60 CHAPTER Body-Stalk Anomaly

Key Points

- Body-stalk anomaly is a sporadic disorder leading to severe deformations of the abdominal wall and spine.
- Prenatal diagnosis is generally straightforward with massive abdominoschisis, severe kyphoscoliosis, and relatively short umbilical cord being clearly visible.
- There is no indication to perform amniocentesis as almost all cases are karyotypically normal.
- The condition is considered uniformally fatal, although there has been at least one case report of a survivor following neonatal surgical closure of omphalocele.
- While there has been one report of recurrence in a subsequent pregnancy, the condition is generally considered to be sporadic.

CONDITION

Body-stalk anomaly is a severe abdominal wall defect that results from abnormalities in the development of the cephalic, caudal, and lateral embryonic body folds. This maldevelopment results in the absence or shortening of the umbilical cord with the abdominal organs lying outside the abdominal cavity and directly attached to the placenta (Shalev et al., 1995; Smrcek et al., 2003). Body-stalk anomaly was first described by Kermauner in 1906 in a newborn with an abdominal wall defect consisting of an amniotic sac that contained viscera; the anterior wall of the sac was directly attached to the placenta and there was no umbilical cord. Other than the references given in textbooks of pathology, body-stalk anomaly was not appreciated in the general obstetric literature until the report of Lockwood et al. in 1986.

After gastrulation, the embryo consists of a three-layered, flat, oval germinal disk. The rapid growth of the embryo, especially along the sagittal axis causes the germinal disk to curve. Through circumferential folding, the embryo becomes cylindrical. As a result of this process, the body of the embryo closes, the body stalk forms, and an intraembryonic coelom (peritoneal cavity) separates from an extraembryonic coelom (chorionic cavity) (Giacoia, 1992). The amniotic cavity, which is initially located dorsal to the germinal disk, grows rapidly and eventually encircles the fetus, obliterates the chorionic cavity, and envelops the umbilical cord. The abnormality in the folding process prevents this obliteration of the

chorionic cavity and formation of the umbilical cord. Without an umbilical cord, the fetus becomes directly attached to the placental chorionic plate. This body-stalk anomaly consists of a sac of amnion–mesoderm that contains the displaced abdominal organs (Giacoia, 1992).

Causes proposed for body-stalk defect include early amnion rupture with direct mechanical pressure and amniotic bands (see Chapter 99), vascular disruption of the early embryo, or an abnormality in the germinal disk that leads to the formation of an anomalous amniotic cavity (Van Allen et al., 1987). In the early amnion-rupture theory, the abdominal wall and spinal defects could be secondary to the passage of the lower half of the fetal body into the coelomic cavity through the defect in the amniotic sac. The fetus has no room to move and remains practically attached to the placenta. Limb amputations and encephalocele could be secondary to the entrapment of the fetal skull and/or limbs in the coelomic cavity (Daskalakis et al., 1997). Alternatively, early generalized compromise of embryonic blood flow could lead to a failure of closure of the ventral body wall and persistence of the coelomic cavity (Van Allen et al., 1987). This could also lead to a rupture of an unsupported amnion and formation of amniotic bands.

INCIDENCE

Body-stalk anomaly is the rarest and most severe of the abdominal wall defects. The incidence of body-stalk anomaly in a population of Scottish patients identified by abnormal maternal serum screening results was 1 in 14,273 (Mann et al., 1984). The incidence of body-stalk anomaly in a Hawaiian birth defects registry that encompassed the years 1986 to 1997 was 0.32 per 10,000 births (Forrester and Merz, 1999). Recently, an increased incidence of body-stalk anomaly was noted in a population of first trimester fetuses studied for nuchal translucency thickness. In this first trimester population, the incidence of body-stalk anomaly was between 10 in 4116 cases and 14 in 106,727 cases or 1 in 7500 fetuses (Daskalakis et al., 1997; Souka et al., 1998). Another series of 11 cases of limb–body wall complex suggested an incidence of 1 in 3000 (Luehr et al., 2002). Several case reports exist of body-stalk anomaly and limb–body wall complex in association with monozygotic twinning, triplet pregnancy, and with maternal cocaine abuse (Viscarello et al., 1992; Martinez et al., 1994; Smrcek et al., 2003).

SONOGRAPHIC FINDINGS

The criteria for the diagnosis of body-stalk anomaly in the first trimester include demonstration of abdominal organs in the extraembryonic coelom and a short umbilical cord with only two vessels (Ginsberg et al., 1997). The diagnosis may be more difficult to make during the second trimester than during the first because of the presence of severe oligohydramnios. During the second trimester, Goldstein et al. (1989) suggested that body-stalk anomaly should be strongly considered when there is a body wall defect, skeletal abnormalities, and the umbilical cord is absent or very rudimentary (Figures 60-1 and 60-2).

Figure 60-1 Longitudinal sonographic image of a fetus with body-stalk anomaly demonstrating severe kyphoscoliosis of the lower spine. *(From Takeuchi K, Fujita I, Nakajima K, Kitagaki S, Koketsu I. Body stalk anomaly: prenatal diagnosis.* Int J Gynecol Obstet. *1995;51:49-52.)*

In a multicenter project of screening for chromosomal defects by fetal nuchal translucency thickness and maternal age, 14 of 106,727 fetuses examined had a body-stalk anomaly (Daskalakis et al., 1997). During the first trimester, the ultrasonographic features observed included a major abdominal wall defect, severe kyphoscoliosis, and short umbilical cord. In all of the cases observed, the upper part of the fetal body was in the amniotic cavity and the lower part was in the coelomic cavity. The nuchal translucency thickness was above the 95th

Figure 60-2 Coronal sonographic image of the fetus in Figure 60-1, with body-stalk anomaly demonstrated a 5- by-6-cm mass with a covering membrane that contained stomach, liver, and bowel. *(From Takeuchi K, Fujita I, Nakajima K, Kitagaki S, Koketsu I. Body stalk anomaly: prenatal diagnosis.* Int J Gynecol Obstet. *1995;51:49-52.)*

percentile in 10 of the 14 cases, but the fetal karyotype was normal in 12 of the 14 fetuses evaluated. These authors suggested that early amnion rupture before obliteration of the coelomic cavity is a possible cause of the syndrome (Daskalakis et al., 1997).

Multiple case reports have described the prenatal sonographic diagnosis of body-stalk anomaly (Lockwood et al., 1986; Jauniaux et al., 1990; Giacoia, 1992; Shalev et al., 1995; Takeuchi et al., 1995; Ginsberg et al., 1997). An additional helpful sonographic finding is the presence of scoliosis, which is observed in approximately 75% of cases (Ginsberg et al., 1997) (Figures 60-3 and 60-4). Scoliosis is thought to be due to the absence of thoracolumbar and paraspinal muscles on the ipsilateral side of the abdominal wall defect. In addition, it is thought that fetal hyperextension and direct attachment to the placenta, which limit fetal movement, result in skeletal anomalies.

A more recent series of 11 cases of body-stalk anomaly showed that the earliest prenatal diagnosis was at 11 weeks, but ranged from 11 to 21 weeks' gestation (Smrcek et al., 2003). Six of the fetuses presented with severe abdominoschisis, while the remaining five had thoracoabdominoschisis. Kyphoscoliosis was diagnosed prenatally in 9 of the 11 cases, and all had a short umbilical cord.

Figure 60-4 Transverse view of the same fetus with body-stalk anomaly at 18 weeks, as in Figure 60-3, demonstrating a massive abdominal wall defect with most of the intra-abdominal contents outside of the abdominal cavity.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for body-stalk anomaly includes isolated omphalocele, isolated gastroschisis, short umbilical cord syndrome (Miller et al., 1981), and limb–body wall complex. Some authors consider body-stalk anomaly to be a severe form of amniotic band syndrome (see Chapter 99) (Takeuchi et al., 1995). Amniotic bands are present in 40% of cases of body-stalk anomaly. In addition, some of the limb defects that can be associated with body-stalk anomaly can be attributed to amniotic bands.

Limb–body wall complex is included in the spectrum of defects seen in the early amnion-rupture sequence. Two phenotypes are thought to exist in limb–body wall complex. In the first one, craniofacial defects, amniotic bands, and/or adhesions are seen. In the second phenotype, urogenital abnormalities, anal atresia, abdominal placental attachment, and a persistent embryonic coelom are seen. The overlap between body-stalk anomaly, limb–body wall complex, and a severe form of amniotic band syndrome can be confusing. In a complete review of the limb–body wall complex, Van Allen et al. (1987) stated that the diagnosis of limb–body wall complex is based on the presence of two of three of the following: exencephaly or encephalocele with facial clefts, thoracoschisis and/or abdominoschisis, and a limb defect. In an evaluation of fetuses with limb–body wall complex, 24 of 25 cases studied by Van Allen et al. had associated internal structural defects. In 85% of these cases, there was evidence of persistence of the extraembryonic coelom by examination of the placenta. The abnormalities observed in this group of fetuses and data from experimental models support vascular disruption during 4 to 6 weeks of gestation as the cause for limb–body wall complex.

Martínez-Frías (1997) disagreed with Van Allen et al.'s definition of limb–body wall complex. He stated that an infant with encephalocele, facial clefts, and limb defects could be considered as having limb–body wall complex. Martínez-Frías has argued that the presence of abdominal wall defect with a variable spectrum of associated anomalies (with or without limb deficiencies) should be called body wall complex. He distinguished body wall complex from the amniotic band sequence without body wall defects, but included amniotic band sequence with body wall defects in the category of body wall complex.

Further adding to the confusion is that the epidemiology of body-stalk anomaly and limb–body wall complex is similar. Both malformations have been associated with cocaine abuse. Both conditions are associated with young maternal age, and inheritance is sporadic, with normal

karyotypes (Negishi et al., 1998). In a series of 11 cases of limb–body wall complex, 50% of patients reported use of cigarette, alcohol, and marijuana during pregnancy (Luehr et al., 2002).

With regard to sonographic diagnosis, it is helpful to remember that body-stalk anomaly is not associated with craniofacial or limb anomalies.

ANTENATAL NATURAL HISTORY

The discrepancy in the prevalence of body-stalk anomaly between 10 to 14 weeks of gestation and 17 to 19 weeks of gestation suggests that body-stalk anomaly is associated with a high incidence of spontaneous abortion early in the second trimester (Daskalakis et al., 1997).

The patterns of malformations associated with body-stalk anomaly depend on the degree of abnormal development of each of the four major embryonic folds. Associated anomalies observed in cases of body-stalk anomaly include colonic atresia, agenesis of the colon, intestinal atresia, cloacal exstrophy, vaginal atresia, agenesis of the uterus and gonads, absent external genitalia, hypoplastic kidneys, absent diaphragm, spina bifida, and dysplastic thorax.

Few data are available on the expectant management of body-stalk anomaly as the majority of cases result in elective pregnancy termination following prenatal diagnosis. In a series of prenatally diagnosed body-stalk anomaly, 10 of 11 cases resulted in pregnancy termination, with the one expectantly managed case being a monochorionic twin that resulted in early neonatal demise following delivery at 32 weeks' gestation (Smrcek et al., 2003).

MANAGEMENT OF PREGNANCY

If the diagnosis of body-stalk anomaly is suspected, the pregnant patient should be referred to a tertiary care center capable of detailed prenatal anatomic sonographic evaluation. The diagnosis of body-stalk anomaly is generally reliable when made prenatally. The major issue is to be certain that the sonographic abnormality observed is not isolated omphalocele or gastroschisis, which would carry a reasonably normal prognosis. If the diagnosis of body-stalk anomaly is certain, chromosomal analysis is not indicated, as almost all reported cases have been associated with a normal karyotype. In one series of 11 prenatally diagnosed cases, 10 of 11 had normal karyotype, with one having mosaic trisomy 2 (Smrcek et al., 2003). If the diagnosis of body-stalk anomaly is made, termination of pregnancy should be offered, as the condition is uniformly fatal in a newborn. A further complication of pregnancy is that abnormal fetal presentation is common and cesarean delivery may be indicated to allow delivery of an intact fetus. The short umbilical cord frequently results in abnormal presentation and lack of descent of the fetus into the pelvis during labor. Infants who are born alive with body-stalk anomaly die shortly after birth.

FETAL INTERVENTION

There are no fetal interventions indicated for body-stalk anomaly.

TREATMENT OF THE NEWBORN

In the rare setting of the limited postnatal survival of an affected newborn with body-stalk anomaly, only comfort care is indicated. The condition is almost uniformly fatal (Figure 60-5). One recent case report described the surgical management of a surviving fetus with body-stalk anomaly, in which surgical closure of the large omphalocele was successfully achieved (Kanamori et al., 2007). Such cases should be

Figure 60-5 Postmortem photograph of the same fetus shown in Figures 60-1 and 60-2 demonstrating a large omphalocele in continuity with the placenta and a very short umbilical cord. *(From Takeuchi K, Fujita I, Nakajima K, Kitagaki S, Koketsu I. Body stalk anomaly: prenatal diagnosis.* Int J Gynecol Obstet. *1995;51:49-52.)*

considered exceptional; these cases typically have associated pulmonary hypoplasia and result in early neonatal demise.

SURGICAL TREATMENT

There are no surgical treatments indicated for body-stalk anomaly, although there has been one case report of a surviving infant following surgical closure of the large omphalocele (Kanamori et al., 2007).

LONG-TERM OUTCOME

In general, fetuses with body-stalk anomaly do not survive, and the condition should be considered a lethal anomaly. However, there is at least one case report of a surviving infant following surgical closure of omphalocele, but no long-term data are available yet regarding this infant (Kanamori et al., 2007).

GENETICS AND RECURRENCE RISK

All cases of body-stalk anomaly reported in the literature have been sporadic. The pregnant patient should be advised that there is unlikely to be an increased recurrence risk in subsequent pregnancies. In one series of 11 cases of limb–body wall complex, there was one patient who delivered two consecutive infants with the condition (Luehr et al., 2002). In addition, an increased incidence of body-stalk anomaly in monozygotic twins has been reported (Shih et al., 1996; Smrcek et al., 2003). This is probably due to an early embryonic cleavage disorder and is thought to represent a gradual transition from monoamniotic twins to conjoined twins. The development of body-stalk anomaly is therefore an intrinsic part of the twinning process and should not carry an increased recurrence risk.

61 CHAPTER

Pentalogy of Cantrell

Key Points

- Pentalogy of Cantrell is defined by the association of five anomalies: (1) epigastric abdominal wall defect, (2) lower sternal defect, (3) defect in the anterior diaphragm, (4) defect in the epicardium, and (5) intracardiac defects.
- Can be associated with other midline ventral defects such as cleft lip and palate, exencephaly, and sirenomelia.
- Rare association thought to occur in only 1 in 65,000 to 200,000 births.
- Most common intracardiac defects include VSD, ASD, pulmonic stenosis, tetralogy of Fallot, and LV diverticulum.
- All the defects are amendable to repair yet outcomes in this condition have been generally poor.
- An X-linked pattern of inheritance has been suggested for ventral midline defects including pentalogy of Cantrell.

CONDITION

Pentalogy of Cantrell is an unusual form of abdominal wall defect that consists of five associated anomalies, including: (1) midline epigastric abdominal wall defect, (2) defect of the lower sternum, (3) deficiency of the anterior diaphragm, (4) defect in the diaphragmatic pericardium, and (5) intracardiac defects. This constellation of anomalies was first described by Cantrell et al. (1958), hence, the term pentalogy of Cantrell, although it has also been referred to as the Cantrell–Haller–Ravitch syndrome and peritoneal pericardial diaphragmatic hernia. Not every case will have all five factors and some cases may have associated anomalies, usually midline defects also such as cleft lip or palate, sirenomelia, exencephaly (Carmi and Boughman, 1992; Egan et al., 1993; Polat et al., 2005). Toyama suggested a classification scheme for pentalogy of Cantrell in which Class 1 included those cases in which the diagnosis was definite and all five defects were present. In Class 2, the diagnosis was probable with the presence of four defects including the pressure of intracardiac and ventral abdominal wall defects. In Class 3, there was incomplete expression and various combinations of defects including a sternal abnormality (Toyama, 1972). Although pentalogy of Cantrell has been used interchangeably with ectopia cordis, in their original description Cantrell et al. (1958) were careful to distinguish between these two anomalies (see Chapter 59).

Cantrell suggested that the defects in this syndrome fell into two groups by mechanism of embryologic development. In the first group, a developmental failure of mesoderm results in diaphragmatic, pericardial, and intracardiac defects. The diaphragmatic defect is a failure of the transverse septum to develop. The pericardial defect arises from the somatic mesoderm immediately adjacent to the region of the same layer from which the transverse septum develops. Defective development of one but not the other of these structures is possible only with highly specific loss of somatic mesoderm. This is rarely seen in pentalogy of Cantrell in which the diaphragmatic and pericardial defects occur together in most patients. The intracardiac lesions result from abnormal development of the epimyocardium, which is derived from the splanchnic mesoderm. While the resulting intracardiac defects vary, almost all include defects of the cardiac septa.

The second group of defects results from failure of the ventral migration of the periprimordial structures and includes the sternal defect and the epigastric omphalocele. All elements of the sternum are present, and the costocartilages connect with the cartilaginous plates, which represent the paired sternal anlagen with variable degrees of fusion. The sternal defect results not from an absence of sternal primordia but from the failure of paired sternal anlagen to complete migration. A similar failure of migration results in the abdominal wall defect. The normal layers of the ventral abdominal wall are present, but there is a lack of ventral

migration of the myotomes. These patients have structurally normal rectus abdominus muscles that correctly attach to the pubic symphysis, but deviate laterally as they run cephalad to insert into the costal margins at the midclavicular line. This lack of migration is thought to be due to a defective development of the paramedian mesoderm.

The heart in pentalogy of Cantrell is normally positioned within the chest. In contrast, ectopia cordis is characterized by abnormal position of the heart outside of the chest (see Chapter 59). This becomes confusing, as classification systems for ectopia cordis list three types: cervical, thoracic, and thoracoabdominal, which is the same as pentalogy of Cantrell. Ectopia cordis may encompass partial or complete sternal defects, and invariably includes intracardiac anomalies, but does not include the pericardial, diaphragmatic, and abdominal wall defects seen in the pentalogy of Cantrell. Kanagusuntheram and Verzin (1962) suggested that ectopia cordis occurs as a result of excessive pericardial coelom formation and subsequent destruction of the transverse septum with rupture of the anterior body wall at 6 weeks of gestation (Kanagusuntheram and Verzin, 1962). Ravitch (1986) has suggested that the high frequency of major intrinsic cardiac defects with true ectopia cordis indicates that there is a primary defect in the splanchnic mesoderm responsible for cardiac development.

The primitive thoracic wall consists of somatopleura covering the ventral wall of the pericardial cavity. The ectodermal layer of the somatopleura forms the skin, but the remainder of the components of the body wall derive from invading dorsal mesoderm during the 6th week of gestation. The sternum appears as two parallel condensations of mesenchyme, the lateral sternal bands. A median cranial condensation, the presternum, appears independently. The lateral sternal bands fuse with the presternum cranially and with the tips of the ribs laterally. During the 7th week, the sternal bands begin fusing at their cephalic end and proceed caudally and cease by the 9th or 10th week.

INCIDENCE

The pentalogy of Cantrell is a rare association of anomalies with fewer than 100 cases having been reported (Craigo et al., 1992; Jochems et al., 2004). Due to the rarity of this condition, its incidence is difficult to accurately estimate. The incidence of the syndrome has been suggested to range between 1:65,000 to 1:200,000 (Martin et al., 1992; Vazquez-Jimenez et al., 1998). Carmi et al. (1993) reported five cases of pentalogy of Cantrell ascertained through the Baltimore–Washington population-based study of infants with congenital cardiovascular malformations, and estimated a regional prevalence of 5.5 cases for 1 million liveborn infants. The prevalence in fetuses is unknown (Aber-Yousef et al., 1987). African Americans may be more predisposed to developing pentalogy of Cantrell (Kousseff et al., 1996). Males appear more at risk with an incidence 2.7 times that of females (Egan et al., 1993). There have been five cases of pentalogy of Cantrell occurring in twins (Baker et al., 1984; Ghidini et al., 1988; Carmi and Boughman, 1992).

SONOGRAPHIC FINDINGS

The most obvious feature of pentalogy of Cantrell is the epigastric omphalocele (Figure 61-1). There are reported cases with diastasis rectus without an omphalocele, which may be difficult to diagnose prenatally. The anterior diaphragmatic and pericardial defects are difficult, if not impossible, to discern sonographically. MRI may offer assistance in defining anterior diaphragmatic defects in some cases (Song and McLeary, 2000).

The three features of the pentalogy that may be most easily detected include the epigastric omphalocele, lower sternal defects, and intracardiac defects (Romero et al., 1988; Craigo et al., 1992).

Even if no other structural defects can be found, any fetus with an epigastric omphalocele should be evaluated for pentalogy of Cantrell, with particular attention paid to possible associated cardiac defects. The abdominal wall defect in pentalogy of Cantrell may vary from a very large omphalocele containing the stomach, liver, and apex of the heart to only widely displaced rectus abdominus muscles with skin covering the other defects and a ventral hernia.

Figure 61-1 Prenatal sonographic image showing the transverse thoracic view of a fetus with pentalogy of Cantrell. The anterior chest wall defect—epigastric omphalocele with the heart in the cephalad portion of the defect—can be appreciated.

Figure 61-2 Postnatal appearance of the fetus in Figure 61-1. The epigastric omphalocele is apparent, with separation of the omphalocele membrane from the skin at the superior aspect of the abdominal wall defect. The heart can be seen in the space between the skin and separated omphalocele membrane.

The heart in the pentalogy of Cantrell is positioned within the fetal chest (Figure 61-2). If the heart is located outside the fetal chest, this indicates ectopia cordis (see Chapter 59). Even though positioned within the chest, there is a subtle shift in the cardiac axis in pentalogy of Cantrell. The heart is normally oriented horizontally, with the apex to the left. However, in this syndrome, the apex is oriented vertically, with the apex at the superior edge of the abdominal wall defect. Usually, but not invariably, the heart in the pentalogy of Cantrell has intracardiac anomalies. The most commonly observed is a ventricular septal defect (Table 61-1).

In addition to the five anomalies that constitute the pentalogy of Cantrell, other associated anomalies have been reported. Care should be taken to adequately visualize the fetal spine and hands, as vertebral and digital anomalies are often seen, including kyphoscoliosis and clinodactyly. Likewise, a detailed inspection of the fetal head and face should be performed to exclude potentially associated craniofacial anomalies, including encephalocele, cleft lip, microphthalmia, and low-set ears (Fox et al., 1988; Ghidini et al., 1988). In addition, a two-vessel cord, absent left lung, cloacal exstrophy, and fetal ascites have all been observed in cases of pentalogy of Cantrell (Toyama, 1972; Baker et al., 1984; Goncalves and Jeanty, 1994). Egan et al. (1993) have reported a case of pentalogy of Cantrell associated with sirenomelia in a monozygotic twin. They suggested that anterior midline ventral wall defects may be caused by either monozygotic twinning or vascular dysplasia. Similarly, a vascular steal phenomenon is thought to cause sirenomelia (see Chapter 86). They suggested that a common cause for these defects, that is, an alteration in vascular development, may be responsible. Carmi and Boughman (1992) found that three of their five patients had associated cleft lip with or without cleft palate. In a review of the literature on pentalogy of Cantrell and the various combinations of the anomalies within the spectrum, they suggested that pentalogy of Cantrell defines a specific midline ventral developmental field. Cleft lip with or without cleft palate and encephalocele tend to associate specifically with ventral midline anomalies within the spectrum of pentalogy of Cantrell. The authors speculated that these associations might be due either to previously observed tendencies or to specific occurrences of certain combinations of midline defects, or they may represent defined subunits of the midline developmental field (Carmi and Boughman, 1992; Martin et al., 1992).

Table 61-1

Intracardiac Anomalies in Pentalogy of Cantrell

	Percentage
Ventriculoseptal defect	37.5
Atrioseptal defect	20.0
Pulmonic stenosis	12.5
Tetrology of Fallot	7.5
Left ventricle diverticulum	7.5
Anomalous venous return (caval)	7.5
Tricuspid atresia	2.3
Truncus arteriosus	2.3
Anomalous venous return (pulmonary)	2.3

DIFFERENTIAL DIAGNOSIS

The differential diagnosis in pentalogy of Cantrell includes ectopia cordis, body-stalk anomaly, simple omphalocele, and amniotic band syndrome (see Chapters 59, 60, 62, and 100).

ANTENATAL NATURAL HISTORY

Our understanding of the antenatal natural history of pentalogy of Cantrell is limited not only by the rarity of this syndrome, but also by the few cases that have been diagnosed prenatally. According to one report, fewer than 90 cases have been reported (Craigo et al., 1992). If seen in isolation, none of the anomalies in pentalogy of Cantrell are associated with an adverse outcome or with in utero fetal death. Even the intracardiac anomalies most often seen in the pentalogy of Cantrell do not affect fetal survival. Ghidini et al. (1988) reported 10 cases from Yale in which there were no survivors. However, five of these pregnancies were terminated electively and the other five died postnatally. The authors did not distinguish between pentalogy of Cantrell and ectopia cordis, however. The prognosis for ectopia cordis, however, is quite different and significantly worse than for pentalogy of Cantrell. The overall prognosis in pentalogy of Cantrell is more closely correlated with the severity of the intracardiac defect and other associated anomalies not part of the pentalogy (Paidas et al., 1994).

MANAGEMENT OF PREGNANCY

An estimation of the size of the omphalocele and the contents of the omphalocele sac should be documented and care taken to ensure that the amnioperitoneal membrane is intact circumferentially. The orientation of the heart should be carefully noted and attempts should be made to discern the anterior diaphragmatic defect. A careful sonographic search for other potential associated anomalies should be performed. Chromosomal analysis, as in all cases of omphalocele, is strongly recommended. Given the complexity of this syndrome, it is useful to have the parents meet with several specialists who provide a team approach for comprehensive counseling. This team should include not only maternal–fetal medicine specialists but also a geneticist, a pediatric surgeon, a pediatric cardiologist, a neonatologist, and a pediatric cardiac surgeon. If a chromosomal abnormality or other significant anomaly is diagnosed, the parents should be counseled appropriately and termination may be offered. After a decision has been reached to continue the pregnancy, in the absence of such associated adverse prognostic indicators, attention should be focused on antepartum surveillance for preterm labor and the possibility of intrauterine growth restriction. Both of these complications can be seen in all forms of omphalocele, including the pentalogy of Cantrell. The rates of preterm delivery and intrauterine growth restriction have ranged from 26% to 65% and from 6% to 35%, respectively (Carpenter et al., 1984; Sermer et al., 1987; Lafferty et al., 1989; Sipes et al., 1990). In addition to surveillance for growth restriction and polyhydramnios, observation for occasional rupture of the omphalocele membrane is necessary, as it would expose the herniated viscera and require emergency surgery once the infant has been delivered.

Delivery of an infant with pentalogy of Cantrell is best managed in a tertiary care center that provides newborn medicine specialists as well as pediatric cardiologists and pediatric surgeons who can provide immediate postnatal care. The mode of delivery is not affected by the diagnosis of pentalogy of Cantrell. We currently recommend that omphaloceles, including pentalogy of Cantrell, be delivered vaginally and reserve cesarean section for routine obstetric indications. However, because severe giant omphalocele may predispose to dystocia, cesarean delivery may be indicated in cases of giant omphalocele.

FETAL INTERVENTION

There are no fetal interventions for pentalogy of Cantrell.

TREATMENT OF THE NEWBORN

Treatment of the newborn is the same as the treatment of any infant born with an intact omphalocele (see Chapter 62). The one confounding variable is the presence of the intracardiac defect. The most common of these is a ventricular septal defect, which does not change the treatment. In severe cases of tetralogy of Fallot, in which the baby may be cyanotic, treatment during the immediate postnatal period may be altered.

SURGICAL TREATMENT

Surgical reconstruction of an infant with pentalogy of Cantrell depends on several features. The timing of the surgery depends on whether or not the omphalocele membrane is intact, or if there is skin covering the defect (see Figure 61-2). Dehiscence of the omphalocele membrane from the abdominal wall requires emergency closure within the first few hours of life to prevent infectious complications. In the absence of such separation, it is prudent to perform a complete postnatal evaluation to confirm the presence of the complete pentalogy and to exclude other potential associated anomalies. Paramount among these is echocardiography to define the nature of the intracardiac defect. Once the infant has been adequately resuscitated and a complete evaluation performed, elective reconstruction may be undertaken. This is

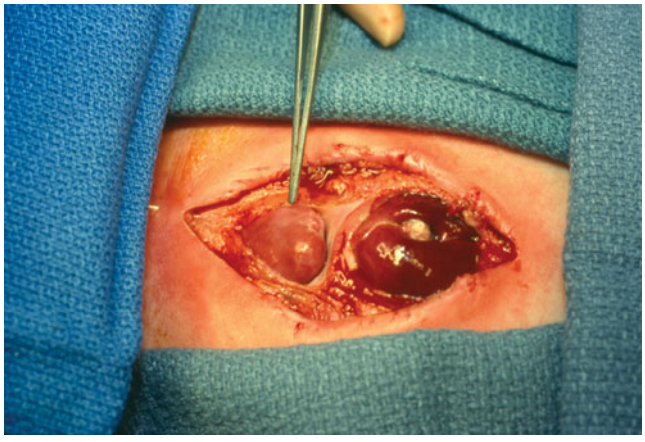

Figure 61-3 Operative repair of pentalogy of Cantrell. Four of the five defects can be seen in this photograph: (1) epigastric abdominal wall defect, (2) defect in anterior diaphragm, (3) defect in anterior pericardium, and (4) lower sternal defect. The intracardiac defect in this newborn was a ventricular septal defect, completing the pentalogy.

performed in a staged fashion, with the initial attention given to closure of the omphalocele, anterior diaphragmatic defect, and pericardial defects. The cardiac defects are repaired at a later date (Abdullah et al., 1993). The one exception to this is a left ventricular diverticulum, which may be readily excised at the time of the abdominal wall and sternal reconstruction. These small lesions may be a source of thrombus, focus for arrhythmia, or may rupture (Hamaoha et al., 1987; Tsujimoto and Takeshita, 2000; Halbertsma et al., 2002).

The omphalocele membrane is excised, which reveals the defect to include a common pericardial peritoneal cavity with the anterior diaphragmatic defect, and a lower sternal defect (see Figure 61-3). Because the rectus abdominal muscles are normally formed with anterior and posterior fascial sheaths intact, albeit laterally displaced with insertion at the midclavicular lines bilaterally, it is possible to do relaxing incisions both anteriorly and posteriorly in the rectus abdominis sheaths to allow rotation of the fascia to a medial location to close the abdominal wall defect. This fascial rotation can be used to close not only the midline abdominal wall defect but also to separate the peritoneal cavity from the mediastinum. This, however, still leaves the anterior thoracic defect and the pericardial defect present. The pericardial defect may be left until a later date, and the lower sternal defect, depending on the extent of the sternal deficiency, may be closed with a Gore-Tex patch to protect the heart. At a later date, the intracardiac defect may be addressed if this is necessary, as in the case with tetralogy of Fallot, or large VSD.

LONG-TERM OUTCOME

Due to the rarity of these cases and the few that have been successfully reconstructed, little information is available about the long-term outcome. We believe that long-term outcome should be most closely correlated with the severity of the intracardiac defect, as few sequelae are anticipated from the abdominal wall, diaphragmatic, and pericardial defects.

GENETICS AND RECURRENCE RISK

Pentalogy of Cantrell is primarily thought to be a sporadic defect. Karyotype abnormality is not a usual feature of pentalogy of Cantrell, but abnormalities of chromosomes 18 and 13 have been described (Fox et al., 1988). However, Martin et al. (1992) suggested that there was an association of sternal fusion defects with various cardiac, diaphragmatic, and anterior body wall defects, including pentalogy of Cantrell and ectopia cordis. This group reported a family in which three consecutively born brothers had extensive diaphragmatic defects; two of them had pentalogy of Cantrell.

It has been suggested that the inheritance pattern for ventral midline defects, including pentalogy of Cantrell, is X-linked. In studies of an extended family including 14 affected individuals, Carmi and Boughman (1992) obtained evidence of genetic linkage to markers in the region Xq22-q27. Additional results indicated that the thoracoabdominal syndrome (TAS) gene is located between the DXS425 and HPRT loci (Xq25-q26.1). Parvari et al. (1994) obtained significant evidence of linkage when the analysis used additional markers in Xq25-q26. Using microsatellite polymorphic markers, they narrowed the region of the TAS gene to an interval of approximately 2.5 Mb (Parvari et al., 1996).

62 CHAPTER Omphalocele

Key Points

- Defect in ventral abdominal wall characterized by absent abdominal muscles, fascia, and skin. Defect is covered by membrane that consists of peritoneum and amnion.
- Incidence 1 in 4000 to 1 in 7000 livebirths.
- Principal sonographic diagnostic feature is umbilical cord insertion into the membrane covering the defect at a location distant from the abdominal wall.
- Differential diagnosis includes gastroschisis, body-stalk anomalies, pentalogy of Cantrell, and Beckwith–Wiedemann syndrome.
- There is a high incidence of both associated malformations and chromosome abnormalities. Prenatal karyotype is indicated. Fetal echocardiogram is recommended.
- Serial prenatal sonograms should be performed to assess fetal growth and amniotic fluid volume.
- Delivery at a tertiary care center provides optimal care for the newborn. Mode of delivery is debatable, except for cases of giant omphalocele or extracorporeal liver, in which cesarean section should be performed.
- Even with primary surgical repair, prospective parents should anticipate a long hospitalization for their neonate.

CONDITION

Omphalocele is a defect in the ventral abdominal wall that is characterized by an absence of abdominal muscles, fascia, and skin. The defect is covered by a membrane that consists of peritoneum and amnion. It can vary in size from a few centimeters to most of the ventral abdominal wall. Unlike gastroschisis, in omphalocele, the umbilical cord inserts into this membrane at a location distant from the abdominal wall (deVries, 1980). The defect is thought to be caused by an abnormality that occurs during the process of body infolding at 3 to 4 weeks of gestation (Dimmick and Kalousek, 1992). At that time, 3 folds occur simultaneously, and each is associated with a distinct type of omphalocele. Cephalic folding defects result in a high or epigastric omphalocele. An example of this is pentalogy of Cantrell (see Chapter 61), which consists of an epigastric omphalocele, anterior diaphragmatic defect, sternal cleft, pericardial defect, and associated intracardiac defects (Figure 62-1A) (Cantrell et al., 1958). A defect in lateral folding results in the classic omphalocele (Figure 62-1B) with a midabdominal defect. A defect in caudal folding results in a low or hypogastric omphalocele, as seen in bladder or cloacal exstrophy (see Chapters 64 and 65) (Duhamel, 1963; Meller et al., 1989; Vasudevan et al., 2006). The spectrum of severity of abdominal wall abnormalities can vary from a small umbilical hernia to a large defect with extrusion of the abdominal viscera.

INCIDENCE

The incidence of omphalocele ranges from approximately 1 in 4000 to 1 in 7000 livebirths (Baird and MacDonald, 1981; Lindham, 1981; Rankin et al., 1999; Stoll et al., 2001). The incidence of omphalocele is higher in combined livebirths and stillbirths (1 in 300 to 1 in 4000), reflecting the increased risk of intrauterine fetal death in cases of omphalocele. In fact, the overall incidence of abdominal wall defects is 20 times greater in stillborn than in liveborn infants (McKeown et al., 1953; Baird and MacDonald, 1981; Lindham, 1981; Carpenter et al., 1984). Unlike gastroschisis, there has not been a change in the incidence of this abnormality, which supports the notion that these are two separate entities with different causes (see Chapter 63). Unlike gastroschisis, omphalocele is associated with advanced, as opposed to younger, maternal age (Redford et al., 1985; Hwang and Kousseff, 2004).

SONOGRAPHIC FINDINGS

The diagnosis of omphalocele was made as early as 10 to 12 weeks of gestation by vaginal sonography, when an echogenic mass nearly equal to the size of the diameter of the fetal abdomen was found anterior to the fetal abdomen (Brown et al., 1989). The use of three-dimensional transvaginal ultrasound examination may facilitate this diagnosis early in gestation (Anandakumar et al., 2002; Tonni and Centini, 2006). The ultrasonographic appearance of omphalocele

Figure 62-1 **A.** Sagittal image demonstrating the intact sac of a liver containing omphalocele in a fetus at 15 weeks; **B.** pathologic appearance of a fetus with omphalocele due to defect in lateral folding. *(Courtesy of Dr. Joseph Semple.)*

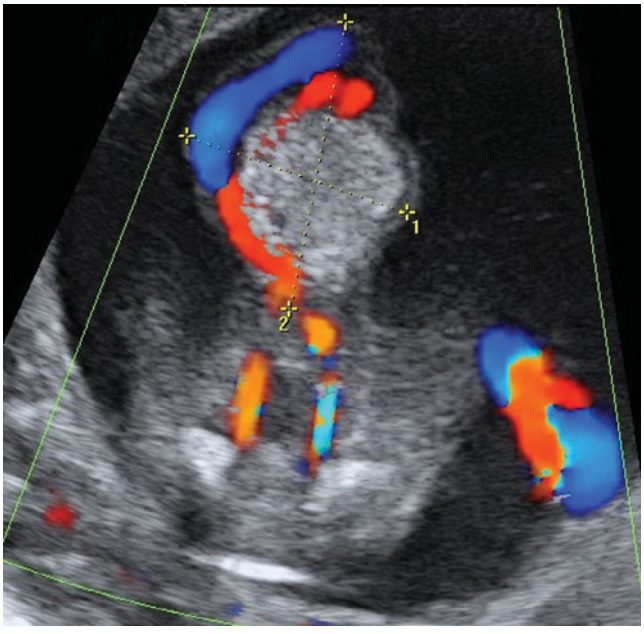

Figure 62-2 Color Doppler ultrasound of a fetus at 17 weeks' gestation with large omphalocele, demonstrating umbilical cord insertion into the membrane covering the abdominal wall defect.

varies depending on the size and location of the defect, the presence of ascites, and the organs contained within the defect. However, a principal diagnostic feature of omphalocele is the umbilical cord insertion into the membrane covering the abdominal wall defect (Figure 62-2). This contrasts with gastroschisis, in which the defect is immediately to the right of the normal umbilical cord insertion into the abdominal wall. The cord insertion site at the caudal apical portion of the omphalocele membrane can be visualized with color flow Doppler studies on sagittal or oblique images. An additional diagnostic feature is the presence of the intrahepatic portion of the umbilical vein coursing through the central portion of the defect. Omphaloceles are characterized in utero by the presence of a membrane; however, occasionally this membrane will rupture. In cases of ruptured omphalocele, the abdominal contents are floating free in the amniotic cavity, similar to gastroschisis. However, unlike gastroschisis, in ruptured omphaloceles, the defects are usually large and have at least exposed, if not extracorporeal, liver (Figure 62-3).

DIFFERENTIAL DIAGNOSIS

It is usually easy to distinguish sonographically between gastroschisis, with its cord insertion on the abdominal wall, and omphalocele, with the cord insertion at the apex of the membrane encompassing the abdominal wall defect. It sometimes is more difficult to distinguish between a small omphalocele and a hernia of the cord than between ruptured omphaloceles, gastroschisis, and body-stalk anomalies.

Two syndromes deserve mention in the context of omphalocele: pentalogy of Cantrell and Beckwith–Wiedemann syndrome (see Chapters 27, 61, and 123). Pentalogy of Cantrell is characterized by the presence of an epigastric omphalocele and defects of the sternum, anterior diaphragm, and diaphragmatic pericardium, with associated intracardiac lesions (Cantrell et al., 1958; Toyama, 1972; Spitz et al., 1975). Cantrell et al. (1958) hypothesized that the syndrome might have resulted from a developmental failure of a segment of lateral mesoderm around 14 to 18 days of embryonic life. Consequently, there is a lack of development of the transverse septum of the diaphragm and a lack of migration of the two paired mesodermal folds of the upper abdomen. A defect in the lower sternal region develops, allowing for protrusion of the heart and the upper abdominal organs. The syndrome is very rare. Fewer than 90 cases have been described (Craigo et al., 1992). Ghidini et al. (1988) reviewed the Yale experience and found 10 cases of pentalogy of Cantrell. Five pregnant patients elected termination and the remaining five delivered infants; there were no survivors beyond 3 months of age. A

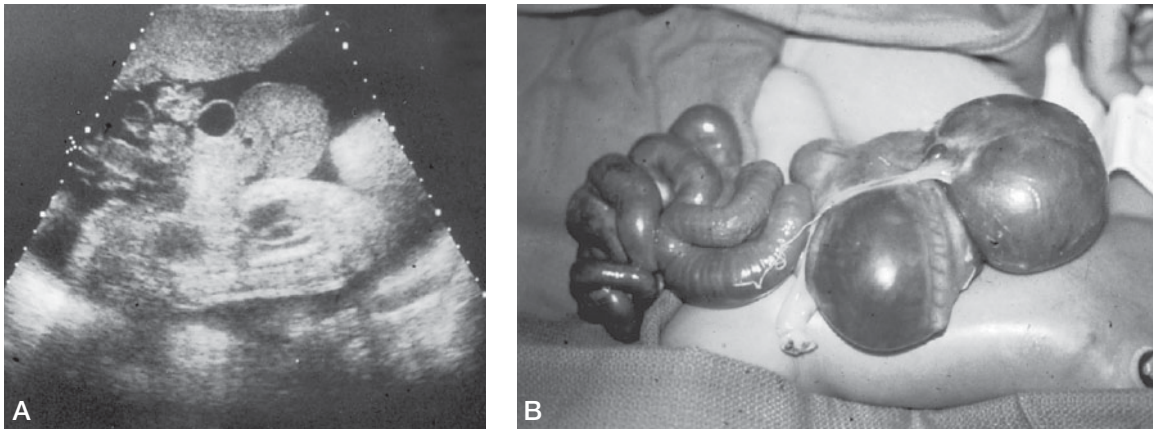

Figure 62-3 **A**. Ultrasound image of fetus with ruptured omphalocele seen in sagittal plane, demonstrating large ventral defect through which the entire liver, stomach, and intestines have herniated. No membrane is seen around the defect. **B**. The appearance of the infant immediately postnatally, with completely exteriorized liver, stomach, and small and large bowel.

number of other anomalies can be associated with pentalogy of Cantrell, including craniofacial abnormalities, chromosomal abnormalities, clubfeet, malrotation of the colon, hydrocephalus, and anencephaly (Craigo et al., 1992). The defects themselves can vary in severity, ranging from only rectus muscle diastasis to a large omphalocele. The most common cardiac abnormalities include atrial and ventricular septal defects, and tetralogy of Fallot (Bryker and Breg, 1990). The prognosis in pentalogy of Cantrell is directly related to the severity of the cardiac defect.

The Beckwith–Wiedemann syndrome, otherwise known as exomphalos-macroglossia-gigantism (EMG) syndrome, consists of the presence of omphalocele, visceromegaly, macroglossia, and severe neonatal hypoglycemia (see Chapters 27 and 123). Cardiac abnormalities are also frequently seen in this syndrome. Greenwood et al. (1977) found that 12 of 13 patients with this syndrome had cardiovascular malformations, and 7 of the 12 had structural abnormalities. Malignant tumors can develop in 10% of patients, including Wilms' tumor, hepatoblastoma, and adrenal tumors (Sotelo, 1977). This syndrome does not have any obligatory anomalies, and the diagnosis has been made without macroglossia or omphalocele (Cohen and Ulstrom, 1979). Evidence of macroglossia, or enlargement of adrenal glands, liver, kidneys, or pancreas, in the setting of omphalocele should alert one to the possible diagnosis of Beckwith–Wiedemann. These findings are rare and seldom seen prior to the third trimester.

ANTENATAL NATURAL HISTORY

Omphalocele can present as part of a syndrome or as an isolated defect. A list of the syndromes associated with omphalocele is given in Table 62-1 (Stoll et al., 2008). The most important prognostic variable is the presence of associated malformations or chromosomal abnormalities. Visceral malformations can accompany omphalocele in 50% to 70% of cases, and chromosomal abnormalities can be seen in 30% to 69% (Paidas et al., 1994; Brantberg et al., 2005; Lakasing et al., 2006). Interestingly, the absence of the liver in the omphalocele has been correlated with fetal karyotypic abnormalities and perinatal mortality.

Nyberg et al. (1989) were the first to report an association between omphalocele contents and fetal chromosomal abnormalities. Other investigators have validated the finding that small defects in omphalocele that contain only bowel are associated with an increased risk of chromosomal abnormalities (Benacerraf et al., 1990; Getachew et al., 1991). In one study, chromosomal abnormalities were present in all 8 fetuses with intracorporeal liver, as opposed to 2 of the 18 fetuses with an extracorporeal liver. They also found a significant association between advanced maternal age (33 years and older) and abnormal karyotype. Gilbert and Nicolaides (1987) found that in a series of 35 fetuses, there was a high rate of chromosomal abnormalities (54%) with a predominance of trisomy 18 (17 of 19 cases of chromosomal abnormalities). Brantberg et al. (2005) found a higher incidence of karyotypic abnormalities when the omphalocele was central (69%) as opposed to epigastric (12.5%) in location.

Table 62-1

Lethal omphalocele—cleft palate syndrome
Marshall–Smith syndrome
Meckel–Gruber syndrome
Triploidy
Trisomy 13
Trisomy 18

The constellation of other associated malformations varies greatly, ranging from single, minor, nonlethal abnormalities to multiple complex life-threatening abnormalities that influence long-term prognosis more than the omphalocele itself. The pediatric literature (as opposed to the obstetric literature) has reported a better prognosis for neonates with omphalocele, due to the fact that many of the fetuses with multiple associated anomalies die in utero or during the immediate perinatal period. The report from Rijhwani et al. (2005) from King's College Hospital is illustrative of this point, with survival of 34 of 35 neonates undergoing primary or staged closure. The same institution reported that fewer than 10% of the 445 prenatally diagnosed cases of omphalocele survived to repair (Lakasing et al., 2006).

Several investigators have described the impact of associated anomalies on survival in cases of omphalocele. Hughes et al. (1989) reviewed a series of 46 cases detected by prenatal ultrasound examination from three high-risk obstetric referral centers. In 43 of 46 cases, adequate follow-up information was available. Twenty-nine of the 43 cases (67%) had additional malformations, with 23 (79%) considered major and 6 (21%) considered minor. Three of the 29 pregnancies were terminated. There was a total of 58 individual anomalies in the 26 fetuses in which the pregnancy was continued. Cardiac anomalies were the most common (14 cases), including ectopia cordis (4). The other systems involved were skeletal (9), gastrointestinal (6), genitourinary (6), and central nervous (7). Fetal mortality was most strongly associated with the presence of concurrent malformations. Twelve of the 15 fetuses (80%) with concurrent malformations died, and the 3 that survived had isolated minor abnormalities. This

was in contrast to 7 fetuses without additional anomalies that survived. In the Hughes et al. (1989) series, the size of the omphalocele was not associated with fetal mortality. Six of the 10 survivors had a transverse omphalocele to abdomen ratio of >0.6 and two omphaloceles measured more than 10 cm. Abnormal amniotic fluid volume was present in 9 of the 12 fetuses that died spontaneously, and 3 of these had no abnormalities detected on sonographic examination.

Tucci and Bard (1990) reviewed a 5-year Canadian experience consisting of 28 cases of omphalocele. They initially divided their cases into two groups on the basis of the size of the defect, small (<5 cm) and giant (>5 cm). Of the 12 fetuses with small omphaloceles only 1 died, whereas 10 of the 16 infants with giant omphalocele died and all except 1 had severe associated anomalies. There were five cases of congenital heart disease, three diaphragmatic hernias, and two central nervous system malformations. Of note, none of the six surviving infants had associated severe malformations. In this series, four of the survivors had liver herniation, which suggests that giant omphaloceles can have a favorable prognosis if other severe anomalies are not present.

Nicolaides et al. (1992) compiled their 8-year experience with omphalocele and reviewed both the obstetric and pediatric literature regarding the presence of chromosomal abnormalities and associated malformations. Of the 116 cases of omphaloceles, 87 (75%) had associated malformations. They also found a higher incidence of chromosomal abnormalities when the omphalocele contained only bowel as compared with omphaloceles that contained liver and bowel (25 of 44 vs. 17 of 72). In their summary, of 349 cases detected antenatally, 229 (65.6%) had associated malformations. Summarizing 13 studies with postnatal follow-up, an overall incidence of associated anomalies is 50%. They also noted an association with neural tube defects in chromosomally normal fetuses (Ardinger et al., 1987).

More recently, Nicolaides' group reported their 11-year experience with 445 cases of omphalocele from the Harris Birthright Centre for Fetal Research at King's College Hospital (Lakasing et al., 2006). In 250 cases (56%) the karyotype was found to be abnormal, and in 130 cases (30%) the karyotype was normal, with the remainder declining karyotype analysis. In the group with karyotype abnormalities, 248 (99%) underwent termination of pregnancy or died in utero. Among the 130 cases with normal karyotype, 74 (56%) were found to have associated structural anomalies.

Lakasing et al. (2006) reported that during an 11-year period from 1991 to 2001, 445 cases of omphalocele experienced less than 10% survival from operative repair due to termination of pregnancy, intrauterine fetal demise, and neonatal death.

MANAGEMENT OF PREGNANCY

Elevated maternal serum α-fetoprotein (MSAFP) levels have traditionally been associated with open neural tube defects, but they are also associated with ventral abdominal wall defects (Brooke et al., 1979; Stiller et al., 1990; Killam et al., 1991). The sensitivity of MSAFP screening for the detection of abdominal wall defects will vary depending on whether it is omphalocele or gastroschisis and on the cutoff value of MSAFP used (Paidas et al., 1994). MSAFP screening has a much higher sensitivity for detecting gastroschisis than for detecting omphalocele. Palomaki et al. (1988) found that at each cutoff value of MSAFP, detection rates were higher for gastroschisis than for omphalocele. For example, at a cutoff value of >2.5 multiples of the median (MoM) and >3.0 MoM, the detection rates were more than 98% and 71%, and 96% and 65% for gastroschisis and omphalocele, respectively. The median MSAFP values for cases of omphalocele in this study were 4.1 MoM (Palomaki et al., 1988). The poorer detection rate for omphalocele is thought to be due to the presence of the intact amnioperitoneal membrane covering the abdominal cavities in unruptured omphalocele, as opposed to direct exposure of bowel to the amniotic fluid in gastroschisis (Paidas et al., 1994).

Once identified, a sonographic estimation of the size of the omphalocele, contents of the omphalocele sac, location of the umbilical cord insertion relative to the herniation, and the presence of an amnioperitoneal membrane should be documented. A careful sonographic search for other fetal anomalies should also be performed, including fetal echocardiography. Because of the high incidence of associated congenital cardiac disease (19%–32%), we recommend fetal echocardiography when an omphalocele is diagnosed (Greenwood et al., 1974; Carpenter et al., 1984; Crawford et al., 1985; Copel et al., 1986). The incidence of congenital heart disease is related to the embryology of the body fold defect. Ten percent of neonates with lateral fold defects have congenital heart disease, whereas the incidence approaches 100% if the cephalic fold is affected. Alternatively, if the caudal fold is involved, the incidence of associated congenital heart disease is low (Greenwood et al., 1974; Carpenter et al., 1984; Crawford et al., 1985; Copel et al., 1986).

Chromosomal analysis is strongly recommended due to the multiple studies that have documented a high rate of karyotype abnormalities. We have found that a team approach provides comprehensive counseling and advice for parents with a fetus diagnosed with this anomaly. In addition to maternal and fetal medicine specialists, the parents should meet with specialists in pediatric surgery, genetics, neonatology, and pediatric cardiology. This type of approach, coordinated by the maternal and fetal medicine specialists, affords the parents the opportunity to ask questions regarding postnatal surgery, postoperative care, and long-term outcome. If chromosomal abnormalities, associated anomalies, or a particular syndrome is suspected, these issues can be further discussed in detail. After a decision has been reached regarding continuation of the pregnancy, attention is then focused on antepartum surveillance for the development of preterm labor and intrauterine growth restriction. Both of these complications are frequently associated with omphalocele. Rates for preterm delivery range from 26% to 65% and for intrauterine

growth restriction from 6% to 35% (Carpenter et al., 1984; Sermer et al., 1987; Lafferty et al., 1989; Sipes et al., 1990 a,b). There is also a high rate of emergency cesarean delivery due to fetal distress (Moretti et al., 1990; Molenaar and Tibboel, 1993). Because of the high incidence of intrauterine growth restriction, we perform serial ultrasound examinations to assess fetal growth and amniotic fluid volume. In addition, during ultrasound assessment we observe for occasional rupture of the omphalocele membrane, which exposes the herniated intestines to amniotic fluid.

In up to 50% of cases, significant pulmonary hypoplasia and pulmonary hypertension may complicate the neonatal course, particularly in giant omphaloceles (Tsakayannis et al., 1996; Lee et al., 2006). We routinely recommend MRI for total lung volume assessment at 32 to 34 weeks' gestation to help identify fetuses at risk for these complications that, if present, become the overriding determinant of management in omphalocele.

The site and mode of delivery have been debated in the obstetric literature (Lewis et al., 1990; Lurie et al., 1999; Segel et al., 2001). The goal of the management of fetuses with omphalocele is to deliver the fetus as close to term as possible. Delivery at a tertiary care center provides optimal immediate care for the newborn (Hsieh et al., 1989; Lafferty et al., 1989; Lewis et al., 1990; Geijn et al., 1991). In addition, transporting the pregnant woman before delivery, rather than transporting the neonate after delivery, provides immediate neonatal surgical care and eliminates the risk of transporting a critically ill newborn.

Mode of delivery—vaginally or by cesarean—has been the subject of several retrospective reviews. No results from available prospective randomized trials have settled this issue. Older literature advocated the use of cesarean section (Cameron et al., 1978). However, the most recent retrospective reviews do not support the idea that cesarean delivery is associated with an improved survival rate (Sermer et al., 1987; Moretti et al., 1990; Sipes et al., 1990a; Kirk and Wah, 1983; Lurie et al., 1999; Segel et al., 2001). None of the six reported series show any benefit to cesarean delivery. The outcome of giant omphaloceles was not specifically addressed in these studies. Several other authors do not support routine cesarean delivery for fetuses with omphalocele (Carpenter et al., 1984; Hasan and Hermansen, 1986; Hsieh et al., 1989; Lafferty et al., 1989; Lewis et al., 1990; How et al., 2000). Labor itself does not seem to adversely affect outcome, based on the study by Lewis et al. (1990), who compared outcome data from infants delivered via elective cesarean section with those whose delivery was preceded by labor. In cases of small omphaloceles, we currently recommend vaginal delivery and reserve cesarean delivery for routine obstetric indications. However, in isolated cases of giant omphalocele with a defect in the fetal abdomen measuring 5 cm or greater by ultrasound examination, cesarean delivery may be necessary to avoid dystocia. Particularly in cases of extracorporeal liver, we recommend delivering by cesarean section. This approach underscores the need for re-evaluation of the defect as pregnancy progresses.

FETAL INTERVENTION

There are no fetal interventions for omphalocele.

TREATMENT OF THE NEWBORN

Delivery should occur in a tertiary care center, with neonatologists available for immediate resuscitation. Initial treatment consists of airway stabilization and sterile wrapping of the abdominal defect to preserve heat and minimize insensible fluid loss. A complete physical examination should be performed to rule out a syndromic diagnosis. Peripheral vascular access should be established and intravenous fluids given. Mechanical ventilation is frequently necessary, especially postoperatively, when abdominal contents replaced into a small abdominal cavity impede diaphragmatic occlusion and lung expansion. Antibiotics are generally given postoperatively. Initial treatment of the newborn is directed toward preoperative stabilization. Significant pulmonary hypoplasia and associated pulmonary hypertension may complicate the neonatal management of omphalocele from the delivery room on. This may be the most challenging management feature of up to 50% of neonates with giant omphaloceles (Tsakayannis et al., 1996; Lee et al., 2006).

SURGICAL TREATMENT

The surgical approach to the treatment of omphalocele has changed considerably over the past four decades. Until 1965, the only approach for the treatment of omphalocele was the skin flap technique described by Gross (1948). The principal disadvantage of this technique was the creation of a large disfiguring ventral hernia that ultimately required reoperation. This is usually not an insurmountable problem, and success has been reported for repair of these hernias. Considerable time (usually 6 months to 2 years, but sometimes longer) can lapse between initial surgery and final correction of the hernia (Swartz et al., 1985). If at all possible, primary fascial closure is the preferred method of repair because of a lower incidence of sepsis, biliary obstruction, and fistula and a reduced number of operations and rate of mortality in patients who undergo this repair (Figure 62-4) (Robin and Ein, 1976; Aaronson and Eckstein, 1977; Canty and Collins, 1983; Mabogunje and Mahour, 1984; Sauter et al., 1991).

For very large omphaloceles, a staged reduction using a prosthetic silo is preferred (Schuster, 1967; Allen and Wrenn, 1969; Othersen and Smith, 1986). This procedure consists of suturing a Silastic mesh to the rim of fascial defect, which then covers the herniated contents of the omphalocele (Figure 62-5). This technique consists of paralysis with neuromuscular blocking agents, enlargement of the fascial defect, and gradual stretching of the abdominal wall. Despite the success of the silon chimney (Allen and Wrenn, 1969), there remains a significant subset of patients in whom complete reduction

Figure 62-4 Silo repair of omphalocele.

is not achieved before complications of wound/fascial dehiscence, infection, enterocotomy, fistula, and systemic sepsis develop (Stringel and Filler, 1979; Towne et al., 1980; Hershenson et al., 1985; Hatch and Baxter, 1987; Adam et al., 1991; Lee et al., 2006). Nonoperative (conservative) approaches to the treatment of omphalocele have grown in popularity with greater success rates in cases of visceroabdominal disproportion and much lower mortality rates, but they have the disadvantages noted above, as well as prolonged hospitalization (Mabogunje and Mahour, 1984; Hatch and Baxter, 1987; Nuchtern et al., 1995; Tsakayannis et al., 1996). As long as the omphalocele membrane is intact, wrapping the newborn with elastic bandage wraps will gradually reduce the size of the omphalocele and enlarge the peritoneal cavity. A delayed primary repair can be performed after a period of days to weeks. We have found this approach particularly useful in premature infants with giant omphaloceles, and in cases in which there is significant pulmonary hypoplasia or diffuse tracheobronchial malacia with concomitantly difficult ventilatory management. In cases with pulmonary hypoplasia or tracheobronchial malacia, this approach is particularly appealing, as improvement in the respiratory status may take 1 to 2 years.

Although the presence of multiple associated anomalies accounts for the majority of deaths in cases of omphalocele, respiratory complications also account for a significant percentage of the morbidity and mortality due to this lesion (Paidas et al., 1994; Tsakayannis et al., 1996; Lee et al., 2006). Newborns with omphalocele, particularly giant omphalocele, have a high incidence of respiratory insufficiency and chest-wall deformity. Some evidence suggests that impaired lung growth and pulmonary hypoplasia may even be evident antenatally (Hershenson et al., 1985; Argyle, 1989; Thompson et al., 1993).

Neonates may require prolonged mechanical ventilation because of the need for positive pressure to expand a chest compressed by a large abdominal mass. Bronchopulmonary dysplasia and chronic lung disease are potential long-term complications. Tracheostomy may be necessary, either due to pulmonary hypoplasia complicated by the development of bronchopulmonary dysplasia, or for tracheobronchial malacia. It is not uncommon for severe tracheobronchial malacia

Figure 62-5 Intraoperative appearance following closure of newborn abdomen after primary omphalocele repair. The umbilical artery has been transposed to a right lower quadrant site for umbilical artery catheter placement for arterial blood pressure monitoring.

to be associated with giant omphaloceles and requires positive end-expiratory pressures (PEEP) of 10 or even 15 cm of H_2O to keep the airway open. There should be a low threshold for bronchoscopic assessment of the airway to exclude this complication in cases of giant omphaloceles.

LONG-TERM OUTCOME

Even with primary repair of omphalocele, a protracted stay in the newborn nursery should be anticipated. Under the best circumstances, except for hernias of the umbilical cord, some period of mechanical ventilation following omphalocele repair is required. In some cases of giant omphaloceles, there may be underlying pulmonary hypoplasia or tracheobronchial malacia that complicates ventilatory management. Following extubation most infants have feeding difficulties because of the prolonged period without oral stimulation and poor coordination of sucking and swallowing. In addition, many infants have high respiratory rates following omphalocele repair. Because of the compromised diaphragmatic excursion and chest wall motion, these infants maintain their minute ventilation by shallow, rapid breathing patterns. This rapid breathing often interferes with suckling, and gavage feeding may be necessary. Gastroesophageal reflux in these infants is common, which may require medical therapy, transpyloric feeding, or antireflux surgery.

As mentioned previously, the particular anomalies associated with omphalocele have a major impact on long-term outcome. This is especially true of chromosomal and cardiac defects. As survival rates of patients with omphalocele improve, more outcome data will become available, particularly with respect to other aspects that have an impact on the quality of life (Figure 62-6). Preliminary studies suggest that there are higher rates of behavioral problems and musculoskeletal abnormalities in children with abdominal wall defects (Ginn-Pease et al., 1991; Loder and Guiboux, 1993). Kaiser et al. (2000) suggest that a favorable long-term outcome can be anticipated, except in cases associated with severe congenital anomalies. There is one reported case of successful pregnancy in adulthood following the staged repair procedure for a large omphalocele (Ein and Bernstein, 1990).

GENETICS AND RECURRENCE RISK

The recurrence risk depends on the cause of the omphalocele. If the fetus has a chromosomal abnormality due to aneuploidy, such as trisomy 18, the recurrence risk is 1% or the age-related maternal risk, whichever is higher. If a syndrome is diagnosed, the recurrence risk is that of the syndrome (Stoll et al., 2008). Familial cases of Beckwith–Wiedemann syndrome may have as high as a 50% recurrence risk. Nonsyndromal (isolated) omphalocele is generally considered to be a sporadic event, with a negligible recurrence risk. However, at least 17 cases of familial omphalocele have been described (Osuna and Lindham, 1976; DiLiberti, 1982; Pryde et al., 1992). Most of these families appear to transmit the gene as an autosomal dominant gene. In one asymptomatic patient, five consecutive pregnancies by two different nonconsanguineous partners were complicated by fetuses with isolated omphalocele (Pryde et al., 1992).

63 Gastroschisis

CHAPTER

Key Points

- Isolated abdominal wall defect to right of normally inserted umbilical cord.
- Associated with young maternal age and maternal smoking.
- Associated with growth restriction and abnormalities of amniotic fluid.
- The efficacy of amnioexchange is under investigation.
- Increased incidence of intrauterine fetal demise in the third trimester.
- Intestinal atresia can complicate 10% to 15% of cases.

Figure 63-1 Newborn infant with gastroschisis demonstrating characteristic "peel."

CONDITION

Gastroschisis (Greek for belly cleft) is a full-thickness defect in the abdominal wall that occurs secondary to incomplete closure of the lateral folds during the 6th week of gestation (Moore and Stokes, 1953; Moore and Persaud, 1993). At birth, the eviscerated bowel characteristically has a thick edematous appearance described by Moore as a "peel" (Figure 63-1). The peel involves the serosa and is composed of fibrin and collagen. The peel in gastroschisis is thought to be caused by an inflammatory reaction as a result of exposure to amniotic fluid, combined with constriction at the abdominal wall defect (Amoury and Holder, 1977; Klein et al., 1983; Tibboel et al., 1986a,b; Amoury et al., 1988; Langer et al., 1990; Moore, 1992). Duhamel (1963) theorized that gastroschisis originates from a discrete teratogenic insult that results in an isolated defect in differentiation of the somatopleural mesenchyme. Others argue that gastroschisis is due to an in utero rupture of an umbilical cord hernia after completion of the infold in the anterior abdominal wall, but before complete closure of the umbilical ring (Shaw, 1975). In at least some cases, in utero rupture of a hernia of the cord that resulted in gastroschisis supports the argument for this being a cause (Glick et al., 1985). DeVries (1980) suggested that gastroschisis could be caused by a congenital weakness on the right side of the umbilical cord. From an umbilical cord hernia, premature atrophy or abnormal persistence of the right umbilical vein could predispose to disruption of the somatopleura at its junction with the body stalk. Because gastrointestinal defects such as atresia associated with gastroschisis are caused by vascular disruptions, Hoyme et al. (1983) suggested that gastroschisis may be caused by disruption of the right omphalomesenteric artery, which connects the yolk sac with the dorsal aorta. The fact that gastroschisis almost always occurs to the right of the umbilical ring is consistent with these latter theories (Torfs et al., 1990).

As second trimester maternal serum-α-fetoprotein (MSAFP) screening has become incorporated into routine prenatal care, more cases of gastroschisis are being detected prenatally. This is due to the association between elevated MSAFP levels and ventral abdominal wall defects (McKeown et al., 1953; Brock et al., 1979; Redford et al., 1985; Stiller et al., 1990; Killam et al., 1991). In one study, Larson et al. (1993) found a 58% incidence of major fetal congenital anomalies when extremely elevated MSAFP levels were detected between 15 and 20 weeks of gestation. Ten percent of these were due to abdominal wall defects. The sensitivity of MSAFP screening for the detection of abdominal wall defects varies depending on the type of abdominal wall defect, the geographical area, and the cutoff value of MSAFP used.

MSAFP screening has a higher sensitivity for detecting gastroschisis than omphalocele. In a population-based study of MSAFP screening, using patients from Maine and Rhode Island, Palomaki et al. (1988) found that the combined incidence of gastroschisis and omphalocele was 4.5 in 10,000 livebirths (excluding neural tube defects, twins, and autosomal chromosomal anomalies). At each cutoff of MSAFP, detection rates were higher for gastroschisis than for omphalocele. For example, at a cutoff of 2 multiples of the mean (MoM), the detection rate was more than 99% for gastroschisis and 78% for omphalocele. At cutoff values of 2.5 MoM and 3 MoM, the detection rates were more than 98% and 71%, and 96% and 65%, for gastroschisis and omphalocele, respectively. The median MSAFP value of the 20 cases of gastroschisis was 7 MoM and the median value for omphalocele was 4.1 MoM (Palomaki et al., 1988). Crandall et al. (1991) have shown that the higher the MSAFP level the greater the prevalence of adverse fetal outcome. A lower detection rate in omphalocele is likely due to the presence of an intact membrane covering the abdominal viscera in unruptured omphaloceles as opposed to the direct exposure of bowel to the amniotic fluid in gastroschisis.

Analysis of amniotic fluid α-fetoprotein and acetylcholinesterase pseudocholinesterase levels (ratio 0.13) is very sensitive in detecting gastroschisis (Goldfine et al., 1989). Human chorionic gonadotropin (hCG) levels have been measured in 16 pregnancies with abdominal wall defects (12 gastroschises, 4 omphaloceles) because this marker is already being increasingly used for fetal aneuploidy screening. It may have utility as an additional marker for the presence of abdominal wall defects. Using a cutoff value of 2.3 MoM, the detection rate using hCG was 31%, as compared with 81% for MSAFP. Using the two markers, the detection rate increased to 87.5%, by finding one additional case (Schmidt et al., 1993). More data are necessary to evaluate the usefulness of hCG levels to prospectively identify abdominal wall defects.

INCIDENCE

Before 1953, gastroschisis was not clearly distinguished from omphalocele (Moore and Persaud, 1993). Consequently, a reliable estimate of the frequency of gastroschisis before then is impossible. Several investigators have found that the prevalence of gastroschisis has increased over the past few decades in different geographic regions (Hwang and Kousseff, 2004). Roeper et al. (1987) documented in California that the rate of gastroschisis has increased from 0.006 in 1000 livebirths in 1968 to 0.089 in 1000 livebirths in 1977. Similarly, Florida, Sweden, Finland, and Spain have reported increased prevalence rates over the same period (Lindham, 1981; Hemmenki et al., 1982; Martinez-Frias et al., 1984; Hwang and Kousseff, 2004). The overall prevalence in Europe has been reported to be 0.07 in 1000 live- and stillbirths (Calzolari et al., 1993). Studies from British Columbia and Italy have not confirmed this trend (Baird and MacDonald, 1981; Calzolari et al., 1993).

Both older and more recent data from epidemiologic studies have consistently demonstrated that young maternal age is associated with an increased risk of gastroschisis (Colombani and Cunningham, 1977; Hemmenki et al., 1982; Martinez-Frias et al., 1984; Roeper et al., 1987). Goldbaum et al. (1990) compared 62 infants who had gastroschisis with 617 randomly selected, unaffected infants matched for the first year of birth in the state of Washington. They found that maternal age younger than 20 years was associated with a fourfold increased risk of having an infant with gastroschisis. A study by Werler et al. (1992) included patients from Boston, Philadelphia, and portions of Ontario and Iowa. They compared 76 cases of gastroschisis with 2582 malformed controls and found a strong inverse association with maternal age. Compared with women 30 years or older, the relative risks for maternal ages 25 to 29, 20 to 24, and younger than 20 were 1.7, 5.4, and 16, respectively (Werler et al., 1992).

In addition to young maternal age, maternal cigarette use has also been associated with an increased risk of gastroschisis. Goldbaum et al. (1990) were the first to suggest this relationship. In a prospective population-based study using 62,103 consecutive second trimester MSAFP samples, Haddow et al. (1993) found that women who smoked had a 2.1-fold greater risk of fetal gastroschisis than nonsmokers. Although their finding was not considered statistically significant, the trend was consistent with the report by Goldbaum et al. (1990). In contrast, Werler et al. (1992) found no association with cigarette use in early pregnancy when heavy (more than 15 cigarettes per day) and light (less than 15 cigarettes per day) were compared. However, when the results of these three studies are combined, the relative risk for having a baby with gastroschisis is 1.6 for women who smoke (Haddow et al., 1993).

Although reports are conflicting, the incidence of gastroschisis has also been associated with seasonal variation. These studies found an increased risk of gastroschisis in deliveries occurring during the first quarter of the year (Egenaes and Bjerkedal, 1982; Hemmenki et al., 1982; Goldbaum et al., 1990). However, three other studies found no seasonal variation (Paulozzi, 1986; Roeper et al., 1987; Haddow et al., 1993). Vascular disruption has been suggested by cases of gastroschisis observed in women who took medications with vasoactive properties during pregnancy (Van Allen, 1981). In a prospective screening study of maternal hair samples using gas chromatography with mass spectroscopy, Morrison et al. (2005) found a 25% incidence of periconceptual recreational drug use. The most commonly detected compounds were methamphetamine, including MDMA and MDEA, and cocaine. There is good evidence from animal data that methamphetamines cause fetal malformations including cardiac defects, facial clefts, eye abnormalities, skeletal malformations, kidney defects, and gastroschisis (Colado et al., 1997; Plessinger, 1998). Amphetamines and cocaine have similar maternal effects, as they are both central nervous system stimulants. They produce different fetal developmental effects (Little et al., 1988). Werler et al. (1992) reported on first trimester medication use in a case–control study of 76 cases of gastroschisis and 2142 matched controls. They found that the decongestant pseudoephedrine was associated with a greater than threefold risk of gastroschisis. Salicylates and acetaminophen were also associated with elevated risk, but these differences were not statistically significant. The authors also evaluated the use of these medications in pregnancies with other fetal anomalies that were presumed to have a vascular cause; no associations were found. Further studies are needed to clarify the role of vasoactive agents in the pathogenesis of gastroschisis.

SONOGRAPHIC FINDINGS

The diagnosis of abdominal wall defects during the first trimester is difficult because it is normal for the midgut to be herniated into the umbilical cord. Cyr et al. (1986) documented the events of bowel migration by abdominal sonographic examination of 10 normal first trimester fetuses, as well as by pathologic examination of several embryo specimens. The midgut that will normally form the small bowel,

cecum, and ascending and proximal transverse colon is connected to the yolk sac. This connection is reduced to a narrow yolk stalk as the amniotic cavity expands and the yolk sac is pulled away from the embryo. The mesentery suspending the midgut then rapidly elongates, creating a U-shaped loop of midgut that herniates into the umbilical cord. The loop of intestine then rotates 90 degrees in a counterclockwise direction about the axis of the superior mesenteric artery. As these loops of bowel return to the abdominal cavity by 11 weeks of gestation, the loops rotate counterclockwise another 180 degrees to complete the bowel rotation. Cyr et al. (1986) have suggested that ultrasound examination should be performed at 14 weeks of gestation because the bowel should be entirely intra-abdominal by 11 weeks, and this allows for errors in estimating gestational age. However, in 20% of fetuses, the bowel was still outside the abdomen at 12 weeks (Green and Hobbins, 1988). The size of the herniated gut may be helpful in distinguishing between physiologic and pathologic bowel herniation. The dimensions of bowel herniation have been reported to be 1 cm in the study by Cyr et al. (1986) and 7 mm in greatest dimension in the study by Bowerman (1993).

Vaginal sonography affords a closer look at the fetus in early gestation and may be helpful in distinguishing the contents of the herniation. In a series of 61 fetuses studied by vaginal sonography, by 12 weeks of gestation the midgut herniation no longer persisted (Timor-Tritsch et al., 1989). The earliest diagnosis of gastroschisis was 12 weeks 3 days (Guzman, 1990).

Gastroschisis is a full-thickness defect in the anterior abdominal wall almost invariably located to the right of the intact umbilical cord, measuring 2 to 3 cm in diameter (Figure 63-2) (Fonkalsrud, 1980). Color Doppler studies assist in demonstrating normal umbilical cord insertion with herniation of intestine to the right of the umbilical cord. Nyberg et al. (1993) have summarized the sonographic features of gastroschisis. In addition to the small abdominal wall defect located to the right of a normal umbilical cord insertion site, there is a variable amount of bowel protruding through the defect, floating in the amniotic fluid, which may be disproportionally large relative to the small size of the abdominal cavity (Figure 63-3).

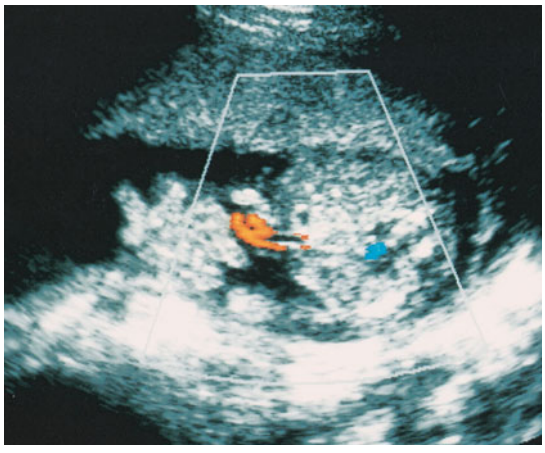

Figure 63-2 Color flow Doppler image in fetus with gastroschisis, demonstrating small defect with herniated midgut.

Despite the frequent use of antenatal ultrasound examination in obstetric care over the past two decades, there is still little information regarding the accuracy of routine ultrasound examination in the detection of abdominal wall defects (Hill et al., 1985; Rosendahl and Kivinen, 1989; Ewigman et al., 1993). Walkinshaw et al. (1992) reported on their experience in the United Kingdom for more than a 4-year period, extending from 1984 to 1988, during which 115 cases of anterior abdominal wall defects were found in 202,488 livebirths and intrauterine deaths beyond 22 weeks of gestation. They found that routine scanning identified 60% of the defects, with a false-positive rate of 5.3%. Gastroschisis

Figure 63-3 Prenatal ultrasound image demonstrating loops of intestine floating free in amniotic fluid.

and omphalocele were accurately distinguished in 79.3% of cases on initial diagnosis and 84.5% of cases after referral for further evaluation. Many factors contribute to the less than 100% detection of abdominal wall defects, including the quality of the ultrasound equipment, the experience of the sonographer, and the defect itself (Paidas et al., 1994). It is possible that one form of gastroschisis, due to rupture of a hernia of the cord as originally described by Moore (1962), would not be detected by routine ultrasound examination because it appears late in pregnancy. Knott and Colley (1987) have described two similar cases of gastroschisis not detected by antenatal ultrasound examination that were felt to occur as a result of late gestational rupture of a hernia of the cord.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of gastroschisis should include omphalocele, ruptured omphalocele, hernia of the cord, and limb–body wall complex. Gastroschisis is distinguished from omphalocele by having no membrane surrounding the herniated loops of intestine. In contrast, omphalocele has a peritoneo-amniotic membrane covering the defect and the size is significantly larger than the defect in gastroschisis. Ruptured omphalocele may be confused with gastroschisis, as the loops of intestine are observed to be floating free in the amniotic cavity. However, extracorporeal liver may be seen in ruptured omphalocele, but is never seen in gastroschisis. The limb–body wall complex may have an abdominal wall defect but is usually easily distinguished from gastroschisis by a short umbilical cord and numerous other associated structural anomalies.

ANTENATAL NATURAL HISTORY

The conventional wisdom regarding abdominal wall defects is that gastroschisis, unlike omphalocele, is not associated with chromosomal abnormalities. This discrepancy regarding the presence of associated chromosomal abnormalities has provided further impetus to distinguish these two entities by sonography. Reports in the literature have confirmed that chromosomal abnormalities are rare or absent in gastroschisis (Mayer et al., 1980; Mann and Ferguson-Smith, 1984; Sermer et al., 1987; Romero et al., 1988; Lewinsky et al., 1990; Sipes et al., 1990a). In the 17-year experience at the Children's Hospital in Columbus, Ohio, chromosomal analysis was available in 128 of 144 cases of gastroschisis and there was only 1 case of chromosomal abnormality (trisomy 18) (King et al., 1980; Caniano et al., 1990). Nicolaides et al. (1992) did not find any chromosomal abnormalities in 26 cases of gastroschisis detected during an 8-year period. Abdullah et al. (2007) found only four cases (0.1%) of aneuploidy among 4344 infants with gastroschisis in the United States. In the absence of sonographically detectable associated anomalies, the risks for fetal aneuploidy are probably comparable to the risks due to maternal age alone. If additional fetal abnormalities are detected sonographically, chromosomal evaluation should be recommended.

In contrast to omphalocele, gastroschisis is usually not associated with extragastrointestinal abnormalities. This is in part responsible for the better outcome observed in gastroschisis. In a survey of 13 years of the National Inpatient Sample Database and 3 years of the KIDs' Inpatient Database, Abdullah et al. found among 4344 cases of gastroschisis reported only 72 (1.7%) cases of pulmonary defects (including agenesis, hypoplasia, and bronchopulmonary dysplasia) and 379 cardiac defects, of which 190 were atrial septal defects (ASDs) and 214 patent ductus arteriosus cases that would not be detectable on prenatal ultrasound examination. There were also 138 cases of undescended testicles (6.8%) and 58 cases of hydronephrosis (1.3%) (Abdullah et al., 2007). However, in a report from Kunz et al. (2005) in a study of California hospital discharge data from 1972 to 1997, 25 of 621 infants with gastroschisis were found to have congenital heart disease (4% incidence). This group also found a significant increase of congenital heart disease if the gastroschisis was complicated by bowel atresia, or if the infant was African American. Gibbin et al. found an incidence of abnormal cardiac findings of 15%, but of the four, one was persistent pulmonary hypertension, two were supraventricular tachycardia, and the last was peripheral pulmonic stenosis (Gibbin et al., 2003). However, gastrointestinal anomalies can commonly be seen in gastroschisis, and occur in 20% to 40% of cases (King et al., 1980; Mayer et al., 1980; DeLorenzo et al., 1987; Nicolaides et al., 1992; Novotny et al., 1993). These gastrointestinal abnormalities may be secondary to the gastroschisis. These include malrotation, atresia, "Christmas-tree deformity," volvulus, and infarction.

Even in the rare cases in which they are present, nongastrointestinal abnormalities are not usually life-threatening. It is interesting that the data registry report from Abdullah et al. (2007) had a lower than expected 8.1% incidence.

Fetuses with gastroschisis are at risk for a number of complications that directly affect survival during the newborn period. Obstetric complications include intrauterine growth restriction (IUGR), which can affect up to 77% of fetuses (Carpenter et al., 1984; Molenaar and Tibboel, 1993). This may be due to nutritional deprivation rather than a constitutional limitation (Gutenberger et al., 1973). In an analysis of biometric data Royner and Richards (1977) found that IUGR was predicted in 43% of infants, but was present in only 23% at birth. This group thought that the prevalence of IUGR is increased in gastroschisis, but is overestimated with prenatal ultrasonography, primarily because of the smaller-than-average abdominal circumference. Carroll et al. (2001) suggested a novel explanation for the frequent observation of growth restriction among fetuses with gastroschisis; protein loss into the amniotic cavity. In a small series of 12 fetuses with prenatally diagnosed gastroschisis were compared with 29 control infants without gastroschisis. They found that fetuses with gastroschisis had significantly lower serum total

protein and significantly higher amniotic fluid total protein, and α-fetoprotein.

Despite the predisposition to IUGR, a more important factor in neonatal outcome is prematurity. Puligandla et al. (2004) found that in a retrospective series of 113 cases of gastroschisis, infants with IUGR had similar outcomes to non-IUGR infants. Factors that were more important with regard to neonatal outcome were prematurity and the presence of atresia (Puligandla et al., 2004).

Other obstetric complications include preterm labor, which occurs in more than one-third of cases due to associated polyhydramnios (Mayer et al., 1980; Kirk and Wah, 1983; Carpenter et al., 1984; Caplan and MacGregor, 1989; Molenaar and Tibboel, 1993). Abnormalities of amniotic fluid volume, both polyhydramnios and oligohydramnios, can accompany gastroschisis (Bair et al., 1986; Crawford et al., 1992). Mercer et al. (1988) reported that in their series of 22 cases of gastroschisis, marked amniotic fluid staining occurred in 73%. The association of amniotic fluid staining with fetal distress is controversial (Carpenter et al., 1984; Crawford et al., 1992).

Because the condition of the bowel at the time of birth is the single most important factor affecting long-term outcome for fetuses with gastroschisis, several investigators have monitored the ultrasonographic appearance of the bowel (Stringel and Filler, 1978; Luck et al., 1985). The extent of bowel damage is variable in gastroschisis and can range from only mild to severe, with bowel atresia and necrosis requiring resection with staged repair. These latter cases are often characterized on sonography by extreme intestinal hypoperistalsis and poor absorptive capacity (O'Neill and Grosfeld, 1974; Oh et al., 1978). Although the cause of bowel damage is not entirely understood, it seems that most of the damage is caused by constriction at the site of the abdominal wall defect and that this occurs primarily late in gestation (Langer et al., 1989, 1990). Based on experimental findings in fetal lambs, Langer et al. (1993) suggested that the mechanism of constriction-induced damage is related mainly to obstruction and not ischemia.

Bond et al. (1988) published a series of 11 cases of gastroschisis correlating the prenatal ultrasonographic appearance of the eviscerated bowel with clinical outcome. The presence of small-bowel dilation and mural thickening correlated with severe intestinal damage and poor clinical outcome. The absence of these findings was associated with a more benign clinical course. These authors suggested that these two ultrasonographic features—bowel dilatation and bowel thickening—could be useful in following fetuses with gastroschisis and in determining the time of delivery. Other reports have not found these findings to be at all predictive of outcome in gastroschisis (Lenke et al., 1990; Sipes et al., 1990b; Alsulyman et al., 1996). Early detection of signs of bowel damage would allow delivery at fetal lung maturity to prevent ongoing injury to the bowel and decrease the likelihood of hypoperistalsis syndrome. Three small series have not found that these two characteristics were useful in predicting outcome (Lenke et al., 1990; Sipes et al., 1990b; Alsulyman et al., 1996).

In a combined retrospective and prospective study, Langer et al. (1993) evaluated 24 fetuses with gastroschisis and found that bowel thickening was associated with an increased time to oral feeding, but this finding did not achieve statistical significance, possibly due to the small number of patients. As opposed to using a specific cutoff for bowel damage, these authors suggested using a value that had a specific threshold for gestational age. From their own data, fetuses above this threshold value had hypoperistalsis and below it only 30% had a hypoperistalsis. Interestingly, Aina-Mumuney et al. (2004) have noted that a dilated fetal stomach found in 13 of 34 prenatally diagnosed cases of gastroschisis was associated with a statistically significant greater incidence of nonreactive nonstress tests, volvulus, neonatal death, as well as delayed time to full oral feeding and longer hospitalization, compared to those that did not have a dilated stomach (Aina-Mumuney et al., 2004).

A disturbingly high incidence of intrauterine fetal demise and stillbirth during the third trimester has consistently been reported, with rates as high as 10.6% (Crawford et al., 1992; Burge and Ade-Ajayi, 1997). Broth et al. (2001) reported that among 78 cases of gastroschisis, the stillbirth rate after 28 weeks' gestation was 85 per 1000 births compared to a control group rate of 5.4 per 1000 births. The cause of stillbirth is thought to be either midgut volvulus or progressive cord compression by eviscerated bowel. Kalache et al. (2002) reported a case of gastroschisis complicated by sudden dilation of the bowel at 34 weeks' gestation with the development of notching of the umbilical artery waveform. This was thought to be due to compression, which has previously been reported with stomach herniation in gastroschisis (Robinson et al., 1997). Notching of the umbilical arterial Doppler waveform has also been observed in cord entanglement in monoamniotic twins (Kofinas et al., 1991). This sign should be looked for in third trimester fetuses with gastroschisis as an indicator for nonstress testing.

Although fetal imaging has not provided useful prognostic indicators of severity of gastroschisis, it is possible that amniotic fluid levels of β endorphins may. Mahieu-Caputo et al. (2002) have found that amniotic fluid β endorphin levels above 10 μg/L ($n = 4$) versus 5 μg/L ($n = 9$) correlated with longer duration of ventilation, parenteral nutrition, and duration of hospitalization. These investigators speculated that elevated β endorphin levels could result from fetal stress caused by bowel damage.

MANAGEMENT OF PREGNANCY

Crawford et al. (1992) have recommended biophysical profile testing for pregnancies with gastroschisis because they found a 12.5% rate of stillbirths. Because these deaths occurred late in the third trimester, they suggested that testing begin at 30 to 32 weeks of gestation.

We are currently monitoring our cases of gastroschisis with biophysical testing beginning at 30 weeks' gestation, and

by performing weekly sonography to assess bowel thickness, dilation, evidence of increased peristalsis, or dilated stomach. If sonographic evidence of bowel damage is detected, consideration can be given to delivery as soon as the lungs mature to prevent ongoing injury. However, detection of bowel dilation alone may be due to atresia, in which case delivery will have no benefit.

The recommended mode of delivery for fetuses with abdominal wall defects is controversial. Part of the difficulty in comparing the vaginal versus abdominal approach is the presence of multiple confounding factors, such as antenatal diagnosis of lesion, presence or absence of labor, maternal and neonatal transport, interval between delivery and surgery, and place of delivery. Kirk and Wah (1983) reported 74 cases of gastroschisis, 65 of which were delivered vaginally and 9 by cesarean section. There were five deaths in each group, resulting in a much higher mortality rate for fetuses delivered by cesarean section. Lenke and Hatch (1986) retrospectively reviewed their series of 24 cases of gastroschisis. Seven of 24 infants were delivered by cesarean section and all had a good outcome. There were 3 deaths among the remaining 17 delivered vaginally. Only 11 of the 17 cases of gastroschisis were able to have primary closure, as opposed to all of the infants delivered by cesarean section. These authors also commented that in all infants delivered by cesarean, there was no evidence of the inflammatory "peel," or inflamed serosa, on the eviscerated bowel seen in the worst cases of gastroschisis. Moretti et al. (1990) reported on 56 fetuses with gastroschisis, and did not find any differences in infant mortality, short- or long-term outcome, or frequency of associated major anomalies. However, in their experience, only 8% of the defects were detected antenatally. Other authors did not find any benefit to abdominal delivery (Kirk and Wah, 1983; Carpenter et al., 1984; Davidson et al., 1984; Calisti et al., 1987; Sermer et al., 1987; Sipes et al., 1990a; Puligandla et al., 2004). In an attempt to control for confounding variables, Lewis et al. (1990) reviewed their experience with 56 cases at level-three institutions and found no benefit to cesarean delivery. Coughlin et al. (1993) have reported the results of a trial of cesarean delivery with staff standing by in an adjacent operating room for immediate repair of the gastroschisis. In this small series of cases, cesarean delivery and immediate repair were associated with a greater rate of primary closure, a shorter period of mechanical ventilatory support, and a shorter interval to enteral alimentation, as compared with historical controls delivered vaginally who underwent more routine gastroschisis repair. As demonstrated in these reports, at present there is no compelling evidence for cesarean over vaginal delivery in gastroschisis except for routine obstetrical indications.

The neonatal outcomes in gastroschisis do not appear to be adversely affected by labor or rupture of membranes (Strauss et al., 2003). However, some have suggested that it is the timing, not the mode of delivery that results in improved outcome (Lenke and Hatch, 1986; Moore, 1988, 1992; Swift et al., 1992; Langer, 2003). These authors mention that most of the bowel injury occurs late in gestation, which may be avoided with early delivery. We recommend transferring the mother to a tertiary care center before delivery to better coordinate the obstetric, neonatal, and pediatric surgical teams (Carlan et al., 1990; Nicholls et al., 1993; Stoodley et al., 1993; Paidas et al., 1994).

In patients managed by vaginal delivery as opposed to elective cesarean section, continuous cardiotocography may be helpful in identifying fetal distress (Brantberg et al., 2004). In a series of all patients prenatally diagnosed with gastroschisis at the National Center for Fetal Medicine in Norway, Brantberg et al. found that cardiotocographic monitoring detected abnormalities in 22% of 64 fetuses. There was only a single case of intrauterine fetal demise (IUFD) in the series. They attributed the improved outcome to better detection of fetal distress.

FETAL INTERVENTION

There is currently no accepted fetal intervention for gastroschisis. However, there is interest in some centers for the use of amnioexchange to improve bowel function in gastroschisis. The rationale for this approach is that bowel damage occurs in utero from two mechanisms: constriction at the abdominal wall (Langer et al., 1989, 1990) and chemical irritants in the amniotic fluid, which stimulate an inflammatory response in bowel serosa (Langer et al., 1989; Albert et al., 1993; Luton et al., 2003). The first published case of amnioexchange to treat fetal gastroschisis was reported by Aktug (Aktuğ et al., 1995), with four amnioexchanges between 29 and 34 weeks of gestation. Enteral nutrition was achieved by 5 days and the infant was discharged to home at day 8.

Based on favorable results in a fetal sheep model demonstrating improved serosal fibrosis, decreased inflammatory cell infiltration and clearance of inflammatory and gastrointestinal waste product (Luton et al., 2000; Thebaud et al., 2002), Luton et al. (2003) conducted a pilot study in human gastroschisis. Amnioexchanges start at 30 weeks of gestation via transabdominal amniotic fluid drainage through a 20-gauge needle. Amniotic fluid is replaced serially 300 mL by 300 mL with warm sterile saline, for a total of 600 to 900 mL replaced at each procedure. Compared to a historical control group, the amnioexchange group had the same mean gestational age at delivery (36.9 ± 1.3 weeks), without chorioamniotic or premature rupture of membranes in the first 30 patients treated.

Analysis of the first 10 patients showed a nonsignificant trend for less severe perivisceritis, reduced time on mechanical ventilation, need for hospitalization, and hospital stay. The authors contend that if extrapolated to the full 30 patients, these trends would achieve statistical significance. This same group reported a favorable effect of amnioexchange on the extra-abdominal mesenteric artery Doppler index (Volumenie et al., 2001). There was, however, no correlation with postnatal outcome. Amnioexchange does not address the constrictive effects at the abdominal wall. As these investigations acknowledge, the data thus far do not prove

efficacy of amnioexchange. The problem with this approach is not the rationale for amnioexchange nor the potential for amnioexchange to reduce perivisceritis. Rather, the weakness lies in the lack of selection criteria. Most newborns with gastroschisis do not have severe perivisceritis or inflammatory peel and they do very well with conventional postnatal treatment. There is a subset of gastroschisis patients (representing 10%–15% of cases) in which there is a severe inflammatory peel, protracted need for parenteral nutrition, compromised gut mobility and prolonged hospitalization. Until accurate sonographic criteria are developed to identify this subset of fetuses with gastroschisis, it is unlikely that anmioexchange will improve outcome and has the potential to expose patients to the risk of this intervention with little hope of benefit.

TREATMENT OF THE NEWBORN

At delivery, the infant's lower body should be placed in a clear plastic bowel bag to minimize evaporative losses. The exposed bowel should be kept moist and handled in a sterile fashion. The intestines should be supported by bolsters of rolled gauze placed on either side of the abdominal wall defect to prevent kinking at the abdominal wall, which would result in venous congestion and subsequent acidosis. The infant should be placed in the right lateral decubitus position to minimize the chances of obstruction at the abdominal wall. The bowel should be covered with nonadherent sterile petroleum gauze and wrapped in sterile dry gauze and placed in a Lahey bag. A nasogastric tube should be inserted and placed for suction to prevent bowel distention from swallowing air. Venous access should be obtained in the upper extremities, antibiotics (ampicillin and gentamicin) should be administered, and crystalloid infusion begun as soon as possible to replace ongoing third-space losses. It is not uncommon for these newborns to become quite dehydrated because of the excessive evaporative losses of the exposed viscera. Adequate volume resuscitation is essential for proper treatment and prevention of necrotizing fasciitis.

SURGICAL TREATMENT

Success has been achieved with both primary closure and staged silo reduction, with the surgery tailored to each individual case (Ein and Rubin, 1980; King et al., 1980; Luck et al., 1985; DeLorenzo et al., 1987; Caniano et al., 1990; Novotny et al., 1993). No matter which operative strategy is employed, the infant is nutritionally supported by parenteral nutrition delivered via PICC line or broviac. The advantages of primary closure are shorter intervals to oral feeding, reduced hospital stay, and the lack of further extensive surgery. However, the success of primary closure depends on the degree of visceroabdominal disproportion. Excessive abdominal wall tension can cause vena caval compression, compromised respiratory function, postrenal oliguria from ureteral obstruction, and even bowel ischemia. Intragastric pressure and central venous pressure recordings have been advocated to detect excessively high intra-abdominal pressures during attempted closure (Yaster et al., 1989). In a review of 30 cases of gastroschisis, Bryant et al. (1985) found that the interval to return to oral alimentation was not related to the type of closure.

The risk of ongoing evaporative water loss, heat loss, and metabolic derangements that occur as a result makes rapid coverage of the bowel a priority (Ledbetter, 2006). In the delivery room or upon arrival in the NICU, the bowel can be placed in a prefabricated, spring-loaded, silastic silo. These preformed silos can be placed at the bedside without anesthesia. If the fascial ring is too small, the defect can be enlarged with local anesthesia and sedation (Minkes et al., 2000). The placement of a prefabricated silo converts the operative closure to an elective procedure once the gravity has reduced the bowel edema, allowing bowel loops to return to the abdominal cavity. This process usually takes 5 to 7 days and can be facilitated by gently reducing the bowel and placing an umbilical tape tie to keep the bowel reduced. The process can usually be accomplished without the need for the infant to be intubated, ventilated, or the use of muscle relaxants. Once the bowel has been completely reduced, the infant is taken to the operating room for a delayed primary closure of the fascia.

Introduction of the silo by Schuster (1967) was a major advance in management of gastroschisis with severe visceroabdominal disproportion. Creation of a silo sutured to the fascia can be performed as a primary procedure or if reduction with a preformed silo is unsuccessful. The viscera are gradually reduced into the abdomen by sequential tightening of the silastic silo (Figure 63-4). The goal of this therapy is the gradual reduction of viscera over 3 to 5 days. After 7 days, the risks of infection with this technique increase significantly. The infant may be intubated and neuromuscular paralysis

Figure 63-4 Intraoperative view during creation of silo for staged closure of gastroschisis.

induced to allow maximal relaxation of the abdominal wall. Once all of the viscera are reduced, the infant is returned to the operating room, where the silastic silo is removed and a fascial closure is performed. Other methods of closure useful in selected cases include extensive skin flaps, umbilical cord patch, Ringer clamp, or Gore-Tex patch closure (Muraji et al., 1989; Zivkovle, 1991; Sawin et al., 1992; Stringel, 1993).

Potential postoperative complications are numerous and include intestinal ischemia, bowel infarction, enterocutaneous fistula, necrotizing enterocolitis, and prolonged intestinal dysfunction (Ein et al., 1988; Oldham et al., 1988; Caniano et al., 1990). Intestinal atresia can complicate gastroschisis, and is reported to occur in 5.5% to 23% of patients (Amoury and Holder, 1977; Pokorny et al., 1981; DeLorenzo et al., 1987; Gornall, 1989; Shah and Woolley, 1991). These may be single or multiple, and may involve the small or large bowel.

The primary goal in gastroschisis complicated by atresia is abdominal wall closure either by primary closure, use of prefabricated silo, or operative silo creation. Even if the atresia is recognized, no attempt should be made at resection of the atresia as the bowel is usually edematous and inflamed. Resection and primary anastomosis are at high risk for breakdown. By 2 weeks following primary repair of the abdominal wall defect, there is complete resolution of edema, inflammation, and peel, making resection and anastomosis readily accomplished (Snyder et al., 2001). Even in the rare instance in which there is perforation at the time of delivery, the proximal and distal bowel should be ligated. There should be at least a 2-week interval from abdominal wall repair to resection of atresia and primary repair.

LONG-TERM OUTCOME

The duration of hospitalization is directly related to the degree of gastrointestinal compromise or presence of gastrointestinal atresia. Some patients with gastroschisis will have hypoperistalsis syndrome. These infants remain dependent on parenteral nutrition for an indefinite period, sometimes permanently. The average hospital stay following closure of gastroschisis is usually on the order of 3 to 4 weeks. Often feeding difficulties after repair of gastroschisis will delay discharge because of the need for gavage feedings. Although primary closure may be achieved and infants are weaned from mechanical ventilatory support, they often remain quite tachypneic, which impairs their ability to suck. Once further abdominal wall relaxation and accommodation has had time to occur, there is less tension and pressure on the diaphragm and the respiratory rate decreases. Once a respiratory rate of less than 70 breaths per minute is achieved, infants can suck effectively and be weaned from supplemental gavage feeding.

Hospitalization for infants with gastroschisis requiring a repair of an atresia can be longer, related to the need for a second procedure to address the atresia. The hospitalization in these infants may be prolonged by several weeks.

There are usually no long-term sequelae from gastroschisis if there is no associated hypoperistalsis syndrome (Lunzer et al., 2001). Inguinal hernias will develop not uncommonly in infants with gastroschisis because of increased intra-abdominal pressure. Occasionally, incisional hernias seen as bulging from attenuated fascia at the closure site will require remedial surgery months or years later.

GENETICS AND RECURRENCE RISK

Gastroschisis has been generally considered to be a sporadic event, with a multifactorial cause, but there have been reports of familial recurrence (Salinar et al., 1979; Lowry and Baird, 1982; Hershey et al., 1989; Schmidt et al., 2005). Torfs et al. (1990) described a 4.3% sibling recurrence rate in a population-based study. An approximately 4% recurrence risk implies a mixture of genetic predisposition with environmental factors (Torfs and Curry, 1993). A single-gene defect is unlikely for this condition. Families should receive genetic counseling regarding recurrence risk. They should be offered MSAFP testing and prenatal sonography in future pregnancies.

64 CHAPTER Cloacal Exstrophy

Key Points

- Arises from maldevelopment of the cloacal membrane, which prevents migration of mesenchymal tissue and impedes normal development of the lower abdominal wall.
- Consists of exstrophy of the urinary bladder, exstrophy of the small or large intestine, anal atresia, hypoplasia of the colon, omphalocele, and malformed genitalia.
- Incidence 1 in 200,000 to 400,000 livebirths.
- Associated sonographic signs may include: large infraumbilical anterior midline defect with a protruding omphalocele, absent bladder, narrowed thorax, distorted spine, sacral myelomeningocele, and bilateral clubfeet. However, a correct prenatal diagnosis is rarely made.
- Differential diagnosis includes bladder exstrophy, omphalocele, gastroschisis, amniotic band syndrome, myelomeningocele, and the limb–body wall deformity.
- Management of pregnancy should include MRI, karyotype, and multidisciplinary consultation with surgery, urology, endocrinology, and genetics.
- Delivery should occur in a tertiary center.
- If the fetus is genetically male, the parents should be counseled about the potential need to reassign gender.

CONDITION

Cloacal exstrophy represents a spectrum of rare congenital anomalies that are thought to arise from maldevelopment of the cloacal membrane, which prevents migration of mesenchymal tissue and impedes normal development of the lower abdominal wall. The cloacal membrane separates the coelomic cavity from the amniotic space during the early embryogenic period. The position and the timing of the disruption of the cloacal membrane will determine the variant of the exstrophy that results. For example, inferior perforation results in epispadias; midperforation results in classic exstrophy; and the superior perforation results in superior-vesicle fissure (Jeffs, 1987). When cloacal exstrophy is present in its classic form, the constellation of severe abnormalities is among the most difficult for the pediatric surgeon to reconstruct. It consists of exstrophy of the urinary bladder, exstrophy of the small or large intestine, anal atresia, hypoplasia of the colon, omphalocele, and malformed genitalia, and associated neural tube defects in 50% of cases (Figure 64-1) (Fujiyoshi et al., 1987).

The anatomy in cloacal exstrophy is complex, with a ventral abdominal wall defect consisting of an omphalocele at the superior margin of the defect and exposed bowel and bladder at the inferior extent (Figure 64-2). The hemibladders are separated in the midline by a zone of intestinal mucosa. Each hemibladder may have a ureteral orifice and the intestinal zone separating the hemibladders may have the orifices of the proximal gut superiorly and the distal gut inferiorly, with one or two appendiceal orifices in between (Warner and Zeigler, 1993). The proximal bowel orifice often prolapses in the characteristic "elephant-trunk" deformity. The distal gut

Figure 64-1 Appearance of a newborn genetic male infant with classic cloacal exstrophy. The infraumbilical omphalocele can be seen at the superior aspect of the defect. There is a prominent elephant-trunk deformity prolapsed throughout the midline intestinal zone. The widely splayed bifid penis can be seen at the lateral aspect of the defect.

