplying vessels play a significant role in the hours and days after birth. Disorders that interfere with the clot formation can lead to postpartum hemorrhage. Medication used to prevent hemorrhage by stimulating uterine contractions may delay the appearance of coagulation disorders. Coagulopathies should be suspected when postpartum bleeding persists without any identifiable cause (American College of Obstetricians and Gynecologists [ACOG], 2012).

Disorders of coagulation are relatively uncommon as a sole cause of postpartum hemorrhage. Coagulation disturbances should be suspected in women with a family history of such abnormalities and women with a history of menorrhagia. Clinical circumstances may also suggest coagulation defect as a cause of postpartum hemorrhage. Diagnosis of a coagulation disorder often requires a high index of suspicion and should not be overlooked in the evaluation of obstetric hemorrhage (Chi & Kadir, 2012).

Ideally, the client's coagulation status is determined during pregnancy. However, if she received no prenatal

care, coagulation studies should be ordered immediately to determine her status. Abnormal results typically include decreased platelet and fibrinogen levels, increased prothrombin time, partial thromboplastin time, and fibrin degradation products, and a prolonged bleeding time (Cunningham et al., 2010). Selected conditions associated with coagulopathies in the postpartum client include idiopathic thrombocytopenic purpura, von Willebrand disease, and disseminated intravascular coagulation.

### IDIOPATHIC THROMBOCYTOPENIA PURPURA

Idiopathic thrombocytopenia purpura (ITP) is a disorder of increased platelet destruction caused by autoantibodies, which can increase a woman's risk of hemorrhaging. It is most common in young women during childbearing age and may be associated with maternal and fetal complications. ITP is a decrease in the number of circulating platelets in the absence of toxic exposure or a disease associated with a low platelet count. The incidence of ITP in adults is approximately 66 cases per 1,000,000 per year (Silverman, 2011). Glucocorticoids and immune globulin are the mainstays of medical therapy (Neunert, 2011).

### VON WILLEBRAND DISEASE

von Willebrand disease (vWD) is a congenital bleeding disorder that is inherited as an autosomal dominant trait. It is characterized by a prolonged bleeding time, a deficiency of von Willebrand factor, and impairment of platelet adhesion (Dorland, 2011). It is the most common hereditary bleeding disorder, affecting approximately 1% to 3% of the general population (Chi & Kadir 2012). Although vWD is thought to affect men and women equally, it is diagnosed more frequently in women because of menorrhagia, and it is more common among white women than black women (Buckley & Schub, 2011). Most cases remain undiagnosed due to lack of awareness, difficulty in diagnosis, a tendency to attribute bleeding to other causes, and variable symptoms. The most common symptoms of vWD include nosebleeds and hematomas. Prolonged bleeding from trivial wounds, oral cavity bleeding, and excessive menstrual bleeding are common. Gastrointestinal bleeding is rare. During pregnancy, the von Willebrand factor level increases in most women; thus, labor and birth usually proceed normally. However, all women should be monitored for excessive bleeding, particularly during the first week postpartum (Pollak, 2012).

### DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC) is a life-threatening, acquired coagulopathy in which the clotting system is abnormally activated, resulting in widespread clot formation in the small vessels throughout the body, which leads to the depletion of platelets and coagulation factors. This is why DIC is also known as consumption coagulopathy.

DIC is always a secondary diagnosis that occurs as a complication of abruptio placentae, amniotic fluid embolism, intrauterine fetal death with prolonged retention of the fetus, severe preeclampsia, HELLP syndrome, septicemia, and hemorrhage. Clinical features include petechiae, ecchymoses, bleeding gums, fever, hypotension, acidosis, hematomas, tachycardia, proteinuria, uncontrolled bleeding during birth, and acute renal failure (Martí-Carvajal, 2011). Treatment goals are to maintain tissue perfusion through aggressive administration of fluid therapy, oxygen, heparin, and blood products. The most important treatment concept in DIC is that it is a secondary manifestation of an underlying disorder. The most important therapeutic maneuver is treating the initiating disorder. Without this, supportive measures ultimately fail (Kanwar & Sills, 2011).

### Traction

Uterine inversion, in which the uterus is turned inside out, is a rare complication that usually results from excessive traction on the umbilical cord in an attempt to hasten the third stage of childbirth. The common etiology is that uterine inversion occurs with an atonic uterus that has not separated well from the placenta as it is being delivered or from excessive traction on the umbilical cord while placental delivery is being assisted. Research studies are yet to demonstrate the typical mechanism for uterine inversion. However, clinical vigilance for inversion, secondary to these potential causes, is generally practiced. Inversion prevents the myometrium from contracting and retracting, and it is associated with life-threatening hemorrhaging as well as profound hypotension from vagal activation (Smith & Brennan, 2012). Maternal symptoms include pain, profuse bleeding, and shock.

Management of uterine inversion involves gentle pushing of the uterus back into position (under general anesthesia) by the health care provider, followed by oxytocin to augment uterine contractions and antibiotic therapy to prevent infection. Prevention can be achieved by not pulling forcefully on the umbilical cord until the placenta separates (Cunningham et al., 2010).

## Therapeutic Management

Therapeutic management focuses on the underlying cause of the hemorrhage. For example, uterine massage is used to treat uterine atony. If retained placental fragments are the cause, the fragments are usually manually separated and removed and a uterine stimulant is given to promote the uterus to expel fragments. Antibiotics are administered to prevent infection. Lacerations are sutured or repaired. Glucocorticoids and intravenous immunoglobulin, intravenous anti-RhoD, and platelet transfusions may be given for ITP. Perinatal management of ITP should also include maintenance of maternal platelet count and

regular monitoring of fetal growth along with prediction and prevention of fetal passive immune thrombocytopenia (Silverman, 2011).

The mainstays of therapy for vWD are desmopressin and plasma concentrates that contain von Willebrand factor. Delayed postpartum hemorrhage may occur, despite adequate prophylaxis. Frequent monitoring and continued prophylaxis and/or treatment are recommended for at least 2 weeks after childbirth (Pollak, 2012).

## Nursing Assessment

Most women will not have identifiable risk factors. Nonetheless, primary prevention of a postpartum hemorrhage begins with an assessment of identifiable risk factors. Pregnancy and childbirth involve significant health risks, even for women with no preexisting health problems. In the United States, where most births occur in hospitals and where resources are likely to be available as compared to developing countries, postpartum hemorrhage still continues to be among the top causes of maternal deaths. Retrospective studies of these events suggest that some cases are preventable. As with many other sources of perinatal harm, delays in recognition, diagnosis, and treatment, problems with hierarchy and communication, and lack of knowledge, policies, and protocols were often cited as contributing factors (Wagner, Meirowitz, Shah, Nanda et al., 2012).

The period after the birth and the first hours postpartum are crucial times for the prevention, assessment, and management of bleeding. Compared with other maternal risks such as infection, bleeding can rapidly become life threatening, and nurses, along with other health care providers, need to identify this condition quickly and intervene appropriately.

Begin by reviewing the mother's history, including labor and birth history, for risk factors associated with postpartum hemorrhage (Table 22.2). The incidence of postpartum hemorrhage has been rising, though the mortality has come down, suggesting improvement in the management of this condition. Although specific risk factors have been identified, postpartum hemorrhage is often unanticipated and still occurs in approximately 5% of all births (Keriakos & Chudhuri, 2012).

Since the most common cause of immediate severe postpartum hemorrhage is uterine atony (failure of the uterus to contract properly after birth), assess uterine tone after birth by palpating the fundus for firmness and location. A soft, boggy fundus indicates uterine atony.

### Take Note!

A soft, boggy uterus that deviates from the midline suggests that a full bladder is interfering with uterine involution. If the uterus is not in correct position (midline), it will not be able to contract to control bleeding.

**TABLE 22.2** FACTORS PLACING A WOMAN AT RISK FOR POSTPARTUM HEMORRHAGE

Clinical Risk Factors	Associated Clinical Conditions
<i>Tone (abnormalities of uterine contractions)</i>	
Overdistension of uterus	Hydramnios Multifetal gestation Macrosomia
Uterine muscle exhaustion	Rapid labor Prolonged labor Oxytocin use
Uterine infection	Maternal fever Prolonged rupture of membranes
<i>Tissue (retained in uterus)</i>	
Products of conception	Incomplete placenta at birth
Retained blood clots	Atonic uterus
<i>Trauma (of the genital tract)</i>	
Lacerations anywhere	Precipitate birth or operative birth
Laceration extensions	Malposition of fetus Previous uterine surgery
<i>Thrombin (coagulation abnormalities)</i>	
Preexisting conditions	Hereditary inheritance Hemophilia von Willebrand's disease History of previous PPH Acquired in pregnancy Idiopathic thrombocytopenia purpura Bruising, elevated BP Disseminated intravascular coagulation
<i>Traction (of the cord, which may cause uterine inversion)</i>	
Forceful pulling when placenta is not separated	Impatience No countertraction applied on the uterine fundus Previous history of inversion Traction on the cord when uterus is not contracted

Operative interventions in the management of major postpartum hemorrhage. <i>Journal of Obstetrics &amp; Gynecology</i> , 32(1), 14–25; Rath, W. (2011). Postpartum hemorrhage—Update on problems of definitions and diagnosis. <i>Acta Obstetrica et Gynecologica Scandinavica</i> , 90(5), 421–428; and Smith, J. R., & Brennan, B. G. (2012). Postpartum hemorrhage. <i>eMedicine</i> . Retrieved from <a href="http://emedicine.medscape.com/article/275038-overview">http://emedicine.medscape.com/article/275038-overview</a> .	

Assess the amount of bleeding. Visual estimation is the most frequently practiced method of determining blood loss during childbirth in the United States, and the results are usually included in the documentation of events pertaining to the birth. This method is used despite repeated studies showing its inaccuracy and underestimation (Gabel & Weeber, 2012). If bleeding continues even though there are no lacerations, suspect retained placental fragments. The uterus remains large with painless, dark-red bleeding mixed with clots. This cause of hemorrhage can be prevented by carefully inspecting the placenta for intactness.

*If trauma is suspected*, attempt to identify the source and document it. Typically, the uterus will be firm with a steady stream or trickle of unclotted bright-red blood noted in the perineum. Most deaths from postpartum hemorrhage are not due to gross bleeding, but rather to inadequate management of slow, steady blood loss (Srivastava, Bartlett, & Thakur, 2012).

*Assess for hematoma*. The uterus would be firm, with bright-red bleeding. Observe for a localized bluish bulging area just under the skin surface in the perineal area (Fig. 22.1). Often the woman will report severe

**FIGURE 22.1** Perineal hematoma. Note the bulging swollen mass.

perineal or pelvic pain and will have difficulty voiding. In addition, she may exhibit hypotension, tachycardia, and anemia (Gilbert, 2011).

Inspect the skin and mucous membranes for gingival bleeding or petechiae and ecchymoses. Check venipuncture sites for oozing or prolonged bleeding. These findings might suggest a coagulopathy as a cause of postpartum hemorrhage. Also assess the amount of lochia, which would be much greater than usual. Urinary output would be diminished, with signs of acute renal failure. Vital signs would show an increased pulse rate and a decreased level of consciousness. However, signs of shock do not appear until hemorrhage is far advanced due to the increased fluid and blood volume of pregnancy.

## Nursing Management

When excessive bleeding is encountered, initial management steps are aimed at improving uterine tone with immediate fundal massage, intravenous fluid resuscitation, and administration of uterotonic medications. If these methods fail to control bleeding, additional resources are mobilized and more aggressive interventions such as bimanual compression, internal uterine packing, and/or balloon tamponade techniques are employed by the health care provider. Other potential causes of bleeding should be thoroughly explored, and laboratory tests such as a complete blood count, type and cross-match, and coagulations studies should be obtained immediately. Transfusion of blood products should be instituted without hesitation once estimates of bleeding reach 1,500 mL (Saule & Hawkins, 2012).

Clearly, in all cases of unexpected hemorrhage, the interventions discussed below must be performed without delay. Peripartum hysterectomy remains the last-resort lifesaving measure and carries with it a mortality rate of 1% to 6% (Bateman, Mhyre, Callahan, & Kuklina, 2012). Moreover, high-volume transfusions are often required, and there are significant postsurgery morbidity risks such as renal failure, hepatic failure, respiratory distress syndrome, coagulopathies, septicemia, tissue hypoxia, and pituitary necrosis (Sheehan syndrome) (Bonnet, Deneux-Tharaux, & Bouvier-Colle, 2011).

Postpartum hemorrhage is a serious complication of pregnancy that is often unanticipated. Even with prompt aggressive management, postpartum bleeding can quickly evolve into a life-threatening event. Perinatal nurses are often the first to observe significant postpartum bleeding and their prompt initial response and continued assessments are pivotal in the anticipation and coordination of necessary interventions. Multidisciplinary team support is critical because obstetric caregivers need a full array of medical and surgical strategies to manage intractable bleeding.

Because all postpartum women are at risk for hemorrhage, nurses need to possess the knowledge and skills to practice active management of the third stage of labor to prevent hemorrhage and to recognize, assess, and respond rapidly to excessive blood loss in their clients.

## Massage the Uterus

*Massage the uterus if uterine atony is noted.* The uterine muscles are sensitive to touch; massage stimulates the muscle fibers to contract. Massage the boggy uterus to stimulate contractions and expression of any accumulated blood clots while supporting the lower uterine segment. As blood pools in the vagina, stasis of blood causes clots to form. These clots need to be expelled as pressure is placed on the fundus. Note, however, that overly forceful massage can tire the uterine muscles, resulting in further uterine atony and increased pain. See Nursing Procedure 22.1 for the steps in massaging the fundus.

## Administer a Uterotonic Drug

*Administer a uterotonic drug.* If repeated fundal massage and expression of clots fail, medication is probably needed to cause the uterus to contract in order to control bleeding from the placental site. The injection of a uterotonic drug immediately after birth is an important intervention used to prevent postpartum hemorrhage. Oxytocin (Pitocin); a synthetic analog of prostaglandin E1, misoprostol (Cytotec) or dinoprostone (Prostin E2); methylergonovine maleate (Methergine); and a derivative of prostaglandin (PGF2 $\alpha$ ), carboprost (Hemabate), are drugs used to manage postpartum hemorrhage (Drug Guide 22.1). However, misoprostol is not approved by the U.S. Food and Drug Administration (FDA) for this

## NURSING PROCEDURE 22.1

## Massaging the Fundus

**Purpose: To Promote Uterine Contraction**

1. After explaining the procedure to the woman, place one gloved hand (usually the dominant hand) on the fundus.
2. Place the other gloved hand on the area above the symphysis pubis (this helps to support the lower uterine segment).
3. With the hand on the fundus, gently massage the fundus in a circular manner. Be careful not to overmassage the fundus, which could lead to muscle fatigue and uterine relaxation.
4. Assess for uterine firmness (uterine tissue responds quickly to touch).
5. If firm, apply gentle yet firm pressure in a downward motion toward the vagina to express any clots that may have accumulated.
6. Do not attempt to express clots until the fundus is firm because the application of firm pressure on an uncontracted uterus could cause uterine inversion, leading to massive hemorrhage.
7. Assist the woman with perineal care and applying a new perineal pad.
8. Remove gloves and wash hands.

purpose. The choice of which uterotonic drug to use for management of bleeding depends on the judgment of the health care provider, the availability of drugs, and the risks and benefits of the drug.

All nurses need to be aware of the contraindications of administering each of the medications used to control postpartum hemorrhage as follows:

- Pitocin—never give undiluted as a bolus injection IV
- Cytotec—allergy, active CVD, pulmonary or hepatic disease
- Prostin E2—active cardiac, pulmonary, renal, or hepatic disease
- Methergine—if the woman is hypertensive, do not administer
- Hemabate—contraindicated with asthma due to risk of bronchial spasm

*Remember Joan, the woman described at the beginning of the chapter? The nurse assesses her and finds that her uterus is boggy. What would the nurse do next? What additional nursing measures might be used if Joan's fundus remains boggy? When should the health care provider be notified?*

**Maintain the Primary IV Infusion**

*Maintain the primary IV infusion* and be prepared to start a second infusion at another site if blood transfusions are necessary. Draw blood for type and cross-match and send it to the laboratory. Administer oxytocics as ordered, correlating and titrating the infusion rate to assessment findings of uterine firmness and lochia. Assess for visible vaginal bleeding, and count or weigh perineal pads.

**Take Note!**

Visual estimation is the most frequently practiced method of determining blood loss during childbirth, but studies show that it is an inaccurate method and that blood loss is underestimated (Gabel & Weeber, 2012).

**Check Vital Signs**

*Check vital signs every 15 to 30 minutes*, depending on the acuity of the mother's health status. Monitor her complete blood count to identify any deficit or assess the adequacy of replacement. Assess the woman's level of consciousness to determine changes that may result from inadequate cerebral perfusion.

**DRUG GUIDE 22.1 DRUGS USED TO CONTROL POSTPARTUM HEMORRHAGE**

Drug	Action/Indication	Nursing Implications
Oxytocin (Pitocin)	Stimulates the uterus to contract/to contract the uterus to control bleeding from the placental site 20–40 units in a liter IV or 10 units IM	Assess fundus for evidence of contraction and compare amount of bleeding every 15 min or according to orders. Monitor vital signs every 15 min. Monitor uterine tone to prevent hyperstimulation. Reassure client about the need for uterine contraction and administer analgesics for comfort. Offer explanation to client and family about what is happening and the purpose of the medication.
Misoprostol (Cytotec)	Stimulates the uterus to contract/ to reduce bleeding; a prostaglandin analog 800 mcg per rectum, one dose (range, 400–1,000 mcg)	Provide nonpharmacologic comfort measures to assist with pain management. Set up the IV infusion to be piggybacked into a primary IV line. This ensures that the medication can be discontinued readily if hyperstimulation or adverse effects occur while maintaining the IV site and primary infusion. Contraindications: Never give undiluted as a bolus injection IV. As above. Not FDA approved for this indication, but a very effective drug therapy for acute postpartum hemorrhage Contraindications: allergy, active CVD, pulmonary or hepatic disease; use with caution in women with asthma
Dinoprostone (Prostin E2)	20 mg vaginal or rectal suppository May be repeated every two hours	Monitor blood pressure frequently since hypotension is a frequent side effect along with vomiting and diarrhea, nausea, temperature elevation
Methylergonovine maleate (Methergine)	Stimulates the uterus/to prevent and treat postpartum hemorrhage due to atony or subinvolution 0.2 mg IM injection May be repeated in 5 min Thereafter every 2–4 hr	Assess baseline bleeding, uterine tone, and vital signs every 15 min or according to protocol. Offer explanation to client and family about what is happening and the purpose of the medication. Monitor for possible adverse effects, such as hypertension, seizures, uterine cramping, nausea, vomiting, and palpitations. Report any complaints of chest pain promptly. Contraindications: Hypertension
Prostaglandin (PGF <sub>2</sub> α), Carboprost, (Hemabate)	Stimulates uterine contractions/ to treat postpartum hemorrhage due to uterine atony when not controlled by other methods 0.25 mg IM injection May be repeated every 15–90 min up to 8 doses Stimulates uterine contractions to reduce bleeding when not controlled by the first-line therapy of oxytocin	Assess vital signs, uterine contractions, client's comfort level, and bleeding status as per protocol. Offer explanation to client and family about what is happening and the purpose of the medication. Monitor for possible adverse effects, such as fever, chills, headache, nausea, vomiting, diarrhea, flushing, and bronchospasm. Contraindications: asthma or active CVD Same as above Contraindications: active cardiac, pulmonary, renal, or hepatic disease

Adapted from King, T. L., & Brucker, M. C. (2011). *Pharmacology for women's health*. Sudbury, MA: Jones & Bartlett; Lilley, L., Collins, S. R., Harrington, S., & Snyder, J. (2011). *Pharmacology and the nursing process*. St. Louis, MO: Mosby; and Skidmore-Roth, L. (2012). *Mosby's 2012 nursing drug reference* (25th ed.). St. Louis, MO: Mosby Elsevier.

If a full bladder is present, assist the woman to empty her bladder to reduce displacement of the uterus. A fundus above the umbilicus and deviated laterally indicates a full bladder. If the woman cannot void, anticipate the need to catheterize her to relieve bladder distention.

### Prepare the Woman for Removal of Retained Placental Fragments

*Prepare the woman for removal of retained placental fragments.* These fragments usually are manually separated and removed by the health care provider. Be sure that the health care provider remains long enough after birth to assess the bleeding status of the woman and determine the etiology. Assist the health care provider with suturing any lacerations immediately to control hemorrhage and repair the tissue.

Nurses should anticipate and prepare the woman for transfer to the operating room for surgical intervention if tamponade techniques fail to achieve hemostasis. The blood bank should be notified that additional transfusions may be required and the woman's condition closely monitored for signs of hypovolemic shock.

### Continually Assess the Woman for Signs and Symptoms of Hemorrhagic Shock

*Continually assess the woman for signs and symptoms of hemorrhagic shock,* a condition in which inadequate perfusion of organs results in insufficient availability of oxygen to satisfy the metabolic needs of the tissues (Dorland, 2011). Hemorrhagic shock is the most common form of shock encountered in obstetric practice. Subsequently a catabolic state develops, leading to inflammation, endothelial dysfunction, and disruption of normal metabolic processes in vital organs. Once these events become established, the process of shock is often irreversible, even if volume and red blood cell deficits are corrected (Pacheco, Saade, Gei, & Hankins, 2011).

A postpartum hemorrhage is a traumatic experience because medical complications are unexpected during what is anticipated as a joyful time. Assess the anxiety level of the woman; the woman going into hypovolemic shock is highly anxious and may lose consciousness. The woman's significant others experience a high level of anxiety as well and need a great deal of support.

Monitor the woman's blood pressure, pulse, capillary refill, mental status, and urinary output. These assessments allow estimation of the severity of blood loss and help direct treatment. If the woman develops hemorrhagic shock, interventions focus on controlling the source of blood loss; restoring adequate oxygen-carrying capacity; and maintaining adequate tissue perfusion. Successful treatment depends on efficient collaboration among all health care team members to meet the woman's specific needs.

For the woman with ITP, expect to administer glucocorticoids, IV immunoglobulin, IV anti-RhoD, and platelet

transfusions. Prepare the woman for a splenectomy if the bleeding tissues do not respond to medical management.

Be alert for women with abnormal bleeding tendencies, ensuring that they receive proper diagnosis and treatment. Teach them how to prevent severe hemorrhage by learning how to feel for and massage their fundus when boggy, assisting the nurse to keep track of the number of and amount of bleeding on perineal pads, and avoiding any medications with antiplatelet activity such as aspirin, antihistamines, or NSAIDs.

### Institute Emergency Measures if DIC Develops

*If the woman develops DIC,* institute emergency measures to control bleeding and impending shock and prepare to transfer her to the intensive care unit. Identification of the underlying condition and elimination of the causative factor are essential to correct the coagulation problem. Be ready to replace fluid volume, administer blood component therapy, and optimize the mother's oxygenation and perfusion status to ensure adequate cardiac output and end-organ perfusion. Continually reassess the woman's coagulation status via laboratory studies.

Monitor vital signs closely, being alert for changes that signal an increase in bleeding or impending shock. Observe for early signs of ecchymosis, including spontaneous bleeding from gums or nose, petechiae, excessive bleeding from the cesarean incision site or IV site, hematuria, and blood in the stool. Late signs include progressive changes in vital signs, skin color, and reduction of urinary output. Collectively, these findings correlate with decreased blood volume, decreased organ and peripheral tissue perfusion, and clots in the microcirculation (Gilbert, 2011).

#### Take Note!

Always remember the five causes of postpartum hemorrhage and the appropriate intervention for each: (1) uterine atony—massage and oxytocics; (2) retained placental tissue—evacuation and oxytocics; (3) lacerations or hematoma—surgical repair; (4) thrombin (bleeding disorders)—blood products; and (5) uterine inversion caused by too much cord traction—gentle replacement of uterus and oxytocics.

Institute measures to avoid tissue trauma or injury, such as giving injections and drawing blood. Also provide emotional support to the client and her family throughout this critical time by being readily available and providing explanations and reassurance.

### Preventing Postpartum Hemorrhage

Avoid an episiotomy unless urgent birth is necessary and the peritoneum is a limiting factor. It is important to have the continuous intrapartum presence of an experienced labor and birth nurse

Provide active management of the third stage of labor, including administration of a uterotonic medication after birth of anterior shoulder, controlled and gentle cord traction to deliver the placenta, and uterine massage after the placenta is out. Authors of a Cochrane review concluded that active management of the third stage of labor is associated with reduced blood loss, reduced risk of postpartum hemorrhage, and a reduced prolonged third stage of labor (Begley et al., 2011).

Frequent staff education and PPH drills will help keep skills up to date. Nurses must identify and correct anemia and screen for coagulopathies before labor and birth. After birth, it is important to inspect the placenta (once it is delivered) for completeness. Assess woman for lower genital tract lacerations immediately after birth and reevaluate the woman's vital signs and vaginal flow after childbirth. Finally, it is important to be aware of the mother's beliefs about blood transfusions (World Health Organization, 2010).

In summary, careful monitoring of the mother's vital signs, laboratory tests (in particular, coagulation testing) and immediate diagnosis of the cause of postpartum hemorrhage are important key factors to reduce maternal morbidity and mortality.

*An IV oxytocin infusion is started for Joan. What assessments will need to be done frequently to make sure Joan is not losing too much blood? What discharge instructions need to be reinforced with Joan?*

## THROMBOEMBOLIC CONDITIONS

A thrombosis (blood clot within a blood vessel) can cause an inflammation of the blood vessel lining (**thrombophlebitis**), which in turn can lead to a thromboembolism (obstruction of a blood vessel by a blood clot carried by the circulation from the site of origin). Thrombi can involve the superficial or deep veins in the legs or pelvis. Superficial venous thrombosis usually involves the saphenous venous system and is confined to the lower leg. Superficial thrombophlebitis may be caused by the use of the lithotomy position during birth. Deep venous thrombosis can involve deep veins from the foot to the calf, to the thighs, or pelvis. In both locations, thrombi can dislodge and migrate to the lungs, causing a pulmonary embolism.

Deep venous thrombosis (DVT) is a common condition that can have serious complications. Deep venous thrombi have a high probability of propagating and leading to pulmonary emboli, which may cause chest pain, breathlessness, and sudden death. Thus, an accurate and timely diagnosis of DVT is imperative. Although DVT is often clinically silent, it may present with a number of signs, including calf pain, edema, and venous distention.

The three most common thromboembolic conditions occurring during the postpartum period are superficial venous thrombosis, deep venous thrombosis, and pulmonary embolism. Although thromboembolic disorders occur in less than 1% of all postpartum women, pulmonary embolism can be fatal if a clot obstructs the lung circulation; thus, early identification and treatment are paramount.

## Pathophysiology

Thrombus (blood clot) formation typically results from venous stasis, injury to the innermost layer of the blood vessel, and hypercoagulation. Venous stasis and hypercoagulation are both common in the postpartum period.

If a clot dislodges and travels to the pulmonary circulation, pulmonary embolism (PE) can occur. Pulmonary embolism is a potentially fatal condition that occurs when the pulmonary artery is blocked by a blood clot that has traveled from another vein into the lungs, causing an obstruction and infarction. When the clot is large enough to block one or more of the pulmonary vessels that supply the lungs, it can result in sudden death. Approximately 600,000 PEs occur yearly in the United States, resulting in 200,000 to 300,000 deaths (Ouellette & Patocka, 2012). Only 150,000 of all clients with PE are actually diagnosed, indicating that thousands of PEs go undetected. Many deaths due to PE are unrecognized and the diagnosis is often made at autopsy. Pulmonary embolism is the leading cause of pregnancy-related death in the United States, occurring in 2 out of 100,000 live births. It most commonly occurs up to 4 weeks postpartum and following a surgical birth (Lussana, Coppens, Cattaneo, & Middeldorp, 2012). A national review of severe obstetric complications found a significant increase in the rate of PE associated with the increasing rate of cesarean births (Miller, Chalhoub, & Bourjeily, 2011).

## Nursing Assessment

Assess the woman closely for risk factors and signs and symptoms of thrombophlebitis. Look for risk factors in the woman's history such as use of oral contraceptives before the pregnancy, smoking, employment that necessitates prolonged standing, history of thrombosis, thrombophlebitis, or endometritis, or evidence of current varicosities. Also look for other factors that can increase a woman's risk, such as prolonged bed rest, diabetes, obesity, cesarean birth, progesterone-induced distensibility of the veins of the lower legs during pregnancy, severe anemia, varicose veins, advanced maternal age (older than 35 years), and multiparity. The likelihood of thrombophlebitis is increased through most of pregnancy and for approximately 6 weeks after childbirth. This is partly due to increased platelet stickiness and partly due

to reduced fibrinolytic activity (Palm, Trizna, & Goldman, 2012).

Ask the woman if she has pain or tenderness in the lower extremities. Suspect superficial venous thrombosis in a woman with varicose veins who reports tenderness and discomfort over the site of the thrombosis, most commonly in the calf area. The area appears reddened along the vein and is warm to the touch. The woman will report increased pain in the affected leg when she ambulates and bears weight.

Manifestations of deep venous thrombosis are often absent and diffuse. If present, they are caused by an inflammatory process and obstruction of venous return. Calf swelling, erythema, warmth, tenderness, and pedal edema may be noted. A positive Homans' sign (pain in the calf upon dorsiflexion) is not a definitive diagnostic sign and is no longer recommended as an indicator of DVT because calf pain can also be caused by a strained muscle, contusion, clients with herniated intervertebral discs, calf muscle spasm, neurogenic leg pain, ruptured Baker's cyst, and cellulitis (Jarvis, 2012).

Be alert for signs and symptoms of pulmonary embolism, including unexplained sudden onset of shortness of breath and severe chest pain. The woman may be apprehensive and diaphoretic. Additional manifestations may include tachypnea, tachycardia, hypotension, syncope, distention of the jugular vein, decreased oxygen saturation (shown by pulse oximetry), cardiac arrhythmias, hemoptysis, and a sudden change in mental status as a result of hypoxemia (Antonella, 2011). Prepare the woman for a lung scan to confirm the diagnosis.

## Nursing Management

Nursing management focuses on preventing thrombotic conditions, promoting adequate circulation if thrombosis occurs, and educating the client about preventive measures, anticoagulant therapy, and danger signs.

### Preventing Thrombotic Conditions

Prevention of thrombotic conditions is an essential aspect of nursing management and can be achieved with the routine use of simple measures:

- Developing public awareness about risk factors, symptoms, and preventive measures
- Preventing venous stasis by encouraging activity that causes leg muscles to contract and promotes venous return (leg exercises and walking)
- Using intermittent sequential compression devices to produce passive leg muscle contractions until the woman is ambulatory
- Elevating the woman's legs above her heart level to promote venous return
- Stopping smoking to reduce or prevent vascular vasoconstriction

- Applying compression stockings and removing them daily for inspection of legs
- Performing passive range-of-motion exercises while in bed
- Using postoperative deep-breathing exercises to improve venous return by relieving the negative thoracic pressure on leg veins
- Reducing hypercoagulability with the use of warfarin, aspirin, and heparin
- Preventing venous pooling by avoiding pillows under knees, not crossing legs for long periods, and not leaving legs up in stirrups for long periods
- Padding stirrups to reduce pressure against the popliteal angle
- Avoiding sitting or standing in one position for prolonged periods
- Using a bed cradle to keep linens and blankets off extremities
- Avoiding trauma to legs to prevent injury to the vein wall
- Increasing fluid intake to prevent dehydration
- Avoiding the use of oral contraceptives

In women at risk, early ambulation is the easiest and most cost-effective method. Use of compression stockings decreases distal calf vein thrombosis by decreasing venous stasis and augmenting venous return (Cavazza, Rainaldi, Adduci, & Palareti, 2012). Women who are at a high risk for thromboembolic disease based on risk factors or a previous history of DVT or PE may be placed on prophylactic heparin therapy during pregnancy. Standard heparin or a low-molecular-weight heparin such as enoxaparin (Lovenox) can be given, because neither drug crosses the placenta. It is typically discontinued during labor and birth and then restarted during the postpartum period.

### Promoting Adequate Circulation

For the woman with superficial venous thrombosis, administer NSAIDs for analgesia, provide for rest and elevation of the affected leg, apply warm compresses to the affected area to promote healing, and use antiembolism stockings to promote circulation to the extremities.

Implement bed rest and elevation of the affected extremity for the woman with deep venous thrombosis. These actions help to reduce interstitial swelling and promote venous return from that leg. Apply antiembolism stockings to both extremities as ordered. Fit the stockings correctly to avoid excess pressure and constriction and urge the woman to wear them at all times. Sequential compression devices can also be used for women with varicose veins, a history of thrombophlebitis, or a surgical birth.

Anticoagulant therapy using a continuous IV infusion of heparin usually is initiated to prolong the clotting time and prevent extension of the thrombosis. Monitor the woman's coagulation studies closely; these might include activated partial thromboplastin time (aPTT),

whole-blood partial thromboplastin time, and platelet levels. A therapeutic aPTT value typically ranges from 35 to 45 seconds, depending on which standard values are used (Pagana & Pagana, 2011). Also apply warm moist compresses to the affected leg and administer analgesics as ordered to decrease the discomfort.

After several days of IV heparin therapy, expect to begin oral anticoagulant therapy with warfarin (Coumadin) as ordered and monitor coagulation studies. In most cases, the woman will continue to take this medication for several months after discharge.

For the woman who develops a pulmonary embolism, institute emergency measures immediately. The objectives of treatment are to prevent growth or multiplication of thrombi in the lower extremities, prevent more thrombi from traveling to the pulmonary vascular system, and provide cardiopulmonary support if needed. Administer oxygen via mask or cannula as ordered and initiate IV heparin therapy titrated according to the results of the coagulation studies. Maintain the client on bed rest, and administer analgesics as ordered for pain relief. Be prepared to assist with administering thrombolytic agents, such as alteplase (tPA), which might be used to dissolve pulmonary emboli and the source of the thrombus in the pelvis or deep leg veins, thus reducing the potential for a recurrence.

### Educating the Client

Provide teaching about the use of anticoagulant therapy and danger signs that should be reported (Teaching Guidelines 22.1). Provide anticipatory guidance, support,

#### Teaching Guidelines 22.1

##### TEACHING TO PREVENT BLEEDING RELATED TO ANTICOAGULANT THERAPY

- Watch for possible signs of bleeding and notify your health care provider if any occur:
  - Nosebleeds
  - Bleeding from the gums or mouth
  - Black tarry stools
  - Brown “coffee grounds” vomitus
  - Red to brown speckled mucus from a cough
  - Oozing at incision, episiotomy site, cut, or scrape
  - Pink, red, or brown-tinged urine
  - Bruises, “black and blue marks”
  - Increased lochia discharge (from present level)
- Practice measures to reduce your risk of bleeding:
  - Brush your teeth gently using a soft toothbrush.
  - Use an electric razor for shaving.
  - Avoid activities that could lead to injury, scrapes, bruising, or cuts.
  - Do not use any over-the-counter products containing aspirin or aspirin-like derivatives.
  - Avoid consuming alcohol.
  - Inform other health care providers about the use of anticoagulants, especially dentists.
  - Be sure to comply with follow-up laboratory testing as scheduled.
  - If you accidentally cut or scrape yourself, apply firm direct pressure to the site for 5 to 10 minutes. Do the same after receiving any injections or having blood specimens drawn.
  - Wear an identification bracelet or band that indicates that you are taking an anticoagulant.

and education about associated signs of complications and risks. Focus teaching on the following issues:

- Elimination of modifiable risk factors for DVT (smoking, use of oral contraceptives, a sedentary lifestyle, and obesity)
- Importance of using compression stockings
- Avoidance of constrictive clothing and prolonged standing or sitting in a motionless, leg-dependent position
- Danger signs and symptoms (sudden onset of chest pain, dyspnea, and tachypnea) to report to the health care provider

## POSTPARTUM INFECTION

Infection during the postpartum period is a common cause of maternal morbidity and mortality. Overall, postpartum infection is estimated to occur in up to 8% of all births. There is a higher occurrence in cesarean births than in vaginal births (Gilbert, 2011). Postpartum infection is defined as a fever of 100.4° F (38° C) or higher after the first 24 hours after childbirth, occurring on at least 2 of the first 10 days after birth, exclusive of the first 24 hours (Dorland, 2011). Risk factors include surgical birth, prolonged rupture of membranes, long labor with multiple vaginal examinations, extremes of client age, low socioeconomic status, and anemia during pregnancy (Bick, Beake, & Pellowe, 2011).

Infections can easily enter the female genital tract externally and ascend through the internal genital structures. In addition, the normal physiologic changes of childbirth increase the risk of infection by decreasing the vaginal acidity due to the presence of amniotic fluid, blood, and lochia, all of which are alkaline. An alkaline environment encourages the growth of bacteria.

Postpartum infections usually arise from organisms that constitute the normal vaginal flora, typically a mix of aerobic and anaerobic species. Generally, they are polymicrobial and involve the following microorganisms: *Staphylococcus aureus*, *Escherichia coli*, *Klebsiella*, *Gardnerella vaginalis*, gonococci, coliform bacteria, group A or B hemolytic streptococci, *Chlamydia trachomatis*, and the anaerobes that are common to bacterial vaginosis (Wong & Rosh, 2012). Common postpartum infections include metritis, wound infections, urinary tract infections, and mastitis.

## Metritis

Although usually referred to clinically as endometritis, postpartum uterine infections typically involve more than just the endometrial lining. **Metritis** is an infectious condition that involves the endometrium, decidua, and adjacent myometrium of the uterus. Extension of metritis can result in parametritis, which involves the broad ligament and possibly the ovaries and fallopian tubes, or septic pelvic thrombophlebitis, which results when the infection spreads along venous routes into the pelvis (Tharpe, Farley, & Jordan, 2013).

The uterine cavity is sterile until rupture of the amniotic sac. As a consequence of labor, birth, and associated manipulations, anaerobic and aerobic bacteria can contaminate the uterus. In most cases, the bacteria responsible for pelvic infections are those that normally reside in the bowel, vagina, perineum, and cervix, such as *E. coli*, *Klebsiella pneumoniae*, or *G. vaginalis*.

The risk of metritis increases dramatically after a cesarean birth; it complicates from 10% to 20% of cesarean births. This is typically an extension of chorioamnionitis that was present before birth (indeed, that may have been why the cesarean birth was performed). In addition, trauma to the tissues and a break in the skin (incision) provide entrances for bacteria to enter the body and multiply (Mattson & Smith, 2011).

## Wound Infections

Any break in the skin or mucous membranes provides a portal for bacteria. In the postpartum woman, sites of wound infection include cesarean surgical incisions, the episiotomy site in the perineum, and genital tract lacerations (Fig. 22.2). Wound infections are usually not identified until the woman has been discharged from the hospital because symptoms may not show up until 24 to 48 hours after birth.

## Urinary Tract Infections

Urinary tract infections are most commonly caused by bacteria often found in bowel flora, including *E. coli*, *Klebsiella*, *Proteus*, and *Enterobacter* species. Invasive manipulation of the urethra (e.g., urinary catheterization), frequent vaginal examinations, and genital trauma increase the likelihood of a urinary tract infection.

## Mastitis

A common problem that may occur within the first 2 weeks postpartum is an inflammation of the breast, termed **mastitis**. An estimated 2% to 33% of breast-feeding women develop lactational mastitis (Jahanfar, 2012). As well as causing significant discomfort, it is a frequent reason for women to stop breast-feeding. It can result from any event that creates milk stasis: insufficient drainage of the breast, rapid weaning, oversupply of milk, pressure on the breast from a poorly fitting bra, a blocked duct, missed feedings, and breakdown of the nipple via fissures, cracks, or blisters (Cusack & Brennan, 2011). The most common infecting organism is *S. aureus*, which comes from the breast-feeding infant's mouth or throat. *Staphylococcus albus*, *E. coli*, and streptococci are also causative agents, but found less frequently. Infection can be transmitted from the lactiferous ducts to a secreting lobule, from a nipple fissure to periductal lymphatics, or by circulation (Gilbert, 2011) (Fig. 22.3). A breast abscess may develop if mastitis is not treated adequately. Flu-like symptoms are often the first symptoms experienced by the mother. Breasts are red, tender, and hot to the touch. The upper, outer quadrant of the breast is the most common site for mastitis to occur because most of the breast tissue is located there with both the right and left breasts being equally affected. Effective milk removal, pain medication, and antibiotic therapy have been the mainstays of treatment.

**FIGURE 22.2** Postpartum wound infections. **(A)** Infected episiotomy site. **(B)** Infected cesarean birth incision.

**FIGURE 22.3** With mastitis, an area on one breast is tender, hot, red, and painful.

## Therapeutic Management

When *metritis* occurs, broad-spectrum antibiotics are used to treat the infection. Management also includes measures to restore and promote fluid and electrolyte balance, provide analgesia, and provide emotional support. In most treated women, fever drops and symptoms cease within 48 to 72 hours after the start of antibiotic therapy.

Management for *wound infections* involves recognition of the infection, followed by opening of the wound to allow drainage. Aseptic wound management with sterile gloves and frequent dressing changes if applicable, good handwashing, frequent perineal pad changes, hydration, and ambulation to prevent venous stasis and improve circulation are initiated to prevent development of a more serious infection or spread of the infection to adjacent structures. Parenteral antibiotics are the mainstay of treatment. Analgesics are also important, because women often experience discomfort at the wound site.

If the woman develops a *urinary tract infection*, fluids are used to treat dehydration. General nutrition measures include acidifying the urine by taking large doses of vitamin C or a regular intake of cranberry juice. Cranberry juice contains a substance with biologic activity that inhibits the growth of *E. coli* in the urinary tract (Robinson & McCormick, 2011). Antibiotics may also be ordered if appropriate.

Treatment of *mastitis* focuses on two areas: emptying the breasts and controlling the infection. Frequent breast emptying helps both infectious and noninfectious mastitis. The breast can be emptied either by the infant sucking or by manual expression. Increasing the

frequency of nursing is advised. Lactation need not be suppressed. Control of infection is achieved with antibiotics. In addition, ice or warm packs and analgesics may be needed. In addition to antibiotics, management of lactational breast infections includes symptomatic treatment, assessment of the infant's attachment to the breast, and reassurance, emotional support, education, and support for ongoing breast-feeding.

### Take Note!

Regardless of the etiology of mastitis, the focus is on reversing milk stasis, maintaining milk supply, and continuing breast-feeding, along with providing maternal comfort and preventing recurrence.

## Nursing Assessment

Perinatal nurses are the primary caregivers for postpartum women and have a unique opportunity to identify subtle changes that place women at risk for infection. Nurses play a key role in identifying signs and symptoms that suggest a postpartum infection. Today women are commonly discharged 24 to 48 hours after giving birth. Therefore, nurses must assess new mothers for risk factors and identify early, subtle signs and symptoms of an infectious process. Factors that place a woman at risk for a postpartum infection are highlighted in Box 22.1.

Review the client's history and physical examination and labor and birth record for factors that might increase her risk for developing an infection. Then complete the assessment (using the "BUBBLE-EE" parameters discussed in Chapter 16), paying particular attention to areas such as the abdomen and fundus, breasts, urinary tract, episiotomy, lacerations, or incisions and being alert for signs and symptoms of infection (Table 22.3).

### Take Note!

A postpartum infection is commonly associated with an elevated temperature, as mentioned previously. Other generalized signs and symptoms may include chills, foul-smelling vaginal discharge, headache, malaise, restlessness, anxiety, and tachycardia. In addition, the woman may have specific signs and symptoms based on the type and location of the infection.

The acronym REEDA is frequently used for assessing a woman's perineum status. It is derived from five components that have been identified to be associated with the healing process of the perineum. These include:

1. Redness
2. Edema
3. Ecchymosis
4. Discharge
5. Approximation of skin edges

BOX 22.1

**FACTORS PLACING A WOMAN AT RISK FOR POSTPARTUM INFECTION**

- Prolonged (>18 to 24 hours) premature rupture of membranes (removes the barrier of amniotic fluid so bacteria can ascend)
- Cesarean birth (allows bacterial entry due to break in protective skin barrier)
- Urinary catheterization (could allow entry of bacteria into bladder due to break in aseptic technique)
- Regional anesthesia that decreases perception of need to void (causes urinary stasis and increases risk of urinary tract infection)
- Staff attending to woman are ill (promotes droplet infection from personnel)
- Compromised health status, such as anemia, obesity, smoking, drug abuse (reduces the body's immune system and decreases ability to fight infection)
- Preexisting colonization of lower genital tract with bacterial vaginosis, *Chlamydia trachomatis*, group B streptococci, *S. aureus*, and *E. coli* (allows microbes to ascend)
- Retained placental fragments (provides medium for bacterial growth)
- Manual removal of a retained placenta (causes trauma to the lining of the uterus and thus opens up sites for bacterial invasion)
- Insertion of fetal scalp electrode or intrauterine pressure catheters for internal fetal monitoring during labor (provides entry into uterine cavity)
- Instrument-assisted childbirth, such as forceps or vacuum extraction (increases risk of trauma to genital tract, which provides bacteria access to grow)
- Trauma to the genital tract, such as episiotomy or lacerations (provides a portal of entry for bacteria)
- Prolonged labor with frequent vaginal examinations to check progress (allows time for bacteria to multiply and increases potential exposure to microorganisms or trauma)
- Poor nutritional status (reduces body's ability to repair tissue)
- Gestational diabetes (decreases body's healing ability and provides higher glucose levels on skin and in urine, which encourages bacterial growth)
- Break in aseptic technique during surgery or birthing process (allows entry of bacteria)

TABLE 22.3

**SIGNS AND SYMPTOMS OF POSTPARTUM INFECTIONS**

Postpartum Infection	Signs and Symptoms
Metritis	Lower abdominal tenderness or pain on one or both sides Temperature elevation (>38° C) Foul-smelling lochia Anorexia Nausea Fatigue and lethargy Leukocytosis and elevated sedimentation rate
Wound infection	Weeping serosanguineous or purulent drainage Separation of or unapproximated wound edges Edema Erythema Tenderness Discomfort at the site Maternal fever Elevated white blood cell count
Urinary tract infection	Urgency Frequency Dysuria Flank pain Low-grade fever Urinary retention Hematuria Urine positive for nitrates Cloudy urine with strong odor
Mastitis	Flu-like symptoms, including malaise, fever, and chills Tender, hot, red, painful area on one breast Inflammation of breast area Breast tenderness Cracking of skin around nipple or areola Breast distention with milk

Adapted from Bick, D., Beake, S., & Pellowe, C. (2011). Vigilance must be a priority: Maternal genital tract sepsis. *The Practicing Midwife*, 14(4), 16–18; Chelmow, D., O'Grady, J. P., & Guzman, G. M. (2011). Normal and abnormal postpartum. *eMedicine*. Retrieved from <http://emedicine.medscape.com/article/260187-overview>; and Cusack, L., & Brennan, M. (2011). Lactational mastitis and breast abscess—Diagnosis and management in general practice. *Australian Family Physician*, 40(12), 976–979.

Each category is assessed and a number assigned (0 to 3 points) for a total REEDA score ranging from 0 to 15. The higher scores indicate increased tissue trauma (Navvabi, Abedian, & Steen-Greaves, 2009). See Figure 22.4 for the REEDA method for assessing perineum healing.

Monitor the woman's vital signs, especially her temperature. Changes may also signal an infection.

### REEDA Method for Assessing Perineum Healing

- **Redness**
  - None = 0 points
  - Redness within .25 cm of incision bilaterally = 1
  - Redness within .50 cm of incision bilaterally = 2
  - Redness reaching beyond .5 cm of incision bilaterally = 3
- **Edema** – the more swelling present, the high the score
  - None = 0 points
  - <1 cm from incision = 1 point
  - 1 to 2 cm from incision = 2 points
  - >2 cm from incision = 3 points
- **Ecchymosis** – the more bruising observed, the higher the score
  - None = 0 points
  - 1–2 cm from incision = 1 point
  - .25–1 cm bilaterally or .5–2 cm unilaterally = 2 points
  - >1 cm bilaterally or 2 cm unilaterally = 3 points
- **Discharge** – range would be from none present to profuse
  - None = 0 points
  - Serum discharge present = 1 point
  - Serosanguineous discharge present = 2 points
  - Bloody, purulent discharge present = 3 points
- **Approximation of skin edges**
  - Closed, skin edges approximated well = 0 points
  - Skin separated 3 cm or less = 1 point
  - Skin and subcutaneous fat separated = 2 points
  - Skin, subcutaneous fat and facial separation = 3 points

**FIGURE 22.4** REEDA method for assessing perineum healing. Adapted from Davidson, N. (1974). REEDA: Evaluating postpartum healing. *Journal of Nurse Midwifery* 19(2), 6–8; and Hill, P. D. (2005). Psychometric properties of REEDA. *Journal of Nurse Midwifery* 35(3), 162–165.

## Nursing Management

Nursing management focuses on preventing postpartum infections. Use the following guidelines to reduce the incidence of postpartum infections:

- Maintain aseptic technique when performing invasive procedures such as urinary catheterization, when changing dressings, and during all surgical procedures.
- Use good handwashing technique before and after each client care activity.
- Reinforce measures for maintaining good perineal hygiene.
- Use adequate lighting and turn the client to the side to assess the episiotomy site.
- Screen all visitors for any signs of active infections to reduce the client's risk of exposure.
- Review the client's history for preexisting infections or chronic conditions.
- Monitor vital signs and laboratory results for any abnormal values.
- Monitor the frequency of vaginal examinations and length of labor.
- Assess frequently for early signs of infection, especially fever and the appearance of lochia.
- Inspect wounds frequently for inflammation and drainage.
- Encourage rest, adequate hydration, and healthy eating habits.
- Reinforce preventive measures during any interaction with the client.

If the woman develops an infection, review treatment measures, such as antibiotic therapy if ordered, and any special care measures, such as dressing changes, that might be needed (Nursing Care Plan 22.1).

Postpartum women should be offered advice on the signs and symptoms of life-threatening conditions,

### NURSING CARE PLAN 22.1

## Overview of the Woman with a Postpartum Complication

Jennifer, a 16-year-old G1P1, gave birth to a boy 3 days ago. It was a cesarean birth due to cephalopelvic disproportion following 25 hours of labor with ruptured membranes. Her temperature is 102.6° F (39.2° C). She is complaining of chills and malaise and says, "My incision really hurts." Jennifer rates her pain as 7 to 8 out of 10. The incision site is red, swollen, and very warm to the touch. A 5-cm area of purulent drainage is noted on the dressing; a 3-cm area of the incision is slightly opened, with the wound edges separated. Jennifer's lochia is scant and dark red, with a strong odor. She asks the nurse to take her baby back to the nursery because she doesn't feel well enough to care for him.

**NURSING DIAGNOSIS:** Ineffective thermoregulation related to bacterial invasion as evidenced by fever, complaints of chills and malaise, and statement of not feeling well

### Outcome Identification and Evaluation

The client will exhibit a return to normothermia as evidenced by a body temperature being maintained below 99° F (37.2° C), reports of a decrease in chills and malaise, and statements of feeling better.

### Interventions: *Promoting Fever Reduction*

- Assess vital signs every 2 to 4 hours and record results *to monitor progress of infection.*
- Administer antipyretics as ordered *to reduce temperature and help combat infection.*
- Encourage fluid intake *to promote fluid balance.*
- Document intake and output *to assess hydration status.*
- Offer cool bed bath or shower *to reduce temperature.*
- Place cool cloth on forehead and/or back of neck *to provide comfort.*
- Change bed linen and gown when damp from diaphoresis *to provide comfort and hygiene.*

**NURSING DIAGNOSIS:** Impaired skin integrity related to wound infection as evidenced by purulent drainage, redness, swelling, and separation of wound edges

(continued)

## NURSING CARE PLAN 22.1

**Overview of the Woman with a Postpartum Complication** (continued)**Outcome Identification and Evaluation**

The client will experience a resolution of wound infection as evidenced by a reduction in redness, swelling, and drainage from wound; absence of purulent drainage; and beginning signs and symptoms of wound healing.

**Interventions: Promoting Wound Healing**

- Administer antibiotic therapy as ordered *to treat infection*.
- Perform frequent dressing changes and wound care as ordered *to promote wound healing*; monitor dressing for drainage, including amount, color, and characteristics, *to evaluate for resolution of infection*.
- Use aseptic technique *to prevent spread of infection*.
- Encourage fluid intake *to maintain fluid balance*; encourage adequate dietary intake, including protein, *to promote healing*.

**NURSING DIAGNOSIS:** Acute pain related to infectious process

**Outcome Identification and Evaluation**

The client will report a decrease in pain as evidenced by pain rating of 0 or 1 on pain scale, verbalization of relief with pain management, and statements of feeling better and ability to rest comfortably.

**Interventions: Relieving Pain**

- Place client in semi-Fowler's position *to facilitate drainage and relieve pressure*.
- Assess pain level on pain scale of 0 to 10 *to quantify pain level*; reassess pain level after intervening *to determine effectiveness of intervention*.
- Assess fundus gently *to ensure appropriate involution*.
- Administer analgesics as needed and on time as ordered *to maintain pain relief*.
- Provide for rest periods *to allow for healing*.
- Assist with positioning in bed with pillows *to promote comfort*.
- Offer nonpharmacologic pain measures such as a backrub *to ease aches and discomfort if desired and enhance effectiveness of analgesics*.

**NURSING DIAGNOSIS:** Risk for impaired parent–infant attachment related to effects of postpartum infection as evidenced by mother's request to take baby back to the nursery

**Outcome Identification and Evaluation**

The client will begin to bond with newborn appropriately with each exposure as evidenced by desire to spend time with newborn, expression of positive feelings toward newborn when holding him, increasing participation in care of newborn as client's condition improves, and statements about help and support at home to care for self and newborn.

**Interventions: Promoting Mother–Newborn Interaction**

- Promote adequate rest and sleep *to ensure adequate energy for interaction and wound healing*.
- Bring newborn to mother after she is rested and has had an analgesic *to allow mother to focus her energies on the child*.
- Progressively allow the client to care for her infant or comfort him as her energy level and pain level improve *to promote self-confidence in caring for the newborn*.
- Offer praise and positive reinforcement for caretaking tasks; stress positive attributes of newborn to mother while caring for him *to facilitate bonding and attachment*.

## NURSING CARE PLAN 22.1

**Overview of the Woman with a Postpartum Complication** (continued)

- Contact family members to participate in care of the newborn *to allow mother to rest and recover from infection.*
- Encourage mother to care for herself first and then the newborn *to ensure adequate energy for newborn's care.*
- Arrange for assistance and support after discharge from hospital *to provide necessary backup.*
- Refer to community health nurse for follow-up care of mother and newborn at home *to foster continued development of maternal–infant relationship.*

including sepsis. Information should include the importance of good hand and perineal hygiene and of the need to seek immediate medical care if feeling unwell. Client teaching is a priority due to today's short lengths of stay after childbirth. Some infections may not manifest until after discharge. Review the signs and symptoms of infection, emphasizing the danger signs that need to be reported to the health care provider. Most importantly, stress proper handwashing, especially after perineal care and before and after breast-feeding. Also reinforce measures to promote breast-feeding, including proper breast care (see Chapter 16). Teaching Guidelines 22.2 highlights the major teaching points for a woman with a postpartum infection.

**Teaching Guidelines 22.2****TEACHING FOR THE WOMAN WITH A POSTPARTUM INFECTION**

- Continue your antibiotic therapy as prescribed.
  - Take the medication exactly as ordered and continue with the medication until it is finished.
  - Do not stop taking the medication even when you are feeling better.
- Check your temperature every day and call your health care provider if it is above 100.4° F (38° C).
- Watch for other signs and symptoms of infection, such as chills, increased abdominal pain, change in the color or odor of your lochia, or increased redness, warmth, swelling, or drainage from a wound site such as your cesarean incision or episiotomy. Report any of these to your health care provider immediately.
- Practice good infection prevention:
  - Always wash your hands thoroughly before and after eating, using the bathroom, touching your perineal area, or providing care for your newborn.
  - Wipe from front to back after using the bathroom.
  - Remove your perineal pad using a front-to-back motion. Fold the pad in half so that the inner

sides of the pad that were touching your body are against each other. Wrap in toilet tissue or place in a plastic bag and discard.

- Wash your hands before applying a new pad.
- Apply a new perineal pad using a front-to-back motion. Handle the pad by the edges (top and bottom or sides) and avoid touching the inner aspect of the pad that will be against your body.
- When performing perineal care with a peribottle, angle the spray of water so that it flows from front to back.
- Drink plenty of fluids each day and eat a variety of foods that are high in vitamins, iron, and protein.
- Be sure to get adequate rest at night and periodically throughout the day.

**POSTPARTUM AFFECTIVE DISORDERS**

The postpartum period involves extraordinary physiologic, psychological, and sociocultural changes in the life of a woman and her family. It is an exhilarating time for most women, but for others it may not be what they had expected. Women have varied reactions to their child-bearing experiences, exhibiting a wide range of emotions. Typically, the delivery of a newborn is associated with positive feelings such as happiness, joy, and gratitude for the birth of a healthy infant. However, women may also feel weepy, overwhelmed, or unsure of what is happening to them. They may experience fear about loss of control; they may feel scared, alone, or guilty, or as if they have somehow failed.

Postpartum affective disorders have been documented for years, but only recently have they received medical attention. Plummeting levels of estrogen and progesterone immediately after birth can contribute to postpartum mood disorders. It is believed that the greater the change in these hormone levels between pregnancy

and postpartum, the greater the chance for developing a mood disorder (Edler & Venis, 2012).

Many types of affective disorders occur in the postpartum period. Although their description and classification may be controversial, the disorders are commonly classified on the basis of their severity as postpartum or baby blues, postpartum depression, and postpartum psychosis.

### Postpartum or Baby Blues

Many postpartum women (approximately 50% to 90%) experience the “baby blues” (ACOG, 2011). The woman exhibits mild depressive symptoms of anxiety, irritability, mood swings, tearfulness, increased sensitivity, feelings of being overwhelmed, and fatigue (Edler & Venis, 2012). The “blues” typically peak on postpartum days 4 and 5 and usually resolve by postpartum day 10. Although the woman’s symptoms may be distressing, they do not reflect psychopathology and usually do not affect the mother’s ability to function and care for her infant.

Baby blues are usually self-limiting and require no formal treatment other than reassurance and validation of the woman’s experience, as well as assistance in caring for herself and the newborn. However, follow-up of women with postpartum blues is important, because up to 20% go on to develop postpartum depression (Buttner, O’Hara, & Watson, 2012).

### Postpartum Depression

Depression is more prevalent in women than in men, which may be related to biological, hormonal, and psychosocial factors. **Postpartum depression (PPD)** is a form of clinical depression that can affect women, and less frequently men, after childbirth. It affects as many as 20% of all mothers in the United States, and as many as 60% of adolescent mothers (ACOG, 2011; Caple & Uribe 2012; Centers for Disease Control and Prevention, 2012; Joy, Contag & Templeton 2012). Unlike the postpartum blues, women with postpartum depression feel worse over time, and changes in mood and behavior do not go away on their own.

Different from the baby blues, the symptoms of PPD last longer, are more severe, and require treatment. Some signs and symptoms of PPD include feeling the following:

- Restless
- Worthless
- Guilty
- Hopeless
- Moody
- Sad
- Overwhelmed
- Loss of enjoyment
- Low energy level
- Loss of libido

The new mother may also:

- Cry a lot
- Exhibit a lack of energy and motivation
- Be unable to make decisions or focus
- Lose her memory
- Experience a lack of pleasure
- Have changes in appetite, sleep, or weight
- Show a lack of concern for herself
- Withdraw from friends and family
- Have pains in her body that do not subside
- Feel negatively toward her baby
- Lack interest in her baby
- Worry about hurting the baby
- Act detached toward others and infant
- Have recurrent thoughts of suicide and death (Miles, 2011)

Postpartum depression affects not only the woman but also the entire family. Identifying depression early can substantially improve the client and family outcomes. PPD usually has a gradual onset and becomes evident within the first 6 weeks postpartum.

The cause of PPD is not known, but research suggests that it is multifactorial. According to ACOG (2011), “postpartum depression is likely to result from body, mind, and lifestyle factors combined.” The levels of estrogen, progesterone, serotonin, and thyroid hormone decrease sharply and return to normal during the immediate postpartum period, which can trigger depression and can change a woman’s mood and behavior. Other aspects that can lead to PPD include:

- Unresolved feelings about the pregnancy
- Fatigue after delivery from lack of sleep or broken sleep
- Feelings of being less attractive
- Inadequate assistance from partner
- Lack of social support network
- Doubts about the ability to be a good mother
- Stress from changes in work and home routines
- Loss of freedom and old identity (Zubaran & Foresti, 2011)

Postpartum depression may lend itself to prophylactic intervention because its onset is predictable, the risk period for illness is well defined, and women at high risk potentially could be identified using a screening tool. This is not the case for all women, however (see Evidence-Based Practice 22.1). Prophylaxis starts with a prenatal risk assessment and education. Based on the woman’s history of prior depression, prophylactic antidepressant therapy may be needed during the third trimester or immediately after giving birth. Management mirrors that of any major depression: a combination of antidepressant medication, antianxiety medication, and psychotherapy in an outpatient or inpatient setting (Wylie, Hollins, Marland, Martin, & Rankin, 2011). Marital counseling may be necessary if marital problems are contributing to the woman’s depressive symptoms.

**EVIDENCE-BASED PRACTICE 22.1****PSYCHOSOCIAL AND PSYCHOLOGICAL INTERVENTIONS FOR PREVENTING POSTPARTUM DEPRESSION****STUDY**

Postpartum depression can be a devastating condition for women and their families. There is a lack of knowledge about its cause, and women receive limited education about the possibility of depression after birth. Research has shown the effectiveness of treatment strategies that integrate psychosocial and psychological variables. The question then arises that if management addressing these variables were effective, would psychosocial interventions provided during pregnancy and the early postpartum period be effective in preventing postpartum depression?

Two reviewers searched multiple databases and contacted experts in the field. They also scanned secondary references and contacted several trial researchers for additional information. Both reviewers were involved in evaluating the methodology of the study and in extracting data. Information was gathered from all published and unpublished randomized controlled trials that compared psychosocial or psychological interventions with typical care during the antepartal, intrapartal, and postpartal periods. The researchers used relative risk for categorical data and weighted mean difference for continuous data. The study included 15 trials involving over 7,600 women.

**Findings**

Women who received some type of psychosocial intervention had the same risk for developing postpartum depression as the women who received routine care; thus, the psychosocial intervention was not effective in preventing postpartum depression. However, statistical analysis found that intensive psychosocial support from public health nurses or midwives in the postpartum period was beneficial. The use of psychosocial interventions primarily during the postpartum period also was more effective than when these interventions were also used in the prenatal period. Interventions focusing on women at risk appear to be more effective than those geared to the overall maternal population. Individualized interventions were found to be more effective than those designed for groups. However, the risk for developing postpartum depression for either group did not differ significantly.

**Nursing Implications**

Although the study failed to identify effective measures for preventing postpartum depression, it did provide some useful information for nurses to incorporate when providing care to pregnant women throughout the perinatal period. Overall psychosocial interventions did not reduce the numbers of women who develop postpartum depression. However, a promising intervention is the provision of intensive, professionally based postpartum support. Nurses need to remain alert for risk factors associated with postpartum depression so they can initiate appropriate interventions for these at-risk women. Nurses can implement psychosocial interventions during the prenatal period, keeping in mind that these interventions need to be continued throughout the postpartum period. They can also advocate for their clients upon discharge to ensure appropriate follow-up and support in the community.

Adapted from Dennis, C. L., & Creedy, D. (2010). Psychosocial and psychological interventions for preventing postpartum depression. *Cochrane Database of Systematic Reviews*, 2010(10). doi:10.1002/14651858.CD001134.pub2.

The father's emotional health should not be overlooked during his partner's pregnancy and throughout the first postpartum year. Postpartum depression, once expected only in new mothers, occurs in new fathers as well. Up to 50% of men whose partners suffer from PPD also have depressive symptoms, and little is known about the impact of maternal PPD on fathers. Depressive symptoms are likely to decrease fathers' ability to provide maternal support. Paternal postpartum depression can be difficult to identify. New fathers may seem more angry and anxious than sad, yet depression is present. When left untreated, paternal postpartum depression limits men's capacity to provide emotional support to their partners and children. The highest rates of depression among fathers have been reported between 3 and 6 months postpartum. Factors that increase the risk of paternal PPD

include a personal history of depression and/or anxiety, a low level of marital satisfaction, excessive financial stressors, a lack of paternal parental leave, and the feeling that there is a great discrepancy between one's expectations of parenthood and its realities (Strayer & Cabrera, 2011).

Assessing paternal postpartum depression is not easy. Nevertheless, it is important for all nurses who have contact with new fathers to remain open to the notion that new fathers are predisposed to postpartum depression, particularly if their partner is afflicted. Delving deeper into understanding behaviors of withdrawing, indecisiveness, cynicism, avoiding, drinking, using drugs, fighting, partner violence, extramarital affairs, and feelings of heightened irritation will reveal important insights. Asking new fathers candidly if they are feeling

depressed, anxious, or angry can open the door to further exploration of these emotions (Davies, 2011).

Although paternal depression is only now beginning to be defined and measured, sufficient evidence exists to warrant nurses' attention and concern. Nurses may be most able to help a new father devastated by postpartum depression when they plant seeds of awareness that the disorder exists, that he is not alone, and that help is available.

Despite the negative outcomes associated with PPD, rates of diagnosis and treatment are low mainly because of lack of recognition by the health care provider. In addition, PPD is the most misinterpreted, frequently dismissed, and most undiagnosed postpartum complication. Early recognition of PPD can eliminate the length of time that women have to suffer with this debilitating condition and can decrease the potentially harmful effects on the infants involved.

Screening for symptoms of postpartum depression is an important preliminary step to diagnosis and treatment, but the effectiveness of depression screening is dependent on the reliability and validity of the screening instruments in the population. Both the Edinburgh Postnatal Depression Scale (EPDS) and the Postpartum Depression Predictor Scale (PDSS) have been used to screen mothers for PPD, but it is not clear which instrument best predicts a diagnosis of postpartum depression (Tandon, Cluxton-Keller, Leis, Le, & Perry, 2012).

The EPDS is a self-report, quick, and easy screening tool for PPD that consists of 10 questions with four possible responses. The women fill out the tool according to their symptoms during the past 7 days, with each response given a score of 0 to 3 points, creating a maximum score of 30. Using a cutoff score of 9 or 10, the sensitivity is 86%; the specificity, 78%; and positive predictive value, 73% (Lee King, 2012).

The PDSS is a self-report, 35-item Likert-type response scale divided into seven conceptual domains:

1. Anxiety/insecurity
2. Sleep/eating disturbance
3. Emotional lability
4. Loss of self-esteem
5. Guilt/shame
6. Cognitive impairment
7. Suicidal thoughts

The scores range from 35 to 175. The scale has five symptoms for each domain, and the woman is asked to identify her degree of disagreement or agreement on the basis of her feelings over the past 2 weeks. The sensitivity of the PDSS is 91%; the specificity is 72% for detecting PPD. The PDSS takes 5 to 10 minutes to administer and is used during the postpartum period (Le, Perry, & Oritz, 2010).

Early identification, screening, prevention, and treatment of PPD are crucial for improving overall

outcomes for the mother and infant, as well as for decreasing mortality and morbidity. This is why it is crucial for nurses to understand and know about the risk factors, signs and symptoms, prevention, and use and interpretation of screening tools and to make appropriate referrals for treatment. Mass screening for PPD using a validated screening tool has been proven to improve the rates of detection and treatment of PPD and should be implemented in obstetricians' and pediatricians' offices and in primary care settings. The Edinburgh tool is shown in Figure 22.5.

## Postpartum Psychosis

At the severe end of the continuum of postpartum emotional disorders is postpartum psychosis, which occurs in 1 in 500 births (Edler & Venis, 2012). Postpartum psychosis, an emergency psychiatric condition, can result in a significant increased risk for suicide and infanticide. Symptoms of postpartum psychosis, such as mood lability, delusional beliefs, hallucinations, and disorganized thinking, can be frightening for the women who are affected and for their families. It generally surfaces within 3 months of giving birth and is manifested by sleep disturbances, fatigue, depression, and hypomania. The mother will be tearful, confused, and preoccupied with feelings of guilt and worthlessness. Early symptoms resemble those of depression, but they may escalate to delirium, hallucinations, extreme disorganization of thought, anger toward herself and her infant, bizarre behavior, delusions, manifestations of mania, and thoughts of hurting herself and the infant. The mother frequently loses touch with reality and experiences a severe regressive breakdown, associated with a high risk of suicide or infanticide (Waters, 2011).

Women with postpartum psychosis should not be left alone with their infants. Most women with postpartum psychosis are hospitalized for up to several months. Psychotropic drugs are almost always part of treatment, along with individual psychotherapy and support group therapy.

### Take Note!

The greatest hazard of postpartum psychosis is suicide. Infanticide and child abuse are also risks if the woman is left alone with her infant. Early recognition and prompt treatment of this disorder are imperative.

## Nursing Assessment

Postpartum affective disorders are often overlooked and go unrecognized despite the large percentage of women who experience them. The postpartum period

# Edinburgh Postnatal Depression Scale

Name: \_\_\_\_\_

Address: \_\_\_\_\_

Your Date of Birth: \_\_\_\_\_

\_\_\_\_\_

Baby's Date of Birth: \_\_\_\_\_

Phone: \_\_\_\_\_

As you are pregnant or have recently had a baby, we would like to know how you are feeling. Please check the answer that comes closest to how you have felt **IN THE PAST 7 DAYS**, not just how you feel today.

Here is an example, already completed.

I have felt happy:

- Yes, all the time
- Yes, most of the time     This would mean: "I have felt happy most of the time" during the past week.
- No, not very often     Please complete the other questions in the same way.
- No, not at all

In the past 7 days:

- 1. I have been able to laugh and see the funny side of things
  - As much as I always could
  - Not quite so much now
  - Definitely not so much now
  - Not at all
- 2. I have looked forward with enjoyment to things
  - As much as I ever did
  - Rather less than I used to
  - Definitely less than I used to
  - Hardly at all
- \*3. I have blamed myself unnecessarily when things went wrong
  - Yes, most of the time
  - Yes, some of the time
  - Not very often
  - No, never
- 4. I have been anxious or worried for no good reason
  - No, not at all
  - Hardly ever
  - Yes, sometimes
  - Yes, very often
- \*5. I have felt scared or panicky for no very good reason
  - Yes, quite a lot
  - Yes, sometimes
  - No, not much
  - No, not at all
- \*6. Things have been getting on top of me
  - Yes, most of the time I haven't been able to cope at all
  - Yes, sometimes I haven't been coping as well as usual
  - No, most of the time I have coped quite well
  - No, I have been coping as well as ever
- \*7. I have been so unhappy that I have had difficulty sleeping
  - Yes, most of the time
  - Yes, sometimes
  - Not very often
  - No, not at all
- \*8. I have felt sad or miserable
  - Yes, most of the time
  - Yes, quite often
  - Not very often
  - No, not at all
- \*9. I have been so unhappy that I have been crying
  - Yes, most of the time
  - Yes, quite often
  - Only occasionally
  - No, never
- \*10. The thought of harming myself has occurred to me
  - Yes, quite often
  - Sometimes
  - Hardly ever
  - Never

FIGURE 22.5 Adapted from Edinburgh Postnatal Depression Scale (EPDS). From Cox, J. L., Holden, J. M., & Sagovsky, R. (1987). Detection of postnatal depression: Development of the 10-item Edinburgh Postnatal Depression Scale. *British Journal of Psychiatry*, 150, 782–786.

is a time of increased vulnerability, but few women receive education about the possibility of depression after birth. In addition, many women may feel ashamed of having negative emotions at a time when they “should” be happy; thus, they don’t seek professional help. Nurses can play a major role in providing guidance about postpartum affective disorders, detecting manifestations, and assisting women to obtain appropriate care.

### Consider This

Even though I was an assertive practicing attorney in my thirties, my first pregnancy was filled with nagging feelings of doubt about this upcoming event in my life. Throughout my pregnancy I was so busy with trial work that I never had time to really evaluate my feelings. I was always reading about the bodily changes that were taking place, and on one level I was feeling excited, but on another level I was emotionally drained. Shortly after the birth of my daughter, those suppressed nagging feelings of doubt surfaced big time and practically immobilized me. I felt exhausted all the time and was only too glad to have someone else care for my daughter. I didn’t breast-feed because I thought it would tie me down too much. Although at the time I thought this “low mood” was normal for all new mothers, I have since found out it was postpartum depression. How could any woman be depressed about this wondrous event?

Thoughts: Now that postpartum depression has been “taken out of the closet” and recognized as a real emotional disorder, it can be treated. This woman showed tendencies during her pregnancy but was able to suppress the feelings and go forward. Her description of her depression is very typical of many women who suffer in silence, hoping to get over these feelings in time. What can nurses do to promote awareness of this disorder? Can it be prevented?

Begin the assessment by reviewing the history to identify general risk factors that could predispose a woman to depression:

- Poor coping skills
- Low self-esteem
- Numerous life stressors
- Mood swings and emotional stress
- Previous psychological problems or a family history of psychiatric disorders
- Substance abuse
- Limited or lack of social support network

Also review the history for specific pregnancy and birth factors that may increase the woman’s risk

for depression. These may include a history of postpartum depression, evidence of depression during the pregnancy, prenatal anxiety, a difficult or complicated pregnancy, traumatic birth experience, or birth of a high-risk or special-needs infant (Doucet, Jones, Letourneau, Dennis & Blackmore, 2011).

Be alert for physical findings. Assess the woman’s activity level, including her level of fatigue. Ask about her sleeping habits, noting any problems with insomnia. When interacting with the woman, observe for verbal and nonverbal indicators of anxiety as well as her ability to concentrate during the interaction. Difficulty concentrating and anxious behaviors suggest a problem. Also assess her nutritional intake: weight loss due to poor food intake may be seen. Assessment can identify women with a high-risk profile for depression, and the nurse can educate them and make referrals for individual or family counseling if needed. Some common assessment findings associated with postpartum depression are listed in Box 22.2.

## Nursing Management

Nurses need to educate themselves about this disorder to facilitate early recognition of signs and symptoms of it, which, in turn, would make early treatment possible, thus supporting recovery. Furthermore, greater knowledge could contribute to providing more effective and compassionate care to these women. Nursing management focuses on assisting any postpartum woman to cope with the changes of this period. Encourage the client to verbalize what she is going through and emphasize the importance of keeping her expectations realistic. Assist the woman in structuring her day to regain a sense of control over the situation. Encourage her to seek help if necessary, using available support systems. Also reinforce the need for good nutrition and adequate exercise and sleep (Engqvist, Ferszt, Åhlin, & Nilsson, 2011).

The nurse can play an important role in assisting women and their partners with postpartum adjustment. Providing facts about the enormous changes that occur during the postpartum period is critical. This information would include changes in the woman’s body. Review the signs and symptoms of all three affective disorders. This information is typically included as part of prenatal visits and childbirth education classes. Know the risk factors associated with these disorders and review the history of clients and their families. Use specific, nonthreatening questions to aid in early detection, such as “Have you felt down, depressed, or hopeless lately?” and “Have you felt little interest or pleasure in doing things recently?”

## BOX 22.2

**COMMON ASSESSMENT FINDINGS ASSOCIATED WITH POSTPARTUM DEPRESSION**

- Loss of pleasure or interest in life
- Low mood, especially in the morning, sadness, tearfulness
- Exhaustion that is not relieved by sleep
- Feelings of guilt
- Weight loss
- Low energy
- Irritability
- Poor personal hygiene
- Constipated
- Preoccupied and unfocused
- Indecisiveness
- Diminished concentration
- Anxiety
- Despair
- Compulsive thoughts
- Loss of libido
- Loss of confidence
- Sleep difficulties (insomnia)
- Loss of appetite
- Bleak and pessimistic view of the future
- Not responding to infant's cries or cues for attention
- Social isolation, won't answer the door or the phone
- Feelings of failure as a mother

Discuss factors that may increase a woman's vulnerability to stress during the postpartum period, such as sleep deprivation and unrealistic expectations, so couples can understand and respond to those problems if they occur. Stress that many women need help after childbirth and that help is available from many sources, including people they already know. Assisting women to learn how to ask for help is important so they can gain the support they need. Also provide educational materials about postpartum emotional disorders. Have available referral sources for psychotherapy and support groups appropriate for women experiencing postpartum adjustment difficulties.

## KEY CONCEPTS

- Postpartum hemorrhage is a potentially life-threatening complication of both vaginal and cesarean births. It is the leading cause of maternal mortality in the United States.
- A good way to remember the causes of postpartum hemorrhage is the "5 T's": tone, tissue, trauma, thrombin, and traction.
- Uterine atony is the most common cause of early postpartum hemorrhage, which can lead to hypovolemic shock.
- Oxytocin (Pitocin), misoprostol (Cytotec), dinoprostone (Prostin E2), methylergonovine maleate (Methergine), and prostaglandin PGF2 $\alpha$  (carbo-prost [Hemabate]) are commonly used drugs used to manage postpartum hemorrhage.
- Failure of the placenta to separate completely and be expelled interferes with the ability of the uterus to contract fully, thereby leading to hemorrhage.
- Causes of subinvolution include retained placental fragments, distended bladder, uterine myoma, and infection.
- Lacerations should always be suspected when the uterus is contracted and bright-red blood continues to trickle out of the vagina.
- Conditions that cause coagulopathies may include idiopathic thrombocytopenic purpura (ITP), von Willebrand disease (vWD), and disseminated intravascular coagulation (DIC).
- Pulmonary embolism is a potentially fatal condition that occurs when the pulmonary artery is obstructed by a blood clot that has traveled from another vein into the lungs, causing obstruction and infarction.
- The major causes of a thrombus formation (blood clot) are venous stasis and hypercoagulation, both of which are common in the postpartum period.
- Postpartum infection is defined as a fever of 100.4° F (38° C) or higher after the first 24 hours after childbirth, occurring on at least 2 of the first 10 days exclusive of the first 24 hours.
- Common postpartum infections include metritis, wound infections, urinary tract infections, and mastitis.
- Postpartum emotional disorders are commonly classified on the basis of their severity: "baby blues," postpartum depression, and postpartum psychosis.
- Management of postpartum depression mirrors the treatment of any major depression: a combination of antidepressant medication, anti-anxiety medication, and psychotherapy in an outpatient or inpatient setting.

## MULTIPLE-CHOICE QUESTIONS

1. A postpartum mother appears very pale and states she is bleeding heavily. The nurse should first:
  - a. Call the client's health care provider immediately.
  - b. Immediately set up an intravenous infusion of magnesium sulfate.
  - c. Assess the fundus and ask her about her voiding status.
  - d. Reassure the mother that this is a normal finding after childbirth.
2. A postpartum woman reports hearing voices and says, "The voices are telling me to do bad things to my baby." The clinic nurse interprets these findings as suggesting postpartum:
  - a. Psychosis
  - b. Anxiety disorder
  - c. Depression
  - d. Blues
3. When implementing the plan of care for a postpartum woman who gave birth just a few hours ago, the nurse vigilantly monitors the client for which complication?
  - a. Deep venous thrombosis
  - b. Postpartum psychosis
  - c. Uterine infection
  - d. Postpartum hemorrhage
4. Which of the following would the nurse expect to include in the plan of care for a woman with mastitis who is receiving antibiotic therapy?
  - a. Stop breast-feeding and apply lanolin.
  - b. Administer analgesics and bind both breasts.
  - c. Apply warm or cold compresses and administer analgesics.
  - d. Remove the nursing bra and expose the breast to fresh air.
5. While assessing a postpartum multiparous woman, the nurse detects a boggy uterus midline 2 cm above the umbilicus. Which intervention would be the priority?
  - a. Assessing vital signs immediately
  - b. Measuring her next urinary output
  - c. Massaging her fundus
  - d. Notifying the woman's obstetrician
6. Methergine has been ordered for a postpartum woman because of excessive bleeding. The nurse should question this order if which of the following is present?
  - a. Mild abdominal cramping
  - b. Tender inflamed breasts
  - c. Pulse rate of 68 beats per minute
  - d. Blood pressure of 158/96 mm Hg

## CRITICAL THINKING EXERCISE

1. Mrs. Griffin had a 22-hour labor before a cesarean birth. Her membranes ruptured 20 hours before she came to the hospital. Her fetus showed signs of fetal distress, so internal electronic fetal monitoring was used. Her most recent test results indicate she is anemic.
  - a. What postpartum complication is this new mother at highest risk for? Why?
  - b. What assessments need to be done to detect this complication?
  - c. What nursing measures will the nurse use to prevent this complication?
2. Tammy, a 32-year-old G9P9, had a spontaneous vaginal birth 2 hours ago. Tammy has been having a baby each year for the past 9 years. Her lochia has been heavy, with some clots. She hasn't been up to void since she had epidural anesthesia and has decreased sensation to her legs.
  - a. What factors place Tammy at risk for postpartum hemorrhage?
  - b. What assessments are needed before planning interventions?
  - c. What nursing actions are needed to prevent a postpartum hemorrhage?
3. Lucy, a 25-year-old G2P2, gave birth 2 days ago and is expected to be discharged today. She had severe postpartum depression 2 years ago with her first child. Lucy has not been out of bed for the past 24 hours, is not eating, and provides no care for herself or her newborn. Lucy states she already has a boy at home and not having a girl this time is disappointing.
  - a. What factors/behaviors place Lucy at risk for an affective disorder?
  - b. Which interventions might be appropriate at this time?
  - c. What education does the family need prior to discharge?

## STUDY ACTIVITIES

1. Compare and contrast postpartum blues, postpartum depression, and postpartum psychosis in terms of their features and medical management.
2. Visit [thePoint](#) and select a website from the Student Resources for Chapter 22. Critique the website regarding its helpfulness to parents, the correctness of the information, and when it was last updated.

3. Interview a woman who has given birth and ask if she had any complications and what was most helpful to her during the experience.
4. The number one cause of postpartum hemorrhage is \_\_\_\_\_.
5. When giving report to the nurse who will be caring for a woman and her newborn in the postpartum period, what information should the labor nurse convey?

*unit eight*

# The Newborn at Risk

**KEY TERMS**

appropriate for gestational age (AGA)  
 asphyxia  
 extremely low birthweight  
 large for gestational age (LGA)  
 late preterm newborn (near term)  
 low birthweight  
 postterm newborn  
 preterm newborn  
 small for gestational age (SGA)  
 term newborn  
 very low birthweight

# Nursing Care of the Newborn with Special Needs

## Learning Objectives

*Upon completion of the chapter, you will be able to:*

1. Define the key terms used in this chapter.
2. Evaluate factors that assist in identifying a newborn at risk due to variations in birthweight and gestational age.
3. Select contributing factors and common complications associated with dysmature infants and their management.
4. Compare and contrast nursing assessment findings and nursing management of a small-for-gestational-age newborn and a large-for-gestational-age newborn; a postterm and preterm newborn.
5. Analyze nursing assessment and management of newborn conditions associated with variations in birthweight and gestational ages.
6. Outline the nurse's role in helping parents experiencing perinatal grief or loss.
7. Integrate knowledge of the risks associated with late preterm births into nursing interventions, discharge planning, and parent education.

*Anna and her husband were stunned when she went into labor at 7 months' gestation. They couldn't understand what would cause her to give birth early, but it happened. When they approached the NICU, Anna took a deep breath and looked down at her tiny baby with tubes coming from everywhere. What feelings might they be experiencing at this moment? Do you think that guilt would be one of those feelings? If so, why?*

## Words of Wisdom

Guiding a parent's hand to touch a frail or ill newborn demonstrates courage and compassion under very difficult circumstances and is a powerful tool in helping parents to deal with the newborn's special needs.

**Most** newborns are born between 38 and 42 weeks' gestation and weigh 6 to 8 pounds, but variations in birthweight or gestational age can occur, and newborns with these variations have special needs. *Healthy People 2020* includes the rate of preterm births and infant deaths as leading health indicators (U.S. Department of Health and Human Services, 2012). While reducing preterm births and low birthweight remain important objectives, the fact remains that 12.2% of infants are born prematurely and 8.2% are of low birthweight (National Center for Health Statistics, 2012).

Gestational age at birth is inversely correlated with the risk that the infant will experience physical, neurologic, or developmental sequelae (March of Dimes,

2011a). Some newborns are born very ill and need special advanced care to survive.

When a woman gives birth to a newborn with problems involving immaturity or birthweight, especially one who is considered high risk, she may go through a grieving process in which she mourns the loss of the healthy full-term newborn she had expected. Through this process she learns to come to terms with the experience she now faces.

The key to identifying a newborn with special needs related to birthweight or gestational age variation is an awareness of the factors that could place a newborn at risk. These factors are similar to those that would suggest a high-risk pregnancy and include:

- Maternal nutrition (malnutrition or overweight)
- Substandard living conditions or low socioeconomic status
- Maternal age of less than 20 or more than 35 years old
- Substance abuse
- Lack of prenatal care
- Smoking or exposure to passive smoke
- Periodontal disease
- Multiple gestation
- Extreme maternal stress
- Abuse and violence
- Placental complications (placenta previa or abruptio placentae)
- History of previous preterm birth
- Maternal disease (e.g., hypertension, diabetes)
- Maternal infection (e.g., urinary tract infection, chorioamnionitis)
- Exposure to occupational hazards, working long hours, or very physical labor (Torricelli, Voltolini, De Bonis, et al., 2012).

The development of new technologies and regionalized care centers for the care of newborns with special needs has resulted in significant improvements in neonatal morbidity and mortality. Being able to anticipate the birth of a newborn at risk allows the birth to take place at a health care facility equipped with the resources to meet the mother's and newborn's needs. Nurses need to have a sound knowledge base to identify the newborn with special needs and to provide coordinated care.

This chapter discusses the nursing management of newborns with special needs related to variations in birthweight and gestational age. It also describes selected associated conditions affecting these newborns. Due to the frailty of these newborns, the care of the family experiencing perinatal loss and the role of the nurse in helping the family cope also are addressed.

### HEALTHY PEOPLE 2020 • 23-1

#### Objective

Increase the proportion of very low birthweight (VLBW) infants born at level III hospitals or subspecialty perinatal centers

Reduce low birthweight (LBW) from a baseline of 8.2% to a target of 7.8%; reduce very low birthweight (VLBW) from a baseline of 1.5% to 1.4%

Reduce the total number of preterm births from a baseline of 12.7% to 11.4%

Reduce the number of late preterm births or live births at 34 to 36 weeks' gestation from a baseline of 9% to 8.1%  
Reduce the number of live births at 32 to 33 weeks' of gestation from a baseline of 1.6% to 1.4%

Reduce the number of very preterm or live births at less than 32 weeks' gestation from a baseline of 2% to 1.8%

USDHHS (2010).

#### Nursing Significance

- Promote the delivery of high-risk infants in settings that have the technological capacity to care for them, ultimately reducing the morbidity and mortality rates for these infants
- Emphasize the issue of LBW as a risk factor associated with newborn death. Promote measures to reduce this risk factor and contribute to significant reductions in infant mortality
- Emphasize the role of preterm birth as the leading cause of newborn deaths unrelated to birth defects
- Promote an overall reduction in infant illness, disability, and death

## BIRTHWEIGHT VARIATIONS

Fetal growth is influenced by maternal nutrition, genetics, placental function, environment, and a multitude of other factors. Assigning size to a newborn is a way to

FIGURE 23.1 A low birthweight newborn in an isolette.

measure and monitor the growth and development of the newborn at birth. Newborns can be classified according to their birthweight and weeks of gestation. Knowing the group into which a newborn fits is important.

**Appropriate for gestational age (AGA)** describes a newborn with a weight that falls within the 10th to 90th percentile for that particular gestational age (Raju, 2012). Infants who are appropriate for gestational age have lower morbidity and mortality than other groups.

**Small for gestational age (SGA)** describes newborns that typically weigh less than 2,500 g (5 lb 8 oz) at term due to less growth than expected in utero. A newborn is also classified as SGA if his or her birthweight is at or below the 10th percentile as correlated with the number of weeks of gestation (Ross & Mansano, 2011).

**Large for gestational age (LGA)** describes newborns whose birthweight is above the 90th percentile on a growth chart and who weigh more than 4,000 g (8 lb 13 oz) at term due to accelerated growth for length of gestation (Raju, 2012).

The following terms describe other newborns with marginal weights at birth and of any gestational age:

- **Low birthweight:** less than 2,500 g (5.5 lb) (Fig. 23.1)
- **Very low birthweight:** less than 1,500 g (3 lb 5 oz)
- **Extremely low birthweight:** less than 1,000 g (2 lb 3 oz) (Vohr & Stephens, 2012)

### Small-For-Gestational-Age Newborns

Newborns are considered SGA when their weight falls below the 10th percentile on a growth chart for gestational age. These infants can be preterm, term, or post-term. Some SGA newborns are constitutionally small; they are statistically small but otherwise healthy.

In some SGA newborns, the rate of growth does not meet the expected growth pattern. These infants are considered to have intrauterine growth restriction (IUGR). IUGR is the pathologic counterpart of SGA. Newborns with IUGR are considered at risk, having increased

morbidity and mortality rates as compared to those of AGA newborns (Ross & Mansano, 2011). The fetus is thought to have an inherent growth potential that, under normal circumstances, yields a healthy newborn of appropriate size. The maternal–placental–fetal units act in harmony to meet the needs of the fetus during gestation. However, growth potential in the fetus can be limited, and this is analogous to failure to thrive in the infant. The causes of both can be intrinsic or environmental. Factors that can contribute to the birth of an SGA newborn are highlighted in Box 23.1 (Moore Simas, Waring, Liao, et al., 2012). IUGR is usually categorized as symmetric or asymmetric. Symmetric IUGR refers to fetuses with equally poor growth rates of the brain, the abdomen, and the long bones and is thought to result from an early global insult (Cunningham et al., 2010a). Asymmetric IUGR refers to infants whose brain growth is spared compared to their abdomen and internal organs (Ross & Mansano, 2011). Fetal growth is dependent on genetic, placental, and maternal factors. Cognitive and motor development during infancy forms the basis for children's subsequent development. Newborns that experience nutritional deficiencies in utero and are born with IUGR are at risk for lifelong developmental deficits, and emotional and behavioral disorders (Ross & Mansano, 2011).

### Nursing Assessment

Assessment of the SGA infant begins by reviewing the maternal history to identify risk factors such as smoking, drug abuse, chronic maternal illness, hypertension, multiple gestation, or genetic disorders. This information allows the nurse to anticipate a possible problem and to be prepared to intervene quickly should one occur. At birth, perform a thorough physical examination, closely observing the newborn for typical characteristics, including:

- Head disproportionately large compared to rest of body (asymmetric)
- Wasted appearance of extremities
- Reduced subcutaneous fat stores
- Decreased amount of breast tissue
- Scaphoid abdomen (sunken appearance)
- Wide skull sutures secondary to inadequate bone growth
- Poor muscle tone over buttocks and cheeks
- Loose and dry skin that appears oversized
- Thin umbilical cord

Also assess the SGA newborn for any congenital malformations, neurologic insults, or indications of infection. SGA newborns commonly face problems after birth because of the decrease in placental function during gestation. Table 23.1 highlights some of the common problems associated with SGA newborns and others experiencing a variation in birthweight or gestational age. Anticipate the need for and provide resuscitation as indicated by the newborn's condition.

## BOX 23.1

## FACTORS CONTRIBUTING TO THE BIRTH OF SGA NEWBORNS

- Maternal causes
  - Chronic hypertension
  - Diabetes mellitus with vascular disease
  - Autoimmune diseases
  - Living at a high altitude (hypoxia)
  - Smoking or exposure to passive smoke
  - Periodontal disease of the mouth
  - Maternal age of >20 or <35 years old
  - Failure to seek any prenatal care
  - Substandard living conditions
  - Low socioeconomic status
  - Abuse and violence
  - Substance abuse (heroin, cocaine, methamphetamines)
  - Hemoglobinopathies (sickle cell anemia)
  - Preeclampsia
  - Exposure to occupational hazards
  - Chronic renal disease
  - Maternal nutrition (malnutrition or obesity)
  - Extreme maternal stress
  - TORCH group infections
- Placental factors
  - Abnormal cord insertion
  - Chronic abruption
  - Decreased surface area, infarction
  - Decreased placental weight
  - Placenta previa
  - Placental insufficiency
- Fetal factors
  - Trisomy 13, 18, and 21
  - Turner's syndrome
  - Chronic fetal infection (cytomegalovirus [CMV], rubella, syphilis, toxoplasmosis)
  - Congenital anomalies (heart, diaphragmatic hernia, tracheoesophageal fistula)
  - Radiation exposure
  - Multiple fetal gestation

Hauth, D. J. Rouse, & C. Y. Spong (eds.), *Williams obstetrics* (23rd ed.). New York: McGraw-Hill; Ross, M. G., & Mansano, R. Z. (2011). Fetal growth restriction. Retrieved February 5, 2012, from <http://emedicine.medscape.com/article/261226-overview#a1>.

## Nursing Management

Interventions for the SGA infant may include obtaining weight, length, and head circumference, comparing them to standards, and documenting the findings on a standardized growth chart. Perform frequent serial blood glucose measurements as ordered and monitor vital signs, being particularly alert for changes in respiratory status that might indicate respiratory distress. Institute measures to maintain a neutral thermal environment to prevent cold stress and acidosis.

Initiate early and frequent oral feedings unless contraindicated. At birth the newborn's glucose level is about 15 mg/dL less than the mother's serum glucose (Thilo & Rosenberg, 2011). A newborn stressed at birth uses up available glucose stores quickly with resulting hypoglycemia, a plasma glucose concentration at or below 40 mg/dL (Cranmer, 2011). With the loss of the placenta at birth, the newborn now must assume control of glucose homeostasis through intermittent oral feedings. If oral feedings are not accepted, an intravenous infusion with 10% dextrose in water may be needed to maintain the glucose level above 40 mg/dL (Cranmer, 2011). Weigh the newborn daily and ensure that he or she has adequate rest periods to decrease metabolic requirements.

Polycythemia is defined as a venous hematocrit above 65%. The hematocrit in a newborn peaks at 2 hours of

age and decreases gradually after that. The relationship between hematocrit and viscosity is almost linear till 65% and exponential thereafter. Increased viscosity of blood is associated with symptoms of hypoperfusion. Clinical features related to hyperviscosity may affect all organ systems. Hyperviscosity of blood results in increased resistance to blood flow and decreased oxygen delivery. In the newborn, hyperviscosity can cause abnormalities of central nervous system function, hypoglycemia, decreased renal function, cardiorespiratory distress, and coagulation disorders. Hyperviscosity has been reported to be associated with long-term motor and cognitive neurodevelopmental disorders (Buonocore, Bracci, & Weindling, 2012). Newborns born small for gestational age (SGA), infants of diabetic mothers (IDM), and multiple births are at risk for polycythemia. They should therefore undergo screening at 2, 12, and 24 hours of age (Buonocore, Bracci, & Weindling, 2012).

Observe for clinical signs of polycythemia and monitor blood results. Asymptomatic newborns with a hematocrit between 65% and 70% may simply be supported with fluids, close observation, and a repeat hematocrit level in 12 hours (Sezik, 2012). If the newborn is symptomatic, a partial exchange transfusion with replacement of removed red blood cell volume with volume expanders may be used, but this treatment is considered controversial and not validated by current evidence-based practice research.

TABLE 23.1

## COMMON PROBLEMS ASSOCIATED WITH NEWBORNS EXPERIENCING A VARIATION IN BIRTHWEIGHT OR GESTATIONAL AGE

Problem	Occurrence	Etiology/Pathophysiology	Assessment Findings	Nursing Implications
Perinatal asphyxia	SGA newborns (common)	<p>Poor tolerance to stress of labor, frequently leading to acidosis and hypoxia</p> <p>Living in hypoxic environment prior to birth due to placental insufficiency, leaving little to no oxygen reserves available to withstand stress of labor:</p> <ul style="list-style-type: none"> <li>–Uterine contractions increase hypoxic stress</li> <li>–Possible depletion of glycogen stores due to chronic hypoxic state, leading to fetal distress</li> <li>–Impaired uteroplacental circulation due to maternal and uterine conditions predisposing to perinatal depression</li> </ul> <p>Compromised newborn at birth experiencing difficulty adjusting to extrauterine environment</p>	<p>Fetal distress (bradycardia, decelerations) during labor</p> <p>Low Apgar scores</p> <p>Potential meconium passage into amniotic fluid</p>	<p>Anticipate possible problem; assess for maternal risk factors</p> <p>Initiate resuscitation measures immediately at birth</p>
	Postterm newborns	<p>Placental deprivation or oligohydramnios, leading to cord compression and subsequent reduction in perfusion to fetus</p>		
	Preterm newborns (common)	<p>Surfactant deficiency</p> <p>Unstable chest wall</p> <p>Immaturity of respiratory control centers in the CNS</p> <p>Small respiratory passages, increasing risk for obstruction</p> <p>Inability to clear mucus from airways</p>		
Difficulty with thermoregulation	SGA newborns (common) Post term newborns	<p>Less muscle mass, less brown fat, less heat-preserving subcutaneous fat, and limited ability to control skin capillaries</p> <p>Associated with depleted glycogen stores, poor subcutaneous fat stores, and disturbances in CNS thermoregulation due to hypoxia (Boxwell, 2010; Veriklan &amp; Walden, 2010)</p> <p>Increased risk for acidosis and hypoglycemia secondary to metabolic stress</p> <p>Loss of subcutaneous fat second to placental insufficiency</p>	<p>Temperature &lt;36.4° C; temperature instability; skin cool to touch; cyanosis of hands and feet</p> <p>Bradypnea (&lt;25 bpm) and tachypnea (&gt;60 breaths/min)</p> <p>Tremors, irritability</p> <p>Wheezing, crackles, retractions</p> <p>Restlessness, lethargy</p> <p>Hypotonia</p>	<p>Maintain a neutral thermal environment to promote stabilization of newborn's temperature</p> <p>Assess skin temperature and respiration characteristics</p> <p>Monitor arterial blood gases and blood glucose levels</p>

(continued)

TABLE 23.1

## COMMON PROBLEMS ASSOCIATED WITH NEWBORNS EXPERIENCING A VARIATION IN BIRTHWEIGHT OR GESTATIONAL AGE (continued)

Problem	Occurrence	Etiology/Pathophysiology	Assessment Findings	Nursing Implications
	Preterm newborns (common) Late preterm infant (common)	Use of stored nutrients for nutrition due to lost ability of placenta to nourish fetus Subsequent wasting of subcutaneous fat, muscle, or both Loss of natural insulation (subcutaneous fat) important in temperature regulation Immaturity of CNS (temperature-regulating center) interferes with ability to regulate body temperature Inadequate amounts of subcutaneous fat Lack of muscle tone and flexion to conserve heat Inadequate brown fat to generate heat Limited muscle mass activity, reducing ability to produce own heat Inability to shiver to generate heat	Weak or high-pitched cry Seizures Poor feeding Grunting Acidosis	Eliminate sources of heat loss: –Dry newborn thoroughly –Wrap in warmed blanket with stockinette cap on head –Use radiant heat source
Hypoglycemia	SGA newborns (common) LGA newborns (common) Postterm newborns Preterm newborns Late preterm infants	Increased metabolic rate and lack of adequate glycogen stores to meet newborn's metabolic needs Commonly associated with infants of diabetic mothers Abrupt cessation of high-glucose maternal blood supply with birth and continued insulin production by the newborn Limited ability to release glucagons and catecholamines, which normally stimulate glucagon breakdown and glucose release Hypoxia secondary to depleted glycogen reserves Placental insufficiency secondary to placental aging contributing to chronic fetal nutritional deficiency further depleting glycogen stores Immature sucking and swallowing leading to insufficient intake Perinatal hypoxia Increased energy expenditure Decreased subcutaneous and brown fat with little to no glycogen stores	Often subtle Lethargy, tachycardia Respiratory distress Jitteriness Drowsiness Poor feeding, feeble sucking Hypothermia, temperature instability Diaphoresis Weak cry Seizures Hypotonia Blood glucose levels <40 mg/dL for term newborns, <20 mg/dL for preterm newborns (Boxwell, 2010; Veriklan & Walden, 2010)	Monitor blood glucose levels, initially on arrival to nursery and hourly thereafter Maintain fluid and electrolyte balance Watch for subtle changes. Initiate early oral feedings if possible; if not, administer IV infusion with 10% dextrose in water

Polycythemia	<p>SGA newborns</p> <p>Chronic mild hypoxia secondary to placental insufficiency</p> <p>Stimulation of erythropoietin release, leading to increased RBC production</p> <p>Secondary to fetal hypoxia, trauma with bleeding, increased erythropoietin production, or delayed cord clamping</p> <p>Postterm newborns</p> <p>Intrauterine hypoxia triggers increased RBC cell production to compensate for lower oxygen levels.</p>	<p>Ensure adequate hydration (orally or IV)</p> <p>Monitor hematocrit levels (goal is ~60%)</p> <p>Administer partial exchange transfusion, albumin, or normal saline IV to reduce RBC volume and increase fluid volume (controversial)</p>	<p>Venous hematocrit &gt;65%</p> <p>Plethora (ruddy appearance)</p> <p>Weak sucking reflex</p> <p>Tachypnea</p> <p>Jaundice</p> <p>Lethargy</p> <p>Jitteriness</p> <p>Hypotonia</p> <p>Irritability</p> <p>Feeding difficulties</p> <p>Difficulty in arousing</p> <p>Seizures</p>	<p>Ensure adequate hydration (orally or IV)</p> <p>Institute early feedings if possible</p> <p>Administer phototherapy (see Chapter 24 for more information)</p>

Provide anticipatory guidance to parents about any treatments and procedures that are being done. Emphasize the need for close follow-up and careful monitoring of the infant's growth in length, weight, and head circumference and feeding patterns throughout the first year of life to confirm any "catch-up" growth taking place.

### Large-For-Gestational-Age Newborns

A newborn whose weight is above the 90th percentile on growth charts or two standard deviations above the mean weight for gestational age is defined as LGA. Large for gestational age is also termed macrosomia. The infant's weight is over 4,000 g (>9 lb). LGA infants may be preterm, term, or postterm. Up to 10% of all infants are designated as LGA at birth (Jazayeri, 2012).

Because of the newborn's large size, vaginal birth may be difficult and occasionally results in birth injury. In addition, shoulder dystocia, clavicular fractures, and facial palsies are common. The incidence of cesarean births is very high with LGA newborns to avoid arrested labor and birth trauma.

#### Take Note!

Diabetes is commonly associated with LGA newborns. However, due to poor placental perfusion, the newborn may experience IUGR and be SGA (Potter & Kicklighter, 2011).

### Nursing Assessment

Assessment of the LGA newborn begins with a review of the maternal history, which can provide clues as to whether the woman has an increased risk of giving birth to an LGA newborn. Maternal factors that increase the chance of bearing an LGA newborn include diabetes mellitus or glucose intolerance, multiparity, prior history of a macrosomic infant, postdates gestation, maternal obesity, male fetus, and genetics (Jazayeri, 2012).

At birth, assess the newborn for common characteristics. The typical LGA newborn has a large body and appears plump and full-faced. The increase in body size is proportional. However, the head circumference and body length are in the upper limits of intrauterine growth. These newborns have poor motor skills and have difficulty in regulating behavioral states. LGA newborns are more difficult to arouse to a quiet alert state (Neonatal Handbook, 2010a).

Thoroughly assess the LGA newborn at birth to identify traumatic birth injuries such as fractured clavicles, brachial palsy, facial paralysis, phrenic nerve palsy, skull fractures, or hematomas. Perform a neurologic examination to identify any nerve palsies, looking for abnormalities such as immobility of the upper arm. Observe

and document any injuries discovered to allow for early intervention and improved outcomes.

LGA infants are at risk for hypoglycemia related to early depletion of glycogen stores in their liver. Obtain frequent blood glucose levels as ordered to evaluate for hypoglycemia. The clinical signs are often subtle and include lethargy, apathy, drowsiness, irritability, tachypnea, weak cry, temperature instability, jitteriness, seizures, apnea, bradycardia, cyanosis or pallor, feeble suck and poor feeding, hypotonia, and coma. Other disorders, including septicemia, severe respiratory distress, and congenital heart disease, may present with similar findings. In addition, be alert for other common problems, such as polycythemia and hyperbilirubinemia (see Table 23.1).

### Nursing Management

Hypoglycemia in a neonate is defined as blood glucose value below 40 mg/dL. It is commonly associated with a variety of neonatal conditions like prematurity, intrauterine growth restriction, and maternal diabetes. Screening for hypoglycemia in high-risk LGA infants is essential. Supervised breast-feeding or formula feeding may be initial treatment options in asymptomatic hypoglycemia. However, symptomatic hypoglycemia should always be treated with a continuous infusion of parenteral dextrose. LGA infants needing dextrose infusion rates above 12 mg/kg/min should be investigated for a definite cause of hypoglycemia. Hypoglycemia has been linked to poor neurodevelopmental outcome, and hence aggressive screening and treatment is recommended (Hay, 2012).

Assist in stabilizing the LGA newborn. Monitor blood glucose levels within 30 minutes of birth and repeat the screening every hour. Recheck levels before feedings and also immediately in any infant suspected of having or showing clinical signs of hypoglycemia, regardless of age (Cranmer, 2011). To help prevent hypoglycemia, initiate feedings, which can be formula or breast milk, with intravenous glucose supplementation as needed. Monitor and record intake and output and obtain daily weights to aid in evaluating nutritional intake.

Observe for signs of polycythemia and hyperbilirubinemia and report any immediately to the health care provider so that early interventions can be taken to prevent poor long-term neurologic development outcomes. Polycythemia and hyperviscosity are associated with fine and gross motor delays, speech delays, and neurologic sequelae (Neonatal Handbook, 2010b). Increasing fluid volume aids in decreasing blood viscosity. Partial exchange transfusion with plasma or normal saline may be used to lower hematocrit and decrease blood viscosity, but this treatment remains controversial. Hydration, early feedings, and phototherapy are used to treat hyperbilirubinemia (see Chapter 24 for more information about hyperbilirubinemia). Provide parental guidance about the treatments and procedures

being done and about the need for follow-up care for any abnormalities identified.

## GESTATIONAL AGE VARIATIONS

The mean duration of pregnancy, calculated from the first day of the last normal menstrual period, is approximately 280 days, or 40 weeks. Gestational age is typically measured in weeks: a newborn born before completion of 37 weeks is classified as a **preterm newborn** and one born after completion of 42 weeks is classified as a **postterm newborn** (Cunningham et al., 2010b; Sielski, 2012). An infant born from the first day of the 38th week through 42 weeks is classified as a **term newborn**. As of 2006, a new classification has been added, the **late preterm newborn (near term)**—one that is born between 34 weeks and 36 weeks, 6 days of gestation (Cunningham et al., 2010b).

- Preterm infant—born before 37 completed weeks of gestation
- Late preterm infant (near term)—34 to 36<sup>6/7</sup> weeks
- Full term infant—38 through 41 completed weeks of gestation
- Postterm infant—42 weeks or more

Precise knowledge of a newborn's gestational age is imperative for effective postnatal management. Determination of gestational age by the nurse assists in planning appropriate care for the newborn and provides important information regarding potential problems that need interventions. See Chapter 18 for more information on assessing gestational age.

### Take Note!

Although preterm and postterm newborns may appear to be at opposite ends of the gestational age spectrum and are very different in size and appearance, both are at high risk and need special care.

## Postterm Newborn

A pregnancy that extends beyond 42 weeks' gestation (294 days) produces a postterm newborn. Other terms used to describe this late birth is a postmature infant. Postterm newborns may be LGA, SGA, or dysmature (newborn weighs less than established normal parameters for estimated gestational age [IUGR]), depending on placental function.

The reason why some pregnancies last longer than others is not completely understood. What is known is that women who experience one postterm pregnancy are at increased risk in subsequent pregnancies. The incidence of prolonged pregnancy, beyond 42 weeks, is approximately 5.5% (Sielski, 2012).

The ability of the placenta to provide adequate oxygen and nutrients to the fetus after 42 weeks' gestation is

thought to be compromised, leading to perinatal mortality and morbidity. After 42 weeks, the placenta begins aging. Deposits of fibrin and calcium, along with hemorrhagic infarcts, occur and the placental blood vessels begin to degenerate. All of these changes affect diffusion of oxygen to the fetus. As the placenta loses its ability to nourish the fetus, the fetus uses stored nutrients to stay alive, and wasting occurs. This wasted appearance at birth is secondary to the loss of muscle mass and subcutaneous fat.

## Nursing Assessment

A thorough assessment of the postterm newborn upon admission to the nursery provides a baseline from which to identify changes in clinical status. Review the maternal history for any risk factors associated with postterm birth. Also be aware of the common physical characteristics and be able to identify any deviation from the expected. Postterm newborns typically exhibit the following characteristics:

- Dry, cracked, peeling, wrinkled skin
- Vernix caseosa and lanugo are absent
- Long, thin extremities
- Creases that cover the entire soles of the feet
- Wide-eyed, alert expression
- Abundant hair on scalp
- Thin umbilical cord
- Limited vernix and lanugo
- Meconium-stained skin and fingernails
- Long nails (Buonocore, Bracci, & Weindling, 2012; Sielski, 2012)

Assess the newborn's gestational age and complete a physical examination to identify any abnormalities. Review the medical record to determine the color of the amniotic fluid when membranes ruptured and observe for a meconium-stained umbilical cord and fingernails to assess for possible meconium aspiration. Careful suctioning at the time of birth and afterwards, if the condition dictates it, reduces the incidence of meconium aspiration (Clark & Clark, 2010). Also be alert for other typical complications associated with a postterm newborn, such as perinatal asphyxia (caused by placental aging or oligohydramnios [decreased amniotic fluid]), hypoglycemia (caused by acute episodes of hypoxia related to cord compression which exhausts carbohydrate reserves), hypothermia (caused by loss of subcutaneous fat), and polycythemia (caused by an increased production of red blood cells to compensate for a reduced oxygen environment), and be prepared to initiate early interventions (see Table 23.1).

## Nursing Management

The birth of a postterm newborn may create stress for the mother and her family. In most situations, birth of a newborn requiring special care was not anticipated.