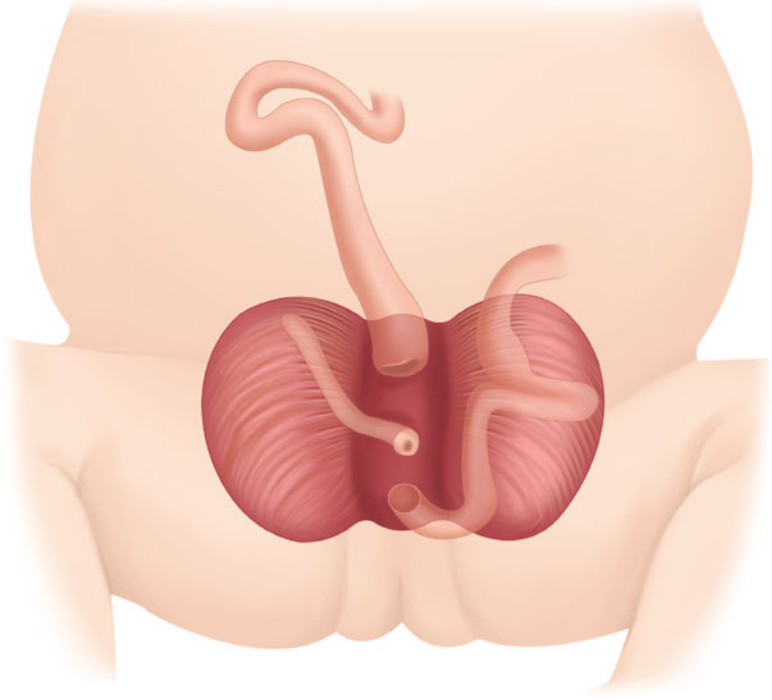

Figure 64-2 Schematic representation depicts the location of the various components of cloacal exstrophy. The omphalocele is at the superior aspect of the defect and is not seen in this diagram. The hemibladders are separated by a midline intestinal zone that has the orifice of the ileum from which prolapse of ileum forms the elephant-trunk deformity. There may also be one or two appendiceal orifices as well as the orifice to the more distal blind-ending rectal pouch. Lateral to the midline intestinal zone are the hemibladders, which each have a ureteral orifice.

is a blind pouch, as these infants all have imperforate anus. All genetically male cases have associated genital anomalies, including undescended testicles and a bifid penis, with each half attached to widely separated pubic rami (Johnston and Penn, 1966).

Although cloacal exstrophy was recognized as early as 1909, it was not until 1960 that the first successful reconstruction was reported (Rickham, 1960; Warner and Zeigler, 1993). It is only in recent decades that repair of this complex anomaly has been routinely undertaken. For years most infants were allowed to die because of the multiple and complex congenital anomalies (Molenaar, 1996). However, in the past two decades, survival after reconstruction for cloacal exstrophy has increased to 90% to 100%, albeit with substantial and lifelong physical and emotional burdens for these patients and their families (Manzoni et al., 1987).

During early development, the cloacal membrane separates the coelomic cavity from the amniotic cavity. The cloaca is first evident in the midline as an area in which ectoderm and endoderm are in opposition, with no mesoderm in between. By the 4th week of development, the cloacal membrane forms the anterior wall of the urogenital sinus at the base of the allantois. Cephalad and lateral to the cloacal membrane are the primordia of the genital tubercle. These primordia enlarge and fuse in the midline superior to the cloacal membrane to form the genital tubercle. At the same time there is ingrowth of mesoderm toward the midline, increasing the distance between the body stalk and the cloacal membrane, setting up the development of normal infraumbilical body wall. The cloaca becomes divided into the urogenital sinus and the rectum by the urorectal septum, which extends in a medial and caudal direction to the cloacal membrane (Pohlman, 1911; Patten and Barry, 1952).

Patten and Barry (1952) suggested the caudal displacement theory for the genesis of cloacal exstrophy. According to this theory, abnormal caudal displacement of the paired primordia of the genital tubercle is responsible for cloacal exstrophy. Epispadias alone would occur if fusion of the primordia in the midline occurred at the level where the urorectal septum joins the cloacal membrane. Exstrophy of both bowel and bladder would be present if even further caudal displacement of the primordia occurred at a level caudal to the anal portion of the cloaca.

In contrast, Marshall and Muecke (1962) suggested that the "wedge effect" of an abnormally large cloacal membrane was responsible for cloacal exstrophy. This abnormally large cloacal membrane acts as a wedge to the developing structure of the abdominal wall. Rupture of this membrane prior to descent of the urorectal septum and fusion of the genital tubercles results in the midline infraumbilical defect, exposure of bladder and bowel mucosa, with bifid genitalia that have epispadias. In a chick embryo model, Muecke (1964) was able to demonstrate that a plastic graft placed in the region of the cloacal membrane produced a wedge defect with persistent cloacal membrane and varying degrees of infraumbilical defects. These theories do not account for involvement of bowel, prolapse of ileum, and foreshortened gut in cloacal exstrophy. Magnus (1969) suggested that a loop of midgut or hindgut prolapses between bladder halves and becomes strangulated. Alternatively, Johnston (1913) suggested that the growth of the hindgut is restricted by its involvement in the exstrophy.

More recently Bruch et al. observed sonographic progression in a fetus with a dilated cloacal abnormality at 18 weeks of gestation associated with oligohydramnios and hydronephrosis. Repeat ultrasound examination performed at 24 weeks of gestation demonstrated rupture of the cloacal abnormality with resolution of both the hydronephrosis and oligohydramnios. This newborn had the classic features of cloacal exstrophy, challenging previous theories of its embryogenesis (Bruch et al., 1996).

Cloacal exstrophy is associated with anomalies of organ systems other than the central defect in up to 85% of cases (Hurwitz et al., 1987) (Table 64-1). Anomalies of the urinary tract are common and in several series occurred in 42% to 60% of cases (Spencer, 1965; Johnston and Penn, 1966; Tank and Lindenauer, 1970; Zeigler et al., 1986; Hurwitz et al., 1987). Vertebral anomalies occur in 48% to 78% of patients (Spencer, 1965; Tank and Lindenauer, 1970; Hurwitz et al., 1987) and myelodysplasia in 29% to 46% of patients (Zeigler et al., 1986; Hurwitz et al., 1987).

INCIDENCE

Fortunately, cloacal exstrophy is rare, with a frequently quoted incidence of 1 in 200,000 to 1 in 400,000 livebirths (Zeigler et al., 1986). However, this may be an underestimate because many fetuses with cloacal exstrophy die in utero or are stillborn (Paidas et al., 1994). Its incidence has been reported to fluctuate in some areas, suggesting possible epidemics (Evans et al., 1985). In one study, preconceptional maternal exposure to smoking was significantly more common in parents whose fetus has cloacal exstrophy than in other related anomalies (Gambhir et al., 2008).

SONOGRAPHIC FINDINGS

The anatomic features of cloacal exstrophy are seen on ultrasound examination, thus enabling prenatal diagnosis of these complex congenital abnormalities (Meizner and Bar-Ziv, 1985; Mirk et al., 1986; Romero, 1988; Nyberg et al., 1990; Langer et al., 1992). Cloacal exstrophy should be suspected when there is a lower abdominal wall defect with absence of a normal bladder. Splaying of the pubic rami may also be present. The association of neural tube defects along with these findings also supports the diagnosis.

At least 14 reported cases of cloacal exstrophy have been prenatally diagnosed by sonography (Gosden and Brock, 1981; Meizner and Bar-Ziv, 1985; Mirk et al., 1986; Chitrit et al., 1993; Meizner et al., 1995; Bruch et al., 1996; Kaya et al., 2000). However, three of these cases were probably body-stalk

Table 64-1

Anomalies Associated with Cloacal Exstrophy

Omphalocele
Split symphysis anomaly
Bladder exstrophy
Two exstrophied hemibladders
Interposed midline colonic segment
Ileocecal exstrophy
Superior orifice prolapsed ileum
Single- or double-inferior orifice short blind-ending hindgut
Usually duplicate appendiceal stumps in intermediate position
Imperforate anus
Bifid external genitalia
Diminutive penis
Bifid clitoris and labia
Cryptorchidism
Duplex mullerian strictures
May have exstrophied vaginas at base of bladder mucosa
May have atretic vaginas
Myelomeningocele
Other defects
Talipes equinovarus
Vertebral anomalies (scoliosis)
Renal anomalies
Agenesis or multicystic
Megaloureter
Hydronephrosis
Fusion anomalies, ectopia

Adapted from Ziegler MM, Duckett JW, Howell C. Cloacal exstrophy. In: Welch KJ, Randolph JG, Ravitch MM, et al., eds. Pediatric Surgery. *Chicago: Medical Year Book; 1986:764-771.*

anomalies (Gosden and Brock, 1981). In an effort to establish criteria for early prenatal diagnosis of cloacal exstrophy, Meizner et al. (1995) reviewed the sonographic findings in six cases of cloacal exstrophy and compared them with the sonographic features of other anterior abdominal wall defects. In all six cases, specific sonographic signs were observed: (1) large infraumbilical anterior midline defect with a protruding omphalocele; (2) an absent bladder; (3) a narrowed thorax; (4) a distorted spine; (5) a large sacral myelomeningocele; and (6) bilateral clubfeet. In all cases the bowel was noted to be floating in a large amount of ascitic fluid. Polyhydramnios was present in four of the six cases. Although not done prospectively, this report has helped to define sonographic features of cloacal exstrophy that may allow early prenatal diagnosis (Figures 64-3 to 64-5). These sonographic features may assist the sonographer in distinguishing cloacal exstrophy from other midline anterior abdominal wall defects. The fetus with suspect cloacal exstrophy may benefit from ultrafast fetal MRI, which may be a useful adjunct to sonography in defining the anomalous pelvic anatomy as well as the potential associated myelomeningocele.

A correct prenatal diagnosis of cloacal exstrophy is rarely made, even if pelvic or genitourinary abnormalities are suspected on prenatal ultrasound examination. In a recent retrospective review by Livingston et al. of prenatal sonographic studies of patients evaluated and treated postnatally at the Children's Colorectal Center at Cincinnati Children's, the most common abnormality noted prenatally was hydronephrosis. The correct diagnosis was rarely suspected (Livingston et al., 2007).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of cloacal exstrophy includes bladder exstrophy (see Chapter 65), omphalocele (see Chapter 62), gastroschisis (see Chapter 63), amniotic band syndrome (see Chapter 100), myelomeningocele (see Chapter 19), and the limb–body wall complex (see Chapter 60). The sonographic features of each of these allow it to be distinguished from cloacal exstrophy. In bladder exstrophy, there is a small soft tissue mass on the surface of the abdominal wall and no normal-appearing bladder, omphalocele, spinal abnormalities or clubfeet. Omphaloceles are usually more cephalad on the abdomen and lack other features of cloacal exstrophy. The loops of intestine floating free in the amniotic fluid in gastroschisis usually can be easily distinguished from the omphalocele of cloacal exstrophy, even with the "elephant-trunk" deformity with a loop of intestine floating in amniotic fluid.

The amniotic band syndrome and limb–body-wall complex usually lack the lower abdominal omphalocele and myelomeningocele, and a normal bladder can usually be seen in the pelvis. Cases of limb–body wall complex usually have large gastropleuroschises with a distorted spine.

ANTENATAL NATURAL HISTORY

Because of the rarity of cloacal exstrophy, and the even rarer prenatal diagnoses of these cases, little is known about its antenatal natural history. In the cases studied by Meizner et al. (1995), four of the six developed polyhydramnios, which may predispose to preterm labor and delivery. The cause of polyhydramnios in cloacal exstrophy is not known. There appears to be an increased incidence of intrauterine fetal death and stillbirth in cloacal exstrophy.

Figure 64-3 Prenatal sonogram of a fetus with cloacal exstrophy demonstrating several sonographic features of cloacal exstrophy. In this image, seen in transverse at the level of the umbilical cord insertion, the lower abdominal-wall defect and omphalocele membrane are evident.

Figure 64-4 A lower abdominal transverse image in the same fetus seen in Figure 64-3, in which no bladder is seen between the umbilical arteries, which appear bright white in this black-and-white version of a color Doppler image, and the elephant-trunk deformity caused by prolapse of the ileum is also seen.

Figure 64-5 The same fetus as in Figures 64-3 and 64-4 is seen in sagittal section of the spine, demonstrating the large sacral myelomeningocele.

MANAGEMENT OF PREGNANCY

The pregnant woman carrying a fetus in which cloacal exstrophy is suspected should be referred to a tertiary care center for level II prenatal sonographic evaluation. If the features of cloacal exstrophy cannot be completely defined sonographically, fetal magnetic resonance imaging (MRI) may be indicated. If the diagnosis is made prior to 24 weeks of gestation, the parents should be offered pregnancy termination. If the parents decide to proceed with the pregnancy, amniocentesis should be performed to determine the genetic sex of the fetus. However, even if the karyotype is 46,XY, female gender reassignment may be a consideration due to the inadequacy of phallic development, which may make reconstruction as a male impossible. The parents should be counseled about the nature of this complex anomaly by a team consisting of a pediatric surgeon, pediatric urologist, pediatric neurosurgeon, neonatologist, geneticist, and pediatric endocrinologist. The delivery should be planned in a center capable of reconstructing this complex lesion, or immediate postnatal transport to a tertiary pediatric center should be planned. The pregnancy may be complicated by polyhydramnios during the third trimester, which may predispose to preterm labor and delivery. The parents should be made aware of the possible increased incidence of intrauterine fetal death and stillbirth in cloacal exstrophy.

FETAL INTERVENTION

There are no fetal interventions for cloacal exstrophy.

TREATMENT OF THE NEWBORN

Ideally, a fetus with cloacal exstrophy should be delivered with neonatologists in attendance. The presence of the omphalocele sometimes predisposes to pulmonary hypoplasia and respiratory insufficiency at birth. The infant should have nonadhesive dressings applied to cover the exposed bladder and bowel mucosa. The increased insensible water loss from the exstrophied bladder and bowel should be factored into the infant's fluid management. Immediate consultation should be obtained from a pediatric surgeon, a pediatric urologist, and a pediatric neurosurgeon. However, emergency surgical correction is not indicated for an infant with cloacal exstrophy. An extensive preoperative evaluation of all defects is essential before operative intervention occurs. Ultrasound examination of the upper urinary tract provides important information regarding position, size, and presence or absence of kidneys. Ultrasound examination will also detect hydronephrosis and hydroureter, which may require preoperative decompression. The infant's spinal cord should be evaluated by sonography and MRI to detect tethered cord, myelodysplasia, and other abnormalities. Radiographic films should be obtained to exclude vertebral or sacral anomalies. Cranial ultrasound examination should be performed to exclude hydrocephalus. Radiographs of the pelvis are also necessary to detect such anomalies as split symphysis and congenital hip dislocation. Karyotype analysis should be obtained if not done prenatally, as gender assignment should be established as soon as possible.

SURGICAL TREATMENT

Before 1960, cloacal exstrophy was uniformly fatal, with intestinal obstruction and urosepsis the leading causes of death. There has been significant progress in the management of cloacal exstrophy, with recent reports of survival ranging from 83% to 100%. This is due to improvements in intravenous alimentation, intensive care, and surgical reconstructive techniques.

Despite improvements in survival, cloacal exstrophy remains a formidable surgical challenge, usually approached in staged procedures. In some cases, gender reassignment as female will be necessary due to insufficient phallic tissue for penile reconstruction in genetic males. If a prenatal diagnosis of cloacal exstrophy is made and karyotype analysis shows 46,XY, the parents should be counseled antenatally about the possibility of gender reassignment. This is a complex area and it may be the most difficult aspect of cloacal exstrophy for the parents to cope with. Gonadectomy is usually performed during the first procedure. Despite early gonadectomy, reconstruction as a phenotypic female and rearing as a female, many individuals will self-identify as male as they mature (Reiner and Gearhart, 2004). This is due to the effects of exposure of the fetal brain to testosterone.

The gastrointestinal tract is often shortened in cloacal exstrophy. Specifically, the colon is usually short and small. Despite this, colonic pull-through to reconstruct the anus is possible in approximately 50% of patients. The remainder of cases are precluded from pull-through procedures by neurologic deficits related to myelomeningocele, sacral malformation, or a sphincter muscle complex that is inadequate for fecal continence.

Reconstruction of the urinary tract in cloacal exstrophy presents a particular challenge for achieving the goals of adequate bladder capacity and outlet resistance. This usually requires bladder augmentation. Due to the shortened gut associated with cloacal exstrophy, the use of the stomach in a gastrocystoplasty has emerged as the preferred technique of bladder augmentation. The advantages of gastrocystoplasty in bladder augmentation include less mucous secretion than small bowel, lower incidence of bladder calculi, and avoidance of hyperchloremic metabolic acidosis seen with the use of intestine. The disadvantages of gastrocystoplasty include problems with excessively acidic urine, with perineal excoriation if incontinence occurs. Various methods of ensuring bladder outlet resistance and continence have been reported, including bladder-neck narrowing with local tissue, using

tapered bowel or ureter to make a urethra, or appendicovesicostomy (Mitchell et al., 1988). In addition, upper urinary tract anomalies that may also require surgical correction may be present occur in up to 45% of patients.

In genital reconstruction, the genetic female can have the rudimentary vagina joined to the perineum. Genetic males undergoing gender reassignment will usually have reconstruction deferred until the teenage years because a vagina is unnecessary for egress of menses and will only be used for coitus.

The condition of the neonate is critical for the decision to proceed with a one-stage versus a two-stage reconstruction (Docimo et al., 1997). In either a one- or two-stage closure, the omphalocele is closed and the bowel is separated from the two bladder halves. The lateral vesicointestinal fissure is closed in continuity and a short colostomy is created from the end of the distal colon segment. The hemibladders are then reapproximated in the midline to create a single exstrophic bladder. In a one-stage procedure, the bladder is closed completely after a bilateral anterior innominate osteotomy has been performed. Table 64-2 shows the one- and two-stage surgical approaches to reconstruction in cloacal exstrophy.

LONG-TERM OUTCOME

With current care, long-term survival is in the range of 90% to 100%. Rare deaths are due to complications of prematurity or associated complex anomalies (Zeigler et al., 1986; Hurwitz et al., 1987; Docimo et al., 1997). Because of the low incidence of this anomaly and the relatively recent success of surgical reconstructive procedures, data on other aspects of long-term outcome are lacking.

Genetic males (46,XY) who undergo gender reassignment are infertile. In successfully reconstructed genetic females (46,XX) there have been documented cases of successful conception and childbirth (Docimo et al., 1997). Bladder continence in patients undergoing reconstructive procedures for cloacal exstrophy can be expected in up to 75% of patients (Hendren and Hendren, 1990). Bowel continence depends on the adequacy of pelvic musculature and innervation. Even after a pull-through procedure, most patients have difficulty with continence and require a bowel regimen, usually daily enemas, to prevent soiling. Alternatively, some patients opt for a permanent colostomy or ileostomy. Recently, the use of a continent catheterizable cecostomy has been used to perform daily antegrade enemas in patients with cloacal exstrophy who have had pull-through procedures, but in whom bowel control is lacking (Malone et al., 1990). As children who have undergone reconstruction grow older, we will learn more about other aspects of long-term outcome, including psychologic adjustment and sexual function.

It has become apparent that genotypic male infants with phallic inadequacy reconstructed as females have a high incidence of male gender identity despite gonadectomy (Reiner and Gearhart, 2004). In a follow-up study of 16 genetic male

Table 64-2

Staged Functional Reconstruction in Cloacal Exstrophy

- Neonatal assessment
  - Evaluate associated anomalies
  - Decide whether to proceed with reconstruction
- Functional reconstruction
  - One-stage repair (few associated anomalies)
    - Excise omphalocele
    - Separate cecal plate from hemibladders
    - Join and close bladder halves
    - Bilateral anterior innominate osteotomies
    - Gonadectomy in males with duplicated or absent penis
    - Terminal ileostomy or colostomy
    - Genital revision if needed
  - Two-stage repair
    - Stage I—newborn period
      - Excision of omphalocele
      - Separate cecal plate from hemibladders
      - Joining bladder halves
      - Gonadectomy in males with duplicated or absent penis
      - Terminal ileostomy or colostomy
    - Stage II—4 to 6 months of age
      - Closure of joined bladder halves
      - Bilateral anterior innominate osteotomy
      - Genital revision if needed
- Anti-incontinence or reflux procedure—4 to 5 years of age
  - Bladder capacity >60 mL minimum
    - Young–Dees–Leadbetter bladder-neck reconstruction
    - Bilateral Cohen ureteral reimplantations
    - Marshall-Marchetti bladder-neck suspension
  - Bladder capacity <60 mL
    - Young–Dees–Leadbetter bladder-neck reconstruction
    - Bilateral Cohen ureteral reimplantations
    - Bowel segment used to augment bladder
    - Continent diversion with abdominal or perineal stoma
- Vaginal reconstruction
  - Vagina reconstructed or augmented using colon, ileum or full-thickness skin graft

Adapted from Gearhart JP. Anomalies of the bladder. In: Kalalis PP, King L, Belman AB, eds. Clinical Pediatric Urology. *3rd ed. Philadelphia: WB Saunders; 1992:1971-1977.*

patients with cloacal exstrophy and phallic inadequacy, 14 underwent neonatal gender reassignment and 2 were raised as male Reiner and Gearhart, 2004). Despite gonadectomy, 8 of the 14 declared themselves male. Both of the infants raised as male had male gender identity. The results of this study raise serious questions about the wisdom of gender reassignment in genetic male infants with cloacal exstrophy.

GENETICS AND RECURRENCE RISK

Cloacal exstrophy occurs as a sporadic event without a recognized associated chromosomal abnormality. There is a higher incidence of cloacal exstrophy in families in which one member is affected as compared with the general population, although the genetic aspects of this malformation are not well understood (Jeffs, 1987).

65 CHAPTER Bladder Exstrophy

Key Points

- Bladder exstrophy is a severe abnormality of the anterior abdominal wall in which the bladder protrudes under the umbilical cord, the pubic bones are separate causing rectus divergence, and frequently is associated with inguinal hernia.
- In females the mons, clitoris, and labia are separated, with hemiclitoris on either side of the bladder, and there is frequently duplication of the vagina and uterus.
- In males the penis is short and broad, with a dorsal urethral plate, dorsal chordee, and splayed glans.
- Bladder exstrophy is very rare, being seen in 1 in 3000 to 1 in 50,000 births, and there is a significant male preponderance.
- Prenatal sonographic diagnosis is possible by noting an absent bladder, but with normal amniotic fluid volume, together with a lower midline abdominal wall mass and abnormal appearing external genitalia.
- Pregnancy management is generally unchanged by the prenatal diagnosis of bladder exstrophy, and the only role for genetic amniocentesis is to assist in assignment of gender if external genitalia are unclear.
- The goal of surgical management is to achieve bladder closure, epispadias repair, and achievement of urinary continence; this can be achieved either in a three-stage process over 4 years or as a single primary repair.
- Bladder exstrophy is generally considered a sporadic abnormality, although there may be a 3%–4% recurrence risk in siblings.

CONDITION

Exstrophy of the bladder has been recognized for centuries, but it was not until the 19th century that surgical correction was first attempted (Hall et al., 1953). The first attempts at diversion of urine into the colon were made in 1850, and the first successful closure of bladder exstrophy was performed in 1862 (Canning et al., 1996). In contrast to patients with cloacal exstrophy that have other unrelated abnormalities, infants with bladder exstrophy have defects confined to the bladder, abdominal wall, perineum, genitalia, and bony pelvis.

At birth the diagnosis of bladder exstrophy is easily made by the presence of characteristic findings. The bladder plate protrudes immediately beneath the umbilical cord (Figure 65-1). The rectus muscles are divergent due to separated pubic bones. There is an outward rotation of the innominate bones and eversion of the pubic rami (Sponsellor et al., 1991). The phallus is short, with a dorsal urethral plate, splayed glans, and dorsal chordee. In females, the mons pubis, clitoris, and labia are separated and the vaginal orifice may be displaced anteriorly. Bilateral inguinal hernias are commonly seen at birth because of the large internal and external inguinal ring caused by the splaying of the rectus musculature and lack of obliquity of the inguinal canal. Hussman et al., (1990) reported that 56% of males and 15% of females have inguinal hernias. In a report by Peppas et al., (1995) in patients presenting with hernia within one year of primary closure, 10%–53% of the hernias were incarcerated.

In bladder exstrophy the umbilical cord inserts low on the abdomen and the anus and scrotum tend to be more anteriorly placed than normal (see Figure 65-1). Although the rectus abdominis muscles insert normally at the pubic tubercles, the diastasis of the pubic symphysis and lateral displacement of the iliac bones causes splaying of the rectus muscles. This lateral displacement of the rectus muscles widens the inguinal canal, predisposing to indirect inguinal hernias in these patients (Connor et al., 1989; Hussman et al., 1990; Stringer et al., 1994). Because the bladder is external, the peritoneal reflection is deeper in the pelvis than normal and the ureters course deeply through the pelvis and enter the

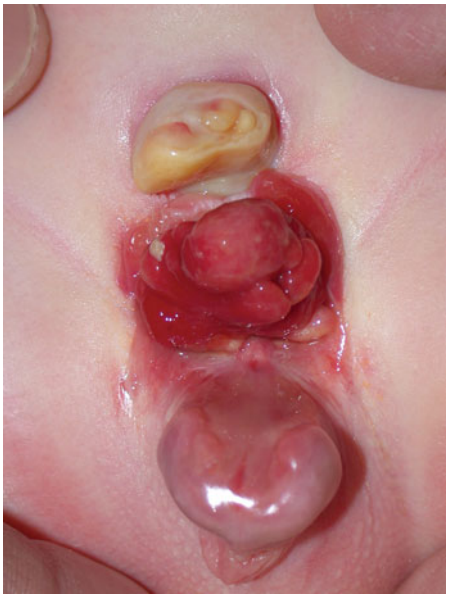

Figure 65-1 Newborn female infant with bladder exstrophy demonstrating the presence of a low umbilical cord with a protruding bladder plate and a hemiclitoris on each side of the bladder.

bladder with almost no submucosal tunnel, which predisposes them to vesicoureteral reflux (Nisonson and Lattimer, 1968).

The penis in males with bladder exstrophy is short and broad because of pubic bone separation, which prevents the midline joining of the corpora cavernosa. Figure 65-1 illustrates the appearance of the female infant with bladder exstrophy. The overall length of the corpora cavernosa is shortened but reasonable length may be obtained with epispadias repair from the deep corporal bodies (Woodhouse and Kallett, 1984). There is usually a marked dorsal chordee and the penile curvature is compounded by shorter dorsal tunica albuginea. Females with bladder exstrophy (Figure 65-1) have a hemiclitoris on each side of the bladder and the vaginal orifice may be duplicated and displaced anteriorly (Damario et al., 1994). The uterus may be duplicated, but the fallopian tubes and ovaries are usually normal.

All patients with bladder exstrophy have some degree of pubic diastasis, with the hips rotated outward. Many patients have a waddling gait in early childhood, but long-term hip or gait problems are rare.

In normal development the cloacal membrane occupies the infraumbilical position of the abdominal wall, and this bilaminar membrane is infiltrated by mesenchyme to form the lower abdominal musculature. The genital folds fuse superiorly to form the genital tubercle. The most widely accepted theory for the cause of exstrophy is based on the work of Muecke, (1964), in chick embryos. In this model, overgrowth or persistence of a thickened cloacal membrane results in truncated mesenchymal migration. Later rupture of the membrane without the mesenchymal reinforcement results in exstrophy. Bladder exstrophy results if the rupture occurs after the descent of urorectal septum. If rupture occurs in the absence of the urorectal septum, then cloacal exstrophy occurs. The prenatal sonographic observation by Langer et al. of an intact cloacal membrane that subsequently ruptured during the second trimester suggests that the presence or absence of the urorectal septum and not timing of membrane rupture distinguishes bladder exstrophy from cloacal exstrophy (Langer et al., 1992).

INCIDENCE

A broad range of incidences have been reported for bladder exstrophy, from 1 in 3000 to 1 in 50,000 livebirths (Lattimer and Smith, 1996; Sanders, 1996). Rickham estimated the incidence of bladder exstrophy at 1 in 10,000 livebirths (Rickham, 1960). The International Clearinghouse for Birth Defects Monitoring Systems estimated the incidence of bladder exstrophy at 3.3 in 100,000 livebirths (Lancaster, 1987). All reports have consistently shown a male predominance, which, derived from multiple series, averages 2.3:1 (Bennett, 1973; Harvard and Thompson, 1951; Higgins, 1962; Jeffs et al., 1982). Individual reports exist that describe a male predominance as high as 5:1 or 6:1 (Ives et al., 1980; Lancaster, 1987). There are no estimates available for the prenatal incidence of bladder exstrophy.

While no definite teratogenic effect has been demonstrated, there is a slightly increased risk of bladder exstrophy with maternal progestin use (Blickstein and Katz, 1991). Also, a single case of bladder exstrophy has been reported in the child of a user of lysergic acid diethylamide. A slightly increased risk of bladder exstrophy has been observed in mothers less than 20 years of age (Lancaster, 1987).

SONOGRAPHIC FINDINGS

The prenatal sonographic diagnosis of bladder exstrophy is based on the association of several findings, including inability to visualize the bladder, normal amniotic fluid volume, presence of a mass on the anterior abdominal wall in the suprapubic region, small penis with an anteriorly displaced scrotum, low umbilical cord insertion, splayed iliac crests, umbilical arteries situated alongside the bulging mass protruding from the lower abdominal wall, malformation of the external genetalia (Barth et al., 1990; Bronshtein et al., 1993; Gearhart et al., 1995a; Jaffe et al., 1990; Lee et al., 2003: Meizner and Bar-Ziv, 1986; Mirk et al., 1986; Pinette et al., 1996; Richards et al., 1992). The fetal bladder is most easily identified between the umbilical arteries, using color Doppler sonography. If completely empty, the bladder may not be seen, but since it normally fills and empties every 5–15 minutes, persistent observation should identify the normal bladder (Gearhart et al., 1995a). However, the normal bladder may not be imaged if there is a lack of urine production, either due to bilateral renal agenesis or bilateral multicystic

dysplastic kidneys. The use of 3-D ultrasound may be particularly useful in identifying the lower abdominal mass in bladder exstrophy (Evangelidis et al., 2004). Similarly, ultrafast fetal MRI may be useful as an adjunct to ultrasound if the diagnosis is not clear as a result of technical limitations of ultrasound such as fetal position or maternal body habitus.

All of the features of bladder exstrophy may not be seen in every patient. In the report by Gearhart et al., (1995a), in 17 fetuses with prenatal sonographic examinations in whom a retrospective diagnosis of bladder exstrophy could be made, not every feature was present. In 71% of cases there was persistent nonvisualization of the fetal bladder. In only 47% of cases were a persistent lower abdominal wall mass or bulge seen. A very small penis with an anteriorly displaced scrotum was seen in 57% of fetuses. Even less commonly appreciated was the low umbilical cord insertion (29%) and abnormal widening of the iliac crests (18%).

In a female, the clitoris is bifocal and there are widely separated labia, but this may be difficult to discern sonographically.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of bladder exstrophy includes cloacal exstrophy, persistent urachus, omphalocele, and gastroschisis. However, the lower abdominal wall bulge with low cord insertion immediately cephalad to the exstrophied bladder usually allows its identification. The kidneys are usually normal in bladder exstrophy. In contrast, in cloacal exstrophy, unilateral renal agenesis is common, as is hydronephrosis. In addition, there is often prolapse of the ileum through the cloaca to form the "elephant trunk" deformity (see Chapter 64). Myelomeningocele and omphalocele are also commonly associated with cloacal exstrophy. Rarely, a small omphalocele may be seen in bladder exstrophy (Gearhart et al., 1989b). The lower abdominal wall bulge or soft tissue mass in cloacal exstrophy is usually larger and more heterogeneous than in bladder exstrophy (Pinette et al., 1996). A persistent urachus may resemble the normal bladder and complicate the diagnosis. However, prolonged observation demonstrates the structure to be constant in size and shape lacking any voiding episodes excluding the possibility of a normal bladder (Goldstein et al., 2001, see Table 65-1).

ANTENATAL NATURAL HISTORY

Although few prospectively diagnosed cases of bladder exstrophy have been reported, review of retrospective cases suggests that this diagnosis has no implications for the pregnancy. These are usually isolated sporadic anomalies, without increased risk for intrauterine death, or neonatal compromise at birth.

MANAGEMENT OF PREGNANCY

Once there is a diagnosis of bladder exstrophy, an attempt to completely define the anomaly should be made. The position of the abdominal wall bulge and umbilical cord insertion, sex of the fetus, and the size and position of the penis should be determined. If the sex of the fetus is in doubt, genetic amniocentesis may be indicated to help counsel the parents and plan the postnatal reconstruction. Prenatal consultation with a pediatric urologist is extremely helpful in advising parents about the reconstructive procedures that will be necessary and about the long-term prognosis. There is no need to alter the delivery plan, and cesarean section should be reserved for obstetrical indications. Because bladder closure is best accomplished during the first 3 days of life, delivery in a tertiary care center with pediatric urologists and anesthesiologists is preferred, but transportation of the newborn to a pediatric center is also possible.

FETAL INTERVENTION

There are no fetal interventions for bladder exstrophy.

TREATMENT OF THE NEWBORN

In the management of bladder exstrophy, staged functional reconstruction and urinary diversion are the two most commonly employed strategies. Urinary diversion is usually undertaken only when reconstruction is unavailable or repeated attempts at functional reconstruction have failed. Gender reassignment is almost never necessary, given modern reconstructive techniques, and is reserved for rare cases in which no other option is available. The staged functional reconstruction is undertaken with specific goals for each stage. During the newborn period, the goal is bladder closure with protection of the upper urinary tract, and preservation for later continent reconstruction. In the second stage, at about 1 year of age in the male, the goal is to optimize genital structure and function and to increase bladder outlet resistance to foster growth of the bladder. In the final stage of functional reconstruction, undertaken at about 4 years of age, the goal is to achieve urinary continence.

SURGICAL TREATMENT

The most commonly used technique for bladder closure involves the conversion of an exstrophied bladder to an incontinent epispadias (Gearhart and Jeffs, 1989b, 1990 a and 1990b; Jeffs et al., 1982). An incision circumscribes the exstrophied bladder extending distal to the verumontanum on both sides

Table 65-1

Absent Bladder

	Kidneys	Amniotic Fluid	Doppler Umbilical Artery	Renal Arteries	Uterine Arteries	Other Findings
Failure of urine production						
BRA	Absent	–	N	–	–	
Severe BRD	Small and large cysts	–	N	N/A		
Severe IUGR	Small and large cysts normal		A	N	A	
Failure to store urine	N/HN	N	N	N	N	–
Bilateral ectopic ureters	N	N	N	N	N	Lower abdominal mass, abnormal external genitalia low umbilical, insertion, splayed iliac bones
Cloacal exstrophy	N, absent or HN	N	N	N	N/A	Omphalocele, cystic anterior mass, meningomyelocele, kyphoscoliosis, lower limb defects, single umbilical artery

N, normal; A, abnormal; HN, hydronephrosis; BRA, bilateral renal agenesis; BRD, bilateral renal dysplasia; IUGR, intrauterine growth retardation.

of the prostatic urethra, resulting in a wide plate of bladder neck and prostatic urethra. The bladder is completely mobilized and the corpora cavernosa directed off the inferior pubic cavernosa with care to preserve the neurovascular bundles. The corpora cavernosa are approximated in the midline. The neourethra, with or without paraexstrophy flaps, is tubularized. Ureteral stents suprapubic to the vesicostomy site are exteriorized prior to closing the bladder. The pelvic ring is closed by a nonabsorbable monofilament suture. The midline abdominal defect is then closed by approximation of the rectus fascia and skin. Pubic approximation is possible during the first days of the life, without osteotomy. After staged reconstruction, all patients should be maintained on prophylactic antibiotics because of the high incidence of vesicoureteral reflux. Although most children will have vesicoureteral reflux, it is unusual for them to require an antireflux procedure before subsequent bladder neck reconstruction.

The second stage of functional reconstruction, undertaken between 6 and 12 months of age, focuses on phallic reconstruction. Epispadias repair and urethroplasty not only reconstruct the phallus, but also result in increased outflow resistance and enhanced bladder capacity (Gearhart and Jeffs, 1989a). The goals of epispadias repair are to provide length for the phallus and to release the dorsal chordee (Gearhart and Jeffs, 1990a; Hendren, 1979; Hinman, 1958). In addition, the urethra is reconstructed to place the meatus at the tip of the glans penis (Kajbafzadeh et al., 1995; Mitchell and Bagli, 1996; Ransley et al., 1989).

The last stage of functional reconstruction in bladder exstrophy is undertaken at about four years of age (Perlmutter et al., 1991). It is important that the child's bladder capacity be at least 60 ml in order to have functional capacity following bladder neck reconstruction (Jeffs et al., 1982). The Young–Dees–Leadbetter technique remains the most commonly used technique to reconstruct the bladder neck (Gearhart and Jeffs, 1990b; Leadbetter, 1964; Marshall et al., 1949; Woodhouse and Kallett, 1984). The ureters are reimplanted in a cephalad position in either a cross-trigonal or cephalotrigonal procedure to prevent vesicoureteral reflux (Brock and O'Neill, 1998; Canning et al., 1990). Next, the posterior bladder mucosa is tubularized over a Foley catheter to create a neourethra, and the muscular layer of bladder is closed over the neourethra to create a new bladder neck. If capacity is inadequate, bladder augmentation is then performed (McLaughlin et al., 1995). The bladder neck and urethra are then sutured to the undersurface of the pubis.

Recently, complete primary exstrophy repair has gained popularity. The procedure combines the goals of the staged reconstruction into a single procedure: bladder closure, epispadius repair, and achievement of urinary continence, all without formal bladder neck reconstruction. Complete primary exstrophy repair offers preservation of renal function and better continence in many patients. However, this is a surgical option best employed only at centers with highly experienced surgeons because of the risk of significant complications including penile ischemia and hypospadias (Husman et al., 2006).

Urinary diversion is reserved for patients who have inadequate anatomy for reconstruction at birth or when attempts at reconstruction have failed. Among the most commonly employed technique is the ureterosigmoidostomy, which allows continence, and with nonrefluxing ureterocolonic anastomoses, protection of the upper urinary tracts. However, long-term hyperchloremic metabolic acidosis, ureteral obstruction, and colonic malignancy are possible complications. Ileal conduits are not considered suitable for urinary diversion in children due to long-term complications. A colon conduit may be an alternative, with fewer long-term complications than ileal conduits. Once a child achieves anal continence, anastomosis of the colon conduit to the rectosigmoid can be performed.

LONG-TERM OUTCOME

One report reviewed the experience at the Johns Hopkins Hospital with 87 patients treated for exstrophy of the bladder (Baker et al., 1999). The age at follow-up ranged from 8 months to 22 years. Bladder neck reconstruction was performed in 58 of 87 patients, with 47 (81%) continent of urine. Among the remaining 11 patients, 4 were less than 6 months from bladder neck repair, 2 were lost to follow-up, 1 was diverted, 1 awaits bladder augmentation, 2 have had bladder augmentation, and 1 is totally incontinent of urine. The average time to continence during the day ranged from 3 months to 5 years (mean, 2 years), and to nighttime continence, a mean of 4 years. Other centers have reported continence rates in the 69%–71% range with bladder neck reconstruction (Jones et al., 1993; Lottman et al., 1996; Mollard et al., 1994).

Patients who do not achieve continence within 1–2 years of bladder neck reconstruction seldom have sufficient continence over time (Gearhart, 1998). These patients may require remedial approaches, including repeat bladder neck reconstruction, often with concomitant bladder augmentation. The majority of patients in whom initial bladder neck reconstruction fails need bladder augmentation (Gearhart et al., 1990a, 1995b).

There may be significant psychologic consequences to this anomaly and the results of reconstructive procedures. Ben-Chaim et al., (1996) reported the results of a diagnostic psychiatric questionnaire and interview with 20 patients with bladder exstrophy and their parents. Behavioral, social, and school competency problems were experienced by 70% of the adolescents and 33% of the school-aged children. In nearly 70% of the participants, concern was present about the sexual function or disfigurement. The mechanics of sexual intercourse and anxiety about the appearance and adequacy of their genitalia were perceived as barriers to relationships by both adults and adolescents.

Children with bladder exstrophy have recently been recognized to be at increased risk for clinically significant anxiety disorders (Reiner et al., 2006). These anxiety disorders are thought to be due, at least in part, to hypothalamic-pituitary-adrenal axis and other neurobiologic developmental disruptions. It is speculated that early anesthetic, surgical, and/or other medical interventions may affect highly active neurobiologic developmental processes. Some of the anxiety problems in these children tend to abate with age, after successful surgical resolution of functional abnormalities (Reiner et al., 2006).

The issue of sexual function, fertility, and self-esteem become more important long-term issues for children born with bladder exstrophy who undergo reconstruction. Ben-Chaim et al., (1996) reported the results of an anonymous questionnaire and chart review in 20 adult patients (16 men and 4 women). Of the 20 patients, 6 are married (4 men, 2 women), 2 men have fathered children, and 1 woman has had two children. Ten of the 16 men ejaculate a volume of 2 ml, with history of retrograde ejaculation in 6. Semen analysis was performed in 4 men, with an average ejaculate volume of 0.4 ml with azoospermia in 3 and oligospermia in 1. All patients experienced normal erections, but were unsatisfactory in 7 because of a small penis, and 12 of 16 experienced satisfactory orgasms. Stein et al., (1994) have suggested that in males, bladder neck reconstruction may be performed at the expense of fertility. Fertility in males is of secondary concern in reconstructive surgery of the urethra and bladder neck. Erectile and sexual functions are well preserved but patients are bothered by small penile length and dorsal chordee. In contrast, females appear to have normal fertility, sexuality, and sexual function (Gearhart, 1998). However, uterine prolapse after pregnancy and delivery is common and is thought to be due to intrinsic weakness of the pelvic floor (Krisiloff et al., 1978). Uterine prolapse is less common after early pelvic closure with osteotomy (Jeffs et al., 1982). Rectal prolapse occurs frequently in untreated patients, possibly due to bladder mucosal irritation–induced straining. This disappears with bladder closure (Jeffs et al., 1982).

There is a higher incidence of latex allergies in children with bladder exstrophy (Ricci et al., 1999). The latex sensitivity is thought to be a consequence of multiple surgical procedures with latex exposure and may cause life-threatening reactions. Infants with bladder exstrophy are best cared for an in a latex-free environment.

Adenosarcoma of the bladder occurs in patients with bladder exstrophy approximately 400 times more commonly than in the normal population (Kanzari et al., 1974; Krishnansetty et al., 1988). It is the most common bladder

tumor occurring in patents with untreated bladder exstrophy (Davillas et al., 1991) and has been reported in adults who had bladder closure after infancy (Facchini et al., 1987). While bladder malignancy has yet to be reported in patients who had bladder closure at birth, long-term monitoring with cytologic evaluation is recommended (Canning et al., 1996).

GENETICS AND RECURRENCE RISK

Bladder exstrophy, in general, is a rare sporadic anomaly. However, there are families at increased risk for recurrence. Of 2500 index cases, Shapiro et al., (1984) found 9 affected siblings with a risk of a second affected family member of 3.6%. A total of 29 familial cases of this otherwise sporadic condition have been reported (Kajbafzadeh et al., 2006; Messelink et al., 1994; Shapiro et al., 1984). It has been suggested, based on anecdotal case reports, that some familial cases may be inherited as an autosomal dominant (Froster et al., 2004). The risk to offspring of a patient with bladder exstrophy is estimated at 1.4%, and the risk of 2 affected siblings is about 1% (Carter, 1984).

The exstrophy epispadius complex appears to occur more frequently in children conceived by in vitro fertilization (Wood et al., 2003). Bladder exstrophy in one study was found to have a 7.3-fold higher risk than normal after in vitro fertilization.

Cystic Lesions of the Abdomen

66
CHAPTER

Key Points

- Cystic abdominal lesions are relatively common.
- Diagnosis of the underlying etiology of a cystic abdominal mass may be difficult but intimate association with adjacent structures may provide clues to diagnosis.
- Fetal MRI may be helpful in determining the cyst's origin.
- Sonographic evidence of associated anomalies should be sought.
- Obstruction of bowel and compression of adjacent organs is common and may result in polyhydramnios.
- Cyst aspiration in utero is rarely indicated.

CONDITION

The prenatal diagnosis of abdominal cystic lesions is relatively common (McEwing et al., 2003). Cystic abdominal masses may either represent a normal structural variant or pathologic entity that may require surgical intervention postnatally (Sherwood et al., 2008). Abdominal cystic lesions may be exceedingly difficult to accurately diagnose prenatally (Khong et al., 2003). In other chapters, we have already addressed many of the lesions in the differential diagnosis including choledochal cysts (Chapter 67), ovarian cysts (Chapter 68), meconium pseudocysts (Chapter 70), and extralobar bronchopulmonary sequestration (Chapter 34). This chapter will focus on some less common, but important, causes of cystic abdominal lesions including hepatic cysts, splenic cysts, pancreatic cysts, duplication cysts, and mesenteric cysts.

Hepatic cysts are most often isolated, simple cysts. Hepatic cysts are thought to arise from aberrant bile ducts (Cowles and Mulholland, 2000; Otani et al., 2005) or intrahepatic, peribiliary glands (Kida et al., 1992). These simple cysts are more common in girls (Otani et al., 2005) and do not communicate with the biliary system (Rogers et al., 2007). At least one case of prenatal hepatic cyst has been found to be a mesothelial cyst (Komori et al., 2008).

The majority of simple unilocular hepatic cysts detected prenatally tend to shrink or resolve postnatally (Rogers et al., 2007). There are cases of hepatic cysts reaching very large sizes with progressive enlargement resulting in symptoms (Byrne and Fonkalsrud, 1982).

Splenic cysts are usually simple serous epithelial-lined cysts in the upper pole of the spleen (Saada et al., 2006). These cysts are often diagnosed prenatally in the third trimester and may be difficult to distinguish from adrenal or pancreatic cysts.

Pancreatic cysts arise from a developmental anomaly of the pancreatic ductal system usually in the body or tail of the pancreas (Choi et al., 2007). These cysts are epithelial lined and are not pseudocysts. Pancreatic cysts can occur as part of Beckwith–Wiedemann syndrome, polycystic disease of the pancreas and kidney, or Hippel–Lindau disease but are usually multiple in these cases (Vane et al., 1993).

Duplication cysts can occur at any point along the gastrointestinal tract (Bhargava et al., 1976). Enteric duplications

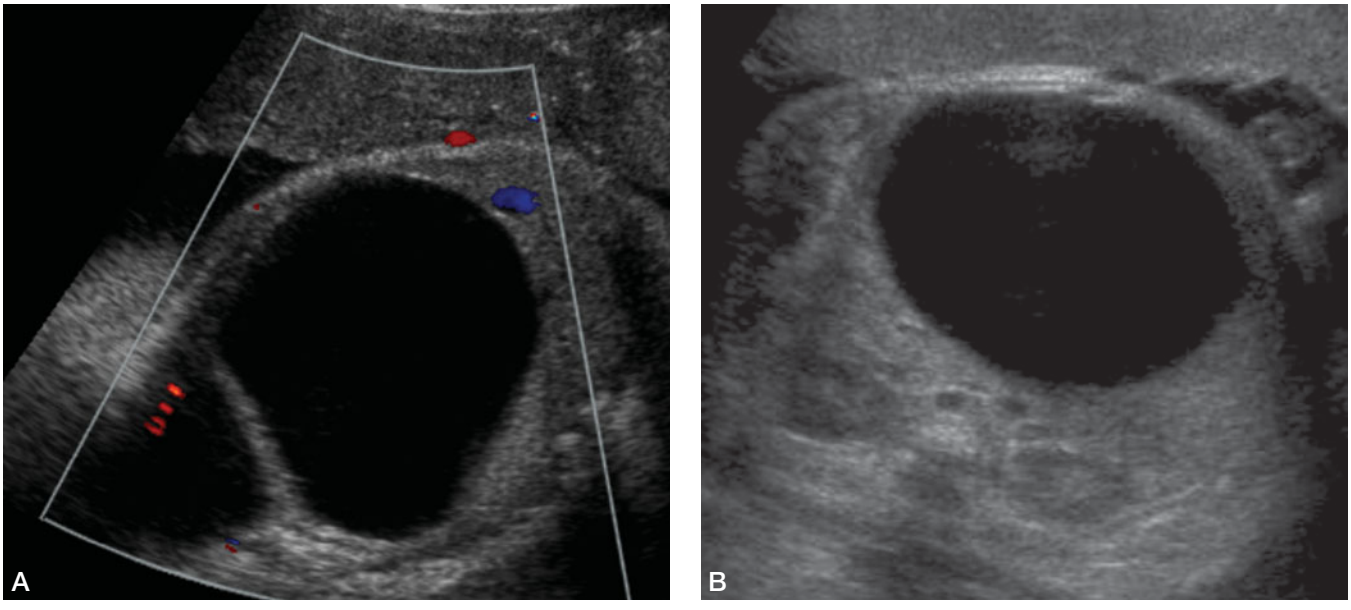

Figure 66-1 **A**. Saggittal ultrasound image demonstrating an anechoic unilocular cyst in the lower fetal abdomen that proved to be a mesenteric cyst on postnatal imaging. Note the absence of internal echogenic lining, absence of septations, and proximity to bowel and mesentery. **B**. Transverse ultrasound image of the same fetus as in (A).

most commonly occur in the jejunum (53%) with 18% occurring in the colon, 6% in the duodenum, and 4% gastric (Khanna et al., 2004). There are several theories that have been proposed to account for enteric duplications ranging from errors in recanalization, partial twinning, embryonic diverticula, and split notochord theory (Goyert et al., 1991; Heis, 1997; Jimenez et al., 1999; Behrman et al., 2000). Colonic duplications frequently present with obstruction of the adjacent bowel (Jimenez et al., 1999). Colonic duplications may be associated with duplications of the genitourinary system (Heis, 1997; Jimenez et al., 1999). Duplication of the intestine may also occur in association with vertebral and spinal cord anomalies such as hemivertebrae, anterior myelomeningocele, duplication of an otherwise normal cord, or a bond between the cyst and the cervical or thoracic spine (Heis, 1997; Behrman et al., 2000).

INCIDENCE

These cystic lesions of the abdomen are sufficiently unusual that no accurate estimates of their incidence are available.

SONOGRAPHIC FINDINGS

Hepatic cysts tend to be simple unilocular cysts but may vary considerably in size. Simple hepatic cysts are thought to develop from aberrant bile ducts or intrahepatic peribiliary glands (Kida et al., 1992; Cowles and Mulholland, 2000; Otani et al., 2005; Rogers et al., 2007). These cysts may enlarge to significant proportions causing bowel obstruction. It may be difficult at times to recognize it as a cyst as it can entirely fill the peritoneal cavity (Figure 66-1A and 66-1B). This can be distinguished from ascites by its compression of the bowel into the retroperitoneum behind the cyst. While there are case reports of cyst aspiration, they do not often require treatment (Rogers et al., 2007; Ito et al., 1997; Arzt et al., 1998).

Determining the origin of a cyst as hepatic, splenic, mesenteric, or pancreatic may be exceedingly difficult unless the cyst is clearly surrounded by parenchyma of a specific organ. Pancreatic cysts usually develop from the ductal system in the body and tail of the pancreas and are usually epithelial lined. Usually these are solitary unilocular nonenzymatic cysts (Choi et al., 2007). Fetal MRI may be a useful adjunct to ultrasound in defining the etiology of a cystic lesion of the abdomen (Veyrac et al., 2004; Wong et al., 2006).

ANTENATAL NATURAL HISTORY

The prenatal diagnosis of intrabdominal cysts is not uncommon but large series of cysts of a given type to help define the prenatal natural history are unavailable. Charlesworth et al. reported a series of fifteen cases of prenatally diagnosed hepatic cysts of which nine had serial ultrasound scans (Charlesworth et al., 2007). In five cases there was cyst enlargement, no change in three cases, and decrease in size in one case during sonographic surveillance. In only one case was cyst aspiration undertaken due to massive enlargement filling the entire abdomen causing polyhydramnios. This was performed at 35 weeks' gestation with 300 mL of fluid removed.

Enteric duplication cyst may present with findings suggestive of bowel obstruction with dilated proximal loops of bowel. Gastric, pyloric, duodenal, or jejunal enteric duplications are more likely to cause polyhydramnios than more distal enteric duplications (Gul et al., 2004; Khanna et al., 2004; Nakazawa et al., 2005; Shah et al., 2005).

Mesenteric cystic lymphangiomas can occur as unilocular or multilocular cystic masses (Deshpande et al., 2001; Chateil et al., 2002; Ho et al., 2002; Groves et al., 2003; Rasidaki et al., 2003). The growth of these cysts is hard to predict but compression of the bowel and obstruction by a cystic mesenteric lymphangioma is possible, although uncommon. The importance of the diagnosis of a cystic mesenteric lymphangioma is the potential for associated problems including genetic syndromes such as Turner, Noonan, or Fryns as well as aneuploidy such as trisomy 18 and 21 (Teixeira et al., 2007).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a cystic abdominal mass can be lengthy if there are no clues to the underlying cause and include: choledochal cyst, Caroli's disease, gastric or pyloric duplication, hepatic cyst, splenic cyst, pancreatic cyst, mesenteric cyst, ovarian cyst, meconium pseudocyst, jejunal or ileal duplication cyst, adrenal hemorrhagic cyst, renal cyst, colonic or rectal duplication cysts. This long list can be narrowed by relying upon anatomic relations and associated findings such as the inner echogenic strip seen in duplication cysts, calcifications seen in meconium pseudocysts, intimate relationship with the hepatic artery in choledochal cyst, or the surrounding parenchyma in hepatic splenic, pancreatic, or adrenal cysts (Malone et al., 1997).

MANAGEMENT OF PREGNANCY

The fetus noted to have a cystic abdominal mass should undergo a detailed sonographic evaluation not only to define the origin of the cyst, but also to exclude possible associated anomalies. In some instances other abnormalities such as single umbilical artery, or other soft markers for aneuploidy may be detected that would indicate the need for a genetic amniocentesis. A fetal MRI may be very helpful in defining the origin of the cyst and its anatomic relations with other structures (Veyrac et al., 2004; Wong et al., 2006). In most cases, even if the exact etiology is not established prenatally, the potential for partial or complete bowel obstruction is present. All cases should be followed sonographically for the development of polyhydramnios and the increased risk of associated preterm labor. In the event that the cyst becomes symptomatic prenatally, consideration should be given to delivering in a setting where immediate evaluation by a pediatric surgeon is available. In most cases, antenatal consultation with a neonatologist and pediatric surgeon is advisable. A consultation with a geneticist may also be indicated if there are indications that the cyst may be one manifestation of a syndrome or there is the potential for aneuploidy.

FETAL INTERVENTION

Fetal abdominal cysts rarely require intervention and with the exception of ovarian cysts (see Chapter 68) there have only been anecdotal reports of cyst aspirations in utero (Ohama et al., 1986; Chen et al., 1997, 2006; Chen, 2001; Charlesworth et al., 2007). These cyst aspirations are often performed to facilitate the diagnosis, as in the case of meconium peritonitis (Chen et al., 2004), choledochal cyst (Chen, 2001), and enteric duplication of the tongue (Ohama et al., 1986; Chen et al., 1997). Current imaging capabilities by ultrasound and MRI, however, obviate the need for cyst decompression to make a diagnosis. In some cases, cyst aspiration may alleviate compression of adjacent organs, including the bowel, and thereby relieving polyhydramnios. In most instances, however, reaccumulation of cyst fluid would be anticipated. To date, there have been no reports of shunting procedures to decompress large abdominal cysts as the risks of such a procedure would likely be greater than the consequences of cyst left undrained.

TREATMENT OF THE NEWBORN

The most important aspect of management of a newborn diagnosed prenatally with an abdominal cyst is an accurate diagnosis and exclusion of associated conditions. A detailed physical exam should identify any dysmorphic features, and a genetic consultation is indicated if findings of concern are identified. Plain abdominal and cross-table radiographs should be obtained to evaluate for possible signs of bowel obstruction. If there was a maternal history of polyhydramnios, such bowel obstruction is likely to be the case. If dilated loops of bowel are present, a nasogastric tube should be placed to decompress the proximal gastrointestinal tract. Bedside ultrasound may indicate the origin of the cyst if this was not identified prenatally. There is no great urgency to take the infant to surgery, and it is helpful to obtain complete preoperative imaging as needed to define the underlying etiology. For right upper quadrant cystic lesions, an MR cholangiogram may help define or exclude choledochal cyst from the differential. MRI scanning of the abdomen may help to refine the differential diagnosis. In the setting of partial or complete bowel obstruction, surgical exploration will be necessary to relieve the obstruction. However, smaller cysts that are not symptomatic do not necessarily require resection. This is true for adrenal cysts, splenic cysts, and small mesenteric or hepatic cysts, provided that the diagnosis is certain. In other cases such as enteric duplication, the risk of bleeding from the duplication should prompt resection even in the absence of

obstruction. In addition, if there is doubt about the etiology of the cyst it may be more prudent to surgically remove them.

Cysts that are not removed should be followed sonographically to exclude further size increase or risk for future complications.

SURGICAL TREATMENT

The surgical approach to an abdominal cyst depends on the underlying etiology, hence the importance of accurate preoperative diagnostic imaging. Choledochal cysts require excision with Roux-en-Y reconstruction to prevent infectious complications and cholangiocarcinoma. Enteric duplications can sometimes be resected with preservation of the adjacent bowel loop. Alternatively, resection of the affected loop and primary anastomosis are required. Splenic and hepatic cysts can often be resected intact. In other cases, the cyst can be resected down to the parenchyma and the lining stripped off. It is rarely indicated to resect underlying normal parenchyma.

Cystic lymphangiomas are a special case in which complete resection may not be advisable leaving open the possibility of recurrence. The goals of this surgery should be to remove as much as is safely possible without risk to adjacent structures.

LONG-TERM OUTCOME

In the majority of cases, cystic abdominal lesions can be dealt with in the newborn period and have few long-term sequelae. One exception to this are choledochal cysts that require long-term follow-up as patients remain at risk for cholangitis. Most other etiologies have no long-term sequelae beyond the risk of laparotomy for adhesive small-bowel obstruction.

GENETICS AND RECURRENCE RISK

There are no reports of familial recurrence of cystic abdominal lesions with the exception of choledochal cyst, which is extremely rare (Clifton et al., 2006). Other exceptions would be cases of mesenteric lymphangiomas that can be associated with a range of genetic syndromes. The potential for recurrence would then be specific to the particular syndrome.

67 Choledochal Cyst

CHAPTER

Key Points

- Choledochal cyst refers to dilation of the common bile duct, with type I being the most common and the only prenatally diagnosed form.
- Prenatal diagnosis is based on the visualization of a single simple cystic structure near the gallbladder.
- Differential diagnosis includes hepatic, adrenal or renal cysts, duodenal duplication, and gallbladder duplication.
- There is no need to alter the management of pregnancy, nor the timing or mode of delivery, following the prenatal diagnosis of choledochal cyst.
- During the newborn period, detailed imaging of the biliary system is required to exclude biliary atresia, including radionuclide imaging.
- Definitive treatment requires surgical excision of the cyst, and long-term outcome is excellent.

CONDITION

Choledochal cysts are rare congenital cystic dilations of the biliary tree and are classified by the portion of the biliary tree affected. The most common form consists of fusiform dilation of the common bile duct (Figure 67-1). Type I choledochal cyst accounts for 85% to 90% of all cases. All cases of choledochal cyst that have been diagnosed prenatally, to date, have been of the type I variety (Bancroft et al., 1994). The less common forms of choledochal cyst include diverticulum of the common bile duct (type II), which are intraduodenal or intrapancreatic; choledochocele (type III); multiple extrahepatic cysts with or without intrahepatic cysts (type IV); and Caroli's disease, which consists of single or multiple intrahepatic cysts associated with hepatic fibrosis and a normal extrahepatic biliary tree (type V) (Caroli et al., 1958).

The wall of a choledochal cyst is usually thickened with dense connective tissue interlaced with strands of smooth-muscle fibers associated with some inflammatory reaction (O'Neill et al., 1987). Normal biliary mucosal lining is absent, although sparse islands of columnar epithelium and microscopic bile ducts within the wall may be seen. In older patients, stones may be seen within the choledochal cyst or within intrahepatic ducts (Landing, 1974; Bhagat and Chaudhrey, 1989). Most newborns with choledochal cysts have complete biliary obstruction at the level of the duodenum, which has been likened to a form of biliary atresia (Landing, 1974; Vergnes et al., 1990). Approximately 60% of choledochal cysts

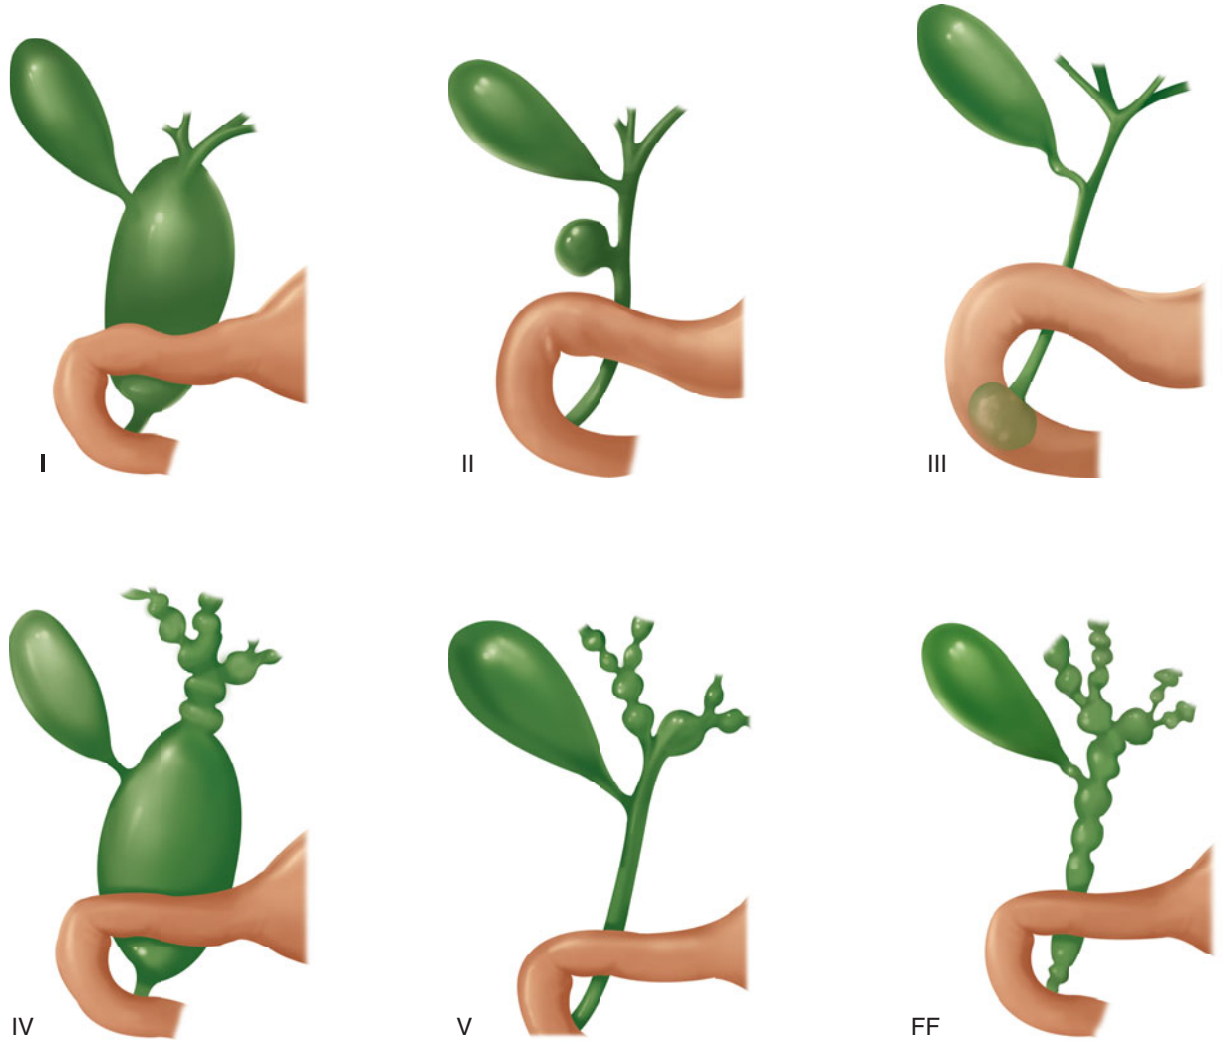

Figure 67-1 Classification scheme of choledochal cysts. Type I is the most common form, with cystic dilation of the extrahepatic bile ducts but normal intrahepatic ducts. Type II is a cystic diverticulum of the common bile duct. Type III is a diverticulum of the distal common bile duct or choledochocele. Both types II and III are rare. Type IV is the second most common form, with cystic dilation of both the extrahepatic and intrahepatic ducts. Type V, or Caroli's disease, has cystic dilation of the intrahepatic ducts but relatively normal extrahepatic ducts. In forme fruste (FF), the extrahepatic ducts are diseased but have only mild or negligible cystic dilation and the intrahepatic ducts have cystic dilation.

detected prenatally were found postnatally to have complete obstruction of the distal bile duct (Bancroft et al., 1994). Liver histology in infants with choledochal cysts is usually normal, but may show mild bile duct proliferation consistent with chronic biliary obstruction (Hanai et al., 1967). Rare cases have been reported with coexistence of choledochal cysts and congenital hepatic fibrosis (Murray-Lyon et al., 1973; Mall et al., 1974; Yamaguchi, 1980; Orenstein and Whittington, 1982; Ramirez et al., 1989). Although malignancies, usually adenosquamous or small cell carcinomas, have been reported in association with choledochal cysts, these lesions occur only after decades of chronic inflammation and recurrent cholangitis, and have not been reported in an infant or a child (Joseph, 1980).

Theories regarding the cause of choledochal cyst disease have evolved from abnormalities in the early stages of embryonic development, to congenital weakness of the wall combined with distal obstruction, to the "common channel" hypothesis (O'Neill et al., 1987). Some authors have suggested that choledochal cysts result from embryologic abnormalities in the growth of hepatic diverticulum and support their assertion by the frequently observed associated anomalies of duplications, gallbladder agenesis, and duodenal atresia (Barlow et al., 1976; Martin and Rowe, 1979). Miyano et al. (1980) have emphasized that weakness of the choledochal wall results primarily from obstruction of the distal duct during fetal development. Spitz (1977) was able to produce cystic dilatation of the common bile duct in neonatal lambs by ligation of the distal common bile duct. In contrast, only dilatation of the gallbladder occurred in their adult controls. The cause of distal common bile duct obstruction in choledochal cyst has been variously suggested to be due to congenital stenosis,

persistence of epithelial membrane, abnormal valves, or neuromuscular incoordination of the sphincter (Ito et al., 1984). Kusanoki et al., (1988) suggested that the obstruction may be due to aganglionosis of the distal bile duct, similar to Hirshsprung's disease of the colon.

Todani et al. (1977) noted that the majority of patients with choledochal cyst have an anomalous arrangement of the pancreatic or biliary duct system in which the pancreatic duct enters at an abnormal angle proximal to the circular muscle fibers of the ampulla of Vater (Todani et al., 1977; Giordani et al., 1984). They suggested that this arrangement would permit reflux of pancreatic enzymes containing trypsin upward into the common bile duct, resulting in damage to the duct wall in utero (Oguchi et al., 1988).

Rustad and Lilly (1987) noted that the "long common channel" that results from an anomalous pancreaticobiliary junction is quite common and seen in up to 50% of patients with biliary disorders other than choledochal cyst. In addition, choledochal cyst has been diagnosed as early as 15 weeks of gestation, well before the development of pancreatic exocrine function (Schroeder et al., 1989). This raises doubts about the common channel theory as the cause for choledochal cyst disease.

INCIDENCE

Choledochal cyst is a rare congenital anomaly with an estimated occurrence ranging from 1 case in 100,000 to 150,000 livebirths (Lippett and Pitt, 2003) to 1 case in every 2 million livebirths (Dewbury et al., 1980). It is more common in females in all ethnic groups, with a ratio of 2.5:1, which some have suggested may indicate that it is a sex-linked defect (Alonzo-Lej et al., 1959; Kim, 1981). Asian populations, particularly Chinese and Japanese, have a much higher incidence of choledochal cyst than any other race.

SONOGRAPHIC FINDINGS

The characteristic sonographic finding in fetal choledochal cyst is a simple anechoic cyst in the upper abdomen in close proximity to the porta hepatis (Figure 67-2). Rarely, the cyst can be imaged in continuity with the bifurcation of the right and left hepatic ducts or joined by the cystic duct from the gallbladder. Elrad et al. (1985) were the first to describe finding dilated ducts leading into a cystic mass that was later confirmed to be a choledochal cyst (Frank et al., 1981). It may be difficult to distinguish a choledochal cyst from gallbladder duplication, duodenal atresia, mesenteric cyst, or even an ovarian cyst that has migrated up into the upper abdomen (Crombleholme et al., 1997). Color flow Doppler studies may be helpful in demonstrating the cyst in relation to the portal vein, hepatic artery, and umbilical vein (Gallivan et al., 1996). Recently, fetal MRI has been used to diagnose choledochal cyst (MacKenzie et al., 2001; Chen et al., 2004; Want et al., 2005).

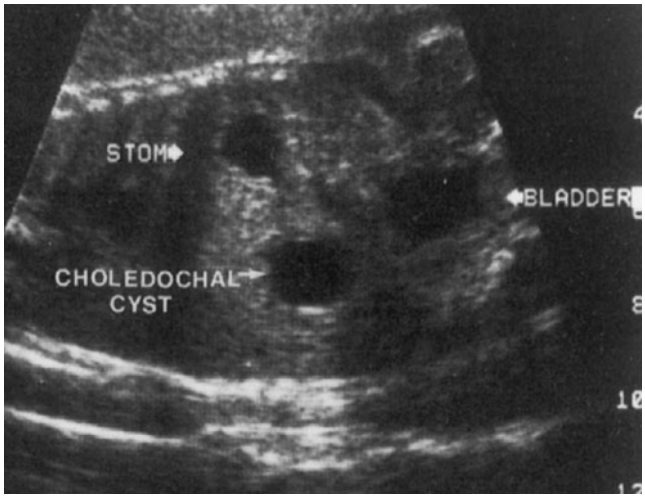

Figure 67-2 A 17-week-old fetus with an anechoic mass in porta hepatis, which postnatal evaluation confirmed to be a type I choledochal cyst. *(Reprinted, with permission, from Gallivan EK, Crombleholme TM, D'Alton ME, et al. Early prenatal diagnosis of choledochal cyst. Prenat Diagn. 1996;16:934-937. Copyright John Wiley & Sons Limited. Reproduced with permission.)*

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a cystic mass in the right upper quadrant includes hepatic or omental cysts, adrenal cysts, renal cysts or hydronephrotic renal pelvis of the right kidney, dilated loop of bowel, mesenteric cysts, duodenal duplications, gallbladder duplications, simple hepatic cysts, duodenal atresia, and situs inversus. Because of the small fetal pelvis, ovarian cysts can move up into the right upper quadrant (Crombleholme et al., 1997). A diagnosis of choledochal cyst is more likely if the location is subhepatic and intraperitoneal and there is no change in appearance with observed peristalsis of the fetal bowel. Color Doppler studies that demonstrate an intimate association of the cyst with the hepatic artery and portal vein also suggest a biliary origin (Gallivan et al., 1996). The diagnosis is most convincing if tubular structures can be identified entering and leaving the cyst.

Dilation of intrahepatic bile ducts occurs in the fetal liver, most often in association with infantile polycystic kidney disease. Substantial ectasia with grossly identifiable cyst formation is rare, but may be seen in Meckel–Gruber syndrome, infantile polycystic kidney disease, and a variant of Ivemark syndrome (Strayer and Kissone, 1979; Blankenberry et al., 1987).

ANTENATAL NATURAL HISTORY

The earliest reported prenatal diagnosis of a choledochal cyst has been at 15 weeks' gestation (Schroeder et al., 1989) (Table 67-1). This early prenatal diagnosis challenges one commonly held theory that choledochal cysts arise from the reflux of

Table 67-1

Clinical Summary of Patients Diagnosed Prenatally with Choledochal Cyst

Report	GA at Diagnostic (wk)	Neonatal Symptoms	Values of Total Bilirubin/ Direct Bilirubin	Surgery	Cholangiogram	Liver Biopsy	Outcome
Schroeder et al., 1989	15	Asymmetry	3.9/NR	5 wk	Type I DO	NR	Well at 4 mo
Gallivan et al., 1997	17	Jaundice	5/NR	1 wk	Type I DO	Mild fibrosis	Well at 3 yr

GA, gestational age; DO, distal obstruction; DP, distal proliferation; NR, not reported; SBO, small-bowel obstruction.

pancreatic enzymes into the common bile duct via the "long common channel." At this gestational age, pancreatic acini are only just appearing and zymogen granules are immature, with no evidence of secretion on electron microscopy (Laitio et al., 1974).

The diagnosis of choledochal cyst in utero is important in identifying a fetus that will require postnatal evaluation as a newborn. It is essential to rule out other cystic masses in the differential diagnosis, which may have a different prenatal history. Our understanding of fetal choledochal cyst is limited to the information gleaned from the relatively few antenatal cases that have been reported to date. This diagnosis has no implications for the pregnancy and has not been associated with adverse fetal or maternal consequences.

Only 1 of 12 cases of fetal choledochal cyst reported had significant cirrhosis, presumed to be due to chronic biliary obstruction in utero (Table 67-1). This infant was observed for a time and it is unknown if early delivery and immediate decompression may have averted some damage to the liver. The other cases did not show evidence of cirrhosis; however, ductal proliferation consistent with bile duct obstruction was common. One case had fibrosis on biopsy but no cirrhosis. Several cases of neonatal choledochal cyst have been reported in association with congenital hepatic fibrosis. This is a slowly progressive condition in which hepatic synthetic function is preserved but significant portal hypertension develops as a result of the progressive hepatic fibrosis (Orenstein and Whittington, 1982).

MANAGEMENT OF PREGNANCY

The prenatal diagnosis of a choledochal cyst has no implications for the method or timing of delivery. In addition, there is no need to refer the pregnant patient for delivery in a tertiary care setting. Sonographic surveillance during the remainder of the pregnancy is unnecessary if the diagnosis is firmly established. This can be difficult, however, and repeated scans may be helpful in arriving at a definitive diagnosis. The infant can be delivered as planned and referred during the immediate postnatal period for complete evaluation of the biliary tract.

It is our practice to have the prospective parents meet with a pediatric surgeon to fully detail the postnatal investigation required to evaluate a newborn with suspected choledochal cyst and to explain the nature of the surgery required for treatment. Although nothing can be done until the baby arrives, this prenatal consultation serves to allay parental fears and minimize anxiety for the remaining weeks of gestation.

FETAL INTERVENTION

There are no fetal interventions for choledochal cyst.

TREATMENT OF THE NEWBORN

The newborn with suspected choledochal cyst should be observed closely for the passage of normal-colored meconium and development of persistent direct hyperbilirubinemia. Although these infants are usually healthy at birth, complete choledochal obstruction is common, and postnatal evaluation in a center familiar with the diagnosis and treatment of both choledochal cyst disease and biliary atresia should be obtained during the immediate postnatal period. It is important to impress on parents that without proper postnatal evaluation choledochal cyst cannot be distinguished from biliary atresia. In biliary atresia, it is important to establish bile drainage within the first 2 months of life, as the success rate for the Kasai procedure (hepaticojejunostomy) drops significantly after that age. In addition, even in cases of choledochal cyst, prompt decompression may be essential to prevent liver damage. Harris and Kahler (1978) reported about an infant who died at 5 months of age from liver failure resulting from an untreated choledochal cyst.

After a detailed physical examination, which often will reveal a nontender cystic mass in the right upper quadrant, baseline liver function studies should be obtained, including total and direct bilirubin, alkaline phosphatase, aspartate and alanine aminotransferases, lactate dehydrogenase, and a blood count with differential. The laboratory values, most often abnormal in choledochal cysts, are conjugated bilirubin and serum alkaline phosphatase. A minimally abnormal coagulation profile may also be seen with prolongation of prothrombin time. There is no confirmatory laboratory study for choledochal cyst and a definitive diagnosis requires imaging studies. A right upper quadrant ultrasound examination should be obtained to confirm prenatal findings, and more importantly, to exclude other causes of cystic masses. If any doubt exists regarding the nature of the cyst, a CT scan with intravenous and oral contrast is indicated (Weissmann et al., 1979; Hoglund et al., 1990). If the postnatal sonogram is consistent with prenatal findings, the next logical study is a ^{99m}Tc-diisopropyliminodiacetic acid (DisHIDA) scan. This nuclear isotopic scan is used in the diagnosis of choledochal cyst, as the radionuclide is taken up by the liver and excreted in the biliary canaliculi, where it becomes concentrated. While the nuclide is usually excreted into the duodenum, in choledochal cysts there is characteristic delay of excretion of the radionuclide in the cyst. In cases of biliary atresia, no excretion of radionuclide will be observed even after priming with the choleretic agent phenobarbital. In order to accurately assess the extent of choledochal cyst disease and distinguish it from biliary atresia, the entire biliary tree must be visualized. While this can readily be done preoperatively by endoscopic retrograde cholangiopancreatography (ERCP) in the older child, in the newborn intraoperative cholangiography is necessary (Hermansen et al., 1979; O'Neill, 1992).

The clinical presentation of infants with choledochal cysts is indistinguishable from infants with biliary atresia and complete biliary obstruction (O'Neill et al., 1987).

Alonzo-Lej et al. (1959) described a classic triad of clinical findings of pain, mass, and jaundice, but the infantile form usually presents with jaundice alone (O'Neill et al., 1987). Howell et al. (1983) suggested that in most prenatally diagnosed cases of choledochal cysts, jaundice develops 1 to 3 weeks after birth. However, in the report by Bancroft et al. (1994), half of the infants diagnosed prenatally with choledochal cyst had jaundice at birth.

SURGICAL TREATMENT

All patients with choledochal cysts (types I to IV), even in absence of obstruction, should undergo cyst excision because of the certainty of complications resulting from remaining cysts, varying from recurrent cholangitis, cirrhosis, portal hypertension, pancreatitis, and malignant transformation (O'Neill, 1992). The first step in the operative management of these cases is the demonstration of the intrahepatic and extrahepatic biliary anatomy to exclude biliary atresia, define cyst type, and plan the resection and reconstruction. This is performed by placing a small cholangiocatheter through a purse-string suture in the dome of the gallbladder for contrast injection (Figure 67-3).

Although internal and external drainage of choledochal cysts was once an accepted form of therapy, it is clear that these procedures are fraught with complications and the results with cyst excision are far superior (O'Neill, 1992). In type I choledochal cysts, excision of the cyst to the confluence of the normal hepatic ducts and reconstruction by Roux-en-Y hepaticojejunostomy is the preferred procedure. Some have advocated intussuscepted nipple valves, jejunal interposition, hepaticoduodenostomy, or nonrefluxing biliary appendicoduodenostomy for reconstruction, but none of these procedures have been proven to be superior to Roux-en-Y hepaticojejunostomy (Raffensperger, 1980; Todani et al., 1981; Reynolds et al., 1985; Crombleholme et al., 1989; Gonzalez et al., 1989; Okada et al., 1989; O'Neill, 1992).

LONG-TERM OUTCOME

The common complications of recurrent cholangitis, cirrhosis, portal hypertension, and malignant transformation comprise the natural history of untreated choledochal cysts. These complications have been eliminated by resection and hepaticojejunostomy (O'Neill, 1992). If recurrent cholangitis occurs in patients who have had total resection, an evaluation to exclude anastomotic stricture at the hepaticojejunostomy must be undertaken (Ohi et al., 1990).

Although the risk of recurrent cholangitis is quite low following hepaticojejunostomy for choledochal cyst, prophylactic antibiotics should be considered when intrahepatic cysts remain, as in Caroli's disease. The overall long-term outcome for patients with choledochal cysts is excellent. Although cure is likely in these patients, lifelong follow-up is necessary, including liver function tests and occasional ultrasound examinations to detect late obstruction of the hepaticojejunostomy (O'Neill, 1992).

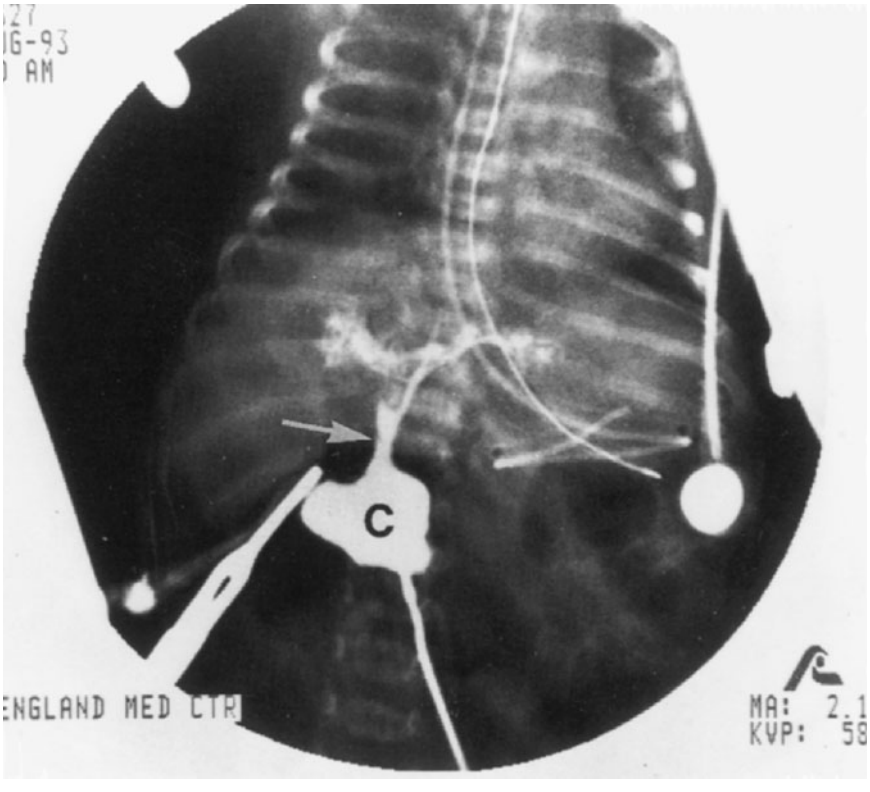

Figure 67-3 Postnatally, intraoperative cholangiography was performed in the same fetus shown in Figures 67-2, demonstrating a type I choledochal cyst. *(Reprinted, with permission, from Gallivan EK, Crombleholme TM, D'Alton ME, et al. Early prenatal diagnosis of choledochal cyst. Prenat Diagn. 1996;16:934-937. Copyright John Wiley & Sons Limited. Reproduced with permission.)*

GENETICS AND RECURRENCE RISK

There have only been 10 (Iwata et al., 1998; Clifton et al., 2006) familial cases of choledochal cyst disease reported. These case reports described four cases of mother–daughter transmission, one case of father–daughter transmission, two affected sisters, and two affected pairs of brother and sister (Hamada et al., 1998). Only one pair of eight reported monozygous twins has been concordant for choledochal cyst (Alonzo-Lej et al., 1959; Clifton et al., 2006; Narita et al., 1990a, 1990b; Iwata et al., 1998). In addition, there has been one reported case of twins with Coroli's disease (Ribeiro et al., 1996). The lack of concordance among twins and rare Mendelian pedigrees argues that a complex pattern of inheritance is likely for the majority of families (Clifton et al., 2006).

68 CHAPTER Ovarian Cysts

Key Points

- The cause of fetal ovarian cysts is unclear but is most likely due to stimulation of the fetal ovaries by fetal gonadotropins, maternal estrogens, and placental chorionic gonadotropin.
- Fetal ovarian cysts are most often unilateral but there have been reported cases that are bilateral.
- Two types of cysts have been described: simple cysts and complicated cysts.
- The antenatal natural history is variable with some cysts resolving, some becoming complex, most likely due to torsion, and some remaining stable.
- Fetal intervention (cyst aspiration) is controversial but should be considered when the cyst is simple in nature and greater than 4 cm in diameter.
- Delivery should occur in a center with appropriate pediatric surgical expertise available.
- After delivery, the neonate should have an ultrasound to confirm the diagnosis.
- Many simple cysts will resolve in the neonatal period. Surgery should be considered for complex cysts.

CONDITION

Ovarian cysts arise from ovarian follicles. The primary stimulus for follicular development is follicle-stimulating hormone (FSH) secreted by the fetal pituitary, but maternal estrogens and placental human chorionic gonadotropin (hCG) also contribute to follicle growth in utero (Pryse-Davies and Dewhurst, 1971). Primary follicles can be seen as early as the 20th week of gestation, and graafian follicles first appear after 28 weeks of gestation (Pryse-Davies and Dewhurst, 1971; Peters et al., 1978). At birth, maternal estrogen and hCG levels decrease sharply, and FSH production is decreased by the inhibitory mechanism of the hypothalamus–pituitary–ovarian axis (Grumbach and Kaplan, 1975). This decrease in circulating estrogen and hCG levels at birth usually precludes the formation of simple ovarian cysts during childhood.

Ovarian cysts develop from mature follicles in hormonally active ovaries and are therefore most often seen after puberty. The cause of fetal ovarian cysts is unclear but is most likely stimulation of the fetal ovaries by fetal gonadotropins, maternal estrogens, and placental chorionic gonadotropin. The increased incidence of ovarian cysts seen in infants of mothers with diabetes mellitus, rhesus sensitization, and preeclampsia—(conditions that are associated with excessive levels of serum chorionic gonadotropins (DeSa, 1975; Nussbaum et al., 1988)—supports this pathogenesis. The association with fetal hypothyroidism has also been reported (Jafri et al., 1984). However, in most cases the cysts are detected in otherwise normal pregnancies (Sakala et al., 1991). It is most common for fetal ovarian cysts to be unilateral; however, bilateral fetal ovarian cysts have been reported. In the review by Sakala et al. (1991) of 65 cases of fetal ovarian cysts, 62 (95%) were unilateral, whereas 3 were bilateral.

INCIDENCE

Ovarian and genital abnormalities account for 20% of all newborn abdominal masses, second only to those of urinary-tract origin (Griscom, 1965; Wilson, 1982). The first report of prenatal diagnosis of a fetal ovarian cyst was by Valenti et al. (1975); subsequently, over 300 cases of prenatally diagnosed ovarian cysts have been reported (Holzgreve et al., 1989). Kirkinen and Jouppila (1985) reported 8 ovarian cysts detected antenatally in 21,000 pregnancies, for an incidence of 1 in 2625. DeSa (1975) found small follicular cysts in 113 (34%) of 332 stillborn fetuses and neonatal deaths. The cysts were defined as cystic structures lined by recognizable granulosa epithelium, with the greatest diameter in excess of 1 mm on microscopical section.

SONOGRAPHIC FINDINGS

The following criteria are used to identify fetal ovarian cysts during fetal ultrasound examination:

1. The presence of a cystic structure, usually located on one side of the fetal abdomen.
2. Identification of normal genitourinary tract (kidneys, ureter, and bladder).
3. Identification of a normal gastrointestinal tract (stomach, small and large bowel).
4. Female fetus.

Two types of cysts have been described: a simple cyst that is completely anechoic (Figure 68-1) and complicated cysts containing internal echoes and fluid levels, internal septations, or anechoic areas intermixed with echogenic foci (Figure 68-2). The antenatal diagnosis of an echogenic cyst is an accurate sonographic indicator of ovarian torsion. In several series of echogenic cysts detected prenatally, postnatal surgery has confirmed the diagnosis (Nussbaum et al., 1988; Brandt et al., 1991; Meizner et al., 1991; Giorlandino et al., 1994).

The distinction between a pathologic cyst and a physiologic, mature follicle is based on size alone, with fetal ovarian cysts >2 cm considered pathologic (Grapin et al., 1987). Cysts may vary in size from 2 × 2 cm to 8 × 11 cm in diameter (Grapin et al., 1987).

DIFFERENTIAL DIAGNOSIS

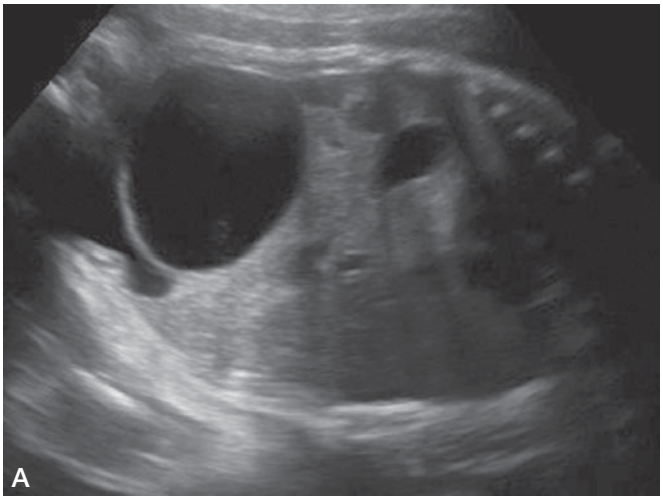
The diagnosis of a fetal ovarian cyst is usually presumptive because mesenteric cysts, urachal cysts, or enteric duplications cannot be ruled out with absolute certainty prenatally. Factors more indicative of a fetal ovarian cyst include bilaterality, echogenicity, and cyst septations. Most cysts are benign; while ovarian neoplasms have been reported, they are extremely rare (Croitoru et al., 1991). Confirmation of normal kidneys and bladder will reduce the potential to confuse renal cysts or posterior urethral valves with persistent distention of the bladder as an ovarian cyst.

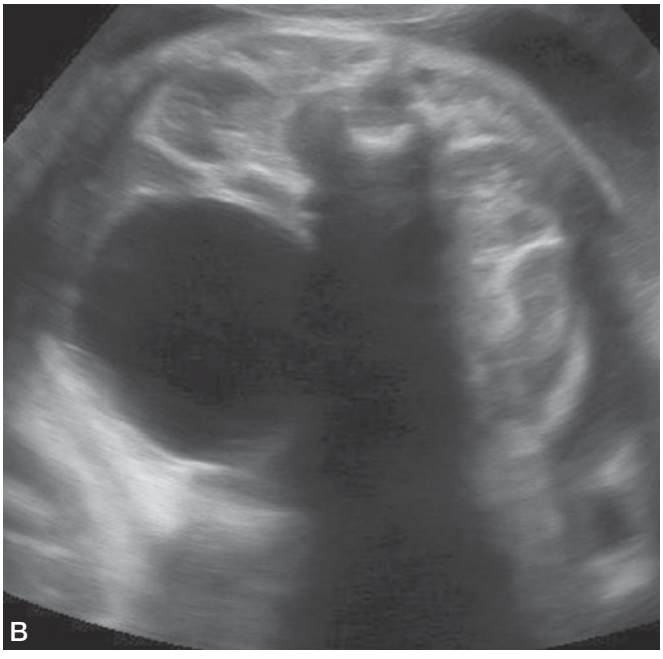
ANTENATAL NATURAL HISTORY

Most cases of fetal ovarian cysts have been reported after 28 weeks of gestation (Brandt et al., 1991). Cases have been reported during the second trimester, beginning as early as 19 weeks (Meizner et al., 1991; Foley et al., 2005). With the exception of a report of congenital hypothyroidism (Jafri et al., 1984), all other series report no associated congenital anomalies.

The size of most cysts remains unchanged in utero. A few cases have been reported to resolve in utero completely (McKeever and Andrews, 1988; Rizzo et al., 1989). Polyhydramnios is present in approximately 18% of cases and is more commonly seen with cysts >6 cm (Sakala et al., 1991). The mechanism of the polyhydramnios has been suggested to be due to partial bowel obstruction secondary to compression by a large cyst (Carlson and Griscom, 1972).

Anechoic cysts have the potential to become complex cysts, with the presence of echogenicity, fluid levels, and internal echoes (Figure 68-3). The presence of these sonographic findings is usually an indicator that the cyst has undergone torsion. The incidence of antenatal torsion documented in a large series of cases is 40%. Torsion is the most common complication of prenatally diagnosed ovarian cysts. It is more common in large cysts (Nussbaum et al., 1988) but has occurred in cysts as small as 2 cm (Grapin et al., 1987). Of the cysts that remain anechoic in utero, a significant proportion, approximately 50%, will undergo spontaneous resolution after birth. There is an ongoing risk of torsion during the neonatal period that underscores the need for neonatal follow-up. It is interesting to note that the longer the cyst is followed in utero, the greater the likelihood that it will become complex (Foley et al., 2005).





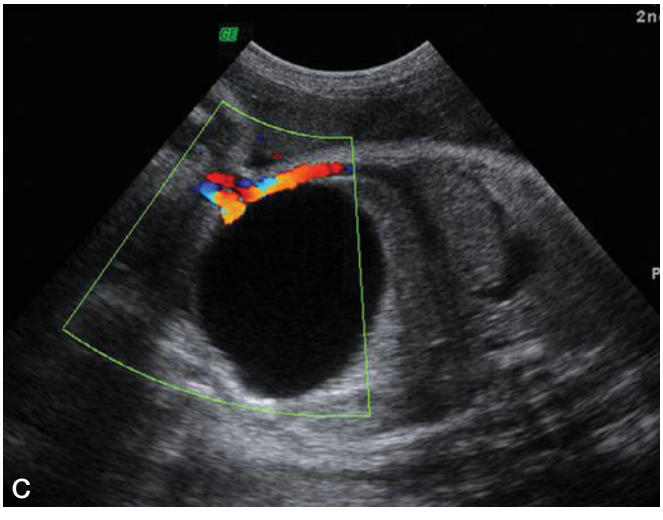


Figure 68-1 **A.** Sagittal image demonstrating large anechoic cystic mass superior to the fetal bladder and inferior to the fetal stomach. This represents a simple ovarian cyst. **B.** Transverse image showing the same cyst anterior to the left kidney. **C.** Large anechoic cyst in lower fetal abdomen at 24 weeks' gestation.

Figure 68-2 Ultrasound image of a complicated ovarian cyst, demonstrating internal echoes and anechoic areas interspersed with echogenic foci.

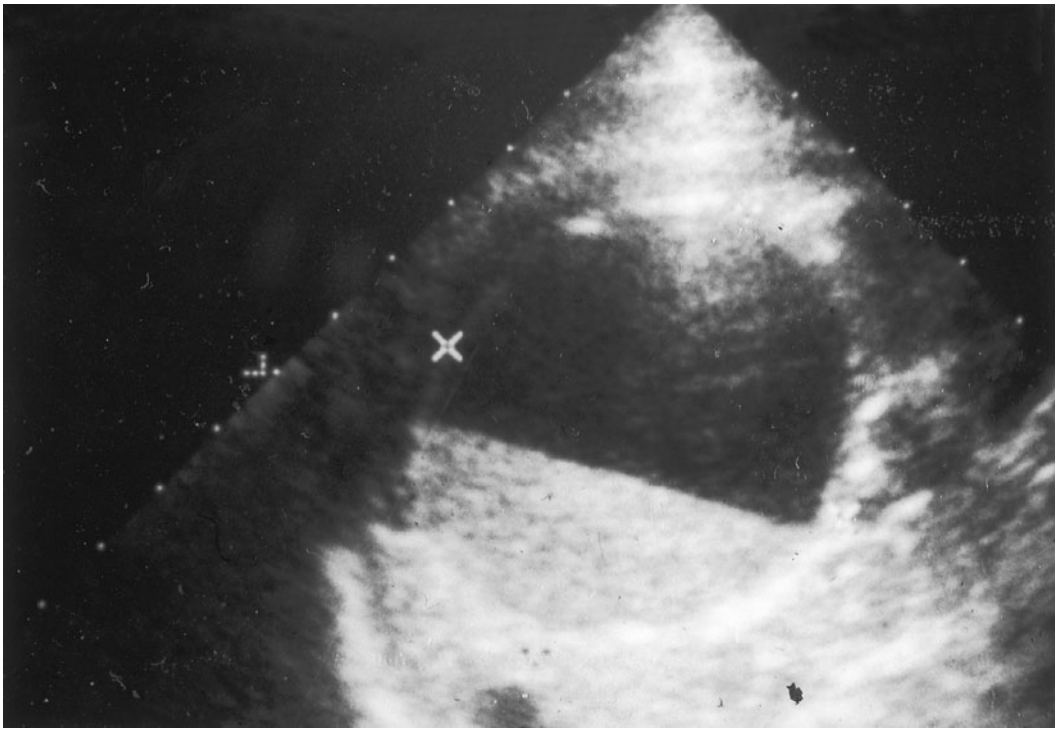

Figure 68-3 Ultrasound image of a cyst demonstrating fluid levels. This is another example of a complicated ovarian cyst.

MANAGEMENT OF PREGNANCY

Amniocentesis for karyotype is not indicated because there is no associated risk of aneuploidy, in excess of the background risk for the patient. No specialized antenatal fetal surveillance testing is necessary unless it is for other obstetric reasons. If a cyst is diagnosed to be echogenic, referral to pediatric surgery or pediatric gynecology is appropriate because all such cysts will require removal during the postnatal period owing to torsion. Delivery should occur in a center with appropriate pediatric surgical expertise available. Premature delivery is not indicated. Previous recommendations for cesarean delivery were based on anecdotal cases of poor outcomes for neonates with ovarian cysts that ruptured or caused soft tissue dystocia. In the most recent series, vaginal delivery has been performed, and cesarean was reserved for obstetric indications.

FETAL INTERVENTION

The indications for fetal intervention in ovarian cysts remain undefined, and in utero aspiration to prevent complications and subsequent oophorectomy remains controversial (Holzgreve and Evans, 1983; Heling et al., 2002; Bryant and Laufer, 2004; Comparetto et al., 2005).

In utero aspiration of cysts >4 cm should be considered. Valenti et al. (1975) reported in utero aspiration for a 7 × 9-cm ovarian cyst with the intent of preventing intrapartum rupture. Landrum et al. (1986) reported aspiration of an 8 × 11-cm cyst in a 31-week-old fetus, ostensibly to prevent pulmonary hypoplasia. Pulmonary hypoplasia from a pelvic mass is unlikely, especially at 31 weeks. Aspiration to prevent in utero torsion and preserve ovarian tissue is a more appropriate goal (Figure 68-4) (Crombleholme et al., 1997). In a review of seven cases of fetal ovarian cyst, indications for prenatal decompression included size >4 cm, the presence of a "wandering" mass, or rapid enlargement of a cystic mass. Analysis of the aspirated fluid revealed high levels of progesterone and testosterone, which was helpful in confirming the diagnosis (Crombleholme et al., 1997).

Giorlandino et al. (1990) have reported a case of an ovarian cyst treated by cyst aspiration and sclerosis with tetracycline. Although this treatment was successful, the use of tetracycline as a sclerosing agent in the fetus is not advised. Subsequently, Giorlandino et al. (1994) reported four cases of successful in utero cyst aspiration for cysts ranging from 5–8 cm in diameter with an 18-gauge needle. Cytologic evaluation of the aspirated fluid showed the presence of cyst-lining epithelial cells. No neonatal surgery was required.

D'Addario et al. (1990) reported in utero aspiration in two cases. One cyst ruptured during aspiration, and both cases required neonatal surgery. No other details were reported. Of the 20 cases reported describing this type of management, there have been no perinatal complications attributed to the intervention.

The disadvantages cited to prenatal aspiration of cysts are the limited published experience, the accuracy of differential diagnosis and the possibility that another type of cysts could be mistakenly aspirated, and that aspiration may

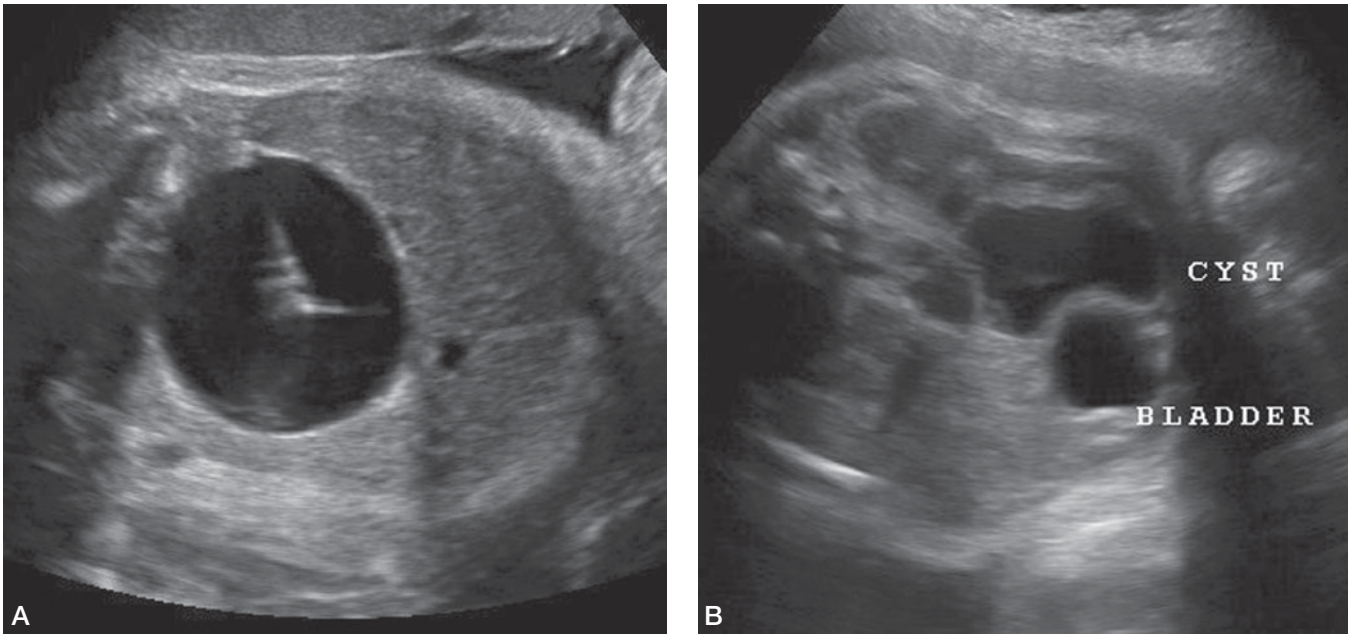

Figure 68-4 **A.** Prenatal image documenting ultrasound-guided drainage of a fetal ovarian cyst; **B.** axial image showing the same fetal ovarian cyst after aspiration.

be less likely to be effective in utero because of continued hormonal stimulation (Brandt et al., 1991). Cyst aspiration is not recommended for echogenic cysts. This sonographic finding indicates that the cyst has already undergone ovarian torsion; thus cyst aspiration would be of no benefit. If cyst aspiration is considered, magnetic resonance imaging (MRI) may be useful as a diagnostic adjunct (Foley et al., 2005).