Postterm newborns are susceptible to several birth challenges secondary to placental dysfunction that place them at risk for asphyxia, hypoglycemia, and respiratory distress. The nurse must be vigilant for complications when managing these newborns.

The postterm newborn is at high risk for perinatal asphyxia, which is usually attributed to placental deprivation or oligohydramnios that leads to cord compression, thereby reducing perfusion to the fetus. Anticipating the need for newborn resuscitation is a priority. The newborn resuscitation team needs to be available in the birthing suite for immediate backup. The newborn may require transport to the neonatal intensive care unit (NICU) for continuous assessment, monitoring, and treatment, depending on his or her status after resuscitation.

Monitor and maintain the postterm newborn's blood glucose levels once stabilized. Intravenous dextrose 10% and/or early initiation of feedings will help stabilize the blood glucose levels to prevent central nervous system sequelae.

Also monitor the postterm newborn's skin temperature, respiration characteristics, results of blood studies, such as arterial blood gases (ABGs) and serum bilirubin levels, and neurologic status. Institute measures to prevent or reduce the risk of hypothermia by eliminating sources of heat loss: thoroughly dry the newborn at birth, wrap him or her in a warmed blanket, and place a stockinet cap on the newborn's head. Providing environmental warmth via a radiant heat source will help stabilize the newborn's temperature.

Closely assess all postterm newborns for polycythemia which contributes to hyperbilirubinemia due to red blood cell destruction. Providing adequate hydration helps to reduce the viscosity of the newborn's blood to prevent thrombosis. Be alert to the early, often subtle signs to promote early identification and prompt treatment to prevent any neurodevelopmental delays (Sielski, 2012).

### Consider This

I had been waiting for this baby my whole married life and now I was told to wait even longer. I was into my third week past my due date and was just told that if I didn't go into labor on my own, the doctor would induce me on Monday. As I waddled out of his office into the hot summer sun, I thought about all the comments that would await me at the office: "You're not still pregnant, are you?" "Weren't you due last month?" "You look as big as a house." "Are you sure you aren't expecting triplets?" I started to get into my car when I felt warm fluid slide down my legs. Although I was embarrassed at my wetness, I was thrilled I wouldn't have to go back to the office and drove myself to the hospital. Within hours my wait was finally over with the birth of my son, a postterm

infant with peeling skin and a thick head of hair. He was certainly worth the wait!

**Thoughts:** Although most due dates are within plus or minus 2 weeks, we can't "go to the bank with it" because so many factors influence the start of labor. This woman was anxious about her overdue status, but nature prevailed. The old adage "when the fruit is ripe, it will fall" doesn't always bring a good outcome: Many women need a little push to bring a healthy newborn forth. What happens when the fetus stays inside the uterus too long? What other features are typical of postterm infants?

## Preterm Newborn

A preterm newborn is one who is born before the completion of 37 weeks of gestation. Although the national birth rate has been declining since the 1990s, the preterm birth rate has been climbing rapidly. Approximately one in eight babies, or 12.3%, are born before the 37th week of gestation (March of Dimes, 2010a). Prematurity is now the leading cause of death within the first month of life and the second leading cause of all infant deaths.

The etiology of half of all preterm births is unknown (Cunningham et al., 2010b). Preterm births take an enormous financial toll, estimated to be in the billions of dollars. They also take an emotional toll on those involved.

Changes in perinatal care practices, including regional care, have reduced newborn mortality rates. Transporting high-risk pregnant women to a tertiary center for birth rather than transferring the neonate after birth is associated with a reduction in neonatal mortality and morbidity (Furdon & Clark, 2012). Despite increasing survival rates, preterm infants continue to be at high risk for neurodevelopmental disorders such as cerebral palsy or mental retardation, intraventricular hemorrhage, congenital anomalies, neurosensory impairment, behavioral problems, and chronic lung disease (Mwaniki, Atieno, Lawn, & Newton, 2012). Making sure that all pregnant women receive quality prenatal care throughout pregnancy is a major method for preventing preterm births.

Preterm newborns face a myriad of possible complications as a result of their fragile health status or the procedures and treatments used. Some of the more common complications in preterm newborns include respiratory distress syndrome, periventricular-intraventricular hemorrhage, bronchopulmonary dysplasia, retinopathy of prematurity, hyperbilirubinemia, anemia, necrotizing enterocolitis, hypoglycemia, infection or septicemia, delayed growth and development, and mental or motor delays (Leone, Ersfeld, Adams, Meyer Schiffer, et al., 2012). Several of these complications are described in Chapter 24.

## Effects of Prematurity on Body Systems

Since the preterm newborn did not remain in utero long enough, every body system may be immature, affecting the newborn's transition from intrauterine to extrauterine life and placing him or her at risk for complications. Without full development, organ systems are not capable of functioning at the level needed to maintain extrauterine homeostasis (Carlo, 2011).

*Recall Anna, who was described at the beginning of the chapter; she gave birth to a newborn at 7 months' gestation. What problems would you anticipate that her newborn might have?*

### Respiratory System

The respiratory system is one of the last body systems to mature. Therefore, the preterm newborn is at great risk for respiratory complications. A few of the problems that affect the preterm newborn's breathing ability and adjustment to extrauterine life include:

- Surfactant deficiency, leading to the development of respiratory distress syndrome
- Unstable chest wall, leading to atelectasis
- Immature respiratory control centers, leading to apnea
- Smaller respiratory passages, leading to an increased risk for obstruction
- Inability to clear fluid from passages, leading to transient tachypnea (Boxwell, 2010; Pramanik, 2012; Bohlin, 2012).

### Cardiovascular System

The preterm newborn has great difficulty in making the transition from intrauterine to extrauterine life in terms of changing from a fetal to a newborn circulation pattern. Higher oxygen levels in the circulation once air breathing begins spur this transition. If the oxygen levels remain low secondary to perinatal asphyxia, the fetal pattern of circulation may persist, causing blood flow to bypass the lungs. Another problem affecting the cardiovascular system is the increased incidence of congenital anomalies associated with continued fetal circulation—patent ductus arteriosus and an open foramen ovale. In addition, impaired regulation of blood pressure in preterm newborns may cause fluctuations throughout the circulatory system. One of special note is cerebral blood flow, which may predispose the fragile blood vessels in the brain to rupture, causing intracranial hemorrhage (Lissauer & Fanaroff, 2011).

### Gastrointestinal System

Preterm newborns usually lack the neuromuscular coordination required to maintain the suck, swallow, and breathing regimen necessary for sufficient calorie and fluid intake to support growth. Perinatal hypoxia causes shunting of blood from the gut to more important organs such as the heart and brain. Subsequently, ischemia and damage to the intestinal wall can occur. This combination of shunting, ischemia, damage to the intestinal wall, and poor sucking ability places the preterm infant at risk for malnutrition and weight loss.

In addition, preterm newborns have a small stomach capacity, weak abdominal muscles, compromised metabolic function, limited ability to digest proteins and absorb nutrients, and weak or absent suck and gag reflexes. All of these limitations place the preterm newborn at risk for nutritional deficiency and subsequent growth and development delays (Neonatal Handbook, 2010c).

The preterm infant's ability to coordinate sucking, swallowing, and breathing is challenged. As a result, preterm infants often require enteral or intravenous feeding. Enteral tube feeding will help to conserve energy even in an infant who is able to suck (Lutz & Przytulski, 2011).

Currently, minimal enteral feeding is used to prepare the preterm newborn's gut to overcome the many feeding difficulties associated with gastrointestinal immaturity. It involves the introduction of small amounts, usually 0.5 to 1 mL/kg/h, of enteral feeding to induce surges in gut hormones that enhance maturation of the intestine. This minute amount of breast milk or formula given via gavage feeding prepares the gut to absorb future introduction of nutrients. It builds mucosal bulk, stimulates development of enzymes, enhances pancreatic function, stimulates maturation of gastrointestinal hormones, reduces gastrointestinal distention and malabsorption, and enhances transition to oral feedings (Gardner, Carter, Enzman-Hines, & Hernandez, 2011).

### Renal System

The renal system of the preterm newborn is immature, reducing the baby's ability to concentrate urine and slowing the glomerular filtration rate. As a result, the risk for fluid retention, with subsequent fluid and electrolyte disturbances, increases. In addition, preterm newborns have limited ability to clear drugs from their systems, thereby increasing the risk of drug toxicity. Close monitoring of the preterm newborn's acid-base and electrolyte balance is critical to identify metabolic inconsistencies. Prescribed medications require strict evaluation to prevent overwhelming the preterm baby's immature renal system (Boxwell, 2010).

## Immune System

The preterm newborn's immune system is very immature, increasing his or her susceptibility to infections. A deficiency of IgG may occur because transplacental transfer does not occur until after 34 weeks' gestation. This protection is lacking if the baby was born before this time. In addition, preterm newborns have an impaired ability to manufacture antibodies to fight infection if they were exposed to pathogens during the birth process. Moreover, the preterm newborn's thin skin and fragile blood vessels provide a limited protective barrier, adding to the increased risk for infection. Thus, anticipating and preventing infections is the goal; preventing infections has a better outcome than treating them (Gardner et al., 2011).

## Central Nervous System

The preterm newborn is susceptible to injury and insult to the central nervous system (CNS), increasing the potential for long-term disability into adulthood. Like all newborns, preterm newborns have difficulty in temperature regulation and maintaining stability. However, their risk for heat loss is compounded by inadequate amounts of insulating subcutaneous fat; lack of muscle tone and flexion to conserve heat; inadequate brown fat to generate heat; limited muscle mass activity, reducing the possibility of producing their own heat; inability to shiver to generate heat; and an immature temperature-regulating center in the brain (Blackburn, 2012). Preventing cold stress, which would increase the newborn's metabolic and oxygen needs, is crucial. The goal is to create a neutral thermal environment in which oxygen consumption is minimal but body temperature is maintained (Lissauer & Fanaroff, 2011).

In addition, the preterm newborn is especially susceptible to hypoglycemia due to immature glucose control mechanisms, decreased glucose stores, and a reduced availability of alternative fuels such as ketone bodies.

### Take Note!

Glucose is needed by the brain and CNS to maintain and support numerous body system functions.

## Nursing Assessment

Preterm newborns are at high risk for numerous problems and require special care. When preterm labor develops and cannot be stopped by medical interventions, plans for appropriate management of the mother and the preterm newborn are necessary, such as transporting them to a regional center with facilities to care for preterm newborns or notifying the facility's NICU. Depending on the degree of prematurity, the preterm newborn may be kept in the NICU for months.

A thorough assessment of the preterm newborn upon admission to the nursery provides a baseline from which to identify changes in clinical status. Be aware of

the common physical characteristics and be able to identify any deviation from the expected (Fig. 23.2). Common physical characteristics of preterm infants may include:

- Birthweight of less than 5.5 pounds
- Scrawny appearance
- Head disproportionately larger than chest circumference
- Poor muscle tone and flexion
- Fontanels wide and soft with overriding sutures
- Minimal subcutaneous fat
- Undescended testes
- Plentiful lanugo (soft, downy hair), especially over the face and back
- Poorly formed ear pinna, with soft, pliable cartilage
- Fused eyelids
- Soft and spongy skull bones, especially along suture lines
- Matted scalp hair, wooly in appearance
- Absent to a few creases in the soles and palms
- Minimal scrotal rugae in male infants; prominent labia and clitoris in female infants
- Thin, transparent skin with visible veins
- Breast and nipples not clearly delineated
- Abundant vernix caseosa (Mattson & Smith, 2011)

Be alert for evidence that might suggest that the preterm newborn is developing a complication (see Table 23.1).

Review the maternal history to identify risk factors for preterm birth and check antepartum and intrapartum records for maternal infections to anticipate the need for treatment. Maternal risk factors associated with preterm birth include a previous preterm delivery, low socioeconomic status, preeclampsia, hypertension, poor maternal nutrition, smoking, multiple gestation, infection, advanced maternal age, and substance abuse.

Assess the newborn's gestational age and assess for IUGR if appropriate. Inspect the newborn's skin closely, especially skin color. Assess vital signs, including temperature via skin probe to identify hypothermia or fever, and heart rate for tachycardia or bradycardia. Evaluate the newborn's respiratory effort and respiratory rate. Observe for periods of apnea lasting longer than 20 seconds. Monitor oxygen saturation levels by pulse oximetry to validate perfusion status. Note and report any signs of respiratory distress. Auscultate lung and heart sounds, being especially alert for possible murmur, which would indicate the presence of patent ductus arteriosus in a preterm newborn.

Assess neurologic status by observing the newborn's behavior. Note any restlessness, hypotonia, or weak cry or sucking effort and report unusual findings.

Monitor laboratory studies such as hemoglobin and hematocrit for signs of polycythemia. Screen for hypoglycemia upon admission and then hourly, always observing for non-specific signs of hypoglycemia such as lethargy, poor feeding, and seizures. Evaluate serum bilirubin concentrations.

Also assess the mother and family members. Identify family strengths and coping mechanisms to establish a basis for intervention.

**FIGURE 23.2** Characteristics of a preterm newborn. **(A)** Few plantar creases. **(B)** Soft, pliable ear cartilage, matted hair, and fused eyelids. **(C)** Lax posture with poor muscle tone. **(D)** Breast and nipple area barely visible. **(E)** Male genitalia with minimal rugae on scrotum. **(F)** Female genitalia with prominent labia and clitoris.

## Nursing Management

The birth of a preterm newborn creates a crisis for the mother and family. Multiple studies have found that hospitalization for preterm newborns is often followed by negative mental health/behavioral outcomes, anxiety and

depressive disorders, and long-term neurologic sequelae (Simhan, 2010). Premature labor and birth are accompanied by feelings of helplessness, isolation, and loss of control (Gardner et al., 2011). Preterm newborns present with immaturity of all organ systems, abundant physiologic challenges, and significant morbidity and mortality

globally (Boxwell, 2010; Verklan & Walden, 2010). The nurse must be vigilant for complications when managing preterm newborns (Fig. 23.3; Nursing Care Plan 23.1).

### Promoting Oxygenation

Newborns normally start to breathe without assistance and often cry after birth, being stimulated by a change in pressure gradients and environmental temperature. The work of taking that first breath is primarily due to overcoming the surface tension of the walls of the terminal lung units at the gas–tissue interface. Subsequent breaths require less inspiratory pressure since there is an increase in functional capacity and air retained. By 1 minute of age, most newborns are breathing well. A newborn who fails to establish adequate, sustained respiration after birth is said to have **asphyxia**. On a physiologic level, it is defined as impairment in gas exchange resulting in a decrease in oxygen in the blood (hypoxemia) and an excess of carbon dioxide or hypercapnia that leads to acidosis. Asphyxia is the most common clinical insult in the perinatal period that results in brain injury, which may lead to mental retardation, cerebral palsy, or seizures (Blackburn, 2012).

FIGURE 23.3 The physical condition of a preterm newborn demands skilled assessment and nursing care.

#### NURSING CARE PLAN 23.1

### Overview of the Care of a Preterm Newborn

Alice, an 18-year-old, felt she had done everything right during her first pregnancy and certainly didn't anticipate giving birth to a preterm newborn at 32 weeks' gestation. When Mary Kaye was born, she had respiratory distress and hypoglycemia and couldn't stabilize her temperature. Assessment revealed the following: newborn described as scrawny in appearance; skin thin and transparent with prominent veins over abdomen; hypotonia with lax, extended positioning; weak sucking reflex when nipple offered; respiratory distress with tachypnea (70 breaths/min), nasal flaring, and sternal retractions; low blood glucose level suggested by lethargy, tachycardia, jitteriness; axillary temperature of 36° C (96.8° F) despite warmed blanket; weight 2,146 g (4.73 lb); length 45 cm (17.72 inches).

**NURSING DIAGNOSIS:** Ineffective breathing pattern related to immature respiratory system and respiratory distress as evidenced by tachypnea, nasal flaring, sternal retractions, and/or oxygen saturation <87%

#### Outcome Identification and Evaluation

Newborn's respiratory status returns to adequate level of functioning as evidenced by rate remaining within 30 to 60 breaths/min, maintenance of acceptable oxygen saturation levels, and minimal to absent signs of respiratory distress.

#### Interventions: *Promoting Optimal Breathing Pattern*

- Assess gestational age and risk factors for respiratory distress *to allow early detection.*
- Anticipate need for bag and mask setup and wall suction *to allow for prompt intervention should respiratory status continue to worsen.*
- Assess respiratory effort (rate, character, effort) *to identify changes.*
- Assess heart rate for tachycardia and auscultate heart sounds *to determine worsening of condition.*

## NURSING CARE PLAN 23.1

**Overview of the Care of a Preterm Newborn** (continued)

- Observe for cues (grunting, shallow respirations, tachypnea, apnea, tachycardia, central cyanosis, hypotonia, increased effort) *to identify need for additional oxygen.*
- Maintain slight head elevation *to prevent upper airway obstruction.*
- Assess skin color *to evaluate tissue perfusion.*
- Monitor oxygen saturation level via pulse oximetry *to provide objective indication of perfusion status.*
- Provide supplemental oxygen as indicated and ordered *to ensure adequate tissue oxygenation.*
- Assist with any ordered diagnostic tests, such as chest x-ray and arterial blood gases, *to determine effectiveness of treatments.*
- Cluster nursing activities *to reduce oxygen consumption.*
- Maintain a neutral thermal environment *to reduce oxygen consumption.*
- Monitor hydration status *to prevent fluid volume deficit or overload.*
- Explain all events and procedures to the parents *to help alleviate anxiety and promote understanding of the newborn's condition.*

**NURSING DIAGNOSIS:** Ineffective thermoregulation related to lack of fat stores and hypotonia as evidenced by extended positioning, low axillary temperature despite warmed blanket/radiant heat source/isolette, respiratory distress, and lethargy

**Outcome Identification and Evaluation**

Newborn will demonstrate ability to regulate temperature as evidenced by temperature remaining in normal range (36.5° to 37.5° C) and absent signs of cold stress.

**Interventions: Promoting Thermoregulation**

- Assess the axillary temperature every hour or use a thermistor probe *to monitor for changes.*
- Review maternal history *to identify risk factors contributing to problem.*
- Monitor vital signs, including heart rate and respiratory rate, every hour *to identify deviations.*
- Check radiant heat source or isolette *to ensure maintenance of appropriate temperature of the environment.*
- Assess environment for sources of heat loss or gain through evaporation, conduction, convection, or radiation *to minimize risk of heat loss.*
- Avoid bathing and exposing newborn *to prevent cold stress.*
- Warm all blankets and equipment that come in contact with newborn; place warmed cap on the newborn's head and keep it on *to minimize heat loss.*
- Encourage kangaroo care (mother or father holds preterm infant underneath clothing skin-to-skin and upright between breasts) *to provide warmth.*
- Educate parents on how to maintain a neutral thermal environment, including importance of keeping the newborn warm with a cap and double-wrapping with blankets and changing them frequently to keep dry *to promote newborn's adjustment.*
- Demonstrate ways to safeguard warmth and prevent heat loss.

**NURSING DIAGNOSIS:** Risk for imbalanced nutrition: less than body requirements to meet metabolic needs related to poor sucking and lack of glycogen stores necessary to meet the newborn's increased metabolic demands

**Outcome Identification and Evaluation**

Newborn will demonstrate adequate nutritional intake to progressively gain weight toward desired goal, remaining free of signs of hypoglycemia as evidenced by blood glucose levels being maintained above 45 mg/dL, enhanced sucking ability, and appropriate weight gain.

(continued)

## NURSING CARE PLAN 23.1

## Overview of the Care of a Preterm Newborn (continued)

**Interventions: Promoting Optimal Nutrition**

- Identify newborn at risk based on behavioral characteristics, body measurements, and gestational age *to establish a baseline and allow for early detection.*
- Assess blood glucose levels as ordered *to determine status and establish a baseline for interventions.*
- Obtain blood glucose measurements upon admission to nursery and every 1 to 2 hours as indicated *to evaluate for changes.*
- Observe behavior for signs of low blood glucose *to allow early identification.*
- Initiate early oral feedings or gavage feedings *to maintain blood glucose levels.*
- If oral or gavage feedings aren't tolerated, initiate an IV glucose infusion *to aid in stabilizing blood glucose levels.*
- Assess skin for pallor and sweating *to identify signs of hypoglycemia.*
- Assess neurologic status for tremors, seizures, jitteriness, and lethargy *to identify further drops in blood glucose levels.*
- Monitor weight daily for changes *to determine effectiveness of feedings.*
- Maintain temperature using warmed blankets, radiant warmer, or warmed isolette *to prevent heat loss and possible cold stress and reduce energy demands.*
- Monitor temperature *to prevent cold stress resulting in decreased blood glucose levels.*
- Offer opportunities for nonnutritive sucking on premature-size pacifier *to satisfy sucking needs.*
- Monitor for tolerance of oral feedings, including intake and output, *to determine effectiveness.*
- Administer IV dextrose if newborn is symptomatic *to raise blood glucose levels quickly.*
- Decrease energy requirements, including clustering care activities and providing rest periods, *to conserve glucose and glycogen stores.*
- Inform parents about procedures and treatments, including rationale for frequent blood glucose levels, *to help reduce their anxiety.*

The preterm infant lacks surfactant, which lowers surface tension in the alveoli and stabilizes them to prevent their collapse. Even if preterm newborns can initiate respirations, they have a limited ability to retain air due to insufficient surfactant. Therefore, preterm newborns develop atelectasis quickly without alveoli stabilization. The inability to initiate and establish respirations leads to hypoxemia and ultimately hypoxia (decreased oxygen), acidosis (decreased pH), and hypercarbia (increased carbon dioxide). This change in the newborn's biochemical environment may inhibit the transition to extrauterine circulation, thus allowing fetal circulation patterns to persist (Boxwell, 2010).

Failure to initiate extrauterine breathing or failure to breathe well after birth leads to hypoxia (too little oxygen in the cells of the body). As a result, the heart rate falls, cyanosis develops, and the newborn becomes hypotonic and unresponsive. Although this can happen with any newborn, the risk is higher in preterm newborns.

**RESUSCITATING THE NEWBORN**

Approximately 10% of newborns require some assistance to begin breathing at birth (Kattwinkel, 2011). Anticipation, adequate preparation, accurate evaluation, and prompt

initiation of support are critical for successful newborn resuscitation. Have all basic equipment immediately available and in working order. Ensure that the equipment is evaluated daily, and document its condition and any needed repairs. Box 23.2 lists the equipment needed for basic newborn resuscitation.

Determine the need for resuscitation by performing a rapid assessment using the following three questions:

- What is the gestational age of this newborn? Was the amniotic fluid clear of meconium?
- Is the newborn breathing or crying now?
- Does the newborn have good muscle tone?

If the answers are “yes” to all questions, then routine care is initiated: provide warmth, clear the airway, dry the newborn, and assess color. If the answer to any of these questions is “no,” the newborn should receive one or more of the following actions, according to this sequence: 1. Stabilization—Dry the newborn thoroughly with a warm towel; provide warmth by placing him or her under a radiant heater to prevent rapid heat loss through evaporation; position the head in a neutral position to open the airway; clear the airway with a bulb syringe

## BOX 23.2

**BASIC EQUIPMENT FOR NEWBORN RESUSCITATION**

- A wall vacuum suction apparatus
- A wall source or tank source of 100% oxygen with a flow meter
- A neonatal self-inflating ventilation bag with correct-sized face masks
- A selection of endotracheal tubes (2.5, 3.0, or 3.5 mm) with introducers
- A laryngoscope with a small, straight blade and spare batteries and bulbs
- Ampules of naloxone (Narcan) with syringes and needles
- A wall clock to document timing of activities and events
- A supply of disposable gloves in a variety of sizes for staff to use

or suction catheter; stimulate breathing. At times, handling and rubbing the newborn with a dry towel may be all that is needed to stimulate respirations.

2. Ventilation
3. Chest compressions
4. Administration of epinephrine and/or volume expansion (Kattwinkel, 2011)

The decision to progress from one set of actions to the next and the need for further resuscitative efforts is determined by the assessment of respirations, heart rate, and color (American Academy of Pediatrics [AAP] & American Heart Association [AHA], 2010). Nurses need to remember that preterm infants have immature lungs that may be more difficult to ventilate and are also more vulnerable to injury by positive-pressure ventilation. They also have immature blood vessels in the brain that are prone to hemorrhage; thin skin and a large surface area, which contribute to rapid heat loss; increased susceptibility to infection; and increased risk of hypovolemic shock related to small blood volume. Anticipation, adequate preparation, accurate evaluation, and prompt initiation of support are critical for successful neonatal resuscitation.

When performing newborn resuscitation, use the mnemonic “ABCDs” (airway, breathing, circulation, and drugs) to remember the sequence of steps (Box 23.3).

Resuscitation measures are continued until the newborn has a pulse above 100 bpm, a good cry or good breathing efforts, and a pink tongue. This last sign indicates a good oxygen supply to the brain (Kattwinkel, 2011). Throughout the resuscitation period, keep the parents informed of what is happening to their newborn and what is being done and why. Provide support through this initial crisis. Once the newborn is stabilized, encourage bonding by having them stroke, touch, and when appropriate hold the newborn.

## BOX 23.3

**ABCDs OF NEWBORN RESUSCITATION**

- **Airway**
  - Place infant’s head in “sniffing” position.
  - Suction mouth, then nose.
  - Suction trachea if meconium-stained and newborn is NOT vigorous (strong respiratory effort, good muscle tone, and heart rate >100 bpm).
- **Breathing**
  - Use positive-pressure ventilation (PPV) for apnea, grasping, or pulse <100 bpm.
  - Ventilate at rate of 40 to 60 breaths/minute.
  - Listen for raising heart rate, audible breath sounds.
  - Look for slight chest movement with each breath.
  - Use carbon dioxide detector after intubation.
- **Circulation**
  - Start compressions if heart rate is <60 after 30 seconds of effective PPV.
  - Give 3 compressions: 1 breath every 2 seconds.
  - Compress one third of the anterior-posterior diameter of the chest.
- **Drugs**
  - Give epinephrine if heart rate is <60 after 30 seconds of compressions and ventilation.
  - **Caution:** Epinephrine dosage is different for endotracheal and IV routes!
    - Epinephrine: 1:10,000 concentration
      - 0.1 to 0.3 mL/kg IV
      - 0.3 to 1 mL/kg via endotracheal tube

Adapted from Kattwinkel, J. (ed.). (2011). *Neonatal resuscitation textbook* (6th ed.). Elk Grove Village, IL: American Academy of Pediatrics.

**ADMINISTERING OXYGEN**

Oxygen administration is a common therapy in the neonatal intensive care unit, though the normal oxygen concentration for a preterm infant remains unknown. Use of large concentrations of oxygen and sustained oxygen saturations higher than 95% while on supplemental oxygen have been associated with the development of retinopathy of prematurity (ROP) and further respiratory complications in the preterm newborn (Ambalavanan & Soltau, 2011; Chawla, Agarwal, Deorari, et al., 2012). For these reasons, oxygen should be used judiciously to prevent the development of further complications. A guiding principle for oxygen therapy is it should be targeted to levels appropriate to the condition, gestational age, and postnatal age of the newborn. Current common practice is to maintain oxygen saturations in the high 80s to mid-90s, though a wide variation in practice may still occur (Ambalavanan & Soltau, 2011). Refer to Chapter 39 for a more in-depth discussion of ROP.

Respiratory distress in preterm infants is commonly caused by a deficiency of surfactant, retained fluid in the lungs (wet lung syndrome), meconium aspiration, pneumonia, hypothermia, or anemia. The principles of care are the same regardless of the cause of respiratory distress. First, keep the newborn warm, preferably in a warmed isolette or with an overhead radiant warmer, to conserve the baby's energy and prevent cold stress. Handle the newborn as little as possible, because stimulation often increases the oxygen requirement. Provide energy through calories via intravenous dextrose or gavage or continuous tube feedings to prevent hypoglycemia. Treat cyanosis with an oxygen hood or blow-by oxygen placed near the newborn's face if respiratory distress is mild and short-term therapy is needed. Record the following important observations every hour or more frequently if indicated:

- Respiratory rate, quality of respirations, and respiratory effort
- Airway patency, including removal of secretions per facility policy
- Skin color, including any changes to duskiness, blueness, or pallor
- Lung sounds on auscultation to differentiate breath sounds in upper and lower fields
- Equipment required for oxygen delivery, such as:
  - Blow-by oxygen delivered via mask or tube for short-term therapy
  - Oxygen hood (oxygen is delivered via a plastic hood placed over the newborn's head)
  - Nasal cannula (oxygen is delivered directly through the nares) (Fig. 23.4A)
  - Continuous positive airway pressure (CPAP), which prevents collapse of unstable alveoli and delivers high levels of inspired oxygen into the lungs
  - Mechanical ventilation, which delivers consistent assisted ventilation and oxygen therapy, reducing the work of breathing for the fatigued infant (Fig. 23.4B)
- Correct placement of endotracheal tube (if present)
- Oxygen saturation levels via pulse oximetry
- Heart rate
- Administration of medication, such as exogenous surfactant

If the newborn shows worsening cyanosis or if oxygen saturation levels fall below 87%, prepare to give additional oxygen as ordered. Evaluate arterial blood gas results periodically as ordered. Document any deterioration or changes in respiratory status. Administer exogenous surfactant as ordered. Throughout care, maintain strict asepsis and meticulous hand hygiene in order to reduce the risk of infection (Boxwell, 2010; Verklan & Walden, 2010).

### Maintaining Thermal Regulation

Immediately after birth, dry the newborn with a warmed towel and then place him or her in a second warm, dry towel before performing the assessment. This drying prevents rapid heat loss secondary to evaporation. Newborns that are active, breathing well, and crying are stable and can be placed on their mother's chest ("kangaroo care") to promote warmth and prevent hypothermia. Preterm newborns that are not considered stable may be placed under a radiant warmer or in a warmed isolette after they are dried with a warmed towel.

Typically newborns use nonshivering thermogenesis for heat production by metabolizing their own brown adipose tissue. However, the preterm newborn has an inadequate supply of brown fat because he or she left the uterus before it was adequate. The preterm newborn also has decreased muscle tone and thus cannot assume the flexed fetal position, which reduces the amount of skin exposed to a cooler environment. In addition, preterm newborns have large body surface areas compared to weight. This allows an increased transfer of heat from their bodies to the environment.

**FIGURE 23.4 (A)** A preterm newborn receiving oxygen therapy via a nasal cannula. The newborn also has an enteral feeding tube inserted for nutrition. **(B)** A preterm newborn receiving mechanical ventilation.

Typically, a preterm newborn that is having problems with thermal regulation is cool to cold to the touch. The hands, feet, and tongue may appear cyanotic. Respirations are shallow or slow, or signs of respiratory distress are present. The newborn is lethargic and hypotonic, feeds poorly, and has a feeble cry. Blood glucose levels are probably low, leading to hypoglycemia, due to the energy expended to keep warm.

When promoting thermal regulation for the preterm newborn:

- Remember the four mechanisms for heat transfer and ways to prevent loss:
  - Convection: heat loss through air currents (avoid drafts near the newborn)
  - Conduction: heat loss through direct contact (warm everything the newborn comes in contact with, such as blankets, mattress, stethoscope)
  - Radiation: heat loss without direct contact (keep isolettes away from cold sources and provide insulation to prevent heat transfer)
  - Evaporation: heat loss by conversion of liquid into vapor (keep the newborn dry and delay the first bath until the baby's temperature is stable)
- Frequently assess the temperature of the isolette or radiant warmer, adjusting the temperature as necessary to prevent hypo- or hyperthermia.
- Assess the newborn's temperature every hour until stable.
- Observe for clinical signs of cold stress, such as respiratory distress, central cyanosis, hypoglycemia, lethargy, weak cry, abdominal distention, apnea, bradycardia, and acidosis.
- Remember the complications of hypothermia and frequently assess the newborn for signs:
  - Metabolic acidosis secondary to anaerobic metabolism used for heat production, which results in the production of lactic acid
  - Hypoglycemia due to depleted glycogen stores
  - Pulmonary hypertension secondary to pulmonary vasoconstriction
- Monitor the newborn for signs of hyperthermia such as tachycardia, tachypnea, apnea, warm to touch, flushed skin, lethargy, weak or absent cry, and CNS depression; adjust the environmental temperature appropriately.
- Explain to the parents the need to maintain the newborn's temperature, including the measures used; demonstrate ways to safeguard warmth and prevent heat loss (Boxwell, 2010; Lunze & Hamer, 2012).

### Promoting Nutrition and Fluid Balance

Providing nutrition is challenging for preterm newborns because their needs are great but their ability to take in optimal amounts of energy/calories is reduced due to their compromised health status. Individual nutritional needs are highly variable.

Depending on their gestational age, preterm newborns receive nutrition orally, enterally, or parenterally via infusion. Several different methods can be used to provide nutrition: parenteral feedings administered through a percutaneous central venous catheter for long-term venous access with delivery of total parenteral nutrition (TPN), or enteral feedings, which can include oral feedings (formula or breast milk), continuous nasogastric tube feedings, or intermittent gavage tube feedings. Gavage feedings are commonly used for compromised newborns to allow them to rest during the feeding process. Many have a weak suck and become fatigued and thus cannot consume enough calories to meet their needs.

Most newborns born after 34 weeks' gestation without significant complications can feed orally. Those born before 34 weeks' gestation typically start with parenteral nutrition within the first 24 hours of life. Then enteral nutrition is introduced and advanced based on the degree of maturity and clinical condition. Ultimately, enteral nutrition methods replace parenteral nutrition.

To promote nutrition and fluid balance in the preterm newborn:

- Measure daily weight and plot it on a growth curve.
- Monitor intake; calculate fluid and caloric intake daily.
- Assess fluid status by monitoring weight; urinary output; urine specific gravity; laboratory test results such as serum electrolyte levels, blood urea nitrogen, creatinine, and hematocrit; skin turgor; and fontanelles (Gardner et al., 2011). Be alert for signs of dehydration, such as a decrease in urinary output, sunken fontanelles, temperature elevation, lethargy, and tachypnea.
- Continually assess for enteral feeding intolerance; measure abdominal girth, auscultate bowel sounds, and measure gastric residuals before the next tube feeding.
- Encourage and support breastfeeding by facilitating maternal breast pumping.
- Encourage nuzzling at the breast in conjunction with kangaroo care if the newborn is stable.

#### Take Note!

When assessing the fluid status of a preterm newborn, palpate the fontanelles. Sunken fontanelles suggest dehydration; bulging fontanelles suggest overhydration.

### Preventing Infection

Prevention of infection is critical when caring for preterm newborns. Infections are the most common cause of morbidity and mortality in the NICU population (Kaufman, 2012; Verklan & Walden, 2010). Sources of infection in a newborn can be divided into three categories: transplacental acquisition (intrauterine infection); perinatal acquisition during childbirth (intrapartum infection); and hospital acquisition in neonatal period (postnatal infection) from the mother, hospital environment, or staff

(Gardner et al., 2011). Nursing assessment and early identification of infectious problems are imperative to improve outcomes.

Preterm newborns are at risk for infection because their early birth deprived them of maternal antibodies needed for passive protection. Preterm newborns also are susceptible to infection because of their limited ability to produce antibodies, asphyxia at birth, and thin, friable skin that is easily traumatized, providing an entry portal for microorganisms.

Early detection is crucial. The clinical manifestations can be nonspecific and subtle: apnea, diminished activity, poor feeding, temperature instability, respiratory distress, seizures, tachycardia, hypotonia, irritability, pallor, jaundice, and hypoglycemia. Report any of these to the primary care provider immediately so that treatment can be instituted.

Include the following interventions when caring for a preterm or postterm newborn to prevent infection:

- Assess for risk factors in maternal history that place the newborn at increased risk.
- Monitor for changes in vital signs such as temperature instability, tachycardia, or tachypnea.
- Assess oxygen saturation levels and initiate oxygen therapy as ordered if oxygen saturation levels fall below acceptable parameters.
- Assess feeding tolerance, typically an early sign of infection.
- Monitor laboratory test results for changes.
- Avoid using tape on the newborn's skin to prevent tearing.
- Use equipment that can be thrown away after use.
- Adhere to standard precautions; use clean gloves to handle dirty diapers and dispose of them properly.
- Use sterile gloves when assisting with any invasive procedure; attempt to minimize the use of invasive procedures.
- Remove all jewelry on your hands prior to washing hands; wash hands upon entering the nursery and in between caring for newborns.
- Avoid coming to work when ill, and screen all visitors for contagious infections.

*Remember Anna, who was in a state of shock when she entered the NICU to see her preterm baby for the first time? How could the nurse have prepared her for this event? What information needs to be given at the isolette to reduce her anxiety and fear now?*

### Providing Appropriate Stimulation

Newborn stimulation involves a series of activities to encourage normal development. Research on developmental interventions shows that when preterm newborns, in particular, receive sensorimotor interventions such as

rocking, skin-to-skin contact with parents, containment (swaddling and surrounded by blanket rolls), music, non-nutritive sucking, breast-feeding, massage, holding, or sleeping on waterbeds, they gain weight faster, progress in feeding abilities more quickly, and show improved interactive behavior compared to preterm newborns who were not stimulated (Boxwell, 2010; Verklan & Walden, 2010). Conversely, overstimulation may have negative effects by reducing oxygenation and causing stress. A newborn reacts to stress by flaying the hands or bringing an arm up to cover the face. When overstimulated, such as by noise, lights, excessive handling, alarms, and procedures, and stressed, heart and respiratory rates decrease and periods of apnea or bradycardia may follow (Blackburn, 2012).

Appropriate developmental stimulation that would not overtax the compromised newborn might include kangaroo (skin-to-skin) holding, rocking, soft singing or music, cuddling, gentle stroking of the infant's skin, colorful mobiles, gentle massage, waterbed mattresses, and nonnutritive sucking opportunities (Fig. 23.5) or providing sucrose if tolerated.

The NICU environment can be altered to provide periods of calm and rest for the newborn by dimming the lights, lowering the volume and tone of conversations, closing doors gently, setting the telephone ringer to the lowest volume possible, clustering nursing activities, and covering the isolette with a blanket to act as a light shield to promote rest at night (Barfield, 2012; Verklan & Walden, 2010).

Encourage parents to hold and interact with their newborn. Doing so helps to acquaint the parents with

**FIGURE 23.5** A preterm newborn receiving nonnutritive sucking.

FIGURE 23.6 A mother bonding with her preterm newborn.

their newborn, promotes self-confidence, and fosters parent–newborn attachment (Fig. 23.6).

*Think back to Anna, the woman who gave birth to a preterm newborn at 7 months' gestation. Anna will be discharged but her newborn will be staying in the NICU for a while. What interventions would be appropriate to facilitate bonding despite their separation? What support can be provided specifically to her family?*

## Managing Pain

Pain is an unpleasant sensory and emotional experience felt by all humans. Newborns feel pain and require the same level of pain assessment and management as adults. Common indicators of pain in the newborn who is unable to vocalize include facial expressions, body movements, and physiologic changes (Akuma & Jordan, 2012). Even though pain may not be expressed verbally in neonates, this does not negate their experiencing it. Untreated pain in newborns may result in increased morbidity and length of stay in the NICU, exaggerated responses to pain in later life, and altered psychosocial development (Franek, Oulton, & Bruce, 2012). Parents commonly expect that health care providers will use appropriate measure to prevent pain in their newborns, but there are gaps in knowledge about the most effective way to accomplish this.

Recent research findings suggested that infants be given an appropriate-sized pacifier for comfort during

painful procedures. Administration of oral sucrose with and without nonnutritive sucking is frequently used as a nonpharmacologic intervention for procedural pain relief in neonates also. The recommended sucrose concentration is a 24% solution (Meek, 2012). Nurses need to be informed about the effectiveness of nonnutritive sucking, its analgesic mechanisms, and how to use and incorporate it into practice (Liaw, Yang, Wang, Chen et al., 2012).

Assessment of pain in the newborn remains a contentious and vexing problem. Newborns in the NICU are subjected to repeated procedures that cause them pain. Newborns, whether preterm, full term, or post-term, do experience pain, but the pain is difficult to validate with consistent behaviors. Considering that ill newborns undergo multiple noxious stimuli from invasive procedures, such as lumbar punctures, heel sticks, venipuncture, line insertions, chest tube placement, specimen collections, endotracheal intubation and suctioning, and mechanical ventilation, common sense would suggest that newborns experience pain from these many activities and interventions. Historically, pain management in infants was not addressed formally but current guidelines address the nurse's role in assessing and managing neonatal pain (Meek, 2012). Refer to Box 23.4 for an overview of the principles of newborn pain prevention and management that all nurses should utilize.

Several psychometric tools are available to assess pain in the newborn. Examples include the Premature Infant Pain Profile (PIPP), which assesses heart rate and oxygen saturation; the CRIES tool (cry, requires oxygen, increased vital signs, expression, and sleeplessness); and the Neonatal Infant Pain Scale (NIPS), which evaluates respiratory patterns. Most are based on facial expressions, crying patterns, change in vital signs, and body movements (Gardner, Carter, Enzman-Hines, & Hernandez, 2012). See Chapter 36 for a more in-depth discussion of pain assessment and management.

Nurses play a key role in assessing a newborn's pain level. Assess the newborn frequently. Pain is considered the “fifth vital sign” and should be assessed as frequently as the other four vital signs. Differentiate pain from agitation by observing for changes in vital signs, behavior, facial expression, and body movement. Suspect pain if the newborn exhibits the following:

- Sudden high-pitched cry
- Facial grimace with furrowing of brow and quivering chin
- Increased muscle tone
- Oxygen desaturation
- Body posturing, such as squirming, kicking, arching
- Limb withdrawal and thrashing movements
- Increase in heart rate, blood pressure, pulse, and respirations
- Fussiness and irritability (Pasek & Huber, 2012)

## BOX 23.4

**NEWBORN PAIN PREVENTION AND MANAGEMENT GUIDELINES**

- Newborn pain frequently goes unrecognized and undertreated.
- Pain assessment is an essential activity prior to pain management.
- Newborns experience pain, and analgesics should be given.
- A procedure considered painful for an adult should also be considered painful for a newborn.
- Developmental maturity and health status must be considered when assessing for pain in newborns.
- Newborns may be more sensitive to pain than adults.
- Pain behavior is frequently mistaken for irritability and agitation.
- Newborns are more susceptible to the long-term effects of pain.
- Adequate pain management may reduce complications and mortality.
- Nonpharmacologic measures can prevent, reduce, or eliminate newborn pain.
- Sedation does not provide pain relief and may mask pain responses.
- A newborn's response to both pharmacologic and nonpharmacologic pain therapy should be assessed within 30 minutes of administration or intervention.
- Health care professionals are responsible for pain assessment and treatment.
- Written guidelines are needed on each newborn unit.

Adapted from Boxwell, G. (ed.). (2010). *Neonatal intensive care nursing* (2nd ed.). New York: Routledge; Johnston, C. C., Fernandes, A. M., & Campbell-Yeo, M. (2010). Pain in neonates is different. *Pain*, 152(3 suppl), S65–S73; Verklan, M. T., & Walden, M. (2010). *Core curriculum for neonatal intensive care nursing* (4th ed.). St. Louis: Saunders.

The goals of pain management are to minimize the amount, duration, and severity of pain and to assist the newborn in coping. Effective pain management strategies for newborns include preventing, limiting, or avoiding noxious stimuli; using nonpharmacologic techniques to reduce pain; and administering pharmacologic agents when appropriate. Box 23.5 lists some of the more commonly used nonpharmacologic pain management techniques for the preterm newborn.

The number of analgesics available for use with preterm newborns is limited. Morphine and fentanyl, usually administered intravenously, are the most commonly used opioids for moderate to severe pain. Acetaminophen is effective for mild pain. Benzodiazepines are used as sedatives during painful procedures and can be combined with opioids for more effectiveness. Local or topical anesthetics (e.g., EMLA cream) also may be used before procedures such as venipuncture, lumbar puncture, and intravenous catheter insertion (AAP, 2010).

## BOX 23.5

**NONPHARMACOLOGIC TECHNIQUES TO REDUCE PAIN IN THE PRETERM NEWBORN**

- Gentle handling, rocking, caressing, cuddling, and massaging
- Rest periods before and after painful procedures
- Kangaroo care (skin-to-skin contact) during procedure
- Breastfeeding, if able, to reduce pain from minor procedures
- Use of a facilitated tuck (holding arms and legs in a flexed position)
- Application of topical anesthetics prior to venipuncture or lumbar puncture
- Swaddling and positioning to establish physical boundaries
- Nonnutritive sucking (pacifier dipped in sucrose) prior to procedure
- Minimal use of tape, with gentle removal to avoid skin tears
- Warm blankets for wrapping to facilitate relaxation
- Reduction of environmental stimuli by removing or turning down noxious stimuli such as noise from alarms, beepers, loud conversations, and bright lights
- Distraction, such as with colored objects or mobiles

Adapted from Boxwell, G. (ed.). (2010). *Neonatal intensive care nursing* (2nd ed.). New York: Routledge; Johnston, C. C., Fernandes, A. M., & Campbell-Yeo, M. (2010). Pain in neonates is different. *Pain*, 152(3 suppl), S65–S73; Verklan, M. T., & Walden, M. (2010). *Core curriculum for neonatal intensive care nursing* (4th ed.). St. Louis: Saunders.

Be vigilant in assessing for adverse effects (respiratory depression or hypotension) when administering pharmacologic agents for pain management, especially in preterm newborns with neurologic impairment. These negative effects are usually dose and route related, so be knowledgeable about the pharmacokinetics and therapeutic dosing of any drug administered.

**Promoting Growth and Development**

In the late 1970s, researchers evaluated the NICU environment in terms of light and sound levels, caregiving activities, and handling of newborns. As a result of this research, many environmental modifications were made to reduce the stress and overstimulation of the NICU, and the concept of developmentally supportive care was introduced. Developmentally supportive care is defined as care of a newborn or infant to support positive growth and development. Developmental care focuses on what newborns or infants can do at that stage of development; it uses therapeutic interventions only to the point that

they are beneficial; and it provides for the development of the newborn–family unit (Jackson, 2012).

Family-centered developmental care is an essential element of neonatal intensive care. It is of particular importance when the infant is vulnerable and at greater risk for poor outcomes complicated by a family unit that is easily challenged by the unique needs of the infant. Yet, all newborns and their families deserve this philosophy of caregiving. Family-centered developmental care must continue to be tested through research

to determine which interventions work, what does not work, and which interventions need further refinement (McGrath, Samra, & Kenner, 2011).

Developmental care is a philosophy of care that requires rethinking the relationships between newborns, families, and health care providers. It includes a variety of activities designed to manage the environment and individualize the care of the preterm or high-risk ill newborn based on behavioral observations (see Evidence-Based Practice 23.1).

### EVIDENCE-BASED PRACTICE 23.1

### PROMOTING DEVELOPMENT AND PREVENTING MORBIDITY IN PRETERM INFANTS

#### STUDY

Preterm infants experience a range of morbidity related to the immaturity of their organ systems and to concurrent disease states. There is concern that an unfavorable environment in the neonatal intensive care unit (NICU) may compound this morbidity. Modification of the environment could minimize the iatrogenic effects. Developmental care is a broad category of interventions designed to minimize the stress of the NICU environment. These interventions may include elements such as control of external stimuli (vestibular, auditory, visual, tactile), clustering of nursery care activities, and positioning or swaddling of the preterm infant. Individual strategies have also been combined to form programs, such as the Newborn Individualized Developmental Care and Assessment Program (NIDCAP).

A study was done to examine the effects of developmental care on preterm newborns. The study evaluated relevant outcomes such as neurodevelopment, weight gain, length of hospital stay, duration of mechanical ventilation, and physiologic stress. A computerized search of all articles, controlled trials, and conference and symposia proceedings was done. This review found 36 eligible randomized controlled trials involving four major groups of developmental care interventions, 19 subgroups and multiple clinical outcomes. In addition, the long-term outcomes of a previously included trial were added to the review. The results of the review indicate that developmental care interventions demonstrate limited benefit to preterm infants with respect to: decreased moderate-severe chronic lung disease, decreased incidence of necrotizing enterocolitis, and improved family outcome. Conversely, an increase in mild lung disease and an increase in the length of stay were demonstrated in infants receiving developmental care compared to controls. There is also very limited evidence of the long-term positive effect of NIDCAP on behavior and movement at 5 years corrected age, but no effect on cognition. Other individualized developmental care interventions have also demonstrated some effect in enhancing neurodevelopmental outcome.

#### Findings

Because of the inclusion of multiple interventions in most studies, the determination of the effect of any single intervention is difficult. Although there is evidence of limited benefit of **developmental care** interventions overall, and no major harmful effects reported, there were a large number of outcomes for which no or conflicting effects were demonstrated. The single trials that did show a significant effect of an intervention on a major clinical outcome were based on small sample sizes, and the findings were often not supported in other small trials. Before a clear direction for practice can be supported, evidence demonstrating more consistent effects of **developmental care** interventions on important short- and long-term clinical outcomes is needed.

#### Nursing Implications

Although the study found that developmental care for preterm newborns was of limited benefit, it emphasized that this type of care had no major harmful effects. Nurses can integrate these findings into their care for preterm newborns with the understanding that they are beneficial but that the effect may be limited. Nurses can advocate for individualizing the activities involved in developmental care based on the newborn's needs. They also can play a key role in fostering research to help determine which stressors seem to be the most troublesome and which specific activities are of the greatest benefit. In addition, nurses can assist in identifying appropriate short- and long-term outcome measures.

Symington, A., & Pinelli, J. (2009). *Developmental care for promoting development and preventing morbidity in preterm infants*. Cochrane Database of Systematic Reviews 2009. Issue 1. Art. No.: CD001814. DOI: 10.1002/14651858.CD001814.pub2.

Developmental care includes these strategies:

- Clustering care to promote rest and conserve the infant's energy
- Flexed positioning to simulate in utero positioning
- Environmental management to reduce noise and visual stimulation
- Kangaroo care to promote skin-to-skin sensation
- Placement of twins in the same isolette or open crib to reduce stress
- Activities to promote self-regulation and state regulation:
  - Surrounding the newborn with nesting rolls/devices
  - Swaddling with a blanket to maintain the flexed position
  - Providing sheepskin or a waterbed to simulate the uterine environment
  - Providing nonnutritive sucking (calms the infant)
  - Providing objects to grasp (comforts the newborn)
- Promotion of parent–infant bonding by making parents feel welcome in the NICU
- Open, honest communication with parents and staff
- Collaboration with the parents in planning the infant's care (Boxwell, 2010; Verklan & Walden, 2010; Jackson 2012)

Developmental care can be fostered by clustering the lights in one area so that no lights are shining directly on newborns, installing visual alarm systems and limiting overhead pages to minimize noise, and monitoring continuous and peak noise levels. Nurses can play an active role by serving on committees that address these issues. In addition, nurses can provide direct developmentally supportive care. Doing so involves careful planning of nursing activities to provide the ideal environment for the newborn's development. For example:

- Dim the lights and cover isolettes at night to simulate nighttime.
- Support early extubation from mechanical ventilation.
- Encourage early and consistent feedings with breast milk.
- Administer prescribed antibiotics judiciously.
- Position the newborn as if he or she was still in utero (a nesting fetal position).
- Promote kangaroo care by encouraging parents to hold the newborn against the chest for extended periods each day.
- Coordinate care to respect sleep and awake states.

Throughout the newborn's stay, work with the parents, developing a collaborative partnership so they feel comfortable caring for their newborn. Be prepared to make referrals to community support groups to enhance coping (Warren & Phillippi, 2012).

### Promoting Parental Coping

Generally, pregnancy and the birth of a newborn are exciting times, but when the newborn has serious, perhaps life-threatening problems, the exciting experience suddenly changes to one of anxiety, fear, guilt, loss, and grief.

Parents are typically unprepared for the birth of a preterm newborn and commonly experience an array of emotions, including disappointment, fear for the survival of the newborn, and anxiety due to the separation from their newborn immediately after birth. Gaining insight into the experience of parents of premature infants can help nurses ensure services more effectively meet the needs of these families (Boykova & Kenner, 2012). Early interruptions in the bonding process and concern about the newborn's survival can create extreme anxiety and interfere with attachment (Blackburn, 2011).

Nursing interventions aimed at reducing parental anxiety include:

- Reviewing with them the events that have occurred since birth
- Providing simple relaxation and calming techniques (visual imagery, breathing)
- Exploring their perception of the newborn's condition and offering explanations
- Validating their anxiety and behaviors as normal reactions to stress and trauma
- Providing a physical presence and support during emotional outbursts
- Exploring the coping strategies they used successfully in the past and encouraging their use now
- Encouraging frequent visits to the NICU
- Addressing their reactions to the NICU environment and explaining all equipment used
- Identifying family and community resources available to them (Blackburn, 2011; Gooding et al., 2011)

## Preparing for Discharge

Discharge planning typically begins with evidence that recovery of the newborn is certain. However, the exact date of discharge may not be predictable. The goal of the discharge plan is to make a successful transition to home care. Essential elements for discharge are a physiologically stable infant, a family who can provide the necessary care with appropriate support services in place in the community, and a primary care physician available for ongoing care (Boykova & Kenner, 2012; Verklan & Walden, 2010).

The care of each high-risk newborn after discharge requires careful coordination to provide ongoing multidisciplinary support for the family. The discharge planning team typically includes the parents, primary care physician, neonatologists, neonatal nurses, and a social worker. Other professionals, such as surgical specialists and pediatric subspecialists, occupational, physical, speech, and respiratory therapists, nutritionists, home health care nurses, and a case manager, may be included as needed (Boykova & Kenner, 2012; Verklan & Walden, 2010). Critical components of discharge planning are summarized in Box 23.6.

Nurses involved in the discharge process are instrumental in bridging the gap between the hospital and home. When planning for discharge of the high-risk infant, the nurse should:

## BOX 23.6

**CRITICAL COMPONENTS OF DISCHARGE PLANNING**

- Parental education—involvement and support in newborn care during NICU stay will ensure their readiness to care for the infant at home.
  - Evaluation of unresolved medical problems—review of the active problem list and determination of what home care and follow-up is needed.
  - Implementation of primary care—completion of newborn screening tests, immunizations, examinations such as funduscopic exam for ROP, and hematologic status evaluation.
  - Development of home care plan, including assessment of:
    - Equipment and supplies needed for care
    - In-home caregiver's preparation and ability to care for infant
    - Adequacy of the physical facilities in the home
    - An emergency care and transport plan if needed
    - Financial resources for home care costs
    - Family needs and coping skills
    - Community resources, including how they can be accessed
- Assess the physical status of the mother and the newborn
  - Discuss the early signs of complications and what to do if they occur
  - Reinforce instructions for infant care and safety
  - Stress the importance of proper car seat use
  - Provide instructions for medication administration
  - Reinforce instructions for equipment operation, maintenance, and troubleshooting
  - Teach infant cardiopulmonary resuscitation and emergency care
  - Demonstrate techniques for special care procedures such as dressings, ostomy care, artificial airway maintenance, chest physiotherapy, suctioning, and infant stimulation
  - Provide breastfeeding support or instruction on gavage feedings
  - Assist with defining roles in the adjustment period at home
  - Assess the parents' emotional stability and coping status
  - Provide support and reassurance to the family
  - Report abnormal findings to the health care team for intervention
  - Follow up with parents to ensure that they have connected with appropriate support systems in the community (Boykova & Kenner, 2012; Verklan & Walden, 2010)

**Dealing With Perinatal Loss**

Perinatal loss, defined as any pregnancy loss and/or neonatal death up to 1 month of age, continues to be a common

occurrence even though major advances have taken place in perinatal health care. Over 1 million fetal deaths occur in the United States each year. The prevalence of perinatal death reflects a very real possibility that all nurses will meet and care for a woman who has experienced the death of a baby (Bennett, Ehrenreich, Litz, et al., 2012).