TREATMENT OF THE NEWBORN

After delivery the neonate should have an ultrasound examination to confirm the antenatal diagnosis. If the postnatal scan demonstrates the presence of an echogenic cyst, surgery should be performed. Surgery usually consists of oophorectomy, because in most cases no viable ovarian tissue can be seen (Figure 68-5) (Brandt et al., 1991). The pathologic reports of most reported series have revealed follicular cysts; however, many cases have been necrotic, with no specific epithelial findings (Figure 68-6). (Nussbaum et al., 1988; D'Addario et al., 1990; Brandt et al., 1991).

Serious complications may arise if complex cysts are observed without being treated during the neonatal period. Although the unsalvageable necrotic ovarian tissue can theoretically resorb, complex cysts may represent tumors and other pathologic conditions (Hollenbeck et al., 1978; Croitoru et al., 1991). Necrotic ovarian cysts can also adhere to the bowel. These adhesions carry the risk of internal hernias, volvulus, and intestinal hemorrhage. Other reported complications of ovarian torsion include intestinal perforation (Grapin et al., 1987; McKeever and Andrews, 1988) and urinary tract obstruction (Nussbaum et al., 1988).

Many simple ovarian cysts resolve spontaneously after birth. However, there is concern that torsion will develop during observation of an ovarian cyst during the neonatal period. The incidence of torsion in neonatal cysts has been reported to be as high as 50%–78% (Nussbaum et al., 1988; Debeugny et al., 1989). This has led many authors to recommend early surgical intervention (Holzgreve et al., 1985; Grapin et al., 1987). We now know that many of these torsions occur antenatally and that even the earliest surgical intervention would have failed to preserve the ovary in these cases.

In Brandt et al. (1991) review of the literature, ultrasonographic evidence of torsion at or before birth was found in 92% of patients with torsion. This suggests that most torsions occur prenatally and that the risk of torsion may be low in ovarian cysts that are managed conservatively during the neonatal period. In Giorlandino et al. (1994) series, 3 of 12 cases of anechoic cysts developed torsion and 9 demonstrated spontaneous resolution.

SURGICAL TREATMENT

Surgery is performed in infants with ovarian cysts in order to prevent torsion and to save the ovary (see Figure 68-6). Sometimes technical difficulties in separating the cyst from the normal ovary lead to removal of the ovary, an unfortunate outcome as the surgery designed to protect the ovary results in removal of the ovary. Surgery should be considered for these simple anechoic cysts if there is an increase in size or if the cysts persist during postnatal sonographic follow-up. Surgery should also be performed in cases in which clinical symptoms such as abdominal distention, vomiting, or persistent irritability develops.

If surgical exploration is performed, every attempt should be made to salvage the ovary. Even if no ovary is macroscopically identifiable, ovarian tissue may nevertheless

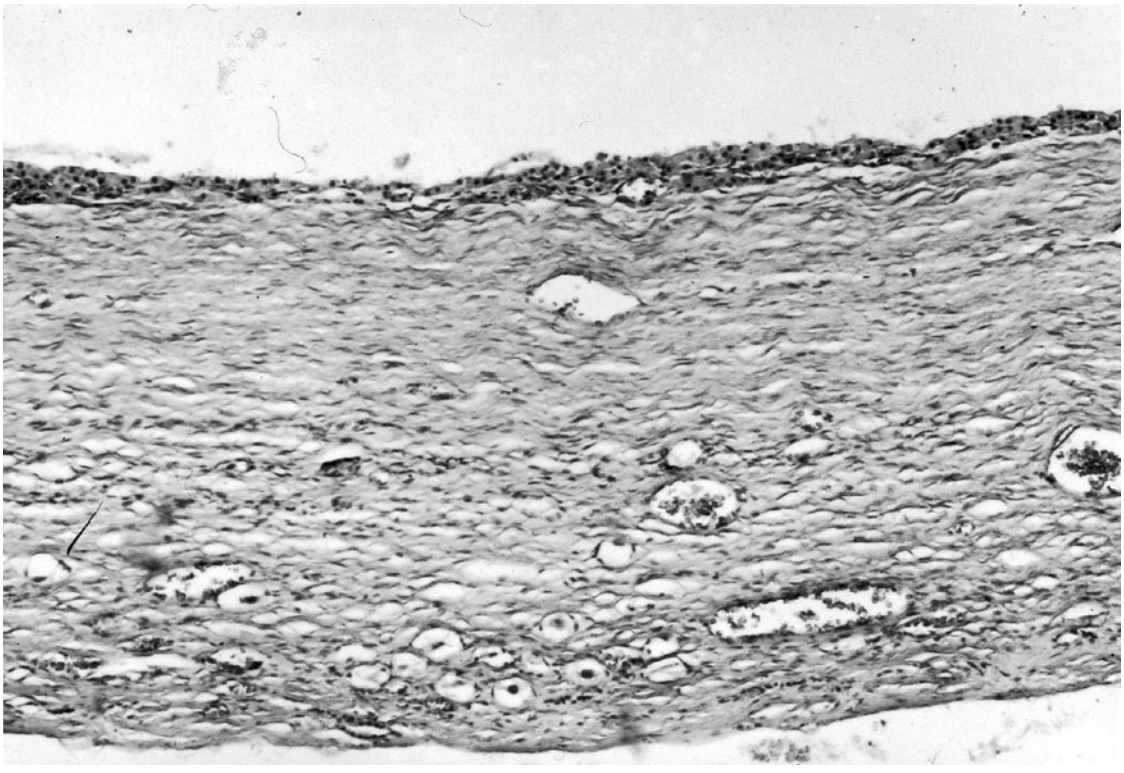

Figure 68-5 Histologic specimen from ovarian cyst demonstrating follicles in the cyst wall.

be present, and surgery should be limited to removal or unroofing of the cyst. Aspiration of large, simple neonatal ovarian cysts has been documented. There have been no reported complications, and recurrence has been noted only in one case (Henrion and Helardot, 1987; Liapi and Evain-Brion, 1987; Eggermont et al., 1988; Debeugny et al., 1989).

LONG-TERM OUTCOME

There are no long-term consequences for a female child with an uncomplicated ovarian cyst diagnosed prenatally. If the cyst has already undergone torsion there may be adverse fertility effects, although there are no long-term data to support or refute this issue.

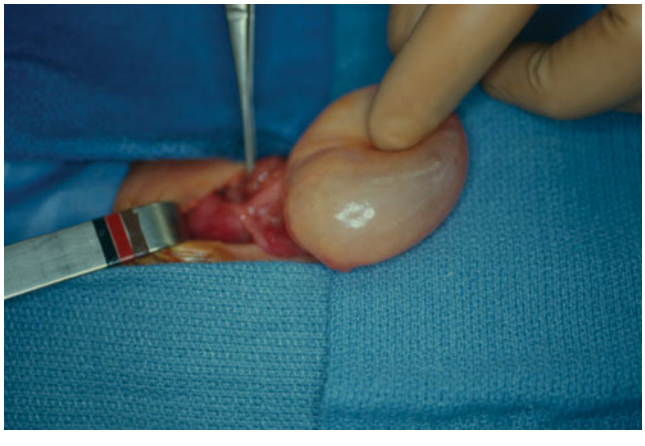

Figure 68-6 Appearance of an ovarian cyst at surgery. Differentiation of normal ovary from the ovarian cyst is usually extremely difficult.

GENETICS AND RECURRENCE RISK

Ovarian cysts are not considered to have a genetic etiology or to be inherited in a specific pattern. The recurrence risk is likely negligible.

69 CHAPTER Intra-abdominal Calcifications—Hepatic

Key Points

- Fetal liver calcifications are found in 1 in 1700 (0.05%) pregnancies.
- One-third is isolated, while two-thirds are associated with other fetal abnormalities.
- Following the diagnosis of calcifications on the surface of the fetal liver, it is important to rule out meconium peritonitis.
- Differential diagnosis includes infection, liver tumors, vascular calcification, and fetal aneuploidy.
- Management should include detailed fetal anatomical scan to look for associated anomalies, maternal TORCH titers, amniocentesis for karyotype and CMV culture, and fetal MRI if an intrinsic hepatic mass is suspected.
- Prognosis depends on presence or absence of associated abnormalities.
- If a detailed work-up is unremarkable, the fetal prognosis is excellent.

CONDITION

Fetal hepatic calcifications can be divided into three main categories: peritoneal, parenchymal, and vascular. Peritoneal hepatic calcifications present as calcified masses on the surface of the fetal liver. Most commonly, this is due to meconium peritonitis resulting from in utero bowel rupture. Meconium peritonitis is the most common cause of fetal abdominal calcifications (Lince et al., 1985) (see Chapter 70). Parenchymal calcifications are due to the presence of intrauterine infection or tumor. Fetal tumors may be primary in the liver or metastatic, presenting as a complex mass with areas of increased echogenicity and possible shadowing. Fetal tumors encompass both benign and malignant varieties, including hemangioendotheliomas, hamartomas, and hepatoblastomas. Parenchymal calcifications appear as scattered nodules, with or without additional evidence of other affected organs. The most common in utero infections that can cause fetal liver calcifications include varicella and the TORCH agents (Figure 69-1). Hepatic calcifications due to vascular abnormalities result from calcified portal or hepatic venous clots, which are due to hypoperfusion or thromboembolism (Nguyen and Leonard, 1986; Bronshtein and Blazer, 1995).

INCIDENCE

With the increased utilization of prenatal sonographic screening, fetal hepatic calcifications are detected prenatally more frequently than they are observed in newborn infants. In one study, evidence of hepatic calcifications was noted in 14 of 24,600 fetuses, an incidence of approximately 1 in 1700 (0.05%) of screened fetuses (Bronshtein and Blazer, 1995). In a population of 1500 spontaneously aborted fetuses, 33 were demonstrated to have hepatic calcification, an incidence of 2.2% in this abnormal patient population (Hawass et al., 1990). In the 33 affected fetuses, 17 hepatic calcifications were found in the first trimester and 16 in the second trimester.

SONOGRAPHIC FINDINGS

Fetal liver calcifications can be detected reliably by the beginning of the second trimester of pregnancy (Figure 69-2). Bronshtein and Blazer (1995) reported their 8-year experience in extensive targeted second trimester sonographic screening for fetal abnormalities, which included hepatic calcifications in 24,600 consecutive pregnancies. Hepatic calcification was identified in 14 fetuses; of these, 12 had one or two areas of focal calcifications. One fetus had evidence of four different foci of calcifications. In one fetus, there were diffuse hepatic, peritoneal, and intestinal calcifications. No correlation was seen between the number or location of calcifications and the occurrence of malformations or eventual outcome for the child. Of the 14 affected fetuses, 13 had persistent hepatic calcifications noted on serial sonographic scans. In one case initially diagnosed at 15 weeks of gestation, calcifications resolved by 24 weeks. Four fetuses had associated anomalies, which included two cases of trisomy 18, one case of dwarfism and hydronephrosis, and one case of polyhydramnios and bowel calcifications. This last fetus died in utero at 32 weeks of gestation and no autopsy was performed. Of the remaining

Figure 69-1 Transverse scan through the abdomen of a fetus with varicella infection demonstrating multiple areas of intraparenchymal calcification. *(Reprinted, with permission, from Drose JA, Dennis MA, Thickman D. Infection in utero: US findings in 19 cases. Radiology. 1991;178:369-374.)*

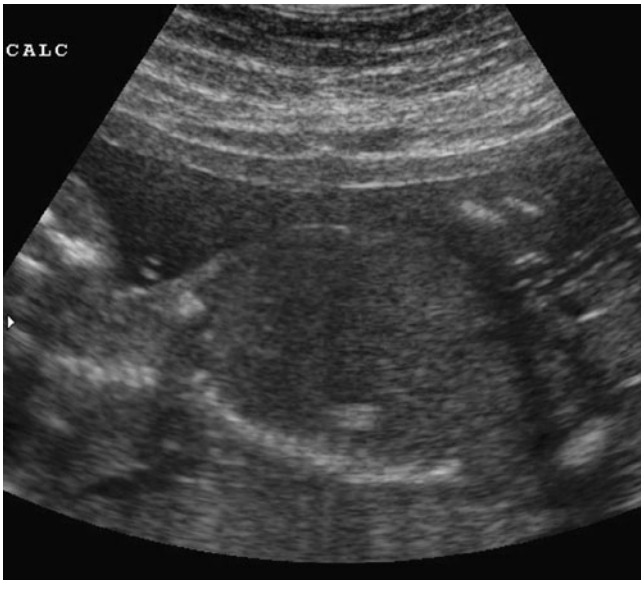

Figure 69-2 Sagittal abdominal scan showing fewer, more punctate, areas of intraparenchymal calcifications. This is the more commonly seen fetal presentation.

10 fetuses, all were normal at birth with no sequelae from the calcifications. Koopman and Wladimiroff (1998) reported their experience with seven fetuses with intrahepatic hyperechogenic foci. One case of trisomy 18 was identified. Another case had associated encephalocele and unilateral renal agenesis. Outcome was normal in five fetuses with isolated intrahepatic findings. More recently, Simchen et al. (2002) performed a 10-year prospective study of the cause and outcome of 61 cases of fetal liver calcifications; 21 of 61 (35%) cases were isolated and 40 (65%) had additional abnormalities. Of the isolated cases, 1 had trisomy 21, 1 had parvovirus B19 infection, 4 were lost to follow-up, and the remaining 15 infants did well. Of the 40 cases with associated abnormalities, 9 had minor findings, such as echogenic bowel or growth restriction. In this group, two were lost to follow-up and seven infants did well. Of the group with major associated sonographic abnormalities ($n = 31$), 10 had abnormal karyotypes and 1 had cytomegalovirus (CMV) infection. There was 1 fetal demise and 18 pregnancies were terminated. The most frequently associated anomalies included central nervous system ($n = 13$), cardiac ($n = 12$), cystic hygroma ($n = 12$), skeletal ($n = 11$), and hydrops fetalis ($n = 9$). Importantly, these investigators found no differences regarding cause and outcome when stratifying their cases by parenchymal or surface calcification; startifying cases by isolated or with additional abnormalities was more informative (Simchen et al., 2002).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of peritoneal surface hepatic calcifications includes meconium peritonitis (see Chapter 69) and ruptured hydrometrocolpos. The differential diagnosis of parenchymal calcifications includes infectious causes, specifically herpes simplex virus type II, varicella–zoster virus (Taylor et al., 1993), rubella virus, CMV (Stein et al., 1995), echovirus 11, syphilis (Kogutt, 1991), parvovirus (Simchen et al., 2002), and toxoplasmosis (Shackelford and Kirks, 1977). The primary tumors likely to cause parenchymal fetal liver calcification include hepatic hemangioma (Pott Bärsch et al., 2003), hemangioendothelioma, hamartoma, teratoma, and hepatoblastoma (Shih et al., 2000). Metastatic neuroblastoma also can cause fetal hepatic calcifications (Friedman et al., 1981). Intrahepatic vascular calcification can be due to portal venous thromboemboli (Blanc et al., 1967; Friedman et al., 1981), hepatic venous thrombi, ischemic necrosis secondary to vascular insufficiency, and subcapsular hematomas, which can be due to hydrops or fetal chromosomal abnormalities (Buxton et al., 1991). Fetal hepatic calcifications have been described in a set of monozygotic twins, most likely due to a thrombotic event (Richards et al., 1988). Fetal hepatic calcifications have been postulated to be a secondary effect of cordocentesis in a fetus with trisomy 9 (Satge et al., 1994). It is hypothesized that such calcifications may have been due to placentofetal embolization from chorionic vein thrombi or intravascular clotting caused by maternal release of thromboplastin. Both of these events are more common in aneuploid fetuses. Many aneuploidies are associated with fetal liver calcifications, including trisomies 13, 18, 21, and 45,X.

ANTENATAL NATURAL HISTORY

In a study biased by ascertaining only miscarried fetuses, Hawass et al. (1990) detected hepatic calcifications in 33 of 1500 cases. Of the 33 affected cases, calcified hepatic venous thrombi were demonstrated in 18. In 12 cases, calcified portal venous thrombi were documented. In only two of the cases were parenchymal calcifications documented, and one case showed mixed findings. In this patient population, 85% of fetuses had associated anomalies. The most common finding was intraluminal meconium calcifications (seen in 27% of fetuses), cystic hygroma (seen in 18% of fetuses), and bony metaphyseal defects (seen in 18% of fetuses) (Hawass et al., 1990). It is unclear whether severe fetal illness or hypoperfusion predisposed the fetus to calcification of the hepatic or portal veins. Since this population spontaneously miscarried, these findings cannot be generalized to a population of pregnant women with continuing pregnancies.

In both the Bronshtein and Blazer (1995) and the Simchen et al. (2002) studies, fetal liver calcifications remained largely unchanged on follow-up scans. With the exception of one case, they did not resolve and no additional findings developed over time. Thus, serial sonographic studies are not necessary.

MANAGEMENT OF PREGNANCY

Recommendations for follow-up of fetal hepatic calcifications include a detailed fetal sonographic examination to look for

associated anomalies. Amniocentesis should be performed for fetal karyotyping as well as obtaining amniotic fluid for CMV culture. Maternal serologic samples should be obtained to diagnose infection with toxoplasmosis, rubella, CMV, or herpes. It is important to document CMV because if it is present, the risk of preterm delivery is increased and the fetus is at risk for hearing damage and developmental abnormalities (Watt-Morse et al., 1995). Simchen et al. (2002) offered cystic fibrosis mutation testing to all women. None screened positive. Thus, CF testing is probably not necessary for fetal liver calcifications.

If the fetal karyotype is normal, TORCH serology is negative, and the CMV culture is negative, the overall prognosis for the fetus is excellent (Bronshtein and Blazer, 1995; Simchen et al., 2002).

However, if fetal hepatic calcifications are associated with an intrahepatic mass, an effort should be made to determine the underlying cause, because the presence of a hepatic tumor has potentially adverse implications for pregnancy outcome. Fetal magnetic resonance imaging (MRI) should be considered. If multiple areas of intraparenchymal calcification are demonstrated, the adrenal glands and sympathetic chain should be examined sonographically to rule out primary neuroblastoma (see Chapter 113).

The recommended hospital site and route of delivery depends on the underlying cause of the calcifications. If the antenatal workup has been completely within normal limits, delivery can take place in the community hospital setting. If, however, other abnormalities have been detected and prolonged postnatal workup requiring pediatric specialists is anticipated, the delivery should occur in a tertiary care center to keep the mother and baby together.

FETAL INTERVENTION

There are no fetal interventions for hepatic calcifications.

TREATMENT OF THE NEWBORN

In the newborn, an infectious cause for hepatic calcifications should be excluded if relevant prenatal infectious disease studies have not been completed. For example, if amniotic fluid was not cultured for CMV, a urine CMV culture should be obtained during the newborn period. Similarly, cultures for newborn TORCH infection should be sent. A detailed physical examination to rule out features suggestive of genetic or chromosomal abnormalities is indicated. Auditory screening is recommended. If antenatally the calcifications were suspected to be due to meconium peritonitis, consideration should be given to obtaining a plain abdominal X-ray film to follow postnatal passage of air throughout the bowel and to rule out intestinal perforation. Consideration should be given to performing abdominal sonography on the newborn infant to determine if the calcifications are still present after birth. If the calcifications are parenchymal, suggesting the presence of tumor, postnatal imaging studies may include abdominal computed tomographic (CT) scanning or MRI. If the pattern of calcifications appears to suggest a vascular accident in utero, consideration should be given to obtaining liver function tests in the infant.

LONG-TERM OUTCOME

Determining long-term prognosis requires knowledge of the location and configuration of calcifications plus the presence or absence of other abnormalities (Nguyen and Leonard, 1986). The long-term outcome will be related to the underlying cause, if determined, of the hepatic calcifications. Bronshtein and Blazer's (1995) study provided reassuring information that all the 10 fetuses with negative cultures, normal karyotype, and absence of additional sonographic abnormalities were confirmed as normal at birth. The gestational age at delivery for these infants was between 37 and 41 weeks, and all were appropriately developed for gestational age. At 4 months to 4.5 years of postnatal life, all of these children were healthy and thriving. Because of this information, parents who have undergone full prenatal testing with completely normal results can, in general, be reassured that the outcome for their fetuses will be good.

GENETICS AND RECURRENCE RISK

When associated sonographic abnormalities are detected there is an association between hepatic calcifications and chromosome abnormalities (Simchen et al., 2002). Autosomal aneuploidies found in cases of liver calcification include trisomies 9, 13, 18, 21, and 45,X. In such cases, recurrence risk will be determined by the underlying chromosomal abnormality. Other unbalanced karyotypes described include 4p−, 22q+, and 8p+. There is a rare autosomal recessive disorder known as idiopathic infantile arterial calcinosis, which is characterized by calcium deposition in the internal elastic lamina of medium and large arteries, and may present with fetal liver calcifications (Wax et al., 2001).

70 CHAPTER Intra-abdominal Calcifications

Key Points

- Causes of intra-abdominal calcification include meconium peritonitis, enterolithiasis, cholelithiasis, and fetus in fetu.
- Meconium peritonitis is the most common cause of intra-abdominal calcifications.
- Cystic fibrosis is seen in only 8% to 13.5% of cases of fetal meconium peritonitis in contrast to 15% to 40% postnatally.
- Enterolithiasis is often associated with rectourinary fistula as in imperforate anus or cloaca.
- Enterolithiasis can be seen in bowel obstruction such as jejunoileal atresia or total colonic Hirschsprung's disease.
- Fetus in fetu is distinguished by the presence of well-formed long bones or vertebral bodies.

CONDITION

The most common causes of intra-abdominal calcifications include hepatic calcifications, meconium peritonitis, enterolithiasis, cholelithiasis, and fetus in fetu. The topic of hepatic calcification is fully covered in Chapter 69 and will not be covered further except to indicate how these can be distinguished from other causes of intra-abdominal calcifications.

Perforation of the bowel that occurs antenatally leads to a sterile chemical peritonitis referred to as meconium peritonitis, which is the most common cause of intra-abdominal calcifications. The peritonitis can be localized or diffuse and can lead to a fibrotic reaction with intraperitoneal calcifications. The clinical manifestations of meconium peritonitis depend on its underlying cause, timing, and whether or not the perforation heals spontaneously. The spectrum of disease ranges from asymptomatic intra-abdominal calcifications to

giant cystic meconium peritonitis (Robertson et al., 1994; Dirkes et al., 1995; Kamata et al., 2000; Tseng et al., 2003; Zangheri et al., 2007). Meconium peritonitis has been associated with intestinal atresia or stenosis, meconium ileus, internal hernia, bowel ileus, intussusception, gastroschisis, Meckel diverticulum, and cytomegalovirus infection (Pletcher et al., 1991; Petrikovsky et al., 1993).

The presence of associated anomalies is unusual and depends on the underlying cause of meconium peritonitis. Up to 15% to 40% of neonates with meconium peritonitis have cystic fibrosis (Park and Grand, 1981; Payne and Nielsen, 1983). However, in prenatally diagnosed meconium peritonitis, cystic fibrosis is reported to be the cause in only 8% to 13.5% of cases (Foster et al., 1987; Dirkes et al., 1995; Casaccia et al., 2003). This apparent discrepancy may be due to the increased sensitivity of prenatal sonographic imaging in detecting abdominal calcification, as compared with postnatal plain films (Williams et al., 1984). It has also been suggested that sonographically detected calcifications could be due to fetal viral infection due to parvovirus B19, cytomegalovirus, herpes viruses, or even taxoplasmosis (Casaccia et al., 2003). It is also possible that cystic fibrosis is less likely to cause calcification due to the deficiency of pancreatic enzymes (Foster et al., 1987). The incidence of cystic fibrosis increases if there are other additional sonographic findings such as dilated bowel and hyperechoic bowel. The presence of calcifications alone suggests the risk of cystic fibrosis of 13% and if associated with evidence of obstruction at 24% (Casaccia et al., 2003). The risk of cystic fibrosis in meconium peritonitis is 330 times the risk in the general population, and the risk of cystic fibrosis in neonatal bowel obstruction is 600 times as high as the general population (1 in 2500) (Casaccia et al., 2003). Enterolithiasis, which is intraluminal calcification of meconium, is a more unusual course of intra-abdominal calcification (Lubusky et al., 2006). Enterolithiasis has been described in association with a number of conditions including imperforate anus, gastrointestinal atresias or stenosis, functional ileal obstruction, and total colonic Hirschsprung's disease (Rickham, 1957; Berdon et al., 1975; Felman et al., 1975; Martin et al., 1976; Cook, 1978; Fletcher and Yullish, 1978; Daneman and Martin, 1979; Berger and Bar-Maor, 1980; Bear and Gilsanz, 1981; Yousefzadeh et al., 1984; Pouillaude et al., 1987; Anderson et al., 1988). Perhaps the most commonly diagnosed setting is in patients with anorectal malformation and rectourinary fistula (Anderson et al., 1988). However, only 10 cases of prenatally diagnosed enterolithiasis associated with anorectal malformations have been reported (Mandell et al., 1992; Pohl-Schickinger et al., 2006; Pohl-Rolle et al., 2008).

The mechanism of calcification of intraluminal meconium has not been fully elucidated. It is assumed that meconium, urine, stasis, and low intraluminal pH may be prerequisites (Shimotake et al., 2006). Most cases of anorectal malformation and rectourethral fistula, however, do not have enterolithiasis. Rolle et al. speculated that relative urinary outflow obstruction would cause reflux of more urine into the colon predisposing to calcification of meconium (Rolle et al., 2008). Shimotake et al., (2006) performed infrared spectrophotometry of intraluminal meconium calculi occurring in a case of anorectal malformation with associated rectourethral fistula. These stones were found to consist of ammonium hydrogen urate having the combined constituents of urine and meconium.

Enterolithiasis can occur in the absence of a rectourethral fistula presumably as a result of stasis and low intraluminal pH. Enterolithiasis has been observed in such cases because of intestinal atresia and total colonic Hirschsprung's disease (Cook, 1978; Fletcher and Yullish, 1978; Yousefzadeh et al., 1984; Miller et al., 1988; Dirkes et al., 1995). It has been suggested that in these cases, the bowel proximal to the intestinal obstruction will have stasis of meconium and swallowed urine (amniotic fluid), in which case urate would become concentrated by fluid resorption by the bowel predisposing to stone formation.

Little is known about the natural history of fetal cholelithiasis. Analysis of a fetal gallstone has never been performed, and it is currently unknown if these stones are primarily made up of cholesterol or pigment or are of mixed type. Cholesterol stones occur as a result of numerous factors, present to varying degrees, acting in concert to promote hepatic secretion of bile saturated with cholesterol, gallbladder stasis, and altered gallbladder secretory function (Carey, 1989). Bile supersaturated with cholesterol is a prerequisite for cholesterol stone formation (Gilger, 1993). Pigment gallstone formation requires bile stasis and the enzymatic hydrolysis of bilirubin glucuronide into free bilirubin and glucuronic acid. Free unconjugated bilirubin, which is insoluble in water, then combines with calcium in the bile to produce the calcium bilirubinate matrix of pigment stones. Brown et al. (1992) observed a number of fetuses with echogenic material in the fetal gallbladder, which they presumed to be sludge. Allen et al. (1981) have demonstrated in adults that this echogenic sludge is composed of calcium bilirubinate crystals.

While numerous predisposing factors for gallstones have been identified in infants and children, with the exception of one case, no predisposing risk factors have been present in reported cases of fetal cholelithiasis (Beretsky and Lonkin, 1983; Heigne and Ednay, 1985; Klingensmith et al., 1988; Brown et al., 1992; Devonald et al., 1992; Suchet et al., 1993; Clarke and Roman, 1994; Munjuluri et al., 2005; Sheiner et al., 2006). One infant diagnosed prenatally with gallstones was found to have hereditary spherocytosis (Beretsky and Lonkin, 1983). Similarly, maternal predisposing factors, other than pregnancy, have been rare. Predisposing factors were present in only four mothers with hemolytic anemia, gallstones in one, and the presence or history of gallstones in three others. While six other mothers had sickle cell trait and one had hemoglobin A_{1C} trait, neither condition is associated with hemolysis.

Fetus in fetu is a rare anomaly in which a fetus incorporates well-differentiated tissue of its monozygotic twin (Khadaroo et al., 2000). Fetus in fetu occurs most commonly in the retroperitoneum of the upper abdomen, although it has been reported to occur in the scrotum, skull,

mediastinum, mouth, and adrenal gland (Aoki et al., 2004; Brand et al., 2004). Fetus in fetu may be confused with meconium pseudocyst or a teratoma. The feature that distinguishes fetus in fetu is the presence on histologic examination of well-differentiated tissues or organs (Gross and Clatworthy, 1951; Griscom, 1965)

INCIDENCE

Meconium peritonitis occurs in approximately 1 in every 35,000 livebirths (Olson et al., 1982; Pan et al., 1983). No estimates are available for enterolithiasis. The incidence of fetal cholelithiasis is not known. Unlike cholelithiasis in children or adults, there is no apparent sex predominance for fetal cholelithiasis. Fetus in fetu is estimated to occur in fewer than 1 in 500,000 livebirths (Iyer et al., 2003).

SONOGRAPHIC FINDINGS

A spectrum of findings may be observed with meconium on prenatal sonographic examination. The most consistent finding is extraluminal abdominal calcifications, which are present in 85% of cases (Figure 70-1A). Meconium peritonitis is the most common cause of fetal intra-abdominal calcifications. The sonographic criteria used for the diagnosis of meconium peritonitis include intra-abdominal calcifications often plaquelike or linear echogenicities that cause acoustic shadowing not caused by solid organ, intraluminal, intravascular, biliary, or tumor calcifications. Other associated findings include polyhydramnios, in 50% fetal ascites, and bowel dilatation in 27% of cases (Foster et al., 1987). The presence of dilated bowel, cysts, or ascites usually predicts complicated meconium peritonitis that will require postnatal surgical intervention. Dirkes et al. (1995) divided sonographically diagnosed cases of fetal intra-abdominal calcifications into simple and complex categories. Simple meconium peritonitis has isolated calcifications seen without any bowel dilatation, meconium pseudocysts, ascites, or polyhydramnios (see Figure 70-1A). Intra-abdominal calcifications in association with any of these features are classified as complex meconium peritonitis (see Figure 70-1B).

While not sufficient for a diagnosis, meconium peritonitis often starts as an echogenic bowel that goes on to perforate with subsequent formation of intraperitoneal calcifications. Serial sonography is indicated to follow this progression. Similarly, simple meconium peritonitis may evolve into complex meconium peritonitis with the development of bowel dilatation, meconium pseudocyst, ascites, or polyhydramnios (Dirkes et al., 1995). Conversely, complex meconium peritonitis with calcifications associated with ascites may see the perforation with resolution of ascites converting from complex to simple meconium peritonitis. The bowel in these cases may heal without atresia or stenosis. This is the presumed sequence of events in which the only evidence of meconium peritonitis is meconium periorchitis (Várkonyi et al., 2000).

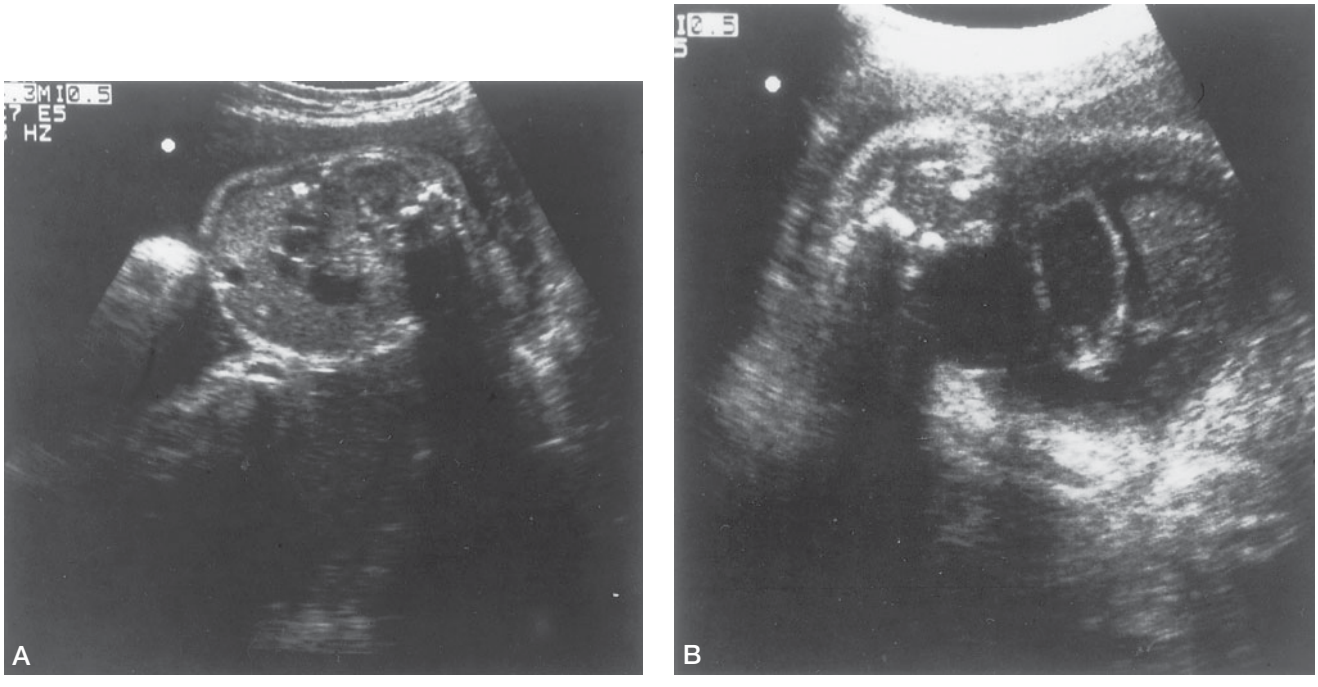

Figure 70-1 **A.** Prenatal sonographic image demonstrating isolated intraperitoneal calcifications with acoustic shadowing. This represents a case of simple meconium peritonitis. **B.** In contrast, this fetus has intraperitoneal calcifications with an associated meconium pseudocyst and ascites. This is an example of complex meconium peritonitis.

Some have proposed classification schemes dividing meconium peritonitis into type I (large meconium ascites), type II (large pseudocyst), or type III (intra-abdominal calcifications and/or resolving ascites or shrinking pseudocyst) (Tseng et al., 2003).

Zangheri et al. (2007) suggest grade 0 for isolated intra-abdominal calcifications; grade 1 for intra-abdominal calcifications and ascites, pseudocyst, or bowel dilation; grade 2 for two associated findings; and grade 3 for all sonographic features present.

In contrast to meconium peritonitis, enterolithiases are calcifications within the bowel lumen. These are often multiple, small, stippled calcifications in contrast to linear, plaquelike calcifications seen in meconium peritonitis. Enterolithiasis often is seen in association with dilated bowel loops and evidence of urinary tract dilation. Calcifications with the bladder may also be observed in the setting of communication between bowel and bladder as in rectourinary fistula or cloaca.

Fetal gallstones are seen as echogenic foci within the lumen of the gallbladder, with associated distal shadowing (Figure 70-2). Brown et al. (1992) have also included echogenic foci within the gallbladder's lumen with either no associated distal shadowing or "comet-tail" or V-shaped artifact. However, echogenic foci without associated distal shadowing more likely represent biliary sludge due to calcium bilirubinate. It is important to distinguish intraluminal calcifications because of fetal gallstones from intrahepatic calcifications, calcified hemangiomas or hamartomas in the liver, or intra-abdominal calcifications due to meconium peritonitis. The best sonographic confirmation is seeing the echogenic foci with associated distal shadowing clearly within the echolucent gallbladder lumen (see Figure 70-2). Sepulveda et al. (1995) reported 8 cases of cholecystomegaly, in which three were found to have aneuploidy (two trisomy 18 and one trisomy 13). While they suggested that cholecystomegaly may be a sonographic marker of aneuploidy, Petrikovsky and Klein (1995) challenged this view. They suggested that the cholecystomegaly may have been due to gallstones or sludge and did not represent a new marker for aneuploidy.

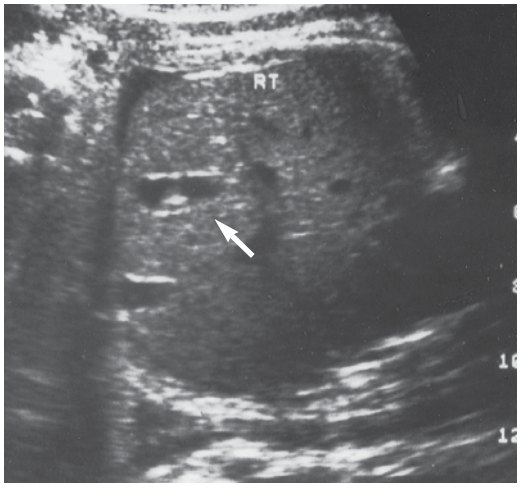

Figure 70-2 Ultrasound of a fetus at 24 weeks of gestation demonstrating dilated gallbladder and an echogenic gallstone with acoustic shadowing (*arrow*).

Fetus in fetu may be mistaken for meconium pseudocyst or teratoma. However, when well-formed vertebral bodies or long bones are seen, this allows a definitive diagnosis to be made.

MRI may be useful in distinguishing not only the cause of intra-abdominal calcifications but also associated findings such as bowel dilation due to atresia, stenosis, volvulus, or intussusception. The presence and definition of complex anorectal malformations with rectourethral fistula or cloaca may be diagnosed. Similarly, characteristic features of fetus in fetu may be more apparent when MRI is obtained as an adjunct to ultrasound.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of intra-abdominal calcification includes meconium peritonitis, fetal gallstones, hepatic calcifications, calcifications within hemangiomas, hematomas, and tumors such as dermoid, hepatoblastoma, neuroblastoma, or teratoma, and in fetus in fetu. Calcifications may also be observed in congenital infections such as cytomegalovirus and toxoplasmosis. Intra-abdominal calcifications also may be due to intraluminal calcification from reflux of urine into the colon in imperforate anus with retrourethral fistula or from stasis due to intestinal atresia or total colonic Hirschsprung's disease.

Several lesions associated with calcifications may be mistaken for gallstones. Calcifications may be seen in the fetal liver within hematomas, hemangiomas, or hamartomas. Calcifications may also be seen in the right upper quadrant as the result of meconium peritonitis, calcified adrenal cyst, hematoma, or neuroblastoma (see Chapters 69 and 113). Calcifications may occur within the lumen of the colon in cases of imperforate anus with rectourethral fistula as a result of urine reflux into rectal lumen (Selke and Cowley, 1978; Miller et al., 1988). These calcifications may be seen proximal to the transverse colon. Hematomas and polyps within the wall of the gallbladder are echogenic but do not cause acoustic shadowing (Durrell et al., 1984).

ANTENATAL NATURAL HISTORY

The natural history of intra-abdominal calcifications depends on the underlying etiology. In meconium peritonitis diagnosed in utero, the natural history is markedly different from meconium peritonitis diagnosed in the newborn nursery. The overall mortality rate in antenatal reports is 11% to 15% (Foster et al., 1987; Chabulinski et al., 1992; Dirkes et al., 1995;

Zangheri et al., 2007). This differs markedly from the mortality rates of 40% to 50% in postnatal series (Park and Grand, 1981; Payne and Nielsen, 1983; Tibboel et al., 1986). A major factor in the survival of patients with meconium peritonitis is the underlying cause. Tibboel et al. (1986) found that primary intestinal obstruction was present in 53% of 1084 neonatal cases of meconium peritonitis reviewed and reported a 54% mortality rate among their own 22 cases (Tibboel et al., 1986). Brugman et al. (1979) reported a 62% mortality rate in cases of meconium peritonitis that were associated with obstruction caused by atresia.

Prenatally diagnosed meconium peritonitis differs from postnatally diagnosed meconium peritonitis in reduced morbidity, lower incidence of cystic fibrosis, and an overall better prognosis (Dunne et al., 1983; Chabulinski et al., 1992; Dirkes et al., 1995; Tseng et al., 2003; Zangheri et al., 2007). It is clear that a prenatal ultrasound examination is more sensitive in detecting intra-abdominal calcifications than postnatal plain radiographs, and this may account for more cases with less severe meconium peritonitis being detected in utero (Dunne et al., 1983; Williams et al., 1984; Foster et al., 1987; Zangheri et al., 2007). Asymptomatic calcifications in hernia sacs, scrotal masses, and the abdomen are common incidental findings detected postnatally (Berdon et al., 1967; Thompson et al., 1973; Gunn et al., 1978; Marchildon, 1978; Várkonyi et al., 2000). These asymptomatic patients may have had bowel perforations in utero that sealed spontaneously and represent the postnatal equivalent of simple meconium peritonitis. Estroff et al. (1992) reported a case of fetal ascites that resolved, leaving abdominal calcifications that were asymptomatic at birth. Because many cases are clinically silent, neonatal series of meconium peritonitis are skewed by sicker infants with more severe meconium peritonitis and a higher attendant morbidity and mortality rate (Dirkes et al., 1995). The natural history of meconium peritonitis diagnosed in utero more clearly reflects the entire spectrum of the disease (Dirkes et al., 1995).

The natural history of enterolithiasis will vary depending on the underlying cause ranging from isolated atresia to complex anorectal malformations with rectourinary fistula. Cases of small-bowel atresia without associated cystic fibrosis have an excellent prognosis. These cases may develop polyhydramnios in the third trimester if the level of obstruction is sufficiently proximal. A small-bowel atresia or obstruction due to intussusception may go on to perforation resulting in meconium peritonitis (see above). Enterolithiasis that occurs as a result of urine refluxing into the colon in cases of complex anorectal malformations has a variable prognosis. Polyhydramnios is unusual in these cases because of the low level of obstruction. At the most severe end of the spectrum would be anorectal septum malformation sequence consisting of the absence of the perineal and anal opening in association with ambiguous genitalia and urogenital, colonic, and lumbosacral anomalies. This is usually lethal in the newborn period because of pulmonary hypoplasia from oligohydramnios (Lubusky et al., 2006). But less severe forms such as cloaca or imperforate anus with rectourinary fistula can have a much more favorable outcome albeit with the need for complex reconstructive surgery.

Although fewer than 35 cases of fetal gallstones have been reported, some aspects of the antenatal natural history have been established. The diagnosis of fetal gallstones has no adverse consequences for the pregnancy. It requires no alteration in the delivery plan and is not associated with fetal loss. Despite recognized associations with gallstones postnatally, few prenatally diagnosed cases have had risk factors for gallstones, with the exception of a single case of hereditary spherocytosis (Beretsky and Lonkin, 1983; Brown et al., 1992). Similarly, predisposing factors, other than pregnancy, were identified rarely in mothers, the most common maternal risk factor being a history of gallstones (Brown et al., 1992). In one case there had been placental abruption with placental hematoma and it was suggested that a possible pigment load might predispose to fetal gallstones (Brown et al., 1992).

Stasis of bile within the gallbladder has been shown to be a critical factor in the pathogenesis of gallstones of any type. Bile stasis is thought to be an important causative factor in gallstone formation during pregnancy (Braverman et al., 1980). It is possible that the hormonal influences predisposing to maternal bile stasis and gallstone formation may affect their fetuses similarly.

Estrogen is a recognized risk factor for gallstones and its levels are known to increase in pregnancy from 14 to 40 weeks (Beischer and Brown, 1972). Estrogen is known to increase cholesterol secretion in bile and depress bile acid synthesis (Cotran et al., 1989). This progressive rise in estrogen levels during the later trimesters may account for fetal cholelithiasis being observed only in the third trimester.

Infants diagnosed prenatally with gallstones appear to have no clinical sequelae. If echogenic foci are associated with distal shadowing, 20% resolve postnatally, but 62% resolve if associated with comet-tail shadowing, and 75% resolve if associated with no distal shadowing (Brown et al., 1992). The remainder of infants with cholelithiasis appear to be asymptomatic. However, awareness of fetal cholelithiasis is important because symptoms referable to the biliary tract may be difficult to diagnose in infants and children. Only awareness of gallstones as a potential cause of symptoms will allow prompt recognition and treatment and minimal morbidity (Jacir et al., 1986).

The natural history of fetus in fetu is remarkably good, usually having no impact on the prenatal course of the pregnancy. It is important to distinguish fetus in fetu from teratoma as the latter has the risk of malignancy developing in up to 10% of patients (Coolen et al., 2007). There has been only a single case of malignant recurrence in fetus in fetu (Hopkins et al., 1997).

MANAGEMENT OF PREGNANCY

Fetal intra-abdominal calcifications detected by prenatal ultrasound examination should prompt an effort to determine

whether these represent biliary, vascular, intraluminal, solid organ, or tumor calcifications; enterolithiasis; intraperitoneal calcification of meconium peritonitis; or fetus in fetu. Intrahepatic calcifications are discussed in Chapter 69. The presence of associated findings, such as dilated loops of bowel, meconium pseudocysts, ascites, and polyhydramnios should be excluded. Because these findings may develop later in gestation, serial sonography is advisable. In the absence of the findings that characterize complex meconium peritonitis, bowel obstruction, or severe complex anorectal anomalies such as urorectal septum malformation sequence, an excellent prognosis can be anticipated and delivery in a community setting can be safely recommended (Dirkes et al., 1995). In cases of enterolithiasis, atresia, or anorectal malformation, delivery in a setting in which these anomalies can be fully evaluated and treated postnatally should be considered. Even in simple meconium peritonitis, however, a postnatal abdominal radiographic examination should be obtained, and if normal, feedings can be initiated. The presence of other associated findings such as pseudocyst, ascites, bowel obstruction, enterolithiasis, anorectal malformation, or fetus in fetu will require additional diagnosis-specific evaluation using a combination of ultrasound, MRI, and voiding cystourethrogram (VCUG).

In cases of meconium peritonitis in which associated abnormalities such as bowel dilatation, meconium cysts, ascites, or polyhydramnios are prenatally diagnosed, there is up to a 52% chance that surgical intervention will be required during the newborn period (Dirkes et al., 1995; Tseng et al., 2003; Zangheri et al., 2007). Consideration should be given to delivery of the infant with complex meconium peritonitis in a tertiary care center.

Although the reported incidence of cystic fibrosis in neonatal meconium peritonitis ranges from 15% to 40%, three of the patients reported by Dirkes et al. (1995) had normal sweat tests and the remaining patients had no clinical manifestations of cystic fibrosis. Other prenatal series of meconium peritonitis have reported only an 8% incidence of cystic fibrosis (Boureau and Pat, 1974; Park and Grand, 1981; Finkel and Slovis, 1982; Foster et al., 1987; Chabulinski et al., 1992). Why the incidence of cystic fibrosis is lower in prenatally diagnosed meconium peritonitis is unknown. Finkel and Slovis (1982) postulated that pancreatic enzymes, which are deficient in 80% of patients with cystic fibrosis, may be necessary for calcification to occur (Boureau and Pat, 1974). Conversely, Foster et al. (1987) speculated that the thick tenacious nature of meconium in cystic fibrosis precludes free spillage into the peritoneum.

Sonographic detection of meconium peritonitis can alert the obstetrician to a fetus potentially at risk for complications from obstruction, perforation, pseudocyst formation, ascites, and polyhydramnios that may precipitate preterm labor and premature delivery. Pediatric surgical consultation may be helpful in providing counseling about the overall favorable prognosis in cases of prenatally diagnosed meconium peritonitis. In cases of complex meconium peritonitis, the parents can be advised of a more guarded prognosis, with a 50% chance of surgical intervention during the neonatal period. Parental DNA testing to define the fetal risk for cystic fibrosis may be appropriate in cases of meconium peritonitis (Robertson et al., 1994). This can be performed by a referral laboratory on blood samples or mouth swabs from the parents. If both parents are carriers and the pregnancy is at less than 24 weeks of gestation, fetal testing for cystic fibrosis mutations may be indicated if termination of the pregnancy is an option for the parents. If an amniocentesis is being performed for other reasons, consideration should be given to testing amniocytes for mutations seen in cystic fibrosis.

A fetus with enterolithiasis should be followed closely for complications related to bowel obstruction, including polyhydramnios and preterm labor. Fetal MRI is indicated to help delineate the underlying etiology, the presence of rectourinary fistula, cloaca, imperforate anus, or intestinal atresia. Delivery should be planned in a setting with appropriate pediatric surgical expertise to manage any of the causes of enterolithiasis.

The diagnosis of fetal gallstones has no implications for the management of the pregnancy. A detailed history should be obtained for risk factors for maternal cholelithiasis. In addition, the mother should have an ultrasound examination to screen for the presence of gallstones.

The fetus diagnosed with fetus in fetu is not likely to develop complications but bowel compression and polyhydramnios can occur. Delivery should take place in a facility with pediatric surgical and radiologic expertise to manage this problem in the newborn.

FETAL INTERVENTION

There are no fetal interventions for any of the causes of intra-abdominal calcifications.

TREATMENT OF THE NEWBORN

The infant should undergo abdominal examination immediately after delivery and an abdominal radiograph and ultrasound study of the abdomen should be obtained to confirm the prenatal findings (Figure 70-3). In the case of meconium peritonitis, an upper gastrointestinal study with small-bowel follow-through using water-soluble contrast may be necessary to confirm or exclude perforation, stenosis, atresia, or meconium pseudocysts (Figure 70-4). Postnatal treatment is directed by the underlying cause of meconium peritonitis. Abdominal radiography will confirm intra-abdominal calcification and demonstrate the presence or absence of cystic lesions or intestinal obstruction. Asymptomatic neonates with calcifications and otherwise normal plain abdominal radiographs and abdominal sonographic examinations may be cautiously observed and fed. If dilated bowel, meconium cysts, or ascites

Figure 70-3 Plain abdominal radiograph in a newborn demonstrating intra-abdominal calcifications, particularly over the dome of the liver and in the scrotum.

Figure 70-4 Upper gastrointestinal contrast study with small-bowel follow-through demonstrating extra-abdominal contrast in a meconium pseudocyst in the right lower quadrant.

are present, nasogastric decompression and intravenous fluids should be administered. Associated anomalies should be evaluated and surgical correction performed when the infant is stable. A sweat chloride test or testing for DNA mutations should be performed during the postoperative period to exclude or definitively diagnose cystic fibrosis in all cases of meconium peritonitis. DNA analysis is preferable in newborns presenting with gastrointestinal symptoms. If DNA analysis reveals the presence of a mutation in the cystic fibrosis transmembrane regulator gene, sweat testing is unnecessary, as some mutations have been found in patients with normal sweat tests (Highsmith et al., 1994).

Physical examination in cases of prenatally diagnosed enterolithiasis is important to exclude imperforate anus or cloaca as an underlying cause. Plain radiographs and ultrasound may be helpful in making a diagnosis, but contrast studies and MRI scans may be necessary to define the anatomy.

The newborn with a prenatal diagnosis of fetal cholelithiasis should have a postnatal ultrasound examination performed during the newborn period. In healthy term infants, sonographic observation alone is indicated unless symptoms develop. The diagnosis of acute or chronic cholelithiasis may be difficult in an infant, but should be suspected with vomiting, irritability, or ileus. Gallstones associated with predisposing risk factors that are detected during the newborn period resolve spontaneously in 75% of cases with elimination of these risk factors—for example, by treatment with diuretics or total parenteral nutrition. It is unclear if gallstones with distal shadowing on an ultrasound examination performed in utero will spontaneously resolve during infancy. The only data on this came from Brown et al. (1992), who observed spontaneous resolution in 40% of cases of fetal gallstones when associated with acoustic shadowing. The higher rate of spontaneous resolution they observed, when echogenic foci were present without acoustic shadowing, may have been because they were "sludge" rather than true gallstones.

In cases of suspected fetus in fetu, ultrasound and plain radiographs may be adequate to confirm the diagnosis if a well-formed long bone or vertebral column is observed. CT or MRI may provide anatomic relations helpful in planning surgical resection.

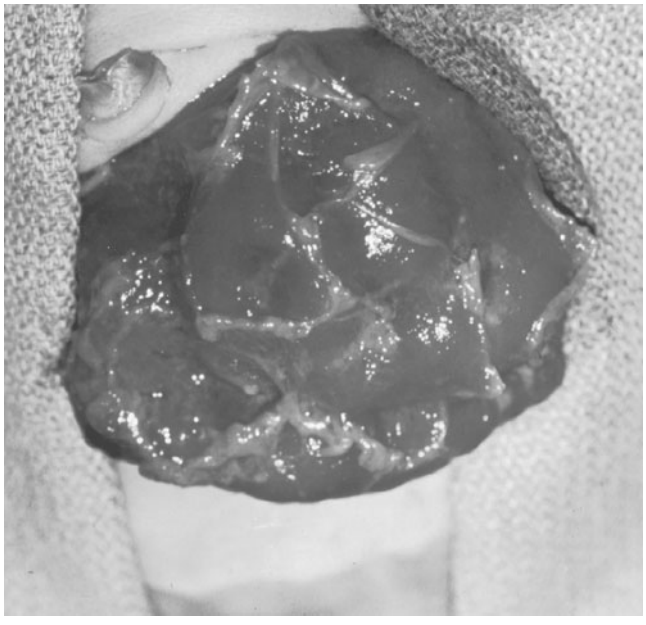

Figure 70-5 Intraoperative appearance of meconium peritonitis in a newborn with a perforated colon. Note the adhesions, which are the results of an inflammatory reaction that occurred in utero.

SURGICAL TREATMENT

The infant with complex meconium peritonitis will require surgical intervention in 50% of cases (Dirkes et al., 1995). The indications for surgery include intestinal perforation with ascites, meconium pseudocyst, intestinal atresia or stenosis, or volvulus. Surgical exploration for complications of meconium peritonitis may be extremely difficult because of the intense inflammatory reaction that occurs within the peritoneal cavity (Figure 70-5). Because of this and bacterial contamination of the peritoneal cavity, cases of meconium peritonitis complicated by perforation or meconium pseudocyst are best managed by resection and enterostomy. In cases of volvulus, the nonviable intestine is resected and proximal and distal stomas are created. In cases involving the proximal intestine, long-term venous access can be obtained to provide parenteral nutritional support until gastrointestinal continuity can be established.

Atresias most often will be amenable to resection and primary anastomoses but may require significant parenteral nutritional support if short gut or dysmotility are associated with the atresia. Anorectal malformations, particularly when associated with rectourinary fistula usually require initial diversion (see Chapter 76) as does a persistent cloaca (see Chapter 85).

The surgical management of fetus in fetu is usually straight forward with resection of the retroperitoneal mass causing few difficulties. Adjacent structures are usually displaced and there is a clear plane of dissection.

In asymptomatic infants diagnosed with fetal gallstones, we currently recommend observation only. If gallstones are radiopaque, periodic plain radiographs may be obtained to observe for spontaneous resolution. If stones are radiolucent, sonographic surveillance is recommended. We have a low threshold for performing cholecystectomy, as symptoms of acute or chronic cholecystitis in infants are often vague and nonspecific, and once it is symptomatic, acute cholecystitis is associated with a high rate of complications (Brill et al., 1982).

In infants undergoing abdominal surgery for other indications, such as pyloric stenosis or intestinal atresia, we recommend a cholecystectomy, as it can be performed with little additional morbidity.

LONG-TERM OUTCOME

The long-term outcome of infants with intra-abdominal calcification depends on the underlying cause. In fetuses with simple meconium peritonitis, the prognosis is excellent. In complex meconium peritonitis, the prognosis relates to the underlying cause of the perforation. In isolated meconium peritonitis, without cystic fibrosis, Hirschsprung's disease, or intestinal pseudo-obstruction, the prognosis is excellent. In infants with cystic fibrosis or chronic pseudo-obstruction, however, the prognosis is more guarded. Enterolithiasis associated with urorectal septal malformations has a grim prognosis, but patients with anorectal malformation or cloaca have an excellent prognosis following reconstruction. The awareness of cholelithiasis in an infant leads to early intervention once symptoms referable to the gallbladder develop. Asymptomatic gallstones require no intervention. There are no long-term sequelae associated with a diagnosis of fetal cholelithiasis. Similarly, cases of fetus in fetu have an excellent outcome following resection.

GENETICS AND RECURRENCE RISK

There is no known risk of recurrence for intra-abdominal calcifications. However, the approximately 8% of antenatally diagnosed meconium peritonitis associated with cystic fibrosis are at a 25% risk for recurrence in subsequent pregnancies. Enterolithiasis has not been reported to recur in subsequent pregnancies.

There are no data on risk of recurrence of cholelithiasis in subsequent pregnancies. If maternal risk factors for cholelithiasis are present, such as a history of hemolytic anemia or of gallstones, a prenatal ultrasound examination during the third trimester is indicated to screen for an affected fetus. Hereditary spherocytosis is inherited as an autosomal dominant disorder. If the family history reveals that either parent is affected, the fetus has a 50% risk of inheriting this gene. Sickle cell anemia is inherited as an autosomal recessive

disorder, with a 25% risk of recurrence. Other inherited enzyme abnormalities of the erythrocyte, such as pyruvate kinase deficiency, are associated with development of gallstones.

Pyloric Atresia and Stenosis

71 CHAPTER

Key Points

- Condition presents only rarely antenatally.
- Incidence of pyloric atresia is 1 in 1 million livebirths. Hypertrophic pyloric stenosis occurs in 1.5–4 per 1000 livebirths.
- Usually associated with polyhydramnios and a "single bubble."
- Differential diagnosis of a dilated fetal stomach includes duodenal atresia or stenosis, malrotation with midgut volvulus, duodenal duplication, and antral duplication.
- Pyloric atresia can be associated with epidermolysis bullosa, a serious and often fatal skin condition that has autosomal recessive inheritance.
- Delivery should occur in a tertiary center with pediatric surgical, dermatologic, and genetic expertise present.

CONDITION

Gastric outlet obstruction due to atresia or membranous antral web is rare, constituting one of the most unusual causes of gastrointestinal obstruction. On the other hand, gastric outlet obstruction due to hypertrophic pyloric stenosis is among the most common causes of gastrointestinal obstruction in the neonate. This condition only rarely presents antenatally (Zimmerman, 1978; Nebekura et al., 1983; Mitchell and Risch, 1993).

A classification system for pyloric stenosis has been proposed: type A, a pyloric membrane or web; type B, the pyloric channel is a solid cord; type C, there is a gap between the stomach and the duodenum. Prenatal diagnosis should preempt consideration of other intestinal atresias (Usta, 2000; Ilce et al., 2003).

INCIDENCE

The incidence of pyloric atresia has been reported at 1 in 1 million livebirths, representing less than 1% of all gastrointestinal atresias (Geber and Aberdeen, 1965; Thompson et al., 1968). Hypertrophic pyloric stenosis occurs in 1.5 in 1000 to 4 in 1000 livebirths among whites, but it is less prevalent in blacks and Asians (Mitchell and Risch, 1993; Grant and McAleer, 1996). The incidence of prenatally diagnosed cases of these conditions is unknown.

SONOGRAPHIC FINDINGS

Prenatal diagnosis of pyloric atresia is associated with polyhydramnios in 61% of reported cases (Colin, 1989). The prenatal sonographic image usually shows polyhydramnios and associated gastric distention (Figure 71-1). If the fetus has recently vomited or if the obstruction is incomplete, the stomach may appear normal in size and polyhydramnios may be absent (Rizzo et al., 1995). This is especially true early in gestation, as polyhydramnios tends to develop during the third trimester. Sonographically, pyloric atresia and stenosis are associated with a "single bubble" as opposed to the "double bubble" observed in duodenal atresia. This appearance is due to either high-grade stenosis or complete atresia of the gastric outlet, resulting in marked dilation of the stomach. However, one should be cautious in the fetus with a "double bubble" sign, as this can be seen due to massive gastric distention and folding of the stomach on itself. The ultrasound beam can pass through the dilated fundus and then through the antrum, giving the impression of a double bubble. The sonographic features of hypertrophic pyloric stenosis are similar to pyloric atresia (Zimmerman, 1978; Nebekura et al., 1983). Isolated gastric distention is seen, but unlike in pyloric atresia, the hypertrophied pylorus is also seen. Because hypertrophic pyloric stenosis creates only a partial obstruction, more distal fluid-filled loops of bowel are seen in contrast to pyloric atresia, in which they are not observed. The hypertrophied pylorus seen in cross section has a characteristic "target" or "bull's-eye" appearance. No prenatal parameters for mural thickness, diameter, or pyloric length exist. However, postnatal values for hypertrophic pyloric stenosis can be used. In the neonate, a pylorus that demonstrates a mural thickness >4 mm, a diameter >11 mm, or a pyloric length of >16 mm is consistent with a diagnosis of hypertrophic pyloric stenosis. It should be pointed out, however, that measurements that do not meet these criteria do not rule out this diagnosis. Hypertrophic pyloric stenosis tends to be progressive, and increases in these parameters are to be expected. Because of the partial gastric outlet obstruction, polyhydramnios may be seen in pyloric stenosis, but not to the same extent as in pyloric atresia.

Figure 71-1 Sonographic image demonstrating an enlarged fetal stomach. This can be due to gastric outlet obstruction as a result of pyloric atresia.

DIFFERENTIAL DIAGNOSIS

In addition to pyloric atresia, the differential diagnosis of a dilated fetal stomach includes duodenal atresia or stenosis (see Chapter 72), malrotation with midgut volvulus, duodenal duplication, and antral duplication. The presence of the double bubble sonographic sign is more consistent with the diagnosis of duodenal atresia, but in pyloric atresia, the stomach may become so grossly distended that in a single ultrasonographic image both the fundus and the antrum may give the appearance of a double bubble (Malone et al., 1997). Polyhydramnios is present in each of these conditions and is less useful in making a distinction between them. In pyloric or duodenal atresia, no distal bowel will be visualized sonographically, but in pyloric stenosis or duodenal stenosis more distal intestine will be seen.

Pyloric atresia associated with epidermolysis bullosa was first reported by Swinburne and Kohler (Swinburne

and Kohler, 1968). Pyloric atresia, in addition to its association with epidermolysis bullosa, has also rarely been reported with esophageal atresia and tracheoesophageal fistula (Korber and Glasson, 1977; Peterson and Hertel, 1977; El Shafie et al., 1979) as well as with cardiovascular and genitourinary anomalies (Lepinard et al., 2000).

It is now recognized that there is a distinct autosomal recessive condition, epidermolysis bullosa with pyloric atresia, also known as Carmi syndrome. This condition presents with congenital pyloric atresia, blistering of the skin with little or no predisposing trauma, and associated renal anomalies, such as multicystic kidney, hydronephrosis, and ureterocele. When associated with pyloric atresia, epidermolysis bullosa is often a fatal disease in infancy. Some authors have recommended that surgical correction of pyloric atresia be withheld for those with a histologic diagnosis of epidermolysis bullosa (Rosenbloom and Ratner, 1987).

ANTENATAL NATURAL HISTORY

The cause of pyloric atresia is thought to be an in utero vascular compromise. This cause is similar to that of other intestinal atresias. The obstruction is due to a solid membranous structure in 67% of cases. Actual absence of the pylorus with a gap between the distal stomach and the duodenum is found in only a fifth of the cases. A fenestrated or nonfenestrated antral membrane is present in 5% of cases (Kume et al., 1980). Gastric outlet obstruction from pyloric atresia results in significant polyhydramnios. The polyhydramnios predisposes these infants to preterm labor and premature delivery. A search for other possible associated anomalies should be undertaken, including malformed ears and genitourinary anomalies (Lepinard et al., 2000). It is worth noting that in cases of pyloric atresia associated with epidermolysis bullosa (EB), both alphafetoprotein and acetylcholinesterase can be elevated (Lepinard et al., 2000).

MANAGEMENT OF PREGNANCY

The fetus diagnosed with gastric outlet obstruction consistent with a diagnosis of pyloric atresia or stenosis should be evaluated to determine the underlying diagnosis and evaluate the possibility of associated epidermolysis bullosa. The pregnant woman should be evaluated by a maternal and fetal medicine specialist, a medical geneticist, and a pediatric surgeon. Level II sonography should specifically look for the presence of renal or ureteral anomalies, which may be a sign of epidermolysis bullosa. A careful family history should be obtained to rule out epidermolysis bullosa and/or consanguinity. If the diagnosis of pyloric atresia is made prior to 24 weeks of gestation, consideration may be given to fetal skin biopsy for electron microscopy to diagnose epidermolysis bullosa (Rodeck et al., 1980). Shimizu et al. (1996) have described the use of immunohistochemistry to demonstrate absence of detectable α_6 integrin in a fetal skin biopsy in pyloric atresia–junctional epidermolysis bullosa syndrome in a family at risk for recurrence. This diagnostic test is appropriate only if the parents would not continue the pregnancy if the fetus was affected. If the familial mutation has been identified because of a prior affected fetus, DNA analysis can be performed on amniocytes or chorionic villi for a genetic diagnosis of EB as early as 10 weeks' gestation (Pfendner et al., 2003).

The pregnancy should be followed closely because of the common occurrence of polyhydramnios and the predisposition to preterm delivery. Cesarean section delivery should be considered to reduce skin trauma if the infant has epidermolysis bullosa with pyloric atresia. The infant should be delivered in a tertiary care center, with pediatric surgical and medical genetic expertise available.

FETAL INTERVENTION

There are no fetal interventions for pyloric atresia and stenosis.

TREATMENT OF THE NEWBORN

The infant born with pyloric atresia should have immediate nasogastric decompression to prevent aspiration and perforation from gastric distention. Intravascular volume and electrolyte deficit should be corrected with intravenous fluid administration. Radiographs demonstrating a distended stomach with no gas in distal viscera confirm the diagnosis of gastric outlet obstruction. An immediate upper gastrointestinal contrast study should be obtained to exclude the possibility of malrotation with midgut volvulus. The surgical repair used depends on the nature of the atresia but usually includes pyloroplasty with or without excision of a pyloric web. The presence of epidermolysis bullosa requires meticulous skin care, using atraumatic technique, minimal handling, and avoidance of adhesive tape. A diagnostic skin biopsy should be performed in consultation with a pediatric dermatologist. If the infant has epidermolysis bullosa, DNA analysis should be performed in consultation with a medical geneticist. Blistering of the skin can lead to fluid and electrolyte loss and severe infection.

SURGICAL TREATMENT

The newborn with pyloric atresia will require a Heineke–Mikulicz pyloroplasty if the duodenum or stomach are in continuity with each other. If complete atresia with separation of stomach and duodenum is present, then a primary gastroduodenostomy should be performed. A period of nasogastric decompression lasting several days may be required until return of gastric function. A transanastomic nasojejunal feeding tube may be placed for enteral nutrition until gastric ileus resolves.

In the case of pyloric stenosis, a pyloromyotomy alone is indicated. This is usually well tolerated, with resumption of feeding within 6 hours of the procedure.

LONG-TERM OUTCOME

Infants who have isolated pyloric atresia treated by pyloroplasty, need to be evaluated for the possibility of dumping syndrome due to excessively rapid gastric emptying. This may be manifested either in irritability, sweating, pallor, or tachycardia immediately following feedings, or by diarrhea and failure to thrive.

Infants diagnosed with pyloric atresia in association with epidermolysis bullosa will require continued meticulous skin care to avoid breaks in the skin. The potential for long-term survival has been demonstrated in patients with pyloric atresia and epidermolysis bullosa even with gradual improvement in symptoms of epidermolysis bullosa over time. However, significant mortality is associated with this combination by 1 year of age (Azarian et al., 2006).

GENETICS AND RECURRENCE RISK

Pyloric atresia occurs as both an isolated anomaly and in association with epidermolysis bullosa. An inherited form of isolated pyloric atresia has been described in several families (Tan and Murugasu, 1973; Olson and Gratte, 1976; Konvolinka and Stewart, 1978; Usta, 2000).

The recessive form of pyloric atresia with epidermolysis bullosa (Carmi syndrome) is associated with mutations in three genes: integrin beta 4 (*ITGB4*) (80% of cases), integrin alpha 6 (*ITGA6*) (5% of cases), and plectin 1 (*PLEC1*) (15% of cases) (Pfendner et al., 2003; Pfendner and Uitto, 2005; Pfendner and Lucky, 2008). Diagnostic DNA testing is clinically available; it has a very high likelihood of finding the causative mutation. Parental DNA should be studied, as the recurrence risk in a future pregnancy is 25%. If the parental mutations are diagnosed, preimplantation diagnosis is available. Alternatively, CVS or amniocentesis can be performed; this is recommended over sonography to diagnose recurrence.

Duodenal Atresia and Stenosis

72 CHAPTER

Key Points

- Often presents due to uterine size greater than the size of dates as a result of polyhydramnios.
- Characteristically diagnosed by ultrasound examination, which shows a "double bubble" sign.
- Differential diagnosis includes annular pancreas, malrotation, gastric or duodenal duplication, and preduodenal portal vein.
- Associated with trisomy 21 in 30% of cases. Amniocentesis should be performed.
- Associated with congenital heart disease in 17% to 33% of cases. Echocardiography should be performed.
- Polyhydramnios rarely develops before 24 weeks' gestation but can contribute to preterm labor.
- Delivery should occur in a tertiary center with pediatric surgical and neonatal expertise available.

CONDITION

Duodenal atresia, or stenosis, is a leading cause of intestinal obstruction in newborns and one of the most common gastrointestinal anomalies that can be diagnosed prenatally. A commonly held developmental theory is that at 1 month of gestation, the lumen of the duodenum is thought to be obliterated by proliferating epithelium. This solid core of epithelium undergoes vacuolization and recanalization, restoring the lumen. Failure of recanalization of the solid stage is thought to result in duodenal atresia or stenosis. Atresia is more common than stenosis and occurs in approximately 70% of cases (Boyden et al., 1967; Skandalakis et al., 1994). Skandalakis et al. (1994) have described 3 types of duodenal atresia. The most common duodenal anomaly (69% of cases) is membranous mucosal atresia (type I) with an intact muscular wall. The proximal duodenum is ballooned out while the duodenum distal to the atresia is narrowed. This mucosal membrane may take on the shape of a "wind sock" because of peristalsis and increased proximal intraluminal pressure (Rowe et al., 1968). The origin of the wind-sock membrane is usually intimately associated with the ampulla of Vater. A type II duodenal atresia is rare (2% of cases) and has a short fibrous cord connecting the two ends of the atretic duodenum. Type III duodenal atresia has a complete separation between the two ends of the duodenum and can be associated with biliary tract anomalies in 6% of cases (Reid, 1973a and b; Jona and Berlin et al., 1976; Paine and Noblett, 1977; Knechtle and Filston, 1990). Duodenal stenosis accounts for the remaining 23% of cases. These anatomic relations are rarely evident sonographically. An annular pancreas occurs in 20% to 30% of patients with duodenal atresia or stenosis (Fonkalsrud et al., 1969; Reid, 1973a and b; Wesley and Mahour, 1977). The developmental relationship between annular pancreas and duodenal atresia and stenosis is unclear.

An annular pancreas can produce extrinsic compression and result in stenosis, but it is more commonly associated with an intrinsic obstruction due to complete atresia (Merrill and Raffensperger, 1976).

INCIDENCE

Duodenal stenosis or atresia occurs in approximately 1 in 10,000 livebirths (Fonkalsrud et al., 1969; Forrester and Merz, 2004).

SONOGRAPHIC FINDINGS

Prenatal sonographic diagnosis of duodenal obstruction has been made as early as 20 weeks of gestation (Hancock and Wiseman, 1989). The majority of cases, however, are not diagnosed until the third trimester. The most common indication for sonography is uterine size greater than dates because

Figure 72-1 Fetus with trisomy 21 at 24 weeks of gestation demonstrating the ''double bubble" sign consistent with duodenal atresia. The distal portion of the stomach is seen communicating with the dilated proximal portion of the duodenum.

of polyhydramnios, which is present in up to 53% of cases (Girvan and Stephens, 1974; Farrant et al., 1981). Prenatal sonography may show the characteristic "double bubble" sign (Figure 72-1) that represents the dilated fluid-filled stomach and proximal duodenum (Balcar et al., 1984; Langer et al., 1989). Although occasionally seen earlier, duodenal atresia is not usually diagnosed prior to 24 weeks of gestation. If the fetus has recently vomited (Figure 72-2), or in cases of stenosis in which sufficient amounts of amniotic fluid pass the obstruction, these features may be subtle or absent (Bowie and Clair, 1982). If the diagnosis of duodenal atresia or stenosis is suspected, serial ultrasound examination may be required to prove the diagnosis. Because 30% of patients with duodenal atresia will have trisomy 21, other sonographic features

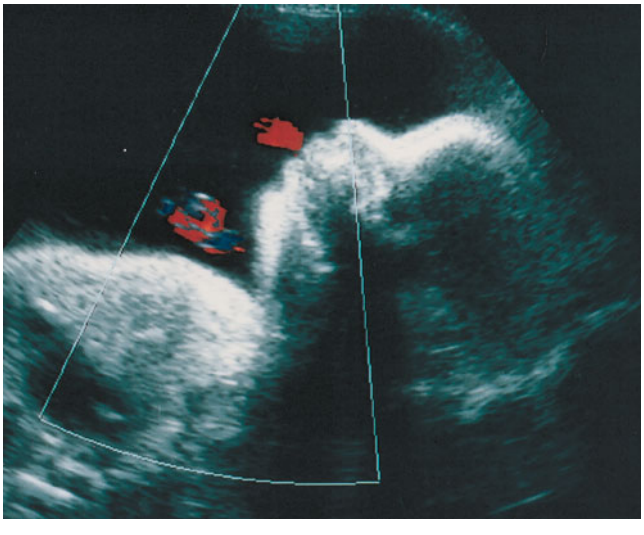

Figure 72-2 Color flow Doppler study demonstrating fetal vomiting in a case of duodenal atresia.

of Down syndrome should be sought, including nuchal fold thickening, hypomineralization of fifth finger middle phalanx (clinodactyly), and elevated biparietal diameter and fetal length ratio (Lockwood, 1993), (see Chapters 2 and 3).

MRI has been used as an adjunct to ultrasound examination in the diagnosis of duodenal atresia. On T2-weighted sequences, the fluid within the stomach and duodenum will appear hyperintense and the post atretic bowel will have normal size bowel loops. The bowel produces sufficient secretions to yield a normal appearance by MRI (Veyrac et al., 2004).

DIFFERENTIAL DIAGNOSIS

A persistently dilated fluid-filled fetal duodenum is always abnormal and should raise the suspicion of possible duodenal atresia or stenosis. This can be a difficult diagnosis to make prior to 24 weeks of gestation (Nelson et al., 1982; Bovicelli et al., 1983). The differential diagnosis, in addition to duodenal atresia or stenosis, should include annular pancreas, malrotation with either obstructing Ladd's bands or midgut volvulus, gastric or duodenal duplications, and preduodenal portal vein. Isolated duodenal stenosis may be indistinguishable from annular pancreas with associated duodenal stenosis until surgical exploration. Malrotation may give a similar "double bubble" appearance but, unlike atresia, there will be some amniotic fluid in loops beyond the duodenum. Ladd's bands may partially obstruct the duodenum, mimicking duodenal stenosis. One sonographic clue to midgut volvulus is the reversed relation of the superior mesenteric vein and artery by Doppler ultrasound study, in which the superior mesenteric vein appears anterior to the superior mesenteric artery. Large gastric or duodenal duplications can be indistinguishable from duodenal atresia (Figure 72-3) (Malone et al., 1997). Anomalous development of the paired embryonic vitelline veins contributes to the myriad complex anatomic defects of this region. Persistence of a primitive vitelline vein results in an anterior or preduodenal portal vein that passes over the pancreas and third portion of the duodenum, which can partially obstruct the duodenum.

ANTENATAL NATURAL HISTORY

More than half of the fetuses with duodenal atresia have associated anomalies. Trisomy 21 is the most frequently associated condition, occurring in 27% to 34% of cases (Fonkalsrud et al., 1969; Nixon and Tawes, 1971; Reid, 1973a and b; Girvan and Stephens, 1974; Davey, 1980; Hancock and Wiseman, 1989) (Table 72-1). In several large series, congenital heart disease was also commonly associated, occurring in 17% to 33% of cases (Fonkalsrud et al., 1969; Nixon and Tawes, 1971; Reid, 1973a and b; Girvan and Stephens, 1974; Davey, 1980; Hancock and Wiseman, 1989). The most common cardiac lesions encountered are atrial or ventricular septal defect. Other

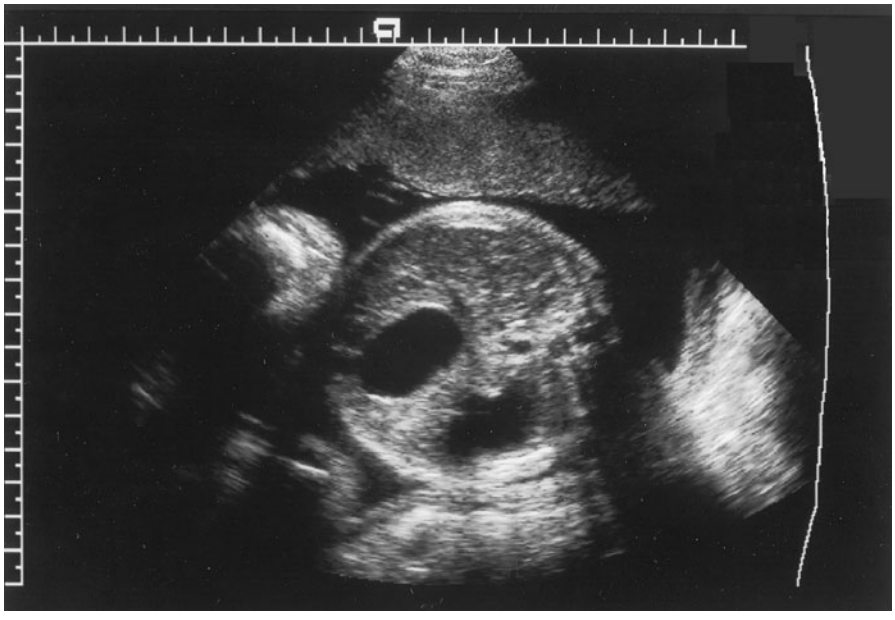

Figure 72-3 Cross-section of fetal abdomen demonstrating the double bubble characteristic of duodenal atresia. This infant proved to have a large duodenal duplication (see Fig. 72-5).

anomalies associated with duodenal atresia include malrotation, annular pancreas, esophageal atresia, tracheoesophageal fistula, and genitourinary and anorectal malformations. Numerous pancreatic and biliary anomalies have been reported in association with duodenal atresia and stenosis. These include biliary atresia, choledochal cyst, pancreatic lipomatosis, pancreas divisum, and persistent dual biliary duct drainage to duodenum proximal and distal to the atresia. Unusual biliary duct anomalies that occur in association with duodenal atresia are seen in infants with type III defects. The association of congenital anomalies with maternal and gestational and preexisting diabetes (Schaefer-Graf et al., 2000) is also thought to increase the frequency of duodenal atresia (Ozturk et al., 2007). Adeyemi (1988) has identified an association between duodenal atresia, partial situs inversus, and right-sided diaphragmatic hernia through the foramen of Bochdalek. This is an extremely rare condition known as multiple organ malrotation syndrome (MOMS) (Adeyemi, 1988).

As to whether or not prenatal diagnosis of duodenal atresia improves postnatal outcome, Bittencourt et al. found that prenatal diagnosis reduced morbidity and shortened hospitalization (Bittencourt et al., 2004). Their series was from São Paulo, Brazil, with a system of regional referral for surgical services. These findings are consistent with those reported by others (Romero et al., 1988; Murshed et al., 1999).

Table 72-1

Fetal Conditions Associated with Duodenal Atresia

Associated Anomaly	% of Cases
Trisomy 21	31
Congenital heart disease	30
Bowel rotation	20
Annular pancreas	20
Esophageal atresia	10
Anorectal atresia	6
Genitourinary	5

MANAGEMENT OF PREGNANCY

If duodenal atresia is suspected, the fetus should undergo genetic amniocentesis because of the high incidence of associated chromosomal anomalies. Fetal echocardiography should also be performed to evaluate possible associated congenital heart anomalies, even in the presence of a normal karyotype. Early detection of associated anomalies may influence decisions regarding continuation of the pregnancy. Although of uncertain clinical value, amniotic fluid bile acid concentration has been found to be markedly elevated in intestinal obstruction (Deleze et al., 1977). Abnormal bile acid concentration has been described in two pregnant women with polyhydramnios, one whose fetus had duodenal atresia and the other ileal atresia. While the amniotic fluid bilirubin and amylase concentrations were normal, the bile acid concentrations were 30.3 and 83.1 μmol/L (normal, 1.2–2.4 μmol/L), respectively (Deleze et al., 1977). Studies of experimentally created intestinal obstruction showed no differences in amniotic fluid values of bilirubin, amylase, or lipase from controls (Touloukian, 1977).

Duodenal atresia is complicated by polyhydramnios in 17% to 53% of cases (Girvan and Stephens, 1974; Farrant et al., 1981; Hancock and Wiseman, 1989; Robertson et al., 1994). Polyhydramnios can contribute to the development of preterm labor. Forty-three percent of affected infants are premature and may be small for gestational age (Jolleys, 1981). We recommend a prenatal pediatric surgical consultation with parents to help alleviate anxiety and to provide answers to questions concerning postnatal intervention. Delivery should be planned in a center with appropriate neonatal and pediatric surgical support.

FETAL INTERVENTION

There are no fetal interventions for duodenal atresia.

TREATMENT OF THE NEWBORN

In the delivery room, the newborn with duodenal atresia should have immediate nasogastric decompression to prevent aspiration of gastric contents and gastric perforation from overdistension. The gastric aspirate will usually be bile stained, since 85% of cases of duodenal obstruction are distal to the entry of the bile ducts. Failure to decompress the stomach will result in bilious vomiting shortly after birth. Intravascular fluid deficit should be corrected with intravenous fluid administration. Nasogastric fluids should be replaced volume for volume, and attention should be paid to electrolyte and acid–base abnormalities induced by large proximal gastrointestinal fluid losses. Abdominal radiography will verify tube placement and confirm the diagnosis in cases of duodenal atresia. The classic "double bubble" sign is seen with absence of gas in the rest of the bowel (Figure 72-4). In cases of duodenal stenosis, the high-grade partial obstruction may allow gas to pass into the small bowel, and the clinical presentation may be indistinguishable from that of bowel rotation with midgut volvulus or high jejunal obstruction. In such cases, or whenever there is doubt about the diagnosis, an emergency radiographic contrast study should be performed to exclude malrotation with midgut volvulus (Figure 72-5).

SURGICAL TREATMENT

The surgical reconstruction is usually performed on the day of delivery after the infant is assessed for the presence or absence of associated anomalies and appropriate volume resuscitation and correction of electrolyte disturbances has occurred. However, as long as the diagnosis of duodenal atresia is certain, nasogastric decompression alone may suffice while other anomalies are addressed, e.g., congenital heart defect, or clinical condition is stabilized, e.g., respiratory distress syndrome. The most common site of obstruction in both duodenal atresia and stenosis is in the second portion of the duodenum adjacent to the ampulla of Vater. In duodenal atresia, there is usually an intrinsic web causing the obstruction. Although some have advocated excision of this web, risk of injury to the ampulla of Vater has prompted most surgeons to bypass this obstruction. This is most commonly done by either a duodenoduodenostomy or a duodenojejunostomy. In cases of suspected stenosis, one must be certain to exclude the presence of a wind-sock deformity. Once the proximal duodenum is opened, a Foley catheter can be passed distally and the inflated balloon can then be withdrawn. In a wind-sock deformity, the membrane can be delivered and safely excised. In 1% to 3% of cases, a second more distal obstruction by an intrinsic web may be detected by this technique. In cases of gross dilatation of the proximal duodenum, it should be tapered or imbricated to prevent stasis, bacterial overgrowth, and complications of blind loop syndrome (Grosfeld and Rescorla, 1993). Because of the risk of late blind loop syndrome, we avoid duodenojejunostomy. In most instances, we employ a transverse proximal duodenum to longitudinal distal duodenal or diamond-shaped anastomosis (Kimura, 1977; Kimura et al., 1990) (Figure 72-6). We perform a proximal imbricating duodenal enteroplasty to prevent late complications of megaduodenum (Table 72-2). Because of chronic in utero obstruction, transient proximal dysmotility may prevent initiation of normal feeding for 10 to 14 days postoperatively.

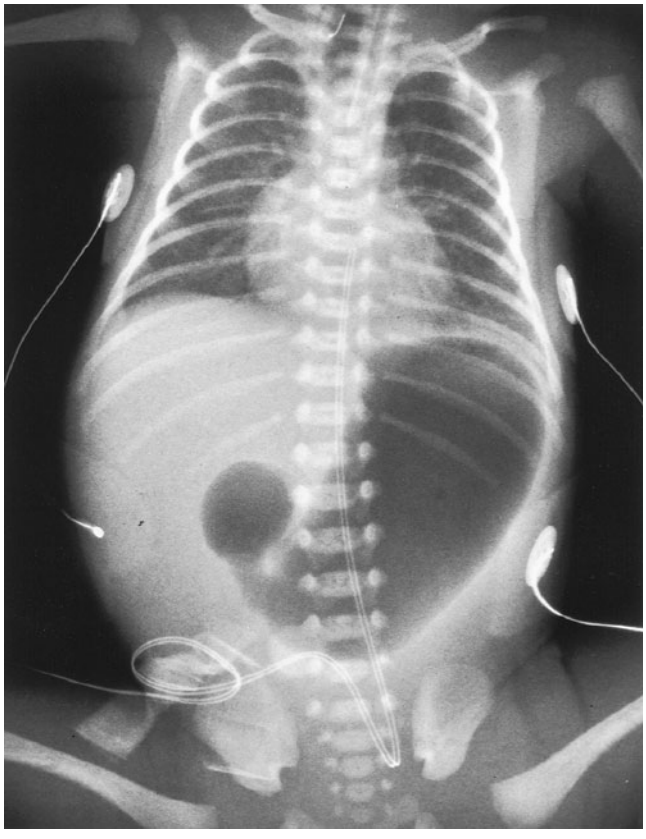

Figure 72-4 Plain radiograph of a newborn, showing dilated stomach and proximal duodenum with lack of air distal to the obstruction.

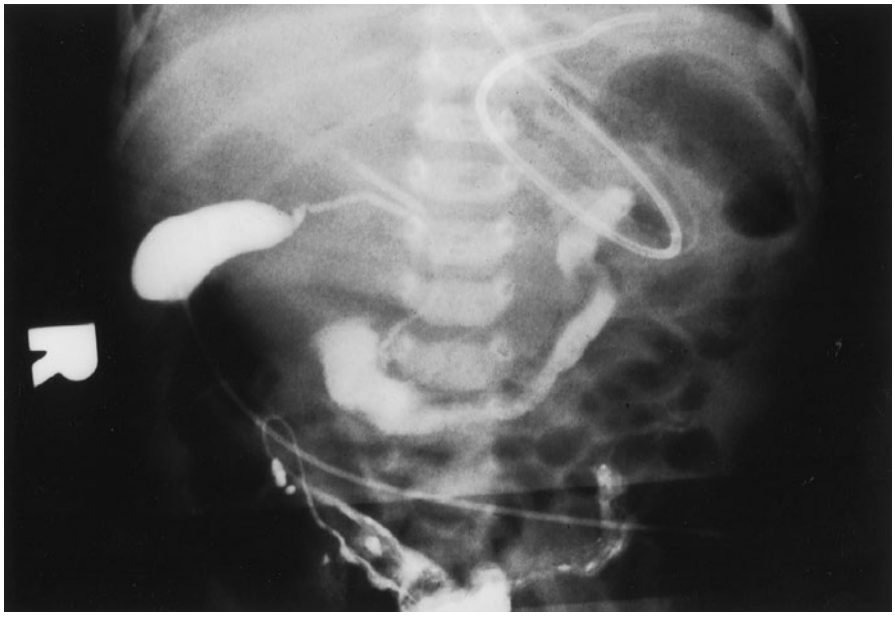

Figure 72-5 Upper gastrointestinal contrast study demonstrating displaced but patent duodenal sweep as a result of a large duodenal duplication.

A transanastomotic nasojejunal feeding tube is passed that allows enteral alimentation until proximal gastroduodenal motility returns. Breast milk can be used often, supplemented by formula as needed. In cases associated with trisomy 21, some surgeons favor the placement of a gastrostomy tube at the time of duodenal atresia repair because of the difficulties these infants have transitioning to oral feedings.

During the past 25 years, there has been steady improvement in the survival of babies with duodenal atresia, from 68% in 1968 to 95% in 1991 (Fonkalsrud et al., 1969; Hancock and Wiseman, 1989; Stauffer and Schwoebel, 1998). The majority of deaths today occur in infants with associated complex congenital heart defects (Hancock and Wiseman, 1989). The improvement in survival, although certainly due in part to advances in neonatal, anesthetic, and surgical care, may also reflect prenatal selection. While often diagnosed after 24 weeks of gestation, duodenal atresia is increasingly being diagnosed earlier. In the setting of a fetal diagnosis of Down syndrome, or severe associated anomalies, the option of pregnancy termination can be discussed with the prospective parents.

LONG-TERM OUTCOME

Late complications of duodenal atresia have been reported to be related to dysmotility of the proximal duodenum, including blind loop syndrome, megaduodenum, duodenal gastric reflux, gastritis, gastroesophageal reflux, pancreatitis, cholelithiasis, and cholecystitis (Grosfeld and Rescorla, 1993; Escobar et al., 2004). Most cases of blind loop syndrome

Figure 72-6 Intraoperative view of duodenal atresia at the time of duodenoduodenostomy.

Table 72-2

Late Complications of Duodenal Atresia and Stenosis

Megaduodenum

Peptic ulcer
Gastroesophageal reflux
Choledochal cyst
Cholelithiasis
Cholecystitis

are seen in patients initially treated by duodenojejunostomy, which can be corrected by conversion to duodenoduodenostomy. Similarly, megaduodenum may be treated by tapering duodenoplasty or duodenal plication. Other complications, such as duodenal gastric reflux or gastritis, may be treated medically to enhance motility by the use of parasympathomimetic agents such as bethanechol, metaclopromide. Similarly, H_2 blocker or proton pump inhibitor therapy may be effective in treating peptic ulcer and gastroesophageal reflux (see Table 72-2). Awareness of these late complications associated with duodenal atresia requires close observation for prompt recognition and institution of appropriate medical or surgical therapy.

GENETICS AND RECURRENCE RISK

More than one-half of the fetuses with duodenal atresia have associated anomalies. Trisomy 21 is the most frequently associated condition, occurring in 27% to 34% of cases (Fonkalsrud et al., 1969; Nixon and Tawes, 1971; Reid, 1973a and b; Girvan and Stephens, 1974; Davey, 1980; Hancock and Wiseman, 1989). In most cases, isolated duodenal atresia or stenosis is a sporadic condition, although Fonkalsrud (1979) has suggested an autosomal dominant pattern of inheritance in some families. Duodenal atresia has also been reported as part of Feingold syndrome, which has an autosomal dominant inheritance as well (Holder-Espinasse et al., 2004). Feingold syndrome consists of duodenal and esophageal atresia, tracheoesophageal fistula, microcephaly, hand and foot anomalies, facial dysmorphism, and developmental delay.

Jejunoileal Atresia and Stenosis

73 CHAPTER

Key Points

- Most common cause of intestinal obstruction.
- Proximal jejunum and distal ileum are the most common locations.
- Vascular disruption is the etiology but this may be precipitated by intussusception or volvulus.
- Cystic fibrosis may be an underlying factor in up to 10% of cases.
- MRI may be helpful in excluding other diagnoses or defining associated intra-abdominal cysts in an evaluation of echogenic bowel.

CONDITION

Jejunoileal atresia and stenosis are among the most common causes of neonatal intestinal obstruction. Atresia is a complete obstruction of the lumen of the bowel. It is far more common than stenosis or partial luminal obstruction. These lesions can occur anywhere in the small bowel but are most common in the proximal jejunum or distal ileum, where they account for 31% and 36% of cases, respectively (Robertson et al., 1994). In addition, multiple atresias of the small bowel are found in 6% of cases (deLorimier et al., 1969). These conditions are thought to result from intrauterine vascular accidents such as volvulus, intussusception, internal hernia, or vascular constriction (Louw and Barnard, 1955). In utero vascular compromise as a cause of intestinal atresias was first suspected because of associated volvulus, intussusceptions, constriction at the abdominal wall defect in gastroschisis, and kinking of bowel that were often found in association with intestinal atresias. This was supported by experimental work by Louw and Barnard (1955), who were able to replicate the pathophysiology of small intestinal atresias in animals by in utero ligation of mesenteric vessels.

The bowel lumen distal to an atresia contains bile (bile is first seen at 11 weeks of gestation), planocellular epithelium (first seen at 12 weeks), and lanugo (first seen at 6–7 months), which suggests that a vascular accident occurred well after organogenesis was complete (Romero et al., 1988). In keeping with the theory of a mesenteric vascular accident, the incidence of associated chromosomal and extraintestinal anomalies associated with jejunoileal atresia is quite low. In addition to sporadic occurrence of jejunoileal atresias, they have also been reported as a complication of amniocentesis (Richwood, 1977; Swift et al., 1979; Therkelson and Rohder, 1981). Intussusception had been considered to be a rare cause of vascular disruption resulting in atresia (Nixon and Tawes, 1971; Dalla Vecchia et al., 1998). Komuro and colleagues suggest that antenatal intussusception with or without associated volvulus may be a more important etiology of small bowel atresia than has been previously recognized (Komuro et al., 2004). In a single institution's review of 48 newborns with small bowel atresia, this group found evidence of intussusception in 12 and volvulus in 13 cases at the time of surgery. They noted that neither intussusception nor volvulus was observed in cases of high jejunal atresia, apple peel deformity, or multiple atresias.

The most useful and commonly accepted classification of intestinal atresias is that proposed by Louw and Barnard in 1955, with numerous subsequent modifications (Figure 73-1). Type I atresias have an intraluminal diaphragm in continuity with the muscular coats of the proximal and distal segments; they account for 32% of cases. Type II atresias have a fibrotic cord connecting the two blind-ending bowel segments with an intact mesentery; they account for 25% of cases. Type III atresias are divided into those with complete separation of the blind-ending loops of bowel with a U-shaped mesenteric defect (type IIIa); they comprise 15% of cases. The other, type IIIb atresia, is associated with an extensive mesenteric defect and an associated "apple peel" deformity. The terminal ileum is perfused in a retrograde fashion from a single ileocolic artery around which the distal ileum coils, giving the appearance of an apple peel. Although these are unusual atresias, accounting for only 11% of cases, they are frequently seen in extremely premature infants and result in significant shortening of bowel length and the short-bowel syndrome (Dickson, 1970). They may also recur in families. Type IV lesions are multiple atresias of the small intestine and account for 6% to 17% of cases.

When associated anomalies occur in jejunoileal atresia, they generally involve the gastrointestinal tract. While the incidence of extragastrointestinal anomalies is very low, other gastrointestinal anomalies may be seen in up to 45% of patients. These abnormalities include malrotation (23%), intestinal duplications (3%), microcolon (3%), and esophageal atresia (3%) (de Lorimier et al., 1969; Nixon and Tawes, 1971). Meconium ileus and meconium peritonitis occur in 12% and 8% of cases, respectively. Associated cardiac and chromosomal anomalies are rare (Rescorla and Grosfeld, 1985) (Table 73-1).

Meconium ileus may be the underlying cause of jejunoileal atresia in infants with cystic fibrosis, who have signs of prenatal volvulus or meconium peritonitis as a result of small-bowel perforation. The incidence of meconium ileus is 20% in most series of jejunoileal atresia (Santulli et al., 1970). For this reason, cystic fibrosis mutation testing or sweat chloride analysis is advisable for all cases of jejunoileal

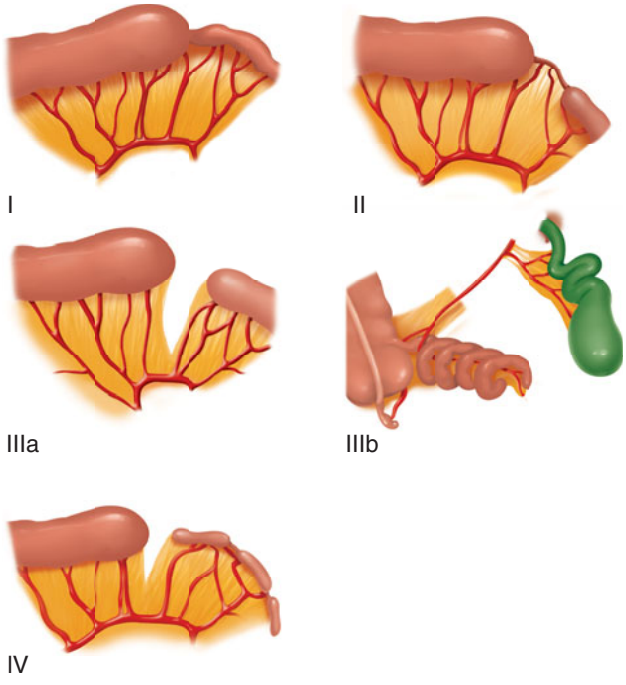

Figure 73-1 Classification of intestinal atresias.

Table 73-1

Associated Anomalies Seen in Jejunoileal Atresia

Anomaly	Percentage of Cases
Malrotation	13
Meconium ileus	12
Meconium peritonitis	8
Volvulus	5
Abdominal wall defect	4
Heart disease	3
Trisomy 21	1

atresia. Gastroschisis is also associated with jejunoileal atresia and is thought to be due to ischemic injury to the bowel from constriction at the abdominal wall defect (see Chapter 63).

It has been also observed that there is an association between small-bowel atresia, particularly multiple atresia and placental vascular abnormalities (Komuro et al., 2004b). In a small series of 48 cases, 4 infants had significant abnormalities associated with either apple peel abnormality or multiple intestinal atresia. The placental abnormalities included marginal cord insertion, placental infarction, calcification, and cyst formation. In contrast to most cases of jejunoileal atresia, these cases were associated with extragastrointestinal abnormalities including brain, ophthalmic, and skeletal anomalies (Komuro et al., 2004b).

INCIDENCE

Jejunoileal atresias occur relatively commonly, with approximately 1 case in every 3000 livebirths. However, the incidence of intestinal atresia has been reported to range from 1 in 400 to 1 in 5000 livebirths, with boys and girls affected equally (Touloukian, 1993). This anomaly is about twice as common as esophageal atresia and three times more common than Hirschsprung's disease (Rowe et al., 1995).

SONOGRAPHIC FINDINGS

The only abdominal structures that normally contain fluid are the stomach and gallbladder, and these are readily visible on prenatal ultrasound examination (Goldstein et al., 1987). Swallowing of amniotic fluid begins at approximately 16 weeks of gestation, and meconium accumulates in the small bowel and colon throughout the second and third trimesters. The diagnosis of obstruction before 18 weeks of gestation is uncommon, and it remains difficult to detect up to 24 weeks. The bowel becomes progressively more visible and peristalsis can be seen with increasing gestational age. The meconium-filled lumen becomes increasingly echogenic as compared with the hypoechogenic muscular wall. Dilated loops of bowel with an internal diameter greater than 7 mm should be considered abnormal and may suggest obstruction (Nyberg et al., 1987). Proximal gastrointestinal obstruction often leads to polyhydramnios, which occurs in 0.4% to 1.5% of pregnancies (Wallenburg and Wladimoroff, 1977). Up to 63% of fetuses with jejunoileal atresia associated with polyhydramnios have additional anomalies, one-third of which involve the gastrointestinal tract (Damato et al., 1993).

Some authors have suggested that the association of polyhydramnios and dilated loops of bowel are markers of more severe bowel obstruction with a larger need for parenteral nutrition and longer predicted length of stay (Iacobelli et al., 2006). In this group's experience, the presence of dilated loops and polyhydramnios were more likely to result in disproportional size of proximal and distal loops of bowel, making delayed anastomosis more likely. This information should be incorporated into prenatal counseling (Basu and Burge, 2004; Iacobelli et al., 2006).

Figure 73-2 Prenatal sonographic image of a fetus with jejunal atresia demonstrating multiple loops of dilated, thick-walled bowel, which was associated with increased peristalsis and polyhydramnios. *(Reprinted, with permission, from Robertson FM, Crombleholme TM, Paidas M, et al. Prenatal diagnosis and management of gastrointestinal anomalies. Semin Perinatol. 1994;18:182-195.)*

Jejunal obstruction may be visualized on prenatal ultrasound examination by the presence of fluid-filled loops and bowel demonstrating increased peristalsis (Figure 73-2). Floating particulate matter may also be observed (Kirkinen and Jouppila, 1984). The abdomen may appear distended, and in the case of meconium ileus, increased bowel echogenicity can be present (Muller et al., 1984). Polyhydramnios occurs in approximately 25% of cases and is seen more commonly in cases of proximal obstruction. Polyhydramnios may be absent in proximal stenosis or very distal obstruction, where adequate absorption of swallowed amniotic fluid occurs. The extent of bowel dilation and mural thickening may correlate with the presence of obstruction. The incidence of obstruction increases significantly when the bowel diameter is greater than 17 mm. Similarly, the incidence of obstruction is approximately 40% with a mural thickness of greater than 3 mm (Langer et al., 1993). Visualization of increased peristalsis associated with bowel dilatation increases the likelihood of obstruction.

In recent years, magnetic resonance imaging has been used more commonly to characterize gastrointestinal anomalies (Quinn et al., 1998; Shinmoto et al., 2000; Ertl-Wagner et al., 2002; Saguintaah et al., 2002). The utility of MRI is in not only characterizing gastrointestinal tract abnormalities but also in demonstrating normal bowel close to an intra-abdominal cyst (Veyrac et al., 2004) MRI is best used as an adjunct to ultrasound examination or in combination with amniotic fluid enzyme analysis (Garel et al., 2006). MRI may

be informative in evaluating sonographically detected bowel dilatation or echogenic bowel (Carcopino et al., 2007).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of dilated, thick-walled loops of intestine, possibly with associated increased peristalsis, includes jejunoileal atresia, meconium ileus, meconium peritonitis, total colonic Hirschsprung's disease, malrotation with or without volvulus, bowel duplication, intestinal hernia, and functional obstruction due to drug ingestion by the mother. Other diagnoses that may produce intra-abdominal anechoic images include ovarian cyst, duodenal atresia, and hydronephrosis.

ANTENATAL NATURAL HISTORY

The fetus with jejunoileal atresia usually comes to medical attention as a result of polyhydramnios. The more proximal the atresia, the greater the likelihood is of developing polyhydramnios. Conversely, the more distal the atresia, the less likely it is that polyhydramnios will develop. If polyhydramnios occurs, it will be late in gestation. Even in proximal jejunal atresia, polyhydramnios rarely develops before the third trimester.

MANAGEMENT OF PREGNANCY

After detection of bowel atresia, subsequent prenatal management includes a complete fetal anatomic survey. In the absence of other structural anomalies or echogenic bowel (see below), no further workup is required. Serial sonographic surveillance should be planned to observe for the development of polyhydramnios, ascites, or meconium cyst formation. If echogenic bowel is present, amniocentesis for fetal karyotype and cystic fibrosis DNA mutation analysis should be performed. If amniocentesis is planned for karyotype analysis in the setting of bowel dilation and echogenic bowel, consideration should be given to amniotic fluid digestion enzyme assays including gamma-glutamyl transpeptidase (GGTP), aminopeptidase (AMP), total alkaline phosphatase (ALP) and its isoenzymes including the intestinal form (iALP) and total protein (Muller et al., 1994; Garel et al., 2006). Muller et al. (1994) have attempted to correlate elevations of amniotic fluid $\gamma\gamma$-glutamyltranspeptidase (GGTP) and intestinal alkaline phosphatase (iALP) in patients who underwent amniocentesis for karyotype analysis because of bowel dilation seen on prenatal ultrasound. Gastrointestinal malfunction was confirmed in 46 of 55 cases. In the 34 cases of gastroduodenal dilation, amniotic fluid GGTP above the 99th percentile was 71% sensitive but 100% specific for an anatomic defect, usually duodenal atresia. However, among fetuses with dilated loops of more distal bowel, high levels of GGTP and/or iALP were only 69% sensitive and 83% specific for fetal gastrointestinal tract anomaly. Normal values of these enzymes in amniotic fluid, however, did not exclude the diagnosis of either duodenal or more distal obstruction.

Delivery should be planned in a center with appropriate high-risk obstetric, neonatal, and pediatric surgical support.

FETAL INTERVENTION

There are no fetal interventions for jejunoileal atresia and stenosis.

TREATMENT OF THE NEWBORN

Postnatal management of jejunoileal atresia or stenosis includes immediate nasogastric decompression and intravenous fluid administration sufficient to correct fluid and electrolyte deficits. Plain abdominal radiography will verify tube placement and may suggest the level of obstruction. Air throughout the intestine with proximal dilated loops of bowel is suggestive of jejunal stenosis. An emergency upper gastrointestinal contrast study may be required to rule out malrotation with midgut volvulus. Associated anomalies should be excluded and surgical correction performed as soon as the infant is adequately resuscitated and prepared for surgery, usually within hours of delivery. During the postoperative period, if not performed antenatally, a sweat chloride test or cystic fibrosis DNA mutation analysis should be performed in cases of atresia associated with meconium peritonitis to evaluate the possibility of cystic fibrosis (Santulli et al., 1970). In the premature infant, DNA analysis is the preferred diagnostic test because of the difficulty of obtaining an adequate sweat sample.

SURGICAL TREATMENT

The infant with intestinal atresia will sequester "third-space" fluid within the bowel lumen, and dehydration is common if fluid resuscitation is inadequate. Although bacterial colonization of the gastrointestinal tract takes 24 to 36 hours to complete, prophylactic intravenous antibiotics (ampicillin/gentamicin) are routinely administered. Nasogastric decompression with a sump-style tube (Replogle or Anderson) is essential to decompress the bowel and prevent perforation as well as minimize risks of aspiration at the time of anesthesia induction.

A transverse supraumbilical abdominal incision provides excellent exposure to the entire gastrointestinal tract.

The site of proximal obstruction is usually obvious, even in cases of type I atresia (membranous intraluminal diaphragm), because of the marked dilatation of the proximal bowel. It is important to exclude other distal atresias that may not be evident from the external appearance of the bowel (Grosfeld et al., 1979). This can be assessed after the bowel is opened, or the atretic segment resected, by instilling normal saline into the lumen of the distal bowel. The fluid will distend the bowel all the way to the anus unless another type I atresia is encountered. If another atresia is found, it is important to again instill fluid distal to it to exclude the "string of sausages" effect of multiple atresias or associated colonic atresia. In cases of multiple atresias, extensive bowel resection is avoided and multiple anastomoses are performed in an effort to preserve bowel length and prevent complications of the short-bowel syndrome.

The dilated proximal bowel, although viable, should be resected to prevent functional obstruction at the anastomoses because of poor motility in this segment (Touloukian, 1993; Ozguner et al., 2005). In addition to poor motility, this dilated loop may be prone to development of blind loop syndrome. Even with resection of the dilated 15 to 20 cm of proximal intestine, a significant size discrepancy exists between proximal and distal bowel (Figure 73-3). This size discrepancy can be minimized by plicating the proximal intestine, which reduces the circumference and may also enhance motility (deLorimier and Harrison, 1983; Yamataka et al., 2005). In addition, the distal loop of intestine can be cut obliquely to spatulate this smaller-caliber bowel and minimize size discrepancy. In cases associated with significant shortening of intestinal length, plicating the proximal intestine preserves intestinal length and mucosal absorptive surface area and minimizes dysmotility. In cases in which considerable bowel length has been already lost, some surgeons have used the serial transverse enteroplasty techniques as a means of preserving bowel length and avoiding complications of the short-gut syndrome (Wales and Dutta, 2005; Modi et al., 2007).

Figure 73-3 Intraoperative photograph of a newborn with jejunoileal atresia. Note the grossly distended proximal jejunum as compared with the bowel distal to the most proximal atresia.

The apple peel deformity in jejunal atresia may be particularly challenging because of loss of intestinal length, marked discrepancies between distal and proximal segments, and the short-bowel syndrome that results from it (Figure 73-4) (Dickson, 1970; Zerella and Martin, 1976; Ahlgren, 1987; Seashore et al., 1987).

In cases in which the jejunal atresia is quite proximal, a transanastomotic nasojejunal feeding tube may be placed to allow enteral feedings to be initiated during the immediate postoperative period. In cases of more distal atresia, we usually place a central venous catheter for parenteral nutrition until normal gut activity has returned. In cases in which foreshortened intestine is found or where short-bowel syndrome is anticipated, a more permanent Broviac intravenous catheter should be placed at the time of surgery.

Figure 73-4 Intraoperative appearance of the apple peel deformity seen in type IIIb jejunal atresia.

LONG-TERM OUTCOME

In general, the outcome in infants with jejunoileal atresia is excellent. During the past two decades, there has been progressive improvement in survival from approximately 70% in the late 1960s to 95% in the 1990s. The rare deaths are usually complications of the short-bowel syndrome, such as line sepsis or liver failure, or more rarely, due to cystic fibrosis. Postoperative deaths in jejunoileal atresias are usually due to severe cardiac defects or ventilator-dependent chronic lung disease (Touloukian, 1993).

Some infants will have a problem with pseudo-obstruction or blind loop syndrome in the dilated proximal bowel loops, but usually these respond to medical management.

The prognosis for isolated jejunoileal atresia is excellent. However, in cases in which significant loss of intestinal length has occurred, complications of the short-bowel syndrome will prolong hospitalization and complicate recovery. Loss of the distal ileum will predispose to megaloblastic anemia from vitamin B_{12} deficiency and gallstones. In cases of isolated atresia, a 7- to 14-day hospitalization can be anticipated. If proximal bowel has become dilated, a prolonged postoperative ileus can be anticipated. These infants require close observation for complications of bacterial overgrowth and secondary growth failure. It is important to emphasize that the majority of infants with jejunoileal atresia have an excellent prognosis. Long-term follow-up by a pediatric surgeon and pediatric gastroenterologist, however, is advisable.

GENETICS AND RECURRENCE RISK

Type IIIb atresia, with apple peel deformity, short bowel, and retrograde perfusion of distal ileum, has an estimated recurrence risk of 18% (Al-Awadi et al., 1981; Arnal-Monreal et al., 1983). This condition has an autosomal recessive pattern of inheritance. Siblings, however, may have atresias of other types or other anomalies.

There is familial recurrence with other types of atresia, including type IV (Dimmick and Hardwick, 1992; Shorter et al., 2006). Hereditary multiple atresia syndrome was first described in the French Canadian population but is increasingly being recognized (Shorter et al., 2006). Consanguinity occurring in the affected families suggests an autosomal recessive mode of transmission. Guttman et al. (1973) reported familial occurrence of both duodenal and jejunoileal atresias (Martin and Zerella, 1976; Arnal-Monreal et al., 1983). Sonographically, this syndrome is of special interest, as in all 5 cases reported by Guttman et al., intraluminal calcified radiopaque densities were diagnosed in utero (Guttman et al., 1975).

Parents of patients who have been identified as having cystic fibrosis in association with the jejunoileal atresia should be advised regarding the 25% risk of recurrence. Preimplantation genetic diagnosis and DNA-based prenatal diagnosis are available for subsequent pregnancies. Shorter et al. have proposed a classification system for familial cases of intestinal atresia based on likely etiologic factors (Shorter et al., 2006). These investigators suggest that familial cases occur as a result of embryologic failure of vessels to develop. They suggest classifying familial cases of gastrointestinal atresia into the following classes, most of which have an autosomal recessive pattern of inheritance: class 1—pyloric atresia; class 2—duodenal atresia limited to the second or third portion of the duodenum; class 3—hereditary multiple atresia syndrome, which includes intraluminal calcification, normal rotation, and cystic dilation of the atresia (possible X-linked inheritance).

In general, parents of patients with jejunoileal atresia and stenosis should receive genetic counseling.

Colonic Atresia

74
CHAPTER

Key Points

- Accounts for up to 15% of intestinal atresias. Incidence is about 1 in 20,000 livebirths.
- On prenatal sonogram appears as multiple dilated loops.
- Fetal MRI may demonstrate dilated proximal colon and absence of meconium in distal colon.
- Colonic atresia can be associated with gastrointestinal anomalies or Hirschsprung's disease.
- Diagnosis has no implications for timing or route of delivery.
- Overall prognosis is excellent.

CONDITION

Colonic atresia is a rare cause of intestinal obstruction and accounts for less than 10% to 15% of all cases of intestinal atresia (Sturim and Ternberg, 1966; Coran and Eraklis, 1969; Bowles et al., 1976; Powell and Raffensperger, 1982; Touloukian, 1993a). Colonic atresia was first recognized in 1673 by Bininger (Powell and Raffensperger, 1982). The first survivor with this condition, treated by colostomy, was not reported until 1922 (Gaub, 1922). Potts (1947) was the first to report a survivor after primary anastomosis. Few series of appreciable size have been reported subsequently because of the rarity of isolated colonic atresia or stenosis (Philippart, 1986). The pathogenesis is thought to be similar to the mechanism responsible for jejunoileal atresia and stenosis (see Chapter 73). The majority of colonic atresias, which occur proximal to the splenic flexure, include a significant segment of absent colon with distal microcolon (Rescorla and Grosfeld, 1985). Anomalies associated with colonic atresia are unusual, but can include gastroschisis and jejunal atresia, Hirschsprung's disease, as well as ocular and skeletal anomalies (Bowles et al., 1976; Powell and Raffensperger, 1982; Rescorla and Grosfeld, 1985; Jackman and Brereton, 1988; Etensel et al., 2005; Draus et al., 2007). The skeletal anomalies most often seen with isolated colonic atresia include syndactyly, polydactyly, absent radius, and clubfoot (Philippart, 1986). Major cardiac anomalies and genetic defects are rare, although they have been reported (Robertson et al., 1994). Colonic atresias may be seen as a complicating factor in abdominal wall defects such as gastroschisis, omphalocele, or vesicointestinal fistulas (Bowles et al., 1976; Powell and Raffensperger, 1982). Hirschsprung's disease has also been reported to occur in association with colonic atresia (Johnson and Dean, 1981). However, it is important to remember that in two-thirds of the cases, colonic atresia occurs as an isolated defect without associated abnormalities. Multiple colonic atresias have been reported but are extremely rare (Touloukian, 1993b).

The classic demonstration by Louw and Barnard (1955) that jejunal atresia results from an in utero mesenteric vascular accident is widely accepted and is thought to also apply to colonic atresia. Vascular compromise may occur as a result of a primary vascular accident in utero, or it may be secondary to a mechanical event, such as intestinal volvulus. Because colonic atresia, proximal and distal to the splenic flexure, differs, the cause may also differ in these regions. Other cases of colonic atresia have been reported due to internal hernia, compression of the tranverse mesocolon by a choledochal cyst, or in association with gastroschisis (Etensel et al., 2005; Al Wafi et al., 1998; Basaran et al., 2002). Rare causes of colonic atresia include those attributed to multiple intestinal atresias due to disturbed intestinal morphogenesis (Fourcade et al., 2001), fetal varicella infection (Hitchcock et al., 1995), and familial cases (Benawra et al., 1981).

INCIDENCE

The occurrence rate of colonic atresia has been reported to vary from 1 in 1498 to 1 in 66,000 livebirths (Sturim and Ternberg, 1966; Davenport et al., 1990). The former appears to overestimate the incidence of colonic atresia and the latter is thought to be an underestimate. One in 20,000 appears to be more nearly correct, based on experience at major pediatric surgical centers (Philippart, 1986). In such centers the occurrence rate approximates 1 case per year of isolated colonic atresia or stenosis. The incidence of colonic atresia is equal in males and females. When there are other associated developmental anomalies, the incidence of colonic atresia increases significantly. Within the gastrointestinal tract, however, only gastric atresia is rarer (Philippart, 1986).

SONOGRAPHIC FINDINGS

The prenatal sonographic appearance of colonic atresia may be indistinguishable from other forms of distal intestinal obstruction. Prenatal diagnosis of colonic atresia may be extremely difficult to make with certainty. The sonographic image in colonic atresia is that of multiple dilated loops of bowel (Figure 74-1). It may be difficult to distinguish dilated loops of small bowel from dilated loops of colon. Polyhydramnios is an unusual finding in isolated colonic atresia and its presence should raise suspicions about a more proximal intestinal obstruction. Perforation may occur proximal to the atresia, with resulting ascites and meconium peritonitis (Agrawala et al., 2005) (Figure 74-2).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of these sonographic findings includes anorectal atresia, cloaca, and Hirschsprung's disease (see Chapters 75 and 76).

Figure 74-1 Fetal sonographic image demonstrating multiple dilated loops of intestine due to an isolated descending colonic atresia.

Figure 74-2 Sonographic examination of the same fetus in Figure 74-1 performed 2 weeks later, demonstrating decompression of the loops of intestine but with the new finding of fetal ascites. This was proven to be due to proximal perforation above the descending colonic atresia with secondary meconium peritonitis.

ANTENATAL NATURAL HISTORY

Half of colonic atresias occur proximal to the splenic flexure and half occur distal to it (Coran and Eraklis, 1969; Etensel et al., 2005). Atresia of the colon proximal to the splenic flexure is more likely to be associated with loss of proximal colon. Atresia distal to the splenic flexure is less likely to result in loss of bowel length. This difference appears to be related to the watershed nature of the blood supply to the colon at the splenic flexure. The atresias occurring in the colon vary from luminal webs to full mesenteric defects. The rarity of colonic atresia and the lack of prospective prenatally diagnosed cases of colonic atresia limit our understanding of its antenatal natural history. We do not believe that this diagnosis has any adverse implications for the pregnancy, and because associated anomalies are less frequent, the overall prognosis is excellent.

MANAGEMENT OF PREGNANCY

Because of the potential for associated anomalies, when colonic atresia is suspected, the fetus should undergo a detailed sonographic examination with special attention to the skeletal system and the four-chamber view of the heart. If the cardiac anatomy is poorly seen, fetal echocardiography should be performed. There is no indication for karyotype analysis in fetuses in which colonic atresia is suspected, except as indicated by maternal age, or if seen in association with anomalies known to be associated with chromosomal abnormalities, such as omphalocele. Colonic atresia is not associated with prematurity, and this diagnosis has no implications for timing or mode of delivery. However, because of the need for radiographic evaluation and surgery during the immediate postnatal period, we recommend delivery in a tertiary care center, with pediatric surgeons, pediatric radiologists, and neonatologists available.

FETAL INTERVENTION

There are no fetal interventions for colonic atresia.

TREATMENT OF THE NEWBORN

In the nursery, the infant with colonic atresia will show abdominal distention, and either fail to pass meconium or pass only a small amount. Plain abdominal radiographs will demonstrate multiple loops of dilated bowel with air-fluid levels consistent with obstruction. A sump-style nasogastric tube should be passed for intestinal decompression and venous access obtained for volume resuscitation. Due to the distal location of the obstruction, fluid can be sequestered within more proximal loops of bowel. Antibiotics should be started and a pediatric surgical consultation obtained.

A plain radiograph of colonic atresia may be indistinguishable from a more proximal intestinal atresia or meconium ileus. Because of this differential diagnosis, a contrast enema should be performed. In cases of meconium ileus, surgery may be avoided if Gastrografin enema is successful in relieving the obstruction. In colonic atresia, a microcolon is noted distal to the site of obstruction. Perforation of the microcolon has been reported during barium enema for colonic atresia (Sturim and Ternberg, 1966).

SURGICAL TREATMENT

In the past, survival was rare for cases of colonic atresia not diagnosed during the first 3 days of life. Most morbidity and mortality associated with colonic atresia occurs in unrecognized cases. In the presence of a competent ileocecal valve, unrecognized colonic atresia may result in a closed-loop obstruction, which may then go on to perforation. Once a diagnosis has been made and the infant has been resuscitated with volume, surgery should be performed. The procedure is determined by the nature and location of the atresia and the physiologic status of the infant. Previously, a primary anastomosis was performed for right-sided atresias because newborns often did not tolerate ileostomy well. Conversely, because colostomy was well tolerated in newborns, this was the preferred procedure in left-sided atresias. Currently, we favor resection, or tapering enteroplasty of the dilated proximal colon with primary anastomosis in colonic atresias of either the left or right colon. It is essential, however, to obtain frozen sections of the more distal colon to rule out Hirschsprung's disease if a primary anastomosis is planned. Failure to diagnose Hirschsprung's disease inevitably leads to breakdown of the anastomosis. In cases in which Hirschsprung's disease is present in association with colonic atresia, either a resection

and leveling colostomy or resection and an endorectal pull-through can be performed. Which of these approaches is preferred depends on the location of the atresia and the degree of dilatation of the proximal colon. In infants who may be compromised by other factors, such as sepsis or severe respiratory distress, we perform a proximal colostomy or ileostomy with closure at a later date when the infant is more stable. Current means of nutritional support have diminished concerns about ileostomy in a newborn.

LONG-TERM OUTCOME

Because of the rarity of isolated colonic atresia, most reported series are small and encompass several decades of observations. Experience with this unusual lesion, as well as marked improvements in supportive care, have improved survival, which currently is greater than 90% (Bowles et al., 1976; Powell and Raffensperger, 1982; Etensel et al., 2005; Draus et al., 2007). Deaths usually occur only as a result of associated congenital anomalies, a marked delay in the recognition of the colonic atresia, or failure to recognize associated Hirschsprung's disease (Philippart, 1986; Etensel et al., 2005; Draus et al., 2007). In most historical reviews, deaths usually occurred prior to the 1970s because of preoperative colonic perforation. Delayed function of the distal colonic segment has been observed in several patients and occasionally required intravenous nutritional support. In such cases, a biopsy to detect the presence of ganglion cells is appropriate to exclude distal aganglionosis consistent with Hirschsprung's disease (Wolloch and Dintsman, 1976; Currie et al., 1983). Occasionally, contrast enemas obtained in patients who have undergone surgery for correction of colonic atresia will demonstrate persistent tapering of the distal segment. In the absence of symptoms, this radiographic feature is of no concern.

GENETICS AND RECURRENCE RISK

Cases of colonic atresia due to genetic or familial occurrence have been reported (Guttman et al., 1973; Benawra et al., 1981; Puri and Fujimoto, 1988). We are aware of one case report of a family in which congenital colonic atresia was present in two maternal half brothers and their maternal uncle (Benawra et al., 1981). The pattern of inheritance was consistent with autosomal dominance with reduced penetrance, or X-linked. A familial syndrome of pyloric atresia associated with small-bowel and colonic atresia has also been described (Guttman et al., 1973). In general, however, recurrence of colonic atresia is rare.

There is recent work in transgenic mice that shows that decreased expression of the fibroblast growth factor receptor 2b in the gastrointestinal tract results in decreased proliferation and increased apoptosis, resulting in atresia (Fairbanks et al., 2004). It is not clear, however, that this proposed genetic mechanism plays any role in colonic atresia.

Hirschsprung's Disease

75 CHAPTER

Key Points

- One of the most common causes of intestinal obstruction in the newborn. Characterized by severe constipation due to functional colonic obstruction with megacolon.
- Hirschsprung's disease rarely presents prenatally, but when it does it is usually due to total colonic aganglionosis.
- Sonographic features may include dilated loops of small intestine occasionally with enterolithiasis.
- About a quarter of affected patients have associated anomalies. There is a strong association with Down syndrome.
- Hirschsprung's disease diagnosed prenatally is at increased risk for syndromic associations by being long segment aganglionosis.
- Level II sonogram and antenatal karyotype are recommended.
- Diagnosis requires postnatal rectal biopsy to confirm aganglionosis.
- Treatment is a pull-through procedure to bring normal ganglionated bowel to the dentate line.

CONDITION

Hirschsprung's disease is one of the most common causes of intestinal obstruction in newborns (Richardson and Brown, 1989; Kleinhaus and Boley, 1993). It usually presents as a low intestinal obstruction without sepsis. In the least severe cases, delayed passage of meconium may be the only abnormality (Potter, 1989; de Lorijn et al., 2007). In more severe cases, the neonate presents with abdominal distention and bilious or feculent vomiting, in addition to failure to pass meconium. In its most serious form, infants present with overwhelming sepsis due to enterocolitis; a smaller number will present with peritonitis from perforation of a normal intestine proximal to the aganglionic segment. The age at diagnosis varies considerably, but half of the cases are diagnosed during the newborn period, 75% within 3 months, and 80% within the first year of life (Ikeda and Goto, 1984; Rowe et al., 1995).

Hirschsprung's disease is characterized by severe constipation due to functional colonic obstruction with megacolon. The condition bears the name of Harald Hirschsprung, a Danish pediatrician, who in 1888 described the autopsy findings of two unrelated infants who died with congenital megacolon. While at least 12 cases had been reported prior to 1888, Hirschsprung's complete description of the clinical and postmortem findings resulted in his name becoming attached to the condition. Hirschsprung focused his attention on the dilated hypertrophied megacolon, but the underlying abnormality was not determined until 1920, when Dalla Valle reported the absence of ganglion cells in the Auerbach plexus in the nondilated transition zone. The absence of ganglion cells in the distal nondilated segment involves the Auerbach plexus (myenteric), the Henle (deep submucosal), and the Meissner plexuses (submucosal) (Skandalakis and Gray, 1994). The dilated proximal segment of colon ends in a funnel-shaped transition zone, which tapers into the narrowed, patent, but functionally obstructed distal segment. This distal segment is usually normal in caliber and appears narrow only compared to the proximal megacolon (Figure 75-1). The peristalsis of the proximal normal colon tends to dilate the proximal aganglionic segment, and so the transition zone is part of the aganglionic segment.

The abnormal innervation in Hirschsprung's disease always extends proximally from the anus, including the internal sphincter (Puri, 1996). Histologically, in the absence of ganglion cells there are hypertrophied parasympathetic nerve bundles in the submucosa and between the muscular layers of the bowel. The parasympathetic (cholinergic) and sympathetic (adrenergic) nervous systems innervate the normal colon. The parasympathetic system is excitatory to the colon and inhibits the internal sphincter. Conversely, the

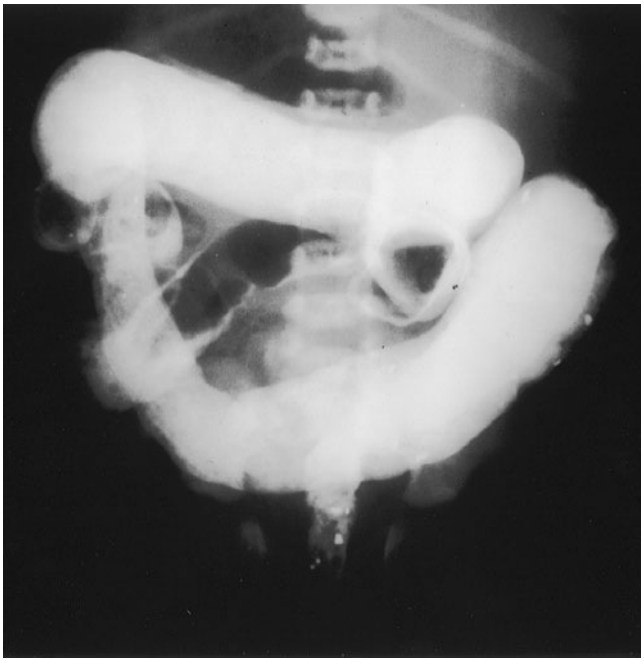

Figure 75-1 Barium enema radiograph from an infant with Hirschprung's disease. The dilated proximal bowel is the segment of bowel with normal ganglion cells. Note the narrow rectum and wide sigmoid. *(Courtesy of Dr. R. S. McCauley.)*

sympathetic nervous system inhibits the colon and excites the internal sphincter. In addition, the colon normally receives intrinsic innervation via purinergic, serotonergic, and peptidergic systems (Nirasawa et al., 1986). Ganglion cells receive impulses from both cholinergic fibers and intrinsic nonadrenergic inhibitory fibers. In Hirschsprung's disease the extrinsic innervation is present with increased cholinergic and adrenergic fibers, but the intrinsic innervation is absent (no purinergic, serotonergic, or peptidergic fibers). In Hirschsprung's disease the wave of relaxation that normally precedes each propulsive peristaltic wave does not occur. In addition, the normal reflex relaxation of the internal sphincter following rectal distention does not occur.

The ganglion cells coordinate intrinsic and extrinsic impulses, and in their absence a functional obstruction results. Absence of the intrinsic nervous system is the underlying neurophysiologic abnormality in Hirschsprung's disease.

During embryonic life, neurenteric ganglion cells migrate from the neural crest to the upper end of the alimentary tract and then follow vagal fibers caudad (Dereymaeker, 1943; Van Campenhout, 1946; Yntema and Hammond, 1947). Ganglion cells can be seen in the proximal small bowel by 7 weeks of gestation, and the rectum by 12 weeks of gestation (Okamoto and Ueda, 1967). Why ganglionic migration stops is unknown. It is not due to failure of vagal fibers to innervate the bowel. Postganglionic fibers from normal ganglia proximal to affected segments and preganglionic parasympathetic vagal fibers that fail to connect with ganglion cells continue to elongate (Bodian et al., 1951; Kamijo et al., 1953; Nixon, 1964).

Megacolon is not always due to Hirschsprung's disease. It is now recognized that several anomalies of the myenteric plexus may produce a similar clinical presentation to Hirschsprung's disease, including neuronal loss, abnormal nerves, and intestinal neuronal dysplasia (Puri and Wester, 1998; Scharli and Sossai, 1998). Several reports have appeared describing a clinical presentation that is indistinguishable from Hirschsprung's disease in which ganglia were present but there was either hypoganglionosis, immature ganglia, or other neuronal abnormalities (Burghaighis and Emery, 1971; Tanner et al., 1976; Munakata et al., 1978).

The internal sphincter is involved in all cases, but the proximal extent of aganglionosis varies. The rectosigmoid is involved in about half of the patients, and an additional 15% have involvement of the splenic flexure or hepatic flexure or have total colonic Hirschsprung's disease. In 8% of the cases, aganglionosis may extend to the small bowel (Bickler, 1992). Rare cases of discontinuous aganglionic segments with normal functioning intervening bowel have been reported (Sprinz et al., 1961; Anderson and Chandra, 1986; Seldenrijk et al., 1986; Skandalakis and Gray, 1994).

INCIDENCE

The incidence figures quoted for Hirschsprung's disease have increased from the earliest report by Hautau in 1960 of 1 in 41,200, as a result of greater appreciation of the spectrum of disease. The incidence of Hirschsprung's disease is now thought to be 1 in 5000 livebirths, second only to pyloric stenosis as a cause of intestinal obstruction in newborns (Passarge, 1967; Parisi and Kapur, 2000). Hirschsprung's disease may be slightly more common in Japan, with an incidence of 1 in 4697 to 5343 (Suita et al., 2005). The highest incidence reported is in the Federated States of Micronesia with a rate of 1 in 1370 livebirths or 3 to 5 times the rate observed in the West (Meza-Valencia et al., 2005). There is no racial predilection. Males are more commonly affected than females, with a ratio of approximately 4:1 (Kleinhaus et al., 1979; Sherman et al., 1989). The number of females with Hirschsprung's disease has varied from 5% to 22% of cases (Bodian et al., 1949; Keefer and Mokrohisky, 1954; Richardson and Brown, 1962). These incidence figures are based on livebirths. It is unknown if Hirschsprung's disease is associated with lethal malformations, as aganglionosis often cannot be recognized grossly at autopsy in a fetus or newborn because dilation and hypertrophy have not yet developed.

Numerous anomalies are associated with Hirschsprung's disease. Two percent of patients with aganglionosis have Down syndrome (Passarge, 1967). Coran et al. (1978) noted that 26% of their patients had associated anomalies, including congenital heart disease, Smith–Lemli–Opitz syndrome, and multiple renal anomalies. Other large series have confirmed this finding, with 16% to 32% of patients having one or more associated anomalies. Except for Down syndrome and anomalies of the genitourinary tract, there is no consistent pattern of associated malformations (Passarge, 1967; Lister, 1977; Seldenrijk et al., 1986) (Table 75-1).

Table 75-1

Anomalies Associated with Hirschsprung's Disease

	Syndromes	MIM	Key Features
Syndromic NCC disorders	WS4 (Shah–Waardenburg)	277580	Pigmentary anomalies (white forelock, iris hypoplasia, patchy hypopigmentation
	Yemenite deaf-blind-hypopigmentation	601706	Hearing loss, eye anomalies (microcornea, coloboma, nystagmus), pigmentary anomalies
	BADS	227010	Hearing loss, hypopigmentation of the skin and retina
	Piebaldism	172800	Patchy hypopigmentation of the skin
	Haddad	209880	Congenital central hypoventilation
	MENZA		Medullary thyroid carcinoma, pheochromocytoma, hyperplasia of the parathyroid
	Riley-Day	223900	Autonomic nervous system anomalies

SONOGRAPHIC FINDINGS

The sonographic findings of Hirschsprung's disease are nonspecific and rare. Hirschsprung's disease has been suspected or diagnosed prenatally in only three cases (Wrobleski and Wesselhoeft, 1979; Vernesh et al., 1986; Eliyahu et al., 1994). The combination of polyhydramnios, diffuse and progressive fetal-bowel distention, and increased abdominal circumference raises the possibility of fetal Hirschsprung's disease (Figure 75-2). Some have argued that because most cases occur in term infants, and cases are rarely symptomatic within the first 24 hours, Hirschsprung's disease does not occur prenatally. The three reported cases challenge this view, as Hirschsprung's disease can present in at least the third trimester. However, these cases resulted from total colonic aganglionosis, and presented with small-bowel dilation and polyhydramnios. Total colonic Hirschsprung's disease accounts for only 3% to 12% of cases (Wildhaber et al., 2005). The majority of cases, however, involve the rectosigmoid region and are unlikely to result in polyhydramnios. Given the absorption of amniotic fluid that occurs in the ileum and colon proximal to this region, functional obstruction at this level would also not be expected to cause bowel dilation.

Figure 75-2 Axial section through fetal abdomen demonstrating dilated bowel loops.

Another sonographic finding that has been suggested as a possible sign of fetal Hirschsprung's disease is echogenic bowel (Wrobleski and Wesselhoeft, 1979). However, no case of Hirschsprung's disease has been diagnosed based solely on the sonographic finding of echogenic bowel. Total colonic Hirschsprung's disease can mimic meconium ileus and result in enterolithiasis present in the terminal ileum (Cowles et al., 2006).

DIFFERENTIAL DIAGNOSIS

The sonographic findings of bowel dilation associated with polyhydramnios suggests a differential diagnosis that includes jejunal, ileal, or colonic atresia or stenosis, persistent cloaca, meconium ileus, and imperforate anus (Table 75-2). The prenatal sonographic features of bowel atresias, especially ileal or colonic, can be indistinguishable from Hirschsprung's disease. Atresias are a more common cause of fetal small-bowel obstruction, however. The sonographic features of persistent cloaca should distinguish it from Hirschsprung's disease. In neonates, perforation of the colon proximal to the aganglionic segment can occur. This has not been reported prenatally, but would be expected to present with sonographic features of meconium peritonitis such as intraabdominal

Table 75-2

Differential Diagnosis of Hirschsprung's Disease

Adrenal hemorrhage
Hypermagnesemia
Hypokalemia

calcifications, ascites, or pseudocyst formation. Total colonic Hirschsprung's disease can result in enterolithiasis due to complete functional obstruction and precipitation of urate within the lumen. In the absence of reflux of urine into the colon in imperforate anus, resulting in intra-abdominal calcification, there are no specific sonographic features for imperforate anus. It is unusual to see bowel dilation in utero with imperforate anus. This must be considered in the differential diagnosis of a fetus with dilated loops of intestine.

ANTENATAL NATURAL HISTORY

The paucity of case material has precluded our defining the natural history of Hirschsprung's disease. However, dilated loops of bowel associated with polyhydramnios are more likely to be the result of a condition other than Hirschsprung's disease. In prenatal cases in which Hirschsprung's disease is suspected, it is likely to be the result of total colonic aganglionosis or aganglionosis extending even further proximally to the small bowel, which results in polyhydramnios.

MANAGEMENT OF PREGNANCY

A suspected case of fetal Hirschsprung's disease is unlikely to affect the management of the pregnancy except for the associated polyhydramnios. There is no need to change the timing or site of delivery. Polyhydramnios may result in uterine irritability between labor and delivery. We reserve amnioreduction, however, for cases in which the increased uterine size results in maternal respiratory compromise. Because of the strong association with other anomalies (Table 75-1), a detailed level II sonographic examination should be performed and amniocentesis for karyotype analysis should be offered.

In cases of fetal dilated bowel and polyhydramnios, the parents should be referred to a center with pediatric surgeons and a pediatric radiologist available for immediate postnatal evaluation. This is not primarily because of the Hirschsprung's disease, which generally does not present as a neonatal surgical emergency, but because of the more common conditions such as jejunal or ileal atresia that do. There is no indication for cesarean section in suspected cases of Hirschsprung's disease except for standard obstetrical indications.

FETAL INTERVENTION

There are no fetal interventions for Hirschsprung's disease.

TREATMENT OF THE NEWBORN

The infant in whom Hirschsprung's disease is suspected should have a careful abdominal and rectal examination to rule out imperforate anus. A plain abdominal radiograph may be helpful after 8 to 12 hours of age to detect dilated loops of intestine after swallowing air. The infant should be observed for the passage of meconium without stimulation. If the infant fails to have spontaneous passage of meconium within 48 hours, a barium enema should be performed. In newborns, the absence of a transition zone detected on contrast enema does not exclude the diagnosis of Hirschsprung's disease, as sometimes days to weeks are required before proximal bowel dilation is evident.

The infant in whom Hirschsprung's disease is suspected prenatally must be evaluated immediately postnatally with the entire differential diagnosis of lower intestinal or functional obstruction in mind (Table 75-2). The differential diagnosis of Hirschsprung's disease is quite lengthy and an

orderly approach to the evaluation is required. The infant with meconium ileus will present with a picture of distal ileal obstruction due to cystic fibrosis. Barium enema in meconium ileus, in contrast to Hirschsprung's disease, reveals a microcolon and characteristic pellets of inspissated meconium in the ileum. However, the presence of right lower calcifications due to enterolithiasis should raise the possibility of long segment intestinal aganglionosis (Cowles et al., 2006).

In the meconium plug syndrome, a characteristic meconium plug is seen with a smaller-than-normal left colon. The infant begins producing stools normally after contrast enema and passage of the plug. The plug is not obstructive and is thought to form as a result of left colonic dysmotility, which improves postnatally. A small percentage of infants with the meconium plug syndrome will subsequently be diagnosed with Hirschsprung's disease and for that reason all cases of meconium plug syndrome should undergo suction rectal biopsy. The neonatal small left colon syndrome is similar to the meconium plug syndrome except that no plug is observed and it is most often seen in infants of diabetic mothers. There appears to be a transition zone at the hepatic flexure in a small left colon syndrome. However, the rectum is normal and the functional obstruction in small left colon syndromes is self-limited.

Other diagnoses listed in Table 75-2 can mimic Hirschsprung's disease but are usually distinguished by their associated clinical or radiographic findings: volvulus by bilious vomiting and proximal bowel obstruction; necrotizing enterocolitis in a premature infant with pneumatosis intestinalis observed on plain radiography; functional obstruction from administration of drugs such as magnesium sulfate to the mother; intracranial hemorrhage, hypothyroidism, adrenal hemorrhage, or hypermagnesemia and hypokalemia.

Once suspicion of Hirschsprung's disease has been raised, plain abdominal radiographs with anteroposterior and cross-table lateral decubitus views should be obtained to evaluate for evidence of intestinal obstruction and to rule out free intraperitoneal air. This can then be followed by barium enema, anorectal manometry, or a suction or full-thickness rectal biopsy.

The characteristic radiographic features of a narrowed rectosigmoid with proximal colonic dilatation forming a transition zone are sometimes missed during the newborn period (Figure 75-1). Some have questioned the usefulness of barium enema during the newborn period. However, if a transition zone is seen, it is diagnostic of Hirschsprung's disease. Failure to evacuate the barium within 24 hours after the study is also highly suggestive of Hirschsprung's disease.

The internal sphincter is invariably involved in all cases of Hirschsprung's disease. Some have used anorectal manometry as a noninvasive bedside diagnostic test for Hirschsprung's disease. The limitation of this approach is the difficulty of positioning the balloon and the lack of sensitivity of the equipment in infants less than 39 weeks of postconceptual age or less than 2.7 kg (Tobon et al., 1968; Holschneider et al., 1976; Tarmate, 1984). This is a technique more commonly employed in Japan (Ikeda and Goto, 1984).

Swenson (1950) established rectal biopsy as the definitive test for the diagnosis of Hirschsprung's disease, which is based on the absence of ganglion cells in the plexuses of Auerbach, Henle, and Meissner. This is often associated with hypertrophic nerve bundles in the aganglionic segments. Because of the need for general anesthesia and occasional postprocedure rectal bleeding, Aldridge and Campbell (1968) suggested the use of suction rectal biopsy. This procedure can be performed without anesthesia, at the bedside, and because it is not a full-thickness biopsy, it does not make a subsequent pull-through procedure more difficult.

SURGICAL TREATMENT

The traditional approach to the treatment of Hirschsprung's disease has been with a prompt diverting colostomy (Figure 75-3). In the past, the major cause of mortality was the development of enterocolitis prior to the diagnosis of Hirschsprung's disease. Colostomy may be lifesaving in an infant with enterocolitis. This is referred to as a "leveling colostomy" because the level of the colostomy is determined by full-thickness biopsies obtained to avoid making the colostomy in the transition zone, which will result in a functionally obstructed colostomy.

There are three commonly performed surgical procedures; each has some modifications. The first procedure, described by Swenson et al. in 1949, involves resection of the aganglionic segment and anastomosis of ganglionated

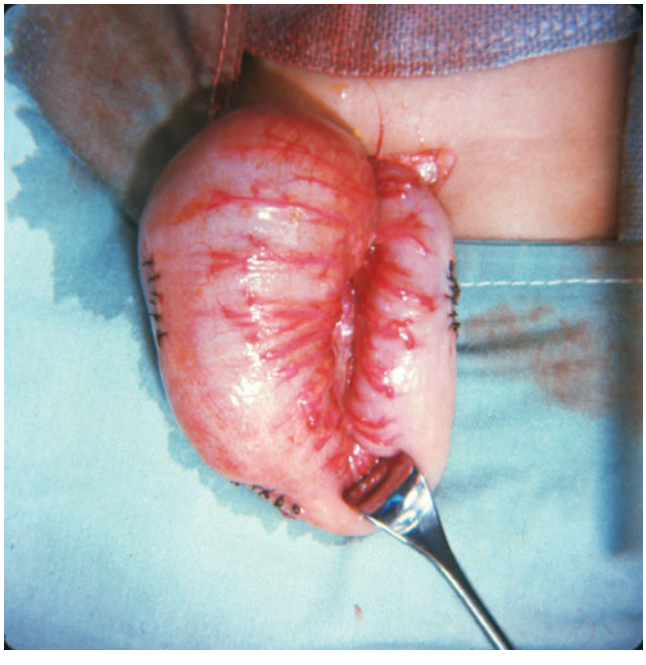

Figure 75-3 Intraoperative view of a typical case of Hirschsprung's disease at the level of the transitional zone. The distal bowel with the relatively normal caliber is the aganglionic segment while the dilated proximal bowel has normal ganglion cells. Sutures are at site of biopsies to check for ganglion cells.

proximal colon to the distal rectum. One concern with this procedure is the need to maintain the dissection immediately adjacent to the rectal wall to avoid injury to the pelvic nerves responsible for rectal, bladder, and sexual function. In 1964 Duhamel, in order to avoid the risk to pelvic innervation, introduced this procedure, which limits dissection to the retrorectal space and anastomoses ganglionated colon to the pectinate line in an end-to-side fashion. The disadvantage of this technique was the long-retained rectal septum and stump of a ganglionated bowel. Martin and Candill (1967) proposed opening the wall between aganglionic rectum and the ganglionated pulled-through colon to alleviate these problems. This procedure has the advantage of technical ease and can be performed in the case of a failed Swenson procedure.

Soave introduced the endorectal pull through in 1964, with subsequent modification by Boley (1984). The major difference between Soave's procedure and Swenson's is that the dissection of the rectum is performed in a submucosal plane protecting the pelvic innervation. The ganglionated bowel is pulled through the aganglionic muscular rectal cuff and anastomosed at the dentate line. The aganglionic muscular rectal cuff is split in the posterior midline to prevent interference with normal function of the pullthrough.

More recently, many pediatric surgeons have begun performing a definitive pull-through procedure at the time of diagnosis without preliminary colostomy, with good results (So et al., 1988; Teitelbaum and Coran, 1998). This is, of course, limited to infants with no evidence of enterocolitis. Georgeson et al., (1995) have also reported success with a laparoscopic Swenson procedure without a need for preliminary colostomy. This approach not only avoids colostomy, but is associated with more rapid postoperative recovery and discharge from the hospital (Craigie et al., 2007). In newborns with a transition zone at the distal descending colon a primary transanal Soave procedure can be performed which avoids even laparoscopy. This approach allows the infant to be discharged within 2 to 3 days of the procedure (Albanese et al., 1999; Langer et al., 1999).

LONG-TERM OUTCOME

The longest follow-up information available for patients with Hirschsprung's disease who have undergone pull-through procedures was reported by Swenson et al. in 1985. The long-term functional results were excellent, with no cases of impotence or urinary incontinence, and a 1.4% incidence of chronic fecal soiling. Normal bowel habits were experienced by 89.7% of these patients. However, these results have not been reproduced by other surgeons performing Swenson's operation. This has led to the more common use of the Soave or Duhamel procedures.

There is growing appreciation of the potential complications observed during long-term follow-up of patients with Hirschsprung's disease. Up to 23% of patients experience enterocolitis despite this pull-through procedure (Surana et al., 1994; Teitelbaum and Coran, 1998; Menezes et al., 2006). Patients with Down syndrome appear to be at increased risk for this complication (Teitelbaum, 1997; Teitelbaum and Coran, 1998; Menezes et al., 2006). The incidence of fecal incontinence ranges from 3% to 10% (Menezes et al., 2006; Swenson et al., 1985). The incidence of constipation following pull-through procedures for Hirschsprung's disease ranges from 6% to 34% (Puri and Nixon, 1977; Quinn et al., 1992; Rescorla et al., 1992; Marty et al., 1995; Yanchar and Soucy, 1999; Saleh et al., 2004). A consistent observation is that bowel function continues to improve with time, regardless of the type of pull-through procedure performed (Menezes et al., 2006).

GENETICS AND RECURRENCE RISK

There is good evidence for a genetic predisposition to Hirschsprung's disease. Siblings of female index patients have 360 times the risk of developing Hirschsprung's disease than that of the general population (recurrence risk, 7.2%). Siblings of male index patients have a risk of the disease 130 times that of the general population (recurrence risk, 2.6%). The proportion of affected siblings also increases when the index patient has a "long" aganglionic segment extending beyond the sigmoid colon (Swenson, 1950; Duhamel, 1964; Passarge, 1967; Carter et al., 1981; Raffensperger, 1990).

It is estimated that mutations in the *RET* proto-oncogene may account for as many as 20% of cases of Hirschsprung's disease (Martucciello and Holschneider, 1998). The association with Down syndrome and other chromosomal abnormalities also suggests a genetic component to the cause of some cases of Hirschsprung's disease. Trisomy 21 is the most common chromosomal abnormality associated with Hirschsprung's disease, occurring in 4.5% to 16% of cases (Polley and Coran, 1986; Puri, 1993; Menezes et al., 2006). Other chromosomal abnormalities associated with Hirschsprung's disease include partial trisomies of 22q11 and 11q23 (Beedgen et al., 1986); deletion of 2p22 in combination with a reciprocal translation (Webb et al., 1988); trisomy 18 mosaicism (Passarge, 1973); and interstitial deletions of 13q (Kiss and Osztovics, 1989; Lamont et al., 1989; Bottani et al., 1991) and 10q (Martucciello et al., 1992; Luo et al., 1993; Fewtrell et al., 1994).

Familial cases of Hirschsprung's disease have been described. Richardson and Brown (1962) reviewed 54 cases in 21 families, including 1 family in which 5 of 6 sons from the same mother, but with 3 different fathers, had Hirschsprung's disease. Bodian et al., (1951) estimated the probability of producing a second male sibling with the disease at 20%. In a large Texas cohort, Reyna described 6 affected members in a 54 member, five-generation pedigree. He suggested autosomal dominant inheritance with variable expression of the phenotype. The incidence of familial Hirschsprung's disease, however, is only on the order of 3% to 7% of total cases (Reyna, 1994). Klein (1964) suggested that males and females are equally affected with long aganglionic segments,

but males are frequently affected with short-segment aganglionosis. They estimated the probability of a second child with Hirschsprung's disease to be 5% if male, but less than 1% if female, with an overall risk of 4% for short-segment cases. The risk for either sex following birth of a child with long-segment Hirschsprung's disease, however, is 12.5% (Klein, 1964).

Complex segregation analysis performed on multiple families seems to indicate two different patterns of inheritance in Hirschsprung's disease. For families in which there is long-segment aganglionosis extending beyond the sigmoid colon, the mode of inheritance appears to be autosomal dominant, with variable expression of the phenotype. For families affected by short-segment aganglionosis, the inheritance pattern is either multifactorial or due to a recessive gene with very low penetrance (Badner et al., 1990).

Isolated Hirschsprung's disease has complex non-Mendelian inheritance. The major susceptibility genes include the *RET* proto-oncogene, on chromosome band 10q11, the glial cell line–derived neurotrophic factor (GDNF) (Angrist et al., 1993; 1996; Ivanchuk et al., 1996; Solomon et al., 1996), the endothelin-B receptor (EDNRB) and its ligand endothelin-3 (Edery et al., 1996; Hofstra et al., 1996; Puffenberger et al., 1996). These susceptibility genes do not account for the etiology of aganglionosis in many patients, especially sporadic cases. A search continues for other candidate susceptibility genes (Kusafuha and Puri, 1998).

Hirschsprung's disease is considered today to be a sex-modified multifactorial congenital malformation with an overall recurrence risk in siblings of a proband to be 4% (Amiel et al., 2008). A greater risk for recurrence would be expected if the proband is female with long segment Hirschsprung's disease (Edery et al., 1994). As a neurocristopathy, Hirschsprung's disease is associated with a number of other neurocristopathies including multiple endocrine neoplasia type II (MEN2), neuroblastoma, conotruncal heart defects, and Waardenburg syndromes (see Table 75-1).

76 CHAPTER Imperforate Anus

Key Points

- Incidence is 1 in 5,000 livebirths. Has been linked to maternal diabetes, thalidomide, ethanol, and assisted reproductive technology.
- Imperforate anus is difficult to diagnose by prenatal sonographic studies.
- Sonographic findings that may be due to imperforate anus include transient bowel dilation in first trimester, intraluminal calcifications in the colon, and persistent distal bowel dilation later in gestation.
- Fetal MRI may be an important adjunct to ultrasound examination if anorectal malformation is suspected.
- 50% of anorectal malformations have associated anomalies of the spine, limbs, genitourinary system, trachea, esophagus and the heart. Echocardiogram is indicated.
- Associated with many syndromes and chromosome abnormalities. Amniocentesis is indicated for fetal karyotype.
- Delivery should occur in a tertiary care center with pediatric surgical, radiologic, and genetic expertise available.
- Bowel continence is usually achieved in 90% of patients.

CONDITION

Imperforate anus has been recognized since antiquity, but has only been treatable in all of its forms in the latter half of the past century. The first surgical anoplasty for a low-type of imperforate anus was performed by Amussat in Paris in 1835. The next significant advance did not occur until the work of Stephens, who described a combined sacral and abdominal perineal approach based on cadaveric dissections. This highlighted the importance of the puborectolia sling (Stephens, 1953). The modern approach to reconstruction of imperforate anus was pioneered by deVries and Pena in 1982, with the posterior sagittal approach to the whole spectrum of anorectal malformations using the posterior sagittal anorectoplasty (PSARP) (deVries and Pena, 1982; Pena and deVries, 1982).

Anomalies of the anus and rectum have usually been explained on the basis of an arrest of the caudal descent of the urorectal septum toward the cloacal membrane between 4 and 8 weeks of gestation (Fitzgerald and Fitzgerald, 1994). At 4 to 6 weeks the cloacal membrane becomes partitioned into the anterior urogenital sinus and the posterior anorectum by the cranial to caudal growth of mesoderm-derived urorectal septum. The urorectal septum fuses with the cloacal membrane at what then becomes the perineal body (Paidas and Pena, 1996). The mesoderm-derived urorectal septum is composed of the midline Tournex fold and two lateral Rathke folds. The lower third of the anal canal is derived from the ectoderm of the anal pit. Fusion of the hindgut mesoderm with the ectoderm occurs at the dentate line. Failure of Rathke folds to develop results in arrest of the inferior urorectal septum, resulting in a rectourethral fistula in the male and a persistent cloaca in the female. This arrest in Rathke folds usually occurs just below the paramesonephric duct, but a more caudal arrest in Rathke folds could result in a high rectovaginal fistula in a female. Failure of both Rathke and Tourneaux folds in males results in rectovesicular fistulas at the bladder neck. In the female it is more likely to result in cloacal anomaly or duplicated vagina and uterus (Paidas and Pena, 1996). The malalignment of Tourneaux and Rathke folds may also result in rectourethral fistula in males and vestibular fistula in females. Isolated imperforate anus without a fistula occurs from failure of the anal pit to form, and despite normal descent of Tourneaux and Rathke folds, the lack of an ectodermal anal pit results in imperforate anus. Failure of the anal membrane to resorb or incomplete resorption despite formation of the anal pit results in rectal atresia or stenosis, respectively. Defects in mesoderm at the level of the perineal body are thought to result in perineal fistula.

An alternative theory of the embryologic origin of anorectal malformation focuses on the dorsal cloacal membrane in observations in pigs with anorectal malformations (Van der Putte, 1986; Van der Putte and Neeteson, 1984). Van der Putte suggests that the division of the anal and urogenital systems is the result of a marked alteration in the shape of the cloaca by disproportionately strong growth of the mantle mesenchyme surrounding the urogenital compartment (Van der Putte, 2006).

As many as 50% of cases of anorectal malformations have associated anomalies (Table 76-1). Spinal or skeletal anomalies are present in 50% of cases, genitourinary anomalies in 58%, tracheoesophageal fistula in 10%, and cardiac anomalies in 5% (Sanders, 1996; Stoll et al., 2007). Imperforate anus is part of the VACTERL association and is not uncommon in trisomy 21 (Torres et al., 1998).

INCIDENCE

The incidence of imperforate anus is 1 in 5000 livebirths (Boocock and Donnai, 1987; Cuschieri and EUROCAT Working Group, 2001; Kiely and Pena, 1998; Schwoebel, 1984; Stephens and Smith, 1971). Most reports note a male preponderance of between 55% and 65% of cases (Kiely and Pena, 1998; Stephens, 1953; Weinstein, 1965). Imperforate anus has been linked to maternal diabetes mellitus, thalidomide exposure, ethanol intake, and assisted reproductive technology (Midrio et al., 2006).

SONOGRAPHIC FINDINGS

It is unusual to make a diagnosis of imperforate anus on a prenatal sonographic examination. In a series of 69 cases of imperforate anus, only 11 (15.9%) were diagnosed prenatally (Brantberg et al., 2006). Similarly, Livingston et al. (2006) found that in a series of 95 children diagnosed postnatally with anorectal malformations, the correct diagnosis was made by antenatal sonography in only one child. Sanders (1996) has noted that the anus can be seen in the normal fetus as an echogenic dot on a transverse view at the level of the genitalia. He notes that this dot is absent in cases of imperforate anus. The reliability of the absence of this echogenic dot is unknown. It likely represents the echogenic sphincter complex, which may be present even if there is imperforate anus. More commonly, a dilated distal colon may be observed in the fetal pelvis (Guzman et al., 1995; Taipale et al., 2005) (Figure 76-1). But as Kaponis et al. (2006) have observed, bowel dilatation in anorectal malformations may be transient, occurring only during the first trimester (Gilbert et al., 2006).

Harris et al. (1987) reviewed sonographic features of 12 cases of anorectal atresia and found evidence of bowel dilatation in the distal colon in 5 of the 12 cases. The features of distal bowel obstruction become more obvious as the fetus approaches term. The earliest reported prenatal diagnosis of imperforate anus is 29 weeks of gestation; however, isolated transient bowel dilation which proved to be due to anorectal malformation has been observed as early as 12 weeks of gestation (Gilbert et al., 2006; Kaponis et al., 2006; Lam et al., 2002).

Because of the distal level of obstruction, some authors found it unusual that any degree of bowel dilatation was detectable and blamed the rectourethral or rectovesical fistula as a cause of bowel dilatation (Goldstein, 1994). In cases in which an anorectal malformation is suspected, amniotic fluid levels of digestive enzymes gammaglutamyl transpeptidase, aminopeptidase M, and intestinal alkaline phosphatase were found to be less than the first percentile (Bourdelat et al., 2001).

Several authors have reported intraluminal colonic calcifications in imperforate anus (Bean et al., 1978; Grant et al., 1990; Sholen et al., 1983). This is presumed to be due to urine refluxing via the associated rectourethral fistula and precipitating as calcified meconium. There are a number of sonographically detectable abnormalities that may be seen in association with imperforate anus, including renal agenesis, renal dysplasia, horseshoe kidney, uterine duplications, cardiovascular, central venous system, and gastrointestinal and skeletal system anomalies.

Table 76-1

Anomalies Associated with Anorectal Malformations (ARM)

Syndrome	Prominent Features	Inheritance Pattern
ARM alone		
Isolated imperforate anus	None	Heterogeneous, AR, XLR, and AD
ARM and neurologic anomalies		
Anosacral defect	Anterior sacral meningocele, teratoma, or cyst Macrocephaly, broad forehead, frontal hair upswept, hypotonia, mental retardation	Heterogeneous, AD, XLD, FG, XL
ARM and skeletal anomalies		
Baller–Gerold	Craniosynostosis, radial defect, short stature	AR
IVIC	Radial defects, strabismus, thrombocytopenia, deafness	AD
Jarcho–Levin	Rib and vertebral defects, respiratory failure in infancy	AR
Presacral teratoma	Sacral dysgenesis	AD
Saldino–Noonan	Short ribs, short limbs, postaxial polydactyly, visceral abnormalities, lethality	AR
Say	Preaxial polydactyly, malformed vertebral bodies and ribs (may be the same as PIV syndrome)	Sporadic
Thanatophoric dysplasia	Micromelia, platyspondyly, early death	Sporadic
Townes–Brocks	Deafness, triphalangeal thumb, overfolded helices, flat feet	AD
ARM and chromosomal anomalies		
Cat eye	Ocular coloboma; ear, cardiac, and renal anomalies; variable mental retardation	Extra small marker chromosome derived from 22
Tetrasomy 12p	Coarse face, sparse anterior scalp hair, hypertelorism, epicanthus, hypotonia, hypomelanotic spots, severe mental retardation	Chromosomal anomaly
ARM and cardiovascular anomalies		
Fuhrmann	Polydactyly, heart defect	Uncertain
ARM and urogenital anomalies		
Hypertelorism–hypospadias	Hypertelorism, hypospadias (may be the same as Opitz G syndrome)	XLR
Opitz BBB	Same as Opitz G	
Opitz G	Hypertelorism, hypospadias, swallowing defects	AD
ARM and multiple anomalies		
Ankyloblepharon filiforme	Fused eyelids and normal globe endocardial cushion defects, fused digits, cleft lip and palate, esophageal atresia	AD
Adnatum ASP association	Anal anomalies, sacral defect, presacral mass (teratoma, cyst, or meningomyelocele)	Chromosomal anomaly
Axial mesodermal defect	Sacral dysgenesis; dysfunction of lower limbs, bladder, and bowel; aphalangy; spinal and rib abnormalities	AR
Caudal regression	Dysgenesis of lower spine; variable dysfunction of bladder, bowel, and lower limbs	Heterogeneous, maternal diabetes mellitus in some cases AD

(*continued*)

Table 76-1

Anomalies Associated with Anorectal Malformations (ARM) (*Continued*)

Syndrome	Prominent Features	Inheritance Pattern
ARM and multiple anomalies (*continued*)		
Christian skeletal dysplasia	Metopic ridge, cervical fusion, dysplastic spine, abducens palsy, mental retardation	XLR
Cryptophthalmos	Palate, ear, renal, laryngeal, genital, digital, and eye malformations	AR
Diabetes, maternal	Fetal overgrowth; increased incidence of neural tube defects, cardiac anomalies, caudal dysgenesis, and renal defects	Exposure of abnormal glucose metabolism during pregnancy
Johanson–Blizzard	Hypoplastic alae nasi, exocrine pancreatic insufficiency, deafness, hypothyroidism	AR
Kaufman–McCusick	Congenital heart defects, polydactyly, hydrometrocolpos	AR
Lowe	Sensorineural deafness, nephritis	AD
Meckel	Encephalocele, polydactyly, cystic kidneys	AR
OEIS	Omphalocele, exstrophy of the bladder, imperforate anus, spinal defects	Uncertain, may have vascular cause
Pallister–Hall	Hypophthalmic hemartoblastoma, hypopituitarism, postaxial polydactyly	Sporadic
Pallister: ulnar mammary	Ulnar ray defects, delayed puberty, oligodactyly or polydactyly, hypoplasia of apocrine glands and breasts, genital anomalies	AD
PIV	Polydactyly, imperforate anus, vertebral anomalies	Sporadic
Potter variant	Renal, lung, thymic, parathyroid, dysplasia	AR (?) chromosomal anomaly
Rieger	Ocular anterior chamber anomalies, hypodontia	AD
Sirenomelia	Single, lower limb, renal agenesis, genital agenesis	Sporadic, based on vascular steal
VACTERL	Vertebral, anal, cardiac, tracheoesophageal, renal, and radial limb defects	Sporadic

KEY: AD = autosomal dominant; AR = autosomal recessive; ASP = anal anomalies, sacral defect, presacral mass; IVIC = Instituto Venezolano de Investigaciones Cientificas; OEIS = omphalocele, exstrophy of bladder, imperforate anus, spinal defects; PIV = polydactyly, imperforate anus, vertebral anomalies; XL = X-linked; XLD = X-linked dominant; XLR = X-linked recessive.

Figure 76-1 Prenatal sonographic image of a fetus who was diagnosed at birth with imperforate anus. Mild colonic distention was noted prenatally.

DIFFERENTIAL DIAGNOSIS

The main differential diagnosis for anorectal atresia includes colonic atresia, Hirschsprung's disease, meconium plug syndrome (Nyberg et al., 1987), distal small-bowel atresia (Vermesch et al., 1986), hydrometrocolpos, ovarian cyst, obstructive uropathy, megacystic-microcolon hypoperistalsis syndrome, urachal cyst, and persistent cloaca (Paidas and Pena, 1996).

Imperforate anus may also occur as part of the VACTERL association. When associated with esophageal atresia, increased amniotic fluid volume and an absent stomach bubble may be noted. Imperforate anus occurs in trisomies 18 and 21; sonographic features of these syndromes should be ruled out (see Chapters 130 and 131). Recently, MRI has become an important adjunct in the prenatal diagnosis of complex malformations including anorectal malformations (Livingston et al., 2006) (Figure 76-2).

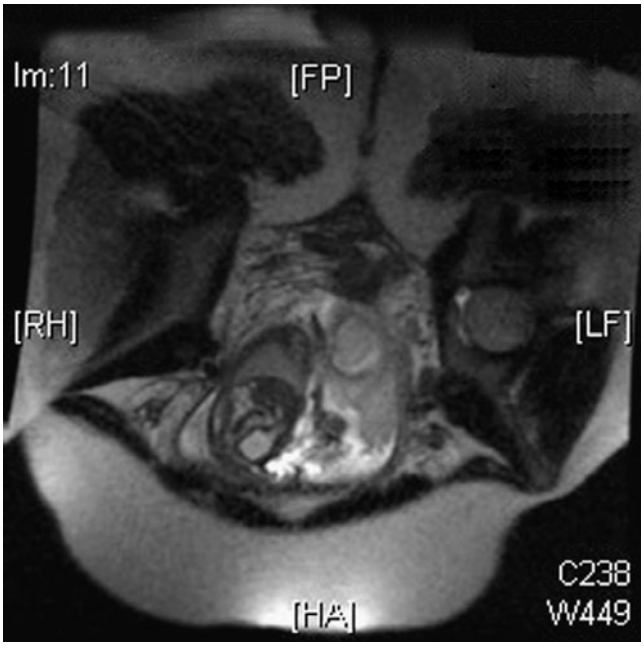

Figure 76-2 Dilated rectum that does not reach the perineum on T2 weighted sagittal image of a fetus with imperforate anus.

ANTENATAL NATURAL HISTORY

Only a few cases of imperforate anus have been prospectively diagnosed prenatally (Bean et al., 1978; Guzman et al., 1995; Harris et al., 1987; Grant et al., 1990; Nyberg et al., 1987). If isolated, the finding of anorectal atresia should not have any direct bearing on the outcome of the pregnancy. If seen as part of the VACTERL association, however, polyhydramnios may appear after 28 weeks of gestation if associated esophageal atresia is present (Greenwood et al., 1975; Smith et al., 1988).

FETAL INTERVENTION

There are no fetal interventions indicated for imperforate anus.

MANAGEMENT OF PREGNANCY

A fetus in which imperforate anus is suspected should undergo a targeted sonographic examination to rule out associated anomalies. In particular, a detailed examination of the genitourinary tract is indicated because of the possibility of associated renal agenesis, renal dysplasia, and horseshoe kidney. Careful examinations of the central nervous system and spine, as well as the gastrointestinal tract, are indicated. Because of the increased risk of structural heart disease, an echocardiogram should be obtained. Because there is also an increased incidence of chromosome abnormalites, such as trisomies 18 and 21, cat eye syndrome, and tetrasomy 12p, amniocentesis for karyotype analysis is recommended. The nature of this anomaly does not alter the indications for delivery. Vaginal delivery should be planned except when standard obstetric indications suggest cesarean delivery. Because the child will require immediate postnatal evaluation and treatment, delivery in a tertiary care center with pediatric radiologists, surgeons, and dysmorphologists available is advisable. Because of the complex nature of this anomaly and the extensive nature of the reconstructive surgery, prenatal consultation with a pediatric surgeon is recommended.

TREATMENT OF THE NEWBORN

The newborn with imperforate anus should be expeditiously evaluated to rule out serious potential associated malformations. Plain chest, abdominal, and pelvic radiographs should be obtained to exclude vertebral anomalies and assess the sacrum, which has a direct bearing on the prognosis in imperforate anus. An abdominal ultrasound examination should be obtained to evaluate the genitourinary tract and the level of the rectal pouch (Willital, 1971).

Once the infant's respiratory status has been assessed, a nasogastric tube should be passed into the stomach to exclude the presence of esophageal atresia. The infant's perineum should be inspected to confirm imperforate anus and look for signs of low imperforate anus, rectoperineal, or rectovestibular fistula (Figure 76-3). The adequacy of the sphincter complex can be evaluated at the bedside by eliciting a reflex contraction by gently scraping the perineum with a swab.

The infant should receive nothing orally and should receive intravenous fluids until the evaluation is complete and a decision is made to proceed with perineal anoplasty (in low lesions) or colostomy (for intermediate and high lesions). An echocardiogram should be obtained, as cardiovascular anomalies are frequently associated with imperforate anus (Boocock and Donnai, 1987; Greenwood et al., 1975; Templeton and Ditesheim, 1985). Duodenal obstruction due to either atresia or to malrotation occurs in 1% to 2% of cases (Greenwood et al., 1975; Partridge and Gough, 1961). Hirschsprung's disease also occurs in association with imperforate anus (Arbell et al., 2006; Kiesewetter et al., 1965; Wangensteen and Rice, 1930).

A flat perineum with missing sacral segments on the pelvic radiograph and poor contraction following perineal scratch suggests a high imperforate anus. In males, passage of meconium via the urethra suggests an intermediate or high lesion. Meconium passing through a perineal fistula suggests a low imperforate anus. After 24 hours, air should have reached the distal rectum. A plain lateral radiograph can be obtained with the body prone and the hips raised, a modification of the so-called invertogram (Narasimharao et al., 1983). A gap of 1 cm or more between the rectum and the skin of the perineum usually represents a high lesion, while a gap of less than 5 mm usually indicates a low lesion.

The infant should remain on prophylactic antibiotics until vesicoureteral reflux is ruled out. Voiding cystourethrography will exclude or confirm vesicoureteral reflux, and may also demonstrate a rectovesical fistula. An ultrasound examination or magnetic resonance imaging (MRI) scan of the

Figure 76-3 Postnatal appearance of the female infant whose prenatal sonographic image is shown in Figure 76-1.

spine should also be obtained to exclude a tethered spinal cord.

SURGICAL TREATMENT

In low imperforate anus several options for management are available. In cases of perineal fistula some form of anal transposition, Y-V anoplasty, or a limited posterior sagittal anorectoplasty are treatment possibilities (Nixon and Puri, 1977; Stone, 1936).

In cases of intermediate and high levels of imperforate anus, a diverting colostomy is performed in the first few days of life. A loop colostomy or colostomy with mucous fistula will allow an antegrade contrast study to determine the level of rectourethral fistula. Anorectal reconstruction can then be carried out at 4 to 8 weeks of age, using the posterior anorectoplasty technique described by deVries and Pena, (1982).

LONG-TERM OUTCOME

The mortality rate associated with imperforate anus is low usually due to associated cardiac or renal abnormalities (Kiely and Pena, 1998). In addition to the usual postoperative complications, voiding dysfunction, stenosis, mucosal prolapse, and constipation may occur. It is uncertain if voiding dysfunction is a consequence of the surgery or reflects a preexisting problem (Kazizoke, 1994; Sheldon, 1991). Anal stenosis may occur in up to 30% of cases but responds to anal dilatations (Nixon and Puri, 1977). Mucosal prolapse may occur after PSARP but requires only trimming the mucosa back in cases that are symptomatic. Constipation is a very common problem in patients following reconstruction for imperforate anus, but this usually responds to medical management.

Continence is usually achieved in about 90% of patients with a low imperforate anus (Matley, 1990; Nixon and Puri, 1977; Rintala et al., 1991). Total continence in high imperforate anus has been disappointing, with rates varying from 0% for cases of bladder neck or vaginal fistula to 26% of cases with a prostatic fistula. Cases of intermediate-level imperforate anus with bulbar or vestibular fistula have continence rates of 34% and 66%, respectively. Voluntary bowel movements occur in cases of intermediate-level imperforate anus at rates of 80% to 93%.

In cases in which continence cannot be achieved, either because of inadequate sphincter complex or inadequate innervation, the Malone antegrade continent enema or MACE procedure may provide a means of staying clean and avoiding a colostomy (Levitt et al., 1997; Malone et al., 1990). In this procedure the appendix is brought out as a catheterizable stoma to deliver daily antegrade enemas to clear the colon and prevent soilage during the day (Squire, 1993).

GENETICS AND RECURRENCE RISK

Imperforate anus occurs in association with a number of syndromes (see Table 76-1). Recurrence risks will depend on whether the anorectal atresia is isolated or syndromic. Most isolated cases are thought to be sporadic, but rare familial cases have been described. Anorectal anomalies may occur as part of a syndrome of multiple malformations (Pinsky, 1978). These patterns of malformations have occurred in clusters, suggesting an autosomal dominant trait that has been transmitted to succeeding generations (Nour et al., 1989; Schwoebel, 1984).

Echogenic Kidneys

77
CHAPTER

Key Points

- Echogenic kidneys can be a normal variant but are also seen in association with renal dysplasia, chromosomal abnormality, adult and fetal polycystic disease, Pearlman syndrome, Beckwith–Wiedemann syndrome, and CMV infection.
- The incidence of echogenic kidneys has been estimated at 1.6 cases per 1000 sonograms.
- Kidneys are considered echogenic if the reflectivity of the renal parenchyma is greater than the reflectivity of the liver.
- Once diagnosed, other sonographic features of aneuploidy, renal anomalies, and CMC infection should be sought.
- Consider genetic amniocentesis, TORCH titers, and fetal MRI to better evaluate the genitourinary tract and renal parenchyma.

CONDITION

There are some conditions that render the renal parenchyma echogenic on ultrasound examination. While increased renal echogenicity can be a normal variant in children, it has been associated with nephrotic syndrome, glomerulonephritis, and renal dysplasia (Krensky et al., 1983; Brenbridge et al., 1986; Cramer et al., 1986; Kraus et al., 1990). Premature infants also have an increased incidence of increased renal echogenicity (Benacerraf, 1998). While increased echogenicity is a subjective assessment, kidneys that are brighter than liver are considered to be echogenic. This becomes a potential indicator of fetal disease because of the association of this finding with chromosomal abnormality, adult and infantile polycystic kidney disease, Pearlman syndrome, Beckwith–Wiedemann syndrome, and cytomegalovirus infection. The cause of the increased echogenicity of the kidney in these conditions is unknown.

INCIDENCE

Little data are available to estimate a true incidence of echogenic kidneys in the fetus, in either normal fetuses or those with underlying pathology. However, De La Vega and Torres (2005) in a retrospective review of prenatally diagnosed renal disease found 13 cases among 7714 sonographic studies for an incidence of 0.16% or 1.6 cases per 1000 sonograms (Han et al., 2003).

SONOGRAPHIC FINDINGS

The kidneys should be considered to be echogenic if the reflectivity of the renal parenchyma is greater than the reflectivity of the liver (Figure 77-1). Once identified, it is important to note other possible associated findings that would aid in the differential diagnosis. It is important to look for other

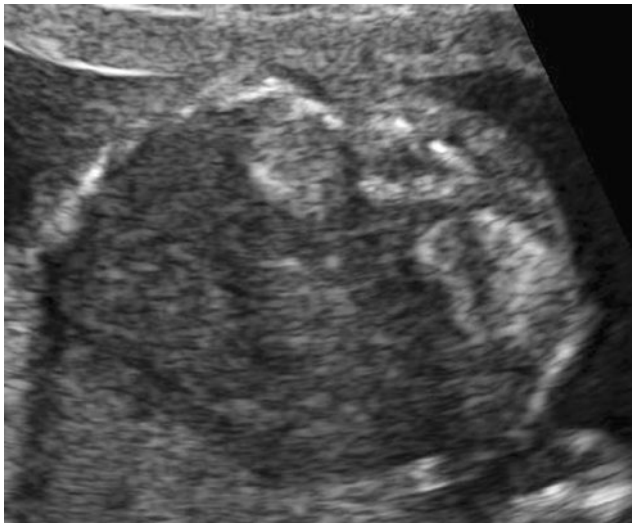

Figure 77-1 Axial image through fetal abdomen demonstrating bilateral echogenic kidneys.

sonographic features that are associated with aneuploidy, especially trisomy 13, including ventriculomegaly, holoprosencephaly, agenesis of the corpus callosum, cleft lip or palate, cyclasia, or microphthalmia. Because of the association of echogenic kidneys with cytomegalovirus infection, attention should be paid to the presence of intracranial calcifications, echogenic bowel, ascites, hydrops, or cardiomegaly (Choong et al., 1993). If the possible renal abnormalities seen with echogenic kidneys (including severe obstructive uropathy at any level from the bladder outlet to the ureteropelvic junction) occur during the second trimester, they can result in increased echogenicity from renal dysplasia. The kidneys in adult and infantile polycystic kidney disease can also be echogenic, but they are usually much larger than normal and may lack normal renal architecture and have severe associated oligohydramnios (see Chapter 79).

DIFFERENTIAL DIAGNOSIS

As noted above, it is important to remember that increased renal echogenicity is a normal variant and there may be no underlying pathology. The differential diagnosis of echogenic kidneys includes cytomegalovirus infection, aneuploidy, particularly trisomy 13, other chromosomal abnormalities such as partial trisomy 10, adult and infantile forms of polycystic kidney disease, and renal dysplasia secondary to obstructive uropathy (see Table 77-1).

ANTENATAL NATURAL HISTORY

What is known about the antenatal natural history of echogenic kidneys is based on two small retrospective reports. Chitty et al. (1991) reported five fetuses with enlarged echogenic kidneys in which the amniotic fluid volume was preserved. The causes of renal echogenicity in their cases included infantile or autosomal recessive polycystic kidney disease, adult or autosomal dominant polycystic kidney disease, trisomy 13, Pearlman syndrome, and cystic renal dysplasia. Estroff et al. (1991) reported their experience with 19 patients with echogenic kidneys in which the process was bilateral in 14 and unilateral in 5 patients. This group excluded cases of renal dysplasia induced by obstructive uropathy as a cause of increased echogenicity. Surprisingly, only 21% of these fetuses proved to be normal at birth. Five fetuses (26%) did not survive because of associated oligohydramnios in cases of infantile polycystic kidney disease or bilateral multicystic dysplastic kidneys. There was a 53% survival rate in this series. However, all infants had abnormalities, including unilateral renal dysplasia, unilateral multicystic dysplastic kidney and hydronephrosis. The most important prognostic factor in this report was the presence or absence of oligohydramnios. If the amniotic fluid volume is preserved and the fetus is otherwise normal except for echogenic kidneys of uncertain cause, the prognosis is good but the infant will be expected to have nonlethal renal disease. In contrast, in cases of echogenic kidneys associated with oligohydramnios the survival rate is dismal (Benacerraf, 1998).

Table 77-1

Differential Diagnosis of Echogenic Kidneys

1. Cystic kidney diseases
   - Autosomal recessive polycystic kidney disease
   - Autosomal positive polycystic kidney disease
   - Multicystic dysplastic kidney disease
2. Kidney neoplasms*
   - Congenital mesoblastic nephroma
   - Wilms tumors
3. Infectious agents

MANAGEMENT OF PREGNANCY

The sonographic detection of echogenic kidneys indicates the need for a targeted fetal anatomy scan to be performed to

evaluate potentially associated conditions. In particular, it is important to evaluate the amniotic fluid volume and genitourinary tract for signs of obstructive uropathy or features of adult or infantile polycystic kidney disease. In addition, features of cytomegalovirus infection should be sought. Because of reported cases of chromosomal abnormality associated with echogenic kidney, we recommend that a genetic amniocentesis be performed (Chitty et al., 1991; Estroff et al., 1991). Because of the prognostic significance of the development of oligohydramnios in patients with echogenic kidneys, serial scans are indicated. Estroff et al. (1991) noted that echogenic kidneys associated with moderate-to-severe oligohydramnios have an extremely poor postnatal outcome. In contrast, normal amniotic fluid volume in a fetus with echogenic kidney was associated with a good prognosis. The most important aspect of management of a pregnancy in which echogenic kidneys are detected is to appropriately counsel the parents and systematically exclude potential causes. TORCH titers should be obtained. A family history is essential to rule out polycystic kidney disease. In addition, maternal and paternal renal ultrasound examinations should be performed because of the high prevalence of adult polycystic kidney disease in the general population (see Chapter 79). The infantile or recessive form of polycystic kidney disease is more commonly observed prenatally, and a fetus with large echogenic kidneys is more likely to have the infantile form if both parents have normal renal ultrasound examinations.

Decisions regarding mode and site of delivery can be deferred until a definitive diagnosis is made or serial scans have demonstrated oligohydramnios or preserved amniotic fluid volume.

FETAL INTERVENTION

There are no fetal interventions for echogenic kidneys.

TREATMENT OF THE NEWBORN

The newborn noted to have echogenic kidneys in utero should undergo careful postnatal examination to exclude potential underlying causes. If a karyotype has not been obtained prenatally, it should be done postnatally. A renal ultrasound examination should be obtained to assess the size and echogenicity of the kidney. If hydronephrosis of any degree is detected, the infant should also undergo voiding cystoureterography (VCUG) and a diuretic renal scan to assess function and to evaluate for obstruction and vesicoureteral reflux (see Chapters 80, 81, 82, 83). By 36 to 48 hours of postnatal age, the newborn's serum creatinine and blood urea nitrogen levels should reflect the infant's renal function. The newborn's blood pressure should be carefully monitored in cases of adult or autosomal dominant polycystic kidney disease (Cole et al., 1997) (see Chapter 79).

LONG-TERM OUTCOME

Tsatsaris et al. (2002) in a prospective cohort study of 43 cases, prenatally detected isolated bilateral echogenic kidneys and followed them for 34 to 132 months. There were 20 autosomal recessive, 8 autosomal dominant polycystic kidney diseases, 9 other renal disorders, and 6 symptom-free survivors without etiological diagnosis. There were 19 terminations of pregnancy, 5 neonatal deaths, and 19 survivors, of whom 14 had normal renal function 3 had mild and 2 had end-stage renal failure. There were no survivors among those with severe oligohydramnios and enlarged fetal kidneys measuring more than 4 SD above the mean ($n = 14$, 10 terminations and 4 neonatal deaths), whereas of the 17 with normal amniotic fluid volume and kidneys measuring less than 4 SD above the mean, 14 survived of whom 9 were symptom free. As this is a sonographic finding and not a specific etiologic diagnosis, the reader is referred to chapters on the specific underlying diagnoses, including polycystic kidneys (see Chapter 79), hydronephrosis (see Chapters 80, 81, 82, 83), multicystic dysplastic kidneys (see Chapter 78), and trisomy 13 (see Chapter 129).

GENETICS AND RECURRENCE RISK

The risk of recurrence of echogenic kidney depends on whether the underlying cause is sporadic (cytomegalovirus infection, trisomy 13, Beckwith–Wiedemann syndrome) or has a recognized pattern of inheritance. Infantile polycystic kidney disease is inherited as an autosomal recessive condition, and there is a 25% chance that a subsequent pregnancy will be affected, while the adult form of autosomal dominant polycystic kidney disease has a 50% chance of affecting subsequent fetuses. It is not known what percentage of affected fetuses will present in utero with echogenic kidneys in a subsequent pregnancy. However, in autosomal dominant polycystic kidney disease, families should have blood samples collected for DNA analysis prior to a subsequent pregnancy (Breuning et al., 1990). Once a mutation has been identified in a specific family, prenatal DNA diagnosis is available as early as 10 weeks via chorionic villi sampling (see Chapter 79).

78 CHAPTER Multicystic Dysplastic Kidney

Key Points

- Multicystic dysplastic kidney (MCDK) is a severe renal abnormality associated with atretic ureter and absence of normal renal parenchyma, which is replaced by multiple large noncommunicating cysts.
- MCDK is generally easily diagnosed prenatally, often due to the large size of the kidney and its constituent cysts.
- It is usually unilateral, while the rare cases of bilateral MCDK present as Potters syndrome.
- In almost half of the cases of unilateral MCDK, the contralateral kidney will have associated malformations, the severity of which determines the overall prognosis.
- Management of pregnancy and delivery generally does not need to be changed following the prenatal diagnosis of MCDK.
- While some cases of unilateral MCDK will regress prenatally or in pediatric life, there is no agreement on need for nephrectomy in those cases with persistent MCDK.
- MCDK greater than 6 cm, cases in which the MCDK obstructs the diaphragm or gastrointestinal tract, or cases in which hypertension develops will generally require nephrectomy.

CONDITION

Multicystic dysplastic kidney (MCDK) is the second most common cause of a flank mass in the newborn (Kaplan, 1998). MCDK was first described by Schwartz in a 7-month-old child in 1929 as a "bunch of grapes" replacing the kidney with associated ureteral atresia. Spence (1955) subsequently described MCDK and distinguished it from other cystic renal diseases.

MCDK is an extreme form of dysplasia associated with an atretic ureter. There is often a lack of normal reniform shape, with multiple large cysts and little stroma, giving the "bunch of grapes" appearance. MCDK is typically unilateral, but bilateral MCDKs have been reported in stillborn infants with oligohydramnios and Potter syndrome facies. In unilateral MCDK, the contralateral kidney is normal but at high risk for other abnormalities (Greene et al., 1971; DeKlerk et al., 1977). The contralateral kidney may be affected by

ureteropelvic junction obstruction, vesicoureteral reflux, or obstructive megaureter.

MCDK often presents as an asymptomatic abdominal mass in the neonate (Langino and Martin, 1958). However, currently approximately 85% to 100% of MCDKs are detected by prenatal sonographic examination (Manzoni and Caldamone, 1998; Kuwertz-Broeking et al., 2004). MCDK was often discovered during the course of investigation of other associated congenital anomalies. In particular, esophageal atresia and cardiac anomalies may be associated with MCDK. Other associated nongenitourinary anomalies include anencephaly, hydrocephalus, spina bifida, cleft palate, microphthalmia, duodenal stenosis, tracheoesophageal fistula, and imperforate anus. The pathogenesis of this disorder is poorly understood but is thought to involve failure of the ureteric bud to integrate and branch appropriately into the metanephron during the development of the kidneys (Kitagawa et al., 2000).

INCIDENCE

The incidence of MCDK is estimated at between 1 in 1000 and 1 in 4300 livebirths (Sanders, 1996; Kaplan, 1998). The incidence of bilateral MCDK is estimated at 1 in 10,000 livebirths (Resnick and Vernier, 1981). The male-to-female ratio is 2:1 in contralateral MCDK (Sanders and Hartman, 1984). No estimates are available for the prenatal incidence of MCDK, but it may be more common than the incidence figures above would indicate. It has been also suggested that MCDK is the major cause of apparent unilateral renal agenesis in adults (Aslam and Watson, 2006) as a result of progressive involution.

SONOGRAPHIC FINDINGS

The sonographic features of MCDK include a cystic paraspinal flank mass. The cysts are usually of various sizes, are distributed along the periphery, do not appear to communicate with each other, and are absent of normal renal sinus echos and normal renal parenchyma (Stuck et al., 1982) (Figure 78-1). The large cysts often distort the kidney shape and no normal renal parenchymal tissue is seen (Mahony, 1994). The size and shape of an MCDK may change significantly during the course of gestation (Hashimoto et al., 1986). The cysts may regress or enlarge and then, subsequently, regress in size. Once the condition is identified, the kidney opposite to the MCDK becomes of paramount importance because of the 40% incidence of contralateral anomalies (Kleiner et al., 1986). Preservation of normal amniotic fluid volume suggests normal renal function in the contralateral kidney. However, oligohydramnios and absence of bladder filling suggest a lethal fetal renal disease, which occurs in 30% of fetuses with MCDK. In two-thirds of the cases of oligohydramnios there is bilateral MCDK, and in the remaining third there is renal agenesis.

The development of oligohydramnios in bilateral MCDK may occur as early as 12 weeks of gestation (Stiller et al., 1988). A first trimester ureteropelvic junction obstruction may be observed to progress during the second trimester to MCDK. In approximately 10% of cases of MCDK, the contralateral kidney shows signs of hydronephrosis, often from obstruction at the ureteropelvic junction (Mahony, 1994).

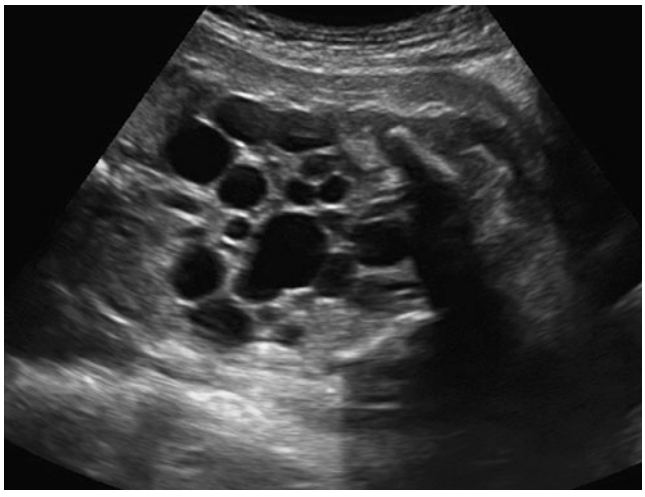

Figure 78-1 Prenatal sonographic image of a fetal kidney in sagittal view demonstrating multiple cysts that do not have a uniform shape and do not communicate, consistent with the diagnosis of multicystic dysplastic kidney.

DIFFERENTIAL DIAGNOSIS

The main differential diagnosis of MCDK includes ureteropelvic junction obstruction, adult or infantile forms of polycystic kidney disease, trisomy 13, and Meckel–Gruber syndrome (D'Alton et al., 1986). Perhaps the most difficult distinction is between ureteropelvic junction obstruction (see Chapter 81) and the hydronephrotic form of MCDK (Rizzo et al., 1987). The sonographic detection of renal parenchymal cysts that communicate with the renal pelvis suggests the diagnosis of ureteropelvic junction obstruction (Romero et al., 1988). In adult polycystic kidney disease (see Chapter 79), the cysts are randomly distributed, in contrast to MCDK, in which the cysts tend to be at the periphery (Sanders, 1996). In Meckel–Gruber syndrome, the cysts are small, uniform, and scattered throughout the kidney. In contrast to MCDK, the kidneys in infantile polycystic kidney disease are very large and echogenic and discrete cysts are not visible (see Chapter 79). In trisomy 13, the kidney is brightly echogenic and has small cysts scattered in the renal parenchyma. The appearance of MCDK should be distinguished from Wilms' tumor or hamartoma, which may have areas of cystic necrosis (Aslam and Watson, 2006).

ANTENATAL NATURAL HISTORY

The natural history of MCDK is becoming better understood, based on studies of serial sonographic examinations of fetuses

with MCDK. Among 64 fetuses diagnosed prenatally with MCDK at the Hospital for Sick Children in London, 33% were diagnosed at 18 to 20 weeks of gestation, 44% between 20 and 30 weeks of gestation, and 33% between 30 and 40 weeks of gestation (Manzoni and Caldamone, 1998). These authors noted that 36% of sonographic examinations were reported as normal on the 18- to 20-week scans, which may indicate that MCDK is easier to diagnose in the latter half of gestation.

In 11% of cases, the MCDK increased in size while in 11% of cases the MCDK disappeared. MCDK can grow to significant proportions, occasionally filling the abdomen. These masses usually regress with time. In cases in which there are bilateral MCDKs, oligohydramnios and absent bladder are observed and this situation is uniformly fatal. In unilateral MCDK, there may be abnormalities in the contralateral system or other nongenitourinary anomalies may be present. However, if renal function is preserved in the contralateral kidney, the prognosis is excellent. One situation that requires careful monitoring is MCDK associated with ureteropelvic junction obstruction in the contralateral kidney. If the obstruction is of high grade, there may be reduced amniotic fluid volume and renal dysplasia may result in the obstructed kidney.

MANAGEMENT OF PREGNANCY

The fetus identified with MCDK should undergo a targeted sonographic examination to evaluate possible associated genitourinary and nongenitourinary anomalies (Table 78-1). Amniocentesis for karyotype analysis should be offered in all cases of MCDK because of the potential for associated chromosomal abnormalities. In cases of bilateral MCDK or unilateral MCDK with contralateral renal agenesis, if diagnosed prior to 24 weeks of gestation, termination of the pregnancy can be considered. If the mother chooses to carry the pregnancy to term, there should be no intervention for fetal distress and neonatologists should be aware of the diagnosis so that no inappropriate attempts at resuscitation are undertaken. In the case of unilateral MCDK, the prognosis depends on other associated abnormalities. Isolated MCDKs have a uniformly good prognosis. It is not necessary to change either the timing or site of delivery in such cases and cesarean delivery should be reserved for standard obstetrical indications. In cases of MCDKs associated with contralateral high-grade ureteropelvic junction obstruction, delivery once lung maturity is likely or decompression in utero may be indicated (see below).

FETAL INTERVENTION

The diagnosis of MCDK does not warrant consideration of fetal intervention except in instances that are associated with high-grade obstructive uropathy, involving either the bladder outlet or the contralateral ureteropelvic junction, with associated oligohydramnios. Under such circumstances, vesicoamniotic shunting for bladder outlet obstruction or pelvic–amniotic shunting for high-grade ureteropelvic junction obstruction can be considered. It should be pointed out that experience with such rare clinical scenarios is limited, and so it may be difficult to recommend such intervention in all cases (Kitagawa et al., 2003).

TREATMENT OF THE NEWBORN

In unilateral MCDKs with a normal contralateral kidney, an excellent prognosis is anticipated and no special measures should be required at delivery. However, if oligohydramnios or a contralateral renal abnormality is present, then newborn resuscitation may be complicated by pulmonary hypoplasia. The newborn should be carefully examined to exclude nongenitourinary abnormalities. The following postnatal studies should be considered for each newborn: renal ultrasound examination to confirm the diagnosis, diuretic renal scan to assess function, and voiding cystourethrography (VCUG) to exclude vesicoureteral reflux. Serum creatinine and blood urea nitrogen levels will begin to reflect newborn renal function

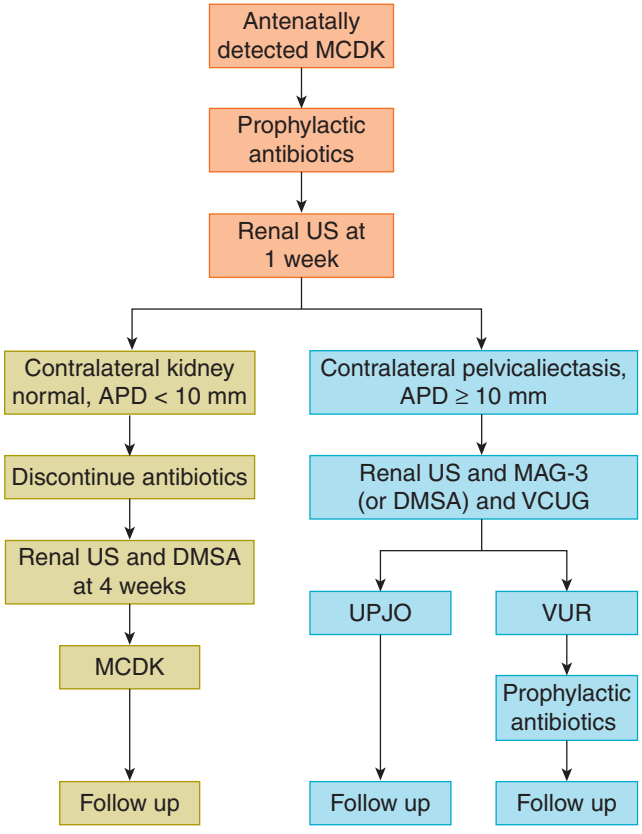

Figure 78-2 Suggested management algorithm for postnatal evaluation of a baby with antenatally detected multicystic dysplasia of the kidney.

after 36 to 48 hours of postnatal age. The infant should be treated with prophylactic antibiotics until vesicoureteral reflux is excluded. Figure 78-2 outlines the management algorithm for postnatal evaluation of a baby with antenatally detected MCDK. If no abnormal pelvic dilation in the contralateral kidney is observed, then follow-up renal ultrasound and DMSA scan should be obtained at 1 month. In contrast, Rabelo et al. reported that spontaneous total involution of MCDKs occurred in 20% and partial involution occurs in 67% (Rabelo et al., 2005). In this study, only those with renal length of ≤62 mm on initial ultrasound had complete involution during follow up (Rabelo et al., 2005). Aslam et al. observed complete involution in 33% during the first 2 years, 47% at 5 years, and 59% at 10 years (Aslam and Watson, 2006).

SURGICAL TREATMENT

See "Long-Term Outcome."

LONG-TERM OUTCOME

Manzoni and Caldamone (1998) compiled the results of 114 patients treated in five series to define the postnatal outcome in MCDKs (Gordon et al., 1988; Rickwood et al., 1992; Gaugh et al., 1995; Webb et al., 1997). Prenatal involution was observed in 6 cases (5%), and there were an additional 16 cases (17.5%) of involution postnatally. Two-thirds of these involutions were observed to occur during the first year of life. Size of the MCDK may influence whether involution occurs. MCDKs less than 5 cm in length will get smaller, disappear, or remain unchanged. Dilation of the contralateral renal pelvis should prompt renal ultrasound, MAG-3 (mercaptoacetyltriglycine-Technetium 99m) or DMSA (technetium dimercaptosuccinic acid), and voiding cystourethrography. If vesicoureteral reflux is found, then the patient should be maintained on prophylactic antibiotics and followed. Similarly, if ureteropelvic junction (UPJ) obstruction is diagnosed, it should be followed closely. Those with MCDK size greater than 6 cm often do not involute. In this study, there was a high incidence of associated genitourinary abnormalities, affecting both the upper and lower urinary tract. Ureteropelvic junction obstruction and megaureter were the most common abnormalities affecting the contralateral kidney. In four cases, renal function in the solitary kidney was already compromised. Hypertension developed in three patients from Manzoni and Caldamone's series, but their blood pressures normalized after nephrectomy. In a review of 29 studies, only 6 cases with MCDK among 1115 cases developed hypertension. Hypertension resolves with nephrectomy in almost all instances (Snodgrass, 2000; Narchi, 2005). The role of nephrectomy in MCDK remains controversial, but for certain indications most authors agree that nephrectomy is warranted. These include cases in which the MCDK represents a large mass that compromises either respiratory or gastrointestinal function (Holloway and Weinstein, 1990). In instances in which the diagnosis of MCDK is in doubt or becomes questionable because of increasing size (Minevich et al., 1996), and in instances in which the MCDK produces symptoms including pain, hematuria, or infection (Ambrose et al., 1982), surgery may be considered. Other authors consider concomitant abdominal surgery reason enough for removal of a MCDK (Hartman et al., 1986). Lastly, maintenance of an observational approach assumes that parents can comply with the long-term follow-up needed to detect hypertension or malignant transformation. If long-term follow-up is in question, nephrectomy should be considered.

The issue of nephrectomy rests on the potential development of hypertension or malignant transformation. In the past 30 years, there have only been 12 cases of malignancy reported in association with MCDK, only 6 of which occurred in children (Raffensperger and Abousleiman, 1968; Oddone et al., 1994; Minevich et al., 1996; Manzoni and Caldamone, 1998). All six pediatric patients had Wilms' tumor, while five adults had renal cell carcinoma and one adult had mesothelioma.

As of 1995, no cases of renal tumor had been described in patients with MCDK reported to the Multicystic Kidney Registry of the Section of Urology of the American Academy of Pediatrics (Wacksman, 1995). Similarly, during the past 30 years there have been only 24 cases of hypertension

reported that arose as a result of MCDK (Susskind et al., 1989; Angermeier et al., 1992; Andretta et al., 1995; Elder et al., 1995; Patterson and Klauber, 1996; Webb et al., 1997; Manzoni and Caldamone, 1998). In 13 of these cases, the hypertension responded to nephrectomy. The long-term data on malignant transformation and hypertension is meager and may not support routine prophylactic nephrectomy, but long-term surveillance is necessary in this group of patients at risk.

GENETICS AND RECURRENCE RISK

Isolated MCDKs are usually sporadic, with no risk of recurrence in subsequent pregnancies. However, there have been familial cases whose defects range from bilateral renal agenesis to hydronephrosis, with an autosomal dominant pattern of inheritance and a 50% chance of a subsequent pregnancy being affected. MCDKs can also be seen as part of numerous syndromes (see Table 78-1). Features of the genetic syndromes should be sought and excluded, as they may be associated with a specific recurrence risk.

79 CHAPTER

Polycystic Kidney Disease

Key Points

- Autosomal recessive polycystic kidney disease (ARPKD) is characterized by bilaterally enlarged echogenic kidneys.
- Autosomal dominant polycystic kidney disease (ADPKD) is the most common lethal genetic disease inherited as a dominant Mendelian trait.
- ARPKD is less common in the general population because of its early mortality, with an incidence of 1:40,000 births.
- ADPKD has an incidence of 1 in 1000 living individuals with near 100% penetrance.
- The differential diagnosis of PKD includes Bardet–Biedl syndrome, Meckel–Gruber syndrome, Ivemark syndrome, and Jarcho–Levin syndrome.
- In the absence of associated malformations, bilaterally symmetrically enlarged echogenic kidneys with renal cysts and oligohydramnios are most likely due to either ARPKD or ADPKD.
- Renal ultrasound examinations of both parents should be obtained to evaluate for ADPKD.
- Oligohydramnios-induced pulmonary hypoplasia is a leading cause of perinatal mortality in polycystic kidney disease.
- The clinical course for prenatally presenting ADPKD is generally milder than for ARPKD.
- Aggressive neonatal management of infants with ARPKD has led to 1-year survival rates of the order of 82% to 85%.

CONDITION

Polycystic kidney disease (PKD) is an inherited disorder with diffuse involvement of both kidneys. Aside from the presence of the cysts, there is no evidence of renal dysplasia. Multiple renal cysts frequently coexist with lesions in other viscera, especially the liver (Kaplan et al., 1989a). A renal cyst is defined as an enclosed sac or nephron segment lined by epithelial cells dilated to more than 200 μm. A cystic kidney is a kidney with three or more cysts present. Cystic kidney disease is the illness caused by a cystic kidney (Kaplan et al., 1989a).

As early as 1902, it was known that the age distribution of cystic renal disease had two peaks: one close to birth and the other between 30 and 60 years of age (Kaplan et al., 1989b). In general, the use of the term *polycystic kidney disease* is restricted to single-gene disorders: autosomal dominant PKD (traditionally known as adult onset) and recessively inherited PKD (traditionally known as the infantile form). Since the 1970s, physicians have understood that the adult form can also present during infancy. In the recessive form of PKD, generalized dilatation of the collecting tubules exists, whereas in dominant PKD, cysts develop in localized segments of the kidney anywhere along the nephron (Kaplan et al., 1989a).

The dominantly inherited form of PKD (ADPKD) is a highly penetrant nephropathy with variable clinical expression that presents mainly during adulthood, but the disease can also occur at any other time during life. Autosomal dominant polycystic kidney disease is the most common lethal genetic disease inherited as a dominant Mendelian trait (Wilson et al., 2006). Mutations in the *PKD1* on chromosome 16 and *PKD2* on chromosome 4 are responsible for 85% and 15%, respectively, of cases of ADPKD (Harris, 1999). In ADPKD, progressive asymptomatic enlargement of both kidneys occurs with a gradual decline in renal function. Ultrasonography can detect renal cysts in 56% of affected patients during the first decade of life, 80% during the second decade of life, and almost 100% of individuals by the third decade of life (Michaud et al., 1994). The infantile presentation of the adult onset form of PKD was not appreciated until 1971 (Shokeir, 1978).

Bilateral PKD can be attributed to two genetically determined conditions. The so-called infantile form of PKD is inherited as an autosomal recessive condition. The cystic

dilations are fusiform and arranged radially throughout the kidney. The cysts are due to dilations of the distal convoluted tubules and collecting ducts. Concomitant cystic hepatic involvement is observed. Among survivors, hepatic fibrosis, cirrhosis, and portal hypertension occur.

From the perspective of prenatal diagnosis and neonatal presentation, the adult form of PKD is much rarer. It usually presents during the fourth to fifth decade of life. The kidney contains multiple cysts, ranging in size from microscopic to gross, located in both the cortex and the medulla. The intervening areas of the kidney may be normal (Shokeir, 1978).

ADPKD is now considered a systemic disorder. The extrarenal manifestations include liver cysts, cysts of the pancreas, and intracranial aneurysms, which occur in 5% of patients and lead to subarachnoid hemorrhage. There is also an increased prevalence of cardiac valve defects, hernias, and colonic diverticulum (European Polycystic Kidney Disease Consortium, 1994).

The recessively inherited form of polycystic disease (ARPKD) manifests during the neonatal period with respiratory distress or during early infancy with renal insufficiency. There is a wide variation in clinical course (Wisser et al., 1995). The renal involvement in autosomal recessive polycystic kidney disease (ARPKD) is invariably bilateral and largely symmetrical. It is always associated with generalized portal and interstitial fibrosis of the liver (Romero et al., 1984; Zerres et al., 1988). In 1971, Blyth and Ockenden subdivided patients with ARPKD into four groups according to the proportion of dilated renal tubules present. The perinatal classification was associated with the onset of renal failure in utero or at birth and resulted in perinatal or neonatal death. These patients had at least 90% involvement of the renal tubules. The neonatal presentation resulted in a smaller kidney size and mild hepatic fibrosis, but these patients died within 1 year and had 60% of their kidneys affected. The infantile presentation resulted in clinical symptoms by the age of 3 to 6 months, moderate hepatic fibrosis, and hepatosplenomegaly with progressive chronic renal failure, and systemic and portal hypertension. These patients had 25% of their kidneys affected. The latest presentation was the juvenile onset, which occurred between 6 months and 1 year of age and had only 10% of the kidney affected (Blyth and Ockenden, 1971).

INCIDENCE

ADPKD is one of the most common hereditary disorders in humans. It is 10 times more common than sickle cell disease, 15 times more common than cystic fibrosis, and 20 times more common than Huntington disease (Gabow, 1993). The incidence of ADPKD is 1 in 1000 living individuals, with a penetrance rate of 100% (McHugo et al., 1988). Approximately half of the affected patients present during the third to fifth decade of life with hypertension or uremia. ADPKD has been noted to occur in 1 of 500 autopsies (Pretorius et al., 1987). Because of its effect on mortality, ARPKD is less common in the general population, but it is disproportionately increased in the prenatally diagnosed population. The incidence of ARPKD is 1 in 40,000 births (Zerres et al., 1988).