Perinatal loss is a profound experience for the family. It engenders a unique kind of mourning since the infant is so much a part of the parents' identity. Instead of celebrating a new life as they expected, parents are mourning the loss of dreams and hopes and the loss of an extension of themselves. NICU nurses face a difficult situation when caring for newborns who may not survive. Newborn death is incomprehensible to most parents. This makes the grieving process more difficult because what is happening "can't be real." Deciding whether to see, touch, or hold the dying newborn is extremely difficult for many parents. Nurses play a major role in assisting parents to make their dying newborn "real" to them by providing them with as many memories as possible and encouraging them to see, hold, touch, dress, and take care of the infant and take photographs. These actions help to validate the parents' sense of loss, relieve the experience, and attach significance to the meaning of loss. A lock of hair, a name card, or an identification bracelet may serve as important mementoes that can ease the grieving process. The memories created by these interventions can be useful allies in the grieving process and in resolving grief (Boxwell, 2010; Gibson, Finney, & Boilange, 2011).

A nurses' willingness to sit quietly and observe, to remain open and nonjudgmental, and to explore what might be helpful are useful strategies to bridge cultural differences. Statements such as "Help me understand how your family cares for someone who is dying," or "What would be important for me to know about how best to care for your baby's body?" convey a nurse's willingness to learn what is most important to each family. Parents' answers may help guide nurses in providing culturally appropriate care for diverse populations. Nurses who are attentive to learning what is most important to parents, and subsequently work to incorporate such interventions into their care, foster relationships between parents and their infant (Breeze, Statham, Hackett, et al., 2012).

Parent–newborn interaction is vital to the normal processes of attachment and bonding. The detachment process involved in a newborn's death is equally important for parents. Nurses can aid in this process by helping parents to see their newborn through the maze of equipment, explaining the various procedures and equipment, encouraging them to express their feelings about the newborn's status, and providing time for them to be with their dying newborn (Boxwell, 2010; Gibson et al., 2011).

A common reaction by many people when learning that a newborn is not going to survive is one of avoidance. Nurses are no exception. It is difficult to initiate a conversation about such a sensitive issue without knowing how the parents are going to react and cope with the impending loss. One way to begin a conversation with the

parents is to convey concern and acknowledge their loss. Active listening can give parents a safe place to begin the healing process. The relationship that the nurse establishes with the parents is a unique one, providing an opportunity for both the nurse and the parents to share their feelings.

Be aware of personal feelings about loss and how these feelings are part of one's own life and personal belief system. Actively listen to the parents when they are talking about their experiences. Communicate empathy (understanding and feeling what another person is feeling), respect their feelings, and respond to them in helpful and supportive ways (Boxwell, 2010; Gibson et al., 2011). Table 23.2 highlights appropriate interventions for a family experiencing a perinatal loss before and after a newborn dies.

In a time of crisis or loss, people are often more sensitive to other people's reactions. For example, the parents may be extremely aware of the nurse's facial expressions, choice of words, and tone of voice. Talking quickly, in a businesslike fashion, or ignoring the loss may inhibit parents from discussing their pain or how they are coping with it. Parents may need to vent their frustrations and

anger, and the nurse may become the target. Validate their feelings and attempt to reframe or refocus the anger toward the real issue of loss. An example would be to say, "I understand your frustration and anger about this situation. You have experienced a tremendous loss and it must be difficult not to have an explanation for it at this time." Doing so helps to defuse the anger while allowing them to express their feelings.

The death of an infant will more than likely be one of the toughest moments in a family's life. Giving families some sense of control in an otherwise hopeless situation can provide some comfort. Some ideas to provide them a sense of control include:

- Ask the family who they wish to have present as the infant dies.
- Give the family a choice of rooms in which they can say good-bye to their infant.
- Provide privacy for the family during this time period by placing a sign on the door.
- Provide ideas for making or selecting memorial items for a memory box.

**TABLE 23.2** ASSISTING PARENTS TO COPE WITH PERINATAL LOSS

<p>Before the newborn's death</p>	<p>Respect variations in the family's spiritual needs and readiness.            Assess cultural beliefs and practices that may bring comfort; respect culturally appropriate requests for truth telling and informed refusal.            Initiate spiritual comfort by calling the hospital clergy if appropriate; offer to pray with the family if appropriate.            Encourage the parents to take photographs, make memory boxes, and record their thoughts in a journal.            Explore with family members how they dealt with previous losses.            Discuss techniques to reduce stress, such as meditation and relaxation.            Recommend that family members maintain a healthy diet and get adequate rest and exercise to preserve their health.            Participate in early and repeated care conferencing to reduce family stress.            Allow family to be present at both medical rounds and resuscitation; provide explanations of all procedures, treatments, and findings; answer questions honestly and as completely as possible.            Provide opportunities for the family to hold the newborn if they so choose.            Assess the family's support network.            Provide suggestions as to how friends can be helpful to the family.</p>
<p>After the newborn's death</p>	<p>Help the family to accept the reality of death by using the word "died."            Acknowledge their grief and the fact that their newborn has died.            Help the family to work through their grief by validating and listening.            Provide the family with realistic information about the causes of death.            Offer condolences to the family in a sincere manner.            Encourage the father to cry and grieve with his partner.            Provide opportunities for the family to hold the newborn if they desire.</p>
<p>At the time of the release of the newborn's body</p>	<p>Reassure the family that their feelings and grieving responses are normal.            Encourage the parents to have a funeral or memorial service to bring closure.            Suggest that the parents plant a tree or flowers to remember the infant.            Address attachment issues concerning subsequent pregnancies.            Provide information about local support groups.            Provide anticipatory guidance regarding the grieving process.            Present information about any impact on future childbearing, and refer the parents to appropriate specialists or genetic resources.</p>

Adapted from Boxwell, G. (ed.). (2010). *Neonatal intensive care nursing* (2nd ed.). New York: Routledge; Gibson, J., Finney, S., & Boilage, M. (2011). Developing a bereavement program in the newborn intensive care unit. *Journal of Perinatal & Neonatal Nursing*, 25(4), 331-341.

- The family should never be left to handle their emotions alone unless they request it.
- Respect a family's wishes if they refuse to be with their infant during the dying process or afterward. Everyone grieves differently.

When assisting bereaved parents, start where the parents are in the grief process to avoid imposing your own agenda on them. You may feel uncomfortable at not being able to change the situation or take the pain away. The nurse's role is to provide immediate emotional support and facilitate the grieving process. Supporting and strengthening the family bond in the face of perinatal loss is essential.

Comforting the family after the infant's death is vital to give them a sense of closure and start the healing process. Some things the nurse can do to help the family during this time include:

- Sending the family a card from the nursing staff, signed by all who worked with their infant within a week of leaving the hospital
- Attending the funeral to allow for a public good-bye and to support others in their time of loss
- Providing the family with a memory box, which might contain an outfit worn by their infant, a blanket used to cover their infant, a lock of hair, and a card with hand and foot prints, a photo with someone holding their infant
- Remembering their infant at various anniversaries by sending a card or calling the family to see how they are doing provides families much-needed comfort
- Donating to a charity in memory of the infant, such as to March of Dimes
- Providing the family with resources that might help them. Information might include listings of local or online support groups as well as grief websites such as Share.org

Being present during this traumatic event for families is tough. Serving infants and their families by bearing witness to their pain and grief is a special privilege. Being present for the family with compassion, comfort, support, and resources during their time of loss is truly an honorable gesture. Nurses are remembered years later for their kindness and guidance of the family members through this adverse event with dignity (Discenza, 2010).

### Take Note!

Infants born prematurely between 34 and 37 weeks are at higher risk for morbidity and mortality than those born before 28 weeks or after 37 weeks (Premji, Young, Rogers, & Reill, 2012).

## Late Preterm Newborn ("Near Term")

The late preterm is a newborn that is born between 34 weeks 0 days and 36 weeks 6 days of gestation. Previously, infants born during this time frame were called

“near term” or “slightly premature,” which was a misnomer because the infants have special care needs. Some of the most common complications for late preterm infants are cold stress, respiratory distress, hypoglycemia, sepsis, cognitive delays, hyperbilirubinemia, and feeding difficulties (Souto, Pudell, & Hallas, 2011). In recent years, the subject of late preterm birth has received much attention, since this population of preterm newborns represents more than 70% of all preterm births in the United States and has increased by 19% in singleton births and 30% in multiples since 1990 (CDC, 2010). With the sharp rise in the number of cesarean births performed, the incidence of late preterm newborns will also rise. Perinatal nurses need to understand the risks of late preterm births and the unique needs of this population in order to facilitate timely assessment and intervention to improve outcomes. Some of the challenges facing the late preterm newborn include:

- Respiratory distress (related to pulmonary immaturity, lack of adequate surfactant, retained lung fluid, cesarean section)
- Thermoregulation issues (less brown and white, limited ability to flex the trunk and extremities to decrease exposed surface area)
- Hypoglycemia related to the first two challenges (respiratory distress and cold stress)
- Apnea (related to poor respiratory control and immaturity)
- Jaundice and hyperbilirubinemia (related to immature bilirubin conjugation and excretion)
- Feeding challenges related to immature suck and swallowing reflexes
- Sepsis because maternal antibodies are not fully transferred prior to the 37th week
- Neurodevelopmental delay (related to brain and central nervous system immaturity) (Premji, Young, Rogers, & Reilly, 2012; Verklan & Walden, 2010)

These challenges are similar to those facing the preterm newborn and require similar management. Late preterm newborns have more clinical problems, longer lengths of stay, higher costs when compared with full-term newborns, and increased mortalities (Corso & De Buty, 2011). Anticipatory guidance for parents of late preterm infants should include recommending an infant cardiopulmonary resuscitation course, educating about sudden infant death syndrome prevention protocol (Back to Sleep), and advising the parents to avoid public places and limit visitors for the first few weeks after being discharged from the hospital. Consistent follow-up medical care, weekly weight checks, and up-to-date immunizations can help late preterm infants avoid complications (Souto et al., 2011). Nurses and parents must be aware of the risks associated with late preterm births to optimize care and outcomes for this group of newborns. For information related to discharge teaching for the family of the late preterm infant, refer to Teaching Guidelines 23.1.

## Teaching Guidelines 23.1

### DISCHARGING THE LATE PRETERM INFANT

When discharge planning for the late preterm infant, validate parents' understanding of:

- Dressing the infant appropriately in order to maintain appropriate temperature
- Practice good handwashing and limit contact with ill persons
- Maintain adequate nutritional and fluid intake to promote growth and development; breastfeeding is preferred
- Avoid secondhand smoke exposure
- Practice safe sleep practices: avoid soft mattresses or blankets, place infant supine to sleep
- Keep appointments for health maintenance visits (check-ups) as scheduled
- Notify the pediatrician or nurse practitioner immediately if the infant:
  - Has difficulty breathing or turns blue (call for emergency services in this case)
  - Has a temperature below 97° F (36.1° C) or above 100.4° F (38° C)
  - Displays a yellow color to the skin (jaundice)
  - Feeds poorly
  - Vomits
  - Fails to void for 12 hours, or to pass a bowel movement in 24 hours
  - Acts lethargic, irritable or “just not right”

Adapted from Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN). (2011). *Assessment and care of the late preterm infant: Evidence-based clinical practice guideline*. Retrieved March 11, 2012, from <http://www.guidelines.gov/content.aspx?id=24066>.

to cephalopelvic disproportion, hypoglycemia, and jaundice secondary to hyperbilirubinemia.

- Variations in gestational age include postterm and preterm newborns. Postterm newborns may be large or small for gestational age or dysmature, depending on placental function.
- The postterm newborn may develop complications after birth, including fetal hypoxia, hypoglycemia, hypothermia, polycythemia, and meconium aspiration.
- Preterm birth is the leading cause of death within the first month of life and the second leading cause of all infant deaths.
- The preterm newborn is at risk for complications because his or her organ systems are immature, thereby impeding the transition from intrauterine life to extrauterine life.
- Newborns can experience pain, but their pain is difficult to validate with consistent behaviors.
- Newborns with gestational age variations, primarily preterm newborns, benefit from developmental care, which includes a variety of activities designed to manage the environment and individualize the care based on behavioral observations.
- Nurses play a key role in assisting the parents and family of a newborn with special needs to cope with this crisis situation, including dealing with the possibility that the newborn may not survive. Nurses working with parents experiencing a perinatal loss can help by actively listening, understanding the parents' experiences, and communicating empathy.
- The goal of discharge planning is to make a successful transition to home care.

## KEY CONCEPTS

- Variations in birthweight and gestational age can place a newborn at risk for problems that require special care.
- Variations in birthweight include the following categories: small for gestational age, appropriate for gestational age, and large for gestational age. Newborns who are small or large for gestational age have special needs.
- The small-for-gestational-age newborn faces problems related to a decrease in placental function in utero; these problems may include perinatal asphyxia, hypothermia, hypoglycemia, polycythemia, and meconium aspiration.
- Risk factors for the birth of a large-for-gestational-age infant include maternal diabetes mellitus or glucose intolerance, multiparity, prior history of a macrosomic infant, postdates gestation, maternal obesity, male fetus, and genetics. Large-for-gestational-age newborns face problems such as birth trauma due

## MULTIPLE-CHOICE QUESTIONS

- The nurse documents that a newborn is postterm based on the understanding that he was born after:
  - 38 weeks' gestation
  - 40 weeks' gestation
  - 42 weeks' gestation
  - 44 weeks' gestation
- SGA and LGA newborns have an excessive number of red blood cells related to:
  - Hypoxia
  - Hypoglycemia
  - Hypocalcemia
  - Hypothermia
- Because subcutaneous and brown fat stores were used for survival in utero, the nurse would assess an SGA newborn for which of the following?
  - Hyperbilirubinemia
  - Hypothermia
  - Polycythemia
  - Hypoglycemia
- In assessing a preterm newborn, which of the following findings would be of greatest concern?
  - Milia over the bridge of the nose
  - Thin transparent skin
  - Poor muscle tone
  - Heart murmur
- In dealing with parents experiencing a perinatal loss, which of the following nursing interventions would be most appropriate?
  - Sheltering the parents from the bad news
  - Making all the decisions regarding care
  - Encouraging them to participate in the newborn's care
  - Leaving them by themselves to allow time to grieve
- The nurse is providing care to several newborns with variations in gestational age and birthweight. When developing the plan of care for these newborns, the nurse focuses on energy conservation to promote growth and development. Which measures would the nurse include in the nursing plans of care? Select all that apply.
  - Keeping the handling of the newborn to a minimum
  - Maintaining a neutral thermal environment
  - Decreasing environmental stimuli
  - Initiating early oral feedings
  - Using thermal warmers in all cribs
- Which of the following concepts would the nurse incorporate into the plan of care when assessing pain in a newborn with special needs?
  - Newborns experience pain primarily with surgical procedures.
  - Preterm newborns in the NICU are at least risk for pain.
  - Pain assessment needs to be comprehensive and frequent.
  - A newborn's facial expression is the primary indicator of pain.
- Evidenced-based practice refers to the use of which of the following to validate your practice?
  - Research findings
  - Written guidelines
  - Traditional practices
  - Institutional policies

## CRITICAL THINKING EXERCISES

- After fetal distress was noted on the monitor, a post-term newborn was delivered via a difficult vacuum extraction. The newborn had low Apgar scores and had to be resuscitated before being transferred to the nursery. Once admitted, the nurse observed the following behaviors: jitteriness, tremors, hypotonia, lethargy, and rapid respirations.
  - What might these behaviors indicate?
  - For what other conditions might this newborn be at high risk?
  - What intervention is needed to address this newborn's condition?
- A preterm newborn was born at 35 weeks following an abruptio placenta due to a car accident. He was transported to the NICU at a nearby regional medical center. After being stabilized, he was placed in an isolette close to the door and placed on a cardiac monitor. A short time later, the nurse notices that he is cool to the touch and lethargic, has a weak cry, and has an axillary temperature of 36°C.
  - What might have contributed to this newborn's hypothermic condition?
  - What transfer mechanism may have been a factor?
  - What intervention would be appropriate for the nurse to initiate?

3. A term SGA newborn weighing 4 pounds was brought to the nursery for admission a short time after birth. The labor and birth nurse reports the mother was a heavy smoker and a cocaine addict and experienced physical abuse throughout her pregnancy. After stabilizing the newborn and correcting the hypoglycemia with oral feedings, the nurse observes the following: acrocyanosis, ruddy color, poor circulation to the extremities, tachypnea, and irritability.
- What complication might this SGA newborn be manifesting?
  - What factors may have contributed to this complication?
  - What would be an appropriate intervention to manage this condition?

## STUDY ACTIVITIES

- At a community health department maternity clinic, secure permission to interview the parents of a special needs child. Ask about their feelings throughout the experience. How are they managing and coping now?
- Visit the March of Dimes website and review this group's national campaign to reduce the incidence of prematurity. Are their strategies workable or not? Explain your reasoning.
- A common metabolic disorder present in both SGA and LGA newborns after birth is \_\_\_\_\_.
- A 10-pound LGA newborn is brought to the nursery after a difficult vaginal birth. The nursery nurse should focus on detecting birth injuries such as \_\_\_\_\_.

#### KEY TERMS

asphyxia  
 acute bilirubin  
   encephalopathy  
 chronic bilirubin  
   encephalopathy  
 fetal alcohol  
   spectrum disorder  
   (FASD)  
 gastroschisis  
 hyperbilirubinemia  
 infant of a diabetic  
   mother (IDM)  
 kernicterus  
 meconium aspiration  
   syndrome (MAS)  
 neonatal abstinence  
   syndrome  
 neonatal sepsis  
 omphalocele  
 respiratory distress  
   syndrome (RDS)

## Nursing Management of the Newborn at Risk: Acquired and Congenital Newborn Conditions

### Learning Objectives

*After completion of the chapter, you will be able to:*

1. Define the key terms used in this chapter.
2. Distinguish the most common acquired conditions affecting the newborn.
3. Characterize the nursing management of a newborn experiencing respiratory distress syndrome.
4. Outline the birthing room preparation and procedures necessary to prevent meconium aspiration syndrome in the newborn at birth.
5. Differentiate risk factors for the development of necrotizing enterocolitis.
6. Analyze the impact of maternal diabetes on the newborn and the care needed.
7. Select the assessment and intervention for a newborn experiencing substance withdrawal after birth.
8. Develop assessment and nursing management for newborns sustaining trauma and birth injuries.
9. Outline the assessment, interventions, prevention, and management of hyperbilirubinemia in newborns.
10. Summarize the interventions appropriate for a newborn with neonatal sepsis.
11. Research four gastrointestinal system congenital anomalies that can occur in a newborn.
12. Formulate a plan of care for a newborn with an acquired or congenital condition.
13. Relate the importance of parental participation in care of the newborn with a congenital or acquired condition, including the nurse's role in facilitating parental involvement.

*Kelly, a 27-year-old G2P1, comes to the labor and birth area in active labor. She tells you she is overdue and relieved to finally be giving birth. Her membranes rupture on admission, revealing meconium-stained fluid. What additional nursing assessments need to be carried out now? What risk factors need to be considered when developing Kelly's plan of care?*

#### Words of Wisdom

Courage and faith in oneself project onto others, giving them the strength to persevere.

**Advances** in prenatal and neonatal medical and nursing care throughout the industrialized world have led to a marked increase in the number of newborns who have survived a high-risk pregnancy but experience acquired or congenital conditions. These newborns are considered at risk—that is, they are susceptible to morbidity and mortality because of the acquired or congenital disorder. One of the leading health indicators as identified by *Health People 2020* refers to decreasing the number of infant deaths. Acquired and congenital conditions account for a significant percentage of infant deaths. See *Healthy People 2020* 24.1.

Technological and pharmacologic advances, in conjunction with standardized policies and procedures, over the past several decades have significantly improved survival rates for at-risk newborns. However, morbidity remains an important sequela. For example, some of these newborns are at risk for continuing health problems that require long-term technological support. Other newborns remain at risk for physical and developmental problems into the school years and beyond. Providing the complex care needed to maintain the child's health and well-being will have a tremendous emotional and economic impact on the family. Nurses are challenged to provide support to mothers and their families when neonatal well-being is threatened.

Acquired disorders typically occur at or soon after birth. They may result from problems or conditions experienced by the woman during her pregnancy or at birth, such as diabetes, maternal infection, or substance abuse, or conditions associated with labor and birth, such as prolonged rupture of membranes or fetal distress. However, there may be no identifiable cause for the disorder.

Congenital disorders are disorders present at birth, usually due to some type of malformation that occurred during the antepartal period. Congenital disorders, which often involve a problem with inheritance, include structural anomalies (commonly referred to as

birth defects), chromosomal disorders, and inborn errors of metabolism. Most congenital disorders have a complex etiology, involving many interacting genes, gene products, and social and environmental factors during organogenesis. Some alterations can be prevented or compensated for with pharmacologic, nutritional, or other types of interventions, while others cannot be changed. Only through a better understanding of the complex interplay of genetic, environmental, social, and cultural factors can these devastating and life-changing outcomes be prevented (March of Dimes, 2011).

The field of genomics and genetic medicine has witnessed an explosion of new knowledge, much of it learned from the Human Genome Project. Advances in understanding of the genetic basis of development and function, as well as the interaction of genes and the environment, continue to foster new insights into human health. Only through increased insight into the complex interplay of genetic, environmental, social, and cultural factors can these devastating and life-changing outcomes be prevented (Gonzaga-Jauregui, Lipski, & Gibbs, 2012).

This chapter addresses selected acquired and congenital newborn conditions. In addition, it describes the nurse's role in assessment and management, emphasizing parental education and support. Nurses play a key role in helping the parents cope with the stress of having an ill newborn.

## ACQUIRED DISORDERS

### Perinatal Asphyxia

As the newborn makes the transition to life outside the fluid-filled intrauterine environment, dramatic changes must occur to facilitate newborn respirations. Newborns normally start to breathe with routine warming, drying, airway suctioning, and mild stimulation. Most newborns

## HEALTHY PEOPLE 2020 • 24-1

### Objective

Reduce the rate of fetal and infant deaths

Decrease the number of all infant deaths (within 1 year) from a baseline of 6.7/1,000 live births to 3.0/1,000 live births.

Decrease the number of neonatal deaths (within the first 28 days of life) from a baseline of 4.5 to 4.1 deaths/1,000 live births.

Decrease the number of post-neonatal deaths from a baseline of 2.2 to 2.0 deaths/1,000 live births.

Reduce the number of deaths related to all birth defects from a baseline of 1.4 to 1.3 deaths/1,000 live births.

USDHHS, 2012

### Nursing Significance

- Foster early and consistent prenatal care.
- Include education to place infants on their backs for naps and sleep to prevent sudden infant death syndrome (SIDS).
- Avoid exposing newborns to cigarette smoke.
- Ensure that infants with birth defects receive health care needed in order to thrive.

make this transition such that by 1 minute of age, they are breathing well on their own. A newborn who fails to establish adequate, sustained respiration after birth is said to have **asphyxia**. Physiologically, asphyxia can be defined as impairment in gas exchange resulting in a decrease in blood oxygen levels (hypoxemia) and an excess of carbon dioxide or hypercapnia that leads to acidosis.

Asphyxia is the most common clinical insult in the perinatal period. As many as 10% of U.S. newborns require some degree of active resuscitation to stimulate breathing with 1.5% requiring extensive resuscitation (Cunningham et al., 2010b). More than a million newborns who survive asphyxia at birth develop long-term problems such as cerebral palsy, mental retardation, speech disorders, hearing and/or visual impairment, and learning disabilities (Zanelli & Stanley, 2012).

## Pathophysiology

Asphyxia occurs when oxygen delivery is insufficient to meet metabolic demands, resulting in hypoxia, hypercarbia, and metabolic acidosis. Any condition that reduces oxygen delivery to the fetus can result in asphyxia. These conditions may include maternal hypoxia, such as from cardiac or respiratory disease, anemia, or postural hypotension; maternal vascular disease that leads to placental insufficiency, such as diabetes or hypertension; cord problems such as compression or prolapse; and post-term pregnancies, which may trigger meconium release into the amniotic fluid.

Initially, the newborn uses compensatory mechanisms including tachycardia and vasoconstriction to help bring oxygen to the vital organs for a time. However, without intervention, these mechanisms fail, leading to hypotension, bradycardia, and eventually cardiopulmonary arrest.

With failure to breathe well after birth, the newborn will develop hypoxia (too little oxygen in the cells of the body). As a result, the heart rate falls, cyanosis develops, and the newborn becomes hypotonic and unresponsive.

*Think back to Kelly, described at the beginning of the chapter. She gives birth to a son weighing approximately 2,500 g; he appears postterm and small for gestational age. His skin is stained yellow-green and he is limp, cyanotic, and apneic at birth. The initial assessment once the newborn is under the radiant warmer indicates that resuscitation and tracheal suctioning are needed. What is the nurse's role during resuscitation? What assessments will be needed during this procedure?*

## Nursing Assessment

The key to successful treatment of newborn asphyxia is early identification and recognition of newborns that may be at risk. Review the perinatal history for risk factors, including:

- Trauma: injury to the central or peripheral nervous system secondary to a long or difficult labor, a precipitous birth, multiple gestation, abnormal presentation, cephalopelvic disproportion, shoulder dystocia, or extraction by forceps or vacuum
- Intrauterine asphyxia: for example, fetal hypoxia secondary to maternal hypoxia, diabetes, hypertension, anemia, cord compression, or meconium aspiration
- Sepsis: acquired bacterial or viral organisms from infected amniotic fluid, maternal infection, or direct contact while passing through the birth canal
- Malformation: congenital anomalies including facial or upper airway deformities, renal anomalies, pulmonary hypoplasia, neuromuscular disorders, esophageal atresia, or neural tube defects
- Hypovolemic shock: secondary to abruptio placentae, placenta previa, or cord rupture resulting in blood loss to the fetus
- Medication: drugs given to mother during labor that can affect the fetus by causing placental hypoperfusion and hypotension; use of hypnotics, analgesics, anesthetics, narcotics, oxytocin, and street drugs during pregnancy (Adcock & Stark, 2011).

At birth, assess the newborn immediately. Observe the infant's color, noting any pallor or cyanosis. Assess the work of breathing. Be alert for apnea, tachypnea, gasping respirations, grunting, nasal flaring, or retractions. Evaluate heart rate and note bradycardia. Assess the newborn's temperature, noting hypothermia. Determine the Apgar score at 1 and 5 minutes; if less than 7 at 5 minutes, repeat the assessment at 10 minutes of age.

Laboratory or diagnostic testing may be used to identify etiologies for the newborn's asphyxia. For example, a chest x-ray may identify structural abnormalities that might interfere with respiration. A blood culture may identify an infectious process. A blood toxicology screen may detect any maternal drugs in the newborn (Kattwinkle, 2012).

Methods of testing to identify the fetus at risk for developing perinatal asphyxia continue to be developed and refined. The perinatal nurse needs to be knowledgeable of each test's purpose, capabilities, limitations, and clinical issues. Appropriate nursing interventions based on this knowledge facilitate the testing process and promote the goal of improved perinatal outcome.

## Nursing Management

Management of the newborn experiencing asphyxia includes immediate resuscitation. Ensure that the equipment needed for resuscitation is readily available and

in working order. Essential equipment includes a wall suction apparatus, an oxygen source, a newborn ventilation bag, endotracheal tubes (2 to 3 mm), a laryngoscope, and ampules of naloxone (Narcan) with syringes and needles for administration (see Chapter 23 for a more detailed discussion of resuscitation).

Dry the newborn quickly with a warm towel and then place him or her under a radiant heater to prevent rapid heat loss through evaporation. Handling and rubbing the newborn with a dry towel may be all that is needed to stimulate the onset of breathing. If the newborn fails to respond to stimulation, then active resuscitation is needed.

The procedure for newborn resuscitation is easily remembered by the “ABCDs”—airway, breathing, circulation, and drugs (see Chapter 23, Box 23.3). Continue resuscitation until the newborn has a pulse above 100 bpm, a good cry, or good breathing efforts and a pink tongue. This last sign indicates a good oxygen supply to the brain (Kattwinkel, 2011).

### Take Note!

According to the American Heart Association and American Academy of Pediatrics Emergency Care Guidelines for Neonatal Resuscitation, resuscitation efforts may be stopped if the newborn exhibits no detectable heart rate after 10 minutes of continuous and adequate resuscitation (Kattwinkel, 2011).

Provide continued observation and assessment of the newborn that has been successfully resuscitated. Monitor the newborn’s vital signs and oxygen saturation levels closely for changes. Maintain a neutral thermal environment to prevent hypothermia, which would increase the newborn’s metabolic and oxygen demands. Check the blood glucose level and observe for signs of hypoglycemia; if this develops, it can further stress the newborn.

The need for resuscitative measures can be extremely upsetting for the parents. Explain to them the initial resuscitation activities being performed and offer ongoing explanations about any procedures being done, equipment being used, or medications given.

Therapeutic hypothermia is a promising neuroprotective intervention for newborns with moderate to severe perinatal encephalopathy after perinatal asphyxia and has currently been incorporated in many neonatal intensive care units. However, only 1 in 6 babies with encephalopathy will benefit from hypothermia therapy; many infants still develop significant adverse outcomes. To enhance the outcome, specific diagnostic predictors are needed to identify newborns likely to benefit from hypothermia treatment (Wachtel & Hendricks-Muñoz, 2011). This treatment decision must be made a collaborative one with the parents’ full understanding of the risks involved. Nurses are in a unique position to detect

FIGURE 24.1 A father and sibling interacting with his newborn once the newborn’s condition has stabilized.

parent anxiety and to maintain therapeutic communication that may help support them through this crisis.

Provide physical and emotional support to the parents through the initial crisis and throughout the newborn’s stay. When the newborn is stable, allow parents to spend time with their newborn to promote bonding (Fig. 24.1). Point out the newborn’s positive attributes and give frequent updates on his or her status. Role-model techniques for holding, interacting with, and caring for the newborn will assist to decrease the parents’ anxiety.

Nurses need to remember developmental care practices for infants with perinatal asphyxia. A team approach incorporating developmental goals and intervention strategies into the nursing care of these infants is essential for optimal developmental outcome. Therapeutic management must always be appropriate for the infant’s health status and gestational age. An understanding of the scientific basis for intervention and the therapeutic management techniques for newborns that are sick, recuperating, or convalescing will help the nurse to promote optimal development when caring for the asphyxiated infant (Cooper, 2011).

*Remember Kelly, the young woman described at the beginning of the chapter? Her son is intubated and tracheal suctioning is performed. Positive-pressure ventilation is also started with a self-inflating bag and 50% oxygen. Ventilation is continued for 1 minute and then gradually discontinued. The heart rate is now 120 bpm, and spontaneous respirations are noted. When free-flow oxygen is administered, the newborn begins to cry and turn pink. What continued care is needed in the special care nursery? What explanation should be offered to Kelly regarding her son?*

## Transient Tachypnea of the Newborn

Transient tachypnea of the newborn (TTN) is a condition involving a mild degree of respiratory distress. It is described as the retention of lung fluid or transient pulmonary edema. It usually occurs within a few hours of birth and resolves by 72 hours of age. TTN occurs in approximately 0.5% of all live births (Yurdakok & Ozek, 2012).

Lower gestational age, cesarean birth, and male sex are independent risk factors for TTN. Performing elective cesarean sections no earlier than 38 weeks' gestation may decrease the risk of TTN. Labor before a cesarean section is not sufficient to decrease the frequency of TTN, even after 37 weeks of gestation, whereas vaginal birth appears to be protective against it (Derbent et al., 2011).

## Pathophysiology

Most newborns make the transition from fetal to newborn life without incident. During fetal life, the lungs are filled with a serous fluid because the placenta, not the lungs, is used for nutrient and gas exchange. During and after birth, this fluid must be removed and replaced with air. An infant born by cesarean birth is at risk of having excessive pulmonary fluid as a result of not having experienced all of the stages of labor. Passage through the birth canal during a vaginal birth compresses the thorax, which helps remove the majority of this fluid. Pulmonary circulation and the lymphatic drainage remove the remaining fluid shortly after birth. TTN occurs when the liquid in the lung is removed slowly or incompletely.

## Nursing Assessment

Attentively observe the newborn with respiratory distress because TTN is a diagnosis of exclusion. Initially it might be difficult to distinguish this condition from respiratory distress syndrome or group B streptococcal pneumonia, since the clinical picture is similar. However, the symptoms of transient tachypnea rarely last more than 72 hours (Subramanian, Bahri & Kicklighter, 2010).

## Health History and Physical Examination

Review the perinatal history for risk factors related to TTN such as absence of labor, cesarean birth, precipitous delivery, macrosomia, male gender, or maternal asthma (Yurdakok & Ozek, 2012).

Closely assess the newborn for signs of TTN. Within the first few hours of birth, observe for tachypnea, expiratory grunting, retractions, labored breathing, nasal flaring, and mild cyanosis. Mild to moderate respiratory distress is present by 6 hours of age, with

respiratory rates as high as 100 to 140 breaths per minute. Also inspect the newborn's chest for hyperextension or a barrel shape. Auscultate breath sounds, which may be slightly diminished secondary to reduced air entry (Jobe, 2012).

## Laboratory and Diagnostic Testing

To aid in the diagnosis, a chest x-ray may be done. It usually reveals mild symmetric lung overaeration and prominent perihilar interstitial markings and streaking. These findings correlate with lymphatic engorgement of retained fetal fluid (Jobe, 2012). In addition, an arterial blood gas (ABG) assessment is important to ascertain the degree of gas exchange and acid-base balance. It typically demonstrates mild hypoxemia, mildly elevated CO<sub>2</sub>, and a normal pH (Lee, 2012).

## Nursing Management

Management of transient tachypnea of the newborn (TTN) is supportive. As the retained lung fluid is absorbed by the infant's lymphatic system, the pulmonary status improves. Nursing management focuses on providing adequate oxygenation and determining whether the newborn's respiratory manifestations appear to be resolving or persisting. Provide supportive care while the retained lung fluid is reabsorbed. Administer intravenous (IV) fluids and/or gavage feedings until the respiratory rate decreases enough to allow safe oral feeding. Provide supplemental oxygen via a nasal cannula or oxygen hood to maintain adequate oxygen saturation. Maintain a neutral thermal environment with minimal stimulation to minimize oxygen demand.

Provide ongoing assessment of the newborn's respiratory status. As TTN resolves, the newborn's respiratory rate declines to 60 breaths per minute or less, the oxygen requirement decreases, and the chest x-ray shows resolution of the perihilar streaking. Provide reassurance and progress reports to the parents to help them cope with this crisis.

## Respiratory Distress Syndrome

Despite improved survival rates and advances in perinatal care, many high-risk newborns are at risk for respiratory problems, particularly **respiratory distress syndrome (RDS)**, a breathing disorder resulting from lung immaturity and lack of alveolar surfactant. Since the link between RDS and surfactant deficiency was discovered more than 30 years ago, tremendous strides have been made in understanding the pathophysiology and treatment of this disorder. The introduction of prenatal steroids to accelerate lung maturity and the development

of synthetic surfactant can be credited with the dramatic improvements in the outcome of newborns with RDS (Pramanik, 2012).

RDS affects an estimated 20,000 to 30,000 infants born alive in the United States annually. The incidence declines with degree of maturity at birth. It occurs in 50% of preterm newborns born at 26 to 28 weeks' gestation, and in 30% of those born at 30 to 31 weeks (Pramanik, 2012). Intensive respiratory care, usually with mechanical ventilation, is necessary.

## Pathophysiology

Lung immaturity and surfactant deficiency contribute to the development of RDS. Surfactant is a complex mixture of phospholipids and proteins that adheres to the alveolar surface of the lungs. Anatomically, the immature lung cannot support oxygenation and ventilation, because the alveolar sacs are insufficiently developed, causing a deficient surface area for gas exchange. Physiologically, the amount of surfactant is insufficient to prevent collapse of unstable alveoli. Surfactant forms a coating over the inner surface of the alveoli, reducing the surface tension and preventing alveolar collapse at the end of expiration. In the affected newborn, surfactant is deficient or lacking, and this deficit results in stiff lungs and alveoli that tend to collapse, leading to diffuse atelectasis. The work of breathing is increased because increased pressure similar to that required to initiate the first breath is needed to inflate the lungs with each successive breath. Hypoxemia and acidemia result, leading to vasoconstriction of the pulmonary vasculature. Right-to-left shunting occurs and alveolar capillary circulation is limited, further inhibiting surfactant production. As the disease progresses, fluid and fibrin leak from the pulmonary capillaries, causing hyaline membranes to form in the bronchioles, alveolar ducts, and alveoli. These membranes further decrease gas exchange. These factors decrease the total surface area of the gas exchange membrane. The end result is hypoxemia, acidemia, and a worsening respiratory distress. A vicious cycle is created, compounding the problem (Cunningham et al., 2010a; Pramanik, 2012).

## Nursing Assessment

Nursing assessment focuses on keen observation to identify the signs and symptoms of respiratory distress. In addition, assessment aids in differentiating RDS from other respiratory conditions, such as TTN or group B streptococcal pneumonia.

## History and Physical Examination

Review the history for risk factors associated with RDS. The most common risk factor for the development of RDS is premature birth. Additional risk factors particularly in

the term infant include cesarean birth in the absence of preceding labor (related to the lack of thoracic squeezing), male gender, and maternal diabetes (Cunningham et al., 2010a; Pramanik, 2012).

### Take Note!

Prolonged rupture of membranes, gestational or chronic maternal hypertension, maternal narcotic addiction, and use of prenatal corticosteroids reduce the newborn's risk for RDS because of the physiologic stress imposed on the fetus. Chronic stress experienced by the fetus in utero accelerates the production of surfactant before 35 weeks' gestation and thus reduces the incidence of RDS at birth (Pramanik, 2012).

The newborn with RDS usually demonstrates signs at birth or within a few hours of birth. Observe the infant for expiratory grunting, nasal flaring, chest wall retractions (Fig. 24.2), see-saw respirations, and generalized cyanosis. Auscultate the heart and lungs, noting tachycardia (rates above 150 to 180), fine inspiratory crackles, and tachypnea (rates above 60 breaths per minute).

The Silverman-Anderson Index is an assessment scoring system that can be used to evaluate five parameters of work of breathing as it assigns a numerical score for each parameter. Each category is scored as "0" for normal, "1" for moderate impairment, or "2" for severe impairment. Parameters assessed are retractions of the upper chest, lower chest, and xiphoid; nasal flaring; and expiratory grunt. Normally functioning infants should have a cumulative score of 0, whereas critically ill and severely depressed infants will have scores closer to 10 (Fig. 24.3).

**FIGURE 24.2** Sternal retractions are a sign of respiratory distress requiring immediate intervention, such as mechanical ventilation and other monitoring devices. Copyright Caroline Brown, RNC, MS, DEd.

	Score		
Feature observed	0	1	2
Chest movement	 Synchronized respirations	 Lag on respirations	 Seesaw respirations
Intercostal retraction	 None	 Just visible	 Marked
Xiphoid retraction	 None	 Just visible	 Marked
Nares dilation	 None	 Minimal	 Marked
Expiratory grunt	 None	 Audible by stethoscope	 Audible by unaided ear

A controlled clinical trial of effects of water mist on obstructive respiratory signs, death rate, and necropsy findings among premature infants. *Pediatrics*, 17[4], 1–9.)

### Laboratory and Diagnostic Testing

The diagnosis of RDS is based on the clinical picture and x-ray findings. A chest x-ray reveals hypoaeration, underexpansion, and a “ground glass” pattern. (Pramanik, 2012.)

### Nursing Management

If untreated, RDS will worsen. In many infants respiratory symptoms decline after 72 hours, paralleling the production of surfactant in the alveoli (Gardner, Carter, Enzman-Hines, & Hernandez, 2011). The newborn needs supportive care until surfactant is produced. Effective therapies for established RDS include conventional

mechanical ventilation, continuous positive airway pressure (CPAP), or positive end-expiratory pressure (PEEP) to prevent volume loss during expiration, and surfactant therapy. The use of exogenous surfactant replacement therapy to stabilize the newborn’s lungs until postnatal surfactant synthesis matures has become a standard of care, but not necessarily evidence-based.

Despite recent advances in the perinatal management of neonatal respiratory distress syndrome (RDS), controversies still exist. Strong evidence exists for the role of a single course of prenatal steroids in RDS prevention, but the potential benefit and long-term safety of repeated courses are unclear. Many practices involved in preterm neonatal stabilization at birth are not evidence-based, including oxygen administration

and positive-pressure lung inflation, and they may at times be harmful. Surfactant replacement therapy is crucial in the management of RDS, but the best preparation, optimal dose and timing of administration at different gestations is not always clear. Respiratory support in the form of mechanical ventilation may also be lifesaving, but can cause lung injury, and protocols should be directed at avoiding mechanical ventilation where possible by using nasal continuous positive airway pressure or nasal ventilation. For newborns with RDS to have best outcomes, it is essential that they have optimal supportive care, including maintenance of a normal body temperature, proper fluid management, good nutritional support, and support of the circulation to maintain adequate tissue perfusion (Marraro, 2012).

As recommended, care of the newborn with RDS is primarily supportive and requires a multidisciplinary approach to obtain the best outcomes. Therapy focuses on improving oxygenation and maintaining optimal lung volumes. Expect to transfer the newborn to the neonatal intensive care unit (NICU) soon after birth. Apply the basic principles of newborn care, such as thermoregulation, cardiovascular and nutritional support, normal glucose level maintenance, and infection prevention, to achieve the therapeutic goals of reducing mortality and minimizing lung trauma.

Anticipate the administration of surfactant replacement therapy, prophylactically or as a rescue approach. With prophylactic administration, surfactant is given within minutes after birth, thus providing replacement surfactant before severe RDS develops. Rescue treatment is indicated for newborns with established RDS who require mechanical ventilation and supplemental oxygen. The earlier the surfactant is administered, the better the effect on gas exchange (Pramanik, 2012).

Surfactant therapy in treating RDS has been well studied through random controlled research studies. A recent Cochran meta-analysis review showed increased survival rates, improved oxygenation and ventilation, and a decreased incidence of pneumothorax with the administration of surfactant for respiratory distress syndrome (Rojas-Reyes, Morley, & Soll, 2012).

Administer the prescribed oxygen concentration via nasal cannula. Anticipate the need for ventilator therapy, which has greatly improved in the past several years, with significant advances in conventional and high-frequency ventilation therapies (Fig. 24.4). Recent studies show no difference in outcomes for newborns who received early treatment with high-frequency oscillatory ventilation compared with those receiving conventional mechanical ventilation (Blackburn, 2012). Although mechanical ventilation has increased survival rates, it is also a contributing factor to bronchopulmonary dysplasia, pulmonary hypertension, and retinopathy of prematurity (Cunningham et al., 2010a).

**FIGURE 24.4** A newborn with RDS receiving mechanical ventilation.

In addition, support the newborn with RDS using the following interventions:

- Continuously monitor the infant's cardiopulmonary status via invasive or noninvasive means (e.g., arterial lines or auscultation, respectively).
- Monitor oxygen saturation levels continuously; assess pulse oximeter values to determine oxygen saturation levels.
- Closely monitor vital signs, acid-base status, and arterial blood gases.
- Administer broad-spectrum antibiotics if blood cultures are positive.
- Administer sodium bicarbonate or acetate as ordered to correct metabolic acidosis.
- Provide fluids and vasopressor agents as needed to prevent or treat hypotension.
- Test blood glucose levels and administer dextrose as ordered for prevention or treatment of hypoglycemia.
- Cluster caretaking activities to avoid overtaxing and compromising the newborn.
- Place the newborn in the prone position to optimize respiratory status and reduce stress.
- Perform gentle suctioning to remove secretions and maintain a patent airway.
- Assess level of consciousness to identify intraventricular hemorrhage.
- Provide sufficient calories via gavage and IV feedings.
- Maintain adequate hydration and assess for signs of fluid overload.
- Provide information to the parents about treatment modalities; give thorough but simple explanations about the rationales for interventions.
- Encourage the parents to participate in care (Blackburn, 2012).

Provide ongoing assessment and be alert for complications. These may include air leak syndrome, bronchopulmonary dysplasia (chronic lung disease), patent ductus arteriosus, congestive heart failure, intraventricular

hemorrhage, retinopathy of prematurity, necrotizing enterocolitis, complications resulting from intravenous catheter use (infection, thrombus formation), and developmental delay or disability (Kliegman, Stanton, St. Geme, Schor, & Behrman, 2011).

## Meconium Aspiration Syndrome

Meconium is a viscous green substance composed primarily of water and other gastrointestinal secretions that can be noted in the fetal gastrointestinal tract as early as 10 to 16 weeks' gestation (Clark & Clark, 2012). It is expelled as the newborn's first stool after birth. Meconium is sterile and does not contain bacteria, the primary factor that differentiates it from stool. Intrauterine distress can cause passage into the amniotic fluid. Factors that promote the passage in utero include placental insufficiency, maternal hypertension, preeclampsia, oligohydramnios, and maternal drug abuse, especially of tobacco and cocaine (Clark & Clark, 2012). It is usually expelled as the newborn's first stool after birth.

**Meconium aspiration syndrome (MAS)** occurs when the newborn inhales particulate meconium mixed with amniotic fluid into the lungs while still in utero or on taking the first breath after birth. It is a common cause of newborn respiratory distress and can lead to severe illness. Meconium staining of the amniotic fluid, with the possibility of aspiration, occurs in approximately 8% to 25% of births after 34 weeks' gestation (Clark & Clark, 2012). Aspiration induces airway obstruction, surfactant dysfunction, hypoxia, and chemical pneumonitis with inflammation of pulmonary tissues. Only 5% of infants with meconium-stained amniotic fluid actually progress to MAS (Dargaville, 2012). Severe MAS can lead to persistent pulmonary hypertension and death.

## Pathophysiology

Meconium may be passed in utero secondary to hypoxic stress. Hypoxia induces the fetus to gasp or attempt to breathe. The fetus may bear down and pass meconium into the amniotic fluid or he or she may experience a vagal reflex that causes relaxation of the anal sphincter, allowing meconium to be passed into the amniotic fluid. The fetus then sucks or swallows this amniotic fluid in utero, or the infant may aspirate meconium with the first breath after birth as air rushes into the lungs.

Although the etiology is not well understood, the effects of meconium can be harmful to the fetus. Meconium alters the amniotic fluid by reducing antibacterial activity and subsequently increasing the risk of perinatal bacterial infection. Additionally, meconium is very irritating because it contains enzymes from the fetal pancreas.

When aspirated into the lungs, meconium blocks the bronchioles, causing an inflammatory reaction as well as

a decrease in surfactant production. Gas exchange is impaired and atelectasis occurs. A ball-valve effect occurs when air is inspired into the alveoli but cannot be fully expired secondary to reduced airway diameter. Significant respiratory distress is followed by persistent pulmonary hypertension, right-to-left shunting of blood, and patent ductus arteriosus. Conventional mechanical ventilation, extracorporeal membrane oxygenation (ECMO), nitric oxide, high-frequency ventilation, or liquid ventilation may be necessary (Clark & Clark, 2012).

## Nursing Assessment

Review prenatal and birth records to identify newborns that may be at high risk for meconium aspiration. Predisposing factors for meconium aspiration syndrome include postterm pregnancy; breech presentation, forceps, or vacuum extraction births; prolonged or difficult labor associated with fetal distress in a term or postterm newborn; maternal drug abuse, especially of tobacco and cocaine; maternal infection/chorioamnionitis; maternal hypertension or diabetes; oligohydramnios; IUGR; prolapsed cord; or acute or chronic placental insufficiency (Swarnam, Soraisham, & Sivanandan, 2012).

Assess the amniotic fluid for meconium staining when the maternal membranes rupture. Green-stained amniotic fluid suggests the presence of meconium in the amniotic fluid and should be reported immediately. After birth, note any yellowish-green staining of the umbilical cord and nails and skin. This staining indicates that meconium has been present for some time.

*Consider Kelly, the 27-year-old woman who gave birth to a son who required resuscitation. What findings would lead the nurse to suspect that her son aspirated meconium? What risk factors in Kelly's history would support the diagnosis of meconium aspiration syndrome?*

### Take Note!

Standard prevention and treatment for meconium aspiration syndrome previously included suctioning the mouth and nares upon head delivery before body delivery. However, recent evidence suggests that aspiration occurs in utero, not at delivery; therefore, the infant's birth should not be impeded for suctioning. After full delivery, the infant should be handed to a neonatal team for evaluation and treatment. Although infants previously have been given intubation and airway suctioning, routine tracheal suction is recommended only for depressed infants (e.g., nonvigorous with depressed tone and respirations and/or heart rate <100 bpm) and those with respiratory symptoms. Use of orogastric suctioning to prevent MAS is not supported by evidence from any studies (Gardner et al., 2011).

Observe the newborn for a barrel-shaped chest with an increased anterior-posterior (AP) chest diameter (similar to that found in a client with chronic obstructive pulmonary disease), prolonged tachypnea, progression from mild to severe respiratory distress, intercostal retractions, end-expiratory grunting, and cyanosis (Clark & Clark, 2012). Auscultate the lungs, noting coarse crackles and rhonchi.

Chest x-rays show patchy, fluffy infiltrates unevenly distributed throughout the lungs and marked hyperaeration mixed with areas of atelectasis. Arterial blood gas analysis will indicate metabolic acidosis with a low blood pH, decreased PaO<sub>2</sub>, and increased PaCO<sub>2</sub> (Gardner et al., 2011). Direct visualization of the vocal cords for meconium staining using a laryngoscope can confirm the presence of meconium below the larynx.

## Nursing Management

Nursing management focuses on ensuring adequate tissue perfusion and minimizing oxygen demand and energy expenditure. Caring for the newborn with meconium aspiration begins in the birthing unit when the birth attendant identifies meconium-stained amniotic fluid with membrane rupture during labor. Upon delivery of the newborn's head, before the newborn takes the first breath, the nasal cavity and then the posterior pharynx are gently suctioned to decrease the potential for aspiration. If the newborn is significantly depressed at birth, secondary clearing of the lower airways by direct tracheal suctioning may be necessary. Repeated suctioning and stimulation are limited to prevent overstimulation and further depression. In pregnancies complicated by meconium-stained amniotic fluid, suctioning of the hypopharynx before the birth of the infant's shoulders and postnatal suction of vigorous infants have been used in an effort to clear the airway and decrease the incidence and the severity of MAS. Based on the results of two large randomized controlled studies, international guidelines from scientific societies for intrapartum and postpartum management of pregnancies with meconium-stained amniotic fluid have radically changed. Intrapartum suction and postnatal intubation and suction of vigorous infants are no longer recommended (Aguilar & Vain, 2011). Usually the newborn is transferred to the NICU for close monitoring.

Maintain a neutral thermal environment, including placing the newborn under a radiant warmer or in a warmed isolette, to prevent hypothermia. In addition, minimize handling to reduce energy expenditure and oxygen consumption that could lead to further hypoxemia and acidosis.

Administer oxygen therapy as ordered via nasal cannula or with positive-pressure ventilation. Monitor oxygen saturation levels via pulse oximetry to evaluate the newborn's response to treatment and to detect

changes. Increased pulmonary pressures associated with meconium aspiration may cause blood to be shunted away from the lungs. The newborn may exhibit uneven pulmonary ventilation, with hyperinflation in some areas and atelectasis in others. This leads to poor perfusion and subsequent hypoxemia, which in turn may increase pulmonary vasoconstriction, resulting in a worsening of hypoxemia and acidosis.

Expect to administer hyperoxygenation to dilate the pulmonary vasculature and close the ductus arteriosus or nitric oxide inhalation to decrease pulmonary vascular resistance, or to use high-frequency oscillatory ventilation to increase the chance of air trapping (Clark & Clark, 2012). In addition, administer vasopressors and pulmonary vasodilators as prescribed and administer surfactant as ordered to counteract inactivation by meconium. Monitor arterial blood gas results for changes and assist with measures to correct acid-base imbalances to facilitate perfusion of tissues and prevent pulmonary hypertension (Cunningham et al., 2010). If these measures are ineffective, be prepared to assist with the use of ECMO, a modified type of heart-lung machine.

In addition, perform the following interventions:

- Cluster newborn care to minimize oxygen demand.
- Prevent and treat any complications such as hypotension, metabolic acidosis, or anemia.
- Incorporate developmental care practices when applicable.
- Administer broad-spectrum antibiotics to treat bacterial pneumonia.
- Administer sedation to reduce oxygen consumption and energy expenditure.
- Continuously monitor the newborn's condition (cardiac and respiratory status, oximetry).
- Provide continuous reassurance and support to the parents throughout the experience. (Witt 2011.)

### Persistent Pulmonary Hypertension of the Newborn

Persistent pulmonary hypertension of the newborn, previously referred to as persistent fetal circulation, is a cardiopulmonary disorder characterized by marked pulmonary hypertension that causes right-to-left extrapulmonary shunting of blood and hypoxemia. Persistent pulmonary hypertension can occur idiopathically or as a complication of perinatal asphyxia, meconium aspiration syndrome, maternal smoking, maternal obesity, maternal asthma, pneumonia, congenital heart defects, metabolic disorders such as hypoglycemia, hypothermia, hypovolemia, hyperviscosity, acute hypoxia with delayed resuscitation, sepsis, and RDS. It occurs in 2 to 6 newborns per 1,000 live births of term, near-term, or postterm infants (Steinhorn, 2011).

## Pathophysiology

Normally, pulmonary artery pressure decreases when the newborn takes the first breath. However, interference with this ability to breathe allows pulmonary pressures to remain increased. Hypoxemia and acidosis also occur, leading to vasoconstriction of the pulmonary artery. These events cause an elevation in pulmonary vascular resistance. Normally, the decrease in pulmonary artery pressure and pulmonary vascular resistance with breathing leads to the closure of the ductus arteriosus and foramen ovale. However, with persistent pulmonary hypertension, pulmonary vascular resistance is elevated to the point that venous blood is diverted to some degree through fetal structures, such as the ductus arteriosus or foramen ovale, causing them to remain open, leading to a right-to-left shunting of blood into the systemic circulation. This diversion of blood bypasses the lungs, resulting in systemic arterial hypoxemia (Oishi, Datar, & Fineman, 2011).

## Nursing Assessment

Assess the newborn's status closely. A newborn with persistent pulmonary hypertension demonstrates tachypnea within 12 hours after birth. Observe for marked cyanosis, grunting, respiratory distress with tachypnea, and retractions. Auscultate the heart, noting a systolic ejection harsh sound (tricuspid insufficiency murmur), and measure blood pressure for hypotension resulting from both heart failure and persistent hypoxemia (Polin, Fox, & Abman, 2011). Measure oxygen saturation via pulse oximetry and report low values. Prepare the newborn for an echocardiogram, which will reveal right-to-left shunting of blood that confirms the diagnosis.

## Nursing Management

When caring for the newborn with persistent pulmonary hypertension, pay meticulous attention to detail, with continuous monitoring of the newborn's oxygenation and perfusion status and blood pressure. The goals of therapy include improving alveolar oxygenation, inducing metabolic alkalosis by administering sodium bicarbonate, correcting hypovolemia and hypotension with the administration of volume replacement and vasopressors, and anticipating use of ECMO when support has failed to maintain acceptable oxygenation (Steinhorn, 2011).

Provide immediate resuscitation after birth and administer oxygen therapy as ordered. Early and effective resuscitation and correction of acidosis and hypoxia are helpful in preventing persistent pulmonary hypertension. Monitor arterial blood gases frequently to evaluate the effectiveness of oxygen therapy. Provide respiratory support, which frequently necessitates the use of

mechanical ventilation. Administer prescribed medications, monitor cardiopulmonary status, cluster care to reduce stimulation, and provide ongoing support and education to the parents.

### Take Note!

Almost any procedure, such as suctioning, weighing, changing diapers, or positioning, can precipitate severe hypoxemia due to the instability of the pulmonary vasculature. Therefore, minimize the newborn's exposure to stimulation as much as possible.

## Intraventricular Hemorrhage

Intraventricular hemorrhage (IVH) is defined as bleeding that usually originates in the subependymal germinal matrix region of the brain, often extending into the ventricular system (Annibale & Hill, 2012). IVH occurs in 20% to 50% of infants with birthweight less than 1500 g and/or born at less than 35 weeks' gestation. It is uncommon in term neonates but may occur with birth trauma or asphyxia (Annibale & Hill, 2012). Complications resulting from IVH include hydrocephalus, seizure disorder, periventricular leukomalacia (an ischemic injury resulting from inadequate perfusion of the white matter adjacent to the ventricles), cerebral palsy, learning disabilities, vision or hearing deficits, and cognitive impairment (Hawkins & Zaman, 2011).

## Pathophysiology

The preterm newborn is at greatest risk for IVH because cerebral vascular development is immature, making it more vulnerable to injury. The earlier the newborn is, the greater the likelihood for brain damage. While all areas of the brain can be injured, the periventricular area is the most vulnerable (Hawkins & Zaman, 2011).

Each ventricular area contains a rich network of capillaries that are very thin, fragile, and easily ruptured. The causes of rupture vary and include fluctuations in systemic and cerebral blood flow, increases in cerebral blood flow from hypertension, IV infusions, seizure activity, increases in cerebral venous pressure due to vaginal delivery, hypoxia, and respiratory distress. With a preterm birth, the fetus is suddenly transported from a well-controlled uterine environment into a highly stimulating one. This tremendous physiologic stress and shock may contribute to the rupture of periventricular capillaries and subsequent hemorrhage. Most hemorrhages occur in the first 72 hours after birth (Annibale & Hill, 2012).

IVH is classified according to a grading system of I to V (least severe to most severe) (Polin et al., 2011). The prognosis is guarded, depending on the grade and severity of the hemorrhage. Generally, newborns with

mild hemorrhage (grades I and II) have a much better developmental outcome than those with severe hemorrhage (grades III and IV) (Blackburn, 2012).

## Nursing Assessment

The signs of intraventricular hemorrhage vary significantly and some infants may display no clinical signs. Assess for risk factors such as:

- Preterm birth
- Low birth weight
- Acidosis
- Asphyxia
- Unstable blood pressure
- Seizures
- Acute blood loss or hypovolemia
- Respiratory distress with mechanical ventilation, intubation, apnea, hypoxia, or suctioning
- Use of hyperosmolar solutions or rapid volume expansion

Evaluate the newborn for an unexplained drop in hematocrit, pallor, and poor perfusion as evidenced by respiratory distress and oxygen desaturation. Note seizures, lethargy or other changes in level of consciousness, weak suck, high-pitched cry, or hypotonia. Palpate the anterior fontanel for tenseness. Assess vital signs, noting bradycardia and hypotension. Evaluate laboratory data for changes indicating metabolic acidosis or glucose instability. Frequently a bleed can progress rapidly and result in shock and death. Prepare the newborn for cranial ultrasonography, the diagnostic tool of choice to detect hemorrhage (McCarthy, Donoghue, & Murphy, 2011).

## Nursing Management

Prevention of preterm birth is essential in preventing IVH. Identify risk factors that can lead to hemorrhage, and focus care on interventions to decrease the risk of hemorrhage. For example, institute measures to prevent perinatal asphyxia and birth trauma and provide developmental care in the NICU. If a preterm birth is expected, having the mother deliver at a tertiary care facility with a NICU would be most appropriate.

Care of the newborn with IVH is primarily supportive. Correct anemia, acidosis, and hypotension with fluids and medications. Administer fluids slowly to prevent fluctuations in blood pressure. Avoid rapid volume expansion to minimize changes in cerebral blood flow. Keep the newborn in a flexed, contained position with the head elevated to prevent or minimize fluctuations in intracranial pressure. Continuously monitor the newborn for signs of hemorrhage, such as changes in the level of consciousness, bulging fontanel, seizures, apnea, and reduced activity level. Also, measuring head circumference daily to assess for expansion in size is essential in identifying complications early.

Minimize handling of the newborn by clustering nursing care, and limit stimulation in the newborn's environment to reduce stress. Also reduce the newborn's exposure to noxious stimuli to avoid a fluctuation in blood pressure and energy expenditure. Provide adequate oxygenation to promote tissue perfusion but controlled ventilation to decrease the risk of pneumothorax (Hawkins & Zaman, 2011).

Support for the parents to cope with the diagnosis and potential long-term sequelae is essential. The long-term neurodevelopmental outcome is determined by the severity of the bleed. Provide education and emotional support for the parents throughout the newborn's stay. Discuss expectations for short-term and long-term care needs with the parents and assist them in obtaining the necessary support from appropriate community resources (Gardner et al., 2011).

## Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is a serious gastrointestinal disease occurring in newborns. It is the most common and most serious acquired gastrointestinal disorder among hospitalized preterm neonates and is associated with significant acute and chronic morbidity and mortality. NEC occurs in up to 2.4 cases per 1,000 live births, affecting as many as 40% to 50% of newborns with birth weights less than 1,000 g (Gregory, Deforge, Natale, Phillips, & Van Marter, 2011). Attempts to improve gastrointestinal function and reduce the risk of NEC include enteral antibiotics, judicious administration of parenteral fluids, human milk feedings, antenatal corticosteroids, enteral probiotics (*Lactobacillus acidophilus*), and slow continuous drip feedings (Springer & Annibale, 2012).

## Pathophysiology

The pathophysiology of NEC is not clearly understood and is thought to be multifactorial in nature. Current research points to three major pathologic mechanisms that lead to NEC: bowel hypoxic-ischemia events, perinatal stressors, an immature intestinal barrier, abnormal bacterial colonization, and formula feeding (Springer & Annibale, 2012).

During perinatal or postnatal stress, oxygen is shunted away from the gut to more important organs such as the heart and brain. Ischemia and intestinal wall damage occur, allowing bacteria to invade. High-solute feedings allow bacteria to flourish. Mucosal or transmucosal necrosis of part of the intestine occurs. Although any region of the bowel can be affected, the distal ileum and proximal colon are the regions most commonly involved. NEC usually occurs between 3 and 12 days of life, but it can occur weeks later in some newborns (Springer & Annibale, 2012). See  **Point** for links to websites that provide additional information.

## Nursing Assessment

NEC can be devastating, and astute assessment is crucial. Assessing the newborn for the development of NEC includes the health history and physical examination as well as laboratory and diagnostic testing. The onset of NEC is heralded by the development of feeding intolerance, abdominal distention, and bloody stools in a preterm infant receiving enteral feedings. As the disease worsens, the infant develops signs and symptoms of septic shock (respiratory distress, temperature instability, lethargy, hypotension, and oliguria). Nurses need to be suspicious of this condition in caring for this preterm infant.

### Health History and Physical Examination

Assess the newborn's history for risk factors associated with NEC. In addition to preterm birth, prenatal and postnatal predisposing risk factors are highlighted in Box 24.1.

Also observe the newborn for common signs and symptoms, which may include:

- Abdominal distention and tenderness
- Bloody or hemocult-positive stools
- Diarrhea
- Temperature instability

#### BOX 24.1

### PREDISPOSING FACTORS FOR THE DEVELOPMENT OF NECROTIZING ENTEROCOLITIS

#### Prerenatal Factors

- Preterm labor
- Prolonged rupture of membranes
- Preeclampsia
- Maternal sepsis
- Amnionitis
- Uterine hypoxia

#### Postnatal Factors

- Respiratory distress syndrome
- Patent ductus arteriosus
- Congenital heart disease
- Exchange transfusion
- Low birthweight
- Low Apgar scores
- Umbilical catheterization
- Hypothermia
- Gastrointestinal infection
- Hypoglycemia
- Asphyxia

- Feeding intolerance, characterized by bilious vomiting
- Signs of sepsis
- Lethargy
- Apnea
- Shock

Always keep the possibility of NEC in mind when dealing with preterm newborns, especially when enteral feedings are being administered. Note respiratory distress, cyanosis, lethargy, decreased activity level, temperature instability, feeding intolerance, diarrhea, bile-stained emesis, or grossly bloody stools. Assess blood pressure, noting hypotension. Evaluate the neonate's abdomen for distention, tenderness, and visible loops of bowel. Measure the abdominal circumference, noting an increase. Determine residual gastric volume prior to feeding; when it is elevated, be suspicious for NEC (Verklan & Walden, 2012).

### Laboratory and Diagnostic Testing

Common laboratory and diagnostic tests ordered for assessment of NEC include:

- Kidney, ureter, and bladder (KUB) of the abdomen x-ray: confirms the presence of pneumatosis intestinalis (air in the bowel wall) and persistently dilated loops of bowel
- Blood values: may demonstrate metabolic acidosis, increased white blood cells, thrombocytopenia, neutropenia, electrolyte imbalance, or disseminated intravascular coagulation (DIC) (Springer & Annibale, 2012)

## Nursing Management

Nursing management of the newborn with NEC focuses on maintaining fluid and nutritional status, providing supportive care, and teaching the family about the condition and prognosis. Therapeutic management initially consists of bowel rest and antibiotic therapy. Serial KUB x-rays and C-reactive protein levels are used to assess the resolution or progression of NEC. If medical treatment fails to stabilize the newborn or if free air is present on a left lateral decubitus film, surgical intervention will be necessary to resect the portion of necrotic bowel while preserving as much of the intestinal length as possible. Surgery for NEC usually requires the placement of a proximal enterostomy until the anastomosis site is ready for reconnection. After surgery, post-op supportive care includes fluids, TPN, antibiotics, and bowel rest for 10 to 14 days.

### Maintaining Fluid and Nutritional Status

If NEC is suspected, immediately stop enteral feedings until a diagnosis is made. Administer IV fluids initially to restore proper fluid balance. If ordered, administer total parenteral nutrition (TPN) to keep the newborn

supported nutritionally. Give prescribed IV antibiotics to prevent sepsis from the necrotic bowel (if surgery is required, antibiotics may be needed for an extended period of time). Institute gastric decompression as ordered with an orogastric tube attached to low intermittent suction. Carefully monitor intake and output. Restart enteral feedings once the disease has resolved (normal abdominal examination and KUB negative for pneumatosis) or as determined postoperatively by the surgeon.

### Providing Supportive Care

Manage pain by administering analgesics as ordered. Infection control is important, with an emphasis on careful handwashing. In addition, implement these interventions in an ongoing manner:

- Check stools for evidence of blood and report any positive findings.
- Measure the abdominal girth.
- Palpate the abdomen for tenderness and rigidity.
- Auscultate for normal bowel sounds.
- Observe the abdomen for redness or shininess, which indicates peritonitis.

### Teaching the Family

The diagnosis of NEC may cause significant family anxiety. Listen to the family's worries and fears. Answer their questions honestly. Inform the family that medically treated NEC is usually limited to a short period and resolves within 48 hours of stopping oral feedings, but surgically treated NEC can be a much lengthier process. The amount of bowel that has necrosed, as determined during the bowel resection, significantly increases the likelihood of long-term medical problems. Short bowel syndrome may result from a large resection (short bowel syndrome is discussed in Chapter 42). Reassure the family that although some infants have more involved cases of NEC, the improved parenteral nutrition formulations have improved the outcomes for these infants. Provide education about ostomy care if surgery is required (refer to page xxx for a discussion of ostomy care). Promote interaction with their newborn. Nursing actions of active engagement with parents and the sick infant (providing NICU orientation and physical care), providing cautious guidance (offering information and instruction on infant care), and their subtle presence (overseeing parent's interaction with their infant) all contribute to fostering a positive, trusting relationship with parents (Gephart & McGrath, 2012).

### Infants of Diabetic Mothers

An **infant of a diabetic mother (IDM)** is one born to a woman with pregestational or gestational diabetes (see Chapter 20 for additional information). The newborn of

a diabetic woman is at high risk for numerous health-related complications, especially hypoglycemia. Gestational diabetes mellitus (GDM) from all causes of diabetes is the most common medical complication of pregnancy and is increasing in incidence, particularly as type 2 diabetes continues to increase worldwide. Despite advances in perinatal care, IDMs remain at risk for a multitude of physiologic, metabolic, and congenital complications such as preterm birth, macrosomia, asphyxia, respiratory distress, hypoglycemia, hypocalcemia, hyperbilirubinemia, polycythemia and hyperviscosity, hypertrophic cardiomyopathy, and congenital anomalies, particularly of the central nervous system. Overt type 1 diabetes around conception produces marked risk of neural tube defects, cardiac defects, and caudal regression syndrome; later in gestation, severe and unstable type 1 maternal diabetes carries a higher risk of intrauterine growth restriction, asphyxia, and fetal death. IDMs born to mothers with type 2 diabetes are more commonly obese (macrosomic) with milder conditions of the common problems found in IDMs. IDMs from all causes of GDM also are predisposed to later-life risk of obesity, diabetes, and cardiovascular disease (Hay 2012).

### Impact of Diabetes on the Newborn

For more than a century, it has been known that diabetes during pregnancy can have severe adverse effects on fetal and newborn outcomes. Infants of diabetic mothers have increased morbidity and mortality in the perinatal period. The incidence of major congenital anomalies is much greater for these newborns than for other newborns (Potter & Kicklighter, 2011). Poor glycemic control in the first trimester, during organogenesis, is thought to be a major reason for congenital malformations. The most common types of malformations in infants of diabetic mothers involve the cardiovascular, skeletal, central nervous, gastrointestinal, and genitourinary systems. Cardiac anomalies are the most common (Gardner et al., 2011).

Infants of diabetic mothers can be large for gestational age (LGA) or small for gestational age (SGA), depending on the vascular impact of this chronic systemic disease on the mother prior to and during the pregnancy. Fetal macrosomia occurs in 25% to 42% of diabetic pregnancies because of hyperinsulinemia (Gardner et al., 2011). LGA infants (>90th percentile on growth chart) are longer and weigh more than newborns of similar gestational age. They also have increased organ weights (organomegaly) and excessive fat deposits on their shoulders and trunk, contributing to the increased overall body weight and predisposing them to shoulder dystocia. These oversized newborns frequently require cesarean births for cephalopelvic disproportion and dysfunctional labor patterns. They are frequently hypoglycemic in the first few hours after birth (Potter & Kicklighter, 2011).

SGA infants (<10th percentile on growth chart) of diabetic mothers usually suffer from intrauterine malnutrition and have few glucose reserves to tolerate the rigors of labor and birth. Uteroplacental circulation is often impaired, leading to poor growth patterns and hypoxemia.

Despite their increased or decreased size and weight, they may be remarkably frail, showing behaviors similar to those of a preterm newborn. Thus, birthweight may not be a reliable criterion of maturity. Newborns of women with diabetes but without vascular complications often tend to be LGA, whereas those of women with diabetes and vascular disease are usually SGA (Baptiste-Roberts, Nicholson, Wang, & Brancati, 2012).

## Pathophysiology

The large size of the IDM occurs secondary to exposure to high levels of maternal glucose crossing the placenta into the fetal circulation. Maternal hyperglycemia acts as a fuel to stimulate increased production of fetal insulin, which in turn promotes somatic growth within the fetus. The fetus responds to these high levels by producing more insulin, which acts as a growth factor in the fetus (Blackburn, 2012). How the fetus will be affected and the problems that the newborn experiences depend on the severity, duration, and control of the diabetes in the mother. Table 24.1 summarizes the common problems that may occur in infants of diabetic mothers.

Condition	Description	Effects
Macrosomia	Newborn with an excessive birthweight; arbitrarily defined as a birthweight >4,000 g (8 lb 13 oz) to 4,500 g (9 lb 15 oz) or >90% for gestational age Complication in 10% of all pregnancies in the United States	Increased risk for shoulder dystocia, traumatic birth injury, birth asphyxia Risks for newborn hypoglycemia and hypomagnesemia, polycythemia, and electrolyte disturbances Increased maternal risk for surgical birth, postpartum hemorrhage and infection, and birth canal lacerations Increased risk of developing type 2 diabetes later in life for both Higher weight and accumulation of fat in childhood and a higher rate of obesity in adults
Respiratory distress syndrome (RDS)	Cortisol-induced stimulation of lecithin/sphingomyelin (phospholipids) necessary for lung maturation is antagonized due to the high insulin environment within the fetus due to mother's hyperglycemia Less mature lung development than expected for gestational age Decrease in the phospholipid phosphatidylglycerol (PG), which stabilizes surfactant, compounding risk	Most commonly, breathing normally at birth but developing labored, grunting respiration with cough and a hoarse complaining cry within a few hours with chest retractions and varying degrees of cyanosis IDMs with vascular disease seldom develop RDS because the chronic stress of poor intrauterine perfusion leads to increased production of steroids, which accelerates lung maturation
Hypoglycemia	Glucose is the major source of energy for organ function Typical characteristics: <ul style="list-style-type: none"> <li>• Poor feedings</li> <li>• Jitteriness</li> <li>• Lethargy</li> <li>• High-pitched or weak cry</li> <li>• Apnea</li> <li>• Cyanosis and seizures</li> </ul> Some newborns are asymptomatic	Low blood glucose levels are problematic during early postbirth period due to abrupt cessation of high-glucose maternal blood supply and the continuation of insulin production by the newborn Limited ability to release glucagon and catecholamines, which normally stimulate glucagon breakdown and glucose release Prolonged and untreated hypoglycemia leads to serious, long-term adverse neurologic sequelae such as learning disabilities and mental retardation

(continued)

TABLE 24.1

COMMON PROBLEMS OF INFANTS OF DIABETIC MOTHERS (continued)

Condition	Description	Effects
Hypocalcemia and hypomagnesemia	Hypocalcemia (drop in calcium levels) is manifested by tremors, hypotonia, apnea, high-pitched cry, and seizures due to abrupt cessation of maternal transfer of calcium to the fetus, primarily in the third trimester and experiencing birth asphyxia Associated hypomagnesemia is directly related to the maternal level before birth About half of IDMs affected	Newborn is at risk for a prolonged delay in parathyroid hormone production and cardiac dysrhythmias
Polycythemia	Venous hematocrit of >65% in the newborn Increased oxygen consumption by IDM secondary to fetal hyperglycemia and hyperinsulinemia Increased fetal erythropoiesis secondary to intrauterine hypoxia due to placental insufficiency from maternal diabetes Hypoxic stimulation of increased red blood cell (RBC) production as compensatory mechanism	Increased viscosity, resulting in poor blood flow predisposing newborn to decreased tissue oxygenation and development of microthrombi
Hyperbilirubinemia	Usually seen within the first few days after birth, manifested by a yellow appearance of the sclera and skin Excessive red cell hemolysis necessary to break down increased RBCs in circulation due to polycythemia Resultant elevated bilirubin levels Excessive bruising secondary to birth trauma of macrosomic infants, further adding to high bilirubin levels	If untreated, high levels of unconjugated bilirubin may lead to kernicterus (neurologic syndrome that results in irreversible damage) with long-term sequelae that include cerebral palsy, sensorineural hearing loss, and mental retardation
Congenital anomalies	Occur in up to 10% of infants of diabetic mothers, accounting for 30% to 50% of perinatal deaths incidence is greatest among small-for-gestational-age newborns Overall, infants of diabetic mothers have ~3 times the usual incidence of congenital anomalies compared to newborns from the nondiabetic general population	Most common anomalies: <ul style="list-style-type: none"> <li>• Coarctation of the aorta</li> <li>• Atrial and ventricular septal defects</li> <li>• Transposition of the great vessels</li> <li>• Sacral agenesis</li> <li>• Hip and joint malformations</li> <li>• Anencephaly</li> <li>• Spina bifida</li> <li>• Caudal dysplasia</li> <li>• Hydrocephalus</li> </ul>

Sources: Blackburn (2012); Gardner, Carter, Enzman-Hines, & Hernandez (2011); Hay (2012)

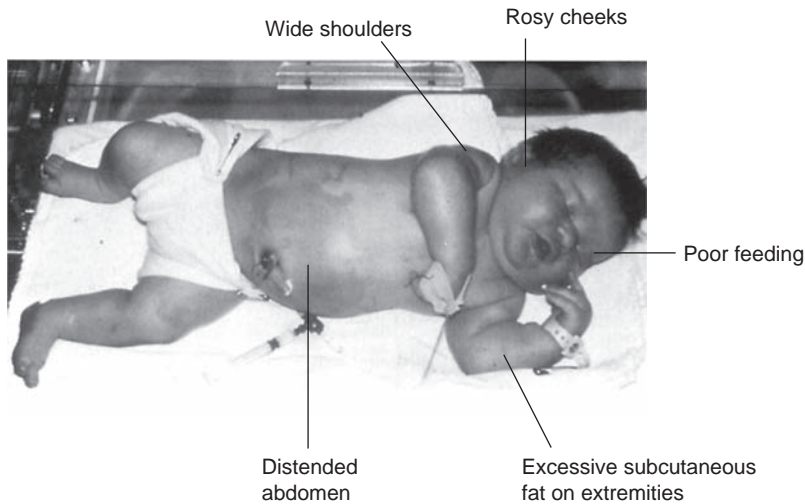

## Nursing Assessment

Assessment begins in the prenatal period by identifying women with diabetes and taking measures to control maternal glucose levels (see Chapter 20 for information on management of the pregnant woman with diabetes).

## Physical Examination

At birth, inspect the newborn for the following characteristic features. See also Fig. 24.5.

- Full rosy cheeks with a ruddy skin color
- Short neck (some describe “no-neck” appearance)
- Buffalo hump over the nape of the neck

**FIGURE 24.5** Characteristics of an infant of a diabetic mother. A macrosomic infant of a diabetic mother (IDM) has head circumference and length that are at the 90th percentile; the IDM's body weight greatly exceeds the 90th percentile. The IDM has considerable fat deposition in the shoulder and intrascapular area. (McDonald, M.G., Seshia, M. M. K., et al. [2005]. *Avery's Neonatology Pathophysiology & Management of the Newborn*, (6th ed.). Philadelphia: Lippincott Williams & Wilkins)

- Massive shoulders with a full intrascapular area
- Distended upper abdomen due to organ overgrowth
- Excessive subcutaneous fat tissue, producing fat extremities

Be alert for hypoglycemia, which may occur immediately after birth or within an hour. Assess blood glucose levels, which should remain above 40 mg/dL. Closely assess the newborn for signs of hypoglycemia, including listlessness, hypotonia, apathy, poor feeding, apneic episodes with a drop in oxygen saturation, cyanosis, temperature instability, pallor and sweating, tremors, irritability, and seizures.

Assess the newborn for signs of birth trauma involving the head (tense, bulging fontanels, cephalhematoma, skull fractures, and facial nerve paralysis), shoulders and extremities (posturing, paralysis), and skin (bruising). Inspect the newborn for compromised oxygenation by examining the skin for cyanosis, pallor, mottling, and sluggish capillary refill. Take the newborn's temperature frequently and provide a neutral thermal environment to prevent cold stress, which would increase the glucose utilization and contribute to the hypoglycemic state.

### Laboratory and Diagnostic Testing

Determine baseline serum calcium, magnesium, and bilirubin levels and monitor them frequently for changes (Table 24.2). Hypocalcemia is typically manifested in the first 2 to 3 days of life as a result of birth injury or a prolonged delay in parathyroid hormone production. Hypomagnesemia parallels calcium levels and is suspected only when hypocalcemia does not respond to calcium replacement therapy. Red blood cell breakdown leads to increased hematocrit and polycythemia. In addition, hyperbilirubinemia may be caused by slightly decreased extracellular fluid volume, hepatic immaturity, and birth trauma forming enclosed hemorrhages. It can appear within the first 24 hours of life (pathologic) or after 24 hours of life (physiologic).

## Nursing Management

The focus of care for these infants is early detection and initiation of therapy to address potential problems (Nursing Care Plan 24.1). Perform a head-to-toe physical assessment to identify congenital anomalies. Institute measures to correct hypoglycemia, hypocalcemia, hypomagnesemia, dehydration, and jaundice. Provide oxygenation and ventilatory support as necessary.

### Preventing Hypoglycemia

Prevent hypoglycemia by providing early oral feedings with formula or breast milk at frequent intervals (every 2 to 3 hours). Feedings help to control glucose levels, reduce hematocrit, and promote bilirubin excretion. Maintain a neutral thermal environment to avoid cold stress, which may stimulate the metabolic

**TABLE 24.2**

### CRITICAL LABORATORY VALUES FOR INFANTS OF DIABETIC MOTHERS

Hypoglycemia	<40 mg/dL
Hypocalcemia	<7 mg/dL
Hypomagnesemia	<1.5 mg/dL
Hyperbilirubinemia	>12 mg/dL (term infant)
Polycythemia	>65% (venous hematocrit)

## NURSING CARE PLAN 24.1

## Overview of an Infant of a Diabetic Mother

Jamie, a 38-year-old Hispanic woman, gave birth to a term large-for-gestational-age newborn weighing 10 lb. She had a history of gestational diabetes but had not received any prenatal care. She arrived at the hospital in active labor. Despite macrosomia, the newborn's Apgar scores were 8 and 9 at 1 and 5 minutes, respectively. No resuscitative measures were needed.

One hour after birth, assessment revealed a pale, irritable newborn with sweating and several episodes of apnea. A glucose level obtained at this time via a heel stick was 35 mg/dL. Two hours later, the newborn begins exhibiting signs of respiratory distress—grunting, nasal flaring, retractions, tachypnea (respiratory rate 72 breaths/minute), and tachycardia (heart rate 176 bpm).

**NURSING DIAGNOSIS:** Risk for unstable glucose level related to hypoglycemia secondary to intrauterine hyperinsulin state resulting from maternal gestational diabetes as evidenced by low blood glucose level, irritability, pallor, sweating, and apnea

## Outcome Identification and Evaluation

The newborn will exhibit adequate glucose control *as evidenced by maintaining blood glucose levels above 40 mg/dL and an absence of clinical signs of hypoglycemia.*

## Interventions: Promoting Glucose Control

- Monitor blood glucose levels hourly for the first 4 hours and then every 3 to 4 hours or as necessary *to detect hypoglycemia, which would be <40 mg/dL.*
- Continue to observe for manifestations of hypoglycemia, such as pallor, tremors, jitteriness, lethargy, and poor feeding, *to allow for early detection and prompt intervention, thereby minimizing the risk of complications associated with hypoglycemia.*
- Monitor temperature frequently and institute measures to maintain a neutral thermal environment *to prevent cold stress, which would increase metabolic demands and further deplete glycogen stores.*
- Initiate early feedings every 2 to 3 hours or as appropriate or administer glucose supplements as ordered *to prevent hypoglycemia caused by the newborn's hyperinsulin state.* Administer IV glucose infusions as ordered *to correct hypoglycemia if glucose levels do not stabilize with feeding.*
- Cluster infant care activities and provide for rest periods *to conserve the newborn's energy and reduce use of glucose and glycogen stores.*
- Reduce environmental stimuli by dimming lights and speaking softly *to reduce energy demands and further utilization of glucose.*
- Explain all events and procedures to the mother *to help alleviate anxiety and promote understanding of the newborn's condition.*

**NURSING DIAGNOSIS:** Impaired gas exchange related to respiratory distress secondary to delayed lung maturity resulting from inhibition of pulmonary surfactant production due to fetal hyperinsulinemia as evidenced by grunting, nasal flaring, retractions, tachypnea, and tachycardia

## Outcome Identification and Evaluation

Newborn will demonstrate signs of adequate oxygenation without respiratory distress *as evidenced by respiratory rate and vital signs within acceptable parameters, absence of nasal flaring, retractions, and grunting, and oxygen saturation and arterial blood gas levels within acceptable parameters.*

## NURSING CARE PLAN 24.1

**Overview of an Infant of a Diabetic Mother** (continued)**Interventions: Promoting Oxygenation**

- Monitor newborn's vital signs *to establish a baseline and evaluate for changes.*
- Assess airway patency and perform gentle suctioning as ordered *to ensure patency and allow for adequate oxygen intake.*
- Position the newborn prone *to optimize respiratory status and reduce stress.*
- Assess lung sounds for changes *to allow early detection of change in status.*
- Continuously monitor oxygen saturation levels via pulse oximetry *to determine adequacy of tissue perfusion.*
- Assess arterial blood gas results *to detect changes indicating acidosis, hypoxemia, or hypercarbia, which would suggest hypoxia.* Administer medications as ordered *to correct acidosis.*
- Administer oxygen as ordered *to promote adequate tissue perfusion.*
- Assess newborn's skin to identify cyanosis, pallor, and mottling *to detect changes indicating compromised oxygenation.*
- Administer surfactant replacement therapy as ordered *to aid in stabilizing the newborn's lungs until postnatal surfactant synthesis improves.*
- Institute measures to maintain normal blood glucose levels and a neutral thermal environment, cluster care activities, and reduce excessive stimuli *to reduce oxygen demand and consumption.*

rate, thereby increasing the demand for glucose. Provide rest periods to decrease energy demand and expenditure.

Monitor blood glucose levels via heel stick every hour for the first 4 hours of life and then every 3 to 4 hours until stable. Document the results. Report unstable glucose values if oral feedings do not maintain and stabilize the newborn's blood glucose levels. If glucose levels are not stabilized, initiate IV glucose infusions as ordered and monitor that the infusions are flowing at the prescribed rate.

**Maintaining Fluid and Electrolyte Balance**

Monitor serum calcium levels for changes indicating the need for supplementation, such as with oral or IV calcium gluconate. Assess the newborn for signs of hypocalcemia, such as tremors, jitteriness, twitching, seizures, and high-pitched cry.

Also administer fluid therapy as ordered to maintain adequate hydration. Monitor serum bilirubin levels and institute phototherapy if the newborn is over 24 hours old.

**Providing Parental Support**

Assist the parents and family in understanding the newborn's condition and need for frequent monitoring. Offer support and information to the parents and family. They may erroneously interpret the newborn's large size as an indication that the newborn is free of

problems. Encourage open communication and listen with empathy to the family's fears and concerns. Provide frequent opportunities for the parents to interact with their newborn. Make appropriate referrals to social services and community resources as necessary to help the family cope.

**Birth Trauma**

Injuries to the newborn from the forces of labor and birth are categorized as birth trauma. In the past, numerous injuries were associated with difficult births requiring external or internal version or mid- or high forceps deliveries. Today, however, cesarean births have contributed to the decline in birth trauma. Damage occurs to the tissues and organs of the newborn caused by mechanical forces during childbirth often accompanied by impaired blood circulation and organ functioning. The most frequent and significant birth injuries are to the skull, brain, and spinal cord (Simpson, 2011).

Significant birth trauma accounts for fewer than 2% of neonatal deaths and stillbirths in the United States (Simpson, 2011). They estimate that birth trauma in the United States occurs in approximately 29 per 1,000 births with the three most frequently diagnosed birth trauma conditions being injuries to the scalp, injuries to the skeleton, and fracture of the clavicle (Gardner et al. 2011). Improved prenatal diagnosis and monitoring during labor have helped to reduce the incidence of birth injuries today.

## Pathophysiology

The process of birth is a blend of compression, contractions, torques, and traction. When fetal size, presentation, or neurologic immunity complicates this process, the forces of labor and birth may lead to tissue damage, edema, hemorrhages, or fractures in the newborn. For

example, birth trauma may result from the pressure of birth, especially in a prolonged or abrupt labor, abnormal or difficult presentation, cephalopelvic disproportion, or mechanical forces, such as forceps or vacuum used during delivery. Table 24.3 summarizes the most common types of birth trauma.

TABLE 24.3

COMMON TYPES OF BIRTH TRAUMA

Type	Description	Findings	Treatment
Fractures	<p>Most often occur during breech births or shoulder dystocia in newborns with macrosomia</p> <p>Midclavicular fractures are the most common type of fracture, secondary to shoulder dystocia</p> <p>Long bone fractures of the humerus or femur, usually midshaft, also can occur</p>	<p>Midclavicular fractures: The newborn is irritable and does not move the arm on the affected side either spontaneously or when the Moro reflex is elicited</p> <p>Femoral or humeral long bone fractures: The newborn shows loss of spontaneous leg or arm motion, respectively; usually swelling and pain accompany the limited movement</p> <p>X-rays confirm the fracture</p>	<p>Midclavicular fractures typically heal rapidly and uneventfully; arm motion may be limited by pinning the newborn's sleeve to the shirt</p> <p>Femoral and humeral shaft fractures are treated with splinting. Healing and complete recovery are expected within 2 to 4 weeks without incident</p> <p>Explanation to the parents and reassurance are needed</p>
Brachial plexus injury	<p>Primarily in large babies, babies with shoulder dystocia, or breech delivery</p> <p>Results from stretching, hemorrhage within a nerve, or tearing of the nerve or the roots associated with cervical cord injury</p> <p>Associated traumatic injuries include fracture of the clavicle or humerus or subluxations of the shoulder or cervical spine</p> <p>Erb's palsy is an upper brachial plexus injury</p> <p>Klumpke's palsy is an injury to the lower brachial plexus (lower brachial injuries are less common)</p>	<p>In Erb's palsy, the involved extremity usually presents adducted, prone, and internally rotated; shoulder movement is absent; Moro, bicep, and radial reflexes are absent, but the grasp reflex is usually present</p> <p>Klumpke's palsy is manifested by weakness in the hand and wrist; grasp reflex is absent</p>	<p>Erb's palsy usually involves immobilization of the upper arm across the upper abdomen/chest to protect the shoulder from excessive motion for the first week; then gentle passive range-of-motion exercises are performed daily to prevent contractures. There is usually no associated sensory loss, and this condition usually improves rapidly</p> <p>Treatment for Klumpke's palsy involves placing the hand in a neutral position and using passive range-of-motion exercises</p> <p>In some cases deficits may persist, requiring continuing observation</p>
Cranial nerve trauma	<p>Most common is facial nerve palsy</p> <p>Frequently attributed to pressure resulting from forceps</p> <p>May also result from pressure on the nerve in utero, related to fetal positioning such as the head lying against the shoulder</p>	<p>Physical findings include asymmetry of the face when crying; mouth may be drawn toward the unaffected side; wrinkles are deeper on the unaffected side</p> <p>The paralyzed side may be smooth, with a swollen appearance. Eye is persistently open on the affected side</p>	<p>Most infants begin to recover in the first week, but full resolution may take up to several months; parents need reassurance about this</p> <p>In most cases, treatment is not necessary, only observation</p> <p>If the eye is affected and unable to close, protection with patches and synthetic tears may be necessary</p> <p>Parents need instruction about how to feed the newborn, since he or she cannot close the lips around the nipple without having milk seep out</p>

TABLE 24.3

COMMON TYPES OF BIRTH TRAUMA (continued)

Type	Description	Findings	Treatment
Head trauma	<p>Mild trauma can cause soft tissue injuries such as cephalhematoma and caput succedaneum; greater trauma can cause depressed skull fractures</p> <p><b>Cephalhematoma</b> (subperiosteal collection of blood secondary to the rupture of blood vessels between the skull and periosteum) occurs in 2.5% of all births and typically appears within hours after birth</p> <p><b>Caput succedaneum</b> (soft tissue swelling) is caused by edema of the head against the dilating cervix during the birth process</p> <p>Subarachnoid hemorrhage (one of the most common types of intracranial trauma) may be due to hypoxia/ischemia, variations in blood pressure, and the pressure exerted on the head during labor. Bleeding is of venous origin, and underlying contusions also may occur</p> <p>Subdural hemorrhage (hematomas) occurs less often today because of improved obstetric techniques. Typically, tears of the major veins or venous sinuses overlying the cerebral hemispheres or cerebellum (most common in newborns of primiparas and large newborns, or after an instrumented birth) are the cause. Increased pressure on the blood vessels inside the skull leads to tears</p> <p>Depressed skull fractures (rare) may result from the pressure of a forceps delivery; can also occur during spontaneous or cesarean births and may be associated with other head trauma causing subdural bleeding, subarachnoid hemorrhage, or brain trauma</p>	<p>In cephalhematoma, suture lines delineate its extent; usually located on one side, over the parietal bone</p> <p>In caput succedaneum, swelling is not limited by suture lines: it extends across the midline and is associated with head molding. It does not usually cause complications other than a misshapen head. Swelling is maximal at birth and then rapidly decreases in size</p> <p>In subarachnoid hemorrhage, some RBCs may appear in the CSF of full-term newborns. Newborns may present with apnea, seizures, lethargy, or abnormal findings on a neurologic examination</p> <p>Subdural hemorrhage can be asymptomatic, or the neonate can exhibit seizures, enlarging head size, decreased level of consciousness, or abnormal findings on a neurologic examination, with hypotonia, a poor Moro reflex, or extensive retinal hemorrhages</p> <p>Depressed skull fractures can be observed and palpated as depressions. Confirmation by x-ray is necessary</p>	<p>Cephalhematoma resolves gradually over 2–3 weeks without treatment</p> <p>Caput succedaneum usually resolves over the first few days without treatment</p> <p>Subarachnoid hemorrhage requires minimal handling to reduce stress</p> <p>Subdural hematoma requires aspiration; can be lifethreatening if it is in an inaccessible location and cannot be aspirated</p> <p>Depressed skull fractures typically require a neurosurgical consultation</p>

## Nursing Assessment

Recognition of trauma and birth injuries is imperative so that early treatment can be initiated. Review the labor and birth history for risk factors, such as a prolonged or abrupt labor, abnormal or difficult presentation, cephalopelvic disproportion, or mechanical forces, such as forceps or vacuum used during delivery. Also review

the history for multiple fetus deliveries, large-for-date infants, extreme prematurity, large fetal head, or newborns with congenital anomalies.

Complete a careful physical and neurologic assessment of every newborn admitted to the nursery to establish whether injuries exist. Inspect the head for lumps, bumps, or bruises. Note if swelling or bruising crosses the suture line. Assess the eyes and face for facial paralysis,

observing for asymmetry of the face with crying or appearance of the mouth being drawn to the unaffected side. Ensure that the newborn spontaneously moves all extremities. Note any absence of or decrease in deep tendon reflexes or abnormal positioning of extremities.

Assess and document symmetry of structure and function. Be prepared to assist with scheduling diagnostic studies to confirm trauma or injuries, which will be important in determining treatment modalities.

## Nursing Management

Nursing management is primarily supportive and focuses on assessing for resolution of the trauma or any associated complications along with providing support and education to the parents. Provide the parents with explanations and reassurance that these injuries usually resolve with minimal or no treatment. Parents are alarmed when their newborn is unable to move an extremity or demonstrates asymmetric facial movements. Provide parents with a realistic picture of the situation to gain their understanding and trust. Be readily available to answer questions and teach them how to care for the newborn, including any modifications that might be necessary. Allow parents adequate time to understand the implications of the birth trauma or injury and what treatment modalities are needed, if any. Provide them with information about the length of time until the injury will resolve and when and if they need to seek further medical attention for the condition. Spending time with the parents and providing them with support, information, and teaching are important to allow them to make decisions and care for their newborn. Anticipate the need for community referral for ongoing follow-up and care, if necessary.

### Newborns of Substance-Abusing Mothers

It is generally assumed that all pregnant women want to provide a healthy environment for their unborn child and know how to avoid harm. However, for women who use substances such as drugs or alcohol, this may not be the case. Perinatal substance abuse is a significant public health issue particularly affecting children, with high rates of reported abuse, neglect, and foster care placement. Substance use during pregnancy exposes the fetus to the possibility of IUGR, prematurity, neurobehavioral and neurophysiologic dysfunction, birth defects, infections, and long-term developmental sequelae (Wong, Ordean, & Kahan, 2011). Infants of mothers who abuse substances are more likely to suffer substantiated harm, enter foster care, and have more negative child protection outcomes. The effects of fetal alcohol syndrome and spectrum disorders are well documented in the literature; studies attest to developmental delays, intellectual disabilities, attention disorders, and psychopathologies during the child's lifetime (Wang, 2012).

The full extent of the effects of prenatal drug exposure on a child is not known. However studies show that various drugs of abuse may result in premature birth, miscarriage, low birthweight, and a variety of behavioral and cognitive problems.

It is difficult to establish the true prevalence of substance use in pregnant women; many women deny taking any nonprescribed substance because of the associated social stigma and legal implications. The National Institute on Drug Abuse (NIDA) suggests that over 15% of women use alcohol or illicit drugs thus exposing their fetuses to their effects (NIDA, 2011). Drug exposure may go unrecognized in these newborns, and they may be discharged from the newborn nursery at risk for medical and social problems, including abuse and neglect.

Tobacco, alcohol, and marijuana are the substances most commonly abused during pregnancy. Other drugs may include opioids such as morphine, codeine, methadone, meperidine, and heroin; CNS stimulants such as amphetamines and cocaine; CNS depressants such as barbiturates, diazepam (Valium), and sedative-hypnotics; and hallucinogens such as LSD, inhalants, glue, paint thinner, nail polish remover, and nitrous oxide (NIDA, 2011). Table 24.4 highlights commonly used substances and their effects on the fetus and newborn.

### Consider This

I admit, I had led a reckless life since I was a teen. I rebelled against my mother's authority and started smoking and doing drugs just to "check out" of my painful world. It was one big blast after another with a high and then a low. I never considered the consequences of my behavior then and never thought it would hurt anyone until I learned I was about 4 months pregnant. I convinced myself that if I cut back, everything would be fine.

Now, as I stand here in the NICU watching my tiny son struggle for air and tremble all over, I am not so convinced that I didn't hurt anyone except myself. As I witness my son fight against MY nicotine and drug addiction, my heart is heavy with guilt. I wonder how I could have thought that my troubles wouldn't become another's plight sooner or later. What must I have been thinking to isolate my addiction and not consider the impact that it would have on my mother and my son?

Thoughts: This woman honestly regrets what her addiction has done to her son as she stands watching him go through withdrawal. Her lifestyle choices do affect others, despite her previous denial. One problem with addiction is the difficulty in getting help after deciding to finally quit. There aren't enough rehab centers to deal with the large numbers needing their services and it can be difficult to get into one. What can be offered to pregnant women who abuse substances? How can nurses increase community awareness about the impact of this problem, especially during pregnancy?

**TABLE 24.4** SUBSTANCES AND THEIR EFFECTS ON THE FETUS AND NEWBORN

Substance	Description	Effects on Fetus and Newborn	Nursing Implications
Alcohol	Consumption is pervasive and widely accepted, with use, abuse, and addiction affecting all levels of society It is a common misconception that a substance sold to the public without restriction is safe	Fetal alcohol syndrome (one of the most common known causes of mental retardation) Fetal alcohol spectrum disorders Alcohol-related birth defects	Provide education that decreasing or eliminating alcohol consumption during pregnancy is the only way to prevent fetal alcohol syndrome and fetal alcohol effects Assist pregnant woman in finding a treatment program if possible Inform all women who are pregnant or planning to become pregnant about the detrimental effects of alcohol during pregnancy Educate women using a nonjudgmental, culturally connected approach Warn women that there is no safe time to drink or amount of alcohol they can consume
Tobacco/ nicotine	Nicotine is an addictive substance. It causes epinephrine release from the adrenal cortex, leading to initial stimulation followed by depression and fatigue, causing the user to seek more nicotine Increased numbers of women are smoking (at least 11% smoke during pregnancy) Over 2,500 chemicals are found in cigarette smoke, including nicotine, tar, carbon monoxide, and cyanide. It is unknown which are harmful, but nicotine and carbon monoxide are believed to play a role in causing adverse pregnancy outcomes	Impaired oxygenation of mother and fetus due to nicotine crossing placenta and carbon monoxide combining with hemoglobin Increased risk for low birth-weight (risk almost doubled), small for gestational age, and preterm birth Increased risk for sudden infant death syndrome (SIDS) and chronic respiratory illness	Provide teaching to women about healthy behaviors Provide support for smoking cessation Individualize counseling based on factors associated with the woman's smoking and challenges faced (why woman smokes, stressors in life, and social support network) Suggest options such as group smoking cessation programs, relaxation techniques, individual counseling, hypnosis, and partner-support counseling
Marijuana	Most widely used illicit psychoactive substance in Western world and most commonly used illicit drug in the United States Derived from <i>Cannabis sativa</i> plant	Not shown to have teratogenic effects on fetus; no consistent types of malformations identified Intrauterine growth restriction (IUGR) is common due to delivery of carbon monoxide to fetus Increased risk for small for gestational age Altered responses to visual stimuli, sleep-pattern abnormalities, photophobia, lack of motor control, hyperirritability, increased tremulousness, and high-pitched cry noted in infants of mothers who smoked marijuana Research related to long-term effects is continuing	Provide teaching to women about healthy behaviors Provide support for cessation of marijuana use

(continued)

TABLE 24.4

## SUBSTANCES AND THEIR EFFECTS ON THE FETUS AND NEWBORN (continued)

Substance	Description	Effects on Fetus and Newborn	Nursing Implications
Methamphetamines	<p>Addictive stimulant; use releases high levels of dopamine, which stimulates brain cells, enhancing mood and body movement</p> <p>High potential for abuse and addiction; can be inhaled, injected, smoked, or taken orally</p> <p>Many street names, such as speed, meth, ice, and chalk</p> <p>Primary effects include accelerated heart and respiratory rate, elevated blood pressure, pupillary dilation; secondary effects include loss of appetite</p> <p>Used medically as treatment for obesity and narcolepsy in adults and hyperactivity in children</p>	<p>Little research on use during pregnancy because its use is less common than cocaine or narcotics</p> <p>Fetal effects similar to cocaine (suggesting vasoconstriction as possible underlying mechanism)</p> <p>Possible maternal malnutrition, leading to problems with fetal growth and development</p> <p>Increased risk for preterm birth and low-birthweight newborns</p> <p>Infants may have withdrawal symptoms, including dysphoria, agitation, jitteriness, poor weight gain, abnormal sleep patterns, poor feeding, frantic fist sucking, high-pitched cry, respiratory distress soon after birth, frequent infections, and significant lassitude</p> <p>Long-term effects not known</p>	<p>Provide teaching to women about healthy behaviors</p> <p>Provide support for cessation of methamphetamine use</p> <p>Monitor the woman for weight changes; emphasize the need for adequate nutritional intake to support fetal growth and development</p>
Cocaine	<p>Strong CNS stimulant that interferes with reabsorption of dopamine</p> <p>Physical effects: vasoconstriction; pupillary dilation; increased temperature, heart rate, and blood pressure</p> <p>Taken orally, sublingually, intranasally, intravenously, and via inhalation</p> <p>Estimated that 30 to 40% of cocaine addicts are female</p> <p>Maternal cocaine use during pregnancy is a significant health problem</p> <p>Increased potential for use of multiple drugs if mother using cocaine</p>	<p>Preterm birth and lower birthweight</p> <p>Unclear impact on later development</p> <p>Speculation that cocaine interferes with infant's cognitive development, leading to learning and memory difficulties later in life</p> <p>Associated congenital anomalies: GU, cardiac, and CNS defects, and prune belly syndrome</p> <p>Other typical newborn characteristics: smaller head circumference, piercing cry, limb defects, ambiguous genitalia, poor feeding, poor visual and auditory responses, poor sleep patterns, decreased impulse control, stiff, hyperextended positioning, irritability and hypersensitivity, inability to respond to caretaker</p>	<p>Educate the woman about the effects of cocaine use on the fetus and newborn</p> <p>Assess for use of other substances</p> <p>Provide teaching to women about healthy behaviors</p> <p>Provide support and guidance for cessation of cocaine and other substance use</p>

Substance abuse during pregnancy is the subject of much controversy. The timing of drug ingestion usually determines the type and severity of damage to the fetus. Frequently, the woman uses more than one substance, which

compounds the problem. Nurses must be knowledgeable about the issues of substance abuse and must be alert for opportunities to identify, prevent, manage, and educate women and families about this key public health issue.

**TABLE 24.4** SUBSTANCES AND THEIR EFFECTS ON THE FETUS AND NEWBORN (continued)

Substance	Description	Effects on Fetus and Newborn	Nursing Implications
Heroin	<p>Illegal, highly addictive opiate derived from morphine that can be sniffed, smoked, or injected</p> <p>Possible consequences include HIV infection, tuberculosis, crime, violence, and family disruption</p> <p>Severe physical addiction; CNS depressant producing mental dullness and drowsiness</p>	<p>Newborns of heroin-addicted mothers are born dependent on heroin</p> <p>Increased risk for transmission of hepatitis B and C and HIV to newborns when mothers share needles</p> <p>Significantly increased rates of stillbirth, IUGR, preterm birth, and newborn mortality (3 to 7 times greater)</p> <p>Small-for-gestational-age newborns, meconium aspiration, high incidence of SIDS, and delayed effects from subacute withdrawal (restlessness, continual crying, agitation, sneezing, vomiting, fever, diarrhea, seizures, irritability, and poor socialization [possibly persisting for 4 to 6 months]);</p> <p>Intrauterine death or preterm birth is possible with abrupt cessation of heroin use</p>	<p>Educate the woman about the effects of heroin use on the fetus and newborn</p> <p>Assess for use of other substances</p> <p>Provide teaching to women about healthy behaviors</p> <p>Warn the woman not to abruptly stop heroin use. Encourage her to enroll in a methadone maintenance program</p>
Methadone	<p>Synthetic opiate narcotic used primarily as maintenance therapy for heroin addiction</p>	<p>Improvement in many of the detrimental fetal effects associated with heroin use</p> <p>Withdrawal symptoms are common in newborns.</p> <p>Possible low birthweight due to symmetric fetal growth restriction</p> <p>Increased severity and longer period of withdrawal (due to methadone's longer half-life)</p> <p>Seizures (commonly severe) do not usually occur until 2 to 3 weeks of age, when the newborn is at home.</p> <p>Increased rate of SIDS (3 to 4 times higher);</p>	<p>Methadone maintenance programs are the standard of care for women with narcotic addiction</p> <p>Inform the woman about the benefits and risks of methadone use versus heroin use. Advantages include improved fetal and newborn growth, reduced risk of fetal death, and reduced risk of HIV infections</p> <p>Advise the woman that she will need to return consistently to receive the prescribed methadone dose</p> <p>Reinforce the need for continued prenatal care</p> <p>Inform the woman that she can breast-feed her newborn while receiving methadone</p> <p>Teach mother and caregivers about signs and symptoms of methadone withdrawal</p>

Sources: Blackburn (2012); March of Dimes (2008a, 2008b, 2010, 2011); NIDA (2010a, 2010b, 2010c, 2010d, 2011).

## Fetal Alcohol Spectrum Disorders (FASDs)

Years ago, alcohol was not commonly recognized as a teratogen, an agent that can disrupt the development

of a fetus. Today, we understand that prenatal alcohol exposure induces a variety of adverse effects on physical, neurologic, and behavioral development. Alcohol now is recognized as the leading preventable cause of birth defects and developmental disorders in the United

States Substance Abuse & Mental Health Services Administration [SAMHSA] (2012). The adverse effects of alcohol consumption have been recognized for centuries, but the associated pattern of fetal anomalies was not labeled until the early 1970s. The distinctive pattern identified three specific findings: growth restriction (prenatal and postnatal), craniofacial structural anomalies, and CNS dysfunction. These distinctive findings were called **fetal alcohol syndrome (FAS)**, characterized by physical and mental disorders that appear at birth and remain problematic throughout the child's life. However, there are also circumstances in which the effects of prenatal alcohol exposure are apparent, but the newborn does not meet all of the criteria specific to FAS. Other disorders included in the grouping **fetal alcohol spectrum disorders (FASDs)** are alcohol-related neurodevelopmental disorder (ARND) and alcohol-related birth defects (ARBD). Children with ARND primarily display intellectual disabilities related to behavior and learning while children with ARBD may have birth defects of the heart, kidneys, and/or bones. The problems associated with any of the FASDs are lifelong and are entirely preventable by avoiding alcohol consumption during pregnancy (Centers for Disease Control and Prevention [CDC], 2011). Box 24.2 summarizes the manifestations of fetal alcohol syndrome.

In the United States, about 40,000 babies are born each year with FASDs (March of Dimes, 2008a). Current estimates indicate that approximately 1 in 8 women drinks during pregnancy (CDC, 2011) while 1 in 30 admit to binge drinking (March of Dimes, 2008a). Heavy drinking and binge drinking place the fetus at highest risk (March of Dimes, 2008a).

### HEALTHY PEOPLE 2020 • 24-2

#### Objective

Reduce the occurrence of fetal alcohol syndrome (FAS)

#### Nursing Significance

Counsel girls and women to avoid alcohol use during pregnancy. Participate in programs for at-risk groups, including adolescents, about the effects of substance abuse, especially alcohol, during pregnancy

Source: USDHHS, 2012

Decreasing or eliminating alcohol consumption during pregnancy is the only way to prevent fetal alcohol syndrome and fetal alcohol effects. Unfortunately, few treatment programs address the needs of pregnant women; so many newborns are exposed to alcohol in utero.

### BOX 24.2

#### CLINICAL PICTURE OF FETAL ALCOHOL SYNDROME

- Microcephaly (head circumference <10th percentile)\*
- Small palpebral (eyelid) fissures\*
- Abnormally small eyes
- Intrauterine growth restriction
- Maxillary hypoplasia (flattened or absent)
- Epicanthal folds (folds of skin of the upper eyelid over the eye)
- Thin upper lip\*
- Missing vertical groove in median portion of upper lip\*
- Short upturned nose
- Short birth length and low birthweight
- Joint and limb defects
- Altered palmar crease pattern
- Prenatal or postnatal growth  $\leq$ 10th percentile\*
- Congenital cardiac defects (septal defects)
- Delayed fine and gross motor development
- Poor eye–hand coordination
- Clinically significant brain abnormalities\*
- Mental retardation
- Narrow forehead
- Performance substantially below expected level in cognitive or developmental functioning, executive or motor functioning, and attention or hyperactivity; social or language skills\*
- Inadequate sucking reflex and poor appetite

\*Diagnosis of fetal alcohol syndrome requires the presence of three findings:

1. Documentation of all three facial abnormalities
2. Documentation of growth deficits (height, weight, or both <10th percentile)
3. Documentation of CNS abnormalities (structural, neurologic, or functional)

Sources: CDC (2011b); SAMHSA (2012); Thomas & Hamdan (2012)

## Neonatal Abstinence Syndrome

Newborns of women who abuse tobacco, illicit substances, caffeine, and alcohol can exhibit withdrawal behavior. Withdrawal symptoms occur in 60% of all newborns exposed to drugs (Jansson & Velez, 2012). Drug dependency acquired in utero is manifested by a constellation of neurologic and physical behaviors and is known as **neonatal abstinence syndrome**. Although often treated as a single entity, neonatal abstinence syndrome is not a single pathologic condition.