SONOGRAPHIC FINDINGS

Malformations of the urinary tract are detected at a high rate because they are associated with two easily visualized sonographic markers: cystic accumulation of fluid and change in amniotic fluid volume.

Bronshtein et al. (1990) described transvaginal sonographic studies in 1940 in pregnant women at between 10 and 16 weeks of gestation. In the study population, 35 fetuses with renal anomalies were identified (1.8%), and among this group, 2 cases of ARPKD were diagnosed. These authors demonstrated that the fetal kidneys could be imaged as early as the 12th week of gestation, when they appear as hypoechogenic oval masses on both sides of the fetal spine. Indirect evidence of urine production can be inferred by observing emptying of the bladder as early as 18 weeks of gestation. In two cases, the study's authors were able to identify fetal kidneys as early as 9 weeks of gestation. In this report, two types of cystic renal anomalies were described: microcystic, which was defined as the presence of multiple small cysts in the affected kidney, resulting in a spongiform enlarged kidney that comprised most of the fetal abdomen on the longitudinal and transverse scans; macrocystic, in which the sonographic appearance of the affected kidney resembled polycystic ovaries seen in adult women. In the two cases of ARPKD, the amount of amniotic fluid observed was normal. Zerres et al. (1988) described their observations in the prenatal sonographic diagnosis of ARPKD. They noted that increased echogenicity and renal enlargement were the characteristic findings of ARPKD. Oligohydramnios can be present, but it is not required for the diagnosis. These authors thought that the most useful parameter in the prenatal diagnosis of ARPKD in families known to be at risk were repeated sonographic measurements of fetal kidney length. They concluded that prenatal sonographic diagnosis was possible only in severe cases of ARPKD. Oligohydramnios presenting during the first or second trimester carried a very poor prognosis. In a third study, Romero et al. (1984) described their observations in 19 fetuses at risk for ARPKD because of a known family history. Ten (53%) of these fetuses were affected. A definitive antenatal diagnosis of ARPKD was made by the presence of oligohydramnios, an absent urinary bladder, and bilateral renal enlargement, as measured by the kidney circumference to abdominal circumference ratio. The ratio in affected fetuses was >2 standard deviations (SD) above the mean. These authors described a typical hyperechogenic appearance of the kidneys in ARPKD. They had no false-positive diagnoses, but there was one false-negative diagnosis. In contrast, the unaffected neonates had normal bladders, normal amniotic fluid volume, and normal kidney texture. False-negative diagnosis has been reported in

ARPKD. Luthy and Hirsch (1985) described a couple with two previously affected pregnancies with ARPKD. Ultrasound examination performed at 25 weeks of gestation in a subsequent pregnancy revealed oligohydramnios, increased renal parenchymal echogenicity, and a normal renal size and normal bladder. The pregnancy was terminated electively, and at autopsy, the kidneys were shown to be normal.

Okumura et al. reported that ARPKD can be associated with densely echogenic renal pyramids (Okumura et al., 2006). They found on histology that this was due to the ectatic tubules of the pyramids in ARPKD producing multiple reflection interfaces resulting in increased echogenicity. This is a pattern of increased echogenicity that can also be seen in medullary nephrocalcinosis. This appearance has also been observed in a neonate with ARPKD (Herman and Siegel, 1991).

The prenatal diagnosis of ADPKD was first reported by Zerres et al. in 1982, who described enlarged abnormally reflective kidneys with cysts (see Figure 79-1). In a subsequent study, McHugo et al. (1988) described the presence of enlarged fetal kidneys with accentuation of the corticomedullary differentiation but no cysts. These authors thought that this specific finding distinguished between the recessive and dominantly inherited forms of PKD. Of concern in ADPKD is the fact that the sonographic lesions are detected long before the appearance of symptoms. Very few data exist concerning the rate of progression of disease in ADPKD. One report described normalization of fetal renal size in an unaffected fetus (Jeffery et al., 1998). No ultrasonographic criteria exist for clinical staging of this disease except for the presence of oligohydramnios, which carries a poor prognosis (Michaud et al., 1994). One review of 83 reported cases of ADPKD presenting in utero showed a 67% incidence of hypertension in childhood and a 43% incidence of death in the first year of life (MacDermot et al., 1998).

In a study of prenatal diagnosis of ADPKD, Pretorius et al. (1987) described five cases ascertained at their center and combined their clinical information with eight cases reviewed in the medical literature. All 13 fetuses identified had 1 parent affected, but only 5 of the 13 affected parents were aware of their diagnosis prior to pregnancy. Eleven of the 13 affected fetuses with ADPKD had renal enlargement, 10 had increased echogenicity, and 9 had specific echogenicity of the renal parenchyma. Only 6 of 13 had cysts large enough to be detected by antenatal ultrasound examination.

Echogenic kidneys with normal amniotic fluid volume pose a distinct diagnostic challenge. As reported by Mashiach et al., this can be a normal variant, as was the case in one of their seven patients (Mashiach et al., 2005). However, six of the seven patients had significant renal parenchymal disease, four patients had ADPKD, and two patients had multifocal renal dysplasia.

Fetal MRI has been used more frequently to help delineate the etiology of enlarged kidneys because of the limitations of ultrasound examination in the setting of oligohydramnios. Liu et al., described the following MRI findings on single-shot fast spin echo (SSFSE) sequences in ARPKD: hypointensity of the lungs (because of decrease in airway fluid from oligohydramnios), oligohydramnios, symmetrical nephromegaly, and nonvisualization of fluid in the renal pelvis and bladder (Liu et al., 2006). Hawkins et al., found MRI helpful in diagnosing the underlying basis for severe renal anomalies (Hawkins et al., 2008). Similarly, Cassart et al., found MRI to be complementary to ultrasound examination, and in the case of ARPKD, found a hyperintense signal in the pyramids similar to the increased echogenicity observed by sonography by Okumura et al. (Cassart et al., 2004, Okumura et al., 2006).

DIFFERENTIAL DIAGNOSIS

When cysts are observed in the fetal kidney, it is important to determine whether they are present in only one kidney or in both. Bilateral presentation is more characteristic of ARPKD. Caution must be observed, however, as ADPKD can be difficult or impossible to prenatally distinguish sonographically from ARPKD (Pretorius et al., 1987). Furthermore, the differential diagnosis of diseases that causes echogenic kidneys in the fetus and newborn differs from that of older pediatric patients (Estroff et al., 1991). Renal cysts can be characteristically found as part of other single-gene disorders, including tuberous sclerosis (Blethyn et al., 1991). It is of interest that one of the genes for tuberous sclerosis maps very closely to one of the genes for ADPKD. Blethyn et al. (1991) described a fetus with a large echogenic kidney diagnosed at 28 weeks of gestation. This infant was later noted to have seizures at 5 weeks of postnatal age, and computed tomographic (CT) scan revealed the presence of cortical tubers. Renal lesions occur in 54% to 100% of patients with tuberous sclerosis. These

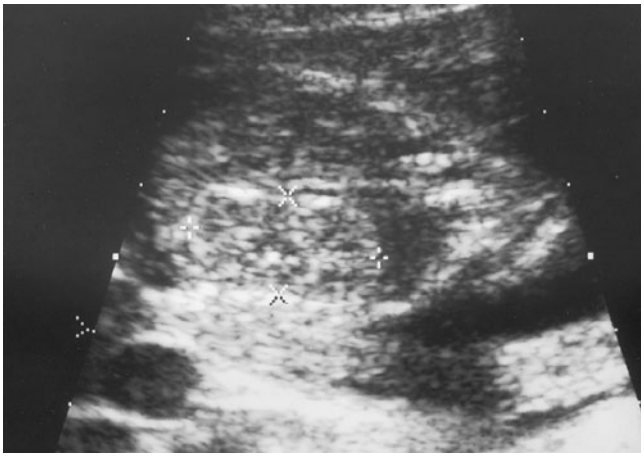

Figure 79-2 Prenatal sonographic image demonstrating increased echogenicity and multiple small cysts in a fetus with Meckel–Gruber syndrome.

consist of angiomyolipomas or renal cysts. Another condition that can present with increased echogenicity of the fetal kidneys and renal enlargement is Beckwith–Wiedemann syndrome. The other condition with bilateral renal enlargement, oligohydramnios, and increased echogenicity that presents prenatally is Meckel–Gruber syndrome (Wapner et al., 1981; Celentano et al., 2006). Sgro et al., have also reported the association of ARPKD and Caroli's disease, which is a rare autosomal recessive condition (Sgro et al., 2004). This fetus was diagnosed at 33 weeks of gestation with dilated intrahepatic bile ducts and enlarged echogenic kidneys (see Figure 79-2). Other conditions that can present with renal cysts are listed in Table 79-1.

When echogenic kidneys are associated with renal cysts, Chaumoitre et al. suggest a differential diagnosis of ADPKD, ARPKD, Bardet–Biedl syndrome, Meckel–Gruber syndrome, Ivemark syndrome, and Jarcho–Levin syndrome, based on their review of 93 fetuses (Chaumoitre et al., 2006). This group found that the key to prenatal diagnosis was the demonstration of associated anomalies that suggested a specific syndrome. In the absence of associated malformations, the main differential is between ARPKD and ADPKD.

ANTENATAL NATURAL HISTORY

The transient embryonic excretory organs—the pronephros and mesonephros—develop around 5 to 7 weeks of gestation. The first fetal urine is formed at approximately 11 weeks of gestation, and this may maintain the patency of the mesonephric duct. At around week 7, the wolffian duct develops a bud from its caudal end that grows medially and dorsally until it meets the caudal end of the nephrogenic cord. This is called the "metanephric blastema," and it induces formation of the definitive kidney. This begins as an interaction between the ureteral bud and metanephros, which results in a series of branching divisions of the ureteral bud, forming

the renal pelvis and major calices around 12 to 14 weeks of gestation. This branching reaches its maximum at 22 weeks of gestation but continues until 34 to 36 weeks of gestation, when the kidney is fully formed (Bronshtein et al., 1990). Pathogenesis of kidney diseases result from one of the six causes (Bronshtein et al., 1990):

1. failure of union between primitive collecting ducts and nephrons;
2. failure of involution of the first generation of nephrons;
3. obstruction of urine flow at the level of the pelvis, urethra, or bladder outlet;
4. intratubular obstruction;
5. abnormalities of the tubular wall and supporting tissues;
6. adrenocortical maternal steroid ingestion.

PKD is characterized by enlargement of renal cysts, interstitial fibrosis, and gradual loss of normal renal tissue in association with progressive deterioration of renal function. In one study, apoptotic DNA fragmentation was detected in polycystic kidneys from five patients with renal failure (Woo, 1995). Apoptotic cells were demonstrated in glomeruli, cyst walls, and both cystic and noncystic tubules of the polycystic kidneys. These authors hypothesize that apoptotic loss of renal tissue may be associated with progressive deterioration of renal function that occurs in patients with PKD. The specific findings in ARPKD, consisting of large, coarsely hyperechoic kidneys, are thought to be secondary to the presence of

innumerable microscopic cortical and medullary cysts. The interfaces of these cysts provide increased echogenicity.

ADPKD is the only form of cystic disease that involves a collecting tubule as well as the nephron. Normal and abnormal nephrons are intermixed (Pretorius et al., 1987). In ADPKD, cysts occur in only 1% to 2% of renal tubules, but it is thought that the affected abnormal nephrons enlarge steadily until they compress and distort the normal parenchyma to the point of causing impaired renal function (Grantham, 1988). Michaud et al. (1994) reported on three cases of ADPKD and performed a literature review. Of 32 affected fetuses, 28 had prenatal sonographic manifestations of disease or siblings with early onset of disease. Pathologic studies demonstrated that the cysts could be found in newly formed nephrons or in more mature nephrons of the deep cortex. The glomeruli were predominantly affected in the fetus. These authors hypothesized that cysts develop in most patients with ADPKD during fetal life and that the rate at which these cysts increase in size determines the clinical severity of the disease (Michaud et al., 1994).

MANAGEMENT OF PREGNANCY

The diagnosis of fetal renal cystic disease mandates complete ascertainment of the family history. It is also recommended that both parents have a renal ultrasound examination performed because of the high prevalence of the ADPKD gene in the general population. Because of the higher prevalence of ARPKD in the prenatally diagnosed population, a fetus with bilateral renal enlargement and echogenicity is more likely to have ARPKD if both parents have normal ultrasound examinations. However, caution must be observed because of the apparent false-positive diagnoses of ARPKD reported in the literature (Lilford et al., 1992). Several authors have described additional diagnostic testing to help with determination of the underlying cause. For example, Tsuda et al. (1994) diagnosed ARPKD in a fetus at risk by measuring hourly fetal urine production. This was reduced in an affected fetus as compared with a normal fetus. Magnetic resonance imaging (MRI) has been performed at 25 weeks of gestation in a fetus diagnosed with bilateral enlarged hyperechogenic kidneys, oligohydramnios, and a small bladder at 22 weeks of gestation. The MRI revealed corticomedullary differentiation but could not demonstrate the presence of renal cysts. The kidneys were noted to be massively increased in size with a very high water content in the renal parenchyma (Nishi et al., 1991). Nicolini et al. (1992) aspirated fetal urine from 21 large cystic renal masses in 18 fetuses diagnosed between 20 and 35 weeks of gestation. They demonstrated that urinary concentrations of sodium, calcium, and phosphate were significantly higher in the multicystic group as compared with the hydronephrotic group. They concluded that reabsorption of phosphate was impaired in multicystic kidneys.

In the absence of the demonstration that one of the parents is affected with ADPKD, counseling regarding expected prognosis can be difficult. Even when one of the parents is known to have ADPKD, the short-, mid-, and long-term prognoses for fetuses in whom renal cysts are demonstrated early in life is unknown (Journel et al., 1981). In the past, fetuses diagnosed with ARPKD were given a dismal prognosis; however, increasing information from the pediatric literature indicates that general health and lifespan for these infants can be better than was previously thought (Guay-Woodford and Desmond, 2003; Beaunoyer et al., 2007). For a presumed diagnosis of ARPKD, the prospective parents should have a complete discussion with a pediatric nephrologist and neonatologist regarding the extent of resuscitation for the affected newborn. Delivery should be planned to occur in a tertiary care center because of the expected problems with respiratory insufficiency due to pulmonary hypoplasia secondary to oligohydramnios and hypertension.

FETAL INTERVENTION

There are no fetal interventions for PKD.

TREATMENT OF THE NEWBORN

Newborns with ARPKD often receive minimal intervention because poor respiratory and renal outcomes are anticipated. In 1995, Bean et al. described two unrelated infants with ARPKD whose respiratory failure was successfully treated with surfactant and mechanical ventilation. Of interest was the fact that the massive kidney size restricted gastrointestinal capacity and limited feeding and growth. In these two cases, unilateral nephrectomy allowed improved feedings. Both patients had their caloric intake supplemented by nightly feedings by gastrostomy tube, to give a caloric equivalent of 120 to 130 kcal per kilogram of body weight per day. Both patients required long-term medications for treatment of hypertension; however, both exhibited normal neurodevelopment for age at 4 years 9 months and 19 months of follow-up. Both of these patients required minimal hospitalization after the neonatal period.

Aggressive neonatal resuscitation was considered to be controversial for ARPKD, but increasing reports have indicated that with ventilatory support, nutrition, and peritoneal dialysis survival rates can be as high as 82% to 85% (Bergmann et al., 2005). Those who survive have hypertension, progressive renal insufficiency, and hepatic fibrosis and will ultimately need renal transplantation (Beaunoyer et al., 2007). All of these issues must be discussed with the prospective parents.

Fetuses affected with ADPKD have far fewer symptoms and are unlikely to present with spontaneous pneumothorax, oligohydramnios, or liver or spleen enlargement (Cole et al., 1997). In the absence of severe oligohydramnios, standard resuscitation and neonatal supportive treatment are appropriate for infants with ADPKD.

Figure 79-3 A neonate with ARPKD. Massive and rapid enlargement of the right kidney compressed the inferior vena cava, which necessitated emergency nephrectomy.

SURGICAL TREATMENT

The only surgical treatment available for severe PKD is nephrectomy (unilateral or bilateral) or renal transplantation. We have performed unilateral nephrectomy on an emergency basis for an infant with ARPKD because the rapid and massive enlargement of the right kidney compressed the inferior vena cava and seriously impeded venous blood return to the heart (Figures 79-3 and 79-4).

LONG-TERM OUTCOME

A critical milestone for PKD appears to be survival past the first few months of age. Kaplan et al. (1989b) reviewed the clinical features in 55 cases of ARPKD. Of the 24 patients who presented during the neonatal period, 12 (50%) survived beyond 2 years of age. These authors performed an actuarial analysis and showed that once a patient survived beyond 1 year of age, the projected chance of survival beyond 15 years of age was 78%. This data is in agreement with that of Cole et al. (1987), who performed a retrospective survey of 48 patients with PKD who survived the first month and were seen before 1 year of age. These authors indicated that most children diagnosed with PKD who survived the first months of life lived for many years. The majority of all affected children require long-term antihypertensive therapy for persistent problems with high blood pressure.

What is not clearly known, however, is the prognosis for fetuses with the dominant form of PKD who are identified antenatally. In a review of 13 prenatal diagnoses of ADPKD, Pretorius et al. (1987) showed that 10 of 13 infants were alive

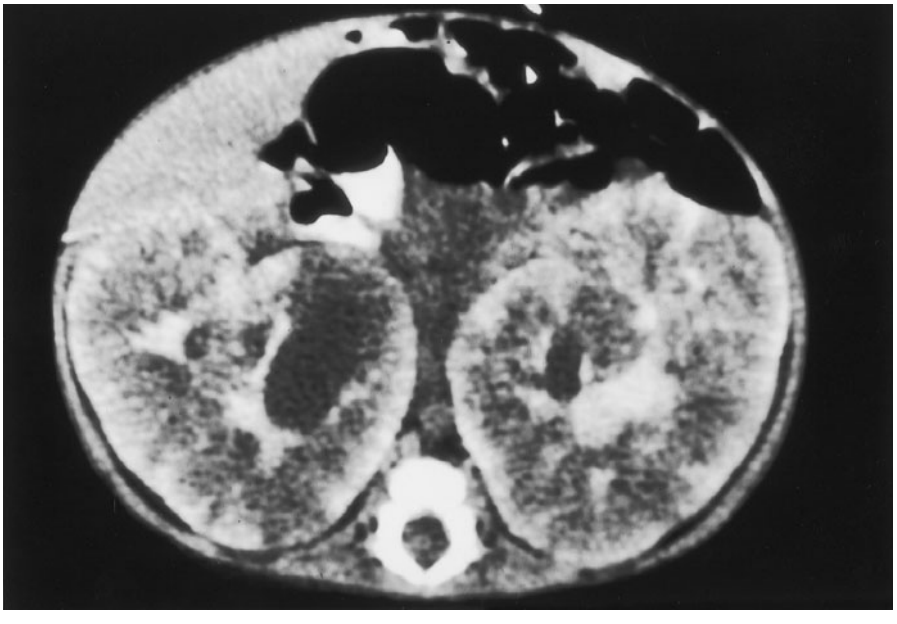

Figure 79-4 Postnatal CT scan from the same infant in Figure 79-3 showing bilateral presence of multiple cysts in enlarged kidneys.

at the time of follow-up. Three were dead because of elective termination of pregnancy, sepsis, or respiratory distress syndrome. Of the 10 surviving children, 8 had normal renal function at the time of follow-up. There is some indication that the neonatal detection of ADPKD correlates with development of hypertension and renal failure in early childhood. However, it is unclear what the fetal presentation of ADPKD implies for future symptoms (Journel et al., 1981).

A review of the literature suggests that fetuses with severe oligohydramnios are unlikely to survive the perinatal period. Improvements in neonatal care permit moderate to severely affected infants with ARPKD to survive the perinatal period. Survival beyond 1 month of life generally indicates the propensity for long-term survival in affected infants with ARPKD. These children require long-term medication and close medical follow-up; however, the literature does not indicate that they spend their entire lives in the hospital. The long-term prognosis for children affected with the dominantly inherited form of PKD is good because in childhood they are more mildly affected. Their clinical situation is also complicated by the fact that in most cases, one of their parents also has the disease, and they may, therefore, be more likely to continue the pregnancy.

GENETICS AND RECURRENCE RISK

Several authors have discussed the difficulties associated with the dual identification of both fetus and parent affected with ADPKD. In Pretorius's study (1987) only 5 of 13 parents were aware of their disease prior to pregnancy. The diagnosis of renal cystic disease in the fetus and young infant should trigger an investigation of the family history. Sonography should be performed on the parents. In ADPKD, however, the severity of parental involvement does not predict either the severity of the child's involvement or the age at onset of symptoms (Michaud et al., 1994). It is well known that difficulties exist in genetic counseling for ADPKD. In one study, 23% of subjects were aware of the hereditary nature of the disease, only 18% had genetic counseling, and 9% had family members examined by sonography (Journel et al., 1981). Fertility is not reduced in ADPKD.

Because it is difficult to distinguish between ADPKD and ARPKD on sonographic examination, and many young parents who have ADPKD are normal on sonographic examination, most geneticists believe that DNA diagnosis is more reliable for prenatal detection of the affected fetus. Fortunately, much recent investigative activity has been directed toward mapping the various genes associated with ARPKD and ADPKD.

ARPKD appears to be genetically homogeneous (Guay-Woodford et al., 1995). ARPKD is caused by a single gene (*PKHD1*) with multiple mutant alleles. This accounts for the relatively high phenotypic concordance within families as well as the broad range of phenotypes evident among different families. The ARPKD gene was mapped to chromosome 6p21-cen in 1994 (Zerres et al., 1994). Most of the families analyzed in this initial report, however, had a milder clinical phenotype compatible with survival beyond infancy. In 1995, Guay-Woodford et al. confirmed and extended Zerres et al.'s findings by performing linkage analysis in families that manifested the severe perinatal lethal form of ARPKD. They narrowed the interval for the gene to 6p21.1-p12 and confirmed that ARPKD results from a single mutant gene.

In contrast, ADPKD is genetically heterogeneous. At least three genes are known to cause ADPKD (Grantham, 1995). ADPKD-1 maps to chromosome 16p13.3 and is responsible for 85% of cases. ADPKD-2 has been mapped to chromosome 4q13-q23 (Peters et al., 1993). It has been postulated that a third gene, ADPKD-3, may be responsible for a small minority of cases, but its chromosomal location is unknown. Spontaneous mutations occur in less than 10% of cases of ADPKD (Gabow, 1993).

DNA linkage analysis in ADPKD was first demonstrated in 1985, when Reeders et al. described a DNA marker located near the α-globin gene cluster on chromosome 16 that was coinherited with ADPKD. The existence of a second gene causing ADPKD was first suspected in 1988 (Kimberling et al., 1988; Romeo et al., 1988). Peters et al. (1993) reported the assignment of a second gene for ADPKD to chromosome 4. Of interest is that patients who do not have ADPKD-1 seem to be diagnosed at an older age, are less likely to have hypertension, live longer, and have fewer renal cysts present at the time of diagnosis. This indicates phenotypic as well as genotypic heterogeneity for ADPKD (Ravine et al., 1992). The first DNA-based prenatal diagnosis of ADPKD was performed in 1986 by Reeders et al.

The *PKD1* gene was cloned and sequenced in 1994 (European Polycystic Kidney Disease Consortium, 1994). It is a very large gene whose protein product is called "polycystin," which is a glycoprotein of approximately 4300 amino acid residues (Harris et al., 1995). Polycystin-1 is a cell–cell matrix interaction protein. It is important for production and maintenance of renal tissue and connective tissue in other organs. It is also expressed in arterial smooth muscle (Griffin et al., 1997). This explains the multisystem nature of the disease. Large sections of the gene are duplicated at separate locations on chromosome 16, and all of these segments of DNA are transcriptionally active. Most *PKD1* mutations have been detected in the single copy 3′ end of the gene, but a group of patients with deletion of *PKD1* and the adjacent tuberous sclerosis 2 gene (with severe infantile PKD) have been characterized (Harris et al., 1995). In the typical patients with adult-onset *PKD1*, small deletions, splicing defects, or a nonsense mutation have been detected in the 3′ end of the gene. In each case, a transcript is produced by the mutant gene. Rarely, large deletions that disrupt, or completely delete, the *PKD1* gene are detected. In every case, these mutations also disrupt the adjacent tuberous sclerosis gene. *PKD2* has also been cloned and sequenced. Both *PKD1* and *PKD2* code for novel proteins (van Adelsberg, 1999). Polycystin-1 is a receptor and similarities between the polycystins and calcium channel subunits suggest that these proteins are subunits of a novel channel.

Families at risk for either ARPKD or ADPKD should have blood samples collected for DNA analysis prior to

contemplating a future pregnancy. For ADPKD, because of the genetically heterogeneous nature of the disorder, there should be enough affected family members tested to determine whether the disease is due to ADPKD-1, ADPKD-2, or other genes (Breuning et al., 1990).

A large review of prenatal DNA analysis in families at risk of ARPKD analyzed 65 diagnoses (Zerres et al., 1998). In the majority of the requesting families, the index child was dead; DNA was extracted from paraffin-embedded tissue. In 4 of the 65 cases, a recombination event occurred between flanking markers and no diagnosis was possible. Forty-three fetuses were diagnosed correctly as unaffected. In 18 fetuses, homozygosity for the disease-associated haplotype was demonstrated. Pathologic changes consistent with ARPKD were seen as early as 13 weeks of gestation in 2 fetuses, both of which were terminated. This study showed that haplotype-based prenatal testing is feasible and reliable in pregnancies at risk for ARPKD (Zerres et al., 1998). Once a mutation has been identified in a specific family, prenatal DNA diagnosis is available as early as 10 weeks of gestation via chorionic villus sampling. DNA diagnosis is recommended for definitive prenatal diagnosis over prenatal sonographic diagnosis, which can be nonspecific. Preimplantation genetic diagnosis is also available for both ARPKD and ADPKD if the familial mutations are known.

Hydronephrosis: Minimal

80 CHAPTER

Key Points

- Minimal fetal hydronephrosis is defined as anterior posterior renal pelvic diameter >4 mm and <9 mm.
- Minimal fetal hydronephrosis is associated with a slightly increased risk of aneuploidy.
- 90% of cases will resolve on their own.
- Newborns with persistent hydronephrosis should be treated with prophylactic antibiotics until postnatal urologic evaluation.

CONDITION

Hydronephrosis is the most common abnormality reported on prenatal sonographic screening (Thomas, 1990; Blyth et al., 1993). The vast majority of cases are mild, so-called physiologic hydronephrosis, which are of no clinical significance. Numerous theories have been proposed to try to account for this common finding. In the past, one popular theory was that mild fetal hydronephrosis resulted from changes in maternal hydration. However, Hoddick et al. (1985) demonstrated that the degree of maternal hydration had no significant influence on fetal urinary tract dilation.

These findings were subsequently confirmed by Allen et al. (1987). Other potential causes suggested for mild dilation of the fetal urinary tract include transient obstruction, compression by fetal vessels crossing the ureter, vesicoureteral reflux, and natural kinks and folds in the ureter that may occur during development, hyperfiltration of fetal kidneys, or the influence of metabolic or hormonal factors (Homsy et al., 1986; Najmaldin et al., 1990; Zerrin et al., 1993). The hormonal milieu of the fetus may influence the renal pelvic diameter. Maternal hydronephrosis commonly occurs during pregnancy because of the influence of progesterone, a known smooth muscle relaxant. It has been suggested that maternal progesterone may also be responsible for mild fetal upper urinary tract dilation (Cendron et al., 1994).

Distinguishing physiologic fetal renal pelvic distention from significant or pathologic hydronephrosis is a challenge that requires accurate prenatal sonography and follow-up evaluation. Renal pelvic distention may range in anterior/posterior (A-P) diameter from 3 to 11 mm in up to 18% of normal fetuses studied after 24 weeks of gestation (Hoddick et al., 1985). Because fetal hydronephrosis is so common, Arger et al. (1985) proposed criteria to help distinguish abnormal renal pelvic dilation. They suggested that a pelvic diameter of > 10 mm or a ratio of the A-P pelvic diameter to the A-P renal diameter > 0.5 indicated significant fetal hydronephrosis (Figure 80-1A and B). These criteria were subsequently modified by addition of caliectasis as an additional indicator of significant hydronephrosis (Kleiner et al., 1987). This study suggested that caliectasis might be an even more sensitive and reliable indicator for predicting pathologic hydronephrosis than simple pelviectasis (Figure 80-1A). Renal pelvic dilation less than these criteria for pathologic hydronephrosis is considered minimal fetal hydronephrosis. Morin et al. (1996) defined minimal hydronephrosis as renal pelvic dilation > 4 mm but < 10 mm in a fetus that was less than 24 weeks of gestation.

Classification of the degree of renal pelvic dilation is also dependent upon when during gestation it is diagnosed. Fetuses at 15 to 20 weeks of gestation with a renal pelvic diameter of 4–7 mm are considered to have minimal fetal hydronephrosis, while those fetuses with A-P diameter greater than 7 mm are classified as having moderate hydronephrosis. In contrast, after 30 weeks of gestation, the threshold for defining mild, moderate, and severe hydronephrosis is defined as 5–8 mm, 9–15 mm, and over 15 mm, respectively (Pates and Dashe, 2006).

INCIDENCE

Antenatal hydronephrosis is a common finding on antenatal ultrasound with incidence reported from 0.3% to 4.5% with most reports around 1% (Havutcu et al., 2002). When a number of clinical studies are pooled, the calculated incidence of detectable dilation of the fetal urinary tract approaches 1 in 100 pregnancies (Thomas, 1990). However, difficulties in assessing the true incidence of pathologic fetal hydronephrosis stem from the high incidence of physiologic hydronephrosis and the limitations of criteria used to define pathologic urinary tract dilation (Gruppe, 1987). The overall incidence of congenital hydronephrosis in a large-scale maternal–fetal screening program in Sweden was 0.17% (Helin and Persson, 1986). This figure was lower than the one reported (0.76%) in Britain, in a well-designed prospective study using antenatal ultrasonography at a specific time during pregnancy (Livero et al., 1989). In many of these cases, however, a large number of the fetuses displayed what would be considered physiologic hydronephrosis, in other words, minimal pyelectasis. Follow-up studies in patients diagnosed with prenatal hydronephrosis showed that only 1 in 500 fetuses required prenatal or postnatal intervention for hydronephrosis (Thomas, 1990).

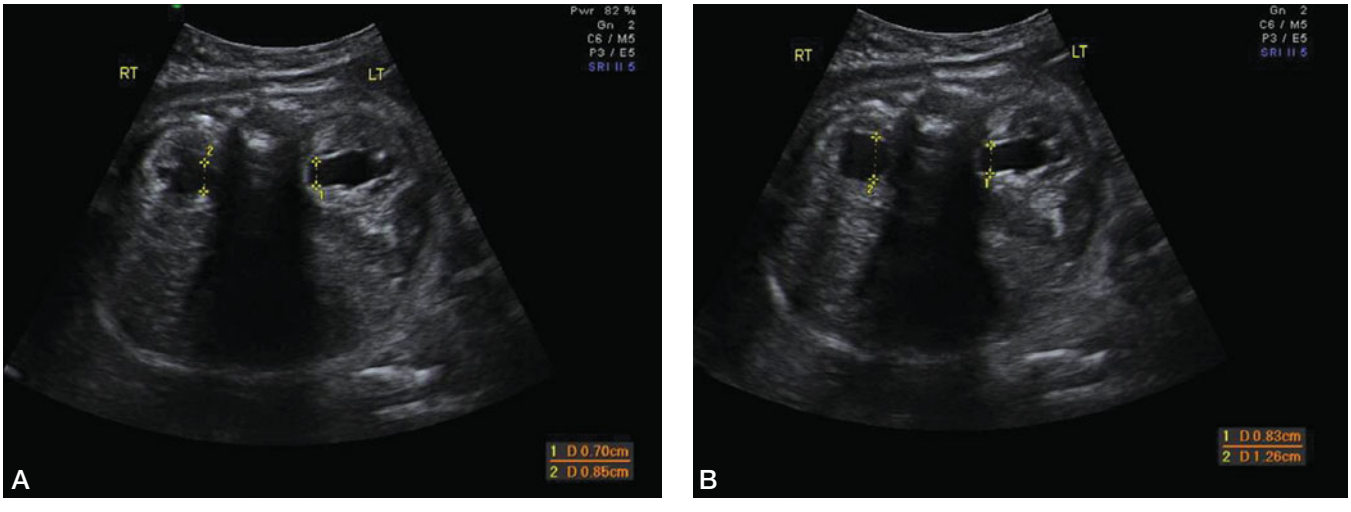

Figure 80-1 **A.** Prenatal sonographic image demonstrating minimal fetal hydronephrosis on the left with an A-P pelvic diameter of 7 mm. The right kidney demonstrates caliectasis even though the A-P pelvic diameter is only 8 mm, which would be considered pathologic. **B.** During bladder contraction there was slight increase on the left in A-P pelvic diameter to 8.3 mm suggesting vesicoureteral reflux.

SONOGRAPHIC FINDINGS

The role of ultrasound examination in the evaluation of the fetal urinary tract is twofold: to monitor the extent of fetal urinary tract dilation and to identify fetuses affected with such severe lesions that intervention or termination of the pregnancy should be considered. Prenatal sonography has irrevocably changed the approach to congenital malformations, particularly those involving the urinary tract (Harrison et al., 1982; Golbus et al., 1983; Mahoney et al., 1984; Harrison and Filly, 1991; D'Alton and DeCherney, 1993). Current diagnostic capabilities allow for the detection of urinary tract anomalies as early as 12 to 14 weeks of gestation (Glazer et al., 1982; Bronshtein et al., 1990; Patten et al., 1990; Blyth et al., 1993). Variables to be considered in the evaluation of fetal hydronephrosis include gestational age at diagnosis, area of urinary tract involved, degree of dilation, and evidence of significant obstruction. Several series have reviewed the accuracy of the diagnosis of hydronephrosis by ultrasound examination of the fetus (Blane et al., 1983; Avni et al., 1985; Watson et al., 1988). Unfortunately, a fairly high rate of false-positive results have been noted, varying between 9% and 22% (Scott and Renwick, 1987; Reznick et al., 1988). It is thought that as our ability to distinguish physiologic from pathologic hydronephrosis becomes more refined, this rate of false-positive scans will be reduced. In order to better define the severity of hydronephrosis, the Society of Fetal Urology has proposed a grading system that uses two parameters: 1) the central renal complex; and 2) renal parenchymal thickness to grade density of the hydronephrosis (see Table 80-1). Most cases of minimal hydronephrosis will fall in the Grade 0 or 1 categories.

Table 80-1

Density of Hydronephrosis

Grade	Central Renal Complex	Renal Parenchymal Thickness
0	Intact	Normal
I	Slight splitting of pelvis and calices	Normal
II	Evident splitting of pelvis and calices	Normal
III	Wide splitting of pelvis and calices	Normal
IV	Further splitting of pelvis and calices	Reduced

Adopted from the Society of Fetal Etiology.

Most authors recommend that all fetuses with an A-P diameter of ≥6 mm should undergo postnatal evaluation (Odibo et al., 2004; Becker and Baum, 2006; Belarmino and Kogan, 2006). Certainly fetuses with an A-P pelvic diameter 10 mm and those who have an A-P pelvic renal cortex ratio >0.5 or with evidence of caliectasis should certainly undergo postnatal evaluation (Cendron et al., 1994).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of minimal fetal hydronephrosis includes extrarenal pelvis, prominent renal veins crossing over the renal pelvis, and vesicoureteral reflux (Table 80-2). The degree of dilation in an extrarenal pelvis can be sufficient to be mistaken for ureteropelvic junction (UPJ) obstruction (see Chapter 81). Color flow Doppler studies should be able to distinguish the crossing renal vein from the true renal pelvis. In vesicoureteral reflux the degree of pelvic dilation will vary over time. In particular, increased renal pelvic diameter may be observed at the time of bladder contractions. Other possibilities include an overlying loop of intestine mistaken for the renal pelvis, a dilated superior pole of a duplex collecting system, and dilated ureter secondary to ureterovesical obstruction. In each of these cases careful sonographic examination should be able to define the fetal anatomy.

ANTENATAL NATURAL HISTORY

Our understanding of the natural history of fetal hydronephrosis is still evolving, especially in cases of hydronephrosis detected before 20 weeks of gestation. In a report describing the use of transvaginal ultrasound screening during the early stages of pregnancy, fetal hydronephrosis was found to vary greatly over the course of gestation (Bronshtein et al., 1990). In fact, of 27 cases of fetal hydronephrosis (renal pelvis >3 mm) diagnosed between 13 and 17 weeks of gestation, only 6 displayed any evidence of hydronephrosis postnatally (Bronshtein et al., 1990). Ten cases of unilateral hydronephrosis gradually disappeared between 15 weeks of gestation and term. The parameters of what constitutes abnormal pelvic distention in fetuses less than 20 weeks of gestation have yet to be clearly established.

In order to better define fetal hydronephrosis and its impact on the developing urinary tract, many ultrasonographic features must be systematically reviewed. The evaluation of the urinary tract should include an assessment of the overall growth and development of the fetus, amniotic fluid index, genitalia, renal parenchymal appearance, extent of dilation of the collecting system, whether involvement is unilateral or bilateral, as well as bladder size, thickness, and emptying. Because of the increased incidence of associated malformations, the fetus should be scanned for extrarenal anomalies. The fetus with hydronephrosis should be evaluated at several points in gestation. In the very early second trimester of pregnancy, a renal pelvic diameter of only 5–8 mm may have functional significance (Blyth et al., 1993). As noted previously, after 20 weeks of gestation, a renal pelvic dilation of

Abbreviations: UPJ, ureteropelvic junction; VUR, vesico-ureteral reflux; MCDK, multicystic dysplastic kidney; PUV, posterior urethral valve.

>6 mm should be considered significant, requiring close prenatal observation and postnatal evaluation. In antenatal hydronephrosis, defined as ≥6 mm A-P renal pelvic diameter, vesicoureteral reflux is the most common cause with ureteropelvic junction obstruction, more often the cause when the renal pelvic diameter is >10 mm (Woodward and Frank, 2002).

Occasionally, progression of physiologic to pathologic hydronephrosis can be seen later in gestation, but the incidence is probably less than 10%. Progression to pathologic hydronephrosis is most often associated with UPJ obstruction and with vesicoureteral reflux (Noe and Magill, 1987; Watson et al., 1988; Zerrin et al., 1993; Morin et al., 1996). Because no criteria are currently available to identify fetuses in which minimal hydronephrosis in the second trimester will progress to pathologic hydronephrosis later in gestation, we currently recommend that a single follow-up sonography be performed at 32 weeks of gestation to rule out progression.

MANAGEMENT OF PREGNANCY

The fetus diagnosed with minimal fetal hydronephrosis prior to 24 weeks of gestation has a 90% chance of complete resolution with no postnatal sequelae. Conversely, 10% of these patients will have worsening of their hydronephrosis (Morin et al., 1996). Because no sonographic criteria discern which fetuses constitute the 10% in which minimal fetal hydronephrosis will progress, we currently recommend that all fetuses with minimal hydronephrosis undergo a repeat ultrasound examination at 32 to 34 weeks to determine which fetuses will require postnatal evaluation. In a review of 127 cases of minimal fetal hydronephrosis, Morin et al. found that 9% had worsening of hydronephrosis during the third trimester and required postnatal evaluation. A retrospective analysis of the sonograms of the fetuses in which minimal hydronephrosis worsened or progressed had one or more of the following features present: caliectasis, in utero progression, or abnormal renal echogenicity. Of the 9% of fetuses with progression of minimal fetal hydronephrosis, four fetuses required postnatal surgery to preserve renal function. This number may be small, but it represents a much larger percentage of pathologic hydronephrosis among fetuses with minimal fetal hydronephrosis than previously described. Of the 23 patients with abnormal findings documented postnatally, 4 were found to have functionally significant UPJ obstruction, 1 had severe vesicoureteral reflux, and all of them required surgical correction of the urologic condition.

Hydronephrosis can be associated with aneuploidy and is a component of several syndromes and the VACTERL association (Benacerraf et al., 1990). A multicenter prospective observational study of unselected fetuses examined between 16 and 26 weeks gestation identified 737 fetuses with mild hydronephrosis in a population of 101,600 births. Of these 737 fetuses, 12 (1.7%) had chromosomal abnormalities (6 trisomy 21, 1 trisomy 13, 1 trisomy 8, 2 Turner's syndrome, 1 unbalanced translocation, and 1 47XXX) (Chudleigh et al., 2001). In this study, the risk of aneuploidy in minimal hydronephrosis was found to be 0.33% and 2.22% in women less than 36 years and greater than or equal to 36 years, respectively. These authors suggested that the presence of hydronephrosis should at least prompt discussion of amniocentesis for karyotype analysis.

Once the fetus is diagnosed sonographically as having progressive minimal fetal hydronephrosis, careful follow-up should be planned to ensure proper postnatal management. At the time of the initial prenatal diagnosis of hydronephrosis, parental counseling is recommended. A multidisciplinary team approach is extremely helpful to inform the parents and to help them understand the implications of this diagnosis.

FETAL INTERVENTION

There is no indication for fetal intervention for minimal fetal hydronephrosis.

TREATMENT OF THE NEWBORN

Every newborn with a prenatal diagnosis of hydronephrosis should undergo a complete physical examination at birth, with specific emphasis on identifying the urethral orifice. Monitoring of the urinary output within the first 24 to 48 hours is unreliable. Failure to void during the first 2 days after birth may reflect normal fluid shifts or may be the first sign of a significant urologic anomaly (Arant, 1992). The differential diagnosis in the neonate who does not void within the first 48 hours includes obstructive uropathy, renal failure, neurogenic bladder, and the effects of maternal medication (Arant, 1992). However, most patients with urinary obstruction will still void, albeit with a weak stream, within the first 2 days of life. Serum electrolyte, blood urea nitrogen, and creatinine levels obtained within the first day of life are a reflection of maternal renal function via placental exchange. It is best to wait at least 24 hours to obtain these values. The most helpful test in the initial evaluation in the newborn with prenatally diagnosed hydronephrosis is an ultrasound examination of the abdomen, including a scan of the bladder. Timing of the ultrasound examination depends on the extent of prenatal hydronephrosis (Dejter and Gibbons, 1989). If severe dilation of the renal pelvis has been detected antenatally, then early ultrasound evaluation within the first 1 to 2 days should be performed to permit early intervention. Otherwise, ultrasound evaluation can be postponed for 3 to 7 days in order to let the physiologic diuresis that occurs during the first 48 hours of life to resolve (Arant, 1992). If the initial postnatal renal ultrasound examination is normal, the evaluation should be pursued with a repeat ultrasound examination in 3 to 4 weeks. The reason for this is that a high incidence of neonates diagnosed with antenatal hydronephrosis have a normal upper urinary tract at the time of their first ultrasound, and are subsequently diagnosed with ureteropelvic obstruction or vesicoureteral reflux (Dejter and Gibbons, 1989).

SURGICAL TREATMENT

Mild cases of hydronephrosis can be observed clinically, and may warrant only one or two ultrasound examinations during the postnatal period. It is rare for mild dilation of the urinary tract to progress. In cases in which additional findings are observed, such as cortical thinning or upper-tract dilation with a normal bladder noted, voiding cystourethrography (VCUG) should be performed to evaluate the presence of vesicoureteral reflux. If vesicoureteral reflux is noted, then a renal nuclear or radionuclide scan, either 99 technetium-diethylenetriaminepentraaccetic acid (DTPA) or mercaptoacetyltriglycine (MAG-3) scans, will be helpful in documenting renal function and degree of obstruction, if present. If no evidence of reflux is noted on VCUG, then a MAG-3 scan with furosemide should be obtained to evaluate the upper renal tract for possible UPJ obstruction (see Chapter 81). If UPJ obstruction is noted, subsequent management is determined by the severity of the obstruction. In severe UPJ obstruction, in which a kidney shows 35% or less function, pyeloplasty should be performed. In the cases in which mild-to-moderate obstruction is noted, and the kidney has more than 35% function, observation alone may be indicated, with a repeat scan in three months. A repeat renal scan will help to assess the changes occurring in renal function. As stated earlier, growing evidence suggests that a mild degree of UPJ obstruction may not be functionally significant and does not warrant surgical intervention (Koff, 1990; Gordon et al., 1991; Duckett, 1993; Woodward and Frank, 2002).

Current recommendations in treatment of the neonate with prenatally diagnosed hydronephrosis include the administration of prophylactic antibiotics, usually a penicillin derivative (Berman and Maizels, 1983). In the past, most patients with hydronephrosis presented with a urinary tract infection later in life. The incidence of urinary tract infection in the setting of prenatally diagnosed hydronephrosis has not been thoroughly evaluated, but a study found that 3% of the patients being evaluated radiologically during the first 6 months of life were found to have a positive urinary culture from a catheterized specimen (Daucher et al., 1992). We currently recommend antibiotic prophylaxis, pending postnatal evaluation, for all neonates with persistent or worsening hydronephrosis diagnosed prenatally. This can be discontinued if no significant urinary tract obstruction or vesicoureteral reflux is noted on the postnatal evaluation.

LONG-TERM OUTCOME

The fetus diagnosed with minimal fetal hydronephrosis who shows no progression at 32 to 34 weeks of gestation requires no postnatal follow-up. Postnatal evaluation is indicated, as discussed above, in fetuses in which there is progression. The long-term outcome is entirely dependent on the diagnosis. In cases of vesicoureteral reflux, complete resolution can often be observed over the first several months of life. Similarly, mild-to-moderate UPJ obstruction, not requiring pyeloplasty, usually has no long-term sequelae. The long-term outcome for specific causes of fetal hydronephrosis is discussed in Chapters 80–83. It is unusual for minimal fetal hydronephrosis that developed during the second trimester to result in renal dysplasia. Good long-term follow-up in these patients is lacking, but we currently do not anticipate late compromise of renal function in these patients. However, recent prospective

studies have found that even mild hydronephrosis that is stable or resolves during pregnancy can redevelop, progress, and may even require surgery later in life (Ismaili et al., 2004; Signorelli et al., 2005).

GENETICS AND RECURRENCE RISK

The risk of recurrence of minimal hydronephrosis with subsequent pregnancies has not been studied. However, given that this condition affects 18% of all pregnancies, chances are at least that high that minimal fetal hydronephrosis will be coincidentally detected in a subsequent pregnancy.

Hydronephrosis can be associated with aneuploidy or syndromes, or the VACTERL association (Benacerraf et al., 1990). Mild hydronephrosis may be associated with a risk of aneuploidy that is slightly higher than age-adjusted risk (Chudleigh et al., 2001).

Hydronephrosis: Ureteropelvic Junction Obstruction

81 CHAPTER

Key Points

- Ureteropelvic junction obstruction (UPJ) prevents urinary flow from the renal pelvis to the ureter, and is the most common cause of significant neonatal hydronephrosis.
- The timing of onset of obstruction determines the clinical presentation, ranging from multicystic dysplastic kidney to pelvicaliceal dilation for first trimester compared with third trimester obstruction respectively.
- Most cases are unilateral, with bilateral cases, or cases in which the contralateral kidney has multicystic dysplastic changes, having much worse prognosis.
- Pregnancy management is generally unchanged in unilateral UPJ cases, while fetal intervention by means of urinary shunting may be necessary in rare cases of severe bilateral UPJ.
- Management of the neonate usually includes delaying imaging until 3–7 days of life to allow completion of normal physiologic diuresis and initiation of prophylactic antibiotics.
- Indications for surgical intervention include renal function less than 40% expected, worsening hydronephrosis, renal pelvic diameter greater than 5 cm, or febrile morbidity.

CONDITION

Obstruction at the ureteropelvic junction (UPJ) is the most common cause of significant neonatal hydronephrosis (Lebowitz and Griscom, 1986). Because 85% to 90% of affected newborns appear entirely normal on physical examination at birth, prenatal recognition permits treatment of a condition that may otherwise be unrecognized (Grignon et al., 1986). This form of hydronephrosis is characterized by obstruction to the flow of urine from the renal pelvis to the ureter. UPJ obstruction may be classified as either primary or secondary. Primary causes of UPJ obstruction would include intrinsic problems such as intraluminal valves, polyps, congenital mucosal folds, muscular hypertrophy, and functional obstruction and extrinsic causes of obstruction such as aberrant crossing vessels. Secondary causes of UPJ obstruction would include vesicoureteral reflux or more distal obstruction. Among the suggested causes are intrinsic valves at the UPJ, abnormally thickened or oriented muscular bands at the UPJ, high insertion of the ureter on the renal pelvis, anomalous crossing bands or vessels at the UPJ, ischemia, and segmental ureteral dismotility (Williams and Karlaftis, 1966; Kelalis et al., 1971; Johnston et al., 1977; Hendren et al., 1980; Maizels and Stephens, 1980). In the majority of cases, however, a patent UPJ is found at the time of surgical correction. In most cases therefore, the obstruction appears to be more functional than mechanical.

While the pathogenesis of UPJ obstruction is poorly understood, some aspects of the prenatal history are known. Complete obstruction at the UPJ before 8 to 10 weeks of gestation results in severe dysplastic changes in the developing kidney (Scholtmeijer and van der Harten, 1975; Potter, 1976; McGrory, 1980; Sanders and Hartman, 1984). The result is a multicystic dysplastic kidney (see Chapter 78). In contrast, incomplete UPJ obstruction that occurs during the second trimester does not result in multicystic dysplastic kidney but may result in variable degrees of renal dysplasia, in addition to pelvicaliceal dilation. In contrast, UPJ obstruction that occurs during the third trimester may result in marked pelvicaliceal dilation, but usually does not cause renal dysplasia.

Most cases of antenatal hydronephrosis are nonobstructive and will resolve spontaneously in the postnatal period (Belarmino and Kogan, 2006; Becker and Baum, 2006; Hanna, 2006). The diagnosis of UPJ obstruction in the fetus

is based on pelvicaliceal dilation that exceeds proposed criteria for minimal fetal hydronephrosis (see Chapter 80). There is no agreement on the absolute cut-off limit for pathologic antenatal pelvic dilation. Most reports suggest postnatal investigation for pelvic dilation of more than 5 mm (Woodward and Frank, 2002; Becker and Baum, 2006). To distinguish primary UPJ obstructions, an anterior-posterior (AP) pelvic diameter of the renal pelvis $\geq$10 mm or the presence of caliectasis could be used (Arger et al., 1985; Kleiner et al., 1987). To distinguish UPJ obstruction from other causes of obstructive uropathy, there must also be pelvic dilation and an absence of findings suggestive of obstructive uropathy at a lower level, such as ureterectasis, vesicomegaly, ectopic ureterocele, and dilated posterior urethra. Although UPJ obstruction is, in a large part, a diagnosis of exclusion, ultrasound examination has proven reliable in determining the level of obstruction (Kleiner et al., 1987).

INCIDENCE

The overall incidence of genitourinary defects diagnosed by prenatal ultrasound examination has been estimated to be between 0.2% and 0.9%. The incidence of UPJ obstruction is estimated at 0.001% with a male to female ratio of 3:1 (Woodward and Frank, 2002). In newborns the left side is affected in almost two thirds of cases. Bilateral UPJ obstruction is seen postnatally in only 15% of cases (Johnston et al., 1977) but may be more common in prenatally diagnosed cases, as observed by Flake et al. (1986).

SONOGRAPHIC FINDINGS

In unilateral UPJ obstruction the renal pelvis and infundibulum are dilated (Figure 81-1). Dilation of the calices may also

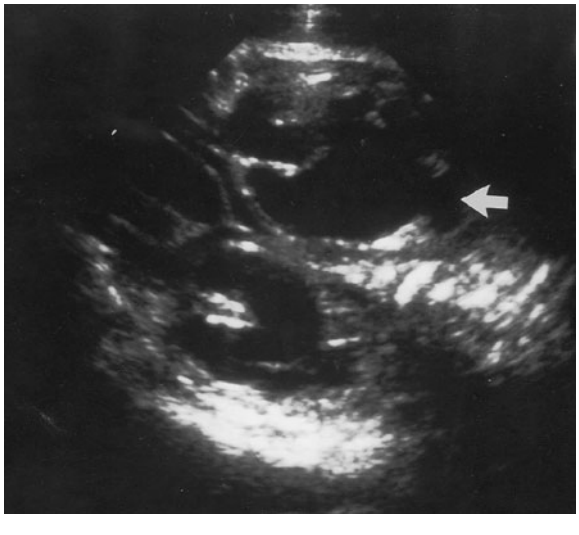

Figure 81-1 Sonogram at 24 weeks of gestation in coronal section of the fetal kidneys demonstrating characteristic features of UPJ obstruction affecting both kidneys with markedly dilated renal pelvis and calices with associated urinary ascites.

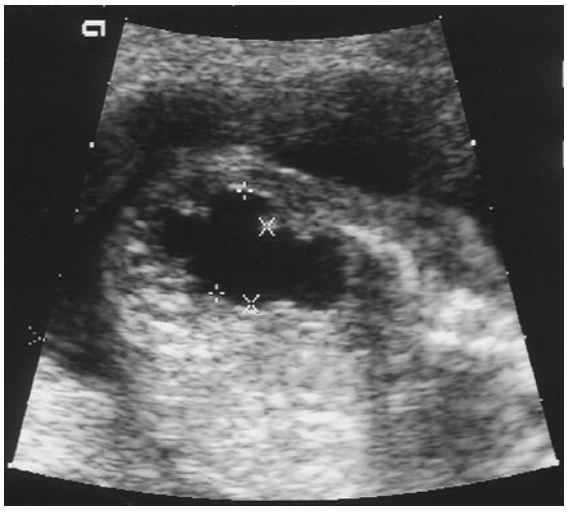

Figure 81-2 Fetal MRI coronal image of the same fetus in Figure 81-1, demonstrating bilateral UPJ obstruction with dilated renal pelvis, caliceal dilation, and urinary ascites.

be seen. The anterior to posterior pelvis to kidney ratio is greater than 50% (Arger et al., 1985). The following findings are not seen in primary UPJ obstruction: dilated ureter, ectopic ureterocele, dilated or thickened urinary bladder, or a dilated posterior urethra. In more severe cases of primary UPJ obstruction only a single fluid-filled structure may be seen, which is the dilated pelvis with only a thin rim of surrounding cortex (Figure 81-2) (Mahony, 1994). In even more severe cases, the renal pelvis may be so dilated that it appears as an abdominal cyst in which not even a rim of renal parenchyma is seen. Such severe UPJ obstructions can reach a significant size, distending the fetal abdomen and elevating the diaphragm (Jaffe et al., 1987). In rare instances, both the infundibulum and the renal pelvis are stenotic and only caliceal dilation is seen (Lucaya et al., 1984). In the most severe form of UPJ obstruction, the collecting system can rupture, with the formation of a perinephric urinoma or urinary ascites. Although some reports suggest it is unusual to have salvageable renal function in a kidney with a perinephric hematoma, in some instances this rupture may be protective (Callen et al., 1983; Friedland et al., 1983; Adzick et al., 1985; Harrison and Filly, 1991). In unilateral UPJ obstruction, the contralateral kidney produces a normal volume of amniotic fluid and the bladder fills and empties normally, even in cases in which the UPJ obstruction has resulted in renal dysplasia. It is important to recognize that UPJ obstruction may be seen frequently in association with contralateral multicystic dysplastic kidney or renal agenesis. Either condition, in association with high-grade UPJ obstruction, may produce profound oligohydramnios and Potters syndrome features (Mahony, 1994).

Bilateral UPJ obstruction is present in 15% to 50% of cases, depending on the series reported (Flake et al., 1986; Kleiner et al., 1987). Fortunately, the involvement is often asymmetric and severe bilateral obstruction is rare. However, as reported by Flake et al. up to 5% mortality can be seen with bilateral UPJ obstruction, which progresses to oligohydramnios and secondary pulmonary hypoplasia. UPJ

obstruction paradoxically results in polyhydramnios in up to 25% of cases (Kleiner et al., 1987). The pathophysiology of the polyhydramnios is uncertain but is thought to be due to hyperfiltration occurring in the partially obstructed kidneys.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of UPJ obstruction includes all other causes of hydronephrosis, including vesicoureteral reflux, megaureter, obstructed duplicated collecting system, and bladder-outlet obstruction (Table 81-1). A detailed sonographic evaluation of the kidneys should differentiate the anatomic level of obstruction causing hydronephrosis. Bladder outlet obstruction, whether due to urethral atresia or posterior urethral valves, should be associated with vesicomegaly with a thick and often trabeculated bladder wall. Cases of ureterovesical obstruction, such as megaureter, are distinguished by the lack of vesicomegaly, with a dilated tortuous ureter extending from the renal pelvis to the ureterovesical junction. A duplex collecting system frequently results in hydronephrosis due to obstruction at the site of the ureteral insertion, often at an ectopic site. This may occur in association with an ureterocele (see Chapter 83). In such cases, the ureter is uniformly dilated up to the superior pole of the kidney, which may have cystic dysplastic changes from long-standing high-grade obstruction.

Vesicoureteral reflux may occur in association with UPJ obstruction and may be difficult to distinguish from UPJ obstruction as a cause of hydronephrosis. One sonographic observation that is helpful in distinguishing between these two diagnoses is observing the degree of pelvic dilation that occurs with bladder emptying. UPJ obstruction is minimally affected by voiding; however, vesicoureteral reflux is usually evidenced by marked fluctuations in the size of the ureter and renal pelvis associated with bladder contraction.

Table 81-1

Differential Diagnosis of Ureteropelvic Junction Obstruction

Bilateral hydronephrosis
Supravesical obstruction
Bilateral UPJ obstruction
Bilateral ureterovesical junction obstruction
Infravesical obstruction
Posterior urethral valves
Urethral atresia
Obstructing ureterocele
Vesicoureteral reflux (bilateral, usually high-grade)
Prune belly syndrome
Megacystis–megaureter complex
Unilateral hydronephrosis
UPJ obstruction
Ureterovesical junction obstruction
Multicystic dysplastic kidney
Megaureter (nonobstructing, nonrefluxing) (may be bilateral)
Renal duplication (may be bilateral)
Dilated loop of bowel

ANTENATAL NATURAL HISTORY

The most important determinants of the outcome of UPJ obstruction in the fetus are the gestational age at onset, severity of obstruction, and whether the UPJ obstruction is unilateral or bilateral. In early gestation, high-grade obstruction at the ureteropelvic junction that occurs during the first trimester results in a multicystic dysplastic kidney. In UPJ obstruction that occurs during the second trimester, the fetal kidneys are at risk for renal dysplasia and compromised renal function at birth. In contrast, UPJ obstruction that occurs during the last trimester rarely causes renal dysplasia, even in cases of high-grade obstruction. This vulnerability of the developing kidney to obstruction-induced dysplasia likely reflects the effect of increased pressure during the nephrogenic phase of renal development between 20 and 30 weeks of gestation (Harrison and Filly, 1991).

Our understanding of the antenatal natural history of UPJ obstruction is still evolving. UPJ obstruction is usually thought to be a benign condition. Flake et al. (1986) challenged this view with their results of a review of 28 fetuses referred to a fetal treatment center with prenatally diagnosed UPJ obstruction in 44 kidneys. This series was unusual, in that over half the cases were bilateral, as compared with the usually quoted lower rates of 5% to 20% (Williams and Karlaftis, 1966; Kelalis et al., 1971; Johnston et al., 1977; Hendren et al., 1980). In some cases, pelvicaliceal dilation due to UPJ obstruction resolves during gestation. In the series reported by Flake et al. (1986), 2 cases resolved. All but five newborns required surgical intervention postnatally, ranging from nephrostomy to pyeloplasty, ureteroureterostomy, or nephrectomy. Nongenitourinary anomalies were noted in 5 of the 28 fetuses. There was a 5% mortality rate in this series, with all deaths occurring in cases of bilateral UPJ obstruction (Flake et al., 1986).

Antenatal progression in the degree of hydronephrosis in cases of UPJ obstruction is a reliable predictor of the need for postnatal surgical decompression. Harrison and Filly (1991) felt that progression was more likely in bilateral UPJ obstruction. However, the degree of hydronephrosis seen in utero does not always correlate with postnatal parenchymal function.

Polyhydramnios may be seen in 25% to 33% of cases of UPJ obstruction (Flake et al., 1986; Kleiner et al., 1987). Polyhydramnios has been described in association with impaired renal function and bilateral obstruction (Henderson et al., 1980; Hadlock et al., 1981; Laing et al., 1984). It has been suggested that polyhydramnios occurring in UPJ obstruction is due to impaired renal concentrating ability, resulting in higher urine output (Harrison and Filly, 1991).

While the prognosis in unilateral UPJ obstruction is usually excellent, there is a high incidence of genitourinary abnormalities in the contralateral side. These abnormalities may range from multicystic dysplasia to vesicoureteral reflux. However, because there is usually a normally functioning kidney on the contralateral side, amniotic fluid volume is maintained, and there is no adverse affect on outcome of pregnancy and neonatal survival. Even in cases in which renal dysplasia complicates UPJ obstruction, there is often a compensatory increase in renal mass and function in the contralateral kidney (Sauer et al., 1986).

The prognosis in bilateral UPJ obstruction is somewhat more guarded. There is a 5% mortality associated with high-grade bilateral UPJ obstruction (Flake et al., 1986). In addition, fetuses with bilateral UPJ obstruction are at increased risk for polyhydramnios, progression in the degree of obstruction, and oligohydramnios in the most severe cases. While unilateral UPJ obstruction is an indication for postnatal genitourinary evaluation, it usually has few implications for the management of the pregnancy. In contrast, fetuses with bilateral UPJ obstruction should undergo serial sonographic assessments of the degree of dilation, renal parenchymal changes, and amniotic fluid volume.

In the series by Flake et al. (1986), oligohydramnios developed in 4 fetuses with bilateral UPJ obstruction, prompting early delivery. All 4 were delivered at 32 to 35 weeks of gestation and underwent pyeloplasty during the neonatal period, with normal renal function after repair. Nineteen of the 23 patients underwent pyeloplasty. Seven pyeloplasties were performed in cases of unilateral UPJ obstruction, with evidence of impaired function in the kidney. All had improved or stable function following pyeloplasty. Twelve pyeloplasties were performed in 9 patients with bilateral UPJ obstruction. In 5 of the 9, renal function was abnormal but became normal after pyeloplasty. An indication of the severity of UPJ obstruction in this group of patients is the 9 nephrectomies performed, either for multicystic dysplastic kidneys, perinephric urinomas, or kidneys with no demonstrable renal function on preoperative diuretic renal scan.

MANAGEMENT OF PREGNANCY

The fetus diagnosed with UPJ obstruction should have a prompt referral for detailed sonographic assessment to confirm the diagnosis, evaluate associated genitourinary abnormalities, and possible associated nongenitourinary abnormalities. There is an overall increased incidence of chromosomal abnormalities in cases of obstructive uropathy, and consideration should be given to amniocentesis for karyotype analysis. It is important to perform a detailed fetal anatomical scan to exclude other associated renal and extrarenal anomalies such as horseshoe kidney, multicystic dysplastic kidney, as well as diaphragmatic hernia, hydrocephalus, and congenital cystic adenomatoid malformation (Harrison and Filly, 1991).

Pregnant women carrying a fetus suspected of having UPJ obstruction should be referred to a pediatric surgeon or pediatric urologist for prenatal consultation. In cases of isolated UPJ obstruction, a favorable prognosis can be anticipated, and routine obstetric care can be performed with planned postnatal genitourinary evaluation. In cases of bilateral UPJ obstruction or unilateral UPJ obstruction associated with either multicystic dysplastic kidney or renal agenesis, serial sonographic examinations at least every 2 to 3 weeks should be performed to evaluate progression in obstruction and development of oligohydramnios or polyhydramnios.

FETAL INTERVENTION

In unilateral UPJ obstruction there is no indication for fetal intervention. However, in high-grade bilateral UPJ obstruction or unilateral UPJ obstruction associated with a contralateral multicystic dysplastic or renal agenesis, consideration may be given to fetal intervention. In such cases presenting after 30 weeks of gestation, consideration should be given to steroid administration and early delivery (Flake et al., 1986; Harrison and Filly, 1991). Cases that present prior to 30 weeks of gestation may be candidates for evaluation for fetal intervention. Prognostic evaluation consists of direct sampling of fetal urine from the renal pelvis in bilateral UPJ or from the bladder in unilateral UPJ with associated MCDK or renal agenesis. Laboratory values associated with a good prognosis include a fetal urine sodium of less than 100 meq per liter, chloride of less than 90 meq per liter, osmolarity of less than 210 mOsm per liter, and a β_2-microglobulin of less than 4 mg per liter (Crombleholme et al., 1990; Mandelbrot et al., 1991; Cendron et al., 1994). Laboratory values for fetal urine electrolytes above these limits may prompt serial fetal urinary sampling in order to be certain that the elevated values accurately reflect renal function.

Fetuses with bilateral high-grade UPJ obstruction, complicated by oligohydramnios, in which a good prognostic profile was obtained by direct renal pelvic tap for fetal urine electrolyte analysis, may be candidates for intervention. Placement of a Harrison catheter into the renal pelvis under ultrasound guidance has been rarely done but may restore amniotic fluid volume and prevent ongoing damage to the obstructed kidney.

TREATMENT OF THE NEWBORN

Once a fetus has been found on prenatal ultrasound examination to have a significant degree of hydronephrosis, careful follow-up should be planned to ensure proper postnatal treatment. At the time of the initial prenatal diagnosis of hydronephrosis, parental counseling is recommended. A team approach is extremely helpful to inform the parents and to help them understand the implications of this prenatal diagnosis (Cendron et al., 1994).

Every newborn with a prenatal diagnosis of hydronephrosis should undergo a detailed physical examination at birth for signs of sequelae from obstructive uropathy. Monitoring of the urinary output within the first 24 to 48 hours is unreliable. Failure to void during the first 2 days after birth may reflect normal fluid shifts or may be the first sign of a significant functional urologic abnormality (Arant, 1992). The differential diagnosis in the neonate who does not void within the first 48 hours includes obstructive uropathy, renal failure, neurogenic bladder, and the effects of maternal medication (Arant, 1992). However, most patients with an obstruction will void, albeit with a weak stream, within the first 2 days of life. Serum electrolytes, blood urea nitrogen, and creatinine levels measured within the first day of life are a reflection of maternal renal function via placental exchange. It is therefore best to wait at least 24 hours to measure these values. The most helpful test in the initial evaluation of the newborn with prenatally diagnosed hydronephrosis is an ultrasound examination of the abdomen, including the bladder. Timing of the postnatal ultrasound examination depends on the degree of prenatal hydronephrosis (Dejter and Gibbons, 1989). If severe dilation of the renal pelvis has been detected antenatally then early ultrasound evaluation should be performed so as to permit early intervention. Otherwise, ultrasound examination can be postponed for 3 to 7 days in order to let the physiologic diuresis that usually occurs in the first 48 hours of life to resolve (Arant, 1992). If the initial postnatal renal ultrasound examination is normal, the evaluation should be pursued with a repeat study in 3 to 4 weeks. Fifty percent of neonates with UPJ and vesicoureteral reflux who were diagnosed antenatally with hydronephrosis have a normal upper urinary tract at the time of the first postnatal ultrasound examination (Dejter and Gibbons, 1989).

Mild cases of hydronephrosis can be treated conservatively with observation, and may warrant only one or two ultrasound examinations during the postnatal period. It is rare for mild dilation of the upper urinary tract to progress. In cases in which other findings are seen, such as cortical thinning or upper tract dilation with a normal bladder, voiding cystourethrography (VCUG) should be performed to evaluate for the presence of vesicoureteral reflux (VUR). If VUR is noted, then a renal nuclear medicine scan using 99 technetiumdiethylenetriaminepentaacetic (DTPA) or preferably mercaptoacetyltriglycine (MAG-3) will be helpful in documenting function of the kidneys (Ismaili et al., 2004). MR urography is an alternative imaging study that provides both anatomic and functional information in children with UPJ obstruction in a single test that does not expose the child to ionizing radiation. Anatomic evaluation combined with renal transit time classification provides a reliable parameter for the identification of obstruction. However, sophisticated software, technical expertise, and cost are limitations of MR urography (McDaniel et al., 2005). If no evidence of reflux is noted on VCUG, then a MAG-3 with furosemide should be obtained to evaluate the upper urinary tract for a possible UPJ obstruction. If UPJ obstruction is noted, treatment is determined by the severity of the obstruction. There is no unanimity of opinion on the indications for surgical treatment of UPJ obstruction. Among the more commonly agreed indications some include reduced renal function to less than 40%, deterioration in differential renal function of more than 5%, persistent or worsening hydronephrosis, unilateral gross hydronephrosis of more than 5 cm renal pelvic A-P diameter, severe hydronephrosis in a solitary kidney, severe bilateral hydronephrosis of more than 3 cm renal pelvic A-P diameter, and febrile breakthrough infection. In severe UPJ obstruction, in which a kidney shows 40% or less function, pyeloplasty should be considered. In the cases in which mild-to-moderate obstruction is noted, and the kidney has more than 40% function, observation alone may be indicated, with a repeat ultrasound examination in three months. A repeat renal scan will help to assess changes in renal function. As stated earlier, there is growing evidence to suggest that a mild degree of UPJ obstruction may not be functionally significant and does not warrant surgical intervention (Koff, 1990; Gordon et al., 1991; Duckett, 1993).

If prenatal ultrasound examination shows a multicystic dysplastic kidney, a VCUG and a renal scan should be obtained. These studies can confirm the lack of function in the affected kidney and rule out any abnormalities in the contralateral kidney (Flack and Bellinger, 1993).

Surgical intervention at birth is required in cases in which a severe obstruction will jeopardize renal function. This applies most often to cases of posterior urethral valves, obstructing ureterocele, and severe UPJ obstruction affecting a solitary kidney. Emergency surgical treatment is seldom warranted. Reconstruction of the urinary tract should not be attempted until the newborn has stabilized from a medical standpoint and has been fully evaluated. Temporary decompression of the urinary tract in cases of severe UPJ obstruction can be achieved by placement of a nephrostomy tube until definitive repair of the urinary tract can be accomplished. In the presence of a solitary kidney, every attempt should be made to ensure adequate drainage so as to not further jeopardize renal function.

Finally, current recommendations for treating the neonate with prenatally diagnosed hydronephrosis include the administration of prophylactic antibiotics, usually a penicillin derivative (Woodward and Frank, 2002; Becker and Baum, 2006; Belarmino and Kogan, 2006; Hanna, 2006). In the past, most patients with hydronephrosis presented with a urinary tract infection later in life. The incidence of urinary tract infection in the setting of prenatally diagnosed hydronephrosis has not been thoroughly evaluated, but one study found that 3% of patients being evaluated radiologically during the first 6 months of life were found to have a positive culture from a catheterized specimen (Dacher et al., 1992).

LONG-TERM OUTCOME

Most pediatric urologists manage the majority of severe fetal hydronephrosis cases due to UPJ obstruction with observation and reserve surgery for patients with deterioration

in renal function or clinical symptoms. No prospective randomized studies comparing operative to nonoperative management of UPJ obstruction have been conducted. There are, however, longitudinal follow-up studies with conversion from observation to surgery when renal function deteriorated by 10% or symptoms occurred (Ransley et al., 1990; Cartwright et al., 1992; Koff and Campbell, 1994). Chertin et al., recently reported that among children diagnosed prenatally with UPJ obstruction that did not appear to need pyeloplasty in infancy, 50% went on to pyeloplasty by 16 years of age (Chertin et al., 2006). The long-term outcome of UPJ obstruction depends on whether it is unilateral or bilateral and if there is an underlying renal dysplasia. In the absence of renal dysplasia, renal function often returns to baseline levels following pyeloplasty. In cases in which UPJ obstruction has caused dysplastic changes, compensatory hypertrophy in the normal contralateral kidney ensures an excellent prognosis. However, in cases of contralateral multicystic dysplastic kidney or renal agenesis, renal dysplasia induced by UPJ obstruction will lead to progressive renal insufficiency and ultimately renal failure necessitating renal transplantation. This latter group of patients requires follow-up with a pediatric nephrologist as well as a pediatric urologist.

GENETICS AND RECURRENCE RISK

In general, VUR has a high familial incidence. It is thought to be an autosomal dominant condition with reduced penetrance (Devriendt et al., 1998). Although UPJ obstruction is a common entity, it is usually sporadic. It is important to note that UPJ obstruction can remain clinically stable for years only to present in adult life with symptoms such as stone formation, pain, or infection. The natural history of antenatal UPJ obstruction may take 30 or more years to fully evolve. Multiple case reports suggest inheritance of a gene that specifically predisposes to UPJ obstruction. These include affected identical twin females, a mother and two children, and multiple siblings in different families (Cohen et al., 1978; Sidebottom and Sadlowski, 1984; Buscemi et al., 1985; Dabra et al., 2003). In one report, histocompatibility typing of a family with 15 members and a history of UPJ stenosis suggested that the renal malformation and histocompatibility haplotype were linked (Senger et al., 1979). More recently, study of a large affected kindred using DNA linkage markers on the short arm of chromosome 6 concluded that there was no linkage between the presence of ureteral abnormalities and the HLA genes (Klemme et al., 1998).

Whether inheritance of UPJ obstruction is dominant or multifactorial, it is clear that siblings are at increased risk for uropathology. In one study, 37 siblings of 20 probands with UPJ obstruction were evaluated with intravenous pyelography and VCUG. Fourteen of the 37 (38%) had some form of uropathology that required subsequent therapy (Dwoskin, 1979). We recommended that siblings of children with UPJ obstruction be investigated for uropathology regardless of age or sex.

Hydronephrosis: Bladder Outlet Obstruction

82 CHAPTER

Key Points

- Posterior urethral valves (PUVs) are the most common cause of bladder outlet obstruction in males.
- PUVs account for 10% of all urologic anomalies detected by prenatal ultrasound.
- PUVs have a broad range of severity from completely asymptomatic to complete obstruction, oligohydramnios, pulmonary hypoplasia, and renal dysplasia.
- Oligohydramnios due to a PUV, if untreated, is associated with nearly uniform neonatal mortality due to pulmonary hypoplasia.
- Sonographic prognostic criteria predicting poor outcome include presence of subcortical cysts and increased echogenicity of the kidneys, which are associated with renal dysplasia.

Key Points (cont.)

- Fetal urine electrolytes (Na <100, Cl <90, Osm <210, β_2-microglobulin <6) are associated with preserved renal function and favorable prognosis with treatment.
- Fetal urine electrolytes are only valid for fetuses at 20 weeks of gestation or later.
- Treatment options include vesicoamniotic shunt placement, fetoscopic ablation of PUV, and open fetal surgery for vesicostomy.
- Fifty percent of successfully treated fetuses with PUV develop growth failure and chronic renal failure requiring dialysis and/or transplantation.

CONDITION

Unlike obstruction of the urinary tract at other levels, bladder outlet obstruction has the potential to affect the development of the whole urinary tract as well as the lungs. In males, the most common cause of bladder outlet obstruction is posterior urethral valves (PUVs) (Atwell, 1983). In contrast, in females the most common cause of bladder outlet obstruction is urethral atresia. As in many other congenital anomalies, there is a broad range of severity, with bladder outlet obstruction ranging from completely asymptomatic to the infant who presents at delivery with respiratory insufficiency due to pulmonary hypoplasia caused by long-standing oligohydramnios and renal failure from renal dysplasia.

PUVs are thought to be embryologically derived from mullerian duct remnants or remnants of the cloacal membrane dating back to between the 7th and 11th weeks of gestation (Dewan et al., 1992, 1995). Young et al. (1919) described a classification scheme for PUVs. In type I, the valves are sail-like leaflets that arise from the crista-urethralis distal to the verumontanum. These valves may cover only the lower half of the urethra or may encircle the urethra and cause complete obstruction. Type II valves are nonobstructing folds of the superficial muscle and mucosa that extend from the verumontanum to the bladder neck (Cuckow, 1998). Type III valves usually cause a diaphragm-like obstruction at the level of the verumontanum, but can be seen at the level of the anterior urethra distal to the external urethral sphincter (Hendren, 1971).

The characteristic prenatal presentation of bladder outlet obstruction is that of a dilated bladder and bilateral hydroureteronephrosis. The severity of prenatal bladder outlet obstruction ranges from mild to severe as is seen postnatally. At the better end of the spectrum, the fetus may have obstructive uropathy with preservation of amniotic fluid volume, minimal changes in the bladder and ureters, and no dysplastic changes in the kidneys. At the severe end of the spectrum are fetuses with profound oligohydramnios, distended bladder, and ureters with cystic dysplastic changes in the kidneys. The longstanding oligohydramnios results in pulmonary hypoplasia, which leads to severe respiratory insufficiency at birth and is a leading cause of death during the neonatal period. Fetuses with obstructive uropathy can also have other associated nongenitourinary anomalies, chromosomal abnormalities, and deformations related to oligohydramnios, emphasizing the importance of careful prenatal evaluation. In cases of isolated bladder outlet obstruction due to PUVs, vesicoamniotic shunting may be lifesaving.

INCIDENCE

The figures reported for the incidence of bladder outlet obstruction vary widely, reflecting the spectrum of severity seen in obstructive uropathy. In PUVs, the most common cause, the range in severity extends from fetuses presenting with oligohydramnios, renal dysplasia, and pulmonary hypoplasia to asymptomatic octogenarians noted to have PUVs at the time of cytoscopy for benign prostatic hypertrophy. The incidence of PUVs has been reported to be between 1 in 5000 and 1 in 25,000 births (Atwell, 1983). PUVs account for 10% of all urologic anomalies detected by prenatal ultrasound, which occur as frequently as 1 in 800 livebirths (Thomas and Gordon, 1989; Hutton et al., 1994). Prenatal ultrasound picks up 50% of new cases of PUVs, suggesting an incidence of 1 in 4000 livebirths (Cuckow, 1998). Recently, there has been increased awareness of PUVs, and Richmond and Atkins reported an increase in apparent prevalence from 1.9 per 10,000 births to 2.4 per 10,000 births (Richmond and Atkins, 2005). This estimate does not take into account cases of intrauterine fetal death, loss to pregnancy termination, stillbirths, or the asymptomatic cases that present later in life with voiding difficulty (Hendren, 1971; Pieretti, 1993).

SONOGRAPHIC FINDINGS

Urinary tract obstruction at the level of the bladder outlet is usually due to PUVs in male fetuses and urethral atresia in females. The cardinal features of bladder outlet obstruction include marked and persistent dilation of the urinary bladder with a thickened, often trabeculated, bladder wall (Glick et al., 1984; Mahony et al., 1985). The posterior urethra is dilated in urethral obstruction due to PUVs. This dilated proximal urethra resembles a keyhole, extending from the bladder toward the fetal perineum (Figure 82-1). The dilated bladder can become quite large, filling both fetal pelvis and abdomen. The mural thickness of the normal bladder is quite thin and bladder wall thickness greater than 2 mm is pathologic. In cases of severe bladder outlet obstruction, the nondilated

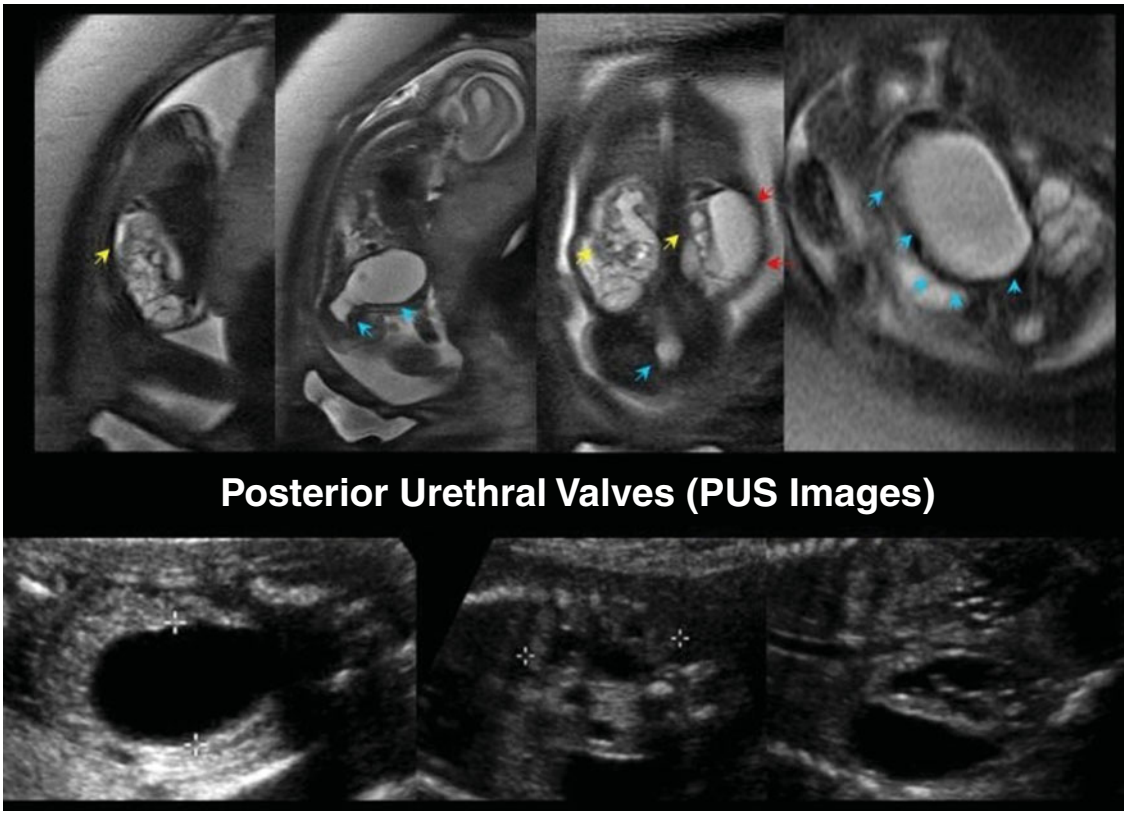

Figure 82-1 The upper panel shows four MRI images of the same fetus. The panel at the left shows a small perinephric urinoma (*small yellow arrow*). The second panel shows the dilated bladder and posterior urethra. The third panel shows in coronal section the dilated urethra and hydronephrosis and calyceal dilatation. The blue arrow points out the dilated posterior urethra. The panel on the right shows the very dilated bladder with thickened walls.

Lower panel demonstrates characteristic findings on ultrasound in posterior urethral valves in a fetus at 21 weeks of gestation. The left panel shows the dilated thick-walled bladder in sagittal plane. The middle panel shows the hydronephrotic kidney with calyceal dilatation. The right panel demonstrates the dilated tortuous ureter. (*Courtesy of Pramod Reddy, MD, Pediatric Urology, Fetal Care Center of Cincinnati)*

bladder (either following bladder tap or spontaneous voiding) can be as thick as 10 to 15 mm (Mahony, 1994). Often, severe bladder outlet obstruction will result in ureterectasis and caliectasis due to vesicoureteral reflux induced by high intravesical pressure. However, the absence of these features does not preclude the diagnosis of bladder outlet obstruction because only 40% of fetuses will demonstrate ureterectasis and pyelectasis in bladder outlet obstruction (Mahony, 1994). In high-grade bladder outlet obstruction, the urinary bladder may spontaneously decompress through rupture of the urinary tract, resulting in either fetal urinary ascites or perinephric urinoma (Callen et al., 1983; Mahony et al., 1984). The end-stage effects of early gestation high-grade bladder outlet obstruction is often bilateral renal dysplasia. This may be sonographically evident from markedly increased renal parenchymal echogenicity and, most specifically, from the presence of subcortical cysts (Mahony et al., 1984; Crombleholme et al., 1991). Paradoxically, the lack of caliectasis in the otherwise obstructed urinary tract may suggest the presence of renal dysplasia and reflects the lack of urine production by severely damaged kidneys. Oligohydramnios is indicative of high-grade obstruction and, if long-standing, may result in deformations including Potter facies and clubfeet.

Fetal MRI has been found to be a useful adjunctive imaging modality in the evaluation of the fetus with obstructive uropathy (Caire et al., 2003). MRI may be more sensitive in defining subcortical cysts, suggesting renal dysplasia. In addition, fetal MRI may provide anatomic detail on pelvic structures not available with ultrasound, particularly in the setting of bladder outlet obstruction presenting prior to 16 weeks of gestation. In these early cases, persistent cloaca may be more clearly diagnosed by MRI than by ultrasound alone.

The functional capacity of the fetal kidney affected by obstructive uropathy depends on the extent and severity of renal dysplasia caused by the obstruction. The dysplastic fetal kidney is characterized by the presence of disorganized metanephric structures surrounded by fibrous tissue which, in addition, may have cortical cysts (Rubenstein et al., 1961; Beck, 1971; Potter, 1972; Risdon, 1975; Bernstein, 1976). More than 90% of dysplastic kidneys with cortical cysts are associated with obstruction during nephrogenesis (Rubenstein et al., 1961; Bernstein, 1976). Detection of cortical cysts

sonographically implies the presence of severe renal dysplasia and irreversible renal damage, excluding the patient from intervention. A normal kidney will display an echotexture similar to that of the liver, with an internal architecture showing a differentiation between cortex and medulla. The medulla containing tubules and fluid will appear darker. A dysplastic kidney, however, will show no internal architecture and may display an increased echogenicity due to a disruption in the normal renal histology. Renal dysplasia may be associated with cystic formation with the parenchyma (Harrison et al., 1982a; Risdon, 1975). Features of multicystic dysplasia of the kidney (MCDK) include the presence of multiple noncommunicating cysts of variable sizes, interfaces between the cysts (presence of echogenic areas within the renal parenchyma), nonmedial location of the largest cyst, and absence of an organized parenchyma (see Chapter 78) (Fong et al., 1986; Kleiner et al., 1986). Multicystic dysplasia of the kidney is most often seen unilaterally and is associated with a high incidence of contralateral urologic anomalies that will warrant postnatal evaluation by a pediatric urologist (Thomas, 1990). Cystic dysplasia should not be confused with severe hydronephrosis.

Mahony et al. (1984) studied the kidneys of 49 fetuses with obstructive uropathy and found that the presence of cortical cysts had a positive predictive value of 100% for the presence of renal dysplasia. Sonography was also 100% specific as no fetus without dysplasia had detectable cortical cysts. The presence of cortical cysts reliably predicts the presence of renal dysplasia and irreversible renal damage, but the absence of cortical cysts cannot ensure the absence of renal dysplasia. Of the kidneys without cortical cysts in the study by Mahony et al., only 44% were free of dysplastic changes. Renal dysplasia may be present without cysts, or the diameter of the cysts may be below the resolution of ultrasound. Technical factors may also limit the ability of the sonographer to adequately image the fetal kidneys, including shadowing from the adjacent spine and oligohydramnios, which often accompanies obstructive uropathy.

In the dysplastic kidney, there is abundant fibrous tissue that may increase the echogenicity of the renal parenchyma. It has been suggested that increased echogenicity at the renal cortex may be a sign of renal dysplasia. However, when this sonographic sign was evaluated, it was shown to be less specific and to have a lower positive predictive value than the presence of cortical cysts (Mahony et al., 1985). The evaluation of renal echogenicity is also a more subjective assessment with inherent interobserver variability, which further limits its utility.

Ultrasonographic examination of the fetal kidneys may provide prognostic information if cortical cysts and increased echogenicity are detected, but is less specific in their absence (Mahony et al., 1985; Crombleholme et al., 1991). Similarly, the volume of amniotic fluid is not a useful prognostic indicator except at the extremes (Harrison et al., 1981a, 1982a, 1987; Glick et al., 1985). Zaccara et al. found that amniotic fluid index remains a reliable predictor of renal function in cases of obstructive uropathy (Zaccara et al., 2005). Preserved amniotic fluid almost always predicts normal renal function at long-term evaluation. Fetuses with bilateral hydronephrosis and normal amniotic fluid may not require intervention. Similarly, fetuses with bilateral hydronephrosis, severe oligohydramnios, and severely dysplastic renal cortex as seen on ultrasound are unlikely to benefit from in utero therapy. It is for the fetuses between these two extremes that prognostic criteria are most important. Assessment of residual fetal renal function by indirect methods such as ultrasound determination of bladder filling and emptying or furosemide stimulation of urine production have not proven reliable (Campbell et al., 1973; Wladimiroff, 1975; Chamberlain et al., 1985). A more sensitive means of assessing fetal renal function is essential for the appropriate selection of fetuses with obstructive uropathy for treatment.

An evaluation of the fetal urinary tract should include an assessment of the overall growth and development of the fetus, amniotic fluid index, gender, renal parenchymal appearance, extent of dilatation of the collecting system, unilateral or bilateral involvement, and bladder size, thickness, and emptying (Cendron et al., 1994). Because of the increased incidence of associated malformations, the fetus should be scanned for extrarenal anomalies. Serial sonographic evaluation is also essential to evaluate for progression of these sonographic features.

DIFFERENTIAL DIAGNOSIS

The sex of the fetus will help narrow the differential diagnosis. Sonographic demonstration of male external genitalia in the setting of bladder outlet obstruction strongly suggests the diagnosis of PUVs. In a female fetus, one should consider the diagnosis of urethral atresia, persistent cloaca, caudal regression anomaly, or megacystis-microcolon–intestinal hypoperistalsis syndrome (Table 82-1). An unusual cause of bladder outlet obstruction that can occur in either sex is prolapse of an ectopic ureterocele from a duplex collecting

Table 82-1

Causes of Bilateral Hydronephrosis

Supravesical obstruction Bilateral ureteropelvic junction obstruction Bilateral ureterovesicular junction obstruction
Infravesical obstruction Posterior urethral valves Urethral atresia Obstructing ureterocele
Vesicoureteral reflux (bilateral, usually high-grade)
Prune belly syndrome
Megacystis-microcolon–hypoperistalsis syndrome

system. In distinguishing urethral atresia in a female fetus, the oligohydramnios is profound and long standing. Particularly when diagnosed prior to 16 weeks of gestation, a dilated "bladder" on ultrasound should raise the possibility of persistent cloaca. The presence of a persistent cloaca may be suspected from the anatomy of the "bladder" and the presence of debris in the cloaca from the intestinal communication. Intraluminal calcifications within bowel loops suggest a communication between intestinal and genitourinary tracts. Caudal regression should be evident from images of the fetal spine. In the megacystis-microcolon–intestinal hypoperistalsis syndrome, the bladder is very dilated but with a thin wall even after decompression, as opposed to the pressure-induced hypertrophy observed in bladder outlet obstruction from PUVs. This is a rare, usually lethal, anomaly in which 80% of affected fetuses are females (Winter and Knowles, 1986). Other features that are clues to this diagnosis include small-bowel dilation, a microcolon with malrotation, and polyhydramnios in the third trimester (Stramm et al., 1991). This is inherited as an autosomal recessive condition and therefore has implications for future pregnancies.

ANTENATAL NATURAL HISTORY

A thorough understanding of the pathophysiology of fetal obstructive uropathy and its sequelae in the developing fetus is essential in formulating a rational approach to clinical management. It is important to understand why obstructive uropathy results in pulmonary hypoplasia, renal dysplasia, and associated malformations and whether or not these changes can be reversed by decompression in utero.

Obstruction of the urethra during the latter half of gestation results in dilatation and hypertrophy of the bladder and megaureter and bilateral hydronephrosis. But obstruction that starts this late in gestation does not usually produce the dysplastic changes in the renal parenchyma seen in human fetuses. Some have argued that dysplasia is caused by an abnormal interaction between the ureteric bud and the metanephric mesenchyme and is only incidentally associated with obstruction. Experiments in a fetal chick in which ureteric buds were denuded of metanephric mesenchyme formed primitive ducts, suggesting that in the chick, dysplasia may be due to nonobstructive causes. These studies have questionable relevance to the pathogenesis in higher animals and humans.

The proponents of obstruction-induced dysplasia argue that after 8 to 10 weeks of gestation, when the kidney begins to make urine, obstruction results in back pressure into the developing nephrons. Potter demonstrated that the collecting tubules of the nephrogenic kidney are straight and short and may be more susceptible to injury from back pressure than the mature nephron. Chevalier (1993) confirmed that early in development, renal injury from ureteral obstruction occurs more frequently than in the adult kidney. It follows that in order to preserve renal function in the face of an obstruction, early recognition and prompt decompression may be necessary. Early obstruction will cause the development of dysplastic changes in the kidney, but further impairment in renal function may occur not so much as a result of nephron loss from a pressure-mediated mechanism, but by a vasoconstrictive effect mediated by an overactivation of the renin–angiotensin system (Chevalier, 1993).

In humans, oligohydramnios, because of obstructive uropathy, renal agenesis, or prolonged amniotic fluid leak, results in severe pulmonary hypoplasia (Kemper and Mueller-Wiefel, 2007). The lungs of infants affected by obstructive uropathy show decreased airway branches from segmental bronchi, reflecting compromised development during the first half of gestation (pseudoglandular stage, 5 to 16 weeks). Although the lung made hypoplastic by compression during the pseudoglandular stage would not be expected to develop new airway branches, it would retain the capacity to make new alveoli and intra-acinar arteries. To evaluate the effect of obstructive uropathy on pulmonary development in an early gestation model, Adzick et al. (1987) performed bilateral ureteral ligation at 60 days of gestation, during the pseudoglandular stage of lung development (60–80 days of gestation), on lambs. Morphometric analysis of the lungs at birth revealed significant reduction of lung volume, radial alveolar count, and mean linear intercept (an indicator of airspace size) in the lambs with bilateral ureteral ligation as compared with the controls (Adzick et al., 1987). In addition, muscularization of the intra-acinar arteries was greater in lambs with bilateral ureteral ligation, indicating increased peripheral pulmonary arteriolar muscularization. These morphometric findings were the same as those in human infants who died from oligohydramnios-induced pulmonary hypoplasia from obstructive uropathy (Potter, 1972; Hislop et al., 1979). These experimental models replicated both the renal dysplastic changes and the pulmonary hypoplasia that are observed in human fetuses who die from severe obstructive uropathy and oligohydramnios.

The mechanism by which oligohydramnios causes pulmonary hypoplasia is uncertain. Several possible contributing factors include the small uterine cavity, which causes thoracic compression and limited intrathoracic space. Fetal breathing movements may be limited by uterine compression of the fetal chest and abdomen. Fetal respiration is thought to be an important factor in lung growth (Wigglesworth and Desai, 1982). Ablation of fetal breathing by cord transection, curare-induced paralysis, or damping fetal breathing movements by thoracoplasty—all result in pulmonary hypoplasia (Liggins et al., 1979; Wigglesworth and Desai, 1979; Moessinger, 1983). Oligohydramnios may also increase the loss of lung fluid, with decreased lung fluid volume within the airway (Lanman et al., 1971). Chronic fetal tracheal drainage of lung fluid results in pulmonary hypoplasia. The amniotic fluid may also act as a hydraulic stent. Increases in amniotic pressure are transmitted to the fluid in the fetal airway and prevent increases in transthoracic pressure, which might restrict lung growth from chest compression. Another possibility is the loss of a growth factor produced by the kidneys (Lanman et al., 1971).

These studies form the basis for in utero intervention to decompress the urinary tract and restore amniotic fluid dynamics to prevent neonatal death due to pulmonary hypoplasia and renal dysplasia.

MANAGEMENT OF PREGNANCY

A fetus with suspected bladder outlet obstruction should undergo a detailed sonographic survey to detect nongenitourinary anomalies. In particular, sonographic features of trisomies 13, 18, and 21 should be ruled out because chromosomal abnormalities can be seen in bladder outlet obstruction in as many as 12% of cases (Crombleholme et al., 1991; Cusick et al., 1995). Deformations due to oligohydramnios such as clubfoot and Potter facies should be ruled out. A sonographic evaluation of the urinary tract should include the sex of the fetus, amniotic fluid volume, presence or absence of ascites, and a detailed examination of the urinary tract itself. Not only the presence of the keyhole sign, but the size of the bladder and evidence of bladder wall hypertrophy should be noted. The presence or absence of an ureterocele should be sought, and the bladder should be observed during voiding for evidence of vesicoureteral reflux. The degree of ureteral dilation, hydronephrosis, and/or caliectasis may increase with voiding in the presence of vesicoureteral reflux. All fetuses with bladder outlet obstruction should have a genetic consultation and should consider amniocentesis. Echocardiography should be performed to rule out structural heart disease. In less severe cases of bladder outlet obstruction, in which amniotic fluid volume is preserved, there should be no adverse effects on pulmonary development and the site, timing, and mode of delivery should be unaffected. In severe cases in which oligohydramnios has occurred, either a decision should be made not to aggressively resuscitate the infant, or the baby should be delivered in a tertiary care setting. In the case of severe long-standing bladder outlet obstruction associated with oligohydramnios and renal dysplasia, there should be no intervention for nonreassuring fetal testing or attempts at resuscitation because these infants have severe pulmonary hypoplasia and renal dysplasia that are incompatible with life. Prenatal consultation with pediatric specialists in urology, nephrology, and neonatology may be helpful in counseling parents about the options for treatment and long-term outcome. The approach to the fetus with bladder outlet obstruction is outlined in the algorithm in Figure 82-2.

It is important to stress that the appearance of the fetus with bladder outlet obstruction may evolve during gestation. The fetus with complete or high-grade bladder outlet obstruction associated with oligohydramnios may spontaneously evolve with development of less-severe outlet obstruction and restoration of amniotic fluid volume. Conversely, the fetus with high-grade partial bladder outlet obstruction but preserved amniotic fluid volume may progress during pregnancy, with the kidneys becoming more echogenic and demonstrating subcortical cysts consistent with the development of dysplasia. Serial sonographic surveillance should be a part of a prenatal management plan of all fetuses with bladder outlet obstruction.

FETAL INTERVENTION

During the past decades, much has been learned about the natural history of obstructive uropathy, and the pathophysiology has been replicated in animal models (Glick et al., 1984; Harrison et al., 1985, 1987; Nakayama et al., 1986; Bronshtein et al., 1990; Crombleholme et al., 1988b, 1991; Mandell et al., 1992; D'Alton and DeCherney, 1993). It has been demonstrated experimentally that bladder decompression in utero can prevent the progression of dysplastic changes seen in obstructive uropathy (Glick et al., 1983, 1984). There are those who question whether animal models accurately replicate the pathophysiology in humans (Berman and Maizels, 1982; Lissauer et al., 2007). A major problem in management is the proper selection of fetuses with bilateral hydronephrosis who might be candidates for intervention, i.e., fetuses with obstruction severe enough to compromise renal and pulmonary development, but not so severe that renal damage is irreversible even if the obstruction is relieved. Several methods have been suggested to assess the functional capacity of the kidneys in a fetus with obstructive uropathy, including the sonographic appearance of the kidneys, amniotic fluid volume, and various fetal urine electrolytes and proteins.

In the 13th week of gestation, the fetus begins to make urine, which is best characterized as an ultrafiltrate of fetal serum (McCance and Widdowson, 1953; Alexander and Nixon, 1961; McGrory, 1972; Mellor and Slatter, 1972; Hill and Lumbers, 1988). The urine is hypotonic because of selective tubular resorption of Na and Cl in excess of free water (Glick et al., 1985). The urine composition normally becomes progressively hypotonic between 16 and 21 weeks and may become even slightly more hypotonic late in gestation as a result of tubular maturation and increased fetal glomerular filtration rate (Glick et al., 1985; Nicolini et al., 1992). Glick et al. (1985) observed that fetuses with congenital hydronephrosis and normal renal function after birth had hypotonic urine but those with poor function produced urine that was isotonic. Similar observations were made in fetuses with hydronephrosis but good renal and pulmonary function was evaluated postnatally by Weinstein and McFaydon and their colleagues (Weinstein et al., 1982; McFaydon et al., 1983).

It is uncertain why the fetus produces isotonic urine in the presence of long-standing obstruction. It has been suggested that dysplastic changes may alter tubular function sufficiently to prevent the resorption of Na and Cl. Rappaport et al. (1960) suggested that the stagnant urine may equilibrate with serum. The fluid aspirated from the fetus with severe obstructive uropathy may also present fluid produced by bladder urothelium.

In order to develop more sensitive fetal renal function tests, Glick et al. (1985) used bladder catheterization to evaluate 20 fetuses with obstructive uropathy. The fetuses who

Table 82-2

Prognostic Criteria in Obstructive Uropathy

Sonography	No Cortical Cyst, Normal Echogenicity
Na	<100 mEq per liter
Cl	<90 mEq per liter
Osm	<210 mEq per liter
Ca	<2 mmol per liter
PO_4	<2 mmol per liter
β_2-microglobulin	<2 mg per liter

subsequently had a poor outcome were all "salt wasters" and those who had a good outcome had hypotonic urine. On the basis of this study, prognostic criteria for renal function in congenital hydronephrosis were proposed (Table 82-2). These results were questioned by other groups, who reported that these prognostic criteria did not accurately predict the renal function at birth. Wilkins et al. (1987) reported results using these prognostic criteria in nine cases of fetal obstructive uropathy. The criteria were accurate in predicting a poor outcome, as all four patients died and three of these four had evidence of renal dysplasia. In the fetuses with a predicted good prognosis, four of the five had poor renal function and the only patient with a good outcome underwent in utero decompression with a vesicoamniotic shunt.

The reports questioning the utility of fetal urine electrolyte levels as prognostic criteria prompted a reevaluation in a series of 40 fetuses with bilateral hydronephrosis. Crombleholme et al. (1991) retrospectively assigned fetuses to a good prognostic group only if they had a Na <100, Cl <90, osmolarity <210, and there was no sonographic evidence of dysplasia (Figure 82-3). Fetuses were assigned to a poor-prognosis group if even one of these criteria was not met. There was a statistically significant difference in survival in the good versus the poor-prognosis group (81% vs. 12.5%) even after excluding pregnancy terminations (87% vs. 30%). These prognostic criteria were intended as a means to select fetuses for in utero intervention. They accurately select the fetuses that have sufficient renal function to have a favorable outcome if decompressed in utero. If the fetal obstruction is unrelieved, however, the renal function is likely to deteriorate despite a favorable prognostic profile. Fetal obstructive uropathy is a dynamic process, and experimental studies in fetal lambs have demonstrated that the severity of renal damage from obstruction depends on the timing, duration, and severity of the obstruction (Harrison et al., 1981a, 1983; Glick et al., 1983, 1984). The fetal urine electrolytes obtained at 20 to 24 weeks of gestation may only reflect the renal function at the time they are assayed. In fact, Nicolini et al. (1992) have demonstrated by serial fetal bladder aspirations the worsening urinary electrolyte profile and renal function in fetuses with obstructive uropathy in which the obstruction was untreated. In the report from Wilkins et al. (1987), the fetuses in the favorable group had unrelieved obstruction and progression in their renal deterioration. The one fetus that was successfully decompressed in utero had a good outcome.