The manifestations of withdrawal are a function of the drug's half-life, the specific drug or combination of drugs used, dosage, route of administration, timing of drug exposure, and length of drug exposure (Bio, Siu, & Poon, 2011). Typical newborn behaviors include CNS hypersensitivity, autonomic dysfunction, respiratory distress, temperature instability, hypoglycemia, tremors, seizures, abnormal cry patterns, feeding difficulties, and gastrointestinal disturbances (Gardner et al., 2011). Neonatal abstinence syndrome has both medical and developmental consequences for the newborn.

## Nursing Assessment

A comprehensive prenatal medical and drug history, especially with respect to polydrug use, is vital. Fear of referral to child welfare agencies or the legal system has prompted women to conceal their drug abuse history. Frequently, the first inkling of drug use appears in the newborn when symptoms of withdrawal begin within 72 hours after birth. Typically the infant has been discharged by this time, unless the nurse has a high degree of suspicion that would prompt toxicology testing earlier. Several assessment tools can be used to assess a drug-exposed newborn. Figure 24.6 shows an example. Regardless of the tool used for assessment, address these key areas:

- Maternal history to identify risk behaviors for substance abuse:
  - Previous unexplained fetal demise
  - Lack of prenatal care
  - Incarceration
  - Prostitution
  - Mental health disorders
  - History of intimate partner violence
  - History of missed prenatal appointments
  - Severe mood swings
  - Precipitous labor
  - Poor nutritional status
  - Abruptio placentae
  - Hypertensive episodes
  - History of drug abuse
- Laboratory test results (toxicology) to identify substances in mother and newborn
- Signs of neonatal abstinence syndrome (Use the WITHDRAWAL acronym; see Box 24.3.)
- Evidence of seizure activity and need for protective environment

The newborn's behavior often prompts the health care provider or nurse to suspect intrauterine drug exposure. The newborn physical examination may also reveal low birthweight for gestational age or drug- or

alcohol-related birth defects and dysfunction. Assess the newborn for signs of neonatal abstinence syndrome (Box 24.4).

### Take Note!

Cocaine-exposed newborns are typically fussy, irritable, and inconsolable at times. Cocaine-exposed infants demonstrate poor coordination of sucking and swallowing, making feeding time frustrating for the newborn and caregiver alike.

Assist with obtaining diagnostic studies to identify the severity of withdrawal. Toxicology screening of the newborn's blood, urine, and meconium identifies the substances to which the newborn has been exposed. Urine drug screening identifies only recent substance exposure, whereas meconium samples may reveal exposure from the second trimester to the present (Hamdan, 2012). Take care to avoid contamination of meconium with urine, as this may affect the accuracy of the sample.

## Nursing Management

The needs of the substance-exposed newborn are multiple, complex, and costly, both to the health care system and to society. Substance abuse takes place among people of all colors, sizes, shapes, incomes, types, and conditions. Most pregnant women are unaware of the adverse impact their substance abuse can have on the newborn.

Nurses are in a unique position to help because they interact with high-risk mothers and newborns in many settings, including the community, health care facilities, and family agencies. It is the responsibility of all nurses to identify, educate, counsel, and refer pregnant women with substance-abusing problems. For example, nurses can be instrumental in increasing the number of pregnant women who make a serious attempt to quit smoking by using the "5 A's" approach:

- **Ask:** Ask all women if they smoke and would like to quit.
- **Advise:** Encourage the use of clinically proven treatment plans.
- **Assess:** Provide motivation by discussing the "5 R's":
  - **Relevance** of quitting to the woman
  - **Risk** of continued smoking to the fetus
  - **Rewards** of quitting for both
  - **Roadblocks** to quitting
  - **Repeat** at every visit
- **Assist:** Help the woman to protect her fetus and newborn from the negative effects of smoking.
- **Arrange:** Schedule follow-up visits to reinforce the woman's commitment to quit.

CENTRAL NERVOUS SYSTEM DISTURBANCES													
SIGNS AND SYMPTOMS	SCORE	AM									PM		
Excessive high-pitched cry	2												
Continuous high-pitched cry	3												
Sleeps <1 hour after feeding	3												
Sleeps <2 hours after feeding	2												
Sleeps <3 hours after feeding	1												
Hyperactive Moro reflex	2												
Markedly hyperactive Moro reflex	3												
Mild tremors disturbed	1												
Moderate–severe tremors disturbed	2												
Mild tremors undisturbed	1												
Moderate–severe tremors undisturbed	4												
Increased muscle tone	2												
Excoloration (specify area)	1												
Myoclonic jerks	3												
Generalized convulsions	5												
METABOLIC / VASOMOTOR/RESPIRATORY DISTURBANCES													
Sweating													
Fever <101 (99–100.8°F/37.2–38.2°C )	1												
Fever >101 (38.2°C and higher)	2												
Frequent yawning (>3–4 times/interval)	1												
Mottling	1

## BOX 24.3

**WITHDRAWAL ACRONYM**

Assess the newborn for signs of neonatal abstinence syndrome using the acronym WITHDRAWAL to focus the assessment:

- W** = **W**akefulness: sleep duration less than 3 hours after feeding
- I** = **I**rritability
- T** = **T**emperature variation, tachycardia, tremors
- H** = **H**yperactivity, high-pitched persistent cry, hyperreflexia, hypertonus
- D** = **D**iarrhea, diaphoresis, disorganized suck
- R** = **R**espiratory distress, rub marks, rhinorrhea
- A** = **A**pneic attacks, autonomic dysfunction
- W** = **W**eight loss or failure to gain weight
- A** = **A**lkalosis (respiratory)
- L** = **L**acrimation (Hamdan, 2012)

Although this approach is geared to smoking cessation, nurses can adapt it to focus on cessation for any substance use. Early, supportive, ongoing nursing care is critical to the well-being of the mother and her newborn.

Caring for a substance-exposed newborn remains a major challenge to health care professionals. The major goals include providing comfort to the newborn by relieving symptoms, improving feeding and weight gain, preventing seizures, promoting mother–newborn interactions, and reducing the incidence of newborn mortality and abnormal development (Hudak & Tan, 2012).

**Promoting Comfort**

Keep environmental stimuli to a minimum. For example, decrease stimuli by dimming the lights in the nursery, and swaddle the newborn tightly to decrease irritability behaviors. Other techniques such as gentle rocking,

## BOX 24.4

**MANIFESTATIONS OF NEONATAL ABSTINENCE SYNDROME****CNS Dysfunction**

- Tremors
- Generalized seizures
- Hyperactive reflexes
- Restlessness
- Hypertonic muscle tone, constant movement
- Shriill, high-pitched cry
- Disturbed sleep patterns

**Metabolic, Vasomotor, and Respiratory Disturbances**

- Fever
- Frequent yawning
- Mottling of the skin
- Sweating
- Frequent sneezing
- Nasal flaring
- Tachypnea >60 bpm
- Apnea

**Gastrointestinal Dysfunction**

- Poor feeding
- Frantic sucking or rooting
- Loose or watery stools
- Regurgitation or projectile vomiting

Sources: Hamdan (2012); Hudak & Tan (2012); Jansson & Velez (2012).

using a flexed position, and offering a pacifier can help manage CNS irritability. A pacifier also helps satisfy the newborn's need for nonnutritive sucking. Swaddling, pacifiers, low lighting, oscillating cribs, and avoidance of abrupt changes in the infant's environment can be helpful. Use a calm, gentle approach when handling the newborn and plan activities to avoid overstimulating the newborn, allowing time for rest periods.

### Meeting Nutritional Needs

When feeding the newborn, use small amounts and position the newborn upright to prevent aspiration and to facilitate rhythmic sucking and swallowing. Frequent small feedings are preferable and should provide 150 to 250 kcal/kg per 24 hours for proper growth of the infant undergoing significant withdrawal (Gardner et al., 2011).

Breast-feeding is encouraged unless the mother is still using drugs. Monitor the newborn's weight daily to evaluate the success of food intake. Assess hydration; check skin turgor and fontanelles. Assess the frequency and characteristics of bowel movements and monitor the newborn's fluid and electrolyte and acid-base status.

### Preventing Complications

Pharmacologic treatment is warranted if conservative measures, such as swaddling and decreased environmental stimulation, are not adequate. The AAP recommends that for newborns with confirmed drug exposure, drug therapy is indicated if the newborn has seizures, diarrhea and vomiting resulting in excessive weight loss and dehydration, poor feeding, inability to sleep, and fever unrelated to infection (AAP Committee on Drugs, 2012). Common medications used in the management of newborn withdrawal include an opioid (morphine or methadone) and phenobarbital as a second drug if the opiate does not adequately control symptoms (Hudak & Tan, 2012). Administer the prescribed medications and document the newborn's behavioral responses.

The newborn is at risk for skin breakdown. Weight loss, diarrhea, dehydration, and irritability can contribute to this risk. Provide meticulous skin care and protect the newborn's elbows and knees against friction and abrasions.

### Promoting Parent–Newborn Interaction

For a mother who abuses substances, the birth of a drug-exposed newborn is both a crisis and an opportunity. The mother may feel guilty about the newborn's condition. Many of these newborns are unresponsive and have disorganized sleeping and feeding patterns. When awake, they can be easily overstimulated and irritated. Such characteristics make parent–newborn interactions

difficult and frustrating, leading to possible detachment and avoidance. Nursing support, which includes a description of symptoms and their management, is vital if maternal–infant attachment is to occur and potential neglect or abuse is avoided (Gardner et al., 2011). Instruct the mother or caretaker how to care for the newborn, including what to do after the newborn goes home (Teaching Guidelines 24.1).

#### Teaching Guidelines 24.1

#### CARING FOR YOUR NEWBORN AT HOME

- Position your newborn with the head elevated to prevent choking.
- To aid your newborn's sucking and swallowing during feeding, position the chin downward and support it with your hand.
- Place your newborn on his or her back to sleep or nap, never on the stomach.
- Keep a bulb syringe close by to suction your newborn's mouth in case of choking.
- Cluster newborn care (bathing, feeding, dressing) to prevent overstimulation.
- If your newborn is fussy or crying, try these measures to help calm him or her:
  - Wrap your newborn snugly in a blanket and gently rock in rocking chair.
  - Take the baby for a ride in the car (using a newborn car seat).
  - Play soothing music and “dance” with the newborn.
  - Use a wind-up swing with music.
- To help your newborn get to sleep, try these measures:
  - Schedule a bath with a gentle massage prior to bedtime.
  - Change diaper and clothes to make the baby comfortable.
  - Feed the baby just prior to bedtime.
  - If the newborn cries when put in crib and all needs are met, allow him or her to cry.
  - Use a rocking chair to feed and sing a soft lullaby.
- Call your primary care provider if you observe withdrawal behaviors such as:
  - Slight tremors (shaking) of hands and legs
  - Stiff posture when held in your arms
  - Irritability and frequent fussiness
  - High-pitched cry, excessive sucking motions
  - Erratic sleep pattern
  - Frequent yawning, nasal stuffiness, sweating
  - Prolonged time needed to feed
  - Frequent vomiting after feeding

On the other hand, the newborn may be a powerful motivator for the mother to undergo treatment and seek recovery. Refer the mother to community agencies to address addiction and the infant's developmental needs (Gilbert, 2011). The nurse can play a pivotal role in assisting her to abstain from drug use and to promote effective parenting skills.

## Hyperbilirubinemia

**Hyperbilirubinemia** is a total serum bilirubin level above 5 mg/dL resulting from unconjugated bilirubin being deposited in the skin and mucous membranes (Blackburn, 2012). Hyperbilirubinemia is exhibited as jaundice (yellowing of the body tissues and fluids). Newborn jaundice is one of the most common reasons for hospital readmission. It occurs in 60% to 80% of term newborns in the first week of life and in virtually all preterm newborns (Lissauer & Fanaroff, 2011).

## Pathophysiology

Newborn jaundice results from an imbalance in the rate of bilirubin production and bilirubin elimination. This imbalance determines the pattern and degree of newborn hyperbilirubinemia (Blackburn, 2012).

During the newborn period, a rapid transition from the intrauterine to the extrauterine pattern of bilirubin physiology occurs. Fetal unconjugated bilirubin is normally cleared by the placenta and the mother's liver in utero, so total bilirubin at birth is low. After the umbilical cord is cut, the newborn must conjugate bilirubin (convert a lipid-soluble pigment into a water-soluble pigment) in the liver on his or her own. The rate and amount of bilirubin conjugation depend on the rate of red blood cell breakdown, the bilirubin load, the maturity of the liver, and the number of albumin-binding sites. Bilirubin levels rise in newborns by three main mechanisms: increased production (accelerated RBC breakdown), decreased removal (transient liver enzyme insufficiency), and increased reabsorption (delay in bowel excretion) (Gardner et al., 2011). Bilirubin production increases after birth mainly because of a shortened red blood cell lifespan (70 days in the newborn versus 90 days in the adult) combined with an increased red blood cell mass. Therefore, the amount of bilirubin the newborn must deal with is large compared to that of an adult.

Bilirubin has two forms—unconjugated or indirect, which is fat-soluble and toxic to body tissues, and conjugated or direct, which is water-soluble and nontoxic. Elevated serum bilirubin levels are manifested as jaundice in the newborn. Typically the total serum bilirubin level rises over the first 3 to 5 days and then declines.

## Physiologic Jaundice

Physiologic jaundice is an unconjugated hyperbilirubinemia that occurs after the first postnatal day and can last up to 1 week. Total serum bilirubin concentrations peak in the first 3 to 5 postnatal days and decline to adult values over the next several weeks.

It occurs in 60% of term infants and up to 80% of preterm infants (Blackburn, 2012). Serum bilirubin levels reach up to 10 mg/dL and then decline rapidly over the first week after birth (Cunningham et al., 2010). Most newborns have been discharged by the time this jaundice peaks (at about 72 hours).

Physiologic jaundice may result from an increased bilirubin load because of relative polycythemia, a shortened red blood cell lifespan, immature hepatic uptake and conjugation process, and increased enterohepatic circulation (Lauer & Spector, 2011). Newborns with delayed passage of meconium are more likely to develop physiologic jaundice because meconium contains high levels of bilirubin (Blackburn, 2012).

Physiologic jaundice differs between breast-fed and bottle-fed newborns in relation to the onset of symptoms. Breast-fed newborns typically have peak bilirubin levels on the fourth day of life; levels for bottle-fed newborns usually peak on the third day of life. The rate of bilirubin decline is less rapid in breast-fed newborns compared to bottle-fed newborns because bottle-fed newborns tend to have more frequent bowel movements. Jaundice associated with breast-feeding presents in two distinct patterns: early-onset breast-feeding jaundice and late-onset breast milk jaundice.

### EARLY-ONSET BREAST-FEEDING JAUNDICE

Early-onset breast-feeding jaundice is probably associated with ineffective breast-feeding practices because of relative caloric deprivation in the first few days of life. Decreased volume and frequency of feedings may result in mild dehydration and the delayed passage of meconium. This delayed defecation allows enterohepatic circulation reuptake of bilirubin and an increase in the serum level of unconjugated bilirubin. To prevent this, strategies to promote early effective breast-feeding are important. The AAP guidelines recommend early and frequent breast-feeding without supplemental water or dextrose-water because they do not prevent hyperbilirubinemia and may lead to hyponatremia (AAP, 2012). Early frequent feedings can provide the newborn with adequate calories and fluid volume (via colostrum) to stimulate peristalsis and passage of meconium to eliminate bilirubin. Successful breast-feeding decreases the risk of hyperbilirubinemia. Infants need to be fed at least 8 to 12 times in the first few days after birth to help improve the mother's milk supply. The best way to judge successful breastfeeding is to monitor infant urine

output, stool output, and weight. Newborns should have four to six wet diapers and three to four yellow, seedy stools per day by the fourth day after birth. Breastfed infants should lose no more than 10% of their body weight by the third or fourth postnatal day (AAP, 2012).

### LATE-ONSET BREAST-FEEDING JAUNDICE

Late-onset breast-feeding jaundice occurs later in the newborn period, with the bilirubin level usually peaking in the first 6 to 14 days of life. Total serum bilirubin levels may be 12 to 20 mg/dL, but the levels are not considered pathologic (Soldi, Tonetto, Varalda, & Bertino, 2011). The specific cause of late-onset breast milk jaundice is not entirely understood, but it may be related to a change in the milk composition resulting in enhanced enterohepatic circulation. Additional research is needed to determine the cause. Interrupting breast-feeding is not recommended unless bilirubin levels reach dangerous levels; if this occurs, breast-feeding is stopped for only 1 or 2 days. Substituting formula during this short break usually results in a prompt decline of bilirubin levels.

### Pathologic Jaundice

Pathologic jaundice is manifested within the first 24 hours of life when total bilirubin levels increase by more than 5 mg/dL/day and the total serum bilirubin level is higher than 17 mg/dL in a full-term infant (Mukherjee & Ozden, 2012). Conditions that alter the production, transport, uptake, metabolism, excretion, or reabsorption of bilirubin can cause pathologic jaundice in the newborn. A few conditions that contribute to red blood cell breakdown and thus higher bilirubin levels include polycythemia, blood incompatibilities, and systemic acidosis. These altered conditions can lead to high levels of unconjugated bilirubin, possibly reaching toxic levels and resulting in a severe condition called *kernicterus*.

Hyperbilirubinemia is a great concern because of the potential for brain injury. The spectrum of bilirubin-induced neurologic dysfunction ranges from acute

bilirubin encephalopathy to the devastating and irreversible chronic bilirubin encephalopathy or kernicterus.

**Acute bilirubin encephalopathy** describes the effects of hyperbilirubinemia in the first weeks of life. Clinical signs include lethargy, poor feeding, poor tone, a poor Moro reflex with incomplete flexion of the extremities, and a high-pitched cry. As symptoms of acute bilirubin encephalopathy worsen, the newborn progresses to apnea, seizures, coma, and death (Gardner et al., 2011).

**Chronic bilirubin encephalopathy** or **kernicterus** is characterized by four clinical manifestations: movement disorder (athetosis, dystonia, spasticity, hypotonia), auditory dysfunction (deafness), oculomotor impairment, and dental enamel hypoplasia of deciduous teeth (Dijk & Hulzebos, 2012). Unconjugated bilirubin enters the brain and acts as a neurotoxin causing long-term neurologic sequelae.

The most common condition associated with pathologic jaundice is hemolytic disease of the newborn secondary to incompatibility of blood groups of the mother and the newborn. The most frequent conditions are Rh factor and ABO incompatibilities.

#### Take Note!

Significant jaundice in the newborn less than 24 hours of age should be immediately reported to the physician, as it may indicate a pathologic process.

### RH ISOIMMUNIZATION

Rh incompatibility or isoimmunization develops when an Rh-negative woman who has experienced Rh isoimmunization subsequently becomes pregnant with an Rh-positive fetus. The maternal antibodies cross the placenta into the fetal circulation and begin to break down the red blood cells (Fig. 24.7). Destruction of the fetal red blood cells leads to fetal anemia and hemolytic disease of the newborn. The severity of the fetal hemolytic process depends on the level and effectiveness of anti-D

**FIGURE 24.7** Rh isoimmunization. **(A)** The Rh-negative mother is exposed to Rh-positive antigens from the fetus. **(B)** Maternal antibodies form against the Rh-positive antigens from the fetus. **(C)** Maternal antibodies are transferred to the fetus that destroys the fetal red blood cells.

antibodies and the capacity of the fetal system to remove antibody-coated cells.

Intrauterine transfusions with Rh-negative, type O blood may be lifesaving if done in time. The widespread administration of Rh immune globulin (RhoGAM), combined with aggressive fetal surveillance and transfusion, has reduced the incidence of hemolytic disease of the newborn if the Rh isoimmunization process has not yet occurred. Phototherapy is the standard treatment in moderately severe hemolytic disease of newborn, whereas exchange transfusion is the second line in progressive cases. Intravenous immunoglobulin (IVIG) has been suggested to decrease the need for exchange transfusion, but research has not validated this therapy (Elalfy, Elbarbary, & Abaza, 2011).

Immune hydrops, also called hydrops fetalis, is a severe form of hemolytic disease of the newborn that occurs when pathologic changes develop in the organs of the fetus secondary to severe anemia. Hydrops fetalis results from fetal hypoxia, anemia, congestive heart failure, and hypoproteinemia secondary to hepatic dysfunction. ABO and Rh incompatibilities can both cause hydrops fetalis, but Rh disease is the more common cause. Typically, hydrops is not observed until the hemoglobin drops below approximately 4 g/dL (hematocrit <15%) (Salem & Singer, 2012). Fetuses with hydrops may die in utero from profound anemia and circulatory failure. The placenta is very enlarged and edematous. One sign of severe anemia and impending death is the sinusoidal fetal heart rate pattern (Cunningham et al., 2010).

### ABO INCOMPATIBILITY

ABO incompatibility is an immune reaction that occurs when the mother has type O blood and the fetus has type A, B, or AB blood. Although it occurs more frequently than Rh incompatibilities, it causes less severe problems and rarely results in hemolytic disease severe enough to be clinically diagnosed and treated. Enlargement of the spleen and liver may be found in newborns with ABO incompatibility, but hydrops fetalis is rare (Rubarth, 2011). Because the antibodies resulting in ABO incompatibility occur naturally, it is impossible to eliminate this type of incompatibility because blood types vary by both nationality and race. The U.S. population as a whole is 44% type O, 42% type A, 10% type B, and 4% type AB. Blood type B is more common in Asian populations whereas blood types A and O are the more common ones for Native Americans (Rubarth, 2011).

Women with type O blood develop anti-A or anti-B antibodies throughout their life through foods they eat and exposure to infections. Most species of anti-A and anti-B antibodies are immunoglobulin M (IgM), which cannot cross the placenta and thus cannot gain access to the fetal red blood cells. Some anti-A and anti-B antibodies from the mother may cross the placenta to the fetus

during the first pregnancy and can cause hemolysis of fetal blood cells.

## Nursing Assessment

Neonatal jaundice first becomes visible in the face and forehead. Identification is aided by pressure on the skin, since blanching reveals the underlying color. Jaundice then gradually becomes visible on the trunk and extremities. This cephalocaudal progression is well described. Jaundice disappears in the opposite direction. Nurses play an important role in early detection and identification of jaundice in the newborn. Keen observation skills are essential.

### Health History and Physical Examination

Review the medical record for factors that might predispose the newborn to hyperbilirubinemia, such as:

- Polycythemia
- Significant bruising or cephalhematoma, which increases bilirubin production
- Infections such as TORCH (toxoplasmosis, hepatitis B, rubella, cytomegalovirus, herpes simplex virus)
- Use of drugs during labor and birth such as diazepam (Valium) or oxytocin (Pitocin)
- Prematurity
- Gestational age of 34 to 36 weeks
- Hemolysis due to ABO incompatibility or Rh isoimmunization
- Macrosomic infant of a diabetic mother
- Delayed cord clamping, which increases the erythrocyte volume
- Decreased albumin binding sites to transport unconjugated bilirubin to the liver because of acidosis
- Delayed meconium passage, which increases the amount of bilirubin that returns to the unconjugated state and can be absorbed by the intestinal mucosa
- Siblings who had significant jaundice
- Inadequate breastfeeding leading to dehydration, decreased caloric intake, weight loss, and delayed passage of meconium
- Ethnicity, such as Asian American, Mediterranean, or Native American
- Male gender (Stevenson, Vreman, & Wong, 2011)

Perform a complete physical examination. Assess the skin, mucous membranes, sclerae, and bodily fluids (tears, urine) for a yellow color. Detect jaundice by observing the infant in a well-lit room and blanching the skin with digital pressure over a bony prominence. Typically, jaundice begins on the head and gradually progresses to the abdomen and extremities. Also inspect for pallor (anemia), excessive bruising (bleeding), and dehydration (sluggish circulation), which may contribute to the development of jaundice and the risk for kernicterus.

Assess the newborn for Rh incompatibility. Be alert for clinical manifestations such as ascites, congestive heart failure, edema, pallor, jaundice, hepatosplenomegaly, hydramnios, thick placenta, and dilation of the umbilical vein (Blackburn, 2012).

The hydropic newborn appears pale, edematous, and limp at birth and typically requires resuscitation. The newborn with immune hydrops exhibits severe generalized edema, organ hypertrophy and enlargement, and effusion of fluid into body cavities.

### Laboratory and Diagnostic Testing

Determine maternal and fetal blood types, checking for incompatibilities (Comparison Chart 24.1). Assess laboratory values for bilirubin (both unconjugated and conjugated). Bilirubin levels establish the diagnosis of hyperbilirubinemia. The newborn with Rh incompatibility demonstrates a rapidly rising unconjugated bilirubin level at birth or in the first 24 hours. Also expect to obtain alkaline phosphatase, liver enzymes, and prothrombin time and partial thromboplastin time, as well as the following:

- Direct Coombs test—to identify hemolytic disease of the newborn; positive results indicate that the newborn's red blood cells have been coated with antibodies and thus are sensitized
- Hemoglobin concentration—for evidence of anemia
- Blood type—to determine Rh status and any incompatibility of the newborn
- Total serum protein—to detect reduced binding capacity of albumin
- Reticulocyte count—to identify an elevated level indicating increased hemolysis

Assist with obtaining blood specimens. Use cord blood for hemoglobin concentration measurements; use a heel stick for direct Coombs testing and bilirubin levels. Prepare the parents and newborn for radiologic

evaluation if necessary to determine abnormalities that may be causing the jaundice.

### Nursing Management

Nursing management of a newborn with hyperbilirubinemia requires a comprehensive approach. As members of the health care team, nurses share in the responsibility for early detection and identification, family education, management, and follow-up of the mother and newborn. Documentation of the timing of onset of jaundice is essential to differentiate between physiologic (>24 hours) and pathologic jaundice (<24 hours). Nurses can improve care by offering their presence and support and by following the AAP guidelines for preventing hyperbilirubinemia:

- Promote and support successful breast-feeding
- Establish nursery protocols for identifying jaundice, including when a serum bilirubin can be ordered by a nurse
- Measure total serum bilirubin on jaundiced infants in the first 24 hours
- Interpret all bilirubin levels according to the infant's age in hours
- Visual estimation of jaundice is inaccurate and shouldn't be used instead of labs
- Infants <38 weeks, particularly if breast-fed, should be considered high risk
- Perform risk assessment on all newborns prior to discharge
- Jaundiced newborns should be treated, if indicated, with phototherapy
- Provide parents with written and oral information about jaundice at discharge
- Follow-up care and referrals should be based on time of discharge and risk
- Empower parents to make appropriate decisions once home (Simmons, 2011)

#### COMPARISON CHART 24.1

#### Rh VERSUS ABO INCOMPATIBILITY

Clinical Picture	Rh Incompatibility	ABO Incompatibility
First-born	Rare	Common
Later pregnancies	More severe	No increase in severity
Jaundice	Moderate to severe	Mild
Hydrops fetalis	Frequent	Rare
Anemia	Frequently severe	Rare
Ascites	Frequent	Rare
Hepatosplenomegaly	Frequent	Common

## Reducing Bilirubin Levels

Encourage early initiation of feedings to prevent hypoglycemia and provide protein to maintain the albumin levels to transport bilirubin to the liver. Ensure newborn feedings (breast milk or formula) every 2 to 3 hours to promote prompt emptying of bilirubin from the bowel. Encourage the mother to breast-feed (8 to 12 feedings per day) to prevent inadequate intake and thus dehydration. Supplement breast milk with formula to supply protein if bilirubin levels continue to increase with breast-feeding only. Monitor serum bilirubin levels frequently to reduce the risk of severe hyperbilirubinemia.

### PHOTOTHERAPY

For the newborn with jaundice, regardless of its etiology, phototherapy is used to convert unconjugated bilirubin to the less toxic water-soluble form that can be excreted. Phototherapy, via special lights placed above the newborn or a fiber-optic blanket placed under the newborn and wrapped around him or her, involves blue wavelengths of light to alter unconjugated bilirubin in the skin. For the newborn receiving phototherapy, place the newborn under the lights or on the fiber-optic blanket, exposing as much skin as possible. Cover the newborn's genitals and shield the eyes to protect these areas from becoming irritated or burned when using direct lights. Assess the intensity of the light source to prevent burns and excoriation (Fig. 24.8). Turn the newborn every 2 hours to maximize the area of exposure, removing the newborn from the lights only for feedings. Maintain a neutral thermal environment to decrease energy expenditure, and assess the newborn's neurologic status frequently.

Assess the newborn's temperature every 3 to 4 hours as indicated. Monitor fluid intake and output closely and assess daily weights for gains or losses. Check skin turgor for evidence of dehydration.

FIGURE 24.8 A newborn receiving phototherapy.

With feedings, remove the newborn from the lights and remove the eye shields to allow interaction with the newborn. Encourage breast or bottle feedings every 2 to 3 hours. Follow agency policy about removing the eye shields periodically to assess the eyes for discharge or corneal irritation secondary to eye shield pressure. Typically, the eyes are assessed and eye shields removed once a shift.

Monitor stool for consistency and frequency. Unconjugated bilirubin excreted in the feces will produce a greenish appearance, and typically stools are loose. Lack of frequent green stools is a cause for concern.

Provide meticulous skin care. Assess skin surfaces frequently for dryness and irritation secondary to the dehydrating effects of phototherapy and irritation from highly acidic stool to prevent excoriation and skin breakdown (Bhutani, 2011). Nursing responsibilities include ensuring effective irradiance delivery, maximizing skin exposure, providing eye protection and eye care, careful attention to thermoregulation, monitoring the newborn's skin turgor, maintaining adequate hydration, promoting elimination, and supporting parent–infant interaction (Stokowski, 2011).

A summary of the nursing care for the newborn undergoing phototherapy is as follows:

- Support parents, encouraging them to interact with their infant.
- Support breastfeeding with one-on-one instruction and patience.
- Place infants on their back to expose as much naked skin as possible.
- Provide eye care/protection every time the infant is exposed to the light.
- Check temperature and environment around infant to prevent overheating.
- Take daily weights to make sure the infant isn't becoming dehydrated.

### EXCHANGE TRANSFUSION

If the total serum bilirubin level remains elevated after intensive phototherapy, an exchange transfusion with albumin administered before the transfusion, the quickest method for lowering serum bilirubin levels, may be necessary (Simmons, 2011). In the presence of hemolytic disease, severe anemia, or a rapid rise in the total serum bilirubin level, an exchange transfusion is recommended. An exchange transfusion removes the newborn's blood and replaces it with nonhemolyzed red blood cells from a donor. During the transfusion, monitor the newborn's cardiovascular status continuously because serious complications can arise, such as acid-base imbalances, infection, hypovolemia, and fluid and electrolyte imbalances. Exchange transfusion is used only as a second-line therapy after phototherapy has failed to yield results. Intensive nursing care is needed.

Assist the physician with an exchange transfusion if necessary. Monitor the newborn's status closely for changes, especially in vital signs and heart rate and rhythm, before, during, and after the procedure.

### Providing Parent Teaching and Support

Nurses can help the parents to understand the diagnostic tests and treatment modalities by offering individualized teaching. Nurses are the ones who give discharge instructions to the family. Explore with the family their understanding of jaundice and treatment modalities to reduce anxiety and gain their cooperation in monitoring the infant. Teach the parents about jaundice and its potential risk using written and verbal material. Also show the parents how to identify newborn behaviors that might indicate rising bilirubin levels. Emphasize the need to seek treatment from their pediatrician should any of the following occur:

- Lethargy, sleepiness, poor muscle tone, floppiness
- Poor sucking, lack of interest in feeding
- High-pitched cry

Teach the parents how to assess their newborn for signs of jaundice because physiologic jaundice may not occur until after the newborn is discharged. After discharge is planned, parent education plays an important role in hyperbilirubinemia prevention, ensuring that the health care provider is contacted if concerning signs arise prior to the scheduled visit and also ensuring that the infant arrives at the scheduled visit. Frequency of breastfeeding, frequency of voiding and stooling, progression of jaundice, and signs of illness can all be monitored by the engaged parent and shared with the provider. Reinforce the need for appropriate follow-up with the primary care provider within 48 to 72 hours after discharge to assess jaundice status (Burgos, Flaherman, & Newman, 2012).

The need for phototherapy can be anxiety-producing for the parents. Explain the rationale for the procedure and demonstrate techniques that the parents can use to interact with their newborn. Additional education about phototherapy may be necessary when home phototherapy is used (Teaching Guidelines 24.2).

#### Teaching Guidelines 24.2

##### CARING FOR YOUR NEWBORN RECEIVING HOME PHOTOTHERAPY

- Inspect your newborn's skin, eyes, and mucous membranes for a yellow color.
- Remember that a home health nurse will come to visit and help you set up the light system.
- Keep the lights about 12 to 30 inches above your newborn.
- Cover your newborn's eyes with patches or cotton balls and gauze to protect them.

- Keep the newborn undressed except for the diaper area; fold the diaper down below the newborn's navel in the front and as far as possible in the back to expose as much skin area as possible.
- Turn your newborn every 2 hours so that all areas of the body are exposed.
- Remove the newborn from the lights only for feeding.
- Remove the eye patches during feedings so that you can interact with your newborn.
- Record your newborn's temperature, weight, and fluid intake daily.
- Document the frequency, color, and consistency of all stools; the stools should be loose and green as the bilirubin is broken down.
- Keep the skin clean and dry to prevent irritation.
- Feed your newborn frequently, including supplemental glucose water if allowed to provide added fluid, protein, and calories.
- Rock, cuddle, or hold the newborn to promote bonding when out of the lights.
- Contact your pediatrician or home health care agency with any questions or changes, including refusing feedings, fewer than five wet diapers in one day, vomiting of complete amounts of feeding, or elevated temperature.
- Keep appointments for follow-up laboratory testing to monitor bilirubin levels.

### Newborn Infections

Newborns have increased susceptibility to infections because their immune systems are immature and slow to react. The antibodies that newborns received from their mother during pregnancy and from breast milk help protect them from invading organisms. However, these need time to reach optimal levels.

Bacterial infections of the newborn affect approximately 2 out of every 1,000 live births (Anderson-Berry, Bellig, & Ohning, 2012). The mortality rate from newborn sepsis may be as high as 50% if untreated (Anderson-Berry et al., 2012). Infection is a major cause of death during the first month of life, contributing to 13% to 15% of all neonatal deaths (Anderson-Berry et al., 2012).

### Pathophysiology

When a pathologic organism overcomes the newborn's defenses, infection and sepsis result. **Neonatal sepsis** is the presence of bacterial, fungal, or viral microorganisms or their toxins in blood or other tissues. Infections that have an onset within the first month of life are termed *newborn infections*. Exposure to a

pathogenic organism, whether a virus, fungus, or bacteria, occurs, and it enters the newborn's body and begins to multiply.

Newborn infections are usually grouped into three classes according to their time of onset: congenital infection, acquired in utero (intrauterine infections) by vertical transmission with onset before birth; early-onset infections, acquired by vertical transmission in the perinatal period, either shortly before or during birth; and late-onset infections, acquired by horizontal transmission in the nursery. About 90% of neonatal infections have their onset in the first 2 days of life (Anderson-Berry

et al., 2012). Comparison Chart 24.2 compares the three classes of newborn infections.

Early-onset neonatal infections are associated with acquisition of microorganisms from the mother. Transplacental infection or an ascending infection from the cervix may be caused by organisms that colonize in the mother's genitourinary tract, with acquisition of the microbe by passage through a colonized birth canal at delivery. The microorganisms most commonly associated with early-onset infection include group B *Streptococcus* (GBS), *Escherichia coli*, coagulase-negative *Staphylococcus*, *Haemophilus influenzae*, and *Listeria monocytogenes*.

COMPARISON CHART 24.2		INTRAUTERINE VERSUS EARLY-ONSET VERSUS LATE-ONSET NEWBORN INFECTIONS		
	Intrauterine (Congenital)	Early-Onset Infections	Late-Onset Infections	
Risk factors	<ul style="list-style-type: none"> <li>– Immature immune system IgM, IgA, and T lymphocytes</li> <li>– Decreased gastric acid, which is needed to reduce organisms</li> </ul>	<ul style="list-style-type: none"> <li>– Prolonged rupture of membranes</li> <li>– Urinary tract infections</li> <li>– Preterm labor</li> <li>– Prolonged or difficult labor</li> <li>– Maternal fever</li> <li>– Colonization with group B streptococci</li> <li>– Maternal infections</li> </ul>	<ul style="list-style-type: none"> <li>– Low birthweight</li> <li>– Prematurity</li> <li>– Meconium staining</li> <li>– Need for resuscitation</li> <li>– Birth asphyxia</li> <li>– Improper handwashing</li> </ul>

Sources: Blackburn (2012); Gardner, Carter, Enzman-Hines, & Hernandez (2011); Anderson-Berry, Bellig, & Ohning (2012)

Late-onset infections, acquired in the postpartum period, are primarily through horizontal transmission from family members or caregivers or through environmental exposures. Infections such as human immunodeficiency virus (HIV) and cytomegalovirus (CMV) can be acquired through breastfeeding (discussed in more detail in chapter 20 [see Table 20.4]), or by direct contact with family members or health care workers. These types of contacts and exposures are especially important in infants, primarily preterm, with prolonged hospital stays, where they are more likely to be exposed to multidrug-resistant hospital-associated organisms potentially from contact with caregivers or contaminated equipment. Comparison Chart 24.2 compares the three classes of newborn infections.

## Nursing Assessment

Diagnosis of neonatal infections is challenging. Most infants will have some risk factors and the presenting symptoms are many and nonspecific, including poor feeding, breathing difficulty, apneas and bradycardia, gastrointestinal problems, increased oxygen requirement or ventilator support needs, lethargy or hypotension, decreased or elevated temperature, unusual skin rash or color change, persistent crying, or irritability. Adding to the challenge of correctly identifying the infection, the list of conditions to consider in the differential diagnosis is extensive, including metabolic and congenital abnormalities (Polin, 2012).

Nursing assessment focuses on early identification of a newborn at risk for infection to allow for prompt treatment, thus reducing mortality and morbidity. Be aware of the myriad risk factors associated with newborn sepsis. Among the factors that contribute to the newborn's overall vulnerability to infection are poor skin integrity, invasive procedures, exposure to numerous caregivers, and an environment conducive to bacterial colonization (Tripathi, Cotten, & Smith, 2012).

Few newborn infections are easy to recognize because manifestations usually are nonspecific. Early symptoms can be vague because of the newborn's inability to mount an inflammatory response. Often, the observation is that the newborn does not "look right." Assess the newborn for common nonspecific signs of infection, including:

- Hypothermia
- Pallor or duskiness
- Hypotonia
- Cyanosis
- Poor weight gain
- Irritability
- Seizures
- Jaundice
- Grunting
- Nasal flaring

- Apnea and bradycardia
- Lethargy
- Hypoglycemia
- Poor feeding (lack of interest in feeding)
- Abdominal distention (Anderson-Berry et al., 2012)

Since infection can be confused with other newborn conditions, laboratory and radiographic tests are needed to confirm the presence of infection. Be prepared to coordinate the timing of the various tests and assist as necessary.

Evaluate the complete blood count with a differential to identify anemia, leukocytosis, or leukopenia. Elevated C-reactive protein levels may indicate inflammation. As ordered, obtain x-rays of the chest and abdomen, which may reveal infectious processes located there. Blood, cerebrospinal fluid, and urine cultures are indicated to identify the location and type of infection present. Positive cultures confirm that the newborn has an infection.

## Nursing Management

To enhance the newborn's chance of survival, early recognition and diagnosis are key. Often the diagnosis of sepsis is based on a suspicious clinical picture. Antibiotic therapy is usually started before the laboratory results identify the infecting pathogen (see Evidence-Based Practice). Along with antibiotic therapy, circulatory, respiratory, nutritional, and developmental support is important. Antibiotic therapy is continued for 7 to 21 days if cultures are positive, or it is discontinued within 72 hours if cultures are negative. With the use of antibiotics along with early recognition and supportive care, mortality and morbidity rates have been reduced greatly.

Nurses possess the education and assessment tools to decrease the incidence of and reduce the impact of infections on women (see Chapter 20 for additional information) and their newborns. Implement measures for prevention and early recognition, including:

- Formulating a sepsis prevention plan that includes education of all members of the health care team on identification and treatment of sepsis
- Screening all newborns daily for signs of sepsis
- Monitoring sepsis cases and outcomes to reinforce continued quality-improvement measures or to modify current practices
- Outlining and carrying out measures to prevent nosocomial infections, such as:
  - Thorough handwashing hygiene for all staff
  - Frequent oral care and inspections of mucous membranes
  - Proper positioning and turning to prevent skin breakdown
  - Use of strict aseptic technique for all wound care

**EVIDENCE-BASED PRACTICE 24.1****TREATING NEONATAL SEPSIS WITH GENTAMICIN GIVEN AS A ONCE-DAILY DOSE OR AS MULTIPLE DOSES PER DAY**

Sepsis in a newborn can be fatal, and the signs and symptoms can be vague. Antibiotic therapy is usually initiated before the infection is confirmed by cultures. Gentamicin is a common antibiotic used to treat neonatal sepsis because of its effectiveness against gram-negative pathogens. However, gentamicin, like other aminoglycosides, can have adverse effects on hearing and kidney function, leading to questions about the most effective dosing regimen. Studies have shown that once-a-day dosing is most effective in older children and adults, but these studies do not address the neonatal population.

**STUDY**

A study involving neonates with confirmed or suspected sepsis was completed to evaluate the effectiveness and safety of two types of dosing regimens: once-a-day dosing and multiple-doses-per-day dosing. All randomized or quasi-randomized controlled trials involving a comparison of one daily dose with multiple doses per day of gentamicin to newborns less than 28 days of age were selected. Information about clinical effectiveness, pharmacokinetic effectiveness, ototoxicity, and nephrotoxicity was collected. Of the 24 studies initially selected, 11 were evaluated. Most of the studies used intravenous infusion of gentamicin as the method of administration. One study used a bolus dose of gentamicin administered over 1 minute; two other studies used intramuscular administration.

**Findings**

There is insufficient evidence from the currently available studies to conclude whether “once a day” or “multiple doses a day” regimen of gentamicin is superior in treating proven neonatal sepsis. However, data suggests that pharmacokinetic properties of “once a day” gentamicin regimen are superior to “multiple doses a day” regimen in that it achieves higher peak levels while avoiding toxic trough levels. There is no change in nephrotoxicity or auditory toxicity. Based on this assessment of pharmacokinetics, the “once a day regimen” may be superior in treating neonatal sepsis in neonates greater than 32 weeks’ gestation.

**Nursing Implications**

The study confirmed the effectiveness of gentamicin in the treatment of neonatal sepsis, but it did not determine whether a once-daily dose was more effective than multiple doses per day in treating sepsis. Nurses can integrate the findings of this study into their practice when caring for newborns that are at risk for or have developed sepsis. Regardless of the regimen ordered, nurses can be diligent in ensuring that peak and trough drug levels are monitored. Although the study showed no evidence of hearing and kidney adverse effects, nurses still need to monitor the newborns for this possibility.

Source: Rao, S. C., Ahmed, M., & Hagan, R. (2011). One dose per day compared to multiple doses per day of gentamicin for treatment of suspected or proven sepsis in neonates. *Cochrane Database of Systematic Reviews* 2011. Issue 11. Art. No.: CD005091. DOI: 10.1002/14651858.CD005091.pub3.

- Frequent monitoring of invasive catheter sites for signs of infection
- Identifying newborns at risk for sepsis by reviewing risk factors
- Monitoring vital sign changes and observing for subtle signs of infection
- Monitoring for signs of organ system dysfunction:
  - Cardiovascular compromise—tachycardia and hypotension
  - Respiratory compromise—respiratory distress and tachypnea
  - Renal compromise—oliguria or anuria
  - Systemic compromise—abnormal blood values
- Providing comprehensive sepsis treatment:
  - Circulatory support with fluids and vasopressors
  - Supplemental oxygen and mechanical ventilation
  - Obtaining culture samples as requested
- Antibiotic administration as ordered, observing for side effects
- Promoting newborn comfort
- Assessing the family’s educational needs and providing instructions as necessary

Perinatal infections continue to be a public health problem, with severe consequences for those affected. By promoting a better understanding of newborn infections and appropriate use of therapies, nurses can lower the mortality rates associated with severe sepsis, especially with appropriate timing of interventions. The potential for nursing interventions to identify, prevent, and minimize the risk for sepsis is significant. Primary disease prevention must be a major focus for nurses. Family education plays a key role in the prevention of perinatal infections, in addition to following accepted practices in immunization.

## CONGENITAL CONDITIONS

Congenital conditions can arise from many etiologies, including single-gene disorders, chromosome aberrations, exposure to teratogens, and many sporadic conditions of unknown cause. Congenital conditions may be inherited or sporadic, isolated or multiple, apparent or hidden, gross or microscopic. They cause nearly half of all deaths in term newborns and cause long-term sequelae for many. The incidence varies according to the type of defect. When a serious anomaly is identified prenatally, the parents can decide whether or not to continue the pregnancy. When an anomaly is identified at or after birth, parents need to be informed promptly and given a realistic appraisal of the severity of the condition, the prognosis, and treatment options so that they can participate in all decisions pertaining to their child.

Congenital conditions can affect virtually any body system. This chapter describes common congenital conditions identified at or after birth. Some of these conditions warrant immediate treatment soon after birth. Other conditions, although identified in the newborn period, are long term with ongoing effects into childhood.

Ultimately, surveillance and research activities are translated into concrete strategies to prevent birth defects. In 1992, with solid evidence from epidemiologic research studies, the U.S. Public Health Service recommended that all women of childbearing age consume 400 micrograms (400 mcg or 0.4 mg) of folic acid daily to reduce the risk (up to 70%) of having a pregnancy affected by a neural tube defect. This has spurred prevention activities at local and national levels to promote the folic acid message (CDC, 2010).

### Esophageal Atresia and Tracheoesophageal Fistula

Esophageal atresia and tracheoesophageal fistula are gastrointestinal anomalies in which the esophagus and trachea do not separate normally during embryonic development. Esophageal atresia refers to a congenitally interrupted esophagus where the proximal and distal ends do not communicate; the upper esophageal segment ends in a blind pouch and the lower segment ends a variable distance above the diaphragm (Fig. 24.9).

Tracheoesophageal fistula is an abnormal communication between the trachea and esophagus. When associated with esophageal atresia, the fistula most commonly occurs between the distal esophageal segment and the trachea. The incidence of esophageal atresia is 1 per 3,000 to 4,500 live births (Blackburn, 2012).

## Pathophysiology

Several types of esophageal atresia exist, but the most common anomaly is a fistula between the distal esophagus and the trachea, which occurs in 86% of newborns with an esophageal defect. Esophageal atresia and tracheoesophageal fistula are thought to be the result of incomplete separation of the lung bed from the foregut during early fetal development. A large percentage of these newborns have other congenital anomalies involving the vertebra, kidneys, heart, and musculoskeletal and gastrointestinal systems (Kliegman et al., 2011); most have several anomalies.

## Nursing Assessment

Review the maternal history for hydramnios. Often this is the first sign of esophageal atresia because the fetus cannot swallow and absorb amniotic fluid in utero, leading to accumulation. Soon after birth, the newborn may exhibit copious, frothy bubbles of mucus in the mouth and nose, accompanied by drooling. Abdominal distention develops as air builds up in the stomach. In esophageal atresia, a gastric tube cannot be inserted beyond a certain point because the esophagus ends in a blind pouch. The newborn may have rattling respirations, excessive salivation, and drooling, and “the three C’s” (coughing, choking, and cyanosis) if feeding is attempted. The presence of a fistula increases the risk of respiratory complications such as pneumonitis and atelectasis due to aspiration of food and secretions (Alberti, Boroni, Corasaniti, & Torri, 2011).

### Take Note!

The “three C’s” of choking, coughing, and cyanosis in conjunction with feeding are considered the classic signs of tracheoesophageal fistula and atresia.

Prepare the newborn and parents for radiographic evaluation. Diagnosis is made by x-ray or an ultrasound or MRI, which will demonstrate a gastric tube coiled in the upper esophageal pouch, and air in the gastrointestinal tract indicates the presence of a fistula (Houfflin-Debarge & Bigot, 2011). Once a diagnosis of esophageal atresia is established, begin preparations for surgery if the newborn is stable.

## Nursing Management

Nursing management focuses on preparing the newborn and parents for surgery and providing meticulous postoperative care.

### Providing Preoperative Care

Preoperative nursing interventions include the following measures:

- Initiate nothing by mouth (NPO) status.
- Elevate the head of the bed 30 to 45 degrees to prevent reflux and aspiration.

**FIGURE 24.9** Esophageal atresia and tracheoesophageal fistula. **(A)** The most common type of esophageal atresia, in which the esophagus ends in a blind pouch and a fistula connects the trachea with the distal portion of the esophagus. **(B)** The upper and distal portions of the esophagus end in a blind pouch. **(C)** The esophagus is one segment, but a portion of it is narrowed. **(D)** The upper portion of the esophagus connects to the trachea via a fistula.

- Monitor hydration status and fluid and electrolyte balance; administer and monitor parenteral IV fluid infusions.
- Assess and maintain the patency of the orogastric tube; monitor the functioning of the tube, which is attached to low continuous suction; and avoid irrigation of the tube to prevent aspiration.
- Have oxygen and suctioning equipment readily available should the newborn experience respiratory distress.
- Assist with diagnostic studies to rule out other anomalies.
- Use comfort measures to minimize crying and prevent respiratory distress; provide nonnutritive sucking.

- Inform the parents about the rationales for the aspiration prevention measures.
- Document frequent observations of the newborn's condition. (Alberti et al., 2011)

### Providing Postoperative Care

Surgery consists of closing the fistula and joining the two esophageal segments. Postoperative care involves closely observing all of the newborn's body systems to identify any complications. Expect to administer TPN and antibiotics until the esophageal anastomosis is proven intact and patent. Then begin oral feedings, usually within a week after surgery (Blackburn, 2012). Keep the parents informed of their newborn's condition and progress. Closely assess the newborn during feeding and report any difficulty with swallowing. Provide parent teaching. Demonstrate and reinforce all teaching prior to discharge.

### Omphalocele and Gastroschisis

Omphalocele and gastroschisis are congenital anomalies of the anterior abdominal wall at or near the umbilicus. An **omphalocele** is a defect of the umbilical ring that allows evisceration of the abdominal contents into an external peritoneal sac. Defects vary in size; they may be limited to bowel loops or may include the entire gastrointestinal tract and liver (Fig. 24.10). Bowel malrotation is common, but the displaced organs are usually normal. Omphaloceles are associated with an abnormal karyotype or genetic syndrome in more than 50% of the cases (Thilo & Rosenberg, 2011). Omphaloceles are associated with other anomalies in more than 70% of the cases. This anomaly is usually detected during routine prenatal ultrasound of the fetus or during investigation of an increased  $\alpha$ -fetoprotein level (Glasser, 2011).

**Gastroschisis** is a herniation of the abdominal contents through an abdominal wall defect, at the umbilicus. Gastroschisis differs from omphalocele in that

**FIGURE 24.10** Omphalocele in a newborn. Note the large, protruding sac.

there is no peritoneal sac protecting the herniated organs, and thus exposure to amniotic fluid makes them thickened, edematous, and inflamed (Nichol, 2011). Gastroschisis is associated with significant newborn mortality and morbidity rates. Despite surgical correction, feeding intolerance, failure to thrive, and prolonged hospital stays occur in nearly all newborns with this anomaly (Ledbetter, 2012).

Each of these diagnoses requires that a pediatric surgeon be available at delivery to determine the extent of the defect and complications.

### Nursing Assessment

Abdominal wall defects are readily diagnosed by prenatal ultrasound, which is helpful in planning for the birth and needed therapy. An early birth may be planned if the ultrasound reveals evidence of progressive bowel distention and thickening. Review the maternal history for factors associated with high-risk pregnancies, such as maternal illness and infection, drug use, smoking, and genetic abnormalities. These factors are also associated with omphalocele and gastroschisis. They contribute to placental insufficiency and the birth of a small-for-gestational-age or preterm newborn, the populations in which both of these abdominal defects most commonly occur. The combined incidence of both congenital abdominal wall anomalies is 1 in 2,000 births (Glasser, 2011).

Omphalocele and gastroschisis are readily observed. Note the appearance of the protrusion on the abdomen and evidence of a sac. Inspect the sac closely for the presence of organs, most commonly the intestines but sometimes the liver. Also inspect the contents for any twisting of the intestines. Note the color of the organs within the sac and measure the size of the omphalocele.

Also perform a complete physical examination of the newborn. Typically these congenital conditions are associated with other congenital anomalies, such as those involving the cardiovascular, genitourinary, and central nervous systems.

Assessment findings summary of omphalocele and gastroschisis:

- Usually detected on prenatal ultrasound exams
- Eviscerated bowel without peritoneal covering—gastroschisis
- Eviscerated bowel with peritoneal covering—omphalocele
- Search for additional anomalies if omphalocele is diagnosed

### Nursing Management

Nursing management of newborns with omphalocele or gastroschisis focuses on preventing hypothermia, maintaining perfusion to the eviscerated abdominal contents by minimizing fluid loss, and protecting the exposed

abdominal contents from trauma and infection. Place the infant under a radiant warmer and place a moistening sterile dressing as ordered over the defect (Glasser, 2011). Carefully handle the defect utilizing strict sterile technique to prevent contamination of the exposed abdominal contents as well as traumatic damage (Glasser, 2011).

An orogastric tube attached to low suction is used to prevent intestinal distention. IV therapy is administered to maintain fluid and electrolyte balance and provide a route for antibiotic therapy. Monitor the newborn's fluid status frequently. Closely observe the exposed bowel for vascular compromise, such as changes in color or a decrease in temperature, and report these immediately.

### Providing Postoperative Care

Surgical repair of both defects occurs after initial stabilization and comprehensive evaluation for any other anomalies. It may have to occur in stages, depending on the defect (Box 24.5).

Postoperative care involves providing pain management, monitoring respiratory and cardiac status, monitoring intake and output, assessing for vascular compromise, maintaining the orogastric tube to suction, documenting the amount and color of drainage, and administering ordered medications and treatments (Razmus, 2011). Also be alert for complications, such as short bowel syndrome (see Chapter 42 for additional information).

### Promoting Parent–Newborn Interaction

The parents need continued support and progress reports on their newborn. They may be distraught at the sight of the anomaly, and they may be frightened to

touch their newborn. Encourage the parents to touch the newborn and participate in care as much as possible. Because of the nature of this defect, bonding opportunities will be limited initially. However, strongly encourage frequent visiting. In addition, provide information to the parents about the defect, treatment modalities, and prognosis. After surgery, instruct the parents in care measures and provide them with home care instructions. Anticipate the need for a referral to a home health care agency and community resources for support.

## Anorectal Malformations

An imperforate anus is a gastrointestinal system malformation of the anorectal opening and is identified in the newborn period. The rectum may end in a blind pouch that does not connect to the colon, or it may have fistulas (openings) between the rectum and the perineum (the vagina in girls or the urethra in boys) (Fig. 24.11). The malformations occur during early fetal development and may be associated with numerous other congenital anomalies (Sundaram, Hoffenberg, Kramer, Sondheimer, & Furuta, 2011) in other body systems. Refer to Box 24.6 for anomalies associated with anorectal malformations.

Imperforate anus occurs in about 1 of every 5,000 live births (Levitt & Pena, 2012). The defect can be further classified as a high or low type, depending on its level. The level significantly influences the outcome in terms of fecal continence as well as management (Blackburn, 2012).

Surgical intervention is needed for both high and low types of imperforate anus. Surgery for a high type of defect involves a colostomy in the newborn period, with corrective surgery performed in stages to allow for growth. Surgery for the low type of anomaly, which frequently includes a fistula, involves closure of the fistula, creation of an anal opening, and repositioning of the rectal pouch into the anal opening. A major challenge for either type of surgical repair is finding, using, or creating adequate nerve and muscle structures around the rectum to provide for normal evacuation (Ochi, Okazaki, Miyano, Lane, & Yamataka, 2012).

## Nursing Assessment

In the newborn, observe for an appropriate anal opening. If the anal opening exists, observe for passage of meconium stool within the first 24 hours of life. Assess urine output to identify genitourinary problems. For the newborn with an imperforate anus, inspection of the perineal area would reveal absence of the usual opening. In addition, meconium generally is not passed or present within 24 hours of birth.

In the infant with suspected imperforate anus, assess for common signs of intestinal obstruction, which may occur as a result of the malformation. These include abdominal distention and bilious vomiting.

### BOX 24.5

#### SURGERY TO REPAIR OMPHALOCELE AND GASTROSCHISIS

Surgical repair of gastroschisis is an emergency due to the high risk of intestinal atresia, resulting in obstruction. Primary repair of gastroschisis is usually performed without incident, unless the contents are unable to fit into the abdominal cavity. This occurs more often with a large omphalocele, requiring the surgeon to do a staged closure. This involves covering the defect with a synthetic material that is sequentially squeezed like toothpaste to reduce the defect into the abdominal cavity. After enough of the defect is in the abdominal cavity, a surgical repair is then performed (Glasser, 2011). If damage to the exposed organs occurs, such as necrosis, then the necrotic sections are removed during the repair. If a significant amount of small intestine is lost, then the complication of short bowel syndrome may occur.

**FIGURE 24.11** Imperforate anus, in which the rectum ends in a blind pouch. Image B shows an imperforate anus without fistula. The visible meconium streak along the raphe is consistent with a low imperforate anus. (Courtesy of Kevin P. Lally, MD.)

Prepare the newborn and family for a perineal ultrasound and an abdominal x-ray that will be ordered to identify the level of defect in the absence of a perineal fistula and also to assess for complications associated with imperforate anus.

## Nursing Management

Nursing management focuses on preparing the newborn and parent for surgery and providing postoperative care. Preoperatively, maintain the newborn's NPO status and provide gastric decompression. Administer IV therapy and antibiotic therapy as ordered and monitor

the newborn's hydration status. Provide a full explanation of the defect, surgical options, potential complications, typical postoperative course, and long-term care needed to the parents. Make sure they are aware of the available treatment modalities. Prepare them for the possibility that the newborn may require an ostomy. Provide support to the parents and family.

Postoperative care includes ensuring adequate pain relief, maintaining NPO status and gastric decompression until normal bowel function is restored, and providing colostomy care if applicable. Refer to Chapter 42 for additional information related to ostomy care and postoperative care for children undergoing an intestinal pull-through procedure.

### BOX 24.6

#### ANOMALIES ASSOCIATED WITH ANORECTAL MALFORMATIONS

VACTERL syndrome: vertebral, anorectal, cardiovascular, tracheoesophageal, renal, and limb

Esophageal atresia

Intestinal atresia

Malrotation

Renal agenesis

Hypospadias

Vesicoureteral reflux

Bladder exstrophy

Cardiac anomalies

Skeletal anomalies

## Bladder Exstrophy

In classic bladder exstrophy, a midline closure defect occurs during the embryonic period of gestation, leaving the bladder open and exposed outside of the abdomen. The bony pelvis may also be malformed, resulting in an opening in the pelvic arch. Bladder exstrophy may be diagnosed by prenatal ultrasound. Complications include UTI from ascending organisms. Treatment of bladder exstrophy involves surgical repair (Fig. 24.12).

## Nursing Assessment

On physical examination of the infant or child, note the red appearance to the bladder seen on the abdominal wall. Draining urine will be visible. Note excoriation of abdominal skin around the bladder resulting from

A

B

**FIGURE 24.12** Bladder exstrophy. **(A)** Before surgical repair. **(B)** After surgery.

contact with urine. A malformed urethra may be present in females, whereas males may have an unformed or malformed penis or a normal penis with an epispadias.

## Nursing Management

Nursing management consists of preventing infection and skin breakdown, providing postoperative care, and catheterizing the stoma.

### Preventing Infection and Skin Breakdown

Bladder exstrophy requires surgical repair. In the preoperative period, care is focused on protecting the exstrophied bladder and preventing infection. Keep the infant in a supine position; keep the bladder moist and cover it with a sterile plastic bag. Change soiled diapers immediately to prevent contamination of the bladder with feces. Sponge-bathe the infant rather than immersing him or her in water to prevent pathogens in the bath water from entering the bladder. Prevent breakdown of the surrounding abdominal skin by applying protective barrier creams. In some instances it may be necessary to consult the ostomy nurse for further advice (see Chapter 43 for more information).

#### KEY CONCEPTS

- Asphyxia, the most common clinical insult in the perinatal period, results in brain injury and may lead to mental retardation, cerebral palsy, or seizures.
- Transient tachypnea of the newborn occurs when the liquid in the lung is removed slowly or incompletely.

- Common risk factors for respiratory distress syndrome (RDS) include young gestational age, perinatal asphyxia regardless of gestational age, cesarean birth in the absence of labor (related to the lack of thoracic squeeze), male gender, and maternal diabetes.
- Meconium aspiration has three major pulmonary effects: airway obstruction, surfactant dysfunction, and chemical pneumonitis.
- The management of persistent pulmonary hypertension of the newborn requires meticulous attention to detail, with continuous monitoring of oxygenation, blood pressure, and perfusion.
- Intraventricular hemorrhage is bleeding that usually originates in the subependymal germinal matrix region of the brain with extension into the ventricular system.
- Necrotizing enterocolitis (NEC) is a serious gastrointestinal disease of unknown etiology in newborns that can result in necrosis of a segment of the bowel.
- Infants of diabetic mothers are at risk for malformations most frequently involving the cardiovascular, skeletal, central nervous, gastrointestinal, and genitourinary systems; cardiac anomalies are the most common.
- Factors that place the newborn at risk for birth trauma include cephalopelvic disproportion, maternal pelvic anomalies, oligohydramnios, prolonged or rapid labor, abnormal presentation, fetal prematurity, fetal macrosomia, and fetal abnormalities.
- Women who use drugs during their pregnancy expose their unborn child to the possibility of intrauterine growth restriction, prematurity, neurobehavioral and neurophysiologic dysfunction,

birth defects, infections, and long-term developmental sequelae.

- Newborns of women who abuse tobacco, illicit substances, caffeine, and alcohol can exhibit withdrawal behavior.
- Physiologic jaundice is a common, normal newborn phenomenon that appears during the second or third day of life and then declines over the first week after birth. Pathologic jaundice is manifested within the first 24 hours of life when total bilirubin levels increase by more than 5 mg/dL/day and the total serum bilirubin level is higher than 17 mg/dL in a full-term infant.
- Newborn infections are usually classified according to the time of onset and grouped into three categories: congenital infection, acquired in utero by vertical transmission with onset before birth; early-onset neonatal infections, acquired by vertical transmission in the perinatal period, either shortly before or during birth; and late-onset neonatal infections, acquired by horizontal transmission in the nursery.
- Congenital conditions can arise from many etiologies including single-gene disorders, chromosome aberrations, exposure to teratogens, and many sporadic conditions of unknown cause. Congenital structural anomalies may be inherited or sporadic, isolated or multiple, apparent or hidden, and gross or microscopic.
- Esophageal atresia refers to a congenitally interrupted esophagus where the proximal and distal ends do not communicate; the upper esophageal segment ends in a blind pouch and the lower segment ends a variable distance above the diaphragm. Tracheoesophageal fistula is an abnormal communication between the trachea and esophagus.
- Omphalocele and gastroschisis are congenital anomalies of the anterior abdominal wall. An omphalocele is a defect of the umbilical ring that allows evisceration of abdominal contents into an external peritoneal sac. Gastroschisis is a herniation of abdominal contents through an abdominal wall defect, usually to the left or right of the umbilicus.

## MULTIPLE-CHOICE QUESTIONS

- Which finding would lead the nurse to suspect that a newborn is experiencing respiratory distress syndrome?
    - Abdominal distention
    - Acrocyanosis
    - Depressed fontanels
    - Nasal flaring
  - When assessing the substance-exposed newborn, which finding would the nurse expect?
    - Calm facial appearance
    - Daily weight gain
    - Increasing irritability
    - Feeding and sleeping well
  - A newborn with tracheoesophageal fistula is likely to present with which assessment finding?
    - Subnormal temperature
    - Absent Moro reflex
    - Inability to swallow
    - Drooling from mouth
  - The nurse would be most alert for the development of transient tachypnea in a newborn who:
    - Was born by cesarean birth
    - Received no sedation
    - Has a mother with heart disease
    - Is small for gestational age
- Terry, a day-old baby girl, is very fretful, and calming measures don't seem to work. As the nursery nurse you notice that she is losing weight and her formula intake is poor, even though she is manifesting hungry behavior. The mother received no prenatal care and denied drug use, but her drug screen was positive for heroin.
    - What additional information do you need to obtain from the mother?
    - What additional laboratory work might be needed for Terry?
    - What specific measures need to be made for her ongoing care?
  - Baby boy Sims, a term newborn, was brought to the nursery. His mother received no prenatal care, but the newborn's Apgar scores were fine. As the nurse carried out her newborn assessment, she noted an imperforate anus and palpated no testicles in the scrotal sac.
    - What additional assessments should the nurse complete?
    - Are anorectal agenesis and genitourinary tract anomalies common?
    - What diagnostic tests might be ordered? What might be included in the treatment plan for this newborn?

## CRITICAL THINKING EXERCISES

- As the nursery nurse, you receive a newborn from the labor and birth suite and place him under the radiant warmer. The nurse who gives you the report states that the mother couldn't remember when her membranes broke before labor and that she ran a fever during labor for the past few hours. The Apgar scores were good, but the newborn seemed lethargic. As you begin your assessment, you note that he is pale and floppy and has a subnormal temperature; heart rate is 180 bpm and respiratory rate is 70 breaths per minute.
  - What in the mother's history should raise a red flag to the nurse?
  - For what condition is this newborn at high risk?
  - What interventions are appropriate for this condition?
- Select a website from the list online at [thePoint](#). What kind of information is given? How helpful would it be for parents with an infant diagnosed with a specific condition?
- A herniation of a newborn's abdominal contents present at birth describes \_\_\_\_\_.

# Growth and Development of the Newborn and Infant

## Learning Objectives

*Upon completion of the chapter, you will be able to:*

1. Define the key terms used in this chapter.
2. Identify normal developmental changes occurring in the newborn and infant.
3. Identify the gross and fine motor milestones of the newborn and infant.
4. Express an understanding of language development in the first year of life.
5. Describe nutritional requirements of the newborn and infant.
6. Develop a nutritional plan for the first year of life.
7. Identify common issues related to growth and development in infancy.
8. Demonstrate knowledge of appropriate anticipatory guidance for common developmental issues.

*Allison Johnson is a 6-month-old girl brought to the clinic by her mother and father for her 6-month check-up. As new parents, they have a list of questions and concerns. On assessment you find that Allison's weight is 16 pounds, length 25 $\frac{3}{4}$  inches, and head circumference 17 inches. As the nurse caring for her, assess Allison's growth and development, and then teach the parents what changes to expect in Allison over the next few months.*

### Words of Wisdom

Of all the joys that lighten our hearts, what joy is welcomed like a newborn child?

The newborn or neonatal period of infancy is defined as the period from birth until 28 days of age. Infancy is defined as the period from birth to 12 months of age. Growth and development are interrelated, ongoing processes in infancy and childhood. **Growth** refers to an increase in physical size. **Development** is the sequential process by which infants and children gain various skills and functions. Heredity influences growth and development by determining the child's potential, while environment contributes to the degree of achievement. **Maturation** refers to an increase in functionality of various body systems or developmental skills.

## GROWTH AND DEVELOPMENT OVERVIEW

Growth and developmental changes in the first year of life are numerous and dramatic. Physical growth, maturation of body systems, and gross and fine motor skills progress in an orderly and sequential fashion. Though timing may vary from infant to infant, the order in which developmental skills are acquired is consistent. Infants also exhibit vast amounts of learning in the psychosocial and cognitive, language and communication, and social/emotional domains. Adequate growth and development are indicative of health in the infant or young child. Nurses must be familiar with normal developmental milestones so that they can accurately assess the infant's development as well as provide age-appropriate anticipatory guidance to the parents.

Achievement of developmental milestones may be assessed in a variety of ways. While obtaining the health history, the nurse may ask the parent or caregiver if the skill is present and when it was attained. The infant may also demonstrate the skill during the interview or examination, or the nurse may elicit the skill from the infant. A number of screening tools are also used to assess development, such as the Denver II Developmental Screening Test (see Appendix G), Prescreening Developmental Questionnaire (PDQ II), Ages and Stages Questionnaire (ASQ), Infant Toddler Checklist for Language and Communication, and Infant Development Inventory.

Ill or premature infants may exhibit delayed acquisition of physical growth and developmental skills. When assessing the growth and development of a premature infant, use the infant's adjusted age to determine expected outcomes. To determine adjusted age, subtract the number of weeks that the infant was premature from the infant's chronological age. Plot growth parameters and assess developmental milestones based on adjusted age. For example, a 6-month-old boy who was born at 28 weeks' gestation was born 12 weeks early (3 months), so subtract 3 months from his chronological age of 6 months to obtain an adjusted age of 3 months. This infant would demonstrate healthy growth if he were the size of a 3-month-old, and he should be expected to achieve the developmental milestones of a 3-month-old rather than a 6-month-old.

### Physical Growth

Ongoing assessments of growth are important so that too-rapid or inadequate growth can be identified early. With early identification, the cause can be diagnosed and the potential for further appropriate growth maximized. Infants grow very rapidly over the first 12 months of life. Weight, length, and head and chest circumference are all indicators of physical growth in the newborn and infant (Table 25.1).

### Weight

The average newborn weighs 7 lb 8 oz (3,400 g) at birth. Newborns lose up to 10% of their body weight over the first 5 days of life. The average newborn then gains about 20 to 30 g per day and regains his or her birthweight by 10 to 14 days of age. Most infants double their birthweight by 4 to 6 months of age and triple their birthweight by the time they are 1 year old (Hagan, Shaw, & Duncan, 2008).

### Height

The average newborn is 19 to 21 inches (48 to 53 cm) long at birth. During the first 6 months, length increases

TABLE 25.1

AVERAGE MEASUREMENTS OF INFANTS AT BIRTH AND 6 AND 12 MONTHS

Age	Weight	Length	Head Circumference
<b>Birth</b>	7.5 lb (3,400 g)	19–21 in (48–53 cm)	13–14 in (33–35 cm)
<b>6 months</b>	16 lb (7.3 kg)	25–27 in (63.5–68.5 cm)	16.5–17.5 in (42–44.5 cm)
<b>12 months</b>	23 lb (10.5 kg)	28–30 in (71–76 cm)	17.7–18.7 in (45–47.5 cm)

Adapted from Hagan, J. F., Shaw, J. S., & Duncan, P. M. (Eds.). (2008). *Bright futures: Guidelines for health supervision of infants, children, and adolescents* (3rd ed., rev.). Elk Grove Village, IL: American Academy of Pediatrics.

by 1 inch (2.5 cm) per month, then by about a half-inch per month in the second 6 months (Hagan et al., 2008).

## Head and Chest Circumference

Average head circumference of the full-term newborn is 13 to 14 inches (33 to 35 cm). The head circumference is about 1 inch (2 to 3 cm) greater than the chest circumference, which averages 12 to 13 inches (30.5 to 33 cm). The head circumference increases rapidly during the first 6 months: the average increase is about 0.6 inch (1.5 cm) per month. From 6 to 12 months of age, the head circumference increases an average of 0.2 inch (0.5 cm) monthly. The chest circumference is not routinely measured after the newborn period but does increase in size as the child grows (Hagan et al., 2008).

### Organ System Maturation

The newborn and infant's organ systems undergo significant changes as the infant grows. Systems that undergo significant change include the neurologic system, the cardiovascular system, the respiratory system, the gastrointestinal (digestive) system, the renal system, the hematopoietic system, the immunologic system, and the integumentary system.

## Neurologic System

The infant experiences tremendous changes in the neurologic system over the first year of life. Critical brain growth and continued myelination of the spinal cord are occurring. Involuntary movement progresses to voluntary control, and immature vocalizations and crying progress to the ability to speak as a result of maturational changes of the neurologic system.

### States of Consciousness

The normal term newborn's ability to move sequentially through states of consciousness reassures parents and physicians that the neurologic system, though immature, is intact. A normal newborn will ordinarily move through six states of consciousness:

1. Deep sleep: The infant lies quietly without movement.
2. Light sleep: The infant may move a little while sleeping and may startle to noises.
3. Drowsiness: Eyes may close; the infant may be dozing.
4. Quiet alert state: The infant's eyes are open wide and the body is calm.
5. Active alert state: The infant's face and body move actively.
6. Crying: The infant cries or screams and the body moves in a disorganized fashion (Brazelton & Nugent, 2011).

Newborns usually progress through these states slowly, rather than going from deep sleep immediately into outright crying.

### Brain Growth

The nervous system continues to mature throughout infancy, and the increase in head circumference is indicative of brain growth. The brain undergoes tremendous growth during the first 2 years of life. By 6 months of age the infant's brain weighs half that of the adult brain. At age 12 months, the brain has grown considerably, weighing 2½ times what it did at birth. Usually, the anterior fontanel remains open until 12 to 18 months of age to accommodate this rapid brain growth. However, the fontanel may close as early as 9 months of age, and this is not of concern in the infant with age-appropriate growth and development.

In general, the neurologic system matures a significant amount over the first year of life. Myelination of the spinal cord and nerves continues over the first 2 years. Maturation of the nervous system and continued myelination are necessary for the tremendous developmental skills that are achieved in the first 12 months. During the first few months of life, reflexive behavior is replaced with purposeful action.

### Reflexes

Primitive reflexes are subcortical and involve a whole-body response. Selected primitive reflexes present at birth include Moro, root, suck, asymmetric tonic neck, plantar and palmar grasp, step, and Babinski. Except for the Babinski, which disappears around 1 year of age, these primitive reflexes diminish over the first few months of life, giving way to protective reflexes. Protective reflexes (also termed postural responses or reflexes) are gross motor responses related to maintenance of equilibrium. These responses are prerequisites for appropriate motor development and remain throughout life once they are established. The protective reflexes include the righting and parachute reactions. Appropriate presence and disappearance of primitive reflexes, as well as development of protective reflexes, are indicative of a healthy neurologic system. Persistence of primitive reflexes beyond the usual age of disappearance may indicate an abnormality of the neurologic system and should be investigated.

Table 25.2 gives descriptions and illustrations of several primitive and protective reflexes, as well as the timing of appearance and disappearance of these reflexes.

TABLE 25.2

## SELECTED PRIMITIVE AND PROTECTIVE REFLEXES IN INFANCY

	Description	Age Reflex Appears	Age Reflex Disappears
<b>Primitive Reflexes</b>			
<b>Root</b>	When infant's cheek is stroked, the infant turns to that side, searching with mouth.	Birth	3 months

## Respiratory System

The respiratory system continues to mature over the first year of life. The respiratory rate slows from an average of 30 to 60 breaths in the newborn to about 20 to 30 in the 12-month-old. The newborn breathes irregularly, with periodic pauses. As the infant matures, the respiratory pattern becomes more regular and rhythmic.

In comparison with the adult, in the infant:

- The nasal passages are narrower.
- The trachea and chest wall are more compliant.
- The bronchi and bronchioles are shorter and narrower.
- The larynx is more funnel shaped.
- The tongue is larger.
- There are significantly fewer alveoli.

These anatomic differences place the infant at higher risk for respiratory compromise. The respiratory system

does not reach adult levels of maturity until about 7 years of age. The lack of immunoglobulin A (IgA) in the mucosal lining of the upper respiratory tract also contributes to the frequent infections that occur in infancy.

## Cardiovascular System

The heart doubles in size over the first year of life. As the cardiovascular system matures, the average pulse rate decreases from 120 to 140 in the newborn to about 100 in the 1-year-old. Blood pressure steadily increases over the first 12 months of life, from an average of 60/40 in the newborn to 100/50 in the 12-month-old. The peripheral capillaries are closer to the surface of the skin, thus making the newborn and young infant more susceptible to heat loss. Over the first year of life, thermoregulation (the body's ability to stabilize body

temperature) becomes more effective: the peripheral capillaries constrict in response to a cold environment and dilate in response to heat.

## Gastrointestinal System

### Teeth

Occasionally, an infant is born with one or more teeth (termed natal teeth) or develops teeth in the first 28 days of life (termed neonatal teeth). The presence of natal or neonatal teeth may be associated with other birth anomalies. The vast majority of newborns do not have teeth at birth, nor do they develop them in the first month of life. On average, the first primary teeth begin to erupt between the ages of 6 and 8 months. The primary teeth (also termed deciduous teeth) are lost later in childhood and will be replaced by the permanent teeth. The gums around the emerging tooth often swell. The lower central incisors are usually the first to appear, followed by the upper central incisors (Fig. 25.1). The average 12-month-old has four to eight teeth.

### Digestion

The newborn's digestive system is not developed fully. Small amounts of saliva are present for the first

3 months of life and ptyalin is present only in small amounts in the saliva. Gastric digestion occurs as a result of the presence of hydrochloric acid and rennin. The small intestine is about 270 cm long and grows to the adult length over the first few years of life (Liacouras, 2011). The stomach capacity is relatively small at birth, holding about one-half to 1 ounce. However, by 1 year of age the stomach can accommodate three full meals and several snacks per day. In the duodenum, three enzymes in particular are important for digestion. Trypsin is available in sufficient quantities for protein digestion after birth. Amylase (needed for complex carbohydrate digestion) and lipase (essential for appropriate fat digestion) are both deficient in the infant and do not reach adult levels until about 5 months of age.

The liver is also immature at birth. The ability to conjugate bilirubin and secrete bile is present after about 2 weeks of age. Conjugation of medications may remain immature over the first year of life. Other functions of the liver, including gluconeogenesis, vitamin storage, and protein metabolism, remain immature during the first year of life.

### Stools

The consistency and frequency of stools change over the first year of life. The newborn's first stools (meconium) are the result of digestion of amniotic fluid swallowed in utero. They are dark green to black and sticky (Fig. 25.2). In the first few days of life the stools become yellowish or tan. Generally the formula-fed infant has stools the consistency of peanut butter. Breastfed infants' stools are usually looser in texture and appear seedy. Newborns may have as many as 8 to 10 stools per day or as few as one stool every day or two. After the newborn period, the number of stools may decrease, and some infants do not have a bowel movement for several days. Infrequent stooling is considered normal if the bowel movement remains soft. Due to the immaturity of the gastrointestinal system, newborns and young infants often grunt, strain, or cry while attempting to have a bowel movement. This is not of concern unless the stool is hard and dry. Stool color and texture may change depending on the foods that the infant is ingesting. Iron supplements may cause the stool to appear black or very dark green (AAP, 2012a).

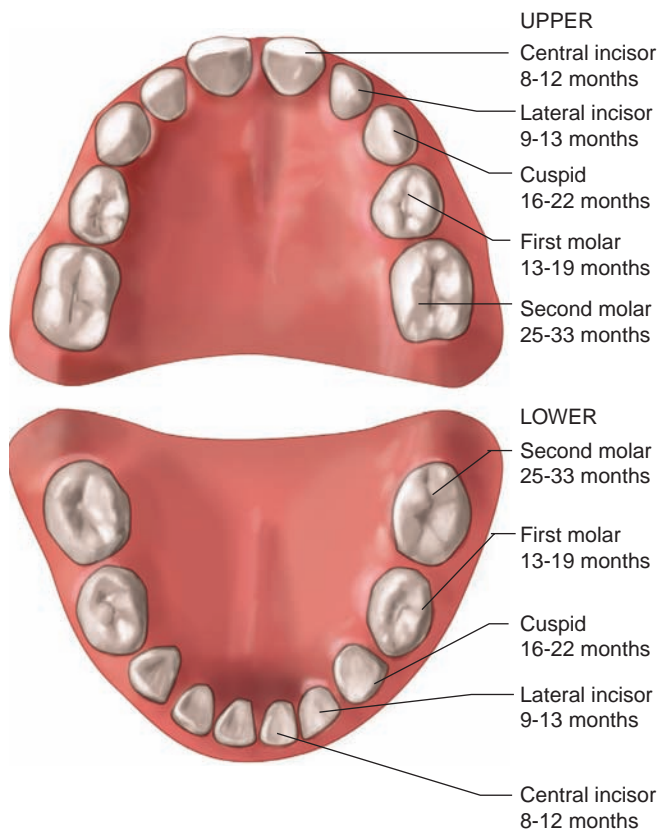

FIGURE 25.1 Sequence and average age of tooth eruption.

#### Take Note!

Parents should call the primary care provider if the infant's stools are red, white, or black; mucuslike; frequent and watery; frothy or foul-smelling; or hard, dry, formed, or pelletlike; or if the baby is vomiting.

**FIGURE 25.2** **A.** Meconium stool. **B.** Typical stool after the first few days. Note the yellowish, seedy stool of a breastfed infant.

## Genitourinary System

In the infant, extracellular fluid (lymph, interstitial fluid, and blood plasma) accounts for about 35% of body weight and intracellular fluid accounts for 40%, compared with the adult quantities of 20% and 40%, respectively (Greenbaum, 2011). Thus, the infant is more susceptible to dehydration. Infants urinate frequently and the urine has a relatively low specific gravity. The renal structures are immature and the glomerular filtration rate, tubular secretion, and reabsorption as well as renal perfusion are all reduced compared with the adult. The glomeruli reach full maturity by 2 years of age.

## Integumentary System

In utero the infant is covered with vernix caseosa, which protects the developing infant's skin. At birth, the infant may be covered with vernix (earlier gestational age) or vernix may be found in the folds of the skin, axilla, and groin areas (later gestational age). Production of vernix ceases at birth. Fine downy hair (lanugo) covers the body of many newborns. Often this hair is lost over time and is not replaced. Darker-skinned races tend to have more lanugo present at birth than those with light skin.

Acrocyanosis (blueness of the hands and feet) is normal in the newborn; it decreases over the first few days of life (Fig. 25.3). Newborns often experience mottling of the skin (a pink-and-white marbled appearance) because of their immature circulatory

system. Mottling decreases over the first few months of life.

The newborn and young infant's skin is relatively thinner than that of the adult, with the peripheral capillaries being closer to the surface. This may cause increased absorption of topical medications.

## Hematopoietic System

Significant changes in the hematopoietic system occur over the first year of life. At birth, fetal hemoglobin (HgbF) is present in large amounts. After birth the production of fetal hemoglobin nearly ceases, and adult hemoglobin (HgbA) is produced in steadily increasing amounts throughout the first 6 months. Since HgbF has a shorter lifespan than HgbA, infants may experience physiologic anemia at age 2 to 3 months (Lerner, 2011). During the last 3 months of gestation, maternal iron stores are transferred to the fetus. The newborn typically has 0.3 to 0.5 g of iron stores available. As the high hemoglobin concentration of the newborn decreases over the first 2 to 3 months, iron is reclaimed and stored. These stores may be sufficient for the first 6 to 9 months of life but will become depleted if iron supplementation does not occur.

### Take Note!

Maternal iron stores are transferred to the fetus throughout the last trimester of pregnancy. Infants born prematurely miss all or at least a portion of this iron store transfer, placing them at increased risk for iron deficiency anemia compared with term infants.

**FIGURE 25.3** **A.** Acrocyanosis. Note blueness of the hands. **B.** Mottling of the skin in a young infant.

## Immunologic System

Newborns receive large amounts of IgG through the placenta from their mothers. This confers immunity during the first 3 to 6 months of life for antigens to which the mother was previously exposed. Infants then synthesize their own IgG, reaching approximately 60% of adult levels at age 12 months (Feigin, Cherry, Kaplan, & Demmler-Harrison, 2009). IgM is produced in significant amounts after birth, reaching adult levels by 9 months of age. IgA, IgD, and IgE production increases very gradually, maturing in early childhood (Feigin et al., 2009).

## Psychosocial Development

Erik Erikson (1963) identifies the psychosocial crisis of infancy as Trust versus Mistrust. Development of a sense of trust is crucial in the first year, as it serves as the foundation for later psychosocial tasks. The parent or primary caregiver can have a significant impact on the infant's

development of a sense of trust. When the infant's needs are consistently met, the infant develops this sense of trust. But if the parent or caregiver is inconsistent in meeting the infant's needs in a timely manner, then the infant develops a sense of mistrust. Table 25.3 lists activities that promote a sense of trust in infancy.

## Cognitive Development

The first stage of Jean Piaget's theory of cognitive development is referred to as the sensorimotor stage (birth to 2 years) (Piaget, 1969). Infants learn about themselves and the world through their developing sensory and motor capacities. Infants' development from birth to 1 year of age can be divided into four substages within the sensorimotor stage: reflexes, primary circular reaction, secondary circular reaction, and coordination of secondary schemes. Cause and effect guides most of the cognitive development seen in infancy (see Table 25.3).

The concept of **object permanence** begins to develop between 4 and 7 months of age and is solidified by about 8 months of age (Piaget, 1969). If an object is hidden from the infant's sight, he or she will search for it in the last place it was seen, knowing it still exists. This development of object permanence is essential for the development of self-image. By age 12 months the infant knows he or she is separate from the parent or caregiver. Self-image is also promoted through the use of mirrors. By 12 months of age, infants can recognize themselves in the mirror. The 12-month-old will explore objects in different ways, such as throwing, banging, dropping, and shaking. He or she may imitate gestures and knows how to use certain objects correctly (e.g., puts phone to ear, turns up cup to drink, attempts to comb hair) (Piaget, 1969).

## Motor Skill Development

Infants exhibit phenomenal increases in their gross and fine motor skills over the first 12 months of life.

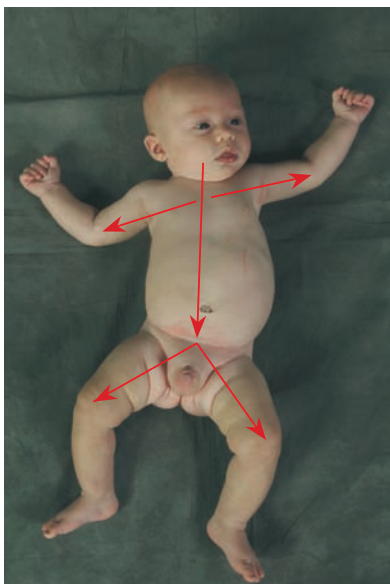

## Gross Motor Skills

The term "gross motor skills" refers to those that use the large muscles (e.g., head control, rolling, sitting, and walking). Gross motor skills develop in a **cephalocaudal** fashion (from the head to the tail) (Fig. 25.4). In other words, the baby learns to lift the head before learning to roll over and sit (Goldson & Reynolds, 2011). At birth, babies have poor head control and need to have their necks supported when being held. They can lift their heads only slightly while in a prone position. Over the next several months

**TABLE 25.3** DEVELOPMENTAL THEORIES

Theorist	Stage	Activities
<b>Erikson</b>	Trust vs. Mistrust (birth to 1 year)	Caregivers respond to the infant's basic needs by feeding, changing diapers, cleaning, touching, holding, and talking to the infant. This creates a sense of trust in the infant. As the nervous system matures, infants realize they are separate beings from their caregivers. Over time the infant learns to tolerate small amounts of frustration and trusts that although gratification may be delayed, it will eventually be provided.
<b>Piaget</b>	<p>Sensorimotor (birth to 2 years)</p> <p>Substage 1: use of reflexes (birth to 1 month)</p> <p>Substage 2: primary circular reactions (1 to 4 months)</p> <p>Substage 3: secondary circular reactions (4 to 8 months)</p> <p>Substage 4: coordination of secondary schemes (8 to 12 months)</p>	<p>Infant uses senses and motor skills to learn about the world. Reflexive sucking brings the pleasure of ingesting nutrition. Infant begins to gain control over reflexes and recognizes familiar objects, odors, and sounds.</p> <p>Thumb sucking may occur by chance; then the infant repeats it on purpose to bring pleasure. Imitation begins. Object permanence begins. Infant shows affect.</p> <p>Infant repeats actions to achieve wanted results (e.g., shakes rattle to hear the noise it makes). The infant's actions are purposeful but the infant does not always have an end goal in mind.</p> <p>Infants coordinate previously learned schemes with previously learned behaviors. They may grasp and shake a rattle intentionally or crawl across the room to reach a desired toy. Infant can anticipate events. Object permanence is fully present at about 8 months of age. The infant begins to associate symbols with events (e.g., waving goodbye means someone is leaving).</p>
<b>Freud</b>	Oral stage (birth to 1 year)	Pleasure is focused on oral activities: feeding and sucking.

Levin, J. M. Sondheimer, & R. R. Deterding (Eds.), *Current pediatric diagnosis and treatment* (20th ed.). New York: McGraw-Hill; and Piaget, J. (1969). *The theory of stages in cognitive development*. New York: McGraw-Hill.

**FIGURE 25.4** Gross motor skills develop in a cephalocaudal direction, fine motor skills in a proximodistal fashion.

the infant's motor skills progress at a dramatic rate. First the infant achieves head control, then the ability to roll over, sit, crawl, pull to stand, and, usually around 1 year of age, walk independently. Table 25.4 gives details on when the infant develops each specific gross motor skill. Progression of gross motor skills is illustrated in Figures 25.5 through 25.7.

**Take Note!**

Warning signs that may indicate problems with motor development include the following: arms and legs are stiff or floppy; child cannot support head at 3 to 4 months of age; child reaches with one hand only; child cannot sit with assistance at 6 months of age; child does not crawl by 12 months of age; child cannot stand supported by 12 months of age.

**Fine Motor Skills**

Fine motor development includes the maturation of hand and finger use. Fine motor skills develop in a

**TABLE 25.4** DEVELOPMENT OF GROSS MOTOR SKILLS IN INFANCY

Age	Gross Motor Skills
<b>1 month</b>	Lifts and turns head to side in prone position Head lag when pulled to sit Rounded back in sitting
<b>2 months</b>	Raises head and chest, holds position Improving head control
<b>3 months</b>	Raises head to 45 degrees in prone Slight head lag in pull-to-sit
<b>4 months</b>	Lifts head and looks around Rolls from prone to supine Head leads body when pulled to sit
<b>5 months</b>	Rolls from supine to prone and back again Sits with back upright when supported
<b>6 months</b>	Tripod sits
<b>7 months</b>	Sits alone with some use of hands for support
<b>8 months</b>	Sits unsupported
<b>9 months</b>	Crawls, abdomen off floor

<b>12 months</b>	Sits from standing position Walks independently

Adapted from Feigelman, S. (2011). The first year. In R. M. Kliegman, Stanton, B. F., St. Geme, J. W., Schor, N. F. & R. E. Behrman, H. B. Jenson, & B. Stanton (Eds.), *Nelson textbook of pediatrics* (19th ed.). Philadelphia, PA: Saunders.; and Shelov, S. P., & Altmann, T. R. (Eds.). (2009). *Caring for your baby and young child: Birth to age 5* (5th ed.). New York: Bantam Books.

**proximodistal** fashion (from the center to the periphery) (see Fig. 25.4). In other words, the infant first bats with the whole hand, eventually progressing to gross grasping, before being capable of fine fingertip grasping (Goldson & Reynolds, 2011) (Fig. 25.8). The newborn's hand movements are involuntary in nature, whereas the 12-month-old is capable of feeding himself or herself with a cup and spoon. By 12 months of age the infant should be able to eat with his or her fingers and assist with dressing (e.g., pushing an arm through the sleeve). Table 25.5 gives details on when the infant develops each specific fine motor skill.

### Sensory Development

Though hearing should be fully developed at birth, the other senses continue to develop as the infant matures. Though they mature at different rates, sight, smell, taste, and touch all continue to develop after birth.

### Sight

The newborn is nearsighted, preferring to view objects at a distance of 8 to 15 inches. Newborns prefer the human face to other objects and may even imitate the facial expressions made by those caring for them. In addition to human faces, newborns show a preference for certain objects, particularly those with contrasts such as black-and-white stripes. The newborn's eyes wander and occasionally cross. At 1 month of age the infant can recognize by sight the people he or she knows best. The infant will study objects within his or her visual range closely. The ability to fuse two ocular images into one cerebral picture (**binocularity**) begins to develop at 6 weeks of age and is well established by 4 months of age. Full color vision develops by 7 months of age, as do distance vision and the ability to track objects.

### Hearing

The newborn's hearing is intact at birth and as acute as that of an adult. Newborns prefer the sound of human

**FIGURE 25.5** When pulled to sit, an infant shows (A) significant head lag (newborn; 2 or 3 weeks old), (B) improving head control (2 months old), and (C) no head lag (4 months old).

voices to nonhuman sounds. By 1 month of age the infant can recognize the sounds of those he or she knows best.

## Smell and Taste

The sense of smell develops rapidly: the 7-day-old infant can differentiate the smell of his or her mother's breast milk from that of another woman and will preferentially turn toward the mother's smell. Newborns prefer sweet tastes to all others. This persists for several months, and eventually the infant will accept nonsweet flavors.

## Touch

The sense of touch is perhaps the most important of all the senses for newborn communication. Even the most immature infant responds to soothing stroking. The infant prefers soft sensations to coarse sensations. The infant dislikes rough handling and may cry. Holding, stroking, rocking, or cuddling calms infants when they are upset and makes them more alert when they are drowsy. Infants

learn to understand their caregiver's moods by the way they touch them.

### Take Note!

Warning signs that may indicate problems with sensory development include the following: young infant does not respond to loud noises; child does not focus on a near object; infant does not start to make sounds or babble by 4 months of age; infant does not turn to locate sound at age 4 months; infant crosses eyes most of the time at age 6 months.

## Communication and Language Development

For several months, crying is the only means of communication for the newborn and infant. The basic reason for crying is unmet needs. The 1- to 3-month-old baby coos, makes other vocalizations, and demonstrates differentiated crying. At 4 to 5 months of age, the infant makes simple vowel sounds, laughs aloud, performs "raspberries," and vocalizes in response to voices. The

**FIGURE 25.6** Development of sitting. **A.** At 4 months, the infant requires significant support. **B.** The 6-month-old infant sits in tripod fashion. **C.** The 8-month-old sits alone.

infant also responds to his or her own name and begins to respond to “no.” Between 4 and 7 months the infant begins to distinguish emotions based on tone of voice. Squealing and yelling begin around 6 months of age; these may be used to express joy or displeasure. At age 7 to 10 months, babbling begins and progresses to strings (e.g., mamama, dadada) without meaning. The infant at this age is also able to respond to simple commands. At 9 to 12 months of age the infant begins to attach meaning to “mama” and “dada” and starts to imitate other speech sounds. The average 12-month-old uses two or three recognizable words with meaning, recognizes objects by name, and starts to imitate animal sounds. At this age, the infant pays increasing attention to speech and tries to imitate words; he or she may also say “uh-oh.” The 12-month-old also babbles

with inflection (this babbling has the rhythm and timing of spoken language, but few of the “words” make sense) (Feigelman, 2011; Goldson & Reynolds, 2011).

It is very important for the parent or caregiver to talk to the infant in order for the infant to learn communication skills. Sometimes regression in language development occurs briefly when the child is focusing energy on other skills, such as crawling or walking. As long as the infant’s hearing is normal, language acquisition should continue to progress. Infants in bilingual families may “language mix” (uses some words from each language). This is considered to be a normal progression in language development for these children, but it makes it more difficult for the physician or nurse practitioner to determine delays in communication skills (De Houwer, 2009).

**FIGURE 25.7** Development of locomotion. **A.** At 4 months the infant pushes up from a prone position. **B.** At 8 months, the infant crawls with the abdomen off the floor. **C.** The infant pulls to stand by 10 months of age. **D.** The infant cruises along furniture or **(E)** takes steps with assistance at 10 to 11 months of age. **F.** The infant independently stands from a crouched position and walks around 12 months of age (plus or minus 3 months).

**FIGURE 25.8** Development of the pincer grasp. Note the gross (whole-hand) approach to grasping a small object (**A**), compared with the fine (thumb-to-finger) ability (**B**).

### Take Note!

Warning signs that may indicate problems in language development are as follows: infant does not make sounds at 4 months of age; infant does not laugh or squeal by 6 months of age; infant does not babble by 8 months of age; infant does not use single words with meaning at 12 months of age (mama, dada).

## Social and Emotional Development

The newborn spends much of the time sleeping, but by 2 months of age the infant is ready to start socializing. The infant exhibits a first real smile at age 2 months. He or

**TABLE 25.5** DEVELOPMENT OF FINE MOTOR SKILLS IN INFANCY

Age	Fine Motor Skills

Adapted from Feigelman, S. (2011). The first year. In R. M. Kliegman, Stanton, B. F., St. Geme, J. W., Schor, N. F. & R. E. Behrman, H. B. Jenson, & B. Stanton (Eds.), *Nelson textbook of pediatrics* (19th ed.). Philadelphia, PA: Saunders.; and Shelov, S. P., & Altmann, T. R. (Eds.). (2009). *Caring for your baby and young child: Birth to age 5* (5th ed.). New York: Bantam Books.

she spends a great deal of time while awake watching and observing what is going on around him or her. By about 3 months of age the infant will start an interaction with a caregiver by smiling widely and possibly gurgling. This prompts the caregiver to smile back and talk to the infant. The infant responds with more smiling, cooing, and gurgles as well as moving the arms and legs. The 3- to 4-month-old will also mimic the parent's facial movements, such as widening the eyes and sticking out the tongue. The baby may hesitate at first, but once the other person responds pleasantly to the infant, the infant engages and gets into the interaction. The infant may cry when the pleasant interaction stops. At 6 to 8 months of age the infant may enjoy socially interactive games such as patty-cake and peek-a-boo (Feigelman, 2011; Goldson & Reynolds, 2011).

## Stranger Anxiety

Around the age of 8 months the infant may develop **stranger anxiety**. The previously happy and very friendly infant may become clingy and whiny when approached by strangers or people not well known. Stranger anxiety is an indicator that the infant is recognizing himself or herself as separate from others. As the infant becomes more aware of new people and new places, he or she may view an interaction with a stranger as threatening and may start crying, even if the parent is right there. Family members whom the child sees infrequently, as well as others the child does not spend a lot of time with, should approach the infant calmly and slowly, with the parent in sight. Sometimes this will prevent a sudden crying spell (Feigelman, 2011; Goldson & Reynolds, 2011).

## Separation Anxiety

Separation anxiety may also start in the last few months of infancy. The infant becomes quite distressed when the parent leaves. The infant will eventually calm down and become engaged with the current caregiver. It is not until the infant is older that cognition and memory are sufficient for him or her to understand that the parent will come back (Feigelman, 2011; Goldson & Reynolds, 2011).

### Take Note!

Warning signs of possible problems with social/emotional development include the following: child does not smile at people at 3 months of age; child refuses to cuddle; child does not seem to enjoy people; child shows no interest in peek-a-boo at 8 months of age.

## Temperament

**Temperament** is an individual's nature; it is referred to as the "how" of behavior (Allard & Hunter, 2010). Temperament ranges from low or moderately active,

regular, and predictable to highly active, more intense, and less adaptable. These are all considered normal along a continuum. An infant's innate temperament affects the way he or she responds to the environment. As parents take note of their infant's usual activity level, how intensely he or she reacts with others and the environment, and how stimulated he or she becomes with interactions, they start to learn about their infant's temperament. The parent should note how adaptable and flexible the infant is as well as how predictable and persistent the baby is.

When parents are familiar with how the baby approaches life on a routine basis, they will be better able to recognize when the baby is not acting like himself or herself. Nurses can help parents interpret observations about their infant's temperament and recommend ways to support the infant's individual behavior. Some infants are slower to warm up than others; those infants should be approached slowly and calmly. Some infants exhibit increased levels of activity compared to quieter, more passive babies; those infants generally require more direct play with the parent or caregiver and will be the type of older infant who is in constant motion. Some infants are loud and some are not. The quiet infant may become overwhelmed with excessive stimulation, whereas the very active baby may need additional stimulation to be satisfied (Child Development Institute, 2010). Becoming familiar with the infant's temperament also helps the parents describe the best approach to the infant by others (e.g., child care workers or health care professionals).

## Cultural Influences on Growth and Development

Many cultural differences have an impact on growth and development. For instance, certain ethnic groups tend to be shorter than others because of their genetic makeup (Ferry, 2010). These children will not grow to be as tall as those of another ethnic background. Cultural feeding practices in some cultures may lead to overweight in some children. Some cultures and certain religions advocate vegetarianism; those children need nutritional assessment to ensure they are getting enough protein intake for adequate growth.

Parenting styles and health promotion behaviors can also be significantly influenced by culture. Parents and extended family are the most significant influences in an infant's life in most cultures. Certain cultures place a high value on independence and may encourage their infants to develop quickly, while other cultures "baby" their infants for longer periods. In most cultures the mother takes primary responsibility for caring for the child, but in some cultures, major health-related decisions may be deferred to the father or grandparents.

Health beliefs are often strongly influenced by an individual's religious or spiritual background. Sometimes this creates conflict in the health care setting when the health providers have a different value system than that of the infant's family.

In some cultures infants and children share a bed with their parents. When an infant or child is hospitalized and is accustomed to sleeping with the parents, it may be difficult and distressing for him or her to try to sleep alone.

The nurse should explore the family's cultural practices related to growth and development. Usually these practices are not harmful and can be supported by the health care team, but safety must always be considered. The nurse should not make assumptions about a family's cultural practices based on their skin color, accent, or name; rather, the nurse should perform an adequate assessment (Leininger & MacFarland, 2006).

### Take Note!

Many communities now include people from a variety of cultures, so it is important for nurses to practice transcultural nursing (nursing care that is directed by cultural aspects and that respects the individual's differences). Many nurse researchers are exploring the cultural aspects of health care and the impact that cultural diversity has upon health.

*Refer back to Allison Johnson, who was introduced at the beginning of the chapter. What developmental milestones would you expect Allison to have reached by this age? How would this be different if Allison had been born 6 weeks premature?*

## THE NURSE'S ROLE IN NEWBORN AND INFANT GROWTH AND DEVELOPMENT

Growth and development affect every aspect of the infant's life. As infants progress through various stages of development, they do so in a predictable fashion. Growth and development are sequential and orderly, though some children develop at faster rates than others. It is important for the nurse to understand growth and development. Health care visits through infancy often focus primarily on **anticipatory guidance** (educating parents and caregivers about what to expect in the next phase of development). The purpose of anticipatory guidance is to give parents the tools they need to support their infant's development in a safe fashion.

Hospital nurses also need to use their knowledge of growth and development when caring for ill infants. Hospitalization often requires the infant to be confined

to the crib or the hospital room. Nurses must support growth and development within the constraints imposed by the child's illness.

## NURSING PROCESS OVERVIEW

After the infant's current growth and development status has been assessed, problems related to growth and development may be identified. The nurse may then identify one or more nursing diagnoses, including:

- Ineffective breastfeeding
- Risk for disproportionate growth
- Imbalanced nutrition, less than body requirements
- Risk for impaired parent/infant attachment
- Delayed growth and development
- Risk for caregiver role strain

Nursing care planning for the infant with growth and development issues should be individualized based on the infant's and family's needs. Nursing Care Plan 25.1 (p. 00) can be used as a guide in planning nursing care for the infant with a growth and development problem. The nurse may choose the appropriate nursing diagnoses from the plan and individualize them as needed. The nursing care plan is intended to serve as a guide, not as an all-inclusive growth and development care plan.

## Promoting Healthy Growth and Development

Adding a new person to the family produces both excitement and anxiety. Newborns are completely reliant upon their parents or caregivers to fill every need. It is quite a burden and precious responsibility that new parents are taking on. Many parents read the latest books about caring for newborns, while others rely on information received from family and friends. Newborns and their mothers spend only a short time in the hospital after delivery, so it is very important that parents can care for their newborn and know when to call the primary care provider with concerns.

Periodic screening for adequate growth and development is recommended by the American Academy of Pediatrics (AAP) for all infants and children. The prevention of devastating disease is another priority for infants and children. The AAP and the Advisory Committee on Immunization Practices (ACIP) have made recommendations for immunization schedules. Immunizations are a very important part of the newborn and infant's health visits. Nurses caring for newborns and infants should be familiar with the recommended infant/child periodic screenings (check-ups) as well as the current immunization schedule (see Chapter 31 for further information on immunizations).

## NURSING CARE PLAN 25.1

## Growth and Development Issues in the Newborn and Infant

**NURSING DIAGNOSIS:** Breastfeeding, ineffective, related to lack of exposure, misconceptions, or knowledge deficit as evidenced by first baby, mother's verbalization, or nursing observations

**Outcome Identification and Evaluation**

Mother/infant dyad will experience successful breastfeeding: *infant will latch on, suck and swallow at the breast; mother will not experience sore nipples.*

**Interventions: Promoting Effective Breastfeeding**

- Educate mother on recognition of and response to infant hunger cues *to promote on-cue breastfeeding, which will establish milk supply.*
- Educate mother on appropriate diet and fluid intake *to ensure ability to manufacture adequate supply of breast milk.*
- Demonstrate breastfeeding positions with infant at the breast *(appropriate positioning increases probability of successful latch).*
- Assess infant's latch technique, sucking motion, and audible swallowing *(an appropriately latched infant will take most of the areola in the mouth, suck in spurts, and demonstrate audible swallowing).*
- Assess infant voiding/stool patterns: *at least six voids per day and passage of stool ranging from one or more per day to one every several days is a normal pattern for breastfed infants.*
- Assess infant weight gain: *gain of 15 to 30 g per day after the second week of life indicates infant is receiving appropriate nutrition.*
- Assess mother's nipples for redness or soreness; *if infant appropriately latches on, nipples will not become sore.*

**NURSING DIAGNOSIS:** Risk for altered growth pattern (risk factors: caregiver knowledge deficit, first infant, premature infant, or maladaptive feeding behaviors)

**Outcome Identification and Evaluation**

Infant will demonstrate adequate growth and appropriate feeding behaviors: *steady increases in weight, length, and head circumference; infant feeds appropriately for age.*

**Interventions: Promoting Adequate Growth**

- Observe mother/infant dyad breastfeeding or bottle-feeding *to determine need for further education or identify infant difficulties with feeding.*
- Educate mother about appropriate breastfeeding or bottle-feeding *so that mother is aware of what to expect in normal feeding pattern.*
- When infant is old enough, provide education about addition of solid foods, spoon and cup feeding: *after 6 months of age breast milk or formula needs to be supplemented with a variety of foods.*
- Determine need for additional caloric intake if necessary *(premature infants and infants with chronic illnesses or metabolic disorders often need adjustments in caloric intake to demonstrate adequate or catch-up growth).*
- Obtain daily weights if hospitalized (weekly if outpatient) and weekly length and head circumference *to determine whether feeding pattern is sufficient to promote adequate growth.*

## NURSING CARE PLAN 25.1

**Growth and Development Issues in the Newborn and Infant** (continued)

**NURSING DIAGNOSIS:** Nutrition, altered, less than body requirements, related to possible ineffective feeding pattern or inadequate caloric intake as evidenced by failure to gain weight or by inadequate increases in weight, length, and head circumference over time

**Outcome Identification and Evaluation**

Infant will take in adequate nutrients using effective feeding pattern: *infant will demonstrate adequate weight gain (15 to 30 g per day) and steady increases in length and head circumference.*

**Interventions: Promoting Adequate Nutritional Intake**

- Assess current feeding pattern and daily intake *to determine areas of concern.*
- Increase frequency of breastfeeding or volume of bottle-feeding *if needed to meet caloric needs.*
- Introduce solid foods on age-appropriate schedule: *introducing solids at the right time improves the chances that the child will learn to take solid foods.*
- Limit juice intake or discontinue altogether (*juice has little nutritive value and displaces nutrients from breast milk or formula.*)
- Use human milk fortifier (if ordered) *to increase caloric density of breast milk.*
- Increase caloric density of formula (if ordered) by mixing to a more concentrated level or with additives (fats or carbohydrates) *to provide increased calories needed to support adequate growth.*
- If infant is taking solids already, choose higher-calorie foods *to maximize nutrient intake.*

**NURSING DIAGNOSIS:** Parent/infant attachment, altered, risk for (risk factors: premature infant, parental knowledge deficit about normal newborn activity and care, infant with difficult temperament or medical problems)

**Outcome Identification and Evaluation**

Parent and infant will demonstrate appropriate attachment via *eye contact, parental response to infant cues, parental verbalization of caring for infant, infant response to parent's caretaking behaviors.*

**Interventions: Encouraging Appropriate Parent-Infant Attachment**

- Assess parent's response to infant cues *to determine degree of attachment and level of parent's knowledge about infant care.*
- Assess infant's response to parent's caretaking behaviors *to determine degree of attachment.*
- Determine infant's temperament *to counsel parent effectively about responses appropriate for that type of temperament.*
- Encourage *en face* positioning for holding or feeding the young infant *to encourage give-and-take response between infant and parent.*
- Encourage parent to meet infant's needs promptly and with affection *to promote sense of trust in the infant.*
- Reinforce parent's attempts at improving attachment with infant (*positive reinforcement naturally encourages appropriate behaviors.*)

(continued)

## NURSING CARE PLAN 25.1

**Growth and Development Issues in the Newborn and Infant** (continued)

**NURSING DIAGNOSIS:** Growth and development, altered, related to speech, motor, psychosocial, or cognitive concerns as evidenced by delay in meeting expected milestones

**Outcome Identification and Evaluation**

Development will be maximized: *infant will make continued progress toward attainment of developmental milestones.*

**Interventions: Maximizing Development**

- Perform developmental evaluation of the infant to determine infant's current level of functioning.
- Offer age-appropriate play, activities, and toys to encourage further development.
- Carry out interventions as prescribed by developmental specialist, physical therapist, occupational therapist, or speech therapist (*repeated exposure to the activities or exercises is needed to make developmental progress*).
- Provide support to parents of infants with developmental concerns, *as developmental progress can be slow and it is difficult for families to stay motivated and maintain hope.*

**NURSING DIAGNOSIS:** Caregiver role strain, risk for (risk factors: first baby, knowledge deficit about infant care, lack of prior exposure, fatigue if premature, ill, or developmentally delayed infant)

**Outcome Identification and Evaluation**

Parent will experience competence in role: *will demonstrate appropriate caretaking behaviors and verbalize comfort in new role.*

**Interventions: Preventing Caregiver Role Strain**

- Assess parent's knowledge of newborn/infant care and the issues that arise as a part of normal development to determine parent's needs.
- Provide education on normal newborn/infant care so that parents have the knowledge they need to appropriately care for their new baby.
- Provide anticipatory guidance related to normal infant development to prepare parents for what to expect next and how to intervene.
- Encourage respite for parents (*even a few hours away from the demands of an infant's care can rejuvenate the parents*).