These prognostic criteria for in utero intervention in obstructive uropathy have become widely used and are being more appropriately applied as selection criteria for intervention. However, Nicolini et al. (1992) have pointed out that one potential problem with these criteria is that they fail to take into account the gestational age of the fetus and that threshold values were established in fetuses with obstructive uropathy and not normal fetuses. The effect of gestational age on fetal urine electrolytes is most marked prior to 21 weeks of gestation, becoming progressively more hypotonic and then remaining relatively stable throughout the remainder of gestation. The criteria proposed by Glick et al. (1985) were selected to establish the threshold for a poor prognosis as 2 SD from the mean value of the patients with a good prognosis. This does skew the criteria toward including potentially compromised fetuses into the good-prognosis group. But as the results reported by Crombleholme et al. (1991) confirm, this has not resulted in the treatment of fetuses with irrevocably compromised renal function. In fact, overly stringent selection criteria for intervention as proposed by Nicolini et al. (1992) may exclude many potentially salvageable fetuses from treatment. There are, however, no established fetal urine electrolyte parameters for fetuses less than 20 weeks of gestation.

In addition to the use of fetal urine Na, Cl, and osmolarity, other groups have suggested the addition of urine Ca^{2+}, PO_4, and β_2-microglobulin to assess fetal renal function. Nicolini et al. (1992) studied fetal urine creatinine, urea, and electrolytes, notably Ca^{2+}, Na, and PO_4 in a group of 24 fetuses with obstructive uropathy and 26 normal controls. They found that the urinary Ca^{2+} and Na were significantly higher in fetuses with renal dysplasia as compared with those with lower urinary tract obstruction but normal renal histology or normal clinical outcome. Urinary Ca^{2+} levels were found to be the most sensitive (100%) indicator of renal dysplasia but lacked specificity (60%). Urinary Na was slightly less sensitive (87%) but was found to be the most specific (80%). Urinary PO_4, creatinine, and urea were not significantly different in fetuses with dysplastic kidneys versus those without dysplasia.

The predictive value of fetal urine electrolytes in bladder outlet obstruction has been found to be enhanced by serial bladder taps (Johnson et al., 1995). Johnson et al. have recommended complete bladder drainage at 24-hour intervals for a minimum of three taps to best establish a clear pattern of increasing or decreasing urinary hypertonicity. While values clearly in the normal range on initial bladder tap may not require additional bladder taps to establish a prognosis, a

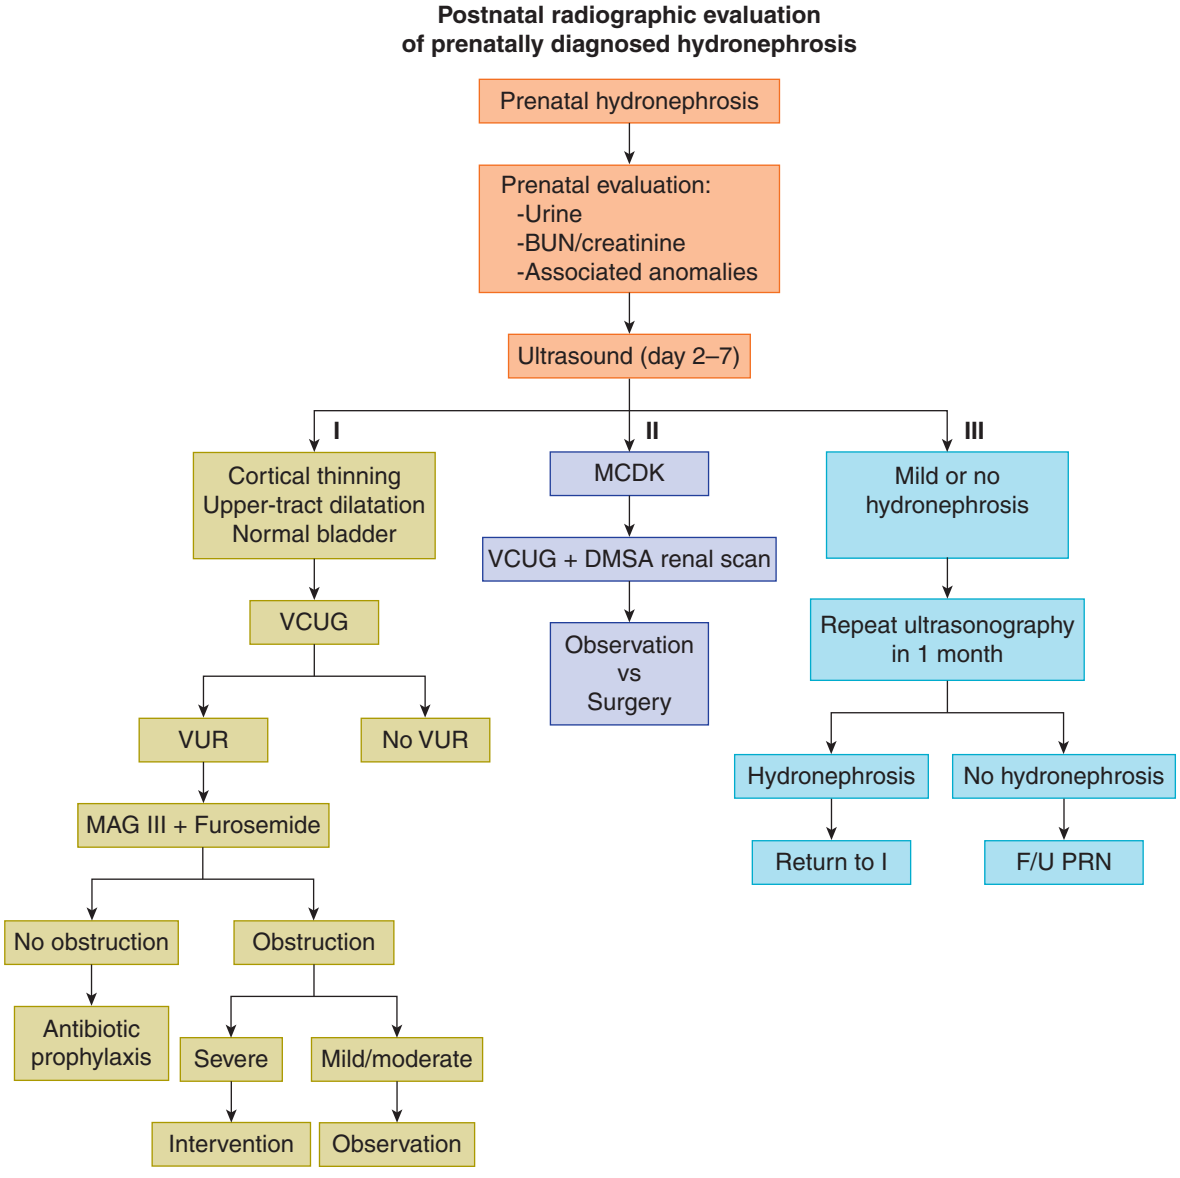

Figure 82-3 Algorithm for the postnatal evaluation of fetal hydronephrosis. MCDK, multicystic dysplastic kidney; VUR, vesicoureteral reflux; VCUG, voiding cystourethrography; F/U PRN, follow up as needed.

fetus with elevated values may show a clear trend of improving electrolyte values with sequential taps. The sequential taps are thought to clear stagnant urine that may not accurately reflect renal function (Qureshi et al., 1996).

It has been observed that obstructive uropathy due to PUVs has a long natural history (Parkhouse et al., 1988; Harrison and Adzick, 1991). Renal failure may not develop for years in a newborn with PUVs. A fetus with obstructive uropathy, a favorable prognostic profile, and normal amniotic fluid is currently not considered a candidate for in utero decompression. A small number of fetuses diagnosed with hydronephrosis were observed to have findings consistent with obstructive uropathy, a favorable prognostic profile, and normal amounts of amniotic fluid, but progressive renal insufficiency subsequently developed during infancy despite good renal function initially. We, thus, have lacked criteria that allow us to identify a fetus with obstructive uropathy and a good prognostic profile that, despite the presence of normal amniotic fluid volume, is at risk for ongoing renal damage. Muller et al. (1993) reported the use of fetal urinary β_2-microglobulin as a predictor of postnatal renal function at 1 year of age. They reported that 17 of 40 patients with normal amniotic fluid volume and a good prognostic profile had a creatinine level of >0.56 mg/L at 1 year of age. This value was selected as the threshold since it was 2 SD from the mean creatinine of normal 1-year-old infants. In this group of patients, the β_2-microglobulin was found to be significantly elevated as compared with patients with the same prognostic profile but with a creatinine of <0.56 mg/L at 1 year of age. β_2-Microglobulin may allow us to identify fetuses at risk for renal damage by unrelieved obstruction even though their amniotic fluid has not diminished.

Our current approach to in utero treatment for obstructive uropathy is to intervene in fetuses with a good prognostic profile only for decreasing amniotic fluid or frank oligohydramnios (Crombleholme et al., 1991; Cendron et al., 1994) (see Figure 82-3). Fetal therapy of obstructive uropathy up to now has been aimed at restoration of amniotic fluid volume to allow pulmonary development, averting neonatal death from pulmonary hypoplasia. The potential utility of β_2-microglobulin is that it may allow us to select for in utero therapy among fetuses with a good prognostic profile those at risk for ongoing renal damage. The goal of this treatment would be preservation of renal function as opposed to prevention of pulmonary hypoplasia. This would significantly expand the indications for fetal intervention in obstructive uropathy. However, this report is preliminary, and longer follow-up of these children as well as confirmation by other investigators will be necessary to define the role of fetal intervention in the setting of an elevated urinary β_2-microglobulin in fetuses with good prognostic profiles and normal amniotic fluid volume.

One major question that is difficult to address in fetal treatment of obstructive uropathy is assessing the efficacy of prenatal decompression. In a report of a large experience with vesicoamniotic shunts at a single institution, Johnson et al. (1995) described the outcome in 55 fetuses that underwent shunt placement. Unfortunately, this was a heterogeneous group of patients with good- and poor-prognosis patients with a range of diagnoses including PUVs, prune belly, urethral atresia, and a variety of other anomalies. In the group with PUVs, the postnatal survival was 60%. Of note is that the incidence of an elevated nadir creatinine level >1 mg/dL in the first year of life was 33%. Coplen et al. (1996) in a review of prenatal intervention for lower urinary tract obstruction from five reported series found an overall survival rate of only 48% and a catheter-related complication rate of 45%. In the report by Crombleholme et al. (1991), in both the good-prognosis and poor-prognosis groups, survival was greater in fetuses who were decompressed in utero as opposed to those who were not decompressed. In the group of 10 fetuses with a poor prognosis, 3 were electively terminated, 4 neonatal deaths were from pulmonary hypoplasia or renal dysplasia, and 3 had survived. All three survivors had restoration of normal amniotic fluid levels, but renal failure developed in two of the three survivors and they have since undergone renal transplantation. Among the 14 patients with no intervention, there were no survivors (11 terminations and 3 neonatal deaths from pulmonary hypoplasia).

In the good-prognosis group of nine fetuses, one was electively terminated, and there were no deaths, leaving eight neonatal survivors. One infant died at 9 months of age from unrelated causes, with normal renal function. Of the seven patients in the good-prognosis group who were not treated, five survived and two died after birth. Renal failure later developed in two of the survivors. The incidence of oligohydramnios in the good-prognosis group was 7 out of 16. All six patients with oligohydramnios who had fetal intervention survived. One patient with oligohydramnios that was untreated died at birth from pulmonary hypoplasia.

When in utero intervention restores amniotic fluid volume, neonatal death from pulmonary hypoplasia is averted. When oligohydramnios develops during the canalicular stage of lung development (16–24 weeks) the fetus usually has pulmonary hypoplasia precluding survival. In the group of fetuses reported by Crombleholme et al. (1991), there was a preponderance of oligohydramnios in the poor-prognosis group (23 of 24 as compared with 7 of 16 in the good-prognosis group). Fetuses from the good-prognosis group appear to survive as a result of fetal treatment in the face of variable rates of oligohydramnios. In the good-prognosis group, six of the seven fetuses with oligohydramnios had intervention and all six survived with normal renal function. However, the seventh patient with oligohydramnios, who was not treated, died at birth from pulmonary hypoplasia. Uncorrected oligohydramnios was associated with a 100% neonatal mortality. Normal or restored amniotic fluid volume was associated with a 94% survival (Crombleholme et al., 1991).

In utero decompression appears to prevent neonatal death from pulmonary hypoplasia, but the effect on renal function is less clear. The development of postnatal renal failure in two infants who were not treated because amniotic fluid volume remained normal raises a question about treating obstructed fetuses before oligohydramnios develops. Because renal development or maldevelopment is complete at birth, relief of obstruction in infancy or childhood may not prevent the progression to end-stage renal failure (Warshaw et al., 1982).

The severity of renal dysplasia at birth depends on the timing and severity of obstruction before birth (Glick et al., 1984; Adzick et al., 1987). Experimental work suggests that relief of obstruction during the most active phase of nephrogenesis (20–30 weeks of gestation) may obviate further damage and allow normal nephrogenesis to proceed (Bronshtein et al., 1990; Patten et al., 1990; Thomas, 1990; Blyth et al., 1993). One fetus in this series evaluated at 18 weeks of gestation had a favorable prognostic profile, but because the amniotic fluid level was normal, it was not a candidate for intervention. While the sonographic appearance of the kidneys was normal at 18 weeks of gestation, postnatal sonography suggested renal dysplasia and development of chronic renal insufficiency.

The maternal morbidity of vesicoamniotic shunts was minimal, but there was a high incidence of chorioamnionitis, in 3 of 21 procedures. However, all cases of chorioamnionitis were early in this particular study experience, before the routine use of prophylactic antibiotics and during a period when long-term (4–16 hours) bladder catheterization rather than aspiration was used for fetal urine sampling (Glick et al., 1985; Crombleholme et al., 1991). Among the five open cases of fetal surgery, there was no fetal morbidity or mortality, but preterm labor was observed in each mother requiring aggressive tocolytic therapy (Crombleholme et al., 1988a).

Harrison et al. (1981a, 1981b) first proposed the concept of in utero decompression in a report of poor outcome

Figure 82-4 Newborn with iatrogenic gastroschisis due to herniation of viscera through the abdominal wall defect created by attempted vesicoamniotic shunt placement. *(Courtesy of Burton Harris, MD)*

in 13 fetuses with obstructive uropathy. This same group subsequently reported the first case of vesicoamniotic shunting for obstructive uropathy using a "Harrison" double pig-tail catheter. Other groups quickly followed suit, and in a 1986 report of the International Fetal Surgery Registry, 62 fetuses had been treated by percutaneous vesicoamniotic shunts (Manning et al., 1986). The overall survival was only 48%; the survival rate was 76% in cases due to PUVs. The procedure-related mortality rate in the registry was 3%. There were several problems with this early experience with vesicoamniotic shunts. Many fetuses were treated inappropriately prior to the development of selection criteria. Secondly, many cases were assessed by indwelling fetal bladder catheters for several hours, which along with the lack of prophylactic antibiotics, predisposed to chorioamnionitis. In addition, as noted by Glick et al. (1985), multiple shunt insertions are often necessary because of shunt occlusion, or dislodgment. Iatrogenic "gastroschisis" has also been reported when trocars used for insertion lacerated the abdominal wall during placement of vesicoamniotic shunts (Manning et al., 1986) (Figure 82-4). Rodeck has reported experience with the KCH catheter, which appears to function better than the Harrison catheter (Rodeck et al., 1988). The utility of vesicoamniotic shunts is limited, however, by the brief duration of decompression, risk of infection, catheter obstruction or dislodgment, fetal injury during placement, and potentially inadequate decompression of the fetal urinary tract. These factors make vesicoamniotic shunting inappropriate for early gestation decompression of the urinary tract. It is not clear that vesicoamniotic shunting has any benefit beyond restoring amniotic fluid volume. Both the Harrison catheter as well as the KCH catheter have a small diameter and are relatively long. According to Poiseuilles's law, very high intravesical pressures are necessary to force urine through the shunt from the bladder to the amniotic cavity. In most cases of high-grade bladder outlet obstruction, there is incompetence of the vesicoureteral junction and intravesical pressure is transmitted to the developing kidney. Despite restoring amniotic fluid volume, vesicoamniotic shunts do not completely decompress the genitourinary tract and do not protect the developing kidneys. This view is consistent with the poor long-term renal outcomes of fetuses successfully treated by vesicoamniotic shunting. Freedman et al., found that 50% of successfully treated fetuses had severely compromised growth and 55% had renal insufficiency or chronic renal failure requiring dialysis or transplantation (Freedman et al., 1999). Biard et al., reported similar growth problems but slightly better renal outcomes in PUV versus urethral atresia. Another underappreciated complication of vesicoamniotic shunts is subsequent severe bladder dysfunction, which may be sufficiently severe to preclude kidney transplantation (Biard et al., 2005).

The presence of oligohydramnios in the second-trimester fetus with bilateral hydronephrosis due to bladder outlet obstruction is uniformly fatal if untreated (Glick et al., 1985; Crombleholme et al., 1991). Complete decompression of the genitourinary tract and elimination of high intravesical pressure can only be achieved by vesicostomy. Vesicoamniotic shunts are inadequate to completely decompress the genitourinary tract and protect the bladder and kidneys from high intravesical pressures, and Harrison et al. have reported their experience with open fetal surgery in eight cases (Crombleholme et al., 1988a, 1991; Harrison et al., 1991). Six of the eight treated were delivered by cesarean section at 32 to 35 weeks of gestation. Four of the six had restoration of amniotic fluid levels by the procedure and had no evidence of pulmonary hypoplasia. The other two fetuses died postnatally of severe pulmonary hypoplasia because of persistent oligohydramnios due to renal dysplasia. They displayed long-standing oligohydramnios prior to treatment and suffered pulmonary hypoplasia despite intervention. These cases would be excluded from treatment by current selection criteria. There were two stillbirths; one pregnancy was

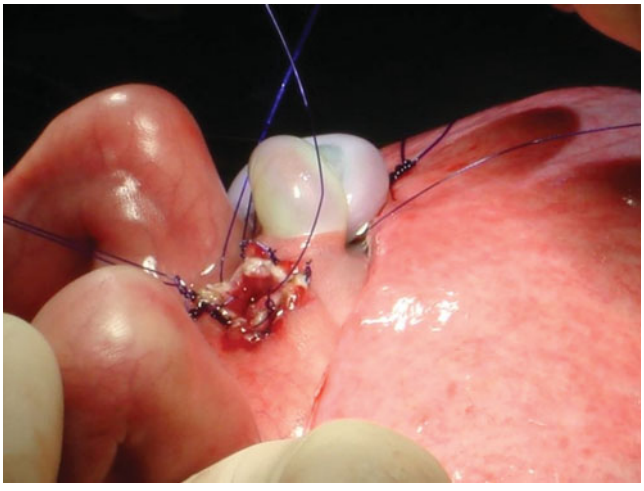

Figure 82-5 Intraoperative photograph taken during open fetal surgery for vesicostomy creation in a 19-week gestation fetus with bladder outlet obstruction due to posterior urethral valves.

terminated (by parental request) because of cloacal anomaly and the other when the mother discontinued tocolytic therapy. Three of the four survivors have had no evidence of renal insufficiency during follow-up of up to 8 years. Progressive renal insufficiency developed in the fourth patient, requiring renal transplantation at 5 years of age; the child was doing well 4 years after transplantation.

Recently, Crombleholme et al. have reintroduced open fetal surgery for vesicostomy in bladder outlet obstruction due to PUVs (T. M. Crombleholme, personal oral communication, 2010) (Figure 82-5). Preliminary experience with this approach suggests that open vesicostomy successfully decompresses the genitourinary tract and preserves renal function and bladder function. No maternal complications have occurred in these patients. However, prematurity with deliveries from 29 to 35 weeks of gestation have been observed. Long-term follow-up will be necessary to accurately assess renal function and bladder function. Open fetal surgery for fetal vesicostomy to relieve bladder outlet obstruction is technically feasible and has been successful in restoring amniotic fluid dynamics and preventing death from pulmonary hypoplasia. However, this is achieved at potentially significant risk to mother and fetus in the form of preterm labor precipitated by hysterotomy. Fetal cystoscopic treatment of bladder outlet obstruction offers the appeal of a minimally invasive approach that can be performed under local anesthesia (Quintero et al., 1998; Agarwal et al., 1999). Fetal cystoscopy can be used to disrupt the valves by hydroablation, guide-wire passage, or laser ablation (Quintero et al., 1995a, 1995b, 2000; Welsh et al., 2003). Clifton et al., have recently reported success with antegrade passage of a transurethral stent, not only restoring amniotic fluid but with normal renal function out to 2 years (Clifton et al., 2008). A limitation of all fetoscopic approaches is the angulation of the posterior urethra, which increases at 20 weeks of gestation, making this approach technically more difficult.

It has been recognized that there is a paucity of high-quality evidence to inform counseling and decision-making regarding fetal therapy (Clark et al., 2003). As a result, a randomized controlled trial of percutaneous shunting in lower urinary tract obstruction (PLUTO trial) is underway (funded by Wellbeing for Women). Even if shunting proves not to be efficacious, other interventions such as fetoscopic techniques and open fetal surgery will still need to be evaluated. (Lissauer et al., 2007).

TREATMENT OF THE NEWBORN

A team approach is extremely helpful to inform the parents and to help them understand and cope with the diagnosis and understand the postnatal evaluation (see Figure 82-2).

Any newborn with a prenatal diagnosis of hydronephrosis should undergo a physical examination at birth. Monitoring of the urinary output within the first 24 to 48 hours is unreliable. Failure to void during the first 2 days after birth may reflect normal fluid shifts or may be the first sign of a significant urologic anomaly. In the neonate who does not void within the first 48 hours, the differential diagnosis of anuria includes obstructive uropathy, renal failure, urogenic bladder, and the effects of maternal medication. However, most patients with an obstructive process will void, albeit with a weak stream, within the first 2 days of life. Serum electrolytes, blood urea nitrogen, and creatinine levels measured within the first day of life are a reflection of maternal renal function via placental exchange. It is best to wait for 24 hours to measure these levels. The most helpful test in the initial evaluation of the newborn with prenatally diagnosed hydronephrosis is ultrasonography of the abdomen including a scan of the bladder. Timing of the ultrasonography depends on the degree of prenatal hydronephrosis. If severe dilatation of the renal pelvis has been detected antenatally, then early ultrasound evaluation should be performed so as to permit early intervention. Otherwise, ultrasound examination can be postponed for 3 to 7 days in order to let the diuresis that occurs during the first 48 hours of life to resolve (Arant, 1992). If the initial postnatal renal ultrasound is normal, the evaluation should be pursued, with a repeat ultrasound in 3 to 4 weeks. There is a high incidence (50%) of additional lesions, such as ureteropelvic junction obstruction (UPJ) and vesicoureteral reflux, diagnosed in neonates with antenatal diagnosis of hydronephrosis that have a normal upper urinary tract at the time of the first ultrasound (Detjer and Gibbons, 1989).

Mild cases of hydronephrosis can be watched and may warrant only one or two ultrasounds during the postnatal period (see Figure 82-2). It is rare for mild dilatation of the upper urinary tract to progress. In cases in which other findings are seen (such as cortical thinning, upper tract dilatation, and a normal bladder) voiding cystorurethrography (VCUG) should be performed. If there is reflux, then a renal scan with 99 technetium diethylenetriaminepentaacetic acid (DTPA) or mercaptoacetyltriglycine (MAG-3) will be

helpful in documenting function within each kidney. If no evidence of reflux is noted by VCUG, then a MAG-3 scan with furosemide should be obtained to evaluate possible UPJ obstruction. If UPJ obstruction is noted, treatment is determined by the severity of the obstruction. In severe UPJ obstruction, in which a kidney shows 35% or less function, pyeloplasty should be performed. In cases in which mild-to-moderate obstruction is noted and the kidney has more than 35% function, observation alone may be indicated, with repeat ultrasonography in 3 months. A repeat renal scan will help to assess changes in renal function. As stated earlier, there is growing evidence to suggest that a mild degree of UPJ obstruction may resolve and may not warrant surgical intervention (see Chapter 81).

If prenatal ultrasound reveals a multicystic dysplastic kidney, a VCUG and renal scan should be obtained. These studies confirm the lack of function in the affected kidney and rule out any abnormalities in the contralateral kidney (Flack and Bellinger, 1993).

SURGICAL TREATMENT

Surgical intervention at birth is required in cases when a severe obstruction will jeopardize renal function. This applies most often to cases of PUVs, obstructing ureterocele, and severe UPJ obstruction affecting a solitary kidney. Emergency surgical treatment is seldom warranted. Reconstruction of the urinary tract should not be attempted until the newborn has stabilized from a medical standpoint and has been fully evaluated. Drainage of the urinary tract can provide decompression by placement of either a urethral catheter, suprapubic catheter, or a nephrostomy tube until definitive repair of the urinary tract can be accomplished.

PUVs and obstructing ureterocele are amenable to early endoscopic treatment but may require further surgical intervention once the child has stabilized and grown. In the presence of a solitary kidney, every attempt should be made to ensure adequate drainage so as to not further jeopardize renal function.

LONG-TERM OUTCOME

Reports in the urologic literature in the late 1970s and early 1980s reviewing experience with PUVs in newborns were notable for the lack of respiratory problems encountered. In contrast, Nakayama et al. (1986) reported 11 cases of PUVs, clinically evident at birth, in which five of the infants died. Three died within hours of birth as a result of respiratory insufficiency and two survived their respiratory insufficiency only to die from renal failure within 3 weeks. Of the six survivors, four had severe respiratory problems requiring prolonged ventilatory support. In addition to the two infants who died early from renal failure, three others developed renal failure despite urinary diversion. Only two of the patients in this series had normal renal function after reconstruction of their urinary tracts.

Clinical experience suggests that the pulmonary and renal consequences of bladder obstruction will vary with the severity of the obstruction. The degree of obstruction will determine the volume of amniotic fluid, the extent of pulmonary hypoplasia, and the dysplastic effects of obstruction on the developing kidney. High-grade bladder outlet obstruction causes megacystis, bilateral hydronephrosis, and oligohydramnios, which results in pulmonary hypoplasia and postnatal respiratory insufficiency. In addition to pulmonary hypoplasia and renal dysplasia, fetal urethral obstruction produces a wide variety of deformations, including Potter facies, limb abnormalities such as clubfoot and hip dislocation, and abnormal abdominal wall muscular development (prune belly). Less severe obstruction may permit enough urine output to allow sufficient pulmonary development for survival. Despite adequate pulmonary development for survival, partial high-grade obstruction may result in renal dysplasia, bladder dysfunction, and irreversible renal failure. Milder forms of obstruction may have normal pulmonary development and mild renal insufficiency or normal renal function. This broad spectrum of severity of fetal obstructive uropathy presents a diagnostic and therapeutic challenge: which cases are severe enough to warrant prenatal intervention, which should be delivered early to prevent ongoing renal damage, and which are best managed postnatally at term?

Freedman et al. (1987) have reported on the long-term outcome of 14 patients who underwent vesicoamniotic shunting for obstructive uropathy. This was a mixed group of patients, with seven cases of prune belly, four cases of PUVs, and one case each of urethral atresia, megacystis–microcolon syndrome, and bilateral vesicoureteral reflux. Growth was observed to be below the 5th percentile in 7 and below the 25th percentile in 12. Four of the patients required ventilatory support at birth; two required it for up to a month. Two children had reactive airway disease and four had chronic bronchitis. Eight of the fourteen void spontaneously, four catheterize in addition to voiding, and the remaining two catheterize only. Bladder augmentation was required in three of the four patients with PUVs. Renal function was normal in six, renal insufficiency in three, and the remaining five had end-stage renal disease and had undergone renal transplantation. Biard et al., reported only slightly better outcomes in the setting of PUVs (Biard et al., 2005).

Sexual function may be impaired because of a much higher incidence of undescended testes, impaired ejaculatory mechanism, and effects of renal failure on potency. The incidence of undescended testes is 12% in patients with PUVs as compared with 0.8% in the normal population (Kruegar et al., 1980). Woodhouse et al. (1989) reported that half of 21 adult patients aged 19 to 37 years with PUVs had dry, slow, or retrograde ejaculations. In addition, one patient had poor erections and another was impotent as a result of renal failure and dialysis. Despite these problems, semen analysis revealed all to be potentially fertile, and 3 of the 21 had fathered children.

GENETICS AND RECURRENCE RISK

In most cases, bladder outlet obstruction due to PUVs is a sporadic event, with no risk of recurrence. However, if associated with chromosomal abnormality, there may be an increased risk of having an affected fetus, depending on the nature of the abnormality. The megacystis–microcolon–intestinal hypoperistalsis syndrome is a rare cause of bladder outlet obstruction that may be difficult to distinguish from other causes. This is an important distinction, as this syndrome has an autosomal recessive inheritance pattern with a 25% risk of affecting a subsequent pregnancy.

83 CHAPTER Hydronephrosis: Ectopic Ureterocele

Key Points

- Ectopic ureteroceles are associated with duplex collecting systems and are more common in females.
- An ectopic ureterocele can be stenotic or refluxing.
- Ectopic ureteocele can result in dysplastic changes in the superior pole of ipsilateral kidney.
- Ectopic ureteroceles can be challenging to diagnose as they intermittently decompress.
- Ectopic ureteroceles are a rare cause of bladder outlet obstruction.

CONDITION

A ureterocele is a cystic dilatation that occurs at the distal end of the ureter at its junction with the bladder. Simple ureteroceles are those that are located in the normal location of the ureteral orifice in the trigone of the bladder. Simple ureteroceles are more commonly detected in adults and usually are associated with a single collecting system. Simple ureteroceles are rarely associated with the upper pole ureter of a complete duplication of the collecting system. Simple ureteroceles may be associated with a varying degree of obstruction, but this is not significant in most patients. In contrast, with an ectopic ureterocele the ureteral orifice is located in an ectopic position, usually distal to the trigone, and this form is typically associated with a duplex collecting system. Ectopic ureterocele is also associated with an increased incidence of duplication in the contralateral kidney. The ureterocele may vary in size, from a tiny cystic lesion within the submucosal ureter, to that of a large cystic balloonlike structure that fills the bladder. The size of the ureterocele may fluctuate from one examination to the next. Histologically, the ureterocele is covered by the mucosa of the bladder and lined by the mucosa of the ureter, with varying degrees of attenuated smooth muscle bundles and connective tissue between the two layers of mucosa.

Several theories have been proposed to account for the embryonic development of a ureterocele. In one theory, a membrane covering the ureteral orifice persists for a long period, leading to the development of the ureterocele (Chwalle, 1927). In another theory, a ureterocele forms as a result of a stimulus to an expansion that transforms the bladder into a globular cap, creating an expanded thin-walled distal ureter (Stephens, 1971). Lastly, a localized embryonic arrest has been hypothesized as the cause of the ureterocele (Tokunaka et al., 1981).

Ectopic ureterocele has been classified anatomically by Stephens (1958, 1983). In this classification scheme, stenotic ectopic ureterocele is characterized by a small stenotic orifice and accounts for approximately 40% of cases. In sphincteric ectopic ureterocele, the orifice of the ureterocele is within the internal sphincter and accounts for an additional 40% of cases. In sphincteric ectopic ureterocele the ureteral orifice may be of normal caliber or may be enlarged and may open either in the posterior urethra in males or distal to the external sphincter in females. Sphincterostenotic ectopic ureterocele accounts for approximately 5% of cases. The stenotic orifice of this type of ectopic ureterocele is located within the urethral floor. There are other rarer types of ectopic ureterocele, including cecoureterocele, in which the lumen extends distal to the level of the orifice as a long tongue or cecum; blind ectopic ureterocele, in which there is no orifice so that the ureter is completely obstructed; and nonobstructive ectopic ureterocele, in which the orifice is enlarged within the bladder.

In complete ureteral duplication, the ureter draining the upper pole moiety usually opens caudal and medial to the ureter draining the lower pole moiety. This upper pole moiety ureter is commonly associated with ureterocele. When a duplex system is found to be present on one side, there is contralateral duplication in approximately 50% of the cases. This occurs far more frequently in females and can potentially result in bladder outlet obstruction if the ureterocele is sufficiently large. The orifice of the ureterocele is usually

obstructed either by stenosis or because it opens at the level of the urogenital diaphragm and is obstructed by the closed bladder neck. Not only can the ureterocele cause obstruction of the ureter from which it arises, but the ureterocele can also result in obstruction of the ureter draining the lower pole moiety, placing the entire kidney at risk. In ectopic ureterocele the upper pole moiety is commonly dysplastic and has poor or no function because of long-standing high-grade obstruction. The ectopic ureterocele may also affect the contralateral ureter and renal unit. Large ectopic ureteroceles may obstruct the ipsilateral lower pole moiety and, if extensive enough, they may even obstruct the contralateral side or induce vesicoureteral reflux (Koyanagi et al., 1980; Harrison and Filly, 1991).

INCIDENCE

The incidence of ureterocele is estimated to be 1 in 4000 autopsies in children (Brock and Kaplan, 1978). Ureteroceles are far more common in whites than in blacks. Ureteroceles are also five times more common among girls than among boys (Brock and Kaplan, 1978). Approximately 80% of ureteroceles are associated with a duplex collecting system. No information is available about the prenatal incidence of ectopic ureteroceles.

SONOGRAPHIC FINDINGS

The common mode of presentation for a fetus with ectopic ureterocele is unilateral hydronephrosis. The dilated upper pole of a duplex collecting system and a normal-appearing lower pole collecting system are key features that permit an accurate sonographic diagnosis of an obstructed duplex collecting system (Mahony, 1994). The dilated upper pole moiety may enlarge sufficiently so that it displaces the nondilated lower pole of the kidney inferiorly and laterally. Sonographic detection of two distinct ureters may be quite difficult in utero. It is important to search for a thin-walled fluid-filled ectopic ureterocele within the bladder (Figure 83-1). This may be very challenging, as the ureterocele may expand and decompress with ureteral peristalsis and bladder emptying. The ureterocele may also prolapse into the urethra if intravesical pressure exceeds intraurethral pressure. The ureterocele will initially collapse then subsequently prolapse or herniate into the urethra (Cremin et al., 1977; Fitzsimmons et al., 1986). Ultrasonographers should be mindful of this potential diagnostic pitfall, especially since ultrasonographic urinary bladder examinations with a full bladder are the very condition most likely to cause difficulty in identifying ureteroceles because of the flattening or intraurethral prolapse it causes. In every patient in whom hydronephrosis is antenatally diagnosed, a detailed examination of the fetal bladder should be performed to look for an intravesical cystic structure or the appearance of an extravesical diverticulum due to the intraurethral prolapse of the ureterocele during micturition (Fitzsimmons et al., 1986).

Antenatal recognition of the ectopic ureterocele and associated duplex collecting system can be exceedingly difficult. While upper pole hydronephrosis may be diagnosed, its cause is often missed. In a series reported by Winters and Lebowitz (1990), of 40 cases of hydronephrosis, prenatal diagnosis of duplex system with upper pole hydronephrosis was suggested in only one-third and only 1 of 19 ureteroceles were correctly diagnosed. This low specificity is thought to be due to the fact that many prenatal sonographers are unfamiliar with this entity. In addition, the duplex collecting system associated with ectopic ureterocele is difficult to diagnose even postnatally. The ureterocele can be mistaken for a bladder if the bladder is empty, or the full bladder can result in effacement

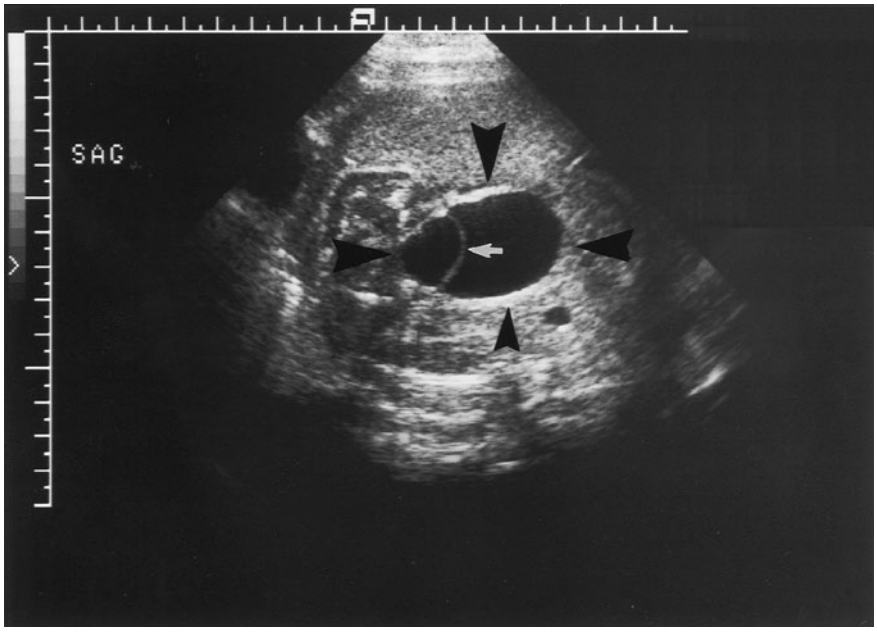

Figure 83-1 Prenatal sonographic image of a fetus that presented with unilateral hydronephrosis and was found to have a large ectopic ureterocele filling the bladder. This sagittal section through the bladder (*black arrowheads*) demonstrates the crescentic membrane (*white arrow*) of the ureterocele filling the bladder. *(Reprinted, with permission, from Cendron M, D'Alton ME, Crombleholme TM. Prenatal diagnosis and management of the fetus with hydronephrosis. Semin Perinol. 1994;18:163-181.)*

of the ureterocele (Lebowitz and Griscom, 1980). Another sonographic pitfall is the recognition of an ectopic ureterocele that on subsequent examinations is not visualized and therefore is thought to have resolved. As noted by Garmel et al. (1996) the "vanishing ureterocele" may be missed as a result of this same phenomenon, either by dilation in an empty bladder or effacement by a full bladder. It is important to recognize that a ureterocele will persist despite failure to demonstrate it on follow-up sonographic examinations. In some cases, the diagnosis may be facilitated by the use of a fetal MRI. As noted by Sozubir et al. (2003) fetal MRI can be an important adjunct to ultrasound enabling the diagnosis, in this case, of ectopic ureterocele with prolapse through the urethra onto the perineum in a female fetus (Sozubir et al., 2003).

DIFFERENTIAL DIAGNOSIS

The presenting sonographic features determine the differential diagnosis. If the most prominent feature is the cystic dilatation of the superior pole moiety of the kidney, then ureteropelvic junction obstruction, adrenal cyst, and mesenteric cyst are part of the differential diagnosis. Megaureter is also considered if a tortuous dilated ureter draining the upper pole moiety is a prominent feature. If the ureterocele prolapses into the urethra and causes bladder outlet obstruction, the fetus may present with a dilated bladder and bilateral hydronephrosis. This needs to be distinguished from posterior urethral valves, urethral atresia, and megacystis–microcolon. In addition, with ureteral dilatation of one or both sides, an ectopic ureterocele should be distinguished from vesicoureteral reflux. This can often be differentiated by the increase in ureteral size noted during fetal bladder contraction. However, the sonographic appearance of the crescentic membrane within the bladder is pathognomonic for ectopic ureterocele and narrows the differential diagnosis to this one condition (Figure 83-1).

ANTENATAL NATURAL HISTORY

Ureterocele is the third most common structural cause of congenital hydronephrosis (Chinn and Filly, 1982). The prenatal history of this condition is usually benign. In most instances the ectopic ureterocele is associated with some degree of obstruction, which, because of its long-standing nature, results in cystic dysplastic changes of the upper pole moiety (Cendron et al., 1994). The presence of the duplex collecting system and the ectopic ureterocele, however, places the ipsilateral kidney at some risk. If the ureter draining the lower pole moiety becomes obstructed this lower pole moiety is also at risk for renal dysplasia. Extremely large ureteroceles or ureteroceles that prolapse through the urethra may present as bladder outlet obstruction. It is only with careful sonographic evaluation that the true nature of the condition can be distinguished from other causes of bladder outlet obstruction. The prolapse of the ureterocele through the urethra results in vesicomegaly and bilateral hydronephrosis. This is the one instance in which ectopic ureterocele must be followed closely because its potential consequences for amniotic fluid volume and dysplastic renal changes in both kidneys are essentially equivalent to other causes of bladder outlet obstruction, such as posterior urethral valves. In most instances, however, the fluctuation in the size of the ectopic ureterocele allows adequate bladder emptying and maintenance of amniotic fluid volume. All fetuses with this form of ectopic ureterocele should be followed closely with serial sonography to exclude the possibility that a more significant degree of bladder outlet obstruction is compromising amniotic fluid volume or that there is an error in diagnosis and another form of bladder outlet obstruction exists.

The most important aspect of prenatal diagnosis of ectopic ureterocele is the prevention of postnatal urosepsis and loss of renal function (Caione et al., 1989). The vast majority of patients with ectopic ureterocele who present postnatally present with urosepsis, a decrease in renal function, or failure to thrive. It has been suggested by some authors that prenatal diagnosis of ectopic ureterocele identifies a group of patients who would otherwise be entirely asymptomatic and for whom a less aggressive approach to their postnatal treatment is indicated. While it may be true that the need for surgery remains to be defined in this group of patients, the identification of such patients warrants immediate initiation of prophylactic antibiotics to prevent reflux associated upper tract infections and secondary decrease in renal function.

MANAGEMENT OF PREGNANCY

The diagnosis of an ectopic ureterocele should prompt a detailed sonographic assessment of the contralateral kidney and exclusion of potential associated nongenitourinary anomalies. All fetuses with suspected ectopic ureterocele should be evaluated by a pediatric surgeon or pediatric urologist. In most instances, the presence of the ureterocele will have no effect on the pregnancy and should not have an impact on the clinical site, mode, or timing of delivery. The only exceptions are ureteroceles that cause bladder outlet obstruction, either because of their very large size or because they prolapse into the urethra. In these cases serial ultrasound examinations are warranted to observe amniotic fluid volume, which may be compromised. Decreasing amniotic fluid volume or oligohydramnios may require intervention. If a fetus is beyond 32 weeks of gestation, consideration should be given to steroid administration and early delivery.

FETAL INTERVENTION

At present there is no indication for fetal intervention following the prenatal diagnosis of an ectopic ureterocele.

TREATMENT OF THE NEWBORN

Chertin et al., have shown that prenatal diagnosis of ectopic ureterocele and associated duplex collecting system leads to fewer urinary tract infections and earlier endoscopic treatment (Chertin et al., 2005). All newborns with suspected duplex collecting systems and associated ectopic ureteroceles should undergo a complete urologic evaluation. It is prudent to wait 72 hours from the time of birth to obtain a postnatal sonogram so that an accurate assessment of the upper tract anatomy can be made. It is not uncommon in patients diagnosed prenatally with hydronephrosis, without a more specific etiologic diagnosis, to have a duplex collecting system with an ectopic ureterocele as the cause of hydronephrosis postnatally. If there is some doubt as to the cause of the hydronephrosis, the most useful test for defining the anatomy is voiding cystourethrography (VCUG). Function of the affected upper pole moiety can best be assessed by a technetium-99m DMSA renal scan.

The management of ectopic ureteroceles is controversial as there are several options for treatment (Rickwood et al., 1992). Churchill et al. (1992) have suggested an approach based on the function of the upper pole moiety. In cases in which there is nonfunctioning of the upper pole and only grade I vesicoureteral reflux, an upper pole nephroureterectomy can be performed in association with cystoscopic ureterocele drainage. If upper pole nonfunction is associated with grade II or III vesicoureteral reflux, then the upper pole nephrectomy can be combined with ureterocele excision and lower pole moiety ureteral reimplantation. If the function of the upper pole moiety is indeterminate, then endoscopic incision of the ureterocele can be performed and the subsequent degree of vesicoureteral reflux and function can be reassessed. In cases in which function of the upper pole moiety is preserved and there is only grade I vesicoureteral reflux, ureteropyelostomy and cystoscopic ureterocele drainage is indicated. If there is associated grade II or grade III reflux in these cases then ureteropyelostomy, ureterocele excision, and ureteral reimplantation are indicated.

Other groups have suggested a more conservative approach to management with initially only a transurethral incision of the ureterocele (Castagnetti et al., 2004). Transurethral incision of the ureterocele is effective in most patients with only a 5% rate of vesicoureteral reflux requiring reimplantation of the incised moiety. Other secondary surgery may be necessary in up to 50% of cases usually due to pre-existing vesicoureteral reflux in either the lower pole moiety or the contralateral system.

LONG-TERM OUTCOME

In general, the long-term outcome in ectopic ureterocele is excellent. Prenatal diagnosis allows initiation of prophylactic antibiotics at birth to prevent urosepsis. The presence or absence of upper pole dysplasia and vesicoureteral reflux will determine the surgical approach taken. The prospects for preservation of renal function and avoiding urosepsis are excellent. It is not uncommon for ectopic ureterocele to be difficult to diagnose postnatally; therefore, persistence is necessary. Ultrasound examination, voiding cystourethrography, and even cystoscopy may be necessary to make the diagnosis. These efforts are rewarded by the avoidance of urinary tract infection and preservation of upper pole renal function if dysplasia has not already developed.

GENETICS AND RECURRENCE RISK

Ectopic ureterocele is a sporadically occurring genitourinary anomaly without a known association with chromosomal abnormality or an increased risk for recurrence in subsequent pregnancies or offspring of an affected patient.

84 CHAPTER

Ambiguous Genitalia

Key Points

- Incidence is 1 in 5,000 livebirths. Most common cause is congenital adrenal hyperplasia (CAH), resulting in a virilized genetic female. This autosomal recessive condition has an incidence of 1 in 14,000 livebirths.
- Prenatal classification of ambiguous genitalia is based on cause. Fetuses can be virilized genetic females, undervirilized genetic males, or true hermaphrodites with both ovarian and testicular tissue present.
- Sonographic prenatal diagnosis of ambiguous genitalia is more accurate in males. Clitoromegaly is associated with false-positive diagnosis in females. The presence of a normal fetal uterus after 19 weeks is strongly predictive of a virilized genetic female.
- Differential diagnosis in a virilized female includes androgen exposure due to CAH or maternal tumors. An undervirilized male may be due to defects in the synthesis of testosterone or its precursor, androgen insensitivity, chromosome abnormalities, or true hermaphroditism. Single-gene disorders, such as Smith–Lemli–Opitz syndrome, should be considered.
- Prenatal management should include fetal karyotype and testing of 7-dehydrocholesterol (7-DHC) levels in the amniotic fluid. Delivery should occur at a tertiary center.
- Fetal treatment is available for CAH and Smith–Lemli–Opitz syndrome.
- Infant sex assignment should occur after birth using a team approach.
- The role of genital surgery in children with ambiguous genitalia is controversial.
- Recurrence risk depends on the etiology of the ambiguous genitalia.

CONDITION

Although the genotype of a fetus is determined at conception, sexual differentiation does not occur until 6 to 7 weeks of gestation (McGillivray, 1992). Before that point, the embryo has bilateral undifferentiated gonads and both müllerian and wolffian duct systems. Fetuses with a Y chromosome containing the gene for the testis-determining factor *(SRY)* will convert the undifferentiated gonad to a testis, which involves the formation of seminiferous tubules that surround the primitive germ cells. As shown in Figure 84-1, Leydig cells begin to produce testosterone, which acts on the wolffian ducts to produce male internal genitalia. Sertoli cells produce antimüllerian hormone (AMH), also known as müllerian duct inhibiting substance (MIS), which causes regression of the müllerian system (McGillivray, 1992).

At 6–7 weeks of gestation, the external genitalia are undifferentiated and consist of a genital tubercle, genital folds, and swellings. During male embryogenesis, masculinization of the common primordia is induced by the activity of dihydrotestosterone (DHT). DHT is formed from testosterone via the enzyme 5α-reductase. The urogenital tubercle then differentiates into the glans. The urogenital folds differentiate into the shaft of the penis and a male type of urethra by 12 to 14 weeks of gestation. The urogenital swellings fuse at the midline into the scrotum. Without testosterone, the müllerian duct develops into the fallopian tubes, uterus, and upper vagina. The genital tubercle becomes the clitoris, and the genital folds and swellings become the labia. Two X chromosomes are needed to maintain the ovaries and germ cells.

Most fetuses with genital ambiguity are otherwise well formed, although malformations of the sex organs sometimes

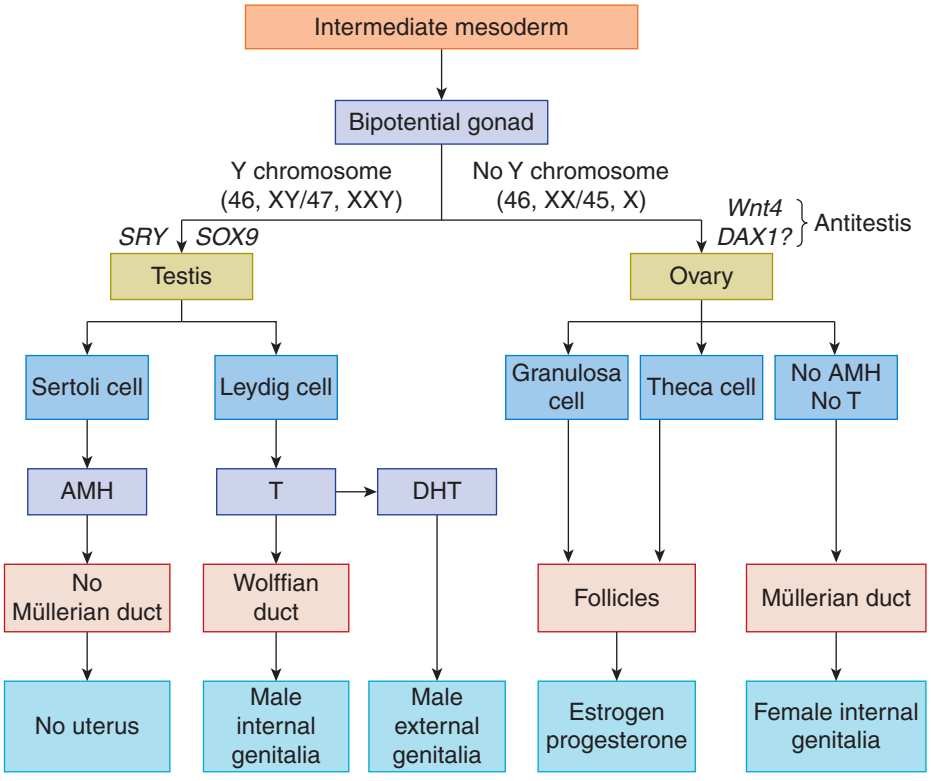

Figure 84-1 Development of genitalia in male and female fetuses. Normal sexual differentiation. SRY: sex determining region on Y chromosome; AMH: anti-Müllerian hormone; T: testosterone; DHT: dihydrotestosterone; Wnt4: Wnt = a group of secreted signaling molecules that regulate cell to cell interactions during embryogenesis; DAX1: DSS-AHC critical region of the X chromosome. *(Reprinted with permission from, Ogilvy-Stuart AL, Brain CE. Early assessment of ambiguous genitalia.* Arch Dis Child. *2004;89:401-407.)*

combine with malformations of the urinary tract (Aarskog, 1992). Abnormalities of sexual differentiation can be classified into disorders of chromosomal sex, gonadal sex, or phenotypic sex. One system of classification is based on the actual gonad found at surgical exploration. This classification divides infants with ambiguous genitalia into five subgroups:

1. Only an ovary is present (female pseudohermaphroditism).
2. Ovary and testis are present (true hermaphroditism).
3. Only a testis is present (male pseudohermaphroditism).
4. Testis and gonadal streak are present (mixed gonadal dysgenesis).
5. Only a gonadal streak is present (pure gonadal dysgenesis).

Unfortunately, this system is not practical to use in the prenatal context.

The more practical classification to use prenatally is based on cause. Three categories can be delineated:

1. True hermaphrodite—these fetuses have both ovarian and testicular tissue present.
2. Female pseudohermaphrodites—these are virilized females.
3. Male pseudohermaphrodites with and without müllerian structures—these are undervirilized males.

Female pseudohermaphrodites have a normal female karyotype (46, XX) and have ovarian gonadal tissue present. They have normal müllerian duct structures (uterus, fallopian tubes, and upper vagina) and no wolffian duct structures (epididymis, vas deferens, seminal vesicles). The female fetus becomes virilized because of exposure to androgens in utero. The causes for this include congenital adrenal hyperplasia (CAH), ingestion of androgens by the mother, and maternal virilizing tumors. Male pseudohermaphrodites with a normal 46, XY karyotype have only testicular tissue present. The Sertoli cells produce anti-müllerian hormone, but the undervirilization is due to inadequate synthesis of testosterone or dihydrotestosterone (see Figure 84-1), or the presence of an androgen receptor defect. Male pseudohermaphrodites with müllerian structures usually have a mixture of cell lines, with at least one cell line having a Y chromosome present, but no cells having two X chromosomes. The gonadal tissue in these cases is either normal testis or a streak gonad.

INCIDENCE

The incidence of ambiguous genitalia is 1 in 5000 livebirths (Kutteh et al., 1995). Hypospadias occurs in 2.5 to 8.2 per 1000 live male births (Bronshtein et al., 1995). Ambiguous

genitalia due to CAH occurs in 1 in 14,000 newborns (Hurtig, 1992).

SONOGRAPHIC FINDINGS

Axial scans often provide optimal visualization of the perineum and external genitalia when the fetal lower extremities are held in flexion. Sagittal scans of the perineum may be helpful to demonstrate the penis. When the fetus is male, testes can be identified within the scrotum after 28 weeks of gestation. de Elejalde et al. (1985) described the sonographic determination of fetal gender in 722 fetuses between 13 and 35 weeks of gestation. They compared their prediction with fetal karyotype, and all of these patients were studied prior to amniocentesis. These authors stated that the fetal genitalia could be imaged in 60.5% of fetuses examined before 18 weeks of gestation and 100% of those examined later than 20 weeks of gestation. In 3% of the cases, an error in sex assignment occurred, but these fetuses were all at less than 24 weeks of gestation. In female fetuses, the labia majora, labia minora, and occasionally the clitoris were visualized. In male fetuses, the scrotum was visualized in coronal and transverse planes. The transverse scan was useful for recognizing the penis. These authors stated that a fetal erection could be seen in utero by 20 weeks of gestation (de Elejalde et al., 1985). In an even larger study, Natsuyama (1984) determined fetal sex in 1879 pregnant women between 12 and 40 weeks of gestation. These authors used transverse, frontal, and sagittal scans of the fetal lower pelvic region. They were able to image 97.1% of cases and stated 99.9% accuracy in fetal gender assignment. These authors confirmed their findings postnatally. The most helpful findings were that between 12 and 23 weeks of gestation, the penis was pointed anteriorly toward the amniotic cavity but the clitoris was turned inferiorly. Another difference was the distance between the anal and genital regions. Males were noted to have a longer distance than females at later than 10 weeks of gestation (Natsuyama, 1984). Other authors described the "dome" sign, which was the sonographic visualization of the fetal scrotum and cranially directed phallus. In females, the diagnostic criterion is the presence of two or four parallel lines representing labial folds and a caudally directed clitoris. Some authors use the length of the phallus as a diagnostic criterion for gender assignment and some do not (Bronshtein et al., 1995). Benacerraf et al. (1989) have stated that sonographic visualization of the fetal genitalia is accomplished 80% to 90% of the time, with a correct sex assignment given 92% to 100% of the time. Fetal cephalic presentation is more favorable than breech for gender determination (Ali, 1992). Subsequent studies have established normal reference ranges for both penile length (Johnson and Maxwell, 2000; Zalel et al., 2001) and uterine development (Soriano et al., 1999).

In a pregnant woman with a positive family history of prior affected children with CAH, ambiguous genitalia were documented by the presence of two angulated lines representing labia and the presence of a central, domelike structure representing an apparent "scrotum" (Sivan et al., 1995) (Figure 84-2). In a follow-up study of 17 fetuses with genital malformations, 12 were raised as males, 4 were raised as females, and 1 genetic male was raised as a female due to congenital absence of a penis. In all cases an extremely small fetal phallus was observed, with undescended gonads (Figure 84-3). Four of the 17 fetuses had a sonographically abnormal phallus. The underlying diagnosis in 3 of the 4 fetuses with an abnormal phallus was congenital adrenal hyperplasia; 1 case was due to panhypopituitarism. The other underlying

Figure 84-2 Prenatal sonographic study from a fetus with ambiguous genitalia at 27 weeks of gestation. This fetus had apparent fusion of the labia minora and a straight (as opposed to curved) clitoris/phallus. Fetal karyotype was 46, XX and the underlying cause of the masculinization was congenital adrenal hyperplasia.

Figure 84-3 Fetoscopic view of a fetus at 20 weeks of gestation undergoing selective fetoscopic laser photocoagulation for twin-to-twin transfusion syndrome. This fetus was found to have ambiguous genitalia by preoperative ultrasound examination and MRI. This fetoscopic view demonstrates the virilized genitalia of a 46, XX female fetus with 21-hydroxylase deficiency. Note the elongated downward curving phallus and vaginal introitus still visible beneath the clitoris.

diagnoses in the remaining 13 cases included 2 cases of male pseudohermaphroditism, 3 cases of severe hypospadias with chordee, 2 cases of microphallus, 2 cases of cloacal anomaly, 2 cases of penoscrotal transposition, 1 case of intra-abdominal testes, 1 case of megaureter, and 1 case of cloacal exstrophy (Mandell et al., 1995).

The accuracy of the sonographic prenatal diagnosis of ambiguous genitalia was addressed by Cheikhelard et al. (2000). In this study, 34/43 cases were accurately diagnosed prenatally. The diagnoses were 100% correct when the fetus was diagnosed as an undervirilized male, but only 46% correct when the fetus was diagnosed as a virilized female. The authors diagnosed clitoromegaly when the clitoris measured more that 5 mm beyond the labia majora. This finding was clearly over diagnosed.

The use of three dimensional (3-D) sonography has been reported to improve visualization of a male fetus with ambiguous genitalia (Naylor et al., 2001). There have been no reports of prenatal use of MRI to diagnose ambiguous genitalia. However, a postnatal study compared 10 children with intersex disorders and found MRI and sonography to be equally sensitive (Biswas et al., 2004). For external detection of the gonads, MRI was marginally more sensitive.

Pinhas-Hamiel et al. (2002) identified 16 fetuses with ambiguous genitalia amongst their practice experience of over 10,000 fetuses. These affected fetuses underwent a full evaluation, including (1) repeated sonographic studies, (2) metaphase karyotype and FISH for *SRY*, and (3) hormonal assays of amniotic fluid. Twelve of the sixteen fetuses were referred because of an abnormal sonogram and 4 had a karyotype discrepancy. The underlying diagnoses were the following: 5 were virilized female fetuses (3 cases of CAH, 2 of urorectal septum malformation), 4 were undervirilized male fetuses (1 steroid sulfatase deficiency, 1 campomelic dysplasia, 2 unknown cause), 5 had chromosome abnormalities, and 2 were 46, XX, *SRY*+ males. These authors concluded that a screening ultrasound examination at 13 to 15 weeks was not sufficiently sensitive or specific to rule out ambiguous genitalia, and that the size and structures of the reproductive tract evolve throughout gestation. Importantly, after 19 weeks the sonographic presence of a normal uterus was strongly predictive of a virilized genetic female.

DIFFERENTIAL DIAGNOSIS

Ambiguous genitalia are either noted as a primary finding on sonographic examination, or as a secondary finding when karyotype and external genitalia are discordant. The key considerations in the differential diagnosis include determining whether the fetus is a virilized female or an undervirilized male (Table 84-1). The important diagnostic considerations include an inborn error of metabolism due to a single gene (mendelian) defect, an underlying chromosomal disorder, or a multiple malformation syndrome. Furthermore, the umbilical cord can be misinterpreted as a penis. Careful attention should be paid to distinguishing between the umbilical cord on longitudinal section and the genitalia (Ali, 1992). The most common cause of virilization of a female fetus is CAH, due primarily to the enzyme 21-hydroxylase deficiency (see Figures 84-2 and 84-3). In this disorder, 17-hydroxyprogesterone is not converted to 11-deoxycortisol. Cortisol is not synthesized and ACTH levels rise due to the lack of negative feedback. Subsequently, the levels of androgenic precursors rise, exposing the female embryo to androgen excess. In the severe form, limited secretion of cortisol as well as aldosterone leads to increased plasma renin activity and ultimately to hyponatremic dehydration and vascular collapse after birth. Other, rarer causes of CAH include 11β-hydroxylase deficiency and 3β-hydroxysteroid dehydrogenase deficiency.

Undervirilized males can occur due to a testosterone synthetic defect (Figures 84-4 and 84-5). The various causes of inadequate synthesis of testosterone are listed in Table 84-1. Testosterone is normally converted to dihydrotestosterone by the action of the enzyme 5α-reductase. Deficiency of 5α-reductase is also known as pseudovaginal perineoscrotal hypospadias. Affected subjects have ambiguous genitalia with hypospadias and a clitoris-like phallus. They also have a bifid scrotum and a blind vaginal pouch. The wolffian structures are normally differentiated, and the müllerian derivatives are fully regressed (al-Attia et al., 1993). Affected infants are usually assigned as female at birth but they virilize selectively at puberty. Because the fetal brain is exposed to a normal level of testosterone in utero and after birth, these patients usually take on the male gender at puberty. Another cause of undermasculinization of a male is the testicular feminization syndrome. The term Reifenstein syndrome has been applied to several disorders that were formerly thought to be separate entities. They are now known collectively to be mutations of the same androgen receptor gene present on the X chromosome and to cause familial partial androgen insensitivity. Affected children present with micropenis, small testes, and genital abnormalities, including hypospadias, bifid scrotum, and vaginal pouch remnants. Most affected patients are reared as males; however, in the setting of complete androgen insensitivity, female gender assignment may be most appropriate (Griffin, 1992; Lumbroso et al., 1994). At puberty, gynecomastia develops and virilization is poor. Considerable phenotypic variability has been reported depending on the molecular basis for the disorder.

A variety of multiple malformation syndromes have ambiguous genitalia as one component, primarily undermasculinization of affected male fetuses. These include Robinow syndrome, which consists of short stature, short arms, and a characteristic facies. The males have micropenis and the females have hypoplastic clitoris and labia minora. Opitz syndrome is characterized by hypertelorism and hypospadias. Affected females are normal. Aarskog syndrome is an X-linked disorder with short stature, hypertelorism, short nose, anteverted nostrils, a long philtrum, and genital dysplasia. There is a characteristic scrotal fold that extends

Table 84-1

Approach to the Fetus with Ambiguous Genitalia

Fetus with ambiguous genitalia or discordance between karyotype and external genitalia

↓

Karyotype

↓ 46, XX	↓ 46, XY	↓ Other abnormality/other chromosomal cause
Masculinized due to androgen exposure	Undermasculinized due to synthetic or receptor defect	Partial or full gonadal dysgenesis
		True hermaphrodite 46, XX/69, XXY
Congenital adrenal hyperplasia:	Inadequate synthesis of	
21-hydroxylase	T:20,22-desmolase	
11β-hydroxylase	3-β hydroxysteroid dehydrogenase	
3β-hydroxysteroid dehydrogenase deficiency	17β-hydrolase	
	17,20-desmolase	
	17α-hydroxylase deficiency	
	17β-hydroxysteroid deficiencies

Virilizing tumors	Inadequate synthesis of dihydrotestosterone:	
	5α-reductase deficiency	
	Receptor defect:	
	Reifenstein (androgen insensitivity) syndrome	
	Testicular feminization	

dorsally around the base of the penis (Aarskog, 1992). Other reasonably common multiple malformation syndromes that include ambiguous genitalia as a component include Smith–Lemli–Opitz syndrome, which is due to an inherited defect in 7-deoxycholesterol (see Figure 84-4). Affected fetuses have intrauterine growth restriction and may have a variety of other malformations, including holoprosencephaly and cleft palate. Patients with Prader–Willi syndrome may have micropenis. Patients with WAGR (Wilms tumor, aniridia, growth restriction, and genital anomalies) may have ambiguous genitalia. This disorder can be associated with a deletion on the short arm of chromosome 11. Other chromosomal abnormalities can also be associated with ambiguous genitalia. The urorectal septum malformation, a lethal condition, consists of ambiguous genitalia with absence of perineal and anal openings (Wheeler et al., 1997).

ANTENATAL NATURAL HISTORY

In the normal scenario, at less than 8 weeks of gestation the male and female genitalia appear identical. Normal female structures form in the absence of testicular hormones. Testosterone is needed by 8 weeks of gestation to induce normal male differentiation. Male differentiation occurs rapidly over 8 to 10 weeks of gestation. By 14 to 16 weeks of gestation, a normal penile urethra has formed. At over 20 weeks of gestation, the androgen levels in male and female fetuses are similar; by this time, the urethral and introital positions are fixed. Testicular descent into the scrotum occurs between 20 and 30 weeks of gestation in 62% of males and in 93% of males by 32 weeks of gestation (Cooper et al., 1985).

In cases of ambiguous genitalia, between 8 and 12 weeks of gestation, increased androgen levels in the female produce clitoromegaly, labial fusion, and persistence of the urogenital sinus. Decreased androgen levels in male fetuses may result in microphallus, incomplete fusion of the penile urethra (hypospadias), cryptorchidism, inadequate scrotal fusion, and the presence of a vaginal pouch (Meyers-Seifer and Charest, 1992).

MANAGEMENT OF PREGNANCY

When ambiguous genitalia is identified in a fetus, the pregnant woman should be asked whether there is any possibility

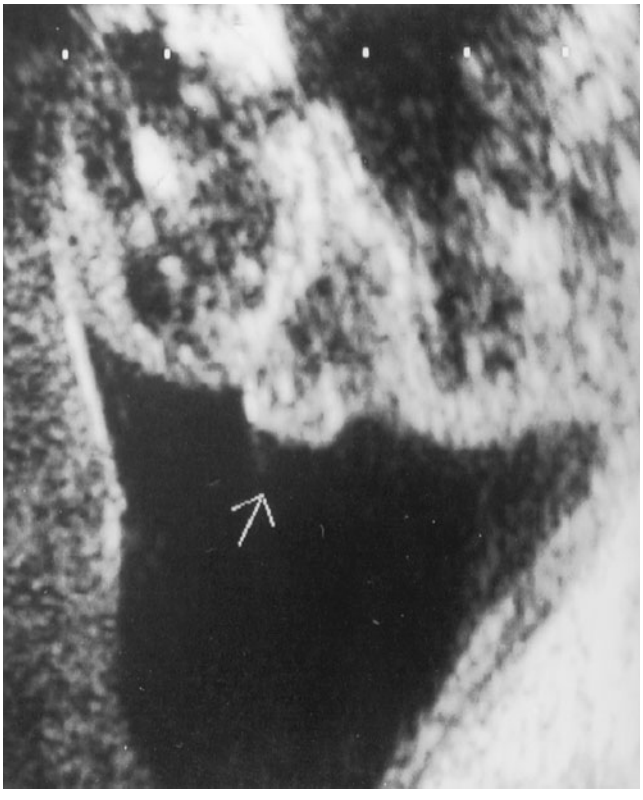

Figure 84-4 Prenatal sonographic study from an undermasculinized male fetus. The arrow indicates an enlarged clitoris rather than a small phallus. No definite testicles are seen lateral to this structure. This image is from a fetus with Smith–Lemli–Opitz syndrome.

Figure 84-5 Postnatal photograph of an infant with ambiguous genitalia. Note small phallus, split foreskin, urethral opening at base of penis and split scrotum. Urine is streaming out of the urethral opening.

that she ingested medications, such as progesterone for threatened miscarriage or androgens for endometriosis during the first trimester. The pregnant woman should be examined for signs of androgen overproduction, such as acne, a deep voice, or the development of hirsutism during pregnancy. A complete family history should be obtained, with specific questions asked regarding history of infertility in family members, prior cases of ambiguous genitalia, neonatal deaths, or consanguinity (Meyers-Seifer and Charest, 1992). Antenatal workup and treatment of the fetus with ambiguous genitalia is best performed in the setting of a multidisciplinary team that includes specialists in pediatric endocrinology, genetics, neonatology, pediatric urology and surgery, and psychology. It is recommended, however, that only one member of the team communicate with the family. We recommend that a prenatal karyotype be offered to determine the genetic sex, as well as to rule out the presence of associated chromosomal abnormalities. If the parents decline an invasive procedure, such as amniocentesis, noninvasive fetal gender testing may be performed using cell-free fetal DNA in maternal blood (Pajkrt and Chitty, 2004). If a Y chromosome sequence is present the fetus is a genetic male. However, the parents should be informed that definitive gender assignment may not be possible until 2 to 3 days after birth. We recommend that fetuses with ambiguous genitalia be delivered in a tertiary care center to avoid confusion on the admitting papers and birth certificate because when the sex of rearing differs from the sex assignment at birth, parents experience a lot of difficulties with changing medical records and the birth certificate. We also recommend admitting the baby to the newborn intensive care unit or special care nursery as "baby," not "baby boy" or "baby girl."

At the time of amniocentesis (if performed), amniotic fluid should be analyzed for the presence of 7-dehydrocholesterol (7-DHC). This metabolite is normally quite low in amniotic fluid; elevated levels are strongly suggestive of Smith–Lemli–Opitz syndrome (Kratz and Kelley, 1999). Measurement of 7-DHC in amniotic fluid is rapid and straightforward. Furthermore, there is a strong correlation between the level of amniotic fluid 7-DHC and clinical severity of the affected fetus. Amniocytes should also be saved as a source of DNA for mutation analysis of the 21-hydroxylase gene.

FETAL INTERVENTION

In families known to be at risk for affected fetuses with congenital adrenal hyperplasia (CAH), prenatal diagnosis for chromosomal sex and DNA analysis can be performed as early as 10 weeks of gestation by chorionic villus sampling (CVS). If the fetus is diagnosed as female and affected with congenital adrenal hyperplasia, consideration can be given to administering dexamethasone to the pregnant woman as early as 5 to 7 weeks of gestation in order to minimize the effect of androgens, not only on the genitalia but also the developing fetal brain. Once the genotype is known, dexamethasone can be discontinued in fetuses found to be 46, XY. Some groups are using analysis of cell-free fetal DNA in maternal blood in the first trimester to noninvasively determine fetal gender (Rijnders et al., 2001). If the fetus is male, maternal steroids are not indicated.

Later in gestation, while consideration must be given to the potential maternal side effects of dexamethasone treatment, we recommend steroid treatment to arrest the growth of the clitoris and limit the severity of virilization that will be present by the time of birth. This may reduce or potentially eliminate the need for clitoral recession and feminizing genitoplasty. In addition, successful prenatal treatment of an affected female with CAH due to 11β-hydroxylase deficiency has also been described (Cerame et al., 1999).

A review of 403 at-risk pregnancies evaluated at the New York Cornell Medical Center diagnosed 84 fetuses with classical 21-hydroxylase deficiency (21-OHD) (Carlson et al., 1999). Of these 52 were female. In 23 affected female fetuses, dexamethasone administered to the mother at or before 10 weeks of gestation was effective in reducing virilization. No significant or permanent side effects were noted in the mothers or the fetuses, indicating that dexamethasone treatment is safe. Treated newborns did not differ in weight, length, or head circumference from untreated affected newborns (Carlson et al., 1999).

Smith–Lemli–Opitz syndrome, a disorder of cholesterol metabolism, can present in utero with growth restriction and ambiguous genitalia. Postnatal treatment with cholesterol supplementation improves plasma sterol levels and enhances growth and development. In one reported case, antenatal treatment of a fetus with Smith–Lemli–Opitz syndrome by administration of fresh frozen plasma (cholesterol level = 219 mg/dl) via repeated transfusions resulted in improved fetal cholesterol levels and increased fetal red cell volume (Irons et al., 1999).

TREATMENT OF THE NEWBORN

Parents of an affected fetus or infant with ambiguous genitalia should be told that their infant has a sex that is incompletely developed and has yet to be determined (Izquierdo and Glassberg, 1993). The major considerations in the treatment of the newborn include: (1) to rule out life-threatening processes, (2) to determine the sex of rearing and gender identity, (3) to plan for surgery if necessary, (4) to plan for as normal pubertal development and fertility as possible, and (5) to provide genetic counseling. The affected newborn with ambiguous genitalia should be admitted to a tertiary care nursery capable of providing diagnostic tests and treatment. The infant's blood pressure should be closely monitored. Physical examination of the genital area should include a measurement of the phallus length as precisely as possible along the dorsum of the stretched penis from the pubic ramus to the tip of the glans (a measurement of 2.5 cm is 2.5 SD below the mean at term) (Meyers-Seifer and Charest, 1992). Although the clitoris reaches a term size at 27 weeks of gestation, the penis continues to grow until full term. On physical examination, an attempt should be made to palpate gonads. If they are palpable, are they symmetric, and is the position above or below the inguinal ring? The infant should be specifically examined for the presence of hypospadias and/or chordee. An assessment should be made of the labioscrotal folds for the degree of fusion (see Figure 84-4). The perineum should be examined for the presence of a urethra, vagina, vaginal pouch, or urogenital sinus. A rectal examination should be performed to try to palpate the uterus (Meyers-Seifer and Charest, 1992). A complete physical examination should be obtained to look for the presence of other abnormalities. A clinical geneticist can help in this regard.

After physical examination of the external genitalia the infant can be classified as having one of Prader's five stages. Stage 1 is isolated clitoral hypertrophy. Stage 2 is clitoral hypertrophy with visibly separate urethral and vaginal openings. Stage 3 is clitoral hypertrophy with a single urogenital sinus opening. Stage 4 is a micropenis with hypospadias. Stage 5 includes the findings of Stage 4 plus cryptorchidism (Sultan et al., 2002).

The initial blood work recommended includes serum electrolytes, glucose, and cholesterol, serum 17-hydroxyketosteroids, and a chromosome analysis, if it was not performed antenatally. The use of the buccal smear is no longer recommended. Fluorescence *in situ* hybridization (FISH) studies using X- and Y-chromosome–specific probes on nondividing cells is equally rapid and more accurate.

Additional studies that can be performed during the newborn period include urogenital sinography, which will outline the urethral and vaginal anatomy, magnetic resonance imaging of the pelvic region, and abdominal sonography. Kutteh et al. (1995) studied 100 term infants with the external genitalia covered. A neonatal uterus was identified in 47 of 50 female infants (sensitivity, 94%). The absence of the uterus correctly predicted 49 of 50 male infants (specificity, 98%). Most of the time the neonatal uterus demonstrated the typical linear echo of the endometrial cavity. The only false-positive was a distended bowel that was incorrectly identified as a uterus. These authors recommended that the bedside determination of the presence of the uterus was

important in the initial studies regarding gender assignment, as infants who have a uterus will almost always be assigned as a female.

Infants with ambiguous genitalia who require medical treatment during the newborn period include those with CAH, who are treated with adrenogenital steroids. This prevents potentially life-threatening urinary salt wasting and dehydration. In addition, it arrests virilization and permits normal growth and development of normal female secondary sex characteristics, menstruation, and fertility. In males who are undermasculinized due to 5α-reductase deficiency, an elevated plasma testosterone:dihydrotestosterone ratio is seen after human chorionic gonadatropin (hCG) stimulation. The diagnostic test is the presence of diminished 5α-reductase activity in skin fibroblasts, usually in the setting of a positive family history. Infants affected with 5α-reductase deficiency who are 46, XY should be assigned as male and given topical dihydrotestosterone therapy. This will enlarge the phallus and allow eventual repair of the hypospadias (al-Attia et al., 1993).

It is beyond the scope of this chapter to thoroughly discuss all of the underlying enzyme abnormalities that can cause ambiguous genitalia. However, female pseudohermaphrodites with 21-hydroxylase deficiency and 3β-hydroxysteroid dehydrogenase deficiency will have hyperkalemia and hyponatremia. Male pseudohermaphrodites with cholesterol side-chain cleavage defects and 3β-hydroxysteroid dehydrogenase defects will also have hyperkalemia and hyponatremia. Female pseudohermaphrodites with 11β-hydroxylase deficiency and male pseudohermaphrodites with 17α-hydroxylase deficiency will have hypokalemia. Diagnoses of most of these inborn errors of metabolism rely on the demonstration of the elevated immediate precursor in the affected infant's serum.

SURGICAL TREATMENT

The role of genital surgery in the management of ambiguous genitalia is becoming increasingly controversial (Creighton, 2004; Crouch and Creighton, 2004; Diamond et al., 2006). In theory, for the virilized female, clitoral recession, labioscrotal reduction, and vaginoplasty can all be performed between 2 and 5 months of age. Undervirilized males who are assigned a female gender can undergo a clitoral reduction, vaginoplasty, gonadectomy, and removal of wolffian ducts if surgery is elected. These patients will require estrogen at puberty (Izquierdo and Glassberg, 1993). Pseudohermaphrodites who are assigned as male can undergo correction of the hypospadias at about 1 year of age. At this time, if indicated, the testes can be placed into the scrotum. Some of these patients will require hCG stimulation during the newborn period and testosterone therapy at puberty. In patients with gonadal dysgenesis, the dysgenetic gonads are prone to neoplasia and should be removed. For patients who are true hermaphrodites, it is recommended that the tissue that is contrary to the sex of rearing be removed. For example, in patients being raised as female, testes and wolffian duct structures should be removed.

In practice, a recent survey of 185 members of the Pediatric Urology section of the American Academy of Pediatrics demonstrated a distinct shift in recommendations (Diamond et al., 2006). These physicians were given two clinical scenarios with photographs. One infant was a severely virilized female with CAH. All respondents favored a female sex assignment to preserve potential fertility. The other infant was a genetic male with phallic disruption due to cloacal exstrophy. Two-thirds of respondents recommended a sex assignment as male due to androgen brain imprinting, but the other third wanted to assign as female due to the difficulty of creating a functional penis. All respondents agreed that a team approach was needed, that parents should be actively involved, and that surgery, if performed, should occur at less than 18 months of age.

Others advocate for a need to re-evaluate "automatic progression" to surgery, especially for feminizing genitoplasty (Creighton, 2004; Crouch and Creighton, 2004). In feminizing genitoplasty some of the clitoris is removed and a vagina or vaginal opening is constructed. The main complication of genitoplasty is vaginal stenosis, which occurs in 30%–100% of cases and necessitates revision in adolescence. Most authors agree that there is a paucity of objective long-term outcome data. In one study, using objective criteria, 66% of patients had good outcomes if their surgery was performed by a surgeon with specific experience in the treatment of children with intersex disorders (Lean et al., 2005).

LONG-TERM OUTCOME

Increasing attention is being paid to the long-term psychological difficulties experienced by adults who encountered a conflict between the appearance of their surgically reconstructed external genitalia and their sexual identity (Reiner, 1999). Furthermore, several groups of adult patients currently advocate that genitalia should be left ambiguous permanently. Support groups such as the Intersex Society of North America and the Androgen Insensitivity Support Group can serve as clearinghouses of information for prospective parents (Warne et al., 1998).

GENETICS AND RECURRENCE RISK

The genes involved in gonadal differentiation are given in Table 84-2. CAH is inherited as an autosomal recessive condition. Partial androgen insensitivity is familial and is now known as Reifenstein syndrome. The androgen receptor gene has been mapped to Xq11–12. Defects in the androgen receptor are responsible for approximately 50%–70% of males with pseudohermaphroditism (Lumbroso et al., 1994). With molecular analysis, it is now known that the main mechanism

Table 84-2

Consequences of Mutations/Deletions and Duplications/Translocations of Genes Involved in Gonadal Differentiation

	Chromosome Location	Gonadal Development	Associated Disorder	Sex Reversal / Genital Ambiguity	Müllerian Development

that causes androgen insensitivity syndrome is a single nucleotide change that introduces a premature stop codon or an amino acid substitution into the coding sequence of the androgen receptor gene. Over 100 point mutations have been reported in this gene (Lobaccaro et al., 1994).

It is of interest that the gene abnormality in the 5α-reductase deficiency, inherited as an autosomal recessive disorder, causes abnormal sexual development only in 46, XY homozygotes. Heterozygous 46, XY males are apparently completely normal. In addition, 46, XX homozygotes with 5α-reductase deficiency are completely normal and fertile (al-Attia et al., 1993). Several Santo Domingan families have been described in the literature with this condition (al-Attia et al., 1993). All of the chromosomal disorders that are the underlying basis for gonadal dysgenesis are generally sporadic.

It is important to make an accurate diagnosis of the underlying cause of the ambiguous genitalia, as the genetic bases for many of these conditions are known and prenatal diagnosis is available for subsequent pregnancies. In particular, prenatal diagnosis and treatment options are available for CAH and Smith–Lemli–Opitz syndrome. Therefore, it is important to rule out these diagnoses in the family of a fetus that presents with ambiguous genitalia.

85 CHAPTER

Persistent Cloaca

Key Points

- Persistent cloaca refers to the continuation of the early embryological stage of a common opening for the rectum, vagina, and urinary tract.
- This is an extremely rare abnormality, being seen in only 1 in 50,000 births.
- Fetal abdominal cystic masses are the most typical prenatal diagnostic features, usually due to hydrocolpos and associated bladder outlet obstruction.
- Following the prenatal diagnosis, targeted fetal ultrasound, amniocentesis, and fetal MRI are helpful in accurately delineating the fetal anatomy.
- Postnatal surgical reconstruction is complex and should be undertaken only by a multidisciplinary pediatric surgical team after complete neonatal radiological and endoscopic anatomic evaluation.
- Long-term outcome appears favorable after surgical correction with the majority of patients being continent of urine and feces and several having successfully delivered children.

CONDITION

Cloaca, the Latin word for sewer, is aptly named as it represents the persistence of a developmental phase (typically in a female fetus) in which the rectum, vagina, and urinary tract share a common channel. In normal human development, there is a stage during which the cloaca forms from the confluence of the allantois and hindgut (Stephens and Smith, 1971). At 4 to 6 weeks of development, the urorectal septum descends, separating the allantois from the hindgut. Failure of this urorectal septum to descend results in persistent cloaca (Figure 85-1). The infant with persistent cloaca usually presents at birth with abdominal distention and an abnormal perineum. Typically, these children have only a single perineal opening without an anus or a vaginal introitus. The genitalia are ambiguous, often with a hooded phalluslike structure suggesting a masculinized gender, yet their chromosomes are consistently 46,XX and they have two normal ovaries. The length of the common channel to the perineum may vary, from 1 to 12 cm (Canning et al., 1998, Pena et al., 2004). In cases with a common channel <3 cm, there is usually a well-developed sacrum and sphincter complex. In contrast, longer common channels are more likely to have an abnormal sacrum and a poor sphincter complex, and these are usually more complex defects. In more than 50% of cases, there is hydrocolpos due to partial obstruction of the entry of the vagina into the common channel. The hydrocolpos can compress the trigone of the bladder, with resulting bladder outlet obstruction and hydroureteronephrosis. The prenatal sonographic detection of hydronephrosis may be the only indication of cloacal malformation. Duplicated vagina and uterus didelphys are commonly seen in persistent cloaca (Figure 85-2).

In 90% of cases of persistent cloaca, there are other associated urogenital anomalies (Rich et al., 1988). There is also a high incidence of nongenitourinary anomalies associated with persistent cloaca, including esophageal atresia, duodenal atresia, diaphragmatic hernia, vertebral anomalies, congenital heart disease (particularly tetralogy of Fallot), spina bifida, and caudal regression syndrome.

INCIDENCE

Persistent cloaca occurs in approximately 1 in 50,000 live-births (Gray and Skandalakis, 1972). Because of the rarity of prenatal diagnosis of persistent cloaca, no data are available on its prenatal incidence.

SONOGRAPHIC FINDINGS

The prenatal sonographic features of persistent cloaca are often secondary effects of the anomaly. A septated or bilateral

Figure 85-1 Line drawing depicting the anatomic relations typically observed in persistent cloaca with dilated rectum and, in this case, hydrocolpos. (*From Pena A. Atlas of Surgical Management of Anorectal Malformations. New York: Springer-Verlag; 1990:60. Lois Barnes Medical Illustrator. Used with permission.*)

cystic pelvic mass may be observed. In as many as 50% of cases, hydrocolpos may be present and may be the most striking feature. This may also partially obstruct the trigone of the bladder, with resulting vesicomegaly and hydroureteronephrosis. The distinction between hydrocolpos and a distended bladder may be very difficult to make. We have had one patient who presented with a dilated cystic pelvic mass (Figure 85-3) due to hydrocolpos and vesicomegaly. It was notable that mucus or meconium from the vagina or colon had refluxed into the bladder, forming a sediment in the trigone of the bladder. With passage of urine from the ureters to the bladder, a striking swirling of this sediment could be observed sonographically. We believe this to be a specific sonographic sign of communication between the urinary tract and either the vagina or colon. This can be seen in either persistent cloaca or, perhaps, a persistent urogenital sinus. The presence of calcifications within the lumen of the bowel should raise the possibility of either imperforate anus and rectourethral fistula or a cloaca, as urine mixing with meconium will create luminal calcifications.

In addition to the cloacal anomaly, the presence of other associated genitourinary anomalies should be sought, including hydronephrosis and horseshoe kidney. The combination of hydronephrosis and sacral anomalies should raise the possibility of a cloacal malformation. In cases of VACTERL (vertebral, anus, cardiac tracheal, esophagus, renal, limbs), cloaca can be seen in association with absent radius, cardiac abnormalities, or esophageal atresia with polyhydramnios and absent stomach. Spinal abnormalities and neural tube defects, such as sacral agenesis, have been reported in association with persistent cloaca.

DIFFERENTIAL DIAGNOSIS

The differential diagnoses to be considered when confronted with a fetus with a cystic pelvic mass, in addition to cloaca, should include urethral atresia, imperforate anus, presacral meningocele, ovarian cyst, bladder duplication, and imperforate hymen with hydrometrocolpos.

ANTENATAL NATURAL HISTORY

There are few reported cases of prenatally diagnosed persistent cloaca, and there is scant information available about its natural history (Cilento et al., 1994, Geipel et al., 2001).

MANAGEMENT OF PREGNANCY

Any fetus suspected of having a persistent cloaca should have a targeted ultrasound, not only to define the genitourinary anatomy but also to exclude potential associated anomalies. An echocardiogram should be obtained because of the increased incidence of congenital heart disease, especially

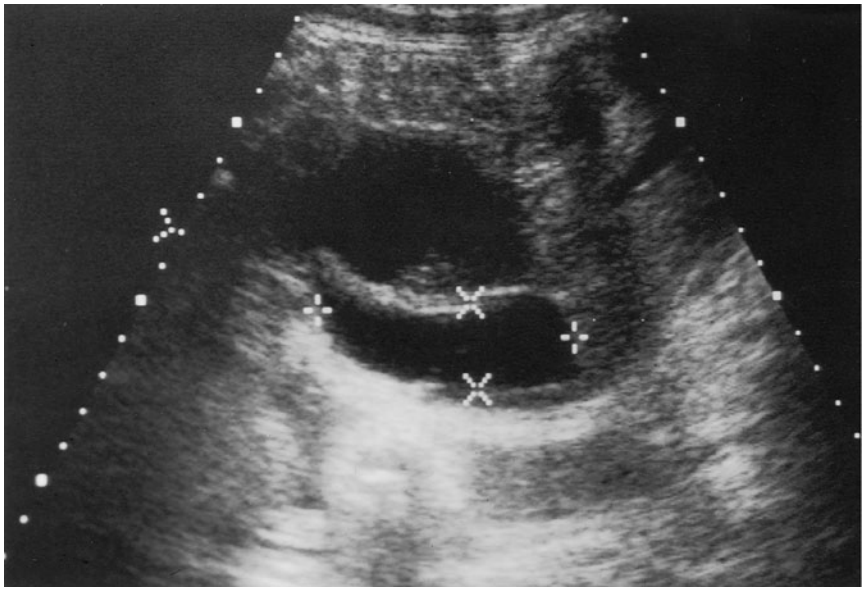

Figure 85-3 Prenatal sonographic image of a fetus at 24 weeks of gestation referred for evaluation of hydronephrosis. This fetus was found to have ambiguous genitalia and an unusual dilated pelvic cystic structure. A layer of sediment can be appreciated in the more anterior cystic space, which is the bladder. The more posterior space is the hydrocolpos outlined by "×" and "+" signs. Dilated colon was not appreciated at this gestational age. In the real-time study of the urine draining from the ureters to the bladder, the sediment was noted to "swirl" in the bladder.

tetralogy of Fallot in persistent cloaca. An amniocentesis should be performed to determine genotype. Ultrafast fetal magnetic resonance imaging (MRI) may be extremely helpful in confirming the diagnosis and defining the anatomy of the cloaca (Hubbard and Pena, 1997). Extensive prenatal counseling should be initiated to not only explain the complex nature of the anomaly but also explain the reconstruction. Consultation with a pediatric surgeon, pediatric urologist, and geneticist may be extremely helpful. The delivery should be in a center with pediatric surgeons and pediatric radiologists who are capable of evaluating an infant with persistent cloaca and can initiate treatment once the anatomy has been defined (Levitt and Pena, 2005). There is no reason to alter the delivery plan, and cesarean section should be reserved for standard obstetric indications.

FETAL INTERVENTION

There is only a single reported case of fetal intervention for cloaca reported by Shimada et al. (Shimada et al., 2001). These cases were decompressed in utero by vesicoamniotic shunt when the diagnosis was presumed to be bladder outlet obstruction. However, in general, most experts consider the presence of an obstructed cloacal anomaly a contraindication to shunt placement. This is because there are no data to demonstrate that the prognosis can be improved in these fetuses by in utero decompression. While decompression may be considered in cases associated with oligohydramnios and evidence of obstruction, evidence of preserved renal function should be demonstrated by fetal urine electrolyte analysis. In addition, the anatomy should be clearly defined by ultrafast fetal MRI. Lastly, parents considering fetal intervention should be extensively counseled about the implications of this diagnosis and have the opportunity to meet with a pediatric surgeon to discuss the extensive reconstructive procedures that may be necessary and the quality of life that the children with this anomaly may expect. Termination of pregnancy should be included in the options available to the parents when a diagnosis of fetal cloaca is made.

TREATMENT OF THE NEWBORN

The first priority in treating a newborn with persistent cloaca is to define the anatomy and to exclude other anomalies. A nasogastric tube should be passed to exclude esophageal atresia. Plain chest, abdominal, and pelvic radiographs should be obtained to exclude vertebral anomalies, especially involving the sacrum. The anatomy of the cloaca can best be defined by a combination of retrograde contrast studies through the single perineal opening and panendoscopy. Typically, the vagina is markedly distended with urine and vaginal secretions (Figure 85-4) (Pena and Levett, 2003). Only after a complete understanding of the anatomy has been achieved should treatment be undertaken (Hendren, 1998). In unusual cases, the entry of the rectum is low in the urogenital sinus, which may be amenable to perineal anoplasty (Hendren, 1980). More commonly, the level of entry of the rectum into the urogenital sinus is above the level of the levators, and this type is best managed by a diverting (as opposed to a loop) colostomy with a rectal pull-through procedure later. The adequacy of urinary tract decompression should be assessed to determine if a perineal cutback procedure is necessary to relieve obstruction.

Cystoscopic examination of the urogenital sinus may simultaneously allow dilation of the vaginal opening into the urogenital sinus to provide decompression of the hydrocolpos. Catheterization via the urogenital sinus preferentially goes to the vagina and not the bladder, allowing catheter decompression. Hydrocolpos, if present, may need to be drained with a tube vaginostomy if these other methods are not successful. In rare circumstances, if drainage of the hydrocolpos fails to improve the associated hydronephrosis, a vesicostomy

Figure 85-4 Postnatal study demonstrating the cloacal anatomy. A catheter has been passed into the urogenital sinus and contrast medium opacifies the bladder anteriorly and the rectum posteriorly.

may be needed to drain the urinary tract. A complete reconstruction by a posterior sagittal anorectovaginourethroplasty can then be performed at approximately 6 months of age (deVries and Pena, 1982). The diverting colostomy should be performed with an end colostomy to prevent contaminating the urinary tract. The downstream mucous fistula allows evaluation to the distal rectum and defines its entry into the urogenital sinus. Our practice is to obtain an MRI scan prior to reconstruction to define adequacy of the musculature, which will aid in planning the surgery and may provide prognostic information about the likelihood of eventual continence. In addition, one-third of these infants will have a tethered spinal cord, which MRI can help in defining (Sato et al., 1988).

SURGICAL TREATMENT

In reconstructing persistent cloaca, a posterior sagittal anorectovaginourethroplasty is performed (Pena and deVries, 1982; Pena et al., 2004). The muscle fibers are separated in the midline via a posterior sagittal incision from the coccyx to the center of the sphincter complex as defined by electrical stimulation. The rectum is identified and the urogenital sinus is opened posteriorly up to the confluence with rectum and vagina. The rectum is dissected free from the vagina. If there is a common channel of less than 4 cm, the urogenital sinus can be mobilized as a unit (Pena, 1997). If the length of the urogenital sinus is greater than 4 cm, a form of vaginal interposition may be necessary. This can be achieved using a segment of small intestine on its mesentery to bridge the gap between the vagina and perineum. The rectum is then mobilized to create a neo-anus within the sphincter complex, with or without a tapering rectoplasty. The new vaginal and anorectal passages are routinely dilated by parents, using a Hegar dilator of appropriate size, beginning several weeks after reconstruction. The colostomy closure is performed 4 to 6 weeks later as long as there is no stricture formation in the new anorectum and an urethrovaginal fistula is ruled out by endoscopy.

LONG-TERM OUTCOME

Hendren's (1998) series of 154 patients and Pena's (2004) series of 339 patients with persistent cloaca are the largest reported experiences of individual surgeons. In Hendren's series, voluntary bowel movements with satisfactory continence were achieved in 82 of 141 individuals (58%). An additional 38 patients were on an enema program and were focally continent; 9 patients had a permanent colostomy; 7 young children continued to soil and their parents had elected further treatment; 5 had undergone surgery too recently to evaluate. In Pena's experience, 203 of 339 (60%) had voluntary bowel movements and the remaining 135 (40%) were fecally incontinent, but all patients were clean with a specifically designed bowel management program.

In terms of urinary continence, in Hendren's series 83 of 141 patients voided spontaneously, 40 of 141 needed to catheterize to empty their bladders, 4 had urinary diversions, and 1 had a continent diversion. Five other patients had urinary incontinence and required further surgery. Eight patients had undergone surgery too recently to judge urinary continence. In Pena's series, when the urogenital sinus was less than 3 cm, 72% were continent of urine and 28% required intermittent catheterization. In those patients who had a urogenital sinus of more than 3 cm, 22% were continent and 78% required intermittent catheterization.

In Hendren's series, 24 patients were adults, of whom 14 were married, 17 had had coitus, and 6 had had children. Five adult women delivered their children by cesarean section and one by vaginal delivery (Greenberg and Hendren, 1997).

GENETICS AND RECURRENCE RISK

Persistent cloaca is a complex embryologic anomaly that is sporadic, with no increased risk of recurrence.

Renal Agenesis

86 CHAPTER

Key Points

- Developmental anomaly that occurs at 4 to 6 weeks of embryonic life.
- Incidence of bilateral renal agenesis is 1 in 3000 livebirths; for unilateral renal agenesis it is 1 in 500–1300 livebirths and higher in twins.
- Sonographic findings are severe oligohydramnios or anhydramnios occurring after 14 to 16 weeks in bilateral renal agenesis. In unilateral cases, the remaining kidney may be >95% in length for gestational age.
- Syndromes associated with bilateral renal agenesis are sirenomelia, caudal regression, branchio-oto-renal, cerebro-oculo-facial, Fraser, and Rokitansky–Kuster–Hauser. DiGeorge syndrome is also associated with unilateral renal agenesis.
- Consider amnioinfusion to obtain a karyotype.
- Most hereditary cases are inherited as an autosomal dominant condition with variable expressivity.
- Sonographic screening of the parental kidneys is recommended.
- Outcome is uniformly fatal for bilateral renal agenesis.
- For unilateral renal agenesis consider postnatal radionucleide scan, voiding cystourethrography, and prophylactic antibiotics.

CONDITION

Renal agenesis is the congenital absence of one or both kidneys as a result of the complete failure of the kidney to form. The sequence of renal agenesis, severe oligohydramnios, amnion nodosum, flattened face, low set and floppy ears, bilateral pulmonary hypoplasia, and perinatal death was first described by Potter in 1946.

Renal agenesis is a developmental anomaly that occurs at 4 to 6 weeks of embryonic life (Kaffe et al., 1977). Normal

renal embryogenesis requires that three events take place: the ureteric buds must arise bilaterally from mesonephric (wolffian) ducts; subsequently, bilateral metanephric blastema must form from mesoderm in the caudal region of the nephrogenic cord; and finally, ureteric buds must grow, contact, and invaginate the metanephric blastema, thereby inducing differentiation of the blastema into two mature kidneys (Wax et al., 1994). Failure of the metanephros to develop results in complete absence of the kidney. This can be due to either nonexistence of the ureteral bud or failure of the ureteral bud to develop from the wolffian duct.

In unilateral renal agenesis, there is complete absence of the kidney on one side, with compensatory hypertrophy on the contralateral side. Most cases of unilateral renal agenesis are due to lack of induction of the metanephric blastema by the ureteral bud, but some cases of absent kidney may be due to in utero regression of a multicystic dysplastic kidney (see Chapter 78) (Mesrobian et al., 1993). In cases of unilateral renal agenesis, compensatory hypertrophy of the remaining kidney occurs prenatally (Zalel et al., 2002). This has been demonstrated by Hartshorne et al. (1991), who performed a retrospective analysis of 20 fetuses who died with unilateral renal agenesis. Total renal mass was measured and was shown to comprise 82.7% of the weight of both kidneys removed from control fetuses at the same gestational age. Had prenatal compensatory hypertrophy not occurred, the total renal mass would have been only 50% of control values (Hartshorne et al., 1991). It is of biologic interest that in unilateral renal agenesis, symmetrical hypertrophy of all nephron components occurs during prenatal life, when the placenta clears all metabolic waste products. These authors hypothesized that it is the change in renal mass, rather than abnormality in function, that triggers compensatory growth of the contralateral kidney. This may be due to an as yet uncharacterized renotropic humoral growth factor (Hartshorne et al., 1991).

INCIDENCE

The incidence of bilateral renal agenesis is 1 in 3000 livebirths (Cardwell, 1988; Droste et al., 1990) and 1 in 240 stillbirths (Whitehouse and Mountrose, 1973). A recent ultrasound study performed in 12 European countries by the EUROSCAN group demonstrated a prevalence of 95 cases of bilateral renal agenesis in 709,030 pregnancies (Weisel et al., 2005). The antenatal detection rate was 91% at a mean gestational age of 21.2 weeks. Bilateral renal agenesis is 2.5 times more common in males than in females. Bilateral renal agenesis is also more common in twins as compared with singletons. Some authors have postulated a common cause for twinning and the development of renal agenesis (Roodhooft et al., 1984). An increased incidence of bilateral renal agenesis is not associated with advanced maternal age or maternal illness.

Unilateral renal agenesis occurs in 1 in 500 to 1 in 1300 livebirths, although many cases are clinically silent (Bronshtein et al., 1995). In the EUROSCAN study, unilateral renal agenesis was found in 58 of 709,030 studied pregnancies (Weisel et al., 2005). The antenatal detection rate was 62% at a mean gestational age of 28.6 weeks. In one study, the missing kidney was nearly always the left one (Hartshorne et al., 1991), but in another study of 46 consecutive cases of unilateral renal agenesis, the right kidney was absent in 19 of 46 individuals (Cascio et al., 1999). The true incidence of unilateral agenesis is likely to be even greater because this abnormality can be asymptomatic throughout life.

SONOGRAPHIC FINDINGS

The sonographic criterion for the diagnosis of bilateral renal agenesis is the presence of severe oligohydramnios or anhydramnios occurring after 14 to 16 weeks of gestation with failure to visualize the fetal urinary bladder and both kidneys (Droste et al., 1990). Prior to the 16th week of gestation, the fetal kidneys contribute relatively little to the amniotic fluid volume. After 28 weeks, premature rupture of the membranes or placental dysfunction may reduce amniotic fluid volume (Dubbins et al., 1981). The accuracy of the diagnosis of renal agenesis was addressed in one study, in which three groups of patients were analyzed (Romero et al., 1985). In the first group, 16 patients who had a positive family history of bilateral renal agenesis were studied. In the second group, an additional 3 patients were diagnosed with possible renal agenesis during a routine anatomic scan. In the last group, 30 patients were studied who had a previously abnormal level 1 scan that was highly suspicious for renal agenesis. In the overall study, 19 truly affected fetuses were present and of these 18 were correctly diagnosed. Seven cases were correctly diagnosed at <24 weeks of gestation. One case was a false-negative due to difficulty in imaging the kidneys at 36 weeks of gestation in a fetus with massive hydrocephaly and oligohydramnios. There were no false-positive diagnoses. In the 19 affected fetuses, no bladder was visualized in 18 of them. All 19 fetuses had oligohydramnios. These authors concluded that an absent fetal bladder diagnosed after 16 weeks of gestation should prompt further investigation for bilateral renal agenesis (Romero et al., 1985). This study demonstrated that sonographic diagnosis of renal agenesis was highly accurate in the second or third trimester (Table 86-1). Figure 86-1 demonstrates the sonographic findings in a case of unilateral renal agenesis.

Other reports of false-negative diagnoses in cases of bilateral renal agenesis have been attributed to the sonographic misidentification of apparently enlarged fetal adrenal glands as fetal kidneys. To answer the question about whether the adrenals were really enlarged, autopsy records were reviewed from 11 affected fetuses with bilateral renal agenesis. These authors compared normal values on 240 fetuses at the same gestational age. They established regression curves for adrenal weights versus foot and crown-to-rump length as an indicator of gestational age. The adrenal weights from the 11 patients

with bilateral renal agenesis were all within the normal limits. Therefore, these authors concluded that adrenal hypertrophy was not a common finding in renal agenesis and that the false-negative diagnosis of renal agenesis was due to a change in the normal adrenal shape rather than an increase in adrenal mass (Figure 86-2) (Droste et al., 1990). In approximately 10% of patients with unilateral renal agenesis, the ipsilateral adrenal gland is also absent (Fortune 1927; Ashley and Mostofi, 1960).

First trimester diagnosis of bilateral renal agenesis is complicated by the fact that at that point in gestation, amniotic fluid volume is not significantly reduced. Bronshtein et al. (1994) identified 9 of 13,252 fetuses with bilateral renal agenesis by transvaginal sonography between 12 and 18 weeks of gestation. The fetal kidneys can be visualized from 10 weeks of gestation by transvaginal sonography, and they appear as bilateral echogenic masses with the same density as fetal lungs. In contrast, the adrenal glands are relatively hypoechogenic. Diagnosis of renal agenesis consists of demonstration of oval bilateral hypoechogenic masses in the renal bed interpreted as adrenal glands. In this study, one false-positive diagnosis was made in a fetus with hypoplastic kidneys due to trisomy 22. These authors noted that the early second trimester sonographic findings in fetuses with bilateral renal agenesis consisted of three different presentations: (1) absence of any masses in the fetal flanks without sonographic evidence of ectopic kidneys, (2) the presence of bilateral hypoechogenic masses in the fetal flanks with no sonographic evidence of a fetal bladder and positive evidence of oligohydramnios at <17 weeks of gestation, and (3) bilateral hypoechogenic masses demonstrated in the fetal flanks with a small bladder present and a normal amount of amniotic fluid (Bronshtein et al., 1994).

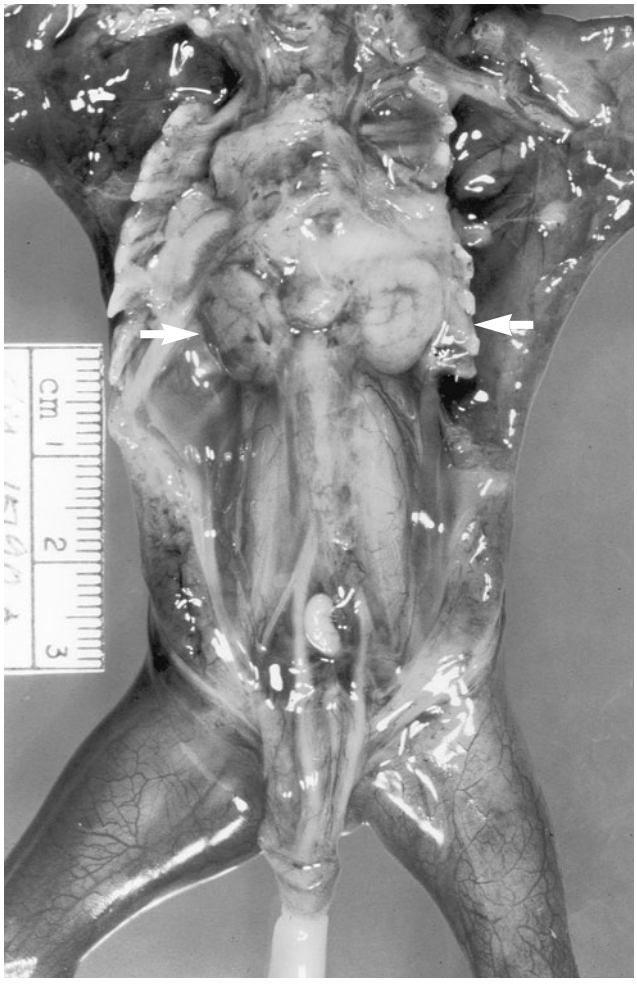

Figure 86-2 Postmortem photograph of a fetus at 17 weeks of gestation. This fetus had multiple congenital anomalies, including bilateral renal agenesis, absent ureters, absent bladder, absent uterus, absent fallopian tubes, and vaginal atresia. The arrows indicate the discoid-shaped adrenal glands. The centrally placed beanlike structure is a dysmorphic ovary. *(Courtesy of Dr. Joseph Semple.)*

Because oligohydramnios can impair visualization of the fetal kidneys and bladder, color Doppler sonography is recommended as an adjunct to the diagnosis of bilateral renal agenesis (Figure 86-3) (Sepulveda et al., 1998). In one study of 33 consecutive second trimester pregnancies complicated by severe oligohydramnios, high-resolution color Doppler ultrasonography was used to establish the presence or absence of renal arteries. The results showed that neither renal artery was visualized in eight fetuses; postmortem examination confirmed bilateral renal agenesis in seven fetuses and unilateral renal agenesis with a contralateral atrophic multicystic kidney in one fetus. In three cases, only one renal artery was visualized; postmortem examination confirmed unilateral renal agenesis in two fetuses and bilateral multicystic dysplastic kidneys in one fetus. When both renal arteries were identified prenatally (22 cases), postnatal or postmortem evaluation confirmed the presence of both kidneys (Sepulveda et al., 1995). Nomograms exist that predict the location of the renal arteries (distance from the bifurcation of the iliac arteries), using the fetal femur length as a reference (DeVore, 1995). In cases in which uncertainty remains after ultrasound, MRI is a useful adjunct to identify fetal kidneys or confirm unilateral or bilateral renal agenesis.

Late second- and third trimester fetuses with bilateral renal agenesis may also have intrauterine growth restriction. Affected infants have an increased incidence of associated malformations, most commonly of the genital system, cardiovascular system, vertebral bodies, or imperforate anus (Roodhooft et al., 1984). In the study by Bronshtein et al. (1994), six of the eight fetuses with renal agenesis had associated malformations. In five of the six affected fetuses, cardiac malformations were demonstrated.

Nomograms exist for kidney length from 13 to 22 weeks of gestation (Zalel et al., 2002). In one study, four cases with unilateral renal agenesis had a single kidney with a length greater than 95% (Zalel et al., 2002). In a postnatal study,

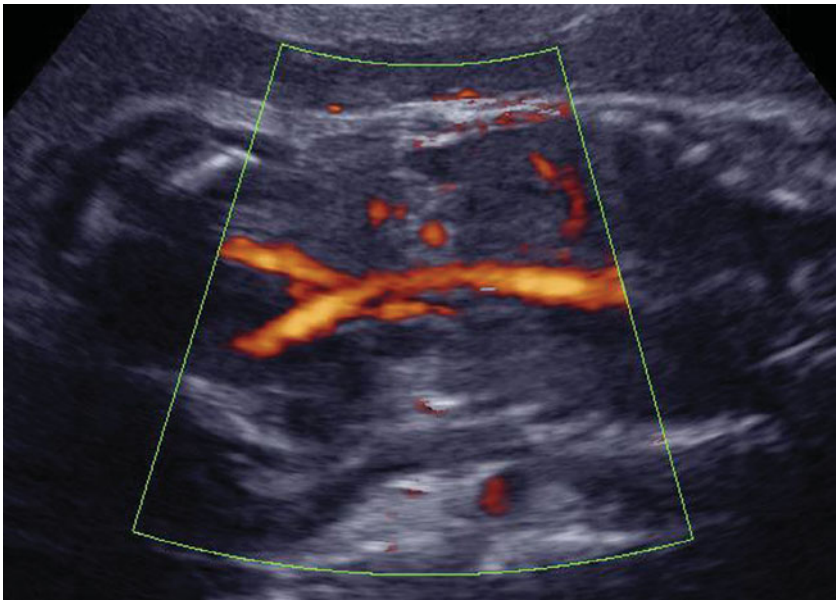

Figure 86-3 Coronal image with power Doppler demonstrating absence of both the right and left renal artery in a fetus with bilateral renal agenesis.

nearly half of the patients with unilateral renal agenesis had associated urological abnormalities, including vesicoureteral reflux, ureterovesical junction obstruction, and uteropelvic junction obstruction in the remaining kidney (Cascio et al., 1999).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of bilateral renal agenesis includes sirenomelia (see Chapter 87), caudal regression syndrome, and other nonanatomic causes for severe oligohydramnios, such as placental insufficiency. Sirenomelia is almost always associated with bilateral renal agenesis. Syndromes that are associated with renal agenesis include branchio-oto-renal syndrome, which is inherited as an autosomal dominant trait. This syndrome consists of preauricular pits, hearing loss, cervical fistulae, and renal abnormalities (Fitch, 1977). In one study, 6% of affected infants born to a parent with branchio-oto-renal syndrome were demonstrated to have severe renal anomalies (Greenberg et al., 1988). An additional syndrome that can present with renal agenesis is the cerebro-oculo-facial syndrome, which is inherited as an autosomal recessive trait. Affected infants with this condition have a dysmorphic face, micrognathia, flexion contractures, and severe renal anomalies. Unilateral and bilateral renal agenesis are often associated with bicornuate uterus and atresia of the vagina in females (also known as Rokitansky–Kuster–Hauser syndrome) and absence of the seminal vesicles and vas deferens in males (Holmes, 1989; Intaraprasert and Benchakan, 1985). Fraser syndrome is a rare autosomal recessive disorder that presents with cryptophthalmos, syndactyly, and renal anomalies. Bilateral renal agenesis is present in 47% of cases and unilateral renal agenesis in 37% (Wellesley and Howe, 2001). Bilateral renal agenesis should also be considered in twin gestations where one twin appears "stuck" due to severe oligohydramnios (Kuller et al., 1994). The differential diagnosis for unilateral renal agenesis includes renal aplasia, multicystic dysplastic kidney (see Chapter 78), crossed and double-crossed renal ectopia, and DiGeorge syndrome (22q11.2 microdeletion) (see Chapter 139) (Stewart et al., 1999).

ANTENATAL NATURAL HISTORY

As many as 33% of affected fetuses with bilateral renal agenesis are stillborn (Droste et al., 1990). It is becoming increasingly appreciated that a multicystic dysplastic kidney may result in the apparent absence of a kidney on sonography. The presence of microscopic residual renal tissue in these cases indicates that renal aplasia, not renal agenesis, is present. Family studies, however, suggest a relationship between renal agenesis and renal dysgenesis (Holmes, 1989). In one study, nine neonates who were previously known by prenatal sonography to have renal abnormalities were subsequently shown on postnatal studies to have unilateral renal absence (Hitchcock and Burge, 1994). Five of these infants had multicystic dysplastic kidney, and two had hydronephrosis noted antenatally. Unilateral renal absence may represent the prenatal involution of a multicystic dysplastic kidney, although this is controversial.

Unilateral renal agenesis is associated with genital anomalies in 12% of males and 40% of females (Heaney et al., 1987). In males, cysts of the seminal vesicle occur because of the common embryologic origin of the ureteral bud and the seminal vesicle from the mesonephric duct at 12 weeks of gestation (Heaney et al., 1987). In 68% of cases of seminal vesicle cysts, ipsilateral renal agenesis exists (Carvalho et al., 1986). In females, bicornuate or unicornuate uterus are common coexisting abnormalities. Also, ipsilateral blind vaginas and müllerian duplications are caused by lesions of the mesonephric duct. These lesions result in a closed urogenital sinus, which is due to the absent upward migration of the ureteral bud toward the metanephric blastema. This prevents the normal subsequent development of the kidney (Acien et al., 1991).

MANAGEMENT OF PREGNANCY

Further management of pregnancy when bilateral renal agenesis has been diagnosed will depend on the indication for the initial sonography and time of gestation. Serial sonography with color Doppler flow studies or MRI can be helpful when any doubt exists regarding the diagnosis. Attempts to diagnose bilateral renal agenesis in the first trimester are complicated by the fact that the renal contribution to amniotic fluid is minimal before 17 weeks of gestation and oligohydramnios is not necessarily present. Bronshtein et al. (1994) showed that an apparent urinary bladder may be seen during the first trimester in cases of bilateral renal agenesis due to retrograde filling or a small urachal cyst. Diagnosis at 13 to 16 weeks of gestation by transvaginal sonography can be made by demonstrating the presence of bilateral hypoechogenic structures that are clearly visualized in the renal bed without evidence of ectopic kidneys in the pelvis. These authors recommend at least a 60-minute period of observation to monitor filling of the bladder. If no bladder is visualized, a presumptive diagnosis of renal agenesis may be made, and the parents should be offered the opportunity to terminate the pregnancy. If, however, minimal amniotic fluid is present and a cystic structure is detected within the pelvis, these authors recommended fetal karyotyping, with follow-up sonography occurring at 17 to 19 weeks of gestation.

Sonographic diagnosis of bilateral renal agenesis can be complicated by poor fetal imaging due to lack of amniotic fluid. Intra-amniotic instillation of physiologic fluids can improve visualization of the fetus in cases of severe oligohydramnios. Cameron et al., recommend a single amnioinfusion, if needed, for sonographic diagnosis of renal agenesis. The amnioinfusion also permits fetal karyotyping. Another option

to visualize fetal anatomy is to perform magnetic resonance imaging (MRI) of the fetal abdomen, although there has been at least one case report of a false diagnosis of renal agenesis on MRI (Sgro et al., 2005). In practice, however, MRI is rarely needed to make the diagnosis.

In one study, pregnancies complicated by known lethal fetal renal anomalies were shown to have higher rates of antepartum complications (such as bleeding) and intrapartum complications (such as breech presentation) that led to statistically and significantly higher rates of primary cesarean section delivery (Carpenter et al., 2000). For fetuses with bilateral renal agenesis, there is no indication for a cesarean section. In cases of unilateral renal agenesis, routine obstetric management should prevail.

FETAL INTERVENTION

In one case report, a fetus with bilateral renal agenesis was presented. Serial amnioinfusions were performed to attempt to prevent pulmonary hypoplasia because the parents insisted that all therapeutic options be maintained. This infant was delivered at 33 weeks of gestation because of chorioamnionitis following multiple amnioinfusions. The infant had no clinical symptoms of pulmonary hypoplasia and no compressive effects on the face and limbs. Aggressive neonatal treatment was undertaken to achieve a goal of eventual renal transplantation. Peritoneal dialysis was initiated, but it ultimately proved unsuccessful. Cameron et al. (1994) strongly discourage this aggressive type of treatment of fetuses with bilateral renal agenesis. While it is possible to achieve survival without pulmonary hypoplasia in some cases with serial amnioinfusion, the family should be well informed regarding the postnatal challenges these infants face. Peritoneal dialysis is difficult to maintain in infants and allow growth to 10 kg, the usual minimal weight required for renal transplantation. In addition, previous experience with neonatal dialysis was associated with significant neurodevelopmental delay later in life. While management of neonatal dialysis has improved, parents should be aware of uncertain neurodevelopmental outcomes, difficulty in getting children to grow to 10 kg and the scarcity of appropriate infant donor kidneys.

TREATMENT OF THE NEWBORN

If the sonographic diagnosis is absolutely certain, no resuscitation of the newborn is indicated. However, if any question exists regarding the diagnosis, a neonatologist should be present at the delivery to confirm the presence of Potter-like features and clinical evidence of pulmonary hypoplasia. Bilateral renal agenesis is considered a lethal diagnosis. Intubation and mechanical ventilation of the newborn, however, may be considered appropriate in the setting of an unknown diagnosis. Once it has been confirmed postnatally that the infant lacks both kidneys, withdrawal of life support systems is appropriate.

Most newborns with bilateral renal agenesis die from pulmonary insufficiency resulting from severe oligohydramnios. In one study, a detailed quantitative analysis of the lungs of eight infants who died from bilateral renal agenesis or dysplasia was described (Hislop et al., 1979). The total lung volume and number of airway generations were reduced. This implied an interference with normal pulmonary development when the amniotic fluid volume was normal. Even at 12 to 16 weeks of gestation, the alveoli were reduced in size and number. These authors hypothesized that factors other than the oligohydramnios affected early lung growth. This was possibly due to the decreased production of proline, which is normally manufactured by the kidneys. Cases of bilateral renal agenesis have the lowest ratio of lung weight to body weight as compared with other types of kidney anomalies (Hislop et al., 1979).

In most newborns, unilateral renal agenesis is clinically silent. For fetuses that have been identified antenatally as having unilateral renal agenesis, a physical examination with palpation of the kidneys is indicated as well as postnatal abdominal sonography. Consideration should also be given to a radionucleide scan of the remaining kidney to document renal function. Because of the increased incidence of vesicoureteral reflux in the remaining kidney, voiding cystourethrography is also recommended. Prophylactic antibiotics are recommended in all cases of unilateral renal agenesis until vesicoureteral reflux has been ruled out.

SURGICAL TREATMENT

There are no surgical treatments for renal agenesis.

LONG-TERM OUTCOME

The longest surviving baby with bilateral renal agenesis was 39 days old (Whitehouse and Mountrose, 1973). Effectively, there is no long-term outcome for infants with bilateral renal agenesis.

In cases of unilateral renal agenesis, the infant may be asymptomatic, but patients with this diagnosis are at increased risk for proteinuria, hypertension, and renal insufficiency. Thirty percent of patients with unilateral renal agenesis have contralateral vesicoureteral reflux (Atiyeh et al., 1993).

GENETICS AND RECURRENCE RISK

Genetic counseling for renal agenesis is complicated by the fact that etiologic heterogeneity exists for this condition.

Many, but not all, cases of renal agenesis are inherited as multifactorial traits. The recurrence risk for an affected fetus or infant with isolated bilateral renal agenesis and a negative family history is in the order of 3% to 4% (Roodhooft et al., 1984; Holmes, 1989). If the renal agenesis is part of a complex of multiple abnormalities, the recurrence rate for siblings is 8% (Holmes, 1989). Chromosomal abnormalities, X-linked inheritance, autosomal dominant and autosomal recessive inheritance have all been reported for this condition. The chromosomal abnormalities most commonly seen in cases of bilateral renal agenesis include trisomy 22 (Bronshtein et al., 1994; Van Buggenhout et al., 1995), microdeletion of 22q11 (Stewart et al., 1999), trisomy 21 (Cardwell, 1988), trisomy 7, trisomy 10 (Schwarzler et al., 1999), 45, X/46, XY (Wax et al., 1994), 45, X/47, XXX (Roodhooft et al., 1984), and double aneuploidy for chromosomes 7 and X (Biri et al., 2005). An association between XYY and renal agenesis may also exist (Rudnik-Schoneborn et al., 1996). Fetuses with renal agenesis and other anomalies may have an underlying syndrome (see "Differential Diagnosis").

As stated earlier, the incidence of renal agenesis is higher in twin pregnancies than in singleton pregnancies. Monozygotic twins can either be concordant (Yates et al., 1984) or discordant (Cilento et al., 1994). Cilento et al. described a monoamniotic twin gestation with normal renal function that provided enough amniotic fluid to avoid the extrarenal manifestations of Potter syndrome. The twin with bilateral renal agenesis had no pulmonary abnormalities because there was enough urine being produced by the other twin. There is an increased incidence of recurrent renal agenesis in families, especially in those affected by hereditary hydronephrosis (Finn and Carruthers, 1974). Several families have been reported with two or more siblings of the same sex who were born with bilateral renal agenesis (Kaffe et al., 1977).

In one report, 9% of parents or siblings of patients with bilateral renal agenesis or dysgenesis had asymptomatic renal malformations (Roodhooft et al., 1984). In this study, 71 parents and 40 siblings of 41 index cases with bilateral renal agenesis, unilateral renal agenesis with dysgenesis of the other kidney, and bilateral severe dysgenesis were studied. Ten of these 111 relatives had an asymptomatic renal malformation. Most commonly, this was unilateral renal agenesis. The incidence of unilateral renal agenesis was 4.5% in the relatives of affected individuals with bilateral renal agenesis versus 0.3% in control adults. The malformation seen in the relatives included a double ureter, hydronephrosis, multicystic kidney, and multiple renal cysts. In addition, 2 of 37 mothers studied had a bicornuate uterus. These authors recommended sonographic screening for parents and siblings of affected fetuses or infants (Roodhooft et al., 1984). In families in which there is evidence of both unilateral and bilateral renal agenesis, the term "hereditary renal adysplasia" has been used. In most cases, this is due to a single gene inherited in an autosomal dominant pattern with variable expression (Pallotta et al., 2004).

To date, specific genes have not been identified in association with bilateral renal agenesis. Prenatal diagnosis in subsequent pregnancies should consist of serial sonographic examinations.

87 CHAPTER

Sirenomelia

Key Points

- Incidence is 1 in 60,000 livebirths.
- Results from localized injury or insult to caudal end of developing embryo between days 13 and 22.
- Classified into 7 types according to the number of long bones present in the lower extremity.
- Associated with monozygotic twinning.
- First trimester sonographic findings include fused lower limb and increased nuchal translucency.
- Second trimester sonographic findings include single umbilical artery, bilateral renal agenesis, oligohydramnios, and growth restriction.
- Differential diagnosis includes bilateral renal agenesis and caudal regression syndrome.
- Chromosomes are usually normal.
- Prognosis is extremely poor for extrauterine survival.

CONDITION

Sirenomelia, also known as "mermaid syndrome," has been noted since the Greco-Roman period. Initially described in the medical literature by Rocheus in 1542 (Murphy et al., 1992), the condition is characterized by a single lower extremity, with the concomitant presence of severe anomalies of the urogenital and gastrointestinal system. Although historical and mythological accounts portray sirens and mermaids as females, the majority of patients with sirenomelia are male (deJonge et al., 1984). In all likelihood, the confusion originated as a result of the fact that most patients with sirenomelia had no obvious external genitalia.

It is often stated that sirenomelia is characterized by apparent fusion of the lower limbs. This terminology is embryologically incorrect because *fusion* refers to two processes joining after breakdown of intervening epithelia. *Merging* is the more correct term, because it does not imply intervening breakdown of epithelium. Sirenomelia, therefore, is a syndrome of merging, malrotation, and dysgenesis of the lower extremities (Kapur et al., 1991).

In 1865, Förster classified sirenomelia into three groups according to the number of feet present (van Zalen-Sprock et al., 1995). In symelia apus, the most common of the three conditions, both legs are merged completely into a single lower extremity. Both feet are absent or rudimentary. On radiographic studies, only one femur is present; there are no fibulae and one or two tibulae. In symelia unipus, 1 foot is present and up to 10 toes also may be seen (see Figure 87-1). In this type of sirenomelia, two femora, two tibia, and two fibulae are present. In symelia dipus, two distinct feet are present, although generally they are malrotated, and often give the appearance of fins. Stocker and Heifetz (1987) further classified sirenomelia according to seven types. In type I, all thigh and leg bones are present. In type II, there is a single fibula. In type III, there is an absent fibula. In type IV, the femurs are

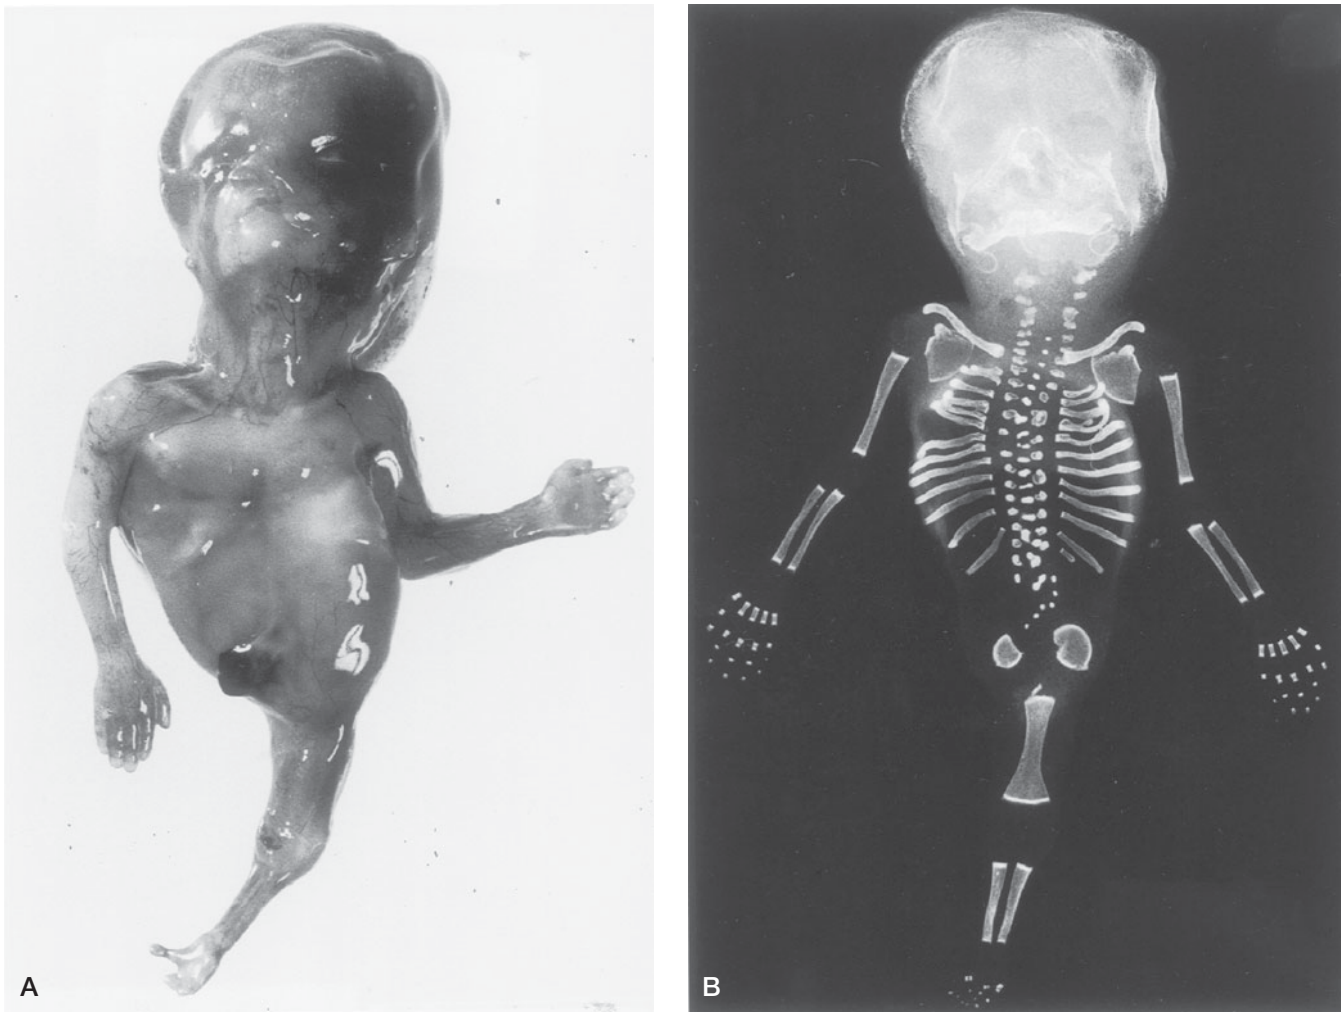

Figure 87-1 **A.** Fetus with symelia apus, demonstrating a single lower extremity and a single foot with four toes. **B.** Radiograph of a fetus with sirenomelia, demonstrating a single femur with broad metaphyses, paired tibiae, scoliosis, hemivertebrae, and minimal ossification of the lumbosacral spine. *(Reprinted, with permission, from Van Zalen-Sprock MM, Van Vugt JMG, Van Der Harten JJ, Van Geijn HP. Early second trimester diagnosis of sirenomelia.* Prenat Diagn. *1995;15:171-177.)*

partially fused and the fibulae are fused. In type V, the femurs are partially fused. In type VI, there is a single femur and a single tibia. In type VII, there is a single femur and an absent tibia.

In 1961, Duhamel coined the term *caudal regression syndrome* and first recognized an association between caudal regression and lower extremity abnormalities. He noted the presence of additional associated anomalies in sirenomelia, including sacral agenesis, anorectal atresia, renal agenesis, single umbilical artery, and ambiguous genitalia (Duhamel, 1961).

The cause of sirenomelia is still debated. Most agree that the site of injury to the embryo is the caudal mesoderm (Murphy et al., 1992). Sirenomelia probably results from a localized insult to the caudal end of the developing embryo between days 13 and 22 of development (Hoyme, 1988). By 23 days of embryonic age, the prospective limb bud regions normally assume a lateral position, separated by allantoic structures. If the lower extremity remains unipodal, the insult must have occurred prior to this point in gestation (Stevenson et al., 1986). Two theories have been developed to explain the occurrence of sirenomelia: vascular and caudal injury. In 1927, Kampmeier reviewed 52 cases of sirenomelia and was the first to note the constant finding of a single umbilical artery. He postulated that the single umbilical artery was very important in the etiology of the sirenomelia and that a vascular abnormality would affect the allantoic circulation with subsequent abnormal development of caudal elements. More recently, Talamo et al. (1982) performed postmortem arteriography on an infant with sirenomelia and documented a persistent vitelline artery and a dorsal hypoplastic distal aorta. They demonstrated that the femoral arteries ran anteriorly and posteriorly along the single femur, rather than in the normal orientation of right and left. They thought that this demonstrated a failure of rotation during early embryonic life and supported the pathogenetic concept of limb bud merging and malrotation after damage to the posterior axis mesoderm. Stevenson et al. (1986) dissected the abdominal vasculature in 11 cases of sirenomelia and documented the common feature of a single large artery arising from high in the abdominal cavity, which they thought diverted nutrients from the caudal end of the embryo in a vascular "steal" phenomenon. The steal vessel was a derivative from the vitelline artery complex, an early embryonic vascular network important in supplying nutrients to the yolk sac. They showed that the fetal arteries below the level of this steal vessel were underdeveloped; the tissues dependent on the normal vasculature for supply of nutrients subsequently failed to develop. This study demonstrated that in sirenomelia, the celiac and superior mesenteric arteries are usually present and normal in size. The inferior mesenteric artery may be missing. If present, it is very small and supplies the distal colon, which usually ends blindly in sirenomelia. In all the cases described by Stevenson et al. (1986), the major abdominal artery was a derivative of the vitelline artery complex; this was the primary artery carrying blood from the fetus to the placenta. Of note, the abdominal aorta distal to the origin of the vitelline artery gave off no tributaries. However, there were renal or inferior mesenteric arteries present proximal to the aortic bifurcation into the iliac arteries. These authors stated that the presence of the vitelline artery alone did not predispose to sirenomelia; rather, it was the stealing of nutrients normally intended for the caudal structures of the body that increased the risk for development of sirenomelia. While single umbilical artery is quite common and occurs in 1% of all livebirths (see Chapter 109), it was the unique point of origin of this single umbilical artery just distal to the celiac axis that predisposed to the caudal steal (Stevenson et al., 1986).

Any hypothesis regarding sirenomelia must also explain the association between this condition and monozygotic twinning (Young et al., 1986). Vascular abnormalities are common in monozygotic twin gestations; thus, development of a vascular steal sequence could be related to abnormalities in development of the placenta occurring in early monozygotic twinning. Alternatively, an abnormal division of the embryo could potentially result in a deficiency of caudal determinants in one of the embryos (Kapur et al., 1991).

INCIDENCE

The incidence of sirenomelia is 1 in 60,000 livebirths (deJonge et al., 1984). A male predominance exists, with a male-to-female ratio of 2.7:1. A strong association between sirenomelia and all caudal regression defects has been noted with maternal diabetes (Kucera, 1971; van Zalen-Sprock et al., 1995). As previously noted, there is a 100- to 150-fold increase in the incidence of sirenomelia in monozygotic twins as opposed to singletons (Smith et al., 1976; Wright and Christopher, 1982; Di Lorenzo et al., 1991; McCoy et al., 1994). In all cases of sirenomelia, 8% to 15% are associated with monozygotic twinning (Stocker and Heifetz, 1987). The association might be even more common than suspected, as at least one case of sirenomelia with a vanishing twin has been reported (Kapur et al., 1991). One case has been described in association with an in vitro fertilization triplet gestation and early intrauterine death of one of the triplets (Drossou-Agakidou et al., 2004). Sarpong and Headings (1992) reported two cases of sirenomelia associated with a history of cocaine exposure during the first trimester, as well as an 18-fold higher than normal incidence of sirenomelia in a cocaine-exposed population. A case of partial sirenomelia has been reported in which the mother took large amounts of vitamins A and E during the periconceptual period (Von Lennep et al., 1985).

SONOGRAPHIC FINDINGS

The diagnosis of sirenomelia may be easier to make in the first trimester as the amniotic fluid volume is relatively normal. The earliest reported diagnosis was made at 9 weeks of gestation in which an intra-abdominal cystic structure was observed (Schiesser et al., 2003). Subsequent scans at 11 and

Table 87-1

Characteristic Anomalies in Sirenomelia

Lower limb	Fusion, flexion, external rotation
Vertebral	Sacral agenesis
Anorectal	Imperforate anus, blind-ending colon
Urinary tract	Bilateral renal agenesis, ureteral, vesical, urethral agenesis
Genital	Absent or rudimentary external genitalia, gonads present
Craniofacial	Potter facies
Pulmonary	Hypoplastic lungs secondary to severe oligohydramnios

13 weeks demonstrated fusion of the lower limbs. In another report, two cases of sirenomelia diagnosed in the first trimester were associated with increased nuchal translucency measurement (Monteagudo et al., 2002).

Later in pregnancy, sonographic diagnosis of sirenomelia may be obscured by severe oligohydramnios. Oligohydramnios, intrauterine growth restriction, a large single umbilical artery, and bilateral renal agenesis are the second- and third trimester hallmarks of the diagnosis. Other findings characteristic of this condition are listed in Table 87-1 (Mok, 1990; Chenoweth et al., 1991). A more subtle finding may be the defective movement of the single lower limb with medially positioned fibulae. In symelia apus, the presence of a single femur may alert the sonographer to the correct diagnosis. When more than one femorae are present, the diagnosis is more challenging, particularly in the setting of little amniotic fluid. van Zalen-Sprock et al. (1995) described two cases at 14 and 16 weeks of gestation detected by transvaginal sonography (Figures 87-2 and 87-3). These cases were notable for the fact that despite the presence of bilateral renal agenesis, the amniotic fluid volume was only slightly decreased as compared with normal fetuses at the same gestational age. A larger series of 11 cases of sirenomelia diagnosed prenatally noted oligohydramnios as a universal finding. In only 5 of 11 cases (45%) was the correct diagnosis made prenatally. The remaining cases were diagnosed as bilateral renal agenesis. Significant additional anomalies noted included cardiovascular defects (36%), abdominal wall defects (36%), severe scoliosis (45%), and other skeletal deformities (90%) (Sirtori et al., 1989). Sonographic features that permit the correct antenatal diagnosis of sirenomelia include consideration of the diagnosis whenever bilateral renal agenesis is demonstrated, demonstration of persistently opposed lower extremities, and observation of a single hypoplastic foot with absent fibulae (Kapur et al., 1991).

Three-dimensional sonography has been used to further characterize the abnormalities in cases of sirenomelia (Monteagudo et al., 2002). The dynamic "live 3D" mode demonstrates the lack of normal fetal leg movement in this condition (Blaicher et al., 2001). Color flow and power Doppler studies may be of benefit in imaging the renal arteries when bilateral renal agenesis is suspected (Sepulveda et al., 1998) and to document abnormal vascular anatomy (Patel and Suchet, 2004). Magnetic resonance imaging has also been suggested as a helpful adjunct to characterize sirenomelia in the setting of oligohydramnios (Fitzmorris-Glass et al., 1989; Twickler et al., 1993).

Early second trimester diagnosis of sirenomelia.* Prenat Diagn. *1995;15:171-177.)*

DIFFERENTIAL DIAGNOSIS

Sirenomelia should be considered when the fetus has severe oligohydramnios. The differential diagnosis for sirenomelia includes isolated bilateral renal agenesis, which is 11 times more common than sirenomelia (Wright and Christopher, 1982), and caudal regression syndrome, which is generally associated with normal amniotic fluid volume.

ANTENATAL NATURAL HISTORY

Most patients with sirenomelia have bilateral renal agenesis. Consequently, oligohydramnios begins during the second trimester, when the kidneys would normally be producing fetal urine. Uterine size may be smaller than the gestational dates indicate. The consequences of severe oligohydramnios eventually manifest during the third trimester and include pulmonary hypoplasia and Potter facies. There is an increased risk of spontaneous pregnancy loss with this condition. Sirenomelia occurs in 4 in 1000 pregnancies that are spontaneously lost (Malinger et al., 1987).

MANAGEMENT OF PREGNANCY

When sirenomelia is suspected antenatally, consideration should be given to obtaining a fetal radiograph to look for the bony abnormalities seen in the lower merged extremity (Wright and Christopher, 1982) (see Figure 87-1B). If there is concern about inability to visualize the fetal bladder, amnioinfusion should be considered (Langer et al., 1996). Maternal furosemide administration is no longer recommended because of the high incidence of false-positive results. In the setting of severe oligohydramnios, chromosome studies from amniocytes may be very difficult to obtain and their indication is debatable. More than 300 cases of sirenomelia have been reported in the literature and the majority have had normal chromosome studies. Only two cases of chromosomal abnormalities have been reported, and in each case the abnormal chromosomes were obtained from specific organ tissue. In one case, chromosome studies were performed on pericardial tissue; they revealed mosaicism for a tandem duplication of the long arm of chromosome 1–46, XX/46, XX, dir dup (1) (q12 → qter) (Stevenson et al., 1986). In the other case, a fibroblast culture was obtained from the abnormal lower limb of an infant with sirenomelia. Metaphase spreads from this culture had a 6-fold increase in chromosomal breaks and a 23-fold increase in abnormal chromosome associations. There were multiple quadriradials observed that involved nonhomologous chromosomes. In contrast, fibroblasts obtained from a skin biopsy from the normal upper limb of the same patient had a normal karyotype (Sprague et al., 1970). Despite these intriguing findings, postnatal karyotyping in a confirmed case of sirenomelia is not indicated.

FETAL INTERVENTION

There are no fetal interventions indicated for sirenomelia.

TREATMENT OF THE NEWBORN

In the past, sirenomelia was considered uniformly fatal due to the known association with other major anomalies, including bilateral renal agenesis. Since 1989, however, there have been two reports of survivors with this condition. Lethality in this condition is due to the associated visceral anomalies that determine prognosis. If adequate renal function is present, survival outside the womb is possible. Savader et al. (1989) described the first survivor with this condition. This patient was noted to have fusion of the lower extremity to the level of the heels with a normal anus and kidneys, a normal heart, and single umbilical artery and transposition of the external genitalia and urethral opening. Postnatal magnetic resonance imaging confirmed the presence of distinct epiphyseal ossification centers and well-developed normal anatomic muscle groups that would permit future separation of the lower extremities. Subsequently, Murphy et al. (1992) described a patient who was diagnosed at 29 weeks of gestation and not expected to survive. Cesarean delivery was performed at term. The infant weighed 2.38 kg and had Apgar scores of 8 and 9. Her physical examination was notable for a fused lower extremity, an imperforate anus, colonic atresia, bilaterally fused pelvic kidneys, a preauricular skin tag, and posterior fusion of two ribs. She did not require aggressive support in the newborn intensive care unit. Because of her stable clinical status, a laparotomy was performed on the second day of life and revealed a malrotation with a blind-ending colon. A colostomy was performed and she was discharged to home. She was reported again at 3 months of age by Clarke et al. (1993), where she was described as neurologically normal. Her only medical problem has been prolapse of the colostomy. Tissue expanders were placed to facilitate a planned reconstruction of her lower limbs.

SURGICAL TREATMENT

The rare survivor with sirenomelia will need postnatal assessment of the genitourinary and gastrointestinal systems. Most patients will have imperforate anus, so a colostomy will be necessary. Postnatal renal imaging and functional studies will be necessary to determine the extent of renal function. Ultimately, there will be significant surgical issues related to appearance of the external genitalia and ambulation.

LONG-TERM OUTCOME

The long-term outcome is currently unknown, as there are only two examples of long-term survivors with sirenomelia that have been reported in the medical literature (Savader et al., 1989; Murphy et al., 1992; Clarke et al., 1993).

GENETICS AND RECURRENCE RISK

Sirenomelia is a developmental abnormality related to early embryogenesis. For most humans, it does not appear to be inherited as a single-gene defect (Gellis et al., 1973). In mice, however, a "sirenomelic syndrome" has been described that is inherited as an autosomal recessive gene (Orr et al., 1982). One family presented with a spectrum of four cases of renal anomalies, including a case of sirenomelia. The inheritance pattern in this family suggests that there is an autosomal dominant gene mutation present that affects renal development (Selig et al., 1993). Sirenomelia is associated with the monozygotic twinning process. Families at risk for increased incidence of monozygotic twins may also have an increased risk of sirenomelia. In general, chromosomal abnormalities have not been described in the etiology of this condition.

Hemivertebrae

88
CHAPTER

Key Points

- Hemivertebrae are a major cause of congenital scoliosis and kyphoscoliosis.
- Incidence is 0.3 to 1 per 1000 livebirths. More common in females.
- Vertebral anomalies develop during first 6 weeks of gestation.
- Hemivertebrae act as a wedge within the vertebral column, causing curvature away from side of defect.
- Prognosis for isolated hemivertebra(e) is good.
- Can be associated with neural tube defects, occult intraspinal defects, renal anomalies, tracheoesophageal atresia/fistula.
- Associated syndromes in the differential diagnosis include: Goldenhar, Jarcho–Levin, Poland, Robinow, chondrodysplasia punctat, Alagille, and Pallister–Hall.

CONDITION

Hemivertebrae are vertebral anomalies that can be detected sonographically by the second trimester of pregnancy. These anomalies develop during the first 6 weeks of gestation, when the future anatomical pattern of the spine is formed in mesenchyme. Once the mesenchymal pattern is established in the embryo, subsequent cartilaginous and osseous stages follow (McMaster and Ohtsuka, 1982). At approximately 6 weeks of gestation, a chondrification center appears for each mesenchymal vertebra. Each vertebral body has a dorsal and ventral primary ossification center. These centers fuse, resulting in three primary centers of ossification, which can be visualized sonographically as early as 12 weeks of gestation, but histologically as early as 8 weeks of gestation (Zelop et al., 1993). Abnormalities of the vertebral bodies result from either failure of formation or failure of segmentation (Abrams and Filly, 1985). Abnormalities in vertebral segmentation result in bar or block vertebrae, whereas abnormalities in formation result in hemivertebrae (McMaster and Ohtsuka, 1982). Nasca et al. (1975) classified hemivertebrae by their morphologic appearance and described six different types: single supernumerary hemivertebrae, single wedge-shaped hemivertebrae, multiple hemivertebrae, multiple hemivertebrae with a unilateral bar defect on the contralateral side, balanced hemivertebrae, and posterior hemivertebrae. This latter defect occurs when the anterior part of the vertebral body fails to develop. Clinically this results in a kyphosis rather than a scoliosis. The medical significance of hemivertebrae is that they act as a wedge within the vertebral column, causing a curvature away from the side of the defect (Zelop et al., 1993). The abnormal vertebral body elongates the convex side of the spine. When growth occurs on the affected side, it causes compression of the superior and inferior vertebral end plates, resulting in decreased growth on the concave side (Nasca et al., 1975).

Hemivertebrae are a major cause of congenital scoliosis and kyphoscoliosis. Prenatal detection of this abnormality

has become possible only within the past few years, so relatively little is known about the clinical significance of isolated asymptomatic vertebral defects.

INCIDENCE

In a study of more than 15,000 chest radiographs, the incidence of congenital scoliosis due to vertebral anomalies was 0.5 in 1000 livebirths (Wynne-Davies, 1975). This estimate of vertebral anomalies is low, as only thoracic abnormalities were included in this study. The probable incidence of hemivertebrae is more on the order of 1 in 1000 livebirths (Wynne-Davies, 1975). All vertebral defects are more common in females. The male to female ratio for patients with multiple vertebral anomalies is 0.31 and 0.68 for patients with single vertebral anomalies (Wynne-Davies, 1975). In a retrospective study over a 17-year period (1985–2001) performed in Israel, 26 cases of hemivertebra(e) were identified among 78,500 liveborn infants (Goldstein et al., 2005). Seventeen cases had a single hemivertebra and 9 had multiple vertebral defects.

SONOGRAPHIC FINDINGS

Examination of the fetal spine should include views in three planes: sagittal, coronal, and transverse (de Elejalde and de Elejalde, 1985). Figures 88-1 and 88-2 demonstrate transverse and sagittal views. The sonographic criterion for hemivertebrae is a disruption in the alignment of one or more vertebral body ossification centers on a coronal section of the fetal spine obtained at 15 weeks of gestation or later. Benacerraf et al. (1986) initially described three cases of hemivertebrae identified sonographically between 17 and 28 weeks of gestation. In a study of 27 fetuses with sonographically detected vertebral anomalies, Zelop et al. (1993) described irregularities along the parallel line formed by vertebral body ossification centers and/or the two posterior neural arch ossification centers on either side (Figure 88-2). In another study, Harrison et al. (1992) described 20 cases of fetal scoliosis. In their study, all fetal spines were examined in the transverse and longitudinal planes for normal vertebral body configuration and curvature. Abnormal spinal curvature was defined as any focal, fixed kyphosis or a fixed curvature of the spine that persisted despite fetal movement. In this latter study, only one case of isolated hemivertebrae accounted for the fetal spinal curvatures. The remaining patients had various associated anomalies. Neural tube defects were the most common, described in 12 of the 20 fetuses studied. This study noted a poor outcome for the fetuses with scoliosis. Only 3 of the 20 infants survived and of these 2 had myelomeningoceles. Twelve of the remaining fetuses were electively terminated, 3 were stillborn, and 2 died on the first day of life.

Zelop et al.'s (1993) study is more relevant to the issue of diagnosis and management of the fetus with hemivertebrae. She and her colleagues described 27 fetuses with abnormalities in the spinal ossification centers visualized during the second and third trimesters. Of the 27 patients studied, 11 (41%) had hemivertebrae as the only anomaly documented. The hemivertebrae were distributed all along the spinal column: four were present in the thoracic region, two were present in the thoracolumbar region, and five were lumbar. All of the patients with isolated hemivertebrae had normal karyotypes. Nine of these 11 fetuses were born alive; 1 was electively terminated and 1 died at 32 weeks of gestation after premature

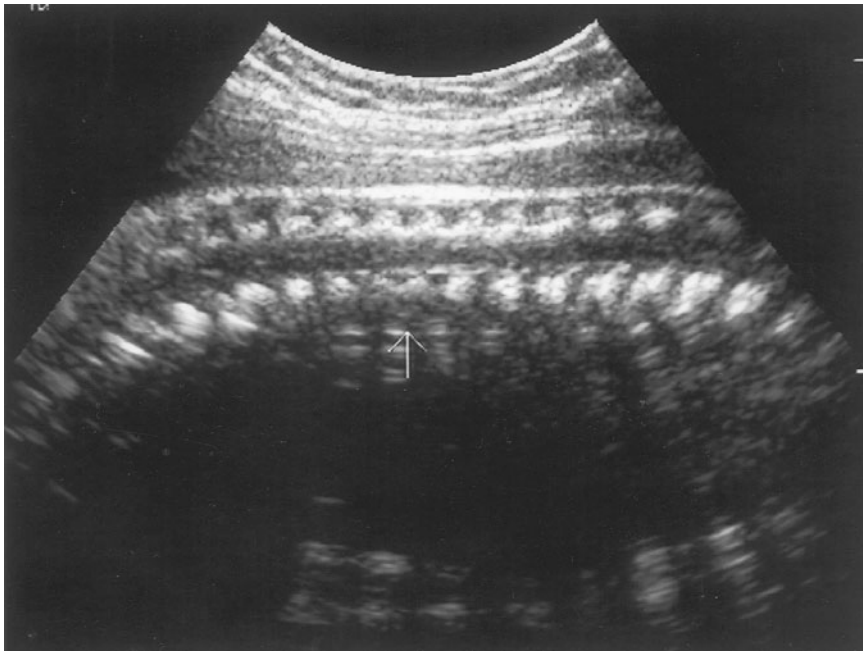

Figure 88-2 Sonographic scan in sagittal plane. The arrow indicates an irregularity in the anterior aspect of the vertebral body.

rupture of the membranes with sepsis. Of the nine liveborn infants, two required spinal surgery during infancy. The others remained well. In the other 16 cases that comprised this report, multiple additional defects were noted. The following abnormalities were noted: renal in 11 cases, gastrointestinal in 6 cases, cardiac in 4 cases, facial in 4 cases, extremity in 2 cases, cranial in 2 cases, and chest in 1 case. Seven of the fetuses had renal dysgenesis and severe oligohydramnios, consistent with Potter sequence. Four of the patients had polyhydramnios. Of the fetal patients with additional anomalies, seven had a chromosome analysis performed and all had normal karyotypes. Of the 16 patients with additional anomalies, 5 of the 16 survived postnatally, an additional 5 died during the newborn period, and 6 were terminated electively. The study concluded that the prognosis for a fetus with isolated hemivertebrae was good. Of note, however, more than half of the patients with hemivertebrae had significant additional anomalies that affected the prognosis.

DIFFERENTIAL DIAGNOSIS

The main consideration in the differential diagnosis of hemivertebrae is to determine whether the anomaly is isolated or part of a syndrome or association. The anatomic location of the hemivertebrae will also affect the differential diagnosis. For example, hemivertebrae in the cervical region are more likely to be part of the Klippel–Feil syndrome or be one manifestation of oculoauriculovertebral dysplasia (Goldenhar syndrome) (Anderson and David, 2005). Hemivertebrae that are present in the sacral region may suggest caudal regression syndrome. Vertebral abnormalities are also significantly associated with neural tube defects. Therefore, demonstration of hemivertebrae or other spinal abnormalities mandates exclusion of myelomeningocele (see Chapter 19). Approximately 2% of cases of esophageal atresia with tracheoesophageal fistula have associated vertebral anomalies (see Chapter 40) (Stevenson, 1972). Thus, a diagnosis of vertebral anomalies, particularly in the thoracic region, requires demonstration of a normal stomach bubble. Vertebral anomalies and tracheoesophageal anomalies are commonly seen as part of the VACTERL association.

Hemivertebrae are a prominent abnormality in the Jarcho–Levin and Robinow syndromes. Jarcho–Levin syndrome (see Chapter 96) is a single-gene disorder that presents with multiple vertebral anomalies at all levels of the spine and rib malformations (Jarcho and Levin, 1938; del Rio Holgado et al., 2005). Robinow syndrome is a recessively inherited disorder that includes mesomelic brachymelia, hemivertebrae, micropenis, a flat facial profile, and midline cleft lip (Vera-Roman, 1973; Wadlington et al., 1973).

There are also individual case reports of families that have constellations of abnormalities, including hemivertebrae, aphalangy, and urogenital and intestinal dysgeneses (Johnson and Munson, 1990). Other disorders in which hemivertebrae infrequently are part of the phenotypic spectrum include: oculoauriculovertebral dysplasia (see Chapter 24); chondrodysplasia punctata, Conradi–Hünermann type (see Chapter 99); Alagille syndrome (arteriohepatic dysplasia), which includes neonatal jaundice, peripheral pulmonic stenosis, and an unusual face; Noonan syndrome; Marfan syndrome; and Pallister–Hall syndrome, a disorder that includes hypothalamic hamartoblastoma, hypopituitarism, imperforate anus, and postaxial polydactyly. Vertebral anomalies are also associated with bladder and cloacal exstrophy (Loder and Dayioglu, 1990). More recently, a fetus with Poland syndrome (unilateral chest wall hypoplasia, ipsilateral hand abnormalities, and hemivertebrae) has been described in the literature (Paladini et al., 2004).

ANTENATAL NATURAL HISTORY

The antenatal natural history for fetuses with hemivertebrae is based primarily on the studies of Zelop et al. (1993) and Harrison et al. (1992). In both of these reports, comprising a total of 47 fetuses, there was no evidence for increased in utero mortality. However, 18 of the fetuses were electively terminated. Harrison's group of patients had severe scoliosis and were presumably more severely affected than the cases described by Zelop. Both studies noted a strong association with extraspinal anomalies, which affect the overall prognosis for the fetus. In Harrison et al.'s study, neural tube defects were the most common finding, whereas in Zelop et al.'s study 41% of fetuses had renal anomalies. The strong association with the renal malformations has been documented in a postnatal study of 231 children with congenital scoliosis (Macewen et al., 1972). Of this group, 42 of the 231 (18%) had an asymptomatic urologic abnormality. The most common finding was unilateral renal agenesis, which was documented in 6.5% of the total cases. This is significantly increased as compared with the 0.2% incidence of unilateral renal agenesis observed in pediatric autopsies. The second most common abnormality demonstrated was a duplication of the kidney or ureter, seen in 4% of total cases. This is also increased as compared with the general pediatric autopsy population, in which a duplication of the kidney or the ureter was seen in 0.7% of cases. Obstructive uropathy, unsuspected clinically, was demonstrated in 6 of 42 cases of congenital scoliosis. In addition, renal ectopia was seen in another six cases. Postnatal studies have also documented a very high association of occult intraspinal anomalies with vertebral defects (McMaster, 1984).

MANAGEMENT OF PREGNANCY

When a fetal hemivertebra has been diagnosed, a detailed anatomic scan should be performed to rule out associated abnormalities. Special attention should be paid to the presence of either oligohydramnios or polyhydramnios. If the vertebral defect is isolated, there is no evidence that there is an increased risk for an abnormal fetal karyotype. All of the patients in Zelop et al.'s study had normal chromosomes. If a vertebral anomaly is seen in association with another anatomic abnormality, we recommend offering an amniocentesis to document the fetal chromosome constitution.

Hypoplastic vertebrae, hemivertebrae, and vertebral coronal clefts have been noted in patients with microdeletions of chromosome 22q11 (see Chapter 139) (Ming et al., 1997). Thus, if congenital heart malformations and/or renal anomalies are noted, fluorescence in situ hybridization studies using a probe for 22q11.2 should be considered.

In the setting of an isolated fetal vertebral defect, there is no indication for delivery in a tertiary care center or for cesarean delivery. Recommendations for delivery of fetuses with hemivertebrae and associated anomalies should be guided by the nature and severity of the anomalies. Antenatal consultation with a pediatric orthopedic surgeon may be warranted to reassure the parents.

FETAL INTERVENTION

There are no fetal interventions for hemivertebrae.

TREATMENT OF THE NEWBORN

When a fetal vertebral defect has been identified antenatally, a detailed and thorough physical examination of the newborn is indicated to specifically rule out congenital scoliosis. Postnatal radiography is indicated to confirm the prenatal sonographic finding and to more specifically delineate the vertebral defect. If scoliosis is absent at birth, the infant can be observed and followed conservatively by a pediatric orthopedic surgeon. If scoliosis is present, approximately one-fourth of cases will progress rapidly, half will progress slowly, and one-fourth will not progress at all (Zelop et al., 1993). Infants with scoliosis need close follow-up by a pediatric orthopedic surgeon. If adequate views of the fetal renal anatomy were not obtained antenatally, consideration should be given to documentation of renal anatomy during the newborn period either by ultrasonography or by intravenous pyelogram. As previously noted, infants with vertebral anomalies have a high incidence of associated renal abnormalities (18% of cases) (Macewen et al., 1972). In addition, in one large study of 251 patients with congenital scoliosis, 18% had occult intraspinal abnormalities. The most frequent abnormality was diastematomyelia, which is a partial or complete sagittal split in a localized segment of either the spinal cord or cauda equina (McMaster, 1984). The problem with diastematomyelia is that an osseous or fibrocartilaginous spur projects backward into the midline from the posterior aspect of one or more adjacent vertebral bodies. This spur invaginates the dura and causes neurologic abnormalities. It is very important to identify diastematomyelia because sensory deficits, bowel or bladder incontinence, muscle weakness, or shortening of one lower extremity can result if the condition is left untreated. In McMaster's study, other occult intraspinal abnormalities were noted, including neurenteric cysts, epidermoid or dermoid cysts, teratoma, lipofibroma, absence of nerve roots, fibrous bands, or a tight filum terminale (McMaster, 1984). Occult neurologic defects are frequently missed because the skin overlying the dura usually appears normal, although some cases of hairy patches have been documented. Thus, newborns with congenital scoliosis due to hemivertebrae should undergo postnatal studies of their spinal cords by magnetic resonance imaging (MRI).

SURGICAL TREATMENT

As indicated above, most newborns are treated nonoperatively. The infant is generally followed with clinical examination and radiography for the development or progression of scoliosis. The indications for surgery include rigid decompensation of the spine, progression of the scoliotic curve, pain, desire for improvement of appearance, or development of dyspnea on exertion due to a restrictive pulmonary disease. Surgery is generally not performed during the newborn period, but the optimal age for surgical treatment has not yet been determined (Holte et al., 1995). In Zelop et al.'s (1993) report, of the nine patients with isolated hemivertebrae, only two required surgery during the first few years of life. Holte et al. (1995) described their experience with 37 patients treated with anterior and posterior wedge resection of hemivertebrae. All of their patients required a cast or brace for a period of 4 to 6 months, and most had to remain on bed rest for a period of more than 2 months. The average age at the time of these spinal operations was 12 years. Postoperatively, the curve containing the hemivertebrae was reduced from 55 to 33 degrees in all the patients. In approximately half of the patients, a measurable improvement in balance was achieved and maintained. This type of treatment is recommended only for patients with the most severe types of scoliosis. More recently, Deviren et al. (2001) described 10 consecutive patients (mean age, 13 years) who underwent excision of thoracic or thoracolumbar hemivertebrae. The mean preoperative coronal curve was 78.2 degrees. This was corrected to 33.9 degrees. There were no major complications and no neurological damage.

LONG-TERM OUTCOME

For fetuses and infants identified with isolated hemivertebrae, the long-term outcome is expected to be good. For patients identified with associated anomalies, the long-term outcome will be related to the underlying cause for the multiple malformations.

GENETICS AND RECURRENCE RISK

As noted in the "Differential Diagnosis" section, many syndromes exist that include hemivertebrae as one component. Recurrence risk would depend upon the particular syndromic diagnosis. In addition, a three-generation pedigree has been described with isolated hemivertebrae, inherited as an autosomal dominant trait (Ishida and Taute, 1973). There is, however, likely an environmental component to the development of hemivertebrae, as many sets of monozygotic twins have been described that are discordant for hemivertebrae (Peterson and Peterson, 1967; Wynne-Davies, 1975). The recurrence risk for isolated vertebral anomalies is on the order of 2% to 3% (Wynne-Davies, 1975). Significantly, an additional increased risk (on the order of 4%) for neural tube defects has been identified for siblings of children with isolated hemivertebrae (Connor et al., 1987). Thus, in subsequent pregnancies, women whose previous children have had hemivertebrae should have detailed scanning for sonographic abnormalities consistent with neural tube defects.

PAX1 is under investigation as a candidate gene for vertebral malformations (Giampetro et al., 2005).

CHAPTER

Achondroplasia

Key Points

- Most common form of short-limbed dwarfism.
- Incidence is 1 in 26,000 livebirths.
- Most consistent sonographic finding is shortening of long bones between 21 and 27 weeks. Additional findings include macrocrania, frontal bossing, trident-shaped hand.
- Differential diagnosis includes diastrophic dysplasia, achondrogenesis, Ellis–van Creveld syndrome, hypochondroplasia.
- Condition is due to mutations in fibroblast growth factor receptor 3 (*FGFR3*) gene, which is a negative regulator of chondrocyte proliferation. Mutations activate the receptor and cause gain of function.
- Pregnant women affected by achondroplasia need baseline pulmonary function tests and cesarean section delivery.
- Prenatal diagnosis can be performed by sonography or by DNA analysis.
- Major pediatric complications include short stature, foramen magnum compression, hydrocephalus, spinal stenosis, restrictive pulmonary disease, hypotonia, and recurrent ear infections. IQ is normal.
- Inherited as an autosomal dominant condition, but 80% of cases are new mutations that always derive from the father and are associated with advanced paternal age.

CONDITION

Achondroplasia is the most common form of short-limbed dwarfism. The condition has been recognized since ancient times. Dwarfs were accepted socially in ancient Egypt, and their daily activities, recorded through art, suggest not only assimilation into daily life, but also in some cases, a high-ranking position in society (Kozma, 2006). The term achondroplasia, meaning total absence of cartilage, was first used by Parrot in 1878 (Scott, 1976). Although this is not correct in a pathologic sense, the designation is commonly accepted.

INCIDENCE

The incidence of achondroplasia is 1 in 26,000 livebirths (Oberklaid et al., 1979). Earlier studies that indicated an incidence of as high as 1 in 10,000 births probably included other causes of short-limbed dwarfism. More than 80% of cases are due to new mutations (Shiang et al., 1994). Advanced paternal age was initially thought to be correlated with an increased incidence of new mutations resulting in achondroplasia (Murdoch et al., 1970). However, more recent observations have led to the alternative theory that sperms bearing the fibroblast growth factor receptor 3 (*FGFR3*) mutation that

causes achondroplasia have a selective advantage over sperms without this mutation (Horton et al., 2007).

SONOGRAPHIC FINDINGS

Virtually all of the bones in the body are affected by achondroplasia. Postnatal radiographic studies of the lumbar spine, pelvis, and cranial regions permit definitive diagnosis (Figure 89-1). Antenatally, diagnosis is complicated by a relatively normal appearance until the early second trimester. The most consistent sonographic finding is shortening of the long bones, particularly the femur, occurring between 21 and 27 weeks of gestation (Figure 89-2) (Kurtz et al., 1986). The overall shape of the femurs is within normal limits. Initially, a normal relationship of biparietal diameter to femur is present, but these measurements become progressively asynchronous over time (Filly et al., 1981). Additional findings that have been described during the second trimester include large head (macrocrania), abnormal facial profile due to frontal bossing (Figure 89-3), protuberant abdomen, and trident-shaped hand (Figure 89-4) (Cordone et al., 1993).

Reprinted, with permission, of John Wiley & Sons, Ltd.*)

For prenatal diagnosis in the setting of one parent affected with achondroplasia, the fetus is considered to be affected if the length of the long bones is less than the third percentile or if polyhydramnios is present (Lattanzi and Harger, 1982; Elejalde et al., 1983). If both parents are affected by achondroplasia, the fetus is at 25% risk of inheriting both mutant alleles. In a retrospective review of 15 fetuses at 25% risk of homozygous achondroplasia, Patel and Filly (1995) demonstrated that fetal femoral length dropped below the third percentile at a mean of 15.6 weeks and 21.5 weeks in fetuses with homozygous and heterozygous achondroplasia, respectively.

If both parents are unaffected, prenatal diagnosis is more challenging. A fetus in which long bone growth is initially normal but then drops below the 10th percentile during the third trimester needs to be serially evaluated for the possibility of achondroplasia or hypochondroplasia. Hypochondroplasia is considered to be an allele of achondroplasia, with less severe clinical manifestations.

Krakow et al. (2003) compared 2D and 3D imaging in the diagnosis of skeletal anomalies. In a case of achondroplasia, 3D imaging captured the trident hands and more clearly delineated the disproportionate aspects of the limbs. For example, the left arm raised to the fetal forehead demonstrated that the level of the elbow was at the chin instead of the nose due to foreshortening of the proximal part of the arm (rhizomelia).

In one case report, an increased nuchal translucency measurement was noted in a fetus that was subsequently confirmed by molecular diagnosis to have achondroplasia. Rhizomelia, narrow thorax, and macrocrania were not observed until 18 weeks (Tonni et al., 2005).

DIFFERENTIAL DIAGNOSIS

The most likely diagnosis for a fetus with shortened long bones is that the fetus is normal or has intrauterine growth restriction that is not due to a skeletal dysplasia. However, the differential diagnosis includes chromosomal abnormalities as well as other types of dwarfism, some of which may be lethal at birth. An important prenatal finding that distinguishes heterozygous achondroplasia from some of the other skeletal dysplasias is the initially normal first and second trimester long bone measurements.

Other considerations in the differential diagnosis include diastrophic dysplasia, a recessively inherited form of short-limbed dwarfism, with the additional findings of thickening of the external ear and the characteristic "hitch-hiker" thumbs (see Chapter 93). In achondrogenesis, a lethal, recessively inherited condition, there is deficient ossification of the vertebral bodies. As compared with achondroplasia, a greater discrepancy between head size and trunk exists in achondrogenesis (see Chapter 97). In chondroectodermal dysplasia (Ellis–van Creveld syndrome), progressive distal shortening of the extremities and postaxial polydactyly are present (see Chapter 94). In addition, congenital heart malformations are present in 50% of cases. In hypochondroplasia, the major findings are short stature and an increased upper-to-lower body segment ratio. The facial features are within normal limits.

ANTENATAL NATURAL HISTORY

Achondroplasia is due to mutations in the fibroblast growth factor receptor 3 (*FGFR3*) gene. *FGFR3* is a negative regulator of chondrocyte proliferation and differentiation in the growth plate. Mutations in the gene therefore activate the receptor and cause a gain of function (Horton, 2006). They predominantly affect bones that develop by endochondral ossification (Kurtz et al., 1986; Horton, 2006). Membranous bone formation occurs at a normal rate (Murdoch et al., 1970). The abnormality in achondroplasia is confined to cartilage, and consists of a failure of interstitial cells to proliferate. Bones that are initially formed from cartilage, such as the long bones of the extremities, bones at the base of the skull, and vertebral bodies are affected by this condition.

In histologic studies of bone and cartilage from patients with achondroplasia, morphology is normal (Rimoin et al., 1976). The arrangement of rows and columns of cells is regular and well organized. The rate of endochondral ossification is reduced and this contrasts with the normal periosteal ossification. This disparity results in periosteal bone extending beyond the growth plate and gives the appearance of short squat bones with cupped ends. Ultrastructural studies are also generally normal. The only abnormalities demonstrated have been a relative increase in the number of dead cells surrounded by microscars that contain focal aggregations of collagen fibrils (Rimoin et al., 1976).

Figure 89-5 Postnatal photograph of an infant with homozygous achondroplasia, demonstrating the narrow chest and short, malformed bones. Homozygous achondroplasia is nearly uniformly fatal.

MANAGEMENT OF PREGNANCY

For an unaffected pregnant woman, the antenatal course for this condition is usually benign. When achondroplasia is suspected, serial sonography may be useful to determine if macrocrania is developing, which may necessitate cesarean delivery.

For the pregnant woman affected with achondroplasia, special problems include increased incidence of fetal loss, preeclampsia, and respiratory compromise in the third trimester (Trotter et al., 2005). Baseline pulmonary function studies should be performed. Cesarean delivery is mandatory for cephalopelvic disproportion secondary to marked pelvic contracture (Lattanzi and Harger, 1982; Allanson and Hall, 1986).

The identification of the gene responsible for achondroplasia, *FGFR3* (Shiang et al., 1994), allows DNA-based prenatal diagnosis. This is especially important for couples in which both partners are affected. In this situation, there is a 25% chance that the fetus will inherit the two mutant genes, resulting in homozygous achondroplasia that is associated with a very high incidence of fetal and neonatal death (Figure 89-5). In one report, first trimester DNA diagnosis has been described in a couple at risk for homozygous achondroplasia (Bellus et al., 1994).

In recent years, fetal chromosome analysis has been increasingly performed for short fetal bones due to the concerns of possible trisomy 21 (see Chapter 131). In the setting of a fetus with short bones and a normal karyotype, amniotic fluid cells may be used as a source of fetal DNA to test for *FGFR3* mutations. If an *FGFR3* mutation is found, this is diagnostic.

FETAL INTERVENTION

There is no fetal intervention for achondroplasia.

TREATMENT OF THE NEWBORN

Most newborn infants with achondroplasia do not require special medical treatment and can be cared for in the regular nursery. In fact, many cases of achondroplasia are missed at birth. According to one study, even at 1 year of age, only 60% of cases are diagnosed (Saleh and Burton, 1991). Due to increased use of prenatal sonography in more recent studies it is estimated that approximately 20% of cases are missed at birth (Horton, 2006). For infants with achondroplasia, the main issues are definitive diagnosis and coordination of subspecialty care. All infants with a suspected diagnosis of achondroplasia should have radiographs taken of their long bones.

The salient clinical findings of achondroplasia in the newborn include short stature of the rhizomelic type. This means that the proximal arms and legs are relatively more shortened than the distal segments of the extremities. However, the short stature may be mild or even absent. Horton et al. (1978) showed that the range of birth length in newborns with achondroplasia overlaps the normal population. Mean growth velocity is also normal during the first year of life. It is after the first year that growth velocity drops significantly. Other features of achondroplasia during the newborn period may include macrocrania, frontal bossing, and midface hypoplasia with coarsened facial features. The lumbar lordosis that is apparent later in life is rarely appreciated at birth. Cognitive development, socialization, speech, and language milestones are achieved normally, but initial gross motor milestones may be delayed (Scott, 1976). The muscular hypotonia responsible for delayed motor development disappears spontaneously at 4 to 6 years of age. The general pediatric recommendations for health supervision for children with achondroplasia have been summarized and updated (Trotter et al., 2005).

A serious potential problem in achondroplasia is cervicomedullary junction compression due to a small foramen

magnum. The foramen magnum is narrowed in a transverse direction (Hecht et al., 1989). This can result in occipitocervical pain, ataxia, incontinence, or the more serious complication of apnea and sudden infant death (Pauli et al., 1984). Magnetic resonance imaging (MRI) studies in five affected patients have demonstrated the discrepancy between the size of the brainstem and the foramen magnum (Thomas et al., 1988). In addition, hydrocephalus is frequently found due to anatomic abnormalities in the occipital bone that produce intracranial venous hypertension. It has been hypothesized that obstruction at the jugular foramen elevates intracranial venous pressure, resulting in decreased absorption of cerebrospinal fluid into the sagittal sinus, producing a communicating hydrocephalus (Thomas et al., 1988). Approximately 5% of affected children require placement of a shunt (Haga, 2004).

Approximately 10% of patients with achondroplasia have respiratory complications due to foramen magnum compression (Stokes et al., 1983; Thomas et al., 1988). It is recommended that computed tomographic (CT) or MRI be performed in conjunction with somatosensory evoked potentials to screen for this problem (Reid et al., 1987). Although posterior fossa decompression and atlantal laminectomy represent major surgical intervention, symptoms have been reported to improve postoperatively (Ryken and Menezes, 1994). The increased mortality seen in achondroplasia (Hecht et al., 1987) is due to this brainstem compression and it primarily affects children younger than 4 years old.

SURGICAL TREATMENT

Cervicomedullary compressive surgery is indicated for individuals with symptoms of foramen magnum compression (Ho et al., 2004). This surgery can treat central apnea that may result in death, and/or relieve neurologic complications secondary to spinal cord damage. In one study, the quality of life and morbidity of individuals with achondroplasia who underwent cervicomedullary decompression surgery was indistinguishable from age and gender matched controls (Ho et al., 2004).

The orthopedic deformities in achondroplasia consist of bowing of the legs, hyperlordosis, and spinal stenosis. In approximately 25% of cases, the bowing of the legs is treated with corrective osteotomies of the tibia. This surgery is usually performed between 3 and 10 years of age. Although spinal stenosis is universal, only in relatively few cases does it cause cauda equina syndrome, which manifests as a lower motor neuron flaccid paralysis. This becomes evident during very late adolescence or adulthood and requires a decompressive laminectomy. The most severe but least common orthopedic problem is thoracolumbar kyphosis, which can cause paraplegia earlier in childhood. This requires aggressive spinal surgery.

Surgical therapies currently being optimized may also significantly improve the cosmetic aspects of achondroplasia. Craniofacial surgery is possible to advance midfacial bones and correct severe dental malocclusion (Denny et al., 1992).

Leg lengthening has received much attention as a means of improving height and appearance for patients with achondroplasia (Figure 89-6). This has been utilized more commonly outside of North America. The surgery is painful; it should be performed on only adolescents; and it may take up to 2 years to complete (Saleh and Burton, 1991). Aldegheri and Dall'Oca (2001) reviewed their experience in performing limb lengthening on 80 achondroplastic individuals. Ten of these individuals also underwent humeral lengthening to improve ability to independently attend to matters of personal

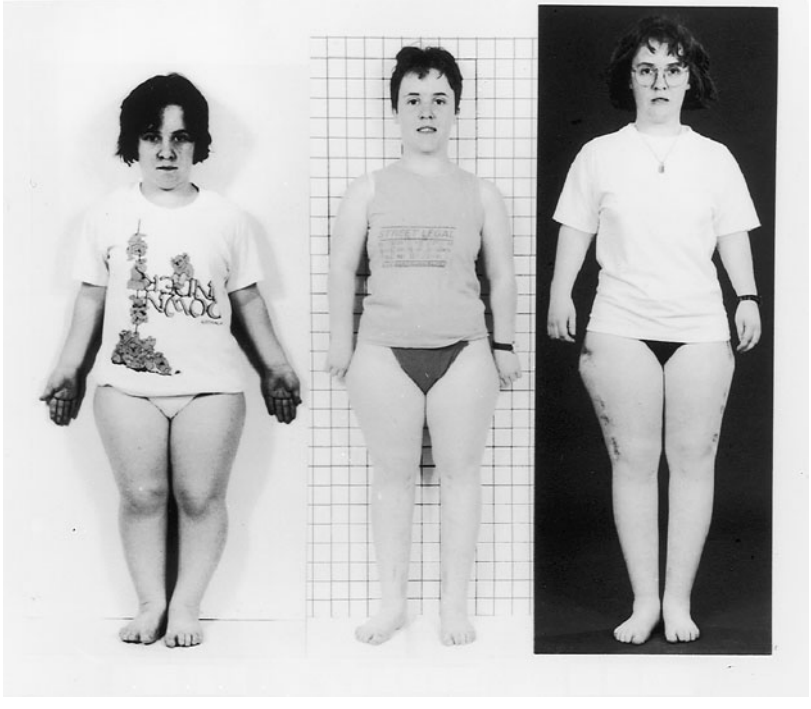

Figure 89-6 Patient with achondroplasia demonstrating cosmetic effects of multiple leg-lengthening operations over an almost 4-year period. (*Courtesy of Professor Michael Saleh, Sheffield Children's Hospital, Sheffield, United Kingdom.*)

hygiene. Patients gained an average of 20.5 cm in height but 39% of them had complications. The treatment time required was approximately 33 months. Limb lengthening surgery is invasive, complex, and potentially dangerous.

LONG-TERM OUTCOME

The long-term consequences of achondroplasia are cervicomedullary compression, hydrocephalus, spinal stenosis, restrictive and obstructive lung disease, otitis media, and thoracolumbar kyphosis (Hunter et al., 1998; Trotter et al., 2005). Mental development is generally normal.

Standard growth curves exist to assess normal growth for children with achondroplasia (Horton et al., 1978). The average adult height for an affected male is 52 inches (129 cm) and an affected female 48.6 inches (122 cm). The average adult weight for a male is 120 lb (55kg) and a female 100 lb (45kg) (Murdoch et al., 1970; Scott, 1976). Obesity is common (Hecht et al., 1988). In sporadic cases, parental height does not significantly influence the adult height of affected offspring (Murdoch et al., 1970; Scott, 1976).

In an initial clinical trial, recombinant human growth hormone given to patients with achondroplasia at doses of 0.3 mg per kilogram of body weight per week moderately increased overall height velocity, particularly in the short term. There were no untoward effects, particularly with regard to worsening of the degree of spinal stenosis (Horton et al., 1992). Further clinical trials have not shown a clear long-term benefit. Currently, most experts do not recommend growth hormone for achondroplasia (Horton et al., 2007).

Further medical problems for children with achondroplasia include recurrent ear infections (in 90% of children) and conductive and sensorineural hearing loss. Patients with achondroplasia have specific structural changes of the temporal bone, although it is unclear how these changes relate to hearing loss (Shohat et al., 1993). Approximately half of the affected children undergo placement of ventilation tubes in the tympanic membrane (Haga, 2004). For many patients, dental crowding necessitates orthodontic treatment.

Intelligence quotient (IQ) is normal for individuals with achondroplasia. One study compared 20 adults affected with achondroplasia with siblings of the same sex and found that the mean number of years of formal education was comparable for each group. Females, more than males, have a significantly lower occupational level as compared with their same-sex siblings (Roizen et al., 1990). It was questioned whether this was due to a self-esteem problem that was more profound in females. The psychiatric aspects of achondroplasia have also been studied. In general, patients with achondroplasia had achieved satisfactory life adjustment and had secure identities as "little people" (Brust et al., 1976). The functional health status of adults with achondroplasia is not drastically reduced in comparison with the general United States population (Mahomed et al., 1998).

Looking toward the future, novel therapies will be directed toward countering the effects of the overactive *FGFR3* (Horton, 2006, Horton et al., 2007). Chemical inhibitors that downregulate the tyrosine kinase activity of *FGFR3* might be used in a manner analogous to the treatment of chronic lymphocytic leukemia with inhibitors to *Bcr-abl* tyrosine kinase. Alternatively, antibodies could be used to interfere with the binding of FGF ligands to *FGFR3*. The molecular mechanism responsible for achondroplasia is the same as in many cancers. Also, C-type natriuretic peptide (CNP) downregulates FGF-induced activation of MAP kinase signaling pathways in growth plate chondrocytes. It has been suggested as a treatment for achondroplasia because of therapeutic effects observed in mouse models (Horton, 2006).

GENETICS AND RECURRENCE RISK

Achondroplasia is inherited as an autosomal dominant condition. Fifty percent of an affected parent's offspring will also have achondroplasia. The phenotype is 100% penetrant, which means that all offspring who carry the gene will express the full clinical appearance of achondroplasia. If both parents are affected, there is a 50% chance of having a child with heterozygous achondroplasia, a 25% chance of having a child with homozygous achondroplasia, and a 25% chance of having a child with normal stature.

As stated earlier, the majority of cases (80%) are due to new mutations. Murdoch et al. (1970) studied 148 patients with achondroplasia. Thirty-one (21%) had one or both parents affected, whereas 117 cases (79%) had no family history of the condition. Although a case has been described of one family in which normal parents gave birth to multiple affected children (Fryns et al., 1983), a larger Canadian study that examined the risk of recurrence due to parental gonadal mosaicism found only 1 case in 443 full siblings of children with achondroplasia (Mettler and Fraser, 2000). Thus the recurrence risk if the parents are normal is only 0.02%.

The gene involved in achondroplasia was localized to chromosome 4 band p16.3 in 1994 (LeMerrer et al., 1994). The disease is caused by mutations in the coding sequences for *FGFR3*. At least nine different heparin-binding fibroblast growth factors are known. All of them have pleiotropic effects on different cell types and have quite different patterns of expression during development. Evidence that the *FGFR3* gene was a good "candidate" gene for achondroplasia included the fact that *FGFR3* mRNA is found in the central nervous system and all of the prebone cartilage structures of the mouse (Shiang et al., 1994).

In a landmark study, Shiang et al. (1994) demonstrated point mutations in the DNA of 15 of 16 individuals studied with achondroplasia. The mutations all occurred at nucleotide 1138, and resulted in the substitution of an arginine residue for a glycine at position 380 of the mature protein, which is in the transmembrane domain of *FGFR3*. This work has been validated and extended by other investigators, who have also shown that all achondroplasia mutations studied result in the same substitutions at the same amino acid of the transmembrane domain of the *FGFR3* protein

(Bellus et al., 1994; Rousseau et al., 1994). The homogeneous nature of these mutations in achondroplasia is unprecedented for an autosomal dominant disorder. This may explain the phenotypic similarity between all patients with achondroplasia. *FGFR3* has subsequently been shown to be one of the most mutable genes in the human genome (Vajo et al., 2000).

Based on these results, rapid polymerase chain reaction-based prenatal diagnosis is available for the condition (Bellus et al., 1994). DNA testing is relatively straightforward because the mutations involved are minimal in number, and they create new recognition sites for restriction endonucleases (Francomano, 1995). In sporadic cases of achondroplasia, the *FGFR3* mutation arises during spermatogenesis and is associated with advanced paternal age (Wilkin et al., 1998; Vajo et al., 2000).

It is now known that achondroplasia is one of six diseases caused by mutations in the *FGFR3* gene. Four are associated with skeletal dysplasias and two are associated with craniosynostosis. The other three skeletal dysplasias are hypochondroplasia, thanatophoric dysplasia (see Chapter 90), and severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN) (Bonaventure et al., 1996; Bellus et al., 1999). *FGFR3* mutations also cause Muenke coronal craniosynostosis and Crouzon syndrome with acanthosis nigricans (Vajo et al., 2000) (see Chapter 10).

90 CHAPTER

Thanatophoric Dysplasia

Key Points

- Most common of the lethal skeletal dysplasias. Presents in the second trimester.
- Two subtypes exist: TD I has short curved femurs with or without a cloverleaf skull; TD II has straight, longer femurs and generally a more severe cloverleaf skull.
- Sporadic inheritance with extremely small recurrence risk associated with advanced paternal age (>35 years).
- Mutations in fibroblast growth factor receptor 3 (*FGFR3*) are the underlying basis for the disorder. There is a strong genotype–phenotype correlation. DNA diagnosis is highly accurate.
- *FGFR3* is also expressed in the brain. Rare survivors are uniformly severely developmentally delayed.

CONDITION

Thanatophoric dysplasia, a lethal chondrodysplasia, was first recognized as a unique clinical entity in 1967 (Maroteaux et al., 1967). *Thanatophoric* is Greek for "death bearing". The classic clinical features include micromelic limbs, short ribs, narrow thorax, relative macrocephaly, frontal bossing, midface hypoplasia, reduced height of the vertebral bodies, and central nervous system abnormalities (Figure 90-1). It is the most common form of lethal dwarfism in the human.

Fetuses and infants affected with thanatophoric dysplasia have been classified according to radiographic differences, such as the presence or absence of a cloverleaf skull and whether the femurs are curved or straight. At one time, the two subtypes of thanatophoric dysplasia (TD), TD I and TD II, were thought to be two separate entities, with possibly two different patterns of inheritance (Young et al., 1989). As of 1995, however, it was demonstrated that mutations in the fibroblast growth factor receptor 3 (*FGFR3*) gene were the underlying basis for both conditions (Tavormina et al., 1995). Mutation analysis of the DNA of affected patients has revealed that individuals with TD type I have short curved femurs with or without a cloverleaf skull deformity, whereas patients with TD type II have straight, somewhat longer femurs and severe cloverleaf skull (Tavormina et al., 1995). In the developing mouse and human fetus, the highest levels of

Figure 90-1 Fetus at 21 weeks of gestation with thanatophoric dysplasia, demonstrating severe micromelia, narrow chest, and prominent abdomen. (*Courtesy of Dr. Joseph Semple.*)

FGFR3 expression are in the skeleton and the central nervous system (Tavormina et al., 1995).

Mutations in FGFR3 are also the underlying basis for achondroplasia (Bonaventure et al., 1996) (see Chapter 89). Both TD and achondroplasia exhibit poor cellular proliferation in the growth plate of the long bone, although heterozygous achondroplasia is clinically less severe than TD. It is of interest that patients with homozygous achondroplasia manifest a more severe clinical phenotype than patients with heterozygous achondroplasia. The features in homozygous achondroplasia clearly resemble TD and result in neonatal lethality (Tavormina et al., 1995).

INCIDENCE

The incidence of TD ranges from 0.27 in 10,000 to 0.4 in 10,000 livebirths (Martínez-Frías et al., 1988; Rasmussen et al., 1996). In a large series of 126,000 deliveries occurring at one institution, TD was the most common osteochondrodysplasia observed (Rasmussen et al., 1996).

In individuals affected with TD, the mean paternal age is elevated as compared with unaffected controls (Martínez-Frías et al., 1988; Orioli et al., 1995). In 50% of cases of TD, the father is >35 years of age (Orioli et al., 1995). There is approximately a threefold increased risk for having a fetus with TD when the father is between the ages of 35 and 39 (Martínez-Frías et al., 1988).

To date, most cases of TD have occurred sporadically. The small number of familial cases reported reveals a paucity of well-documented sibling pairs, except in the case of monozygous twins. There is no evidence for parental consanguinity in affected fetuses (Martínez-Frías et al., 1988).

SONOGRAPHIC FINDINGS

The sonographic findings in cases affected by TD include severe micromelia with limited limb mobility and narrow chest (Figure 90-2A to 90-2C). Although the femur is classically described as curved and resembling a telephone receiver (Figure 90-3), affected fetuses can also have straight femurs. Additional sonographic findings include short, broad ribs, a narrowed chest circumference with consequent pulmonary hypoplasia, and hypoplastic vertebral bodies. The pelvic bones are characteristically small. Polyhydramnios is frequently present (Burrows et al., 1984; Stamm et al., 1987). In one report, an associated cardiac abnormality consisting of an atrioseptal defect and a bicuspid aortic valve was also described (Isaacson et al., 1983).

The *kleeblattschädel* (cloverleaf) deformity was first described in 1960 (Holtermüller and Wiedemann, 1960). This cloverleaf shape of the skull is due to early fusion of the lambdoidal and coronal sutures. This results in a towering calvarium and lateral bulges of the temporal lobes, which form three leaves of the cloverleaf when the head is viewed from the face (Figure 90-4). Because the lambdoidal and coronal sutures are fused, subsequent brain growth results in bulging in the regions of least resistance (Isaacson et al., 1983). The cloverleaf skull is present in only 14% of cases of TD (Iannaccone and Gerlini, 1974). Hydrocephalus is frequently associated with the cloverleaf skull (Shaff et al., 1980; Isaacson et al., 1983). To diagnose the cloverleaf skull deformity, a coronal scan that shows the temporal lobes is recommended (Stamm et al., 1987).

In the literature, multiple reports exist of the second trimester diagnosis of TD on the basis of the severe micromelia (Camera et al., 1984; de Elejalde and de Elejalde, 1985; Loong, 1987; Meizner et al., 1990; Schild et al., 1996). More recent studies report on the molecular diagnostic findings as well (De Biasio et al., 2000; Chen et al., 2001). These reports all describe fetuses with a long bone length of less than the third percentile for gestational age, an extremely narrow chest, a protruberant abdomen, and vertebral bodies of reduced height.

First trimester diagnosis has also been reported (Benacerraf et al., 1988). Benacerraf et al. described a

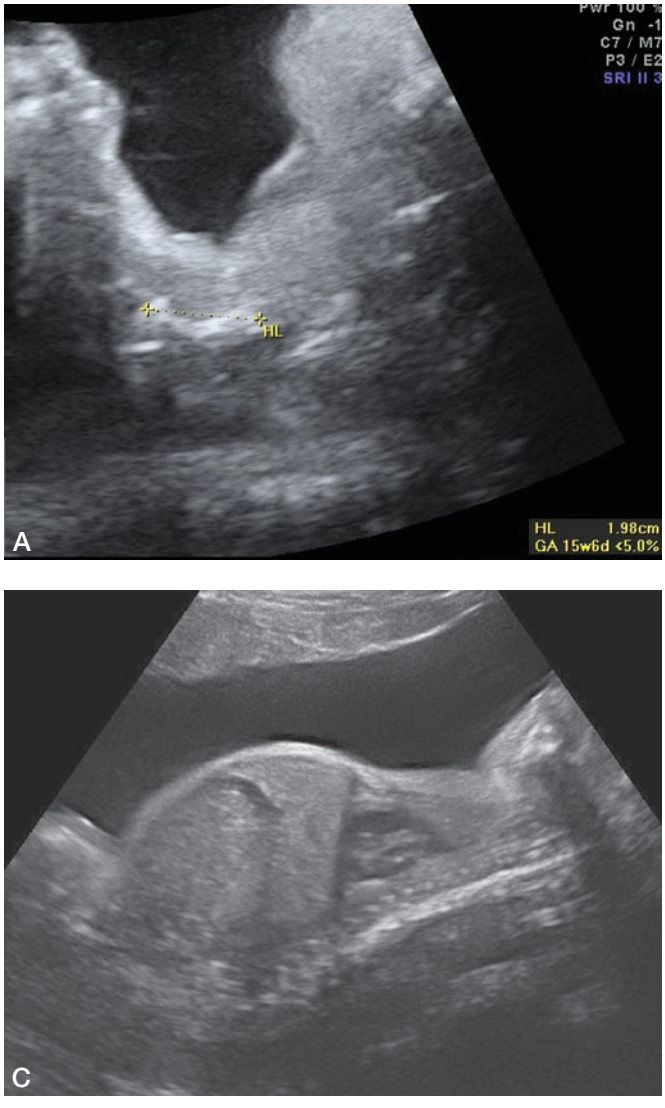

Figure 90-2 Prenatal ultrasound images of a 30-week fetus with thanatophoric dysplasia. (**A**) demonstrates short curved humerus (15-week size); (**B**) demonstrates 15-week size radius and ulna; (**C**) shows sagittal view of narrow chest with normal abdomen.

13-week-old fetus with a narrow chest and foreshortened and bowed femurs. A repeat sonographic examination performed at 15 weeks again demonstrated the abnormalities. The pregnancy was electively terminated. In contrast, another group has described a fetus that appeared normal at 15 weeks of gestation and was subsequently diagnosed at 32 weeks of gestation with TD (Macken et al., 1991). Three-dimensional sonography is considered to be advantageous for evaluation of the midface hypoplasia that is seen in TD (Krakow et al., 2003).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes other skeletal dysplasias that manifest as severe micromelia, such as campomelic dysplasia (see Chapter 92), Ellis van–Creveld syndrome (see Chapter 94), and short-rib polydactyly syndrome (see Chapter 95). Polydactyly is absent in TD. In achondrogenesis, the bones are usually less mineralized than in TD.

The cloverleaf skull is occasionally mistaken for an encephalocele (Chervenak et al., 1983; Mahony et al., 1985; Weiner et al., 1986; Stamm et al., 1987). Any soft tissue bulge in the head or neck must be evaluated for its exact position. Encephalocele and cystic hygroma occur in the midline and most often are posterior. The cloverleaf skull is bilateral, with enlargement of the temporal lobes. The standard teaching that the skull is not intact in encephalocele is not helpful to distinguish between encephalocele and cloverleaf skull. This is because the bony calvarium may be expanded, thinned, or partially absent in the cloverleaf skull deformity, and conversely, in cases of encephalocele, the osseous defect in the skull may be very small (Stamm et al., 1987). A cloverleaf skull may also be noted in Apert, Carpenter, Crouzon, and Pfeiffer syndromes as well as in homozygous achondroplasia.

ANTENATAL NATURAL HISTORY

The underlying defect in TD is in the formation of bone from a cartilage model. There is generalized disruption and decrease

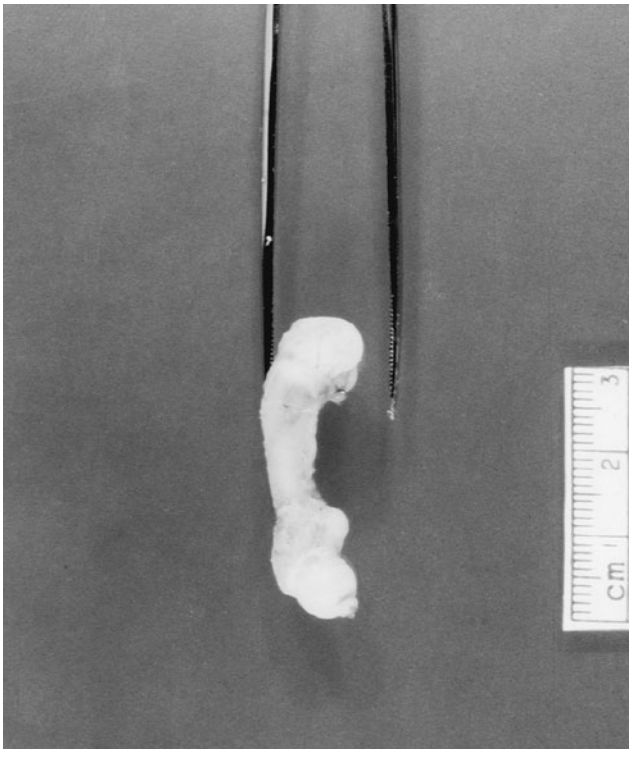

Figure 90-3 Postmortem photograph of an isolated femur from a fetus with thanatophoric dysplasia at 21 weeks of gestation, demonstrating its resemblance to a telephone receiver. (*Courtesy of Dr. Joseph Semple.*)

in endochondral ossification, with membranous ossification being less affected (Lemyre et al., 1999). Fetuses affected with TD show a progressive decrease in the growth rate of the long bones throughout gestation. While sometimes early in the second trimester, the femur length can be in the normal range, the bones become progressively shortened and curved (Burrows et al., 1984).

The function of *FGFR3* can be deduced from the *FGFR3* −/− knockout mouse, which is overgrown with excessively long femurs and elongated vertebrae (Cohen, 2002). The normal function of *FGFR3* is to regulate endochondral ossification by controlling growth. Mutations in FGFR3 result in abnormally early maturation of the skeletal and cranial bones (Cohen, 2002).

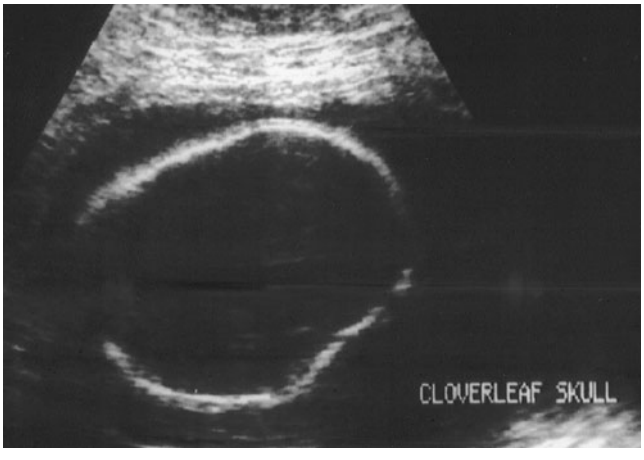

Figure 90-4 Antenatal sonogram demonstrating cloverleaf skull. (*Courtesy of Dr. Marjorie C. Treadwell.*)

The histologic abnormalities in TD include the presence of abnormal mineralizing tissue at the growth plate. In the region normally occupied by growth plate cartilage, cells and matrix have morphologic characteristics of epiphyseal cartilage, and the chondrocytes are not organized into columns or clusters. In addition, there are pyramidal areas of cartilage that resemble a shortened but normal growth plate, but the most characteristic finding is tufts of fibrous tissue scattered randomly along the growth plate. These have been termed "ossification tufts" (Horton et al., 1988). It is unclear whether these ossification tufts represent a primary phenomenon that disrupts endochondral bone growth or a secondary response to defective endochondral ossification. Marked abnormalities in endochondral and perichondral bone structures have been demonstrated by xeroradiography in a 20-week-old fetus (de Elejalde and de Elejalde, 1985).

Increasing evidence exists that the brain is seriously involved in patients affected with TD. This is not surprising given that *FGFR3* expression is very high in the developing central nervous system (Tavormina et al., 1995). In a neuropathologic study of seven affected individuals, Wongmongkolrit et al. (1983) reported that all brains in TD patients were larger than normal and demonstrated maldevelopment of the temporal lobes, characterized by extensive gyration and deep sulcation. The predominant findings were megencephaly, abnormal gyration, polymicrogyria in the temporal cortex, lateral displacement of the basal ganglia, reduced fiber tracts, and dysplasia of several nuclei. Ventricular dilation was present without evidence of obstruction. The most characteristic abnormality was the malformation of the temporal lobe with a pattern of disorganization that was distinctly different from any other condition. These investigators hypothesized that there was a relative vascular hypoperfusion of the developing temporal lobe, which resulted in polymicrogyria. In some cases, partial agenesis of the corpus callosum was also observed.

MANAGEMENT OF PREGNANCY

If it is suspected that a pregnant woman is carrying a fetus with a severe skeletal dysplasia such as TD, she should be evaluated at a center capable of performing a detailed fetal anatomic scan. Specific attention should be paid to measurement of the long bones and the chest circumference, as well as noting the presence or absence of polyhydramnios. There is no indication for a fetal karyotype, as the chromosomes are usually normal in TD. In addition, amniotic fluid α-fetoprotein and cholinesterase are also normal (de Elejalde and de Elejalde, 1985). However, an amniocentesis should be performed to obtain amniotic fluid cells for DNA analysis of

FGFR3, which will provide a definitive diagnosis (Sawai et al., 1999). If the diagnosis is made prior to 24 weeks of gestation, the parents should be counseled regarding the extremely poor prognosis and be given the opportunity to terminate the pregnancy. Pregnancies with fetuses with TD are frequently complicated by polyhydramnios, prematurity, malpresentation, and cephalopelvic disproportion. The presence of the cloverleaf deformity and hydrocephalus may necessitate cephalocentesis and assisted delivery. Vaginal breech deliveries are sometimes complicated by an extended short and rigid neck that may hinder the passage of the fetal head (Loong, 1987). A cesarean section may sometimes be necessary to safely deliver the fetus, although it will not alter the otherwise grim prognosis for fetal survival (Wongmongkolrit et al., 1983).

FETAL INTERVENTION

There are no fetal interventions for TD.

TREATMENT OF THE NEWBORN

Infants affected with TD uniformly experience respiratory distress at birth. Potential explanations for the respiratory distress include the narrow chest with associated pulmonary hypoplasia, abnormalities of the bronchial cartilage, compression of brainstem respiratory centers, and altered pulmonary phospholipids (Isaacson et al., 1983). If the diagnosis is known from antenatal studies, the parents may have the opportunity to request that no newborn resuscitation occurs.

Infants who are delivered with a severe skeletal dysplasia but without antenatal knowledge of the diagnosis may initially require resuscitation until a precise diagnosis can be made. A complete physical examination of the newborn is indicated, which will demonstrate the presence of a bulging forehead, prominent eyes, flattened nasal bridge, narrow chest, and severely shortened extremities (Figure 90-5). Radiographs should be obtained, which will show the severe micromelia and femurs possibly shaped like telephone receivers (Figure 90-6). The chest radiograph will also indicate the presence of short ribs, flat vertebral bodies that are H-shaped in the frontal projection, widened intervertebral disk spaces, a short pelvis with a small sacroiliac notch, and a possible cloverleaf skull deformity (Andersen, 1989). The most important differential radiologic features include the markedly flattened vertebral bodies with widened intervetebral spaces, the shortened bowed extremities, and the irregularly flared metaphyses (Campbell, 1971).

Once the diagnosis of TD has been confirmed, respiratory support may be electively withdrawn, given the nearly uniform neonatal lethality and poor outcome for the rare long-term survivors with this condition (MacDonald et al., 1989). If the diagnosis was not made prenatally, a postmortem skin biopsy should be performed, and a fibroblast line should be established to facilitate DNA mutation studies of the *FGFR3* gene to confirm the diagnosis.

SURGICAL TREATMENT

Information exists on surgical treatment only for the extremely limited number of affected patients who survived past infancy. Affected infants eventually require tracheostomy for prolonged ventilatory support (see Figure 90-5), ventriculoperitoneal shunt for hydrocephalus, and foramen magnum decompression (MacDonald et al., 1989).

LONG-TERM OUTCOME

Several case reports discuss the longer survival of affected infants with TD due to modern neonatal care (Stensvold et al.,

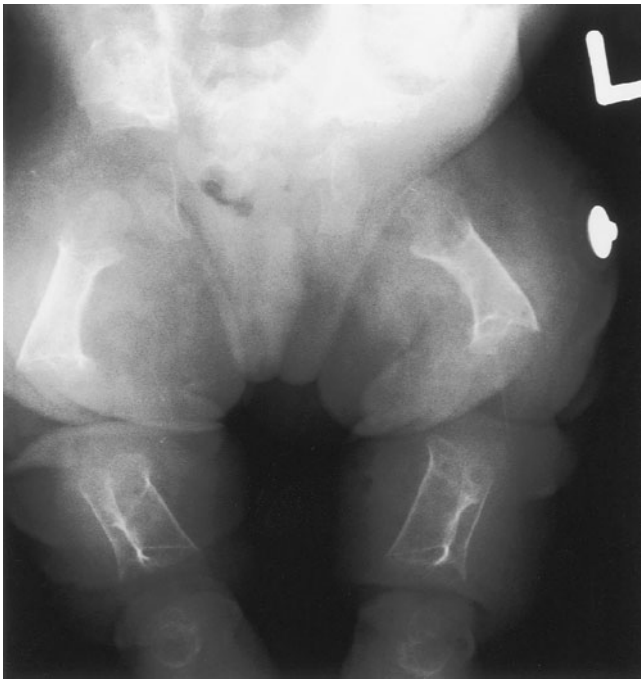

Figure 90-6 Postnatal radiograph of an affected infant demonstrating short tubular bones, metaphyseal widening, and spurs. (*Reprinted, with permission, from MacDonald IM, Hunter AGW, MacLeod PM, MacMurray SB. Growth and development in thanatophoric dysplasia.* Am J Med Genet. *1989;33:508-512. Copyright 1989 Wiley-Liss. 1986; Tonoki, 1987; MacDonald et al., 1989). In one report, a female with TD who survived for 169 days was described. Her postnatal course was complicated by hypotonic muscles, absent reflexes, and increasing hydrocephalus. Eventually she required supplemental oxygen but died from respiratory failure (Stensvold et al., 1986). In another case report, a male was described who survived for 212 days. His delivery was by cesarean section and complicated by severe birth asphyxia. He required oxygen supplementation but was discharged from the hospital at 35 days of age. His neurologic development was normal until 4 months of age, when frequent apnea and cyanosis developed, which was questionably due to cord compression and a small foramen magnum. At 4 months of age, respiratory and cardiac failure developed and he required mechanical ventilation. He eventually died from respiratory failure secondary to pneumonia (Tonoki, 1987).

The most informative reports come from two cases of prolonged survival with TD. In both cases, ventilatory support was initiated due to respiratory distress of the newborn. Both patients eventually required ventriculoperitoneal shunts for hydrocephalus as well as decompression of the posterior fossa (MacDonald et al., 1989). The first patient survived to 5.2 years of age and was dependent on the ventilator. At age 4.75 years, development was estimated to be at the 2-week age level. At age 4.75 years, the patient weighed 8.82 kg (<3% for age), was 65 cm long (<3% for age), and had a head circumference of 47.5 cm (<3% for age) (Figure 90-7). By 10 months of age, growth of the long bones ceased. The femurs maintained their telephone-receiver appearance. An electroencephalogram in this patient initially revealed epileptiform activity, followed later by background disturbance. The computed tomographic scan revealed abnormal differentiation of gray and white matter in both hemispheres.

The second affected patient initially required 40% inspired oxygen and did not need mechanical ventilation. At 2 months of age, however, a respiratory infection developed and intubation and ventilation were required. There was a clinical question of brainstem compression, so a posterior

fossa decompression with laminectomy of the atlas and removal of the posterior third of bone around the foramen magnum occurred. At 4 months of age, the patient again required ventilatory support and a tracheostomy. Progressive hydrocephalus developed and a ventriculoperitoneal shunt was placed. After the placement of the ventriculoperitoneal shunt, the head circumference was <3% for age. At 3.7 years of age, the child could see and track objects, but had limited verbalization. This patient also manifested a prolonged period of nearly absent growth despite adequate nutrition.

On the basis of these two cases, these authors recommended that their long-term clinical experience with these two affected patients would "temper" their approach in the future (MacDonald et al., 1989).