**NURSING DIAGNOSIS:** Injury, risk for (risk factors: developmental age, infant curiosity, rapidly progressing motor abilities)

**Outcome Identification and Evaluation**

Infant safety will be maintained: *infant will remain free from injury.*

**Interventions: Preventing Injury**

- Encourage car seat safety to decrease risk of injury related to motor vehicles.
- Childproof home: *as infant becomes more mobile, he or she will want to explore everything, increasing risk of injury.*

## NURSING CARE PLAN 25.1

**Growth and Development Issues in the Newborn and Infant** (continued)

- Parents should have the Poison Control Center phone number available: *should an accidental ingestion occur, Poison Control can give parents the best advice for appropriate intervention.*
- Never leave an infant unattended in the sink, bathtub, or swimming pool to *prevent drowning.*
- Teach parents first aid measures and infant CPR to *minimize consequences of injury should it occur.*
- Parents should watch the infant at all times (*no amount of childproofing can replace the watchful eye of a caring parent*).

### Promoting Growth and Development Through Play

Experts in child development and behavior have said repeatedly that play is the work of children. Infants practice their gross and fine motor skills and language through play (Goldson & Reynolds, 2011). Play is a natural way for infants and children to learn. Play is critical to infant development, as it gives infants the opportunity to explore their environment, practice new skills, and solve problems. The newborn prefers interacting with the parent to toys. Parents can talk to and sing to their newborns while participating in the daily activities that infants need, such as feeding, bathing, and changing diapers. Newborns and young infants love to watch people's faces and often appear to mimic the expressions they see.

As infants become older, toys may be geared toward the motor skills or language skills that the child is developing. Parents can promote fine motor development in infants by providing age-appropriate toys. For example, a rattle that a young infant can hold promotes reaching and attaining. The older infant builds fine motor skills by stacking cups or placing smaller toys inside of larger ones. Gross motor skills are reinforced and practiced over and over again when the infant wants to reach something he or she is interested in.

When playing with toys, the infant usually engages in **solitary play**; he or she does not share with other infants or directly play with other infants (Feigelman, 2011; Goldson & Reynolds, 2011). A wide variety of toys are available for infants, but infants often enjoy the most basic ones, such as plastic containers of various shapes and sizes, soft balls, and wooden or plastic spoons.

Books are also very important toys for infants. Reading to all ages of infants is appropriate, and the older infant develops fine motor skills by learning to turn book pages.

Table 25.6 lists age-appropriate toys.

### Promoting Early Learning

Research has shown that reading aloud and sharing books during early infancy are critical to the development of neural networks that are important in the later tasks of reading and word recognition. Reading books increases listening comprehension. Infants demonstrate their excitement about picture books by kicking and waving their arms and babbling when looking at them. At 6 to 12 months, the infant reaches for books and brings them to the mouth. Over time, reading leads to acquisition of language skills. Reading picture books and simple stories to infants starts a good habit that should be continued throughout childhood (Zuckerman, 2009).

### Promoting Safety

Hundreds of children younger than 1 year of age die each year as a result of injury (AAP, 2012d). As infants become more mobile, they risk injury from falls down stairs and off chairs, tables, and other structures. Curiosity leads the infant to explore potentially dangerous items, such as electrical outlets, hot stove or furnace vents, mop buckets, and toilets. Since infants explore so much with their mouths, small objects or hard foods pose a choking hazard. The infant will invariably pick up any accessible object and bring it to the mouth. With increasing dexterity, poisoning from medications, household cleaning products, or other substances also becomes a problem.

### Safety in the Car

Motor vehicle accidents are one source of injury, particularly if the infant is improperly restrained. Infants should never be transported in a motor vehicle without proper restraint. Infant car seats should face the rear of the car until the infant is 12 months of age and weighs 20 pounds (AAP, 2012b). The car seat should be secured tightly in the center of the back seat. The infant should

TABLE 25.6

APPROPRIATE TOYS FOR NEWBORNS AND INFANTS

Age	Appropriate Toys
<b>Newborn to</b>	<ul style="list-style-type: none"> <li>• Mobile with contrasting colors or patterns</li> </ul>
<b>1 month</b>	<ul style="list-style-type: none"> <li>• Unbreakable mirror</li> <li>• Soft music via tape or music box</li> <li>• Soft, brightly colored toys</li> </ul>
<b>1 to 4 months</b>	<ul style="list-style-type: none"> <li>• Bright mobile</li> <li>• Unbreakable mirror</li> <li>• Rattles</li> <li>• Singing by parent or caregiver, varied music</li> <li>• High-contrast patterns in books or images</li> </ul>
<b>4 to 7 months</b>	<ul style="list-style-type: none"> <li>• Fabric or board books</li> <li>• Different types of music</li> <li>• Easy-to-hold toys that do things or make noise (fancy rattles)</li> <li>• Floating, squirting bath toys</li> <li>• Soft dolls or animals</li> </ul>
<b>8 to 12 months</b>	<ul style="list-style-type: none"> <li>• Plastic cups, bowls, buckets</li> <li>• Unbreakable mirror</li> <li>• Large building blocks</li> <li>• Stacking toys</li> <li>• Busy boxes (with buttons or knobs that make things happen)</li> <li>• Balls</li> <li>• Dolls</li> <li>• Board books with large pictures</li> <li>• Toy telephone</li> <li>• Push-pull toys (older infants)</li> </ul>

Adapted from Schuman, A. T. (2007). The ABCs of toy safety: More than just child's play. *Contemporary Pediatrics*, 24(7), 49–57, 64; and Shelov, S. P., & Altmann, T. R. (Eds.). (2009). *Caring for your baby and young child: Birth to age 5* (5th ed.). New York: Bantam Books.

never be placed in a front seat that is equipped with an airbag.

Infants should never be left unattended in a motor vehicle. The temperature rises very quickly inside a closed vehicle, and an infant can suffocate from heat in a closed vehicle in the summer. Even during cooler weather, the heat generated within a closed vehicle can reach three to five times the exterior temperature. Kidnapping is also a concern if the baby is left unattended in a vehicle. Additional information on car safety can be found on [thePoint](http://thePoint.lww.com/ricci-kyle2e) at <http://thePoint.lww.com/ricci-kyle2e>.

## Safety in the Home

The baby's crib should have a firm mattress that fits snugly in the crib on a secure support. The distance between crib slats should be  $2\frac{3}{8}$  inches or less to prevent injury (Safe Kids Worldwide, 2009). All crib edges should be smooth. Only well-fitting crib sheets should be used, not sheets intended for large beds. Crib side rails should always be raised when the parent is not right next to the crib. Additional information about crib and playpen

safety can be found on [thePoint](http://thePoint.lww.com/ricci-kyle2e) at <http://thePoint.lww.com/ricci-kyle2e>.

Even before the infant can roll over, he or she wiggles and pushes with the feet. The infant can easily fall from a changing table, sofa, or crib with the side rails down, so the infant should never be left unattended on any surface. If infant seats, bouncy seats, or swings are used, the infant should always be restrained in the seat with the appropriate straps.

The AAP (2012c) does not recommend the use of infant walkers, because the walker may tip over and the baby may fall out of it or the infant may fall down the stairs in it. Walkers allow infants access to things they may not otherwise be capable of reaching until they are able to walk alone, such as hot stoves and items on the edge of the countertop.

As the infant becomes more mobile, learning to crawl and walk, new safety issues arise. Safety gates should be used at the tops and bottoms of stairways. Gates may also be used to block curious infants from rooms that may pose physical danger to them because of sharp-edged furniture or decorative objects. Electrical

outlets should be covered with approved safety covers. Cabinets and drawers should be secured with child safety latches. Medications, household cleaning supplies, and other potentially hazardous substances should be stored completely out of reach of infants (AAP, 2012d).

Choking is a risk because infants immediately bring small items to the mouth for exploration. To avoid choking, recommend the following to parents:

- Use only toys recommended for children 0 to 12 months of age.
- Avoid stuffed animals with eyes or buttons that can be dislodged by the persistent infant.
- Keep the floor free of small items (accidentally dropped coins, paper clips, straight pins).
- Avoid feeding popcorn, nuts, carrot slices, grapes, and hot dog pieces to infants.

Suffocation is also a risk for infants. Cribs should not have pillows, comforters, stuffed animals, or other soft items in them. Keep plastic bags of any size away from infants. Avoid the risk of strangulation by keeping window blind and drapery cords out of the infant's reach (AAP, 2012c, 2012d).

Though no safety measure is as effective as close supervision by a watchful parent or caregiver, the aforementioned safety measures can be critical to the infant's well-being.

## Safety in the Water

Infants can drown in a very small amount of water. Never leave an infant unattended in the sink, a baby bathtub or standard bathtub, a swimming or wading pool, or any other body of water, even if it is quite shallow. The bathroom door should be kept closed and the toilet lid down. Water should be emptied from tubs, pails, or buckets immediately after use. If the family has a swimming pool, a locked fence or locked screen enclosure should surround it. Exterior doors should be kept locked to prevent the older infant from wandering out to the pool (AAP, 2012d). The

AAP recommends that parents use caution when enrolling their infant in an aquatic or swim program. Research has not sufficiently demonstrated that water survival skills taught to infants are effective (AAP, 2010). Completing an aquatic program does not decrease the risk of drowning; vigilant supervision is still always required.

*Remember Allison Johnson, the infant described in the beginning of the chapter? What anticipatory guidance related to safety would you provide to Allison's parents?*

## Promoting Nutrition

Adequate nutrition is essential for growth and development. Breastfeeding and bottle-feeding of infant formula are both acceptable means of nutrition in the newborn and infant. Breast milk or formula supplies all of the infant's daily nutritional requirements until 4 to 6 months of age, at which time solid foods may be introduced (Shelov & Altmann, 2009).

## Cultural Factors

Many dietary practices are affected by culture, both in the types of food eaten and in the approach to progression of infant feeding. Some ethnic groups tend to be lactose intolerant (particularly blacks, Native Americans, and Asians); therefore, alternative sources of calcium must be offered. Explore the cultural practices of the family related to infant feeding so that you can support the family's cultural values.

## Nutritional Needs

Newborns and infants are experiencing tremendous growth and need diets that support these rapid changes. Table 25.7 compares fluid and caloric needs in the newborn and infant.

**TABLE 25.7** NUTRITIONAL REQUIREMENTS

Nutritional Requirements	Newborn	Infant
<b>Fluid</b>	140–160 mL/kg/day	100 mL/kg/day for first 10 kg 50 mL/kg/day for next 10 kg
<b>Calories</b>	105–108 kcal/kg/day	1 to 6 months: 108 kcal/kg 6 to 12 months: 98 kcal/kg

Adapted from Johns Hopkins Hospital, Arcara, K., & Tschudy, M. (2012). *The Harriet Lane handbook* (19th ed.). St. Louis, MO: Mosby.

## Breastfeeding

The NAPNAP, the AAP, the American College of Obstetrics and Gynecology, the American Dietetic Association, and the U.S. Breastfeeding Committee of the Department of Health and Human Services all recommend breastfeeding as the natural and preferred method of newborn and infant feeding (NAPNAP, 2007). In their position statement on breastfeeding (2007), NAPNAP identifies “human milk as superior to all substitute feeding methods.” Breast milk provides complete infant nutrition.

Breastfeeding or feeding of expressed human milk is recommended for all infants, including sick or premature newborns (with rare exceptions). The exceptions include infants with galactosemia, maternal use of illicit drugs and a few prescription medications, maternal untreated active tuberculosis, and maternal HIV infection in developed countries.

Data from the Centers for Disease Control and Prevention’s (CDC) *Breastfeeding Report Card – United States, 2010* indicate that in 2010 75% of US women breastfed in the early postpartum period, 43% of infants were breastfeeding at 6 months of age, and only 22.4% were still breastfeeding at 1 year of age (CDC, 2010). Even partial breastfeeding is helpful and offers some of the health benefits of breastfeeding. Pediatric nurses in the community and the hospital are in an excellent position to promote and support breastfeeding.

### BREAST MILK COMPOSITION

Breast milk includes lactose, lipids, polyunsaturated fatty acids, and amino acids. The ratio of whey to casein protein in breast milk makes it readily digestible. The high concentration of fats and the balance of amino acids are believed to contribute to proper myelination of the nervous system. The concentration of iron in breast milk is less than that of formula, but the iron has increased bioavailability and is sufficient to meet the infant’s requirements for the first 4 to 6 months of life. Additionally, immunologic protection is transferred from mother to infant via breast milk and maternal–infant bonding is promoted. Refer to chapter 18 for additional information related to the composition of colostrum, transitional milk, and established breast milk.

### BREASTFEEDING TECHNIQUE

Breastfeeding mothers may not have established adequate breastfeeding prior to leaving the hospital after birth of the newborn. The pediatric nurse may encounter an infant–mother dyad experiencing difficulty with breastfeeding for a variety of reasons. Thus, the pediatric nurse must be competent in counseling the breastfeeding mother.

Before each breastfeeding session, mothers should wash their hands. It is not necessary to wash the breast in most cases. The mother should be positioned comfortably. A number of positions are possible, and they should be varied throughout the day (refer to chapter 18 for further information related to breastfeeding positions.). The mother

**FIGURE 25.9** Stroking the infant’s cheek with the nipple will elicit the rooting reflex.

may hold the breast in a “C” position if that is helpful to her. Stroke the nipple against the baby’s cheek (Fig. 25.9). This should stimulate the infant to open the mouth widely. Bring the baby’s wide-open mouth to the breast to form a seal around all of the nipple and areola (Fig. 25.10). When the infant is finished feeding, the mother can break the suction by inserting her finger into the baby’s mouth, thus releasing the mouth from the nipple (Fig. 25.11). This technique may prevent the infant from pulling on the nipple, which can lead to soreness and cracking.

Watching and listening to the infant feed may assess the adequacy of the baby’s latch technique. The infant who is properly latched on to the breast will suck rhythmically, taking most or all of the areola into the mouth. Audible swallowing should be heard as milk is delivered into the infant’s mouth. Assess the mother for pain

**FIGURE 25.10** Bringing the infant’s open mouth to the breast, rather than bringing the breast to the infant, helps the infant correctly latch on. The infant’s mouth forms a seal around all of the nipple and areola. Note the “C” position for holding the breast during latching on.

**FIGURE 25.11** Inserting the little finger between the areola and the infant's mouth helps to break the suction.

related to breastfeeding. She should not be in pain if the baby is latched on properly.

Establishment of breastfeeding is best achieved if the infant is allowed to feed on demand, whenever he or she is hungry. This may be as often as every 1½ to 3 hours in the neonate. Infants may feed for 10 to 20 minutes on each breast at each feeding, or longer on just one breast, alternating the breast at each feeding. Both methods are acceptable.

The breastfeeding infant does not need supplementation with water or formula even in the first few days of life as long as the newborn continues to wet six to eight diapers per day. After several days of age, the mother's milk supply should be well established. Adequate urine output and bowel movements, as well as continued weight gain in the infant, indicate the adequacy of breastfeeding. Working mothers in particular may need additional support from the nurse in order to continue breastfeeding if they desire to do so. Common problems occurring with breastfeeding are addressed in Teaching Guidelines 18.2 in chapter 18. Additional reliable resources for mothers who desire to breast-feed may be found on the websites listed on the Point.

### Bottle Feeding

For the mother who does not desire to, or cannot, breast-feed, commercially prepared formulas are available for bottle-feeding. These formulas are designed to imitate human milk. Standard infant formulas based on cow's milk provide 20 kcal/ounce and use lactose as a source for carbohydrates (Shelov & Altmann, 2009). Vegetable oil is used as the source of fat; whey or casein provides protein. Newer cow's milk-based formulas contain long-chain polyunsaturated fatty acids that are thought to

improve brain development. Ordinary cow's milk is not recommended for the first year of life.

#### Take Note!

Cow's milk does not provide an adequate balance of nutrients for the growing infant, especially iron. It may also overload the infant's renal system with inappropriate amounts of protein, sodium, and minerals.

Only formulas that are fortified with iron should be used. Iron stores that the infant received prenatally are depleted by 4 to 6 months of age. To prevent iron deficiency anemia, poor growth patterns, and impaired development, iron-fortified formulas must be used. The AAP recommends that commercial formulas provide 10 to 12 mg of iron per liter (Baker, Greer, & Committee on Nutrition, 2010). Commercial formulas also provide an adequate blend of essential vitamins and minerals.

### FEEDING PATTERNS

Infant feeding is an opportune time to establish good eating behaviors. The infant should always be held while being bottle-fed. Cradling in a semiupright position allows for additional bonding time, as the infant can see the caregiver's face while feeding (Fig. 25.12). Talking or singing during feeding time also increases bonding. As with breastfed infants, the bottle-fed infant should be fed on cue. Overfeeding with the bottle increases the incidence of gastroesophageal reflux, so families need to learn their baby's cues to hunger and satiety (Maqpool et al., 2011).

It is important to feed the baby when he or she displays signs of hunger. Crying is a late sign of hunger; earlier signs include making sucking motions, sucking on hands, or putting the fist to the chin. The infant should be burped

**FIGURE 25.12** Technique for bottle-feeding the infant.

two or three times per feeding, when he or she slows feeding or stops sucking. Newborns may only take a half-ounce to 1 ounce per feeding initially, working up to 2 to 3 ounces in the first few days. They need to feed about 6 to 10 times per day. The infant will gradually be able to ingest more formula per feeding. By 3 to 4 months of age, babies feed four or five times per day and take 6 to 7 ounces per feeding. Most infants will not require specific amounts per feeding; the infant should be fed until full. To prevent overfeeding, healthy bottle-fed infants should be allowed to self-regulate the amount of formula ingested per feeding. When the baby is satiated, he or she might fall asleep, spit out the nipple or formula, play with the nipple, or lie quietly, only sucking once in a while (Shelov & Altmann, 2009).

### TYPES OF FORMULAS AND BOTTLES

Parents may choose to use commercial formulas that are ready to feed or available as a concentrate or as a powder. Parents should follow the instructions for mixing the concentrate or powder to avoid dehydration or fluid and electrolyte imbalances. Ready-to-feed formula should be used as is and never diluted (Maqpool et al., 2011).

A wide variety of baby bottle and nipple types are available for formula feeding, and the choice is purely individual. Few infants require special nipples or bottles. Box 25.1 gives guidelines on preparation and storage of formula and care of bottles.

### SPECIAL FORMULAS

Special formulas may be needed for the infant who is allergic to a particular component of standard formula or

has a renal, hepatic, metabolic, or intestinal disorder. For example, lactose-free cow's milk formulas are available for the lactose-intolerant child. Formulas using soy as the base ingredient instead of whey or casein are also available. Soy formulas are necessary for infants with a milk allergy, and they may be appealing to the vegetarian family.

These special formulas are designed to meet the nutritional needs of infants, depending on the disorder. Infants who fail to gain weight may be placed on standard infant formula prepared to deliver a higher caloric density per ounce. Preterm infants (those born at less than 36 weeks' gestation) need adequate nutrition to exhibit catch-up growth. Good catch-up growth (quadrupling or even quintupling the birth weight) in the first year or so of life is critical for adequate head growth and avoidance of neurodevelopmental consequences. Premature infant follow-up formulas are designed to provide additional calories, protein, and a particular calcium-to-phosphorus ratio as well as the vitamins and minerals needed for adequate catch-up growth.

### Progressing to Solid Foods

After 6 months of age, infants usually require the nutrients available in solid foods in addition to their breast milk or formula. Progressing to feeding solid foods can be exciting and trying. Before solid foods are attempted, the infant should be assessed for readiness to progress. Parents need instruction in choosing appropriate solid foods and support in the progression process.

### ASSESSING INFANT READINESS

Several factors contribute to the appropriate timing of solid food introduction. The tongue extrusion reflex is necessary for sucking to be an automatic reaction—that is, when a nipple or other item is placed in the mouth, the tongue extrudes and sucking begins. This reflex disappears at about 4 to 6 months of age (Shelov & Altmann, 2009). Introducing solid food with a spoon prior to 4 to 6 months of age will result in extrusion of the tongue. The parent may think that the infant does not want the food and is spitting it out intentionally, but this is not the case; the infant simply must be mature enough to eat with a spoon (absence of extrusion reflex).

The ability to swallow solid food does not become completely functional until 4 to 6 months of age. Enzymes to appropriately digest food other than breast milk and formula are also not present in sufficient quantities until the age of 4 to 6 months.

Before the introduction of solid foods and the cup, the infant should be able to sit supported in a high chair. Solids should be fed with a spoon, with the infant in an upright position.

### CHOOSING APPROPRIATE SOLID FOODS

Iron-fortified rice cereal mixed with a small amount of breast milk or formula is a good choice for the first solid

#### BOX 25.1

#### PREPARATION AND STORAGE OF BOTTLES AND FORMULA

- Wash nipples and bottles in hot soapy water and rinse well OR
- Run nipples and bottles through the dishwasher.
- Store tightly covered ready-to-feed formula can after opening in refrigerator for up to 48 hours.
- After mixing concentrate or powdered formula, store tightly covered in refrigerator for up to 48 hours.
- Do not reheat and reuse partially used bottles. Throw away the unused portion after each feeding.
- Do not add cereal to the formula in the bottle.
- Do not sweeten formula with honey.
- Warm formula by placing bottle in a container of hot water.
- Do not microwave formula.

Adapted from Shelov, S. P., & Altmann, T. R. (Eds.). (2009). *Caring for your baby and young child: Birth to age 5* (5th ed.). New York, NY: Bantam Books

food. The cereal is easily digested and its taste is generally well accepted. The cereal should be quite thin at first; it can be mixed to a thicker consistency as the infant gets older. Once the feeding of cereal with a spoon is successful, other single foods may be introduced. The foods should be puréed to a smooth consistency, whether prepackaged “baby food” or puréed at home.

The introduction of one new food every 4 to 7 days is recommended (Hagan et al., 2008; Shelov & Altmann, 2009). This allows for identification of food allergies (Box 25.2). No salt, sugar, or other seasoning should be added to these first foods.

Generally, by 8 months of age the infant is ready for more texture in his or her foods. Soft, smashed table food without large chunks is appropriate. Finger foods such as Cheerios, soft green bean pieces, or soft peas may also be offered. Avoid hard foods that the infant may choke on. Strained, puréed, or mashed meats may be introduced at 10 to 12 months of age.

The cup should be introduced at 6 to 8 months of age. One ounce of breast milk or formula should be placed in the cup while the infant is learning. This will decrease the amount of mess should the cup be spilled. Old-fashioned sippy cups are generally acceptable for use, though older infants quickly learn to drink from an ordinary cup with assistance when they are thirsty. Newer “no-spill” sippy cups are not recommended for general home use. They require sucking much like a bottle and do not really encourage the child to learn cup

drinking. They should be reserved for use on long trips in the car or other instances in which spills should be avoided (Rychnovsky, 2000).

Fruit juice is unnecessary and should not be introduced until 6 months of age. If juice is given, it should be limited to 2 to 4 ounces per day. Fruit itself is much more nutritious than fruit juice. If infants are allowed to consume larger quantities of juice, it can displace important nutrients from breast milk or formula (AAP, 2007).

### PROMOTING HEALTHY EATING HABITS

Infants and children learn about food within a social context, so the family plays an important role in creating healthy eating habits. Families “model” eating behaviors; infants and children learn about eating through watching others. Lifelong eating patterns are often established in childhood, so it is important to emphasize healthy eating practices beginning in infancy. Parents should not let infants eat whatever they want (permissive feeding style); this will lead to fights over eating in the future. Infants may require as many as 20 exposures to a new food before it is accepted. On the other hand, infants should not be coerced into eating all that is provided (authoritarian feeding style). Forcing an infant to eat when he or she is full sets the child up for overeating in the future and may lead to more power struggles (Shelov & Altmann, 2009). Parents need to find a balance between the permissive and authoritarian feeding styles to establish lifelong healthy eating patterns in their children. By providing education about appropriate diet and feeding behaviors, the nurse can help the family to accomplish this goal.

#### BOX 25.2

##### FOODS TO AVOID IN INFANCY

- Honey
- Egg yolks and meats (until 10 months of age)
- Excessive amounts of fruit juice
- Foods likely to cause choking
  - Peanuts
  - Popcorn
  - Other small hard foods (e.g., raw carrot chunks)
  - Grapes and hot dog slices (must be cut in smaller pieces)
- Foods likely to result in allergic reaction
  - Citrus
  - Strawberries
  - Wheat
  - Cow’s milk
  - Egg whites
  - Peanut butter

Adapted from Brown, J. (2011). *Nutrition now* (6th ed.). Florence, KY: Wadsworth Publishing.

*Think back to Allison Johnson. What questions should you ask Allison’s parents related to her nutritional intake? What anticipatory guidance related to nutrition would be appropriate?*

### Promoting Healthy Sleep and Rest

Newborns sleep about 20 hours a day, waking frequently to feed and quickly returning to sleep. By 3 months of age, most infants sleep 7 to 8 hours per night without waking. They will continue to take about three naps a day. By 4 months of age the infant is more active and alert and may have more trouble going to sleep in the evening. Night waking may occur, but the infant should be capable of sleeping through the night and does not require a night feeding. By 12 months of age infants sleep 8 to 12 hours per night and take two naps per day (Feigelman, 2011).

Discuss safe sleeping practices with parents of newborns and infants; the baby should sleep on a firm mattress without pillows or comforters. The baby’s bed should be placed away from air conditioner vents, open windows, and open heaters. Sudden infant death syndrome (SIDS)

has been associated with prone positioning of newborns and infants, so the infant should be placed to sleep on the back (Shelov & Altmann, 2009). See Healthy People 2020.

### HEALTHY PEOPLE 2020 • 25-2

Objective	Nursing Significance
Increase the percentage of infants who are put down to sleep on their backs.	<ul style="list-style-type: none"> <li>• Begin teaching about “back to sleep” at prenatal or newborn visit.</li> <li>• Use each encounter with the young infant as an opportunity to reinforce the supine position for sleep.</li> </ul>
Healthy People Objectives based on data from <a href="http://www.healthypeople.gov">http://www.healthypeople.gov</a> .	

#### Take Note!

The AAP has determined that side sleeping is not as safe as supine sleeping.

In the newborn period, the primary caregiver should try to sleep when the baby is sleeping. Since newborns need to be fed every 1½ to 3 hours around the clock, parents may become exhausted quickly and are often eager for the infant to sleep through the night. Adding rice cereal to the evening bottle has not been proven to discourage night waking and is not recommended (Hagan et al., 2008). Provide support to parents of newborns and educate them on infant sleeping patterns.

It is important to establish a bedtime routine around 4 months of age due to the infant’s increased alertness and activity level. The baby who is 4 months or older needs a time of calming and relaxation before going to sleep. A consistent bedtime routine should be established, perhaps a bath followed by rocking, singing, or reading. The infant should fall asleep in his or her own crib rather than being rocked to sleep or held until sleeping and then put in the crib. After 4 months of age, infants must learn to soothe themselves back to sleep following night waking. Older infants may exhibit head banging as a form of self-soothing and use it to fall asleep at night. Night feedings are unnecessary at this age and will create a routine of further night waking that will be difficult to break (Hagan et al., 2008). Parents should minimize attention and stimulation provided during a night waking. Briefly checking on the infant to ascertain his or her safety, followed by placing the infant back in a lying position and telling him or her good night, is all that is needed. This may have to be repeated several times before the infant falls back to sleep. It is important to keep interactions brief during the night waking so that the infant learns to fall back to sleep on his or her own. Continued issues with night waking should be discussed with the infant’s primary care provider.

*What anticipatory guidance should you provide to Allison’s parents in relation to sleep?*

## Promoting Healthy Teeth and Gums

Healthy teeth and gums require proper oral hygiene and appropriate fluoride supplementation. Children older than 6 months of age who are at risk for developing dental caries and whose drinking water source contains less than 0.3 parts per million may require fluoride supplementation (Rozier, 2010). Excess fluoride ingestion can result in discoloration of the teeth (fluorosis). Early childhood dental caries can result from pooling of milk or juice around teeth and gums.

Before tooth eruption, parents should clean the child’s gums after feeding with a damp washcloth. After teeth have erupted, parents can continue to use a soft cloth for tooth cleaning and then eventually use a small soft-bristled toothbrush. Toothpaste is unnecessary in infancy. Infants should not be allowed to take milk or juice bottles to bed, as the high sugar content of the fluid in contact with the teeth all night leads to dental caries (see section on baby bottle mouth later in this chapter). Weaning from the bottle at age 12 to 15 months may help prevent dental caries. No-spill sippy cups have also been implicated in the development of dental caries and should be avoided. The American Academy of Pediatric Dentistry recommends that infants receive their first dental visit by the age of 1 year.

## Promoting Appropriate Discipline

Parenting requires ever-changing adaptations to the developing infant’s needs. Unconditional love, patience, and compassion must be balanced with the parents’ needs. **Discipline** refers to the molding of a child’s behavior through instruction, practice, and consistency. Discipline helps build self-esteem in children as well as sets standards for social interactions. The primary goal of discipline is to teach an infant limits. Discipline should be used to help the infant solve problems. The infant’s activities are based on the basic needs of food, security, warmth, love, and comfort. Misbehavior is the result of an unmet need, and the parents should respond accordingly.

As the infant is undergoing rapid changes in motor skills, safety needs increase. Nurses should encourage the parents to “childproof” their home so that the infant can develop physical skills without being at risk. In a childproof home, fewer restrictions need to be placed on the infant’s behavior, and he or she can explore.

Physical punishment or spanking should never be used in infancy. Infants are at increased risk for physical injury from spanking and cannot make the connection

between the spanking and the undesirable behavior. Providing a safe environment, redirection away from undesirable behaviors, and saying “no” in appropriate instances are far more effective. For example, when the infant is in potential danger (e.g., inserting a key into an electrical outlet, attempting to ingest a poisonous substance, or reaching into the toilet), the parent must use a firm but calm and brisk approach. If the infant knows the parent is serious, he or she will usually comply more quickly (AAP, 2012; Anderson, 2008).

Remaining calm, firm, and consistent is necessary. Immediacy is also an important component of appropriate discipline. The infant cannot make the connection between a subsequent punishment or discussion of behavior with the earlier event itself. Positive reinforcement should be used to support good behavior (Anderson, 2008).

## Addressing Child Care Needs

Many mothers work outside the home, there are many single-parent families, and many families live a distance away from relatives. In all of these circumstances, infants may need to be cared for outside the home, often in child care settings or home day care centers.

Parents contemplating child care must consider a number of factors. Do they want a sitter to come to their home? Will they use a traditional day care center or a home care situation with fewer children? How much can they afford? If families choose to use a freestanding day care center or a home-based day care center, they should make sure that the provider is appropriately licensed. Parents should feel comfortable with the caregiver-to-child ratio. Are the caregivers trained in infant CPR and first aid? Families may need to visit or interview several facilities before finding one that meets their requirements.

When an older infant is attending a child care situation for the first time, it may be helpful to visit the center once or twice beforehand so that the infant can get used to the caregivers from the comfort and security of the parent’s lap. Warn parents that separation anxiety in late infancy can cause a disturbing crying episode when the parent leaves. Reassure parents that the infant will not suffer harm due to the separation.

### Addressing Common Developmental Concerns

Parents commonly have multiple concerns during normal infant growth and development. Although most of these issues are not actual disease states or behavior problems, nurses must be aware of these issues to recognize them and to intervene appropriately.

## Colic

Healthy 6-week-old infants cry for a total of about 3 hours every day. Crying and fussing are more prevalent in the evenings. By age 12 weeks, the total amount of crying is about 1 hour per day, and infants are better able to soothe themselves by this age. **Colic** is defined as inconsolable crying that lasts 3 hours or longer per day and for which there is no physical cause. It typically resolves by 3 months of age, coinciding with the age at which infants are better able to soothe themselves (e.g., by finger sucking). The cause of colic is thought to be problems in the gastrointestinal or neurologic system (probably system immaturity), temperament, or parenting style of the mother or father. Some parents are overly anxious or overly attentive or, at the other extreme, may not give the infant the attention he or she needs. Any of these may contribute to a baby’s fussing and crying.

Prolonged crying leads to increased stress among caregivers. Failure to stop the crying leads to frustration, and crying that prevents the parents from sleeping contributes to the exhaustion they are already experiencing.

Educate parents that normal crying increases by the time the infant is 6 weeks old and diminishes by about 12 weeks. When faced with a colicky baby, parents should develop a stepwise approach to checking that all of the infant’s basic needs are met. When these needs are met, attempts at soothing the infant may be used. Reducing stimulation may decrease the length of crying. Carrying the infant more may also be helpful. Some infants respond to the motion of an infant swing or a car ride. Vibration, white noise, or swaddling may also help to decrease fussing in some infants. Pacifiers can be soothing to babies who need additional nonnutritive sucking. Parents should try one intervention at a time, taking care not to stimulate the infant excessively in the process of searching for solutions. Nurses should provide ongoing support to the parents of a colicky infant and reassure them that this is a temporary condition that will resolve in time (Shelov & Altmann, 2009).

## Spitting Up

Spitting up (regurgitating small amounts of stomach contents) occurs in all infants, and a significant number of normal infants spit up excessively. Although spitting up after feeding is normal, it can be a cause of great concern to parents. Overfed babies who feed based on a parent-designed schedule and those who burp poorly are more likely to spit up. For some infants, the amount and frequency of spitting up are significant, and it may indicate gastroesophageal reflux.

Teach parents that feeding smaller amounts on a more frequent basis may help to decrease spitting-up episodes. Always burp the baby at least two or three times per feeding. Keep the baby upright for 30 minutes after feeding and do not lay the infant prone after feeding.

Avoid bouncing or excess activity immediately after feeding. Positioning in an infant seat compresses the stomach and is not recommended. When placing the baby in bed, position him or her on the side with the head of the bed slightly elevated (Shelov & Altmann, 2009).

Reassure parents that if the infant is wetting at least six diapers per 24 hours and gaining weight, the spitting up is normal. If the infant vomits one third or more of most feedings, chokes when vomiting, or experiences forceful emesis, the primary care provider should be notified.

## Thumb Sucking, Pacifiers, and Security Items

Infants demonstrate a clear need for nonnutritive sucking: even fetuses can be observed sucking their thumbs or fingers in utero. Thumb sucking is a healthy self-comforting activity. Infants who suck their thumbs or pacifiers often are better able to soothe themselves than those who do not. Studies have not shown that sucking either thumbs or pacifiers leads to the need for orthodontic braces unless the sucking continues well beyond the early school-age period. However, pacifier use has been associated with the increased incidence of otitis media, and hygiene is always a concern as pacifiers often fall on the floor (Marter & Agruss, 2007).

Infants may also become attached to a doll, stuffed animal, or blanket. Just like thumb sucking, the attachment item gives the infant the security to self-soothe when he or she is uncomfortable.

Families need to explore their feelings and cultural preferences about sucking habits and security items. Parents should not try to break the habit during a stressful time for the infant. When the infant is intensely trying to master a new skill such as sitting or walking, he or she may need the sucking or security item to self-soothe.

Pacifiers and security items can be physically taken away at some point, but the thumb is attached. The infant who has become attached to thumb sucking should not have additional attention drawn to the issue, as that may prolong thumb sucking.

Families of infants who use pacifiers may want to wean the infant from the pacifier when the child approaches 1 year of age (Sexton & Natale, 2009). This is the time when the need for additional sucking naturally decreases. Attempts to wean the child from a security blanket or toy should probably be reserved for after infancy (see Evidence-Based Practice 25.1).

## Teething

Discomfort is common as the tooth breaks through the periodontal membrane. Infants may drool, bite on hard objects, or increase finger sucking. Some infants may become very irritable, refuse to eat, and not sleep well. Fever, vomiting, and diarrhea are generally not considered a sign of teething but rather of illness.

Teething pain results from inflammation. Teach parents that application of cold may be soothing to the gums. The infant may chew on a cold teething ring, or parents can rub an ice cube wrapped in a washcloth on the gums. Over-the-counter topical anesthetics such as baby Orajel may also be helpful. Parents should apply the ointment correctly to the gums, avoiding the lips, as these ointments cause numbing. Occasionally, oral acetaminophen or ibuprofen may be given to relieve pain (Tinanoff, 2011).

*Refer back to 6-month-old Allison Johnson. List some common developmental concerns of 6-month-old infants. What anticipatory guidance related to these concerns would you provide to her parents?*

### EVIDENCE-BASED PRACTICE 25.1

#### BENEFITS AND RISKS OF PACIFIER USE

##### STUDY

The authors review a large number of recent randomized controlled research studies and meta-analyses related to pacifier use. The study results were then grouped according to results and consensus recommendations.

##### Findings

Upon analysis of the various research studies, the authors reached several conclusions. Pacifier use has been shown to lower the risk of sudden infant death syndrome (SIDS) when used at the time of sleep. Additional benefits include assisting preterm infants with the transition from tube to bottle feeding and the use of pacifiers to induce analgesia in infants up to 6 months of age. Potential risks include shortening of breastfeeding duration if a pacifier is used

before 1 month of age, increased incidence of otitis media when used after 6 months of age, and development of dental malocclusion with continued use after age 2 years.

##### Nursing Implications

In light of the potential risks and benefits of pacifier use, nurses must be prepared to provide parents with accurate information related to the use of pacifiers. Educate parents to avoid introduction of the pacifier until breastfeeding is well established (4 weeks of age), to use pacifiers only during periods of sleep, and to never force a pacifier on an infant or replace a pacifier in a sleeping infant's mouth. Additionally, parents should begin to wean the infant from the pacifier in late infancy (after 6 months of age).

## KEY CONCEPTS

- Infancy encompasses the period from birth to age 12 months.
- The infant exhibits tremendous growth, doubling the birthweight by 6 months of age and tripling it by 12 months of age.
- Most organ systems are immature at birth and develop and mature over the first year of life.
- Child development is orderly, sequential, and predictable, progressing in a cephalocaudal and proximodistal fashion.
- The infant is mastering the psychosocial task of Trust versus Mistrust.
- Cognitive development in infancy is sensorimotor; infants use their senses and progressing motor skills to master their environment.
- The 12-month-old babbles expressively and uses two or three words with meaning.
- Promotion of safety is of key importance throughout infancy.
- Breastfeeding is the natural and preferred method for infant feeding.
- Breastfed and bottle-fed infants should both be fed on cue rather than on a parent-designed schedule.
- Solid foods should be introduced at age 4 to 6 months. A spoon should be used to feed the infant, and rice cereal should be the first food. New foods should be introduced no more frequently than every 4 to 7 days.
- The cup may be introduced at 6 months of age. No-spill sippy cups are generally not recommended.
- Spitting up and colic are parts of normal development in the otherwise thriving infant and do not require medical intervention.

## MULTIPLE CHOICE QUESTIONS

- The mother of a 3-month-old boy asks the nurse about starting solid foods. What is the most appropriate response by the nurse?
  - "It's okay to start pureed solids at this age if fed via the bottle."
  - "Infants don't require solid food until 12 months of age."
  - "Solid foods should be delayed until age 6 months, when the infant can handle a spoon on his own."
  - "The tongue extrusion reflex disappears at age 4 to 6 months, making it a good time to start solid foods."
- The father of a 2-month-old girl is expressing concern that his infant may be getting spoiled. The nurse's best response is:
  - "She just needs love and attention. Don't worry; she's too young to spoil."
  - "Consistently meeting the infant's needs helps promote a sense of trust."
  - "Infants need to be fed and cleaned; if you're sure those needs are met, just let her cry."
  - "Consistency in meeting needs is important, but you're right, holding her too much will spoil her."
- Parents of an 8-month-old girl express concern that she cries when left with the babysitter. How does the nurse best explain this behavior?
  - Crying when left with the sitter may indicate difficulty with building trust.
  - Stranger anxiety should not occur until toddlerhood; this concern should be investigated.
  - Separation anxiety is normal at this age; the infant recognizes parents as separate beings.
  - Perhaps the sitter doesn't meet the infant's needs; choose a different sitter.
- The nurse is providing anticipatory guidance to the mother of a 6-month-old infant. What is the best instruction by the nurse in relation to the infant's oral health?
  - "Start brushing her teeth after all the baby teeth come in."
  - "Use a washcloth with toothpaste to clean her mouth."
  - "Clean your baby's gums, then new teeth, with a washcloth."
  - "Rinse your baby's mouth with water after every feeding."
- A 9-month-old infant's mother is questioning why cow's milk is not recommended in the first year of life as it is much cheaper than formula. What rationale does the nurse include in her response?
  - It is permissible to substitute cow's milk for formula at this age as he is so close to 1 year old.
  - Cow's milk is iron poor and does not provide the proper balance of nutrients for the infant.
  - As long as the mother provides whole milk, rather than skim, she can start cow's milk in infancy.
  - If the mother cannot afford the infant formula, she should dilute it to make it last longer.

## CRITICAL THINKING EXERCISES

- The mother of an 11-month-old boy who was born at 24 weeks' gestation is concerned about his size and motor skills. What information should the nurse provide?
- An infant's mother thinks there may be something wrong with him because "he spits up so much." What further information should the nurse obtain?
- If you determine that the infant in the question above is experiencing normal spitting up associated with his developmental age, develop a brief teaching plan to review with the mother.

## STUDY ACTIVITIES

- A mother brings her 9-month-old boy to the clinic for a well-child check-up. She has questions about feeding, speech, and walking. Develop a teaching plan of anticipatory guidance for the 9-month-old infant.
- Develop a safety plan for the 12-month-old infant.
- In the clinical setting, observe two infants of the same age, one who is developing appropriately for his or her age and one who is delayed. Note the similarities and differences between the two infants.

#### KEY TERMS

animism  
 echolalia  
 egocentrism  
 expressive language  
 food jag  
 individuation  
 parallel play  
 physiologic anorexia  
 receptive language  
 regression  
 separation  
 separation anxiety  
 sibling rivalry  
 telegraphic speech

# Growth and Development of the Toddler

## Learning Objectives

*Upon completion of the chapter, you will be able to:*

1. Define the key terms used in this chapter.
2. Explain normal physiologic, psychosocial, and cognitive changes occurring in the toddler.
3. Identify the gross and fine motor milestones of the toddler.
4. Demonstrate an understanding of language development in the toddler years.
5. Discuss sensory development of the toddler.
6. Demonstrate an understanding of emotional/social development and moral/spiritual development during toddlerhood.
7. Implement a nursing care plan to address common issues related to growth and development in toddlerhood.
8. Encourage growth and learning through play.
9. Develop a teaching plan for safety promotion in the toddler period.
10. Demonstrate an understanding of toddler needs related to sleep and rest, as well as dental health.
11. Develop a nutritional plan for the toddler based on average nutritional requirements.
12. Provide appropriate anticipatory guidance for common developmental issues that arise in the toddler period.
13. Demonstrate an understanding of appropriate methods of discipline for use during the toddler years.
14. Identify the role of the parent in the toddler's life and determine ways to support, encourage, and educate the parents about toddler growth, development, and concerns during this period.

*Jose Gonzales is a 2-year-old boy brought to the clinic by his mother and father for his 2-year-old check-up. During your assessment, you find that his weight is 30 pounds, height 33 inches, and head circumference 19.5 inches. As the nurse caring for him, assess Jose's growth and development, and then provide appropriate anticipatory guidance to the parents.*

### Words of Wisdom

Toddlers will take risks and make many mistakes, but remember that both are an essential part of their growth.

**The** toddler period encompasses the second 2 years of life, from age 1 year to age 3 years. This period is a time of significant advancement in growth and development for the child. It can also be quite a challenging time for parents. The theme during the toddler years is one of holding on and letting go. Having learned that parents are predictable and reliable, the toddler is now learning that his or her behavior has a predictable, reliable effect on others. The challenge is to encourage independence and autonomy while keeping the curious toddler safe.

### Take Note!

As more grandparents are assuming the primary caregiver role for their grandchildren, nurses should be alert to the possibility of increased stress that is placed upon the older caregiver, particularly during the active and sometimes trying years of toddlerhood (Bigbee et al., 2011).

## GROWTH AND DEVELOPMENT OVERVIEW

Infancy is a time of intense growth and development. Both physical growth and acquisition of new motor skills slow somewhat during the toddler years. Refinement of motor skills, continued cognitive growth, and acquisition of appropriate language skills are of prime importance during toddlerhood. The nurse uses the knowledge of normal toddler development as a roadmap for behavioral assessment of the 1- to 3-year-old child.

### Physical Growth

The toddler's height and weight continue to increase steadily, though the increase occurs at a slower velocity compared to infancy. Toddler gains in height and weight tend to occur in spurts, rather than in a linear fashion (Fig. 26.1). The average toddler weight gain is 3 to 5 pounds per year. Length/height increases by an average of 3 inches per year. Toddlers generally reach about half of their adult height by 2 years of age. Head circumference increases about 1 inch from when the child is between 1 and 2 years of age, then increases an average of a half-inch per year until age 5. The anterior fontanel should be closed by the time the child is 18 months old. Head size becomes more proportional to the rest of the body near the age of 3 years (Hagan, Shaw, & Duncan, 2008).

### Organ System Maturation

Though not as pronounced as the changes occurring during infancy, the toddler's organ systems continue to grow and mature in their functioning. Significant functional

**FIGURE 26.1** The typical toddler appearance is that of a rounded abdomen, a slight swayback, and a wide-based stance.

changes occur within the neurologic, gastrointestinal, and genitourinary systems. The respiratory and cardiovascular systems undergo changes as well.

## Neurologic System

Brain growth continues through toddlerhood, and the brain reaches about 80% of its adult size by 3 years of age (Zero to Three, 2011). Myelination of the brain and spinal cord continues to progress and is complete around 24 months of age. Myelination results in improved coordination and equilibrium as well as the ability to exercise sphincter control, which is important for bowel and bladder mastery. Integration of the primitive reflexes occurs in infancy, allowing for the emergence of the protective reflexes near the end of infancy or early in toddlerhood. The forward or downward parachute reflex is particularly helpful when the child starts to toddle. Rapid increase in language skills is evidence of continued progression of cognitive development.

## Respiratory System

The respiratory structures continue to grow and mature throughout toddlerhood. The alveoli continue to increase in number, not reaching the adult number until about 7 years of age. The trachea and lower airways continue to grow but remain small compared with the adult. The tongue is relatively large in comparison to the size of the mouth. Tonsils and adenoids are large and the Eustachian tubes are relatively short and straight.

## Cardiovascular System

The heart rate decreases and blood pressure increases in toddlerhood. Blood vessels are close to the skin surface and so are compressed easily when palpated.

## Gastrointestinal System

The stomach continues to increase in size, allowing the toddler to consume three regular meals per day. Pepsin production matures by 2 years of age. The small intestine continues to grow in length, though it does not reach the maximum length of 2 to 3 meters until adulthood. Stool passage decreases in frequency to one or more per day. The color of the stool may change (yellow, orange, brown, or green) depending on the toddler's diet. Since the toddler's intestines remain somewhat immature, the toddler often passes whole pieces of difficult-to-digest food such as corn kernels. Bowel control is generally achieved by the end of the toddler period.

## Genitourinary System

Bladder and kidney function reach adult levels by 16 to 24 months of age. The bladder capacity increases, allowing the toddler to retain urine for increased periods of times. Urine output should be about 1 mL/kg/hour. The urethra remains short in both the male and female toddler, making them more susceptible to urinary tract infections compared to adults.

## Musculoskeletal System

During toddlerhood, the bones increase in length and the muscles mature and become stronger. The abdominal musculature is weak in early toddlerhood, resulting in a pot-bellied appearance. The toddler appears to have a swayback along with the potbelly. Around 3 years of age, the musculature strengthens and the abdomen is flatter in appearance.

## Psychosocial Development

Erikson defines the toddler period as a time of autonomy versus shame and doubt. It is a time of exerting independence. Since the toddler developed a sense of trust in infancy, he or she is ready to give up dependence and to assert his or her sense of control and autonomy (Erikson, 1963). The toddler is struggling for self-mastery, to learn to do for himself or herself what others have been doing for him or her. Toddlers often experience ambivalence about the move from dependence to autonomy, and this results in emotional lability. The toddler may quickly change from happy and pleasant to crying and screaming. Exertion of independence

also results in the toddler's favorite response, "no." The toddler will often answer "no" even when he or she really means "yes."

This negativism—always saying "no"—is a normal part of healthy development and is occurring as a result of the toddler's attempt to assert his or her independence. Table 26.1 gives further information related to developing a sense of autonomy.

## Cognitive Development

According to Jean Piaget (1969), toddlers move through the last two substages of the first stage of cognitive development, the sensorimotor stage, between 12 and 24 months of age. Young toddlers engage in tertiary circular reactions and progress to mental combinations. Rather than just repeating a behavior, the toddler is able to experiment with a behavior to see what happens. By 2 years of age, toddlers are capable of using symbols to allow for imitation. With increasing cognitive abilities, toddlers may now engage in delayed imitation. For example, they may imitate a household task that they observed a parent doing several days ago.

Piaget identified the second stage of cognitive development as the preoperational stage. It occurs in children between ages 2 and 7 years. During this stage toddlers begin to become more sophisticated with symbolic thought. The thinking of the older toddler is far more advanced than that of the infant or young toddler, who views the world as a series of objects. During the preoperational stage, objects begin to have characteristics that make them unique from one another. Objects are considered large or small, a particular color or shape, or a unique texture. This moves beyond the connection of sensory information and physical action. Words and images allow the toddler to begin this process of developing symbolic thought by providing a label for the objects' characteristics (Piaget, 1969).

Toddlers also use symbols in dramatic play. First they imitate life with appropriate toy objects, and then they are able to substitute objects in their play. A bowl may be used to pretend to eat from, but then later it can be used upside down on the head as a hat (Fig. 26.2). Human feelings and characteristics may also be attributed to objects (**animism**) (Papalia & Feldman, 2011). See Table 26.1 for further explanation of cognitive development in toddlerhood.

### Take Note!

Mothers who are depressed may not be as sensitive to their children as other mothers. For this reason, maternal depression is a risk factor for poor cognitive development. Be alert to the mental status of a toddler's mother so that appropriate referrals can be made if needed (Cummings & Kouros, 2009).

**TABLE 26.1** DEVELOPMENTAL THEORIES

Theorist	Stage	Activities
<b>Erikson</b>	Autonomy vs. Shame & Doubt Age 1–3 years	Achieves autonomy and self-control Separates from parent/caregiver Withstands delayed gratification Negativism abounds Imitates adults and playmates Spontaneously shows affection Is increasingly enthusiastic about playmates Cannot take turns in games until age 3 years
<b>Piaget</b>	Sensorimotor Substage 5: Tertiary Circular Reactions Age: 12–18 months  Substage 6: Mental Combinations Age: 18–24 months  Preoperational Age: 2–7 years	Differentiates self from objects Increased object permanence (knows that objects that are out of sight still exist [e.g., cookies in the cabinet]) Uses ALL senses to explore environment Places items in and out of containers Imitates domestic chores (domestic mimicry) Imitation is more symbolic Starting to think before acting Understands requests and is capable of following simple directions  Has a sense of ownership (my, mine) Time, space, and causality understanding is increasing Uses mental trial and error rather than physical Makes mechanical toys work Plays make-believe with dolls, animals, and people Increased use of language for mental representation Understands concept of “two” Starting to make connections between an experience in the past and a new one that is currently occurring Sorts objects by shape and color Completes puzzles with four pieces Play becomes more complex
<b>Freud</b>	Anal Stage Age: 1–3 years	Focus is on achieving anal sphincter control. Satisfaction and/or frustration may occur as the toddler learns to withhold and expel stool.

W., Schor, N. F. & R. E. Behrman, H. B. Jenson, & B. Stanton (Eds.), *Nelson textbook of pediatrics* (19th ed.). Philadelphia, PA: Saunders; Feigelman, S. (2011b). The second year. In R. M. Kliegman, Stanton, B. F., St. Geme, J. W., Schor, N. F. & R. E. Behrman, H. B. Jenson, & B. Stanton (Eds.), *Nelson textbook of pediatrics* (19th ed.). Philadelphia, PA: Saunders. Philadelphia: Saunders; and Piaget, J. (1969). *The theory of stages in cognitive development*. New York: McGraw-Hill.

## Motor Skill Development

Toddlers continue to gain new motor skills as well as refine others. Walking progresses to running, climbing, and jumping. Pushing or pulling a toy, throwing a ball, and pedaling a tricycle are accomplished in toddlerhood. Fine motor skills progress from holding and pinching to the ability to manage utensils, hold a crayon, string a bead, and use a computer. Development of eye–hand coordination is necessary for the refinement of fine motor skills. These increased abilities of mobility and manipulation help the curious toddler explore and learn more about his or her environment (Fig. 26.3).

As the toddler masters a new task, he or she has confidence to conquer the next challenge. Thus, mastery in motor skill development contributes to the toddler’s growing sense of self-esteem. The toddler who is eager to face challenges will likely develop more quickly than one who is reluctant. The senses of sight, hearing, and touch are useful in helping to coordinate gross and fine motor movement.

## Gross Motor Skills

As gross motor skills are mastered and then used repeatedly, the large muscle groups in the toddler are strengthened. The “toddler gait” is characteristic of new

**FIGURE 26.2** The toddler will (A) pretend with items in the way they are intended to be used as well as (B) find other creative uses for them.

walkers. The toddler does not walk smoothly and maturely. Instead, the legs are planted widely apart, toes are pointed forward, and the toddler seems to sway from side to side while moving forward (Fig. 26.4). Often the toddler seems to speed along, pitching forward, appearing ready to topple over at any moment. The toddler may fall often, but will use outstretched arms to catch himself or herself (parachute reflex). After about 6 months of practice walking, the toddler's gait is smoother and the feet are closer together. By 3 years of age, the toddler walks in a heel-to-toe fashion similar to that of adults. Toddlers often use physical actions such as running, jumping, and hitting to express their emotions because they are only just learning to express their thoughts and

feelings verbally. Table 26.2 lists motor skill expectations in relation to age.

### Fine Motor Skills

Fine motor skills in the toddler period are improved and perfected. Holding utensils requires some control

**FIGURE 26.3** The toddler's curiosity about the world increases, as does her ability to explore it.

**FIGURE 26.4** The young toddler (early walker) walks with a wide-based stance, feet pointing forward and arms akimbo.

**TABLE 26.2** MOTOR SKILL DEVELOPMENT

Age	Expected Gross Motor Skill	Expected Fine Motor Skills
<b>12–15 months</b>	Walks independently	Feeds self finger foods Uses index finger to point
<b>18 months</b>	Climbs stairs with assistance Pulls toys while walking	Masters reaching, grasping, and releasing: stacks blocks, puts things in slots Turns book pages (singly with board book, multiple if paper) Removes shoes and socks Stacks four cubes
<b>24 months</b>	Runs Kicks ball Can stand on tiptoe Carries several toys, or a large toy while walking Climbs onto and down from furniture without assistance	Builds tower of six or seven cubes Right- or left-handed Imitates circular and vertical strokes Scribbles and paints Starting to turn knobs Puts round pegs into holes
<b>36 months</b>	Climbs well Pedals tricycle Runs easily Walks up and down stairs with alternate feet Bends over easily without falling	Undresses self Copies circle Builds tower of nine or ten cubes Holds a pencil in writing position Screws/unscrews lids, nuts, bolts Turns book pages one at a time