GENETICS AND RECURRENCE RISK

TD is inherited as an autosomal dominant sporadic mutation with an extremely low risk of recurrence, most likely due to paternal gonadal mosaicism (Young et al., 1989). The chromosomes in affected patients have been normal, although one case has been described with a probably unrelated de novo 1:10 balanced translocation (Hersh et al., 1995). The disease is caused by missense mutations in the *FGFR3* gene, which maps to the short arm of chromosome 4 band 16.3 (McKusick et al., 1996). In addition to TD, five other diseases are due to mutations in *FGFR3* gene: achondroplasia (Chapter 89), hypochondroplasia, severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN), Muenke coronal craniosynostosis, and Crouzon syndrome with acanthosis nigricans (Bellus et al., 1999; Lemyre et al., 1999; Vajo et al., 2000) (see Chapter 10).

Several reports of TD have been described in monozygous twins (Young et al., 1989; Corsello et al., 1992). Monozygous twins have also been described who are discordant for the cloverleaf skull deformity (Horton et al., 1983; Corsello et al., 1992).

It is now known that there is a highly conserved genotype–phenotype correlation for the *FGFR3* mutations (Vajo et al., 2000). The subtype TD I consists of curved femurs with the variable presence of the skull deformity. To date all mutations identified in TD I result in a stop codon or missense mutation that creates a cysteine residue (Tavormina et al., 1995; Vajo et al., 2000). However, TD I is molecularly heterogenous. In contrast, in 95% of cases of TD II, there is a lysine-to-glutamine amino acid change at position 650 in the intracellular tyrosine kinase domain of *FGFR3* (Vajo et al., 2000). All individuals with this particular mutation have straight femurs and a severe cloverleaf skull deformity (Tavormina et al., 1995). Nested polymerase chain reaction primers have been designed for the rapid diagnosis of mutations. The mutations causing TD I and II are sporadic, as they were not seen in the parents who were tested (Tavormina et al., 1995). Of interest is that the manifestations of the disease are not simply due to heterozygous deletion of *FGFR3*, because a chromosomal abnormality syndrome, Wolf–Hirschhorn (4p-), does not result in a skeletal dysplasia. Thus, haploinsufficiency of the *FGFR3* gene is not the cause of TD.

Additional mutations have been documented in TD I. Rousseau et al. (1995) found three different base substitutions in the chain termination (stop codon) of the *FGFR3* gene in 5 of 15 TD I patients without a cloverleaf skull deformity. These mutations cause protein elongation, resulting in a highly hydrophobic domain with an α-helix structure at its C-terminal end. This possibly impairs signal transduction. In another report, 7 different sporadic mutations in three different protein domains have now been identified in 25 of 26 patients with TD I. No correlation exists between the position of the mutation and phenotypic or radiologic abnormalities. *FGFR3* mutations in the extracellular receptor create new unpaired cysteine residues (Bonaventure et al., 1996). Review of 91 cases from the International Skeletal Dysplasia registry at Cedars-Sinai Hospital in Los Angeles revealed that every case of TD had an identifiable *FGFR3* mutation (Wilcox et al., 1998). Although the recurrence risk is likely to be extremely small, prenatal diagnosis to reduce anxiety is characteristically performed by sonography with occasional supplementation by radiography. For families who have had a previously affected infant in which the *FGFR3* mutation was identified, definitive molecular prenatal diagnosis can be performed as early as 10 weeks by chorionic villus sampling.

Parents who have an affected fetus with TD may find comfort in an article written by a parent whose son was born with TD and survived for 3 months in a newborn intensive care unit (Stabosz, 1985).

Osteogenesis Imperfecta

91 CHAPTER

Key Points

- Clinically and genetically heterogeneous disorder manifested by bone fragility and low bone mass.
- Seven distinct subtypes exist. Severity is as follows: type II > type III > types IV = V = VI = VII > type I.
- Most cases that present prenatally are types II or III. Only 10% of fetuses with type I have fractures in utero.
- Other findings include blue sclerae, abnormal teeth, joint hyperlaxity, adult-onset hearing loss, and normal intelligence.
- Prenatal sonographic findings include long bone fractures with callus formation, limb shortening, poor mineralization of the skull, and bent femurs.
- Differential diagnosis includes campomelic dysplasia, hypophosphatasia, and achondrogenesis.
- In 90% of cases there is a mutation in one of the genes that codes for type I procollagen, *COL1A1* or *COL1A2*.
- Most cases are dominantly inherited. If parents are asymptomatic there is a 7% recurrence risk due to the surprisingly high incidence of gonadal mosaicism.

CONDITION

Osteogenesis imperfecta is a clinically and genetically heterogeneous disorder of connective tissue, manifested by bone fragility and low bone mass. Affected patients have blue sclerae, hearing abnormalities, defective dentition, hyperlaxity of the joints, and normal intelligence (Brons et al., 1988). The majority of affected individuals are heterozygous for mutations of the *COL1A1* or *COL1A2* gene, which alters the structure of type I procollagen (Cole and Dalgleish, 1995).

Osteogenesis imperfecta was originally classified into four clinically distinct disorders that were first delineated by Sillence et al. (1979), and modified by Rauch and Glorieux (2004) (Table 91-1). Type I is the common mild form, type II is the perinatal lethal form, type III is the severe form, and type IV is the moderately clinically severe form (Cole and Dalgleish, 1995). More recently, an additional three types (V, VI, and VII) have been described (Rauch and Glorieux, 2004). The clinical severity of OI is type II > type III > types IV = V = VI = VII > type I.

Type I is a form of dominantly inherited osteoporosis that leads to fractures. Affected patients have distinctly blue sclerae and between 35% and 50% have presenile conductive hearing loss or deafness. The earliest age of onset of hearing loss is 10 years, and 40% of affected adults eventually require hearing aids. Approximately one fifth of patients with type I osteogenesis imperfecta (OI) have kyphosis and scoliosis, although severe spinal curves are rarely seen. These patients also bruise easily. All patients with type I OI are able to walk independently. Type I is further subdivided into type IA, patients with normal teeth and type IB, patients who have dentinogenesis imperfecta. Only 10% of patients with type I OI have fractures that are identifiable at birth (Sillence, 1981). Patients affected with type I OI have a progressive loss of height due to platyspondyly and kyphosis. Birth weight and length are generally normal and short stature is of postnatal onset. These patients are also notable for a head size that appears large for height.

Patients with type II OI comprise the majority of cases detected pre- and post-natally. Type II has been further subdivided into types IIA, IIB, and IIC. In type IIA broad, crumpled femurs and continuous beading of the ribs are present. In addition, the patients are small for gestational age and have severe osteoporosis of the skull and face. In type IIB, there are minimal or no rib fractures present. Because the ribs are less severely affected, the chest configuration is more normal and the resulting respiratory distress is less severe. Type IIB

Table 91-1

Expanded Sillence Classification of Osteogenesis Imperfecta

Type	Clincal Severity	Typical Features	Typically Associated Mutations
I	Mild nondeforming osteogenesis imperfecta	Normal height or mild short stature; blue sclerae; no dentinogenesis imperfecta	Premature stop codon in *COL1A1*
II	Perinatal lethal	Multiple rib and long bone fractures at birth; pronounced deformities; broad long bones; low density of skull bones on radiographs; dark sclerae	Glycine substitutions in *COL1A1* or *COL1A2*
III	Severely deforming	Very short; triangular face; severe scoliosis; greyish sclerae; dentinogenesis imperfecta	Glycine substitutions in *COL1A1* or *COL1A2*
IV	Moderately deforming	Moderately short; mild-to-moderate scoliosis; greyish or white sclerae; dentinogenesis imperfecta	Glycine substitutions in *COL1A1* or *COL1A2*
V	Moderately deforming	Mild-to-moderate short stature; dislocation of radial head; mineralized interosseous membrane; hyperplastic callus; white sclerae; no dentinogenesis imperfecta	Unknown
VI	Moderately to severely deforming	Moderately short; scoliosis; accumulation of osteoid in bone tissue; fish-scale pattern of bone lamellation; white sclerae; no dentinogenesis imperfecta	Unknown
VII	Moderately deforming	Mild short stature; short humeri and femora; coxa vara; white sclerae; no dentinogenesis imperfecta	Unknown

Reprinted with, permission from, Rauch F, Glorieux FH. Osteogenesis imperfecta. Lancet. *2004;363:1377-1385.*

is the only form with potential postnatal survival. In type IIC there are thin femurs and ribs with extensive fractures. In this form, the fetuses are very small for gestational age and severe osteopenia is present. However, many investigators state that distinction between the subgroups of type II is of limited value because all fetuses and infants with OI type II die during the perinatal period.

Type III is a rare form of OI, characterized by marked fragility and fractures of the long bones and skull, which are sometimes present at birth (Sillence et al., 1986). In utero, the defect in ossification of the skull is not as marked as it is in Type II. Posnatally, there are spine and long bone fractures, which result in progressive short stature and kyphoscoliosis. Although blue sclerae are present at birth, they fade with time. Hearing impairment is rare in type III OI. Affected patients have a triangle-shaped face with a wide bitemporal diameter. These patients are among the smallest of adults with OI. They have considerable difficulty walking. They suffer from multiple pulmonary complications.

Type IV is a dominantly inherited form of osteoporosis that leads to fractures. Variable deformity of the long bones exists, but affected patients have normal sclerae. There are no associated hearing abnormalites. Type IV has been further subdivided into IVA and IVB. In type IVA there is normal dentition and in IVB there is dentinogenesis imperfecta. To date, types V, VI and VII have not been associated with a specific prenatal presentation. All are associated with bone fragility, but none are known to be caused by mutations in *COL1A1* or *COL1A2*. Patients with Type V OI have hypertrophic callus formation at fracture sites, calcification of the interosseous membranes between bones of the forearm, and a radio-opaque metaphyseal band adjacent to the growth plates. The distinctive feature of type VI OI is the histologic appearance of bone lamellae that resemble fish scales. Patients with type VI OI also accumulate excessive osteoid. Type VII OI is inherited in an autosomal recessive pattern, and it is characterized by proximal shortening of the humerus and femur (Roughley et al., 2003).

INCIDENCE

The incidence of type I OI is 1 in 28,500 livebirths, while type II occurs in 1 in 62,000 livebirths and type III occurs in 1 in 68,800 livebirths (Sillence et al., 1979). In Sillence et al.'s original article, they did not quote an incidence for type IV OI (Sillence et al., 1979). Rasmussen et al. (1996) identifed 16 cases of OI among 126,316 deliveries that occurred over a 15-year period in a single teaching hospital. These authors estimated a prevalence (with exclusion of high-risk patients) of 0.24 in 10,000 deliveries of type II OI and 0.4 in 10,000 of types II and III OI combined. OI has been described in all ethnic groups (Sykes et al., 1986).

SONOGRAPHIC FINDINGS

The prenatal sonographic findings in OI are summarized in Table 91-2. The characteristic antenatal findings of OI include

Table 91-2

Prenatal Sonographic Findings in Osteogenesis Imperfecta (Listed in order of detection at earliest gestational age)

Type	Genetics	Clinical Findings	Ultrasound Findings	First Ultrasound Detection
OI II lethal perinatal	Autosomal dominant	Lethal perinatal type: Undermineralized skull, micromelic bones, "beaded" ribs on x-ray, bone deformity, platyspondyly	Undermineralization, broad crumpled and shortened limbs, thin beaded ribs, fractures, angulation or bowing of long bones, normal appearing hands, deformable calvarium	≥14 wks
OI III	Autosomal dominant	Progressively deforming type: Moderate deformity of limbs at birth, scleral hue varies, very short stature, dentinogenesis imperfecta (DI)	Thin ribs, short limbs, fractures, undermineralized skull, long bone length falls away from normal at 16–18 weeks	≥18 wks
OI IV	Autosomal dominant	Normal sclerae, mild/moderate limb deformity with fracture, variable short stature, DI, some hearing loss	Rarely, long bone bowing and/or fracture	After 20 wks but not common
OI I	Autosomal dominant	Fractures with little or no limb deformity, blue sclerae, normal stature, hearing loss, DI	Rarely, long bone bowing or fracture	>20 wks but not common
OI V	Autosomal dominant	Similar to OI IV plus calcification of interosseous membrane of forearm, radial head dislocation, hyperplastic callus formation	Unknown	Not described
OI VI	Unknown	More fractures than OI type IV, vertebral compression fractures, no DI	Unknown	Not described
OI VII	Autosomal recessive	Congenital fractures, blue sclerae, early deformity of legs, coxa vara, osteopenia	Unknown	Not described

in utero fractures that occur with callus formation at the site of healing. These result in prenatally acquired long-bone deformities and significant limb shortening (Figure 91-1). Abnormalities of the fetal skull are the most striking findings in OI (Constantine et al., 1991). In addition, soft and fractured ribs contribute to a small thoracic circumference, which has been described as having a "champagne cork" appearance. The unusual clarity of intracranial structures is due to poor calvarial ossification (Figure 91-2). This has led to the term *supervisualization* (Andrews and Amparo, 1993). The compression of the fetal head by the ultrasound probe and the low echogenicity of the cranium should raise the suspicion of a skull dysplasia. However, this finding is not diagnostic for OI (Berge et al., 1995).

The following sonographic criteria have been proposed for type II OI: multiple fractures, demineralization of the calvarium, and a femoral length less than 3 SD below the mean for gestational age coupled with a wrinkled appearance of the long bones (Munoz et al., 1990). In a retrospective study of 459 fetuses and infants with bent femurs, 18.1% had OI (Alanay et al., 2007).

In the absence of a known family history of OI, most fetuses detected prenatally will have type II. The major diagnostic criteria for this type of OI include shortened deformed long bones, underossification of the cranial vault, which results in easily seen intracranial structures, an abnormal and varying skull shape, a small chest circumference with broad and irregular ribs (Figure 91-3), decreased fetal movements, and unusual fetal limb position (Constantine et al., 1991). In one case report, Morin et al. (1991) described a case of type IIA OI in one of dizygotic twins diagnosed at 27 weeks of gestation. In this report, the affected fetus was so translucent

Figure 91-2 Cross-sectional view of a fetal head demonstrating significantly reduced skull ossification, resulting in unusually clear visualization of intracranial contents.

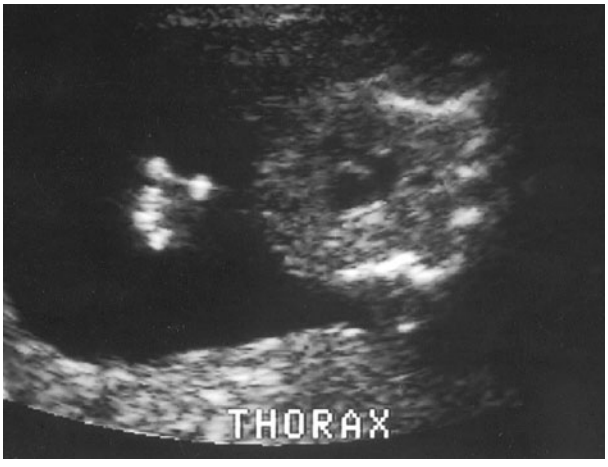

Figure 91-3 Cross-sectional view of fetal thorax, demonstrating small chest circumference with undermineralized, beaded, crumpled ribs.

that only one twin could be seen on a plain radiograph. In another case report, D'Ottavio et al. (1993) described a case of type II OI in the fetus of a woman at 14 weeks of gestation who underwent routine transvaginal ultrasonography. In this fetus, both femurs were short and severely angulated because of fractures. Even at this early point in gestation, the fetal skull was noted to be hypoechogenic, and an abnormal curvature of the right radius was present.

Prenatal diagnosis of OI types I and III is more difficult to make on a sonographic basis. Most of the cases described in the literature have been diagnosed in fetuses known to be at risk because of a positive family history. For example, Robinson et al. (1987) described a fetus at risk for type III OI that was followed with serial sonography. At 15 weeks of gestation, there was a low normal fetal femur length. By 20 and 22 weeks, however, shortening of the long bones and deformity of the femurs were noted. There was not an impressive decrease in ossification of the fetal skull. Several case reports of prenatal diagnosis of type I OI have appeared in families known to be at risk. Chervenak et al. (1982) described a fetus whose mother was affected with type I OI. This fetus had a normal sonographic examination at 20 weeks, but bowed femurs developed at 24 weeks. By 32 weeks of gestation, demineralization of the fetal skull was observed. No fractures were seen in utero, but a right femur fracture developed at 9 days of age, which was postulated to be due to the effect of intrauterine curvilinear stress on weakened bones.

Brons et al. (1988) reported on the sonographic diagnosis of OI in seven fetuses collected from the experience of three major teaching hospitals in the Netherlands. The gestational age at the time of scanning was between 15 and 34 weeks. The indications for sonography included large for gestational age (two fetuses), small for gestational age (two), previous child affected with OI (two), and routine anatomy scan (one). The biparietal diameter was normal in all seven. The abdominal circumference, however, was either normal or small for gestational age. In most cases, the chest circumference was narrow as compared with the abdominal circumference. The heart was noted to completely fill the chest. The limbs were the most severely shortened in type IIA OI. The prenatal diagnoses of types IIB, IIC, and III were made later in gestation than in type IIA (Brons et al., 1988).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes other causes of severe skeletal dysplasia and demineralization. Conditions that most resemble OI on prenatal sonographic examination include hypophosphatasia (see Chapter 98) due to demineralization of the skull, narrow chest circumference, and shortened extremities. Fetuses with hypophosphatasia generally do not have in utero fractures, but they can have bowing or angulation of the long bones (Pauli et al., 1999). The condition that seems to be most commonly confused prenatally with OI is campomelic dysplasia (see Chapter 92). Sanders et al. (1994) described three cases of OI that mimicked campomelic dyplasia and one case of campomelic dysplasia that was prenatally diagnosed as OI. The overlap between campomelic dysplasia and OI relates to the severe bowing of the limbs (Alanay et al., 2007) (see Figure 91-1). Tibial bowing is more pronounced in campomelic dysplasia, but some cases of severe nonlethal OI have tibial bowing without obvious fractures. Conversely, acute angulation of the femur seen in campomelic dysplasia can suggest a fracture. Cranial deformities, such as bossing, hypertelorism, and hydrocephalus can exist in both syndromes. The presence of arm fractures with callus formation, cranial compressibility with unusually clear visualization of the intracranial contents, and asymmetry in the length of the limbs favors a diagnosis of OI. The presence of clubfeet, micrognathia, and hydronephrosis favors the diagnosis of campomelic dysplasia (Sanders et al., 1994). Another condition that can closely resemble OI is achondrogenesis (see Chapter 97).

ANTENATAL NATURAL HISTORY

Two major biochemical phenotypes of OI exist: patients with normal stature and blue sclerae (type I) secrete half of the normal amount of a normal type I procollagen and do not have the presence of identifiable abnormal molecules. Patients with short stature and fractures (types II, III, and IV) produce and secrete both normal and abnormal type I procollagen molecules (Wenstrup et al., 1990) (Table 91-1).

The perinatal lethal form, type II OI, is the result of heterozygous mutations of the *COL1A1* and *COL1A2* genes that encode the α_1(I) and the α_2 (I) chains of type I collagen. These mutations act in a dominant negative manner because the mutant proα-chains are incorporated into type I procollagen molecules that also contain normal proα-chains. The

abnormal molecules that are poorly secreted are more susceptible to degradation and impair formation of the extracellular matrix. The collagen fibers are abnormally organized, and mineralization is impaired (Cole and Dalgleish, 1995).

Histologic and biochemical abnormalities in the dermis obtained from babies with type II OI demonstrate fibroblasts with a dilated rough endoplasmic reticulum due to impaired secretion of mutant type I procollagen molecules. The collagen fibrils are smaller than normal. There is a reduced amount of type I collagen and a mixture of normal and mutant type I collagen. The bone is severely porotic. The normal cortical and trabecular bone is replaced by woven bone. There is an abundance of plump osteoblast surrounded by small amounts of extracellular matrix. The osteoblast may contain dilated rough endoplasmic reticulum. The growth plate is normal but the cartilage cores persist in the trabeculae. The bone matrix is decreased in type I collagen and increased in types III and IV collagen.

These histologic findings suggest that the skeletal dyplasia in type II OI results from the action of muscular forces on a skeleton weakened by a complex disorder of endochondral and intramembraneous ossification. The paucity of primary metaphyseal trabeculae and subperiosteal cortical bone leads to pathologic fracture of the immature fiber bone and abnormal attempts at fracture repair (Marion et al., 1993).

MANAGEMENT OF PREGNANCY

The pregnant patient carrying a fetus in which OI is suspected should be referred to a tertiary care center capable of sophisticated anatomic diagnosis. The patient should meet with a medical geneticist or genetic counselor, who will obtain a detailed family history and a three generation pedigree. Specific questions should be asked regarding the height of first-degree family members, the presence of deafness, the color of the sclerae in family members, and whether there is a history of fractures. If previously affected infants have been born to the family, pathologic studies (if available) should be reviewed. However, most cases of affected fetuses will occur in the setting of a negative family history. Consideration should be given to obtaining a prenatal radiograph if the bones are not adequately visualized on a level II sonogram. For a presumed diagnosis of OI, there is no indication to obtain chromosomal analysis. Chorionic villi and amniotic fluid cells can serve as equally good sources of DNA for mutation analysis of the *COL1A1* and *COL1A2* genes. Amniocytes, however, synthesize inadequate amounts of type I procollagen, so they are not useful for prenatal biochemical diagnosis (Byers et al., 2006). In contrast, chorionic villi do synthesize adequate amounts of procollagen for biochemical analysis.

In the setting of a positive family history and a fetal presentation of skeletal dysplasia at earlier than 20 weeks of gestation, the presumed diagnosis is types II or III OI. In such cases, the poor prognosis should be discussed with the parents, who can be offered the opportunity to electively terminate the pregnancy.

In patients with a known family history of OI, prenatal sonographic and biochemical diagnoses are available. CVS should be offered for biochemical studies in types II, III, and IV. Prenatal diagnosis for type I OI is only accurate if the underlying familial DNA mutation is known. Note that prenatal sonography in fetuses at risk for type I OI can be normal, even when the fetus is affected.

Pregnant women who themselves are affected with type I OI are at risk for uterine rupture during a spontaneous vaginal delivery due to decreased amounts of collagen (Carlson and Harlass, 1993). Previous reports exist of dysfunctional platelet aggregation and prolonged bleeding times in women affected with type I OI. In addition, these patients can have a hypermetabolic state with hyperthermia due to abnormal oxidative metabolism. These women are at increased risk for developing malignant hyperthermia with general anesthesia for cesarean delivery. For affected mothers and fetuses with nonlethal types of OI, the goal is to provide a safe and atraumatic delivery for both mother and fetus.

In a review of 167 pregnancies affected by a fetal diagnosis of OI, Cubert et al. (2001) showed that cesarean section delivery did not decrease fracture rates at birth in infants with nonlethal forms, nor did it prolong survival in those with lethal types. Interestingly, there was an unusually high rate of breech presentation at term (37% of cases). Because of the maternal morbidity and mortality associated with cesarean section delivery, these authors suggested that operative delivery be reserved for standard obstetric indications such as breech presentation or fetal distress.

FETAL INTERVENTION

There has been at least one published report of a 32-week female fetus with OI that underwent transplantation with allogeneic HLA-mismatched male fetal mesenchymal stem cells (MSCs) (Le Blanc et al., 2005). In total, 6.5×10^6 fetal MSCs were injected into the umbilical vein and there were no post-procedural complications. Spontaneous rupture of the membranes occurred at 35 weeks. Delivery was by cesarean section. Postnatal radiography indicated multiple healed fractures and a new right femoral fracture, which was stabilized prior to discharge. Treatment with pamidronate was initiated at 4 months. At 9 months a bone biopsy showed regularly arranged bone trabeculae lined by a columnar layer of normal osteoblasts. FISH analysis was performed using centromeric X- and Y-chomosome specific probes. This showed that 0.3% of cells staining positive for osteopontin or osteocalcin were donor derived. At 2 years of age the patient was small, but had normal development. She had three fractures, but did not require any overnight hospitalization for treatment. This report was the first demonstration of donor MSC engraftment into an immunocompetent human fetus (Le Blanc et al., 2005).

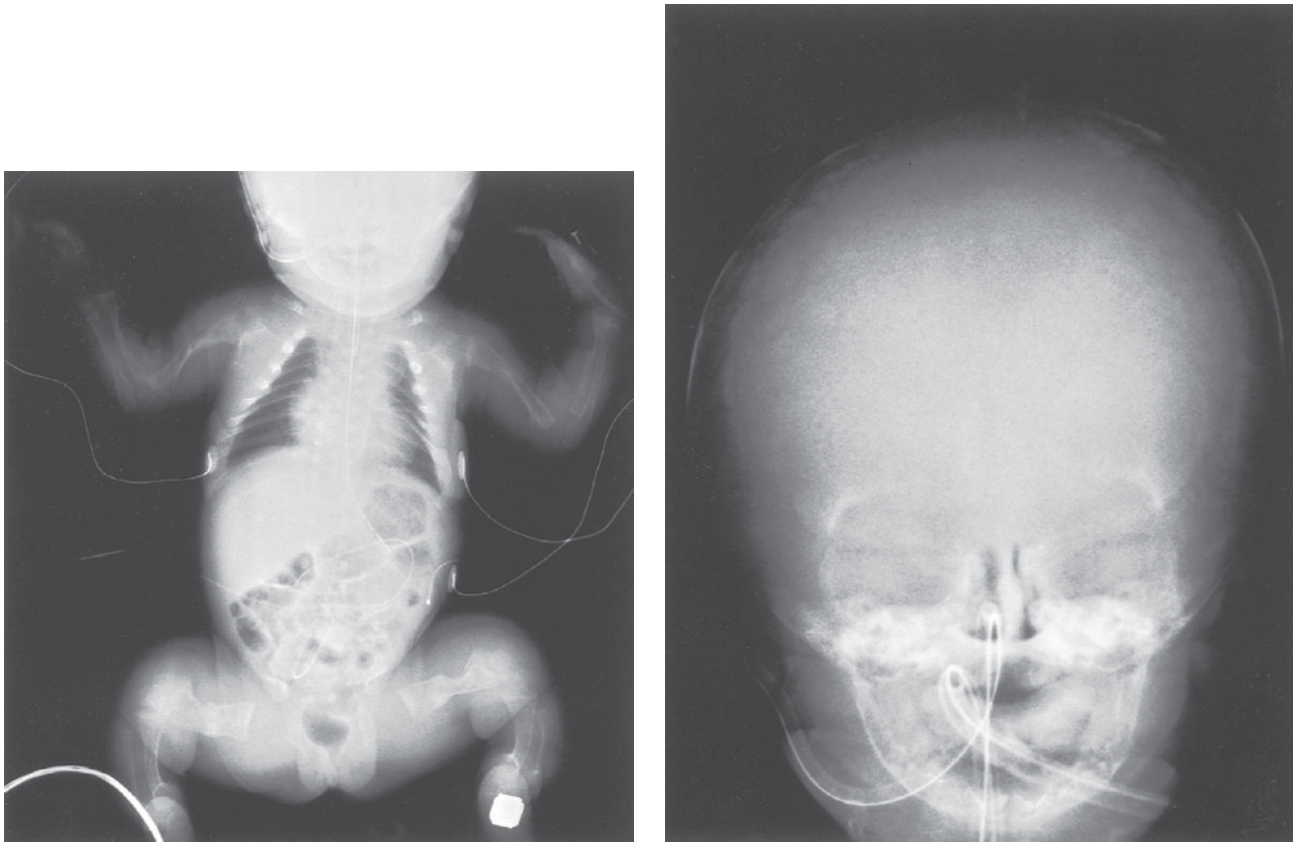

Figure 91-4 Postnatal radiographs of a newborn infant with type II OI. (*Left*) Multiple fractures are present in the long bones. The ribs are poorly mineralized. (*Right*) Close-up skull radiograph in same infant, demonstrating the lack of ossification that is characteristically observed in prenatal sonographic studies.

TREATMENT OF THE NEWBORN

The majority of newborns who present with fractures have type II OI. Postnatal radiography may aid in the determination of a definite diagnosis (Figure 91-4). The prognosis is poor for these infants, and the cause of death is usually secondary to respiratory difficulties associated with mechanical failure of the chest wall (Carlson and Harlass, 1993). Supportive care is indicated for infants likely to have type II OI. A skin biopsy should be obtained for definitive biochemical and/or DNA analysis. A fibroblast culture can be sent to a referral laboratory for analysis of quantity and quality of type I collagen chains.

For infants with nonlethal forms of OI, the mainstays of therapy are physical therapy, rehabilitation, and orthopedic surgery. These infants are likely to benefit from specific exercise, bracing, and ambulation training (Binder et al., 1993). Only routine hearing screening is recommended, as the hearing abnormalities characteristic of type I OI do not develop until later childhood or early adulthood. Parents of affected newborns should be counseled that blue sclerae represent a change in physical appearance and do not affect visual acuity.

Infants who survive the newborn period may benefit from bisphosphonate treatment (Glorieux, 2007). Bisphosphonates are pyrophosphate analogs that inhibit osteoclast-mediated bone resorption. In response to bisphosphonate therapy, bone mass increases due to a relative increase in osteoblastic activity. The first large scale clinical trial of children with severe OI who were treated with intravenous pamidronate (1 mg/kg/d) for 3 consecutive days every 4-6 months was published in 1998 (Glorieux et al., 1998). More than 50% of the study population showed improved mobility, fracture incidence was reduced to 1.7 per year, and the mean annual increment in spinal bone density was 42%. These results were quickly validated by others (Astrom and Soderhall, 1998). Many studies have now shown that treatment increases bone mineral density by increasing cortical bone width and the number of trabeculae present (Roughley et al., 2003). Most important to the affected individuals is the fact that chronic bone pain decreases with treatment. This permits increased mobility and improvement in muscle strenth. Several hundred patients have received bisphosphonate therapy for periods of up to 7 years and it is now considered to be standard care for children with moderate to severe OI (Glorieux, 2007). No benefits have been established for mild cases in which negative effects, such as

decrease in bone remodeling rate, reduction in growth plate cartilage resorption, and delay in osteotomy site healing may outweigh any positive effects. Bisphosphonates also stay in bone for many years following treatment. Although there is potential concern about teratogenic effects in fetuses of treated women with OI, at least one report describing two babies of two pregnant women with types I and IV OI did not show any skeletal modeling abnormalites consistent with in utero pamidronate exposure (Munns et al., 2004). Still unanswered questions regarding bisphosphonate treatment include criteria used to start treatment, optimal length of treatment, duration of treatment effect, dose and frequency of administration, and criteria for discontinuing treatment (Shaw and Bishop, 2005).

It is important to realize that bisphosphonate therapy does not cure OI. Alternative approaches include cellular therapy, such as bone marrow (Horwitz et al., 2002) or mesenchymal stem cell transplantation (Le Blanc et al., 2005), as well as ex vivo gene therapy (Chamberlain et al., 2004).

SURGICAL TREATMENT

The orthopedic manifestations of the nonlethal forms of OI consist of bone fragility, with resulting fractures, deformity, and scoliosis. When these fractures occcur, the bones heal with callus formation and a successive slight malalignment. Repetitive fractures of the same bone may lead to a significant deformity. Eventually, decreased range of motion of the joints and contractures can occur. Fractures are treated with immobilization or intramedullary rodding, which consists of a surgical insertion of a pin into the long bones to stabilize them. Scoliosis occurs in 30% to 70% of patients with OI. This requires body bracing with jackets that prevent progression of the curve.

Stabilization of the long bones in affected patients may help gross motor devlopment (Engelbert et al., 1995). In one study, the gross motor development of 10 children with type III OI was retrospectively studied. All patients were noted to have a severe delay in gross motor development. Interestingly, the sequence of achieving developmental milestones was different as compared with normal individuals. The static milestones, such as complete head control and sitting without support, developed earlier in patients with OI than the dynamic milestones, such as lifting the head in the prone position and rolling over from supine to prone. These authors hypothesize that affected infants protect themselves from developing fractures. They compared the gross motor development in their patients as a function of when they received intramedullary rodding. They found that the patients who underwent intramedullary rodding of the lower extremities before the age of 3.5 years had better neuromotor development. They recommended that before being considered for surgery, affected individuals should be able to sit unsupported. In this series, the median age of achievement of this milestone was 2.1 years. The recommendation, therefore, was that intramedullary rodding should be performed between 2 and 3.5 years of age to permit improved long-term ambulation (Engelbert et al., 1995).

LONG-TERM OUTCOME

Type I OI is the only type in which blue sclerae remain present throughout life. All types of OI put the patient at risk for fractures and scoliosis. The scoliosis may result in decreased cardiopulmonary reserve and predisposition to recurrent respiratory infections. Patients who have dentinogenesis imperfecta have abnormal dentin. The enamel is unable to adhere adequately and chips and erodes easily. Although the teeth are abnormal in appearance, the incidence of dental caries is not increased (Varni and Jaffe, 1984). Presenile hearing loss may develop in early adulthood in patients with type I OI. This is a conductive hearing loss due to the stapes being partially replaced by fibrous tissue.

Patients affected with OI also have an increased incidence of inguinal and umbilical hernias. Hypercalciuria is a common finding that correlates with the severity of the skull disease; renal function and postnatal renal sonographic studies are otherwise normal (Chines et al., 1995).

Paterson et al. (1996) reviewed the life expectancy for 743 patients with OI. Patients with type II, the perinatal lethal form, were excluded from the study. Their patient population included 383 patients with type IA, 77 with type IB, 123 with type III, 90 with type IVA, and 70 with type IVB. Patients with type IA OI had no difference in mortality from the general population. Types IB, IVA, and IVB had a modestly reduced life expectancy as compared with the normal population. Only patients with type III had significant impairment in their life expectancy. Of the 26 deaths reviewed in this study, 19 occurred before the age of 10 years. In a follow-up study, McAllion and Paterson (1996) reviewed 79 causes of deaths in patients affected with OI. Of the 79, 46 were due to respiratory causes and these occurred mainly in patients affected with type III. The respiratory deaths were primarily due to infection, and cardiac failure resulted from kyphoscoliosis. Other causes of death that were directly or indirectly due to OI included basilar invagination of the skull and lethal intracranial bleeding. These authors stress the importance of obtaining prompt care for respiratory infections and prevention of head trauma in affected patients.

GENETICS AND RECURRENCE RISK

In about 90% of cases of OI there is a mutation in either *COL1A1* or *COL1A2* (Byers et al., 2006). The loci *COL1A1* (α_1-chain) and *COL1A2* (α_2-chain) have been mapped to human chromosomes 17 and 7, respectively (Sykes et al., 1986).

The severity of the clinical phenotype is related to the type of mutation, its location on the α-chain, the surrounding amino acid sequences, and the level of expression of the

mutant allele (Cole and Dalgleish, 1995). Point mutations resulting in a substitution of Gly residues in Gly-X-Y amino acid triplets of the triple helical domain of the α_1(I) or α_2 (I) chains are the most frequent mutations. They interrupt the repetitive Gly-X-Y structure that is mandatory for formation of a stable triple helix.

Of affected individuals studied at the molecular level, it has been shown that most babies have their own private de novo mutation in type II OI. Few deletions have been identified. Exon skipping mutations are more common, which usually maintain the translational reading frame and the repetitive Gly-X-Y amino acid triplet structure. Deletions, skipping mutations, and insertions in triple helical domains produce abnormal alignment of the proα-chains. This interrupts the mandatory Gly-X-Y structure and may produce a bulge or a kink in the molecule (Cole and Dalgleish, 1995).

In type I OI, haploinsufficiency of *COL1A1* results in a 50% reduction of type I collagen. Most patients with type I have decreased mRNA levels of *COL1A1* (Willing et al., 1993). In types II, III, and IV there are dominant negative mutations that synthesize abnormal procollagen chains that bind to normal chains, thereby destroying their biologic activity. The dominant negative mutations are more harmful than the null mutations characteristic of type I OI. In fact, the goal of gene therapy is to degrade the mutant mRNA or disrupt the mutant gene to create essentially a null mutation. This would convert the more severe phenotypes seen in types II, III, and IV to a type I phenotype.

Most mutations associated with OI are dominantly inherited. Autosomal recessive phenotypes are rare, except in consanguinous families, and in type VII OI. Even with a negative family history, type II OI that results from an apparently new dominant mutation has an empiric recurrence risk of 7% (Byers et al., 1988). This risk increases significantly for unaffected parents after the diagnosis of a second affected fetus, because it identifies them as mosaic carriers of a mutant allele. Germline mosaicism for a mutation in one of the genes that encodes a chain of type I procollagen is surprisingly common. Both germline mosaicism and somatic mosaicism can occur (Sykes, 1990). In one report, a mutant allele was present in 80% of lymphocytes and 100% of skin fibroblasts of a parent of an affected child. Thus, the mutation must occur very early in embryonic development, before the somatic cell lines and germ cell lines segregate. In a prospective ascertainment of the recurrence risk for couples with one previous affected fetus for whom prenatal diagnostic studies were undertaken, only 1 in 50 pregnancies (2%) was affected (Pepin et al., 1997) (Table 91-3).

Prenatal diagnosis in subsequent pregnancies can be performed by sonography, biochemical, or molecular analysis. In type II OI, transvaginal sonography can readily detect abnormalities during the late first or early second trimester. If the molecular defect is unknown in a specific family, biochemical analysis of the collagen and procollagen molecules in fibroblasts obtained from chorionic villi sampling can provide first trimester prenatal diagnosis in types II, III, and IV OI (Pepin et al., 1997). Specific evidence can be sought of post-translational overmodification of the proα_1(I)-chains of type I procollagen. Cells from chorionic villi produce type I collagen chains with the same electrophoretic abnormalities as skin collagen (Grange et al., 1990). Chorionic villus sampling is the prenatal diagnosis method of choice for families with a positive history of types II, III, and IV OI. In pregnancies at risk for type I OI, identification of reduced amounts of type I collagen is inaccurate. Prenatal diagnosis of type I OI is best achieved by direct mutational analysis (Pepin et al., 1997).

The accuracy of prenatal diagnosis of OI is largely dependent on the prior study of an affected individual in a specific family (Pepin et al., 1997). Diagnostic information is usually available within 20 to 30 days of chorionic villus sampling using biochemical techniques and within 10 to 14 days when molecular analysis is utilized (Pepin et al., 1997).

Table 91-3

Prospectively Ascertained Recurrence Risk in 129 Prenatal Diagnoses of OI

	No. of Cases	Affected	Risk
Type I			
Affected parent	16	11	68%
Type II			
One prior affected fetus	50	1	2%
Two prior affected fetuses	7	2	28%
Type III or IV			
Affected parent	22	11	50%
One prior affected fetus	31	1	3%
Two prior affected fetuses	3	0	—

Campomelic Dysplasia

92 CHAPTER

Key Points

- Distinct skeletal dysplasia characterized by bowing of the long bones of the lower extremity, phenotypic sex reversal, flat face, micrognathia, cleft palate, and renal and cardiac abnormalities.
- Incidence is 0.05 to 1.6 per 10,000 livebirths.
- Sonographic findings include acute femoral angulation, a small bell-shaped chest, and marked micrognathia.
- Differential diagnosis includes osteogenesis imperfecta type II, diastrophic dysplasia, Larsen syndrome, pelvis–shoulder dysplasia, and acampomelic campomelic dysplasia.
- Fetal karyotype is indicated to screen for chromosome 17 rearrangements, which have a better prognosis and to determine chromosomal gender.
- 72% of 46, XY fetuses have female genitalia.
- Delivery at a tertiary center is indicated.
- 95% of affected individuals die either in the perinatal period or during the first year of life.
- Long-term survivors have short stature, recurrent apnea and respiratory infections, progressive kyphoscoliosis, and developmental delay.
- Condition is caused by mutations in *SOX9*, an essential transcription factor in chondrogenesis.
- Campomelic dysplasia is inherited as an autosomal dominant. Rare reports of parent-to-child transmission exist.

CONDITION

Campomelic dysplasia is a distinct clinical and radiologic entity characterized by symmetric bowing of the long bones of the lower extremities, phenotypic sex reversal in some chromosomally male infants, and associated abnormalities including cleft palate, flat facies, micrognathia, hydrocephalus, and renal abnormalities. The term campomelia comes from the Greek *camptos*, meaning bent and *melos*, meaning limbs. Despite the name of the condition, campomelia is not obligatory for a diagnosis of campomelic dysplasia (Ninomiya et al., 1995). MacPherson et al. (1989) described two newborn infants with respiratory distress who demonstrated all of the clinical and radiologic manifestations of campomelic dysplasia except the bent lower extremities. This rare clinical variant is now known as acampomelic campomelia dysplasia (Thong et al., 2000). The various skeletal and extraskeletal manifestations of campomelic dysplasia, including sex reversal, are part of a contiguous gene syndrome that maps to chromosome 17 and is caused by mutations in the transcription factor, *SOX9*.

Classic campomelic dysplasia was first described by Maroteaux et al. (1971) and Bianchine et al. (1971) in independent reports. In a review of 43 affected patients, Hall and Spranger (1980) described four major radiologic features in patients with campomelic dysplasia: characteristic lower-limb bowing, absent or hypoplastic scapulas, nonmineralization of the thoracic pedicles, and narrow, vertical iliac bones (Figure 92-1A). They described other useful diagnostic features of the condition that included hypoplastic cervical vertebrae, widely spaced ischial bones, and absent ossification of the distal femoral and proximal tibial epiphyses. Khajavi et al. (1976) described campomelic dysplasia as a distinct entity consisting of short-limbed dwarfism with pretibial skin dimples, a peculiar facies, cleft palate, hypotonia, absent olfactory bulbs, and respiratory distress ending in neonatal death. These authors suggested that the condition could be classified into three varieties: a long-limbed type, a short-limbed type with craniosynostosis, and a short-limbed type with normocephaly. The long-limbed variety is considered to be the most common (Khajavi et al., 1976).

Figure 92-1 **A.** Postmortem radiograph obtained from a fetus with campomelic dysplasia at 18 to 19 weeks of gestation. Note the bilateral sharp angulation of the femurs, hypoplastic scapulas and narrow, vertical ischial bones. **B.** Postmortem appearance of the same fetus, showing characteristic hypoplastic midface, micrognathia, acute tibial angulation, and bilateral talipes equinovarus deformity.

A unique aspect of this condition is the phenotypic sex reversal. Over half of the apparently female infants have a male, XY, karyotype (Figure 92-2). In one study of 121 reported cases of campomelic dysplasia, 74 individuals had been karyotyped. Of these, 24 were 46, XX and phenotypically female. Of the remaining 50 who were 46, XY, 36 (72%) of them had normal female external genitalia, although a minority of them had some degree of ambiguity (Figure 92-3) (Foster et al., 1994).

Over the past few years, much progress has been made with regard to understanding the underlying molecular mechanisms in campomelic dysplasia. The chromosomal location of the gene has been mapped, the gene involved in the condition has been identified as *SOX9,* and the inheritance pattern has been clarified.

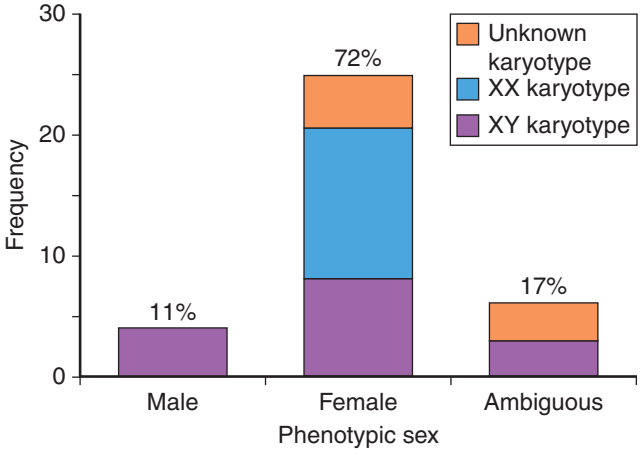

Figure 92-2 Association between phenotypic sex and karyotype in a population of individuals with campomelic dysplasia.

INCIDENCE

The incidence of campomelic dysplasia is 0.05 to 1.6 per 10,000 livebirths (Normann et al., 1993). There is no

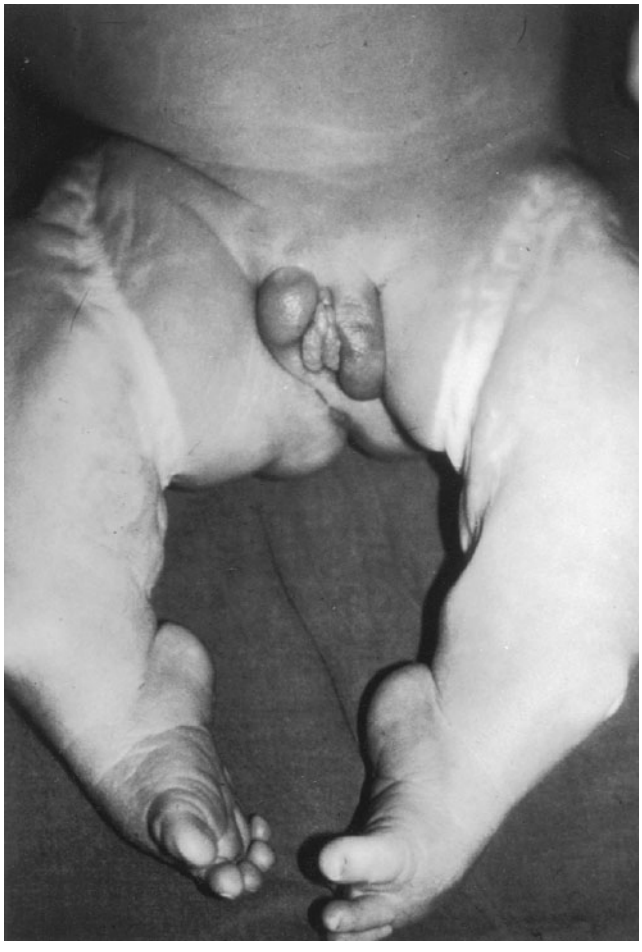

Figure 92-3 An affected infant with campomelic dysplasia, demonstrating skin dimpling over angulation of the femurs, prominent labia majora suggesting ambiguous genitalia, and bilateral clubfeet. *(Reprinted, with permission, from Mansour S, Hall CM, Pembrey ME, Young ID. A clinical and genetic study of campomelic dysplasia.* J Med Genet. *1995;32:415-420.)*

association between the incidence of campomelic dysplasia and advanced maternal or paternal age (Hall and Spranger, 1980; Mansour et al., 1995).

SONOGRAPHIC FINDINGS

Fetuses affected with campomelic dysplasia have a variety of anomalies. The most characteristic is the acute femoral angulation, which typically occurs at the junction of the upper third and lower third of both femora, with resulting symmetrical shortening (Figure 92-4). The femoral angulation is always anterior in the tibia and anterolateral in the femur (Pazzaglia and Beluffi, 1987). Other typical abnormalities include marked micrognathia, a small bell-shaped chest, mild bilateral hydronephrosis, hydrocephalus, cystic hygroma (Foster et al., 1994; Mansour et al., 1995), and clubfeet (Sanders et al., 1994) (Figure 92-1B). Polyhydramnios has been described in 25% to 48% of affected cases (Slater et al., 1985; Mansour et al., 1995). The associated hydrocephalus is thought to be due to atlanto-occipital occlusion (Deschamps et al., 1992). Approximately one fourth of patients may have associated cardiac malformations, which are always of the mild variety (Hall and Spranger, 1980; Mansour et al., 1995). The associated genitourinary anomalies may include hydronephrosis, hydroureter, renal hypoplasia, or renal cysts (Slater et al., 1985; Argaman et al., 1993). The association of hypoplastic scapulae, nonmineralized thoracic pedicles, and vertically narrow iliac bones is unique for this syndrome (Tongsong et al., 2000).

The first successful prenatal diagnoses for this condition occurred in families with a previously affected child. In 1981, Fryns et al. described such a family and successfully diagnosed recurrence of the campomelic dysplasia in a fetus with short, bowed limbs and hydrocephalus at 17 weeks of

Figure 92-4 Sonographic image demonstrating typical femoral angulation seen in campomelic dysplasia. (*Image courtesy of Prenatal Diagnosis Center, Women and Infants' Hospital.*)

gestation. Sonographic examination revealed poorly ossified long tubular bones that were not bowed and massive hydrocephaly. At autopsy the infant was also shown to have a high forehead and micrognathia (Fryns et al., 1981). In families not at risk for campomelic dysplasia, affected infants have been identified by a discrepancy between upper- and lower-limb lengths (Gillerot et al., 1989). Cordone et al. (1989) described a fetus at 26 weeks of gestation with a normal amniotic fluid volume that demonstrated symmetrical anterior bowing of the lower extremities with hypoplasia of the fibulas and talipes equinovarus, hypoplastic scapulas, a bell-shaped chest, and facial abnormalities including a flat nasal bridge and micrognathia.

As in other skeletal dysplasias, an increased nuchal translucency measurement has been demonstrated at 13 weeks' gestation in a fetus that was subsequently shown to have campomelic dysplasia (Michel-Calemard et al., 2004). Three-dimensional ultrasound examination has aided in the diagnosis of campomelic dysplasia (Seow et al., 2004). Surface rendering 3-D studies demonstrate skin dimpling over a convex surface at the point of maximal deformity as well as the characteristic flat face and mid-facial hypoplasia.

DIFFERENTIAL DIAGNOSIS

A prenatal diagnostic overlap occurs between campomelic dysplasia and osteogenesis imperfecta type II (see Chapter 91). This is due to the presence of bowing in the lower limbs, which can be a manifestation of osteogenesis imperfecta. The tibial bowing, however, is more pronounced in campomelic dysplasia (Sanders et al., 1994). Campomelic dysplasia is also accompanied by mild bowing of the femurs. In one report, the authors described three cases of osteogenesis imperfecta in which tibial bowing was present without apparent fractures. They also described two cases of campomelic dysplasia misdiagnosed as osteogenesis imperfecta because the femurs showed an acute angulation that was suggestive of a fracture (Sanders et al., 1994). The presence of additional fetal anomalies – including clubfeet, micrognathia, and hydronephrosis – is more consistent with a diagnosis of campomelic dysplasia than osteogenesis imperfecta.

Other conditions that should be included in the differential diagnosis include diastrophic dysplasia (see Chapter 93). Both campomelic and diastrophic dysplasia share cervical vertebral anomalies, cleft palate, joint dislocations, bilateral talipes equinovarus, and laryngotracheal abnormalities, as well as abnormal ears, micrognathia, and brachydactyly (Hall and Spranger, 1980). Individuals with Larsen syndrome also manifest many of these abnormalities as well as a flat nasal bridge and apparent hypertelorism. Hall and Spranger (1980) recommended comparison of the scapulas, thoracic pedicles, and iliac bones to allow a specific diagnosis of campomelic dysplasia. The following major features of campomelic dysplasia occur with greater than 50% frequency in affected individuals: hypoplastic scapulas, nonmineralized thoracic pedicles, and vertically narrow iliac bones. These are rare findings when seen individually, but pathognomonic for campomelic dysplasia when found in combination (Hall and Spranger, 1980).

Other authors have indicated that in postnatal radiographs, scapular hypoplasia is the most consistent and unique feature. Potential overlap occurs between campomelic dysplasia and pelvis–shoulder dysplasia, which results in symmetric hypoplasia of the iliac wings and scapulas. In this condition, the iliac bones are small and square with flat acetabular roofs, which are different from the narrow iliac bones and steep acetabula of campomelic dysplasia. In pelvis–shoulder dysplasia, the lumbar vertebral bodies are rounded anteriorly, which gives them a bulletlike shape. Lordosis eventually develops in these patients. In campomelic dysplasia, however, the cervical and thoracic vertebral bodies are dysplastic, small, and flattened, and eventually result in development of a thoracic scoliosis. In the chest, the lack of ossification of the thoracic pedicles is the major feature of campomelic dysplasia (MacPherson et al., 1989).

ANTENATAL NATURAL HISTORY

Campomelic dysplasia is caused by mutations in *SOX9*, which is an essential transcription factor in chondrogenesis. It regulates expression of the type II collagen gene, *COL2A1*. In the absence of *SOX9,* there is a complete block in chondrocyte differentiation at the stage of mesenchymal condensation (Bi et al., 1999, 2001). Heterozygous *SOX9* mutant mice have many skeletal symptoms compared to that which are seen in human campomelic dysplasia, including bent bones (Bi et al., 2001). Premature mineralization occurs in many bones, including vertebrae and craniofacial bones. Two critical steps are sensitive to *SOX9* gene dosage: (1) early, at the stage of mesenchymal condensation of cartilage primordia, and (2) later at a step preceding the transition of chondrocytes into hypertrophic chondrocytes.

The various manifestations of campomelic dysplasia are associated with an increased incidence of stillbirth. It is thought that up to 50% of cases are lost during gestation (Slater et al., 1985).

Bone histology in infants affected with campomelic dysplasia suggests an ongoing repair process in the areas of angulation in the femur. New periosteal bone is laid down on the concave side, and remodeling of the mass of woven bone occurs. The process is similar to the healing of malaligned fractures. For most affected individuals, the growth plate cartilage and metaphyses appear normal (Pazzaglia and Beluffi, 1987). Other investigators have identified identical changes occurring in the bend at the diaphysis. Parallel masses of periosteal bone have been demonstrated to extend into the medullary cavity at right angles to the axis of the bone. A triangular wedge of woven bone extends from the cortex into the medulla of the diaphysis (Khajavi et al., 1976).

MANAGEMENT OF PREGNANCY

Fetuses in which campomelic dysplasia is suspected should be referred to a tertiary care center capable of anatomic sonographic diagnosis of the fetus. Fetal karyotyping is indicated for two reasons: to determine the chromosomal gender and prepare the parents for the possibility of phenotypic sex reversal, and to specifically screen for chromosome 17 rearrangements, which are associated with a milder phenotype and a better prognosis (Foster et al., 1994). Once a definitive sonographic diagnosis has been made, the parents should meet with a medical geneticist and/or genetic counselor to discuss the implications of the diagnosis. The overwhelming majority (95%) of cases are lethal during the newborn period or during the first year of life. The poor prognosis should be discussed with the prospective parents, and termination of pregnancy can be offered at less than 24 weeks of gestation.

Rare survivors with campomelic dysplasia have been reported. All affected infants manifest respiratory distress. Delivery at a tertiary care center is therefore indicated. The mean gestational age at delivery is 39.8 weeks (Mansour et al., 1995). There are no specific indications for delivery by cesarean section.

If the parents terminate the pregnancy or delivery results in a stillborn infant, placental material should be collected to establish a fibroblast culture, which can serve as a source of DNA for *SOX9* mutation analysis. Campomelic dysplasia is now considered to be inherited in an autosomal dominant manner. Although the majority of cases occur as a new mutation, occasional cases of parental mosaicism warrant prenatal diagnosis in subsequent pregnancies.

FETAL INTERVENTION

There are no fetal interventions for campomelic dysplasia.

TREATMENT OF THE NEWBORN

A complete physical examination should be performed on all infants in whom campomelic dysplasia is suspected. The physical examination will typically reveal a low-to-normal birth weigh; apparent macrocephaly (mean occipitofrontal circumference, 37 cm) (Argaman et al., 1993); extreme hypotonia; disproportionately short trunk and lower limbs; and flattened face, high forehead, and flattened nasal bridge. The palpebral fissures are narrow and give the appearance of hypertelorism. A cleft of the soft palate is present in two thirds of affected infants (Argaman et al., 1993). In the affected newborn the thighs are held in abduction (see Figure 92-3). The hips are frequently dislocated. There are characteristic subcutaneous dimples present over the bend of the tibia. These dimples result from the loss of subcutaneous tissue secondary to in utero stretching at the point of curvature (Gillerot et al., 1989; Argaman et al., 1993).

Table 92-1

Characteristic Clinical Findings in Campomelic Dysplasia

Bilateral bowing of the long bones of the legs, especially tibia	100%
Talipes equinovarus	100%
Skin dimpling overlying the tibial angulations	99%
Hypoplastic pelvis	97%
Hypoplastic scapulas	92%
Macrocephaly	90%
Cleft palate	50–80%
Scoliosis	70%
Cystic renal disease	33%
Hydrocephalus	23–25%
Polyhydramnios	25–48%

Source: Slater CP, Ross J, Nelson MM, Coetzee EJ. The campomelic syndrome: prenatal ultrasound investigations: a case report. S Afr Med J *1985;67:863-869.*

A complete set of radiographs should be obtained during the newborn period, which will demonstrate the bladeless scapulas, the small bell-shaped chest, the frequent occurrence of only 11 pairs of ribs, and a poorly mineralized sternum. Radiographs may also demonstrate a short first metacarpal (Mansour et al., 1995). The characteristic clinical findings for infants affected with campomelic dysplasia are summarized in Table 92-1.

All affected infants manifest respiratory distress syndrome and generally require mechanical ventilation. Respiratory distress is due to a small thoracic cage with consequent pulmonary hypoplasia, a narrow larynx, and underlying abnormalities of the tracheobronchial cartilage (MacPherson et al., 1989). The majority of patients die during the neonatal period from the respiratory abnormalities.

SURGICAL TREATMENT

Rare survivors with campomelic dysplasia have had severe orthopedic problems that can be treated surgically, including

kyphoscoliosis, hip dislocation, and clubfeet (Gillerot et al., 1989). In one report, a 6.5-year-old girl was described who survived initial respiratory problems and was subsequently treated with a Pavlik harness for subluxation of the hips. She underwent two cervical and two thoracic spinal fusions, a release of complex foot deformities, and had an osteostomy of her right tibia (Ray and Bowen, 1984). At 6.5 years of age, she had the height and weight of a 2.5-year-old child and the bone age of a 3.5-year-old child. She sat at 22 months of age. Despite the multiple orthopedic problems and apparent developmental delay, by age 6.5 years she was able to attend a normal first-grade class. In another report, an 18-year-old high school graduate with normal psychomotor development was described who required plastic surgery and orthodontic treatment to advance her hypoplastic midface (Mintz and Adibfar, 1994). In survivors, aggressive surgical treatment for kyphoscoliosis is now recommended, as this condition is always progressive and affects cardiopulmonary function at a young age (Khoshhal and Letts, 2002).

LONG-TERM OUTCOME

The outcome for most individuals with campomelic dysplasia is poor. Of 81 patients described with the more common long-limbed variety of campomelic dysplasia, 61 were stillborn or died during the first month of life. An additional 13 died between 35 days and 1 year of age. In this report, only 2 patients survived beyond the age of 2 years (Ray and Bowen, 1984). Other authors emphasize that most affected individuals who do not die during the perinatal period die within the first 10 months of life (Slater et al., 1985). Aspiration and severe feeding difficulties are common in affected infants, even while on mechanical ventilatory support. Infants who are on the respirator for prolonged periods tend to die of diffuse alveolar or massive tracheobronchial pulmonary hemorrhage (Argaman et al., 1993). Infants who come off the ventilator have complications of apnea, atelectasis, and pneumonia.

For the 5% of affected individuals who survive beyond the first year of life, the outlook improves somewhat. Infants can still have stridor, retractions, and chronic pulmonary disease, as well as bronchitis and frequent otitis media. In one report, a 5-year-old girl with campomelic dysplasia was described whose condition was extremely unstable during her first year of life, but she eventually experienced a progressive decrease in the number of respiratory infections. Her early childhood years were characterized by marked hypotonia and mental retardation, but surprisingly, at 4 years of age she experienced a dramatic improvement in her development so that she could eventually speak and play and walk. At 5 years of age, however, her size was extremely small for her age (weight, 10.5 kg; height, 89 cm; normal head size of 53.5 cm). The original patient of Maroteaux was again reported on at 17 years of age and was shown to have an IQ of 45, hearing loss, and severe kyphosis (Houston et al., 1983).

Mansour et al. (2002) described 5 long-term survivors with molecular or cytogenetic evidence of campomelic dysplasia. All had disproportionate short stature (<3% for age), recurrent apnea and upper respiratory infections, progressive kyphoscoliosis, mild-to-moderate learning difficulties, and hip dislocation. All 5 had very similar facial features. Other problems included global developmental delay and tracheomalacia that required tracheotomy.

All patients who survive beyond the age of 6 months have also been shown to have a profound hearing loss (Takahasi et al., 1992; Argaman et al., 1993). The deafness is now known to be due to histologic abnormalities in the temporal bone as well as deformities of the vestibular and semicircular canals. In this condition, the endochondral layer of the optic capsule contains no cartilage cells. In addition, the facial nerve follows an aberrant course. The size and position of the ossicles are abnormal (Tokita et al., 1979; Takahasi et al., 1992). Patients affected with campomelic dysplasia have a mixed type of hearing loss. Conductive hearing loss derives from anomalies of the ossicles and frequent otitis media. Sensorineural hearing loss derives from hypoplasia of the cochlea.

GENETICS AND RECURRENCE RISK

It is now known from molecular analyses that campomelic dysplasia is inherited as an autosomal dominant condition, with the majority of patients representing heterozygosity for a new mutation (Rimoin, 1996). Recurrence in families is now thought to be due to rare cases of parental gonadal mosaicism or mildly affected parents with unrecognized symptoms. One case report described a mildly affected mother with a more severely affected daughter who died during the newborn period from respiratory distress (Lynch et al., 1993). In another case, a man with normal intelligence and mild phenotypic and radiologic evidence of campomelic dysplasia had a 46, XY daughter with severe skeletal and neurologic manifestations of the syndrome. On retrospective analysis the father's early medical history was complicated by clubfeet, laryngobronchomalacia, and recurrent chest infections (Savarirayan et al., 2003). These cases demonstrate that there is variable expressivity within families. Therefore, both parents must be examined and questioned for specific mild symptoms of campomelic dysplasia. If a parent is shown to be affected, there is a 50% recurrence risk.

Cytogenetic studies performed in affected patients played a large role in gene mapping of this condition. In one patient with campomelic dysplasia, a de novo paracentric inversion of chromosome 17 was documented (Maraia et al., 1991). This report was followed by the description of a phenotypically female fetus with campomelic dysplasia whose karyotype was 46, XY, (2;17)(q35;q23-24). These authors suggested that the long arm of chromosome 17 was likely to be the site of the gene mutation in campomelic dysplasia (Young et al., 1992). A total of 5 different patients with chromosomal rearrangements in campomelic dysplasia enabled the *SOX9*

gene locus to be mapped to 17q 24.1-25.2 (Tommerup et al., 1993). Interestingly, patients who have the translocation survive longer (Foster et al., 1994). It is now known that the breakpoints involved in the chromosome 17 rearrangements are always 5' to the *SOX9* locus. Pop et al. (2004) used comparative genomic hybridization (CGH) arrays to show that there are cis-acting regulatory elements more than 380 kb upstream of *SOX9*.

The gene *SOX9* encodes a putative transcription factor that is strongly conserved throughout mammalian evolution. *SOX9* is structurally related to the testis-determining factor *SRY*, and is expressed in many adult tissues, fetal testes, and fetal skeletal tissue (Wagner et al., 1994). It is now known that haploinsufficiency for the *SOX9* gene is the cause of campomelic dysplasia and autosomal XY sex reversal. This was proven by demonstration of inactivating mutations of one *SOX9* allele. In one of the cases reported by Wagner et al. (1994), one parent of an affected child was shown to have a low-grade mosaic mutation and had DNA that contained both the normal and mutant *SOX9* genes. Simultaneously, Foster et al. (1994) demonstrated that both campomelic dysplasia and sex reversal were caused by mutations in the *SOX9* gene. They described mutations in a single allele of *SOX9* on chromosome 17 in 6 of 9 patients affected with campomelic dysplasia. These mutations destroyed gene function by causing premature chain termination and loss of one-third of the protein gene product. DNA analysis of parents of affected children demonstrated the absence of similar mutations. Therefore, this conclusively proves that most cases of campomelic dysplasia are new mutations that are inherited as autosomal dominant conditions (Foster et al., 1994).

Campomelic dysplasia arises by point mutations, truncations, and frameshift mutations that impede the ability of *SOX9* to activate target genes during organ development (McDowall et al., 1999). Although many different mutations are known, there is no correlation between genotype and phenotype (Meyer et al., 1997). Acampomelic campomelic dysplasia is also caused by mutations in *SOX9* (Thong et al., 2000).

Prenatal diagnosis is indicated for the rare survivors with mild manifestations of campomelic dysplasia, as their offspring will have a 50% likelihood of recurrence. Their offspring could be more severely affected, as demonstrated by the cases of Lynch et al. (1993) and Savarirayan et al. (2003). For completely normal parents who have previously had an affected fetus or infant with campomelic dysplasia, prenatal diagnosis by sonography is indicated in subsequent pregnancies, although the recurrence risk is extremely low. Parental DNA can be studied to detect rare cases of mosaicism for *SOX9* mutations (Cameron et al., 1996). DNA studies will detect a *SOX9* mutation in 90% to 95% of cases.

93 CHAPTER Diastrophic Dysplasia

Key Points

- Distinct skeletal dysplasia characterized by disproportionate short stature, clubfoot, cleft palate, "hitch-hiker's thumb," and "cauliflower ear."
- Results from mutation in the diastrophic dysplasia sulfate transporter gene, *DTDST* (also known as *SLC26A2*).
- More common in individuals of Finnish ancestry due to a founder effect.
- Sonographic findings are short and curved limbs, micrognathia, clubfeet, abducted and proximally inserted thumbs and great toes, and normal ossification.
- Associated with normal intelligence and postnatal development.
- Autosomal recessive condition.
- Delivery should occur in a tertiary center due to the high incidence of associated airway problems.

CONDITION

Diastrophic dysplasia is a distinct clinical entity characterized by disproportionate short stature, cleft palate, clubfoot, progressive scoliosis, limited joint mobility, proximally placed first metacarpals ("hitch-hiker's thumb"), and cystic degeneration of the pinnae of the ear ("cauliflower deformity") (Figure 93-1) (Lachman et al., 1981). This condition was first described by Lamy and Maroteaux (1960), who used the Greek word *diastrophos*, meaning twisted, to describe the prominent involvement of the feet and spine in this type of dwarfism (Diab et al., 1994).

Diastrophic dysplasia exhibits distinctive histopathology, which consists of cytoplasmic accumulation of glycogen and fat in the chondrocytes, resulting in variability of chondrocyte size, shape, and viability (Diab et al., 1994). There is

Figure 93-1 (*Left*) Postnatal photograph of a 19-week fetus with diastrophic dysplasia, illustrating severe micromelia, bilateral clubfeet, micrognathia, and bilateral hitch-hiker thumbs. (*Right*) Close-up of extreme lateral displacement of thumbs. (*Courtesy of Dr. Joseph Semple.*)

nonuniformity of the cartilage matrix with fibroblast and vascular ingrowth, resulting in fibrotic foci and areas of intracartilaginous calcification (Diab et al., 1994). The abnormalities of the cartilage matrix are considered pathognomonic and are visible with light microscopy. The underlying problem is an excessive amount of collagen deposition within the cartilage matrix rather than a lack of collagen. The excessive deposition of structurally abnormal collagen occurs predominantly in the growth cartilage rather than the resting cartilage (Shapiro, 1992). This cartilage abnormality affects the entire epiphyseal area, which leads not only to shortening of the long bones, but also to extreme malformation of the epiphyseal ends of the bones. This abnormality affects the articular surfaces, causing precocious osteoarthritis (Shapiro, 1992).

The underlying genetic basis of diastrophic dysplasia is the result of a mutation in a novel sulfate transporter gene, known as the diastrophic dysplasia sulfate transporter (*DTDST*) and also, more recently, as *SLC26A2* (Hästbacka et al., 1994, 1996). Impaired function of this gene product leads to undersulfation of proteoglycans in cartilage matrix, which leads to abnormal cartilage formation and results in the disease phenotype (Hästbacka et al., 1994).

INCIDENCE

Diastrophic dysplasia has been observed only in whites. To date, more than 300 patients with diastrophic dysplasia have been described, and interestingly, the majority of them are in Finland (Ryöppy et al., 1992), where the gene for diastrophic dysplasia is unusually common due to an apparent founder effect in this relatively genetically isolated population (Hästbacka et al., 1994). The incidence of diastrophic dysplasia is 1 in 32,600 livebirths in Finland, where it is the most common skeletal dysplasia (Poussa et al., 1991). The carrier frequency is 1 in 90 individuals there.

SONOGRAPHIC FINDINGS

Because of the rarity of this condition in the non-Finnish population, relatively few reports of the prenatal sonographic diagnosis of diastrophic dysplasia exist in the literature (Mantagos et al., 1981; Kaitila et al., 1983; Jung et al., 1998; Tongsong et al., 2002; Wax et al., 2003). The earliest prenatal diagnosis of this condition was made at 13 weeks using

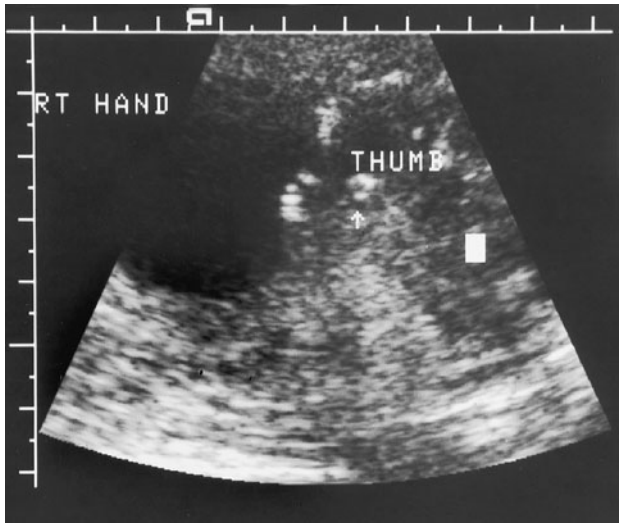

Figure 93-2 Prenatal sonogram of displaced ("hitch-hiker") thumb in a fetus with diastrophic dysplasia.

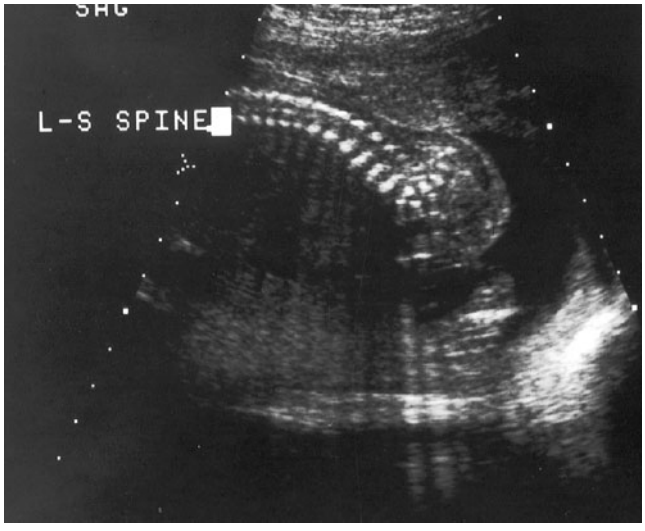

Figure 93-3 Prenatal sonogram demonstrating kyphosis in a fetus with diastrophic dysplasia.

transvaginal sonography (Severi et al., 2003). The prenatal diagnosis of diastrophic dysplasia was first described in 1980, when O'Brien et al. (1980) reported the diagnosis in a family with a previous affected child. Prenatal sonography was performed at 13 weeks 5 days of menstrual age, and revealed a crown-to-rump length of 43 mm, which corresponded to a gestational age of 11 weeks. The study was repeated at 16 weeks of gestation, when the femur length measured 13 mm (normal for gestational age: 19–26 mm). Thus, long bone shortening was retrospectively demonstrated in this condition during the early second trimester (13 weeks 5 days). In this report, fetoscopy demonstrated extremely short and curved limbs in the affected fetus. Examination of the face and oral cavity also showed micrognathia and cleft palate, other findings that are typically seen in diastrophic dysplasia. In another case, also complicated by a positive family history, prenatal sonography performed at 16 weeks of gestation demonstrated abnormally short limbs (less than 3 SD below the mean for gestational age) and lateral projection of the thumbs (Figure 93-2). These findings revealed an affected fetus. These authors recommended assessing fetuses at risk with serial examinations at 16, 20, 24, and 32 weeks of gestation because they were concerned that normal findings at 16 weeks might still be consistent with a diagnosis of an affected infant (Gollop and Eigier, 1987). In another affected case with no family history of diastrophic dysplasia, ultrasound examination performed at 31 weeks revealed severe micromelia (all long bones less than 2 SD below the mean for gestational age), normal amniotic fluid, ulnar deviation of the hands, abducted and proximally inserted thumbs and great toes, bilateral clubfeet, apparent elbow and knee joint contractures, cervical kyphosis (Figure 93-3), and micrognathia. The diagnosis of diastrophic dysplasia was confirmed postnatally (Gembruch et al., 1988).

Other sonographic findings in diastrophic dysplasia include normal skull and vertebral body ossification and occasional scoliosis. In a summary of 18 at-risk pregnancies in Finland, prenatal sonography performed during the second trimester was highly accurate in the diagnosis of this condition (Hästbacka et al., 1993). Of the 18 fetuses at risk, 5 were predicted to be affected and 13 were predicted to be unaffected by long bone measurements. All diagnoses were confirmed by postnatal or post-termination assessment.

More recently, three-dimensional ultrasound studies were compared to two-dimensional studies in a case of diastrophic dysplasia (Sepulveda et al., 2004). The three-dimensional study provided clearer views of the limb anomalies and the facial micrognathia.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes campomelic dysplasia, osteogenesis imperfecta, thanatophoric dysplasia, Kniest dysplasia, and chondrodysplasia punctata.

Other conditions to be considered within the differential diagnosis include pseudodiastrophic dysplasia and atelosteogenesis type II. In pseudodiastrophic dysplasia, patients exhibit a large cranium with midface hypoplasia, long clavicles, short limbs, and platyspondyly (Eteson et al., 1986), but the cauliflower ear characteristic of diastrophic dysplasia does not occur in this condition. The distinguishing features of pseudodiastrophic dysplasia include elbow and proximal interphalangeal joint dislocation and progressive scoliosis in infancy. Joint abnormalities seen in pseudodiastrophic dysplasia respond well to physical therapy. This is not true for diastrophic dysplasia. Pathologically, the two conditions are quite different. In pseudodiastrophic dysplasia the resting cartilage is normal, with no areas of fibrous degeneration in the cartilage matrix of these patients.

In atelosteogenesis type II, patients exhibit marked shortness of limbs with metaphyseal widening, a characteristic bifid humerus, cervical scoliosis, and abnormalities of the digits. Radiographs reveal more severe abnormalities of

the tubular bones of the hands and feet as compared with diastrophic dysplasia (Qureshi et al., 1995). On the other hand, the histologic abnormalities of the resting cartilage in atelosteogenesis type II are similar to those seen in diastrophic dysplasia. This is not surprising, as atelosteogenesis type II is caused by mutations in the same gene that causes diastrophic dysplasia, *DTDST* (Hästbacka et al., 1996).

ANTENATAL NATURAL HISTORY

In one report, Qureshi et al. (1995) described characteristic histopathologic abnormalities seen in three cases of diastrophic dysplasia diagnosed by prenatal sonography. In all three cases there was a negative family history, and routine second trimester sonography diagnosed a nonspecific skeletal dysplasia. All pregnancies were terminated electively and extensively studied, postmortem. Postmortem radiographs demonstrated moderately short long bones with a slight inward bowing. Broad metaphyses were demonstrated, especially in the femurs; mineralization of the bones was normal, and the vertebral bodies had normal widths. The ribs were normal, and there was no scoliosis demonstrated prenatally. On the postnatal radiographs, the characteristic hitch-hiker thumb deformity was easily demonstrated.

Histopathologic studies demonstrated morphologic abnormalities that were very similar to those reported in postnatally diagnosed cases. The predominant changes were demonstrated in the resting cartilage, where chondrocytes were surrounded by a halo of dense-appearing cartilage matrix. The chondrocytic nuclei were larger than normal and some lacunae contained two or more nuclei. Degenerative changes were also seen in the vertebral bodies and tracheal cartilage. Cystic degeneration was demonstrated in the pinnae of the ears, the larynx, and the costal cartilages. These findings clearly demonstrate that the morphologic consequences of the abnormal sulfate transporter gene occur relatively early in fetal life.

No evidence exists for increased in utero mortality due to diastrophic dysplasia.

MANAGEMENT OF PREGNANCY

Pregnancy management will depend on whether there is a family history of a pregnancy previously affected with diastrophic dysplasia. If there is, and if DNA was obtained from the previously affected fetus or infant, DNA analysis should be performed. If DNA is available from a previously affected individual, family studies should be performed prior to planned pregnancy to identify the specific mutation that occurs in the family. A limited number of mutations are present in individuals of Finnish ancestry. For non-Finnish individuals, however, mutations can occur in several places within the diastrophic dysplasia gene. Thus, it is important to identify the mutation that occurs within a specific family. If the family previously had an affected child and DNA was not obtained from the affected individual, prenatal diagnosis can be reliably performed by serial sonography, which is highly accurate in the detection of affected fetuses (Hästbacka et al., 1993).

The more likely scenario is a fetus that has no known family history of diastrophic dysplasia, but has a skeletal dysplasia demonstrated on a sonogram performed for uterine size less than gestational date. If findings characteristic of diastrophic dysplasia are demonstrated by sonography, the potential diagnosis can be discussed with the family. Discussion of the outcome in this condition should include the facts that intelligence is normal and that wide variation in the phenotype of diastrophic dysplasia exists. Reported adult heights include a range of 100 to 159 cm (3 feet 9 inches to 6 feet) (Gembruch et al., 1988), although the mean height in a series of 72 American patients with diastrophic dysplasia was 118 cm (3 feet 11 inches) (Horton et al., 1982). Termination of pregnancy can be offered if the diagnosis is made prior to 24 weeks of gestation. If the family elects pregnancy termination, a complete perinatal autopsy should be performed, because the cartilage abnormalities demonstrated by light and electron microscopy are pathognomonic for this condition. At termination of pregnancy, DNA should be obtained from the fetus or placenta to store for future DNA analysis. There is no indication for cesarean delivery other than for standard obstetrical reasons. Consideration should be given, however, to delivery at a tertiary care center for respiratory support of the newborn. In one report, 12% of patients with diastrophic dysplasia had respiratory difficulties at birth caused by glossoptosis (Rintala et al., 1986).

FETAL INTERVENTION

There are no fetal interventions for diastrophic dysplasia.

TREATMENT OF THE NEWBORN

The characteristic postnatal clinical findings seen in patients with diastrophic dysplasia are summarized in Table 93-1 and shown in Figures 93-4 and 93-5. Because of the high incidence of cleft palate and micrognathia, a neonatologist should be present at the delivery to manage the airway. The lungs are normal and not hypoplastic. Postnatal radiographs can be obtained to confirm the diagnosis (Figure 93-6). They may demonstrate calcification of the pinnae, precocious calcification of the larynx and costal cartilage, marked epiphyseal irregularities, delayed secondary ossification centers, and extreme shortening of the long bones (Diab et al., 1994). A clinical geneticist should be consulted for confirmation of the diagnosis and to provide genetic counseling for the family. The incidence of neonatal mortality is increased because of respiratory insufficiency related to tracheal cartilage weakness (Gustavson et al., 1985). After the newborn period, the lifespan is normal.

Table 93-1

Clinical Findings in Diastrophic Dysplasia

Cleft palate
Cystic changes in pinnae ("cauliflower" ear)
Lordosis, scoliosis
Joint limitation
Rhizomelic and/or mesomelic shortening
Ulnar deviation of hand
Shortened ovoid first metacarpal ("Hitch-hiker" thumb)
Clubfoot deformity
Symphalangy

Modified from Lachman et al. 1981

LONG-TERM OUTCOME

Patients with diastrophic dysplasia exhibit normal intelligence and development. Long-term medical problems include short stature, cleft palate, scoliosis (Remes et al., 2001), difficulty walking, and the need for osteotomies for hip, knee, and foot contractures (Shapiro, 1992). Specific growth curves for height are available for patients with diastrophic dysplasia (Horton et al., 1982).

In one report, 95 Finnish patients with diastrophic dysplasia were studied until 79 years of age. Of these, 41 (43%) had an open cleft palate and surgery was required in 37 of these patients. An additional 30 (32%) had submucous cleft palate or microforms of cleft palate. In these patients, no hypernasality of speech was noted. Only 16 (17%) of patients had a normal palate. Most patients had micrognathia (Rintala et al., 1986).

Figure 93-4 Postnatal photograph of the facial features seen in a newborn with diastrophic dysplasia. (*Photograph courtesy of Dr. Jodi Hoffman.*)

Figure 93-5 Postnatal photograph of the lower extremities of a newborn with diastrophic dysplasia, showing clubfeet and displaced great toe. (*Photograph courtesy of Dr. Jodi Hoffman.*)

In another study of a large cohort (101 patients) with diastrophic dysplasia, one-third were noted to have cervical kyphosis. Three of these cases resolved spontaneously before 5 years of age. Scoliosis was demonstrated in 49% of females and only 22% of males with diastrophic dysplasia. Only two of these patients required operation. In addition, spina bifida occulta was demonstrated in 73% of females and 59% of males (Poussa et al., 1991). Spinal involvement may be severe in affected patients, resulting in odontoid hypoplasia and C1–C2 subluxation. Atlanto-axial instability has also been reported (Richards, 1991; Diab et al., 1994). Spinal stenosis with cord compression can lead to neurologic complications (Gembruch et al., 1988; Diab et al., 1994). Joint changes are progressive in nature and painful osteoarthroses and joint contractures can develop at an early age (Hästbacka et al., 1994).

A wide spectrum of foot deformities exists in patients with diastrophic dysplasia. In one study of 102 patients, 43% were demonstrated to have a foot with a tarsal valgus deformity and metatarsus adductus. An additional 29% of patients had equinovarus adductus and 8% had equinus deformity. Sixty-three percent of feet studied were plantigrade (Ryöppy et al., 1992). These authors noted that the abnormality of cartilage in diastrophic dysplasia results in cartilage that is softer than normal. Thus, the cartilaginous parts of the skeleton tend to become progressively deformed with weight bearing. This particularly involves the feet, hips, and knees of affected patients. MRI studies have demonstrated degenerative changes in the articular cartilage of the knees from 6 years of age (Peltonen et al., 2003). After growth has been completed, total knee replacement may result in significant functional improvement. In a study of walking ability in adults with diastrophic dysplasia, 82% of affected individuals drove

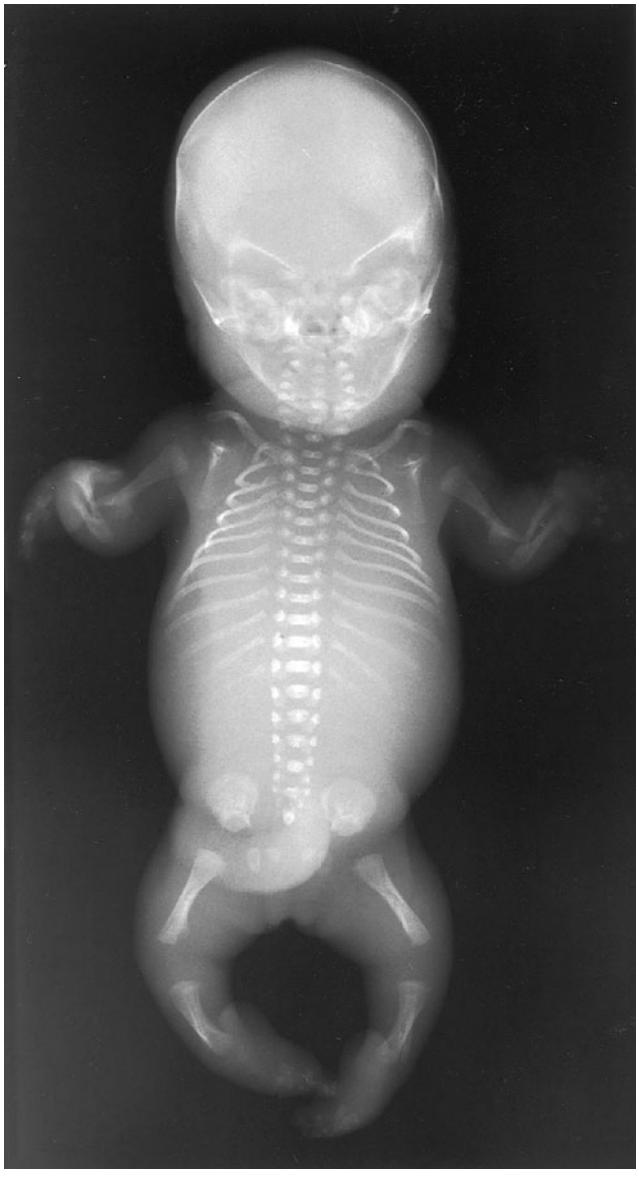

Figure 93-6 Postmortem radiograph of the fetus shown in Figure 93-1.

their own (adapted) car as their primary method of transportation (Remes et al., 2004)

Sexual development is normal in patients with diastrophic dysplasia and there is no indication that fertility is reduced.

GENETICS AND RECURRENCE RISK

Diastrophic dysplasia is inherited as an autosomal recessive trait with a wide variability of expression, even among siblings. The causative gene in diastrophic dysplasia, *SLC26A2* maps to chromosome 5q32-33. (Hästbacka et al., 1990, 1991). More than 30 different disease-associated mutations have been identified in the *SLC26A2* gene (Dawson and Markovich, 2005). Mutations in *SLC26A2*, also known as the diastrophic dysplasia sulfate-transporter gene (*DTDST*), lead to four different chondrodysplasias. Impaired function of this gene product leads to undersulfation of proteoglycans in the cartilage matrix. It has been demonstrated that the mRNA for this gene is minimally present in Finnish patients. Evidence of deficient sulfate transport has been shown in skin fibroblasts from an affected patient (Hästbacka et al., 1994). Population-based screening is possible in Finland because of the high carrier frequencies due to a founder effect.

The disorders atelosteogenesis type II, achondrogenesis type IB (see Chapter 97), and multiple epiphyseal dysplasia are also caused by mutations in the *DTDST* gene (Hästbacka et al., 1993; Superti-Furga, 1994; Superti-Furga et al., 1996). All four chondrodysplasias appear to demonstrate a correlation between genotype and phenotype. The most severe disorder, achondrogenesis type IB, always shows homozygosity for null mutations in the coding regions of both alleles (Karniski, 2001). Patients with atelosteogenesis type II have a null mutation on one allele and an intermediate or near-normal mutation on the opposite allele. Most individuals with diastrophic dysplasia or multiple epiphyseal dysplasia have 2 mutations with intermediate or near-normal sulfate transport activity (Karniski, 2001). This is presumably the reason that the phenotypes associated with diastrophic dysplasia and multiple epiphyseal dysplasia are milder.

First trimester prenatal diagnosis has been performed successfully by DNA-based diagnosis for five fetuses at risk because of a positive family history. In fetal DNA obtained by chorionic villus sampling at 10 weeks, three fetuses were predicted to be unaffected and two were predicted to be affected with >95% probability. These diagnoses were considered to be concordant with the sonographic findings and were ultimately confirmed by analysis of DNA obtained at termination or after the birth of the infant (Hästbacka et al., 1993).

94 CHAPTER Ellis–van Creveld Syndrome

Key Points

- Autosomal recessive condition that results in short-limbed dwarfism, polydactyly, congenital heart disease, oral frenulae, defective teeth, and generally normal intelligence.
- Thirty percent of cases occur in consanguineous families.
- Differential diagnosis includes Jeune syndrome (asphyxiating thoracic dystrophy), short-rib polydactyly syndrome, achondroplasia, and Weyers acrodental dysostosis.
- Karyotype of affected individuals is usually normal.
- Caused by genetically heterogenous mutations in two genes, *EVC* and *EVC2*, that are next to each other on chromosome 4p16.
- Compatible with long-term survival.

CONDITION

Ellis–van Creveld syndrome is a recessively inherited single-gene disorder that results in short-limbed dwarfism, polydactyly, cardiac abnormalities in 50% to 60% of cases, fingernail dystrophy, oral frenulae, and defective teeth. It was first described in 1940 (Ellis and van Creveld, 1940). The other name for the condition, chondroectodermal dysplasia, does not adequately describe the extent of tissue involvement. Ellis–van Creveld syndrome is characterized by multisystem abnormalities, encompassing: (1) ectodermal dysplasia, affecting the teeth, nail, hair, gums, and lips but not the skin or sweat glands; (2) mesodermal involvement, affecting bone growth and shape, formation of the heart, and occasionally, the kidneys; and (3) endodermal involvement, affecting formation of the lungs and liver (Blackburn and Belliveau, 1971). At least three of the four following criteria are required for diagnosis: ectodermal dysplasia, chondrodysplasia, polydactyly, or the presence of congenital heart disease (Hill, 1977).

The chondrodystrophy in this condition is manifested by shortening of the extremities, with the distal segments more markedly affected than the proximal segments. In addition, there is metaphyseal thickening of the long bones, and curvature of the weight-bearing bones (Lynch et al., 1968). In Ellis–van Creveld syndrome, the fibula is usually 50% of its normal length (Feingold, 1966). Pathologic studies performed on long bones in affected patients reveal a decreased number of cartilage cells in the cartilage plate and a disorganized columnar arrangement of the chondrocytes (Blackburn and Belliveau, 1971).

Distinctive cardiac abnormalities are found in this syndrome, such as single atrium or large atrioseptal defect (Blackburn and Belliveau, 1971). Other cardiac abnormalities associated with this condition include aortic atresia, hypoplastic ascending aorta, and hypoplastic left ventricle (Blackburn and Belliveau, 1971).

Speculation exists as to whether King Richard III of England (1452–1485) had Ellis–van Creveld syndrome. He was the product of a consanguineous union, which makes an autosomal recessive condition more likely. In their writings, both Shakespeare and Sir Thomas Moore alluded to the presence of neonatal teeth, short stature, a skeletal dysplasia, and a crooked back when describing Richard III (Aird and McIntosh, 1978).

INCIDENCE

Ellis–van Creveld syndrome has been described in both sexes and all ethnic groups. The incidence of the syndrome is approximately 1 in 60,000 livebirths (Zangwill et al., 1988). It is notable that the syndrome is much more common in highly inbred genetic isolates. The birth frequency of Ellis–van Creveld syndrome is 5 in 1000 livebirths in the old-order Amish population of Pennsylvania (McKusick et al., 1964; Goldblatt et al., 1992). McKusick et al. described 52 cases of Ellis–van Creveld syndrome in 30 sibships in Lancaster County, Pennsylvania. They estimated that 13% of the Amish population was heterozygous for the gene mutation that resulted in Ellis–van Creveld syndrome (McKusick et al., 1964). All affected members can trace their lineage to one founding couple who emigrated to the United States during the 18th century from Southwestern Germany (McKusick, 2000). Other relatively isolated populations have also described an increased incidence of Ellis–van Creveld syndrome. For example, the incidence of Ellis–van Creveld syndrome in Western Australian aborigines is 1 in 6123 livebirths. This population has a calculated carrier frequency of the gene mutation of 1 in 39 individuals, making the Western Australian aborigines the second most common group worldwide to carry the mutation (Goldblatt et al., 1992). Also, a relatively high incidence of the disorder has been reported in an inbred rural Brazilian community (Oliveira da Silva et al., 1980).

SONOGRAPHIC FINDINGS

Sonographic findings that have been described in fetuses with Ellis–van Creveld syndrome include short long bones with normal density, a narrow thorax, appropriate weight for gestational age, and the presence of hand polydactyly, with the malformed finger usually occurring on the ulnar side (Guschmann et al., 1999; Tongsong and Chanprapaph, 2000) (Figure 94-1). Polydactyly of the feet only occurs in 10% of cases (Bui et al., 1984; Qureshi et al., 1993). Congenital heart disease, manifesting as an atrioseptal defect, ventriculoseptal defect, or a single atrium occurs in 50% to 60% of cases (Oliveira da Silva et al., 1980; Zangwill et al., 1988). Two

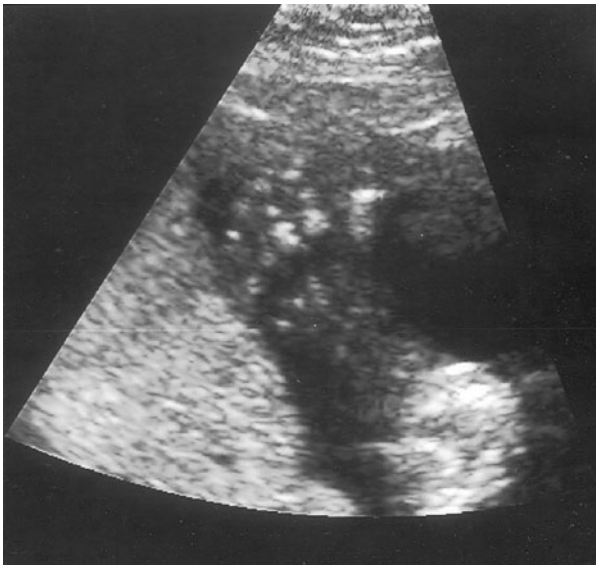

Figure 94-1 Prenatal sonographic image of a hand with polydactyly. The extra digit on the ulnar side is a characteristic finding in patients with Ellis–van Creveld syndrome.

patients have been described with Ellis–van Creveld syndrome and Dandy–Walker malformation (Zangwill et al., 1988), but, in general, central nervous system defects are not associated with the condition.

The earliest prenatal diagnosis of Ellis–van Creveld syndrome was made at 12 weeks in a family at risk for the condition (Dugoff et al., 2001). Both hands were noted to have polydactyly and there were no normal septal structures in the fetal heart. Increased nuchal translucency (NT) measurement has been reported in association with Ellis–van Creveld syndrome (Venkat-Raman et al., 2005).

The combined use of fetoscopy and ultrasound examination for prenatal diagnosis of Ellis–van Creveld syndrome was described in two families at risk for the condition due to previously affected offspring. In one case, sonography demonstrated a shortened femur and humerus. Fetoscopy permitted the visualization of the left hand, which had a well-formed sixth digit. On the basis of these findings, a presumed diagnosis of Ellis–van Creveld syndrome was made, and the condition was verified after termination (Mahoney and Hobbins, 1977).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes Jeune syndrome (asphyxiating thoracic dystrophy and short-rib polydactyly syndrome (see Chapter 95). Patients with Jeune syndrome may have similar radiologic and sonographic features, but do not have polydactyly, nail dystrophy, or the oral findings that are considered pathognomonic of Ellis–van Creveld syndrome. Also, the narrow chest seen in Jeune syndrome is less severe in Ellis–van Creveld syndrome. Jeune syndrome is also associated with cystic renal dysplasia. Another consideration in the prenatal diagnosis of Ellis–van Creveld syndrome is achondroplasia (see Chapter 89) but, in achondroplasia, there is more striking proximal shortening of the limbs. Ellis–van Creveld syndrome is characterized by mild micromelia and distal shortening of the limbs. In the postnatal differential diagnosis, ectodermal dysplasia might be considered for a patient with mild features of Ellis–van Creveld syndrome. However, patients affected with ectodermal dysplasia have completely normal bone growth and morphology and their defects are limited to the hair, teeth, nails, and sweat glands. Characteristically, patients with ectodermal dysplasia do not have polydactyly. Finally, Weyers acrodental dyostosis is in the differential diagnosis. It presents with polydactyly and similar heart defects to Ellis–van Creveld but is not associated with short stature.

ANTENATAL NATURAL HISTORY

Little is known about the antenatal natural history of Ellis–van Creveld syndrome. The histopathology of affected fetal cartliage shows disorganization of chondrocytes in the physeal growth plate (Qureshi et al., 1993).

MANAGEMENT OF PREGNANCY

For fetuses in which Ellis–van Creveld syndrome is suspected, a complete anatomic scan is indicated at a center capable of performing a detailed anatomic survey of the fetus. The chromosomes are normal in Ellis–van Creveld syndrome, so there is no indication to perform fetal karyotyping. Cesarean section should be performed only for the standard obstetric indications. This condition is compatible with postnatal survival outside the womb. Because of the narrowing of the chest seen in this condition, there is significant potential for respiratory distress in the newborn. Therefore, we recommend that the infant be delivered in a tertiary care center to permit resuscitation by a skilled neonatologist and evaluation for heart defects. An individual capable of mechanically ventilating the newborn should be present at the delivery.

FETAL INTERVENTION

There are no fetal interventions for Ellis–van Creveld syndrome.

TREATMENT OF THE NEWBORN

A newborn affected with Ellis–van Creveld syndrome can present in severe respiratory distress, so as stated above, a person trained in newborn resuscitation and endotracheal intubation should attend the delivery (Simon and Young, 1986).

A complete physical examination is indicated at birth. Typically, patients with Ellis–van Creveld syndrome have a normal birth weight, but a length that is less than the third percentile for gestational age (Reddy and Madenlioglu, 1967). Physical findings that may be present in the newborn include sparse hair, the suggestion of a cleft lip with a narrow upper lip, and characteristic oral findings. These include an abnormally short upper lip bound down by multiple frenulae, or "lip tie." The superior gingivolabial sulcus may be entirely missing or may be obliterated (Feingold, 1966). This finding is diagnostic for Ellis–van Creveld syndrome in an infant with a skeletal dysplasia. Other oral findings include a serrated or notched alveolar process and the presence of neonatal teeth (Mintz et al., 2005). Affected patients may have deep-set hypoplastic nails, cryptorchidism, epispadias, hypospadias, and clubfoot. Occasional patients have coloboma of the iris or strabismus.

Patients in whom Ellis–van Creveld syndrome is suspected should have a skeletal survey, which may demonstrate the presence of squat pelvic bones. The base of the iliac bones has a trident configuration in the acetabular region, similar to that seen in Jeune syndrome (Cremin and Beighton, 1974). The thoracic cage is less narrowed than in Jeune syndrome. In addition, patients have micromelia, and the metaphyses have a dumbbell appearance due to flaring of the lower ends. In the hand films, there is polymetacarpalia and polydactyly

(Cremin and Beighton, 1974; Taylor et al., 1984). The skull and spine are usually within normal limits.

Patients in whom Ellis–van Creveld syndrome is suspected should also have an echocardiogram and a cardiac consultation because of the high incidence of associated congenital heart disease. Ventriculoseptal defect is the most common abnormality, followed by atrioseptal defect, which may be large enough to effectively create a single atrium. Additional abnormalities seen in this condition include cleft mitral and tricuspid valves, an atrioventricular communis defect, and total anomalous pulmonary venous return (Lynch et al., 1968).

SURGICAL TREATMENT

Patients affected with Ellis–van Creveld syndrome may require hand surgery to remove the extra digits. These digits are usually associated with additional metacarpals, and the surgery may be complex (Feingold, 1966). Because of the high incidence of dental abnormalities, dental surgery may be required, and missing teeth may need to be replaced with dental prostheses. Patients who are affected with congenital heart disease may require cardiac surgery.

LONG-TERM OUTCOME

The overall prognosis for patients affected with Ellis–van Creveld syndrome is related to the presence or absence of cardiac abnormalities. Patients who do not have cardiac disease have a much better long-term prognosis. Pulmonary deaths associated with this condition are unusual, although they have been attributed to underlying abnormalities in the tracheobronchial tree (Lynch et al., 1968). Survivors are generally healthy except for limb bowing and joint pain (Simon and Young, 1986). Adults with this condition have moderately disproportionate short stature and achieve an adult height of between 107.5 and 150 cm (Simon and Young, 1986). Multiple case reports exist in the literature of functional adults with this condition. Mental retardation is the exception rather than the rule. Most adults described in the literature with this condition have average intelligence (Goor et al., 1965; Hill, 1977).

The long-term issues for affected patients include orthopedic problems, such as genu valgum (knock knees) and wrist problems. Affected adults are unable to make a tight fist due to the relatively long metacarpals (Reddy and Madenlioglu, 1967). In addition, an extracarpal bone is present in the wrists of all patients older than 5 years of age (Taylor et al., 1984). The carpal bones are deformed in this condition. Fusions occur between the capitate and hamate bones of the wrist. A medial supernumerary bone is present in the distal row of carpal bones. The fusions that occur between the supernumerary bones and the hamate and capitate bones may be a unique finding in Ellis–van Creveld syndrome (Taylor et al., 1984).

GENETICS AND RECURRENCE RISK

Ellis–van Creveld syndrome is caused by a single-gene mutation and is inherited in an autosomal recessive pattern. Thirty percent of cases occur in consanguineous families (Feingold, 1966). Results of chromosome analysis have been normal in patients affected with this condition (Goor et al., 1965). One case has been reported resulting from segmental uniparental disomy of chromosome 4 (Tompson et al., 2001).

Mutations in two genes have been identified in Ellis–van Creveld syndrome: *EVC* and *EVC2* (Ruiz-Perez et al., 2000, 2003). *EVC* and *EVC2* map to chromosome 4 band p16 (McKusick et al., 1996; Polymeropoulos et al., 1996). These two genes lie in a head-to-head configuration that is conserved in species from fish to humans. This gene is expressed in vertebrae and limb bones, but also in embryonic kidney. Affected individuals with mutations in *EVC* and *EVC2* are phenotypically indistinguishable from each other. There have been several case reports of unilateral postaxial polydactyly in parents and unaffected siblings of family members who have Ellis–van Creveld syndrome. It has been postulated that polydactyly may be a manifestation of the heterozygote in this condition (Fryns, 1991). Interestingly, another disorder, Weyers acrodental dysostosis, is also caused by mutations in *EVC*. Weyers acrodental dysostosis is milder than Ellis–van Creveld syndrome and is not associated with short stature. It is inherited as an autosomal dominant condition. Symptoms include heart defects and polydactyly (Ruiz-Perez et al., 2000).

For the family who has had a previously affected child with Ellis–van Creveld syndrome, the recurrence risk is 25%. At present, prenatal diagnosis in families at risk is most commonly performed by prenatal sonography, although the diagnosis has been made by embryoscopy or fetoscopy (Bui et al., 1984). Prior to the identification of the disease gene, linkage markers were used to diagnose a heterozygous (clinically unaffected) fetus with a 96% chance of accuracy (Torrente et al., 1998). Now that the disease genes are known, every attempt should be made to perform DNA testing to identify the specific familial mutation. Once that has been identified, prenatal DNA diagnosis can be performed in subsequent pregnancies by chorionic villus sampling or amniocentesis.

95 CHAPTER

Short-Rib Polydactyly Syndrome

Key Points

- Refers to a group of rare, generally lethal skeletal dysplasias that have short limbs, short ribs, and polydactyly. Clinical overlap exists between the four subtypes.
- Extremely rare in the general population.
- Differential diagnosis includes Ellis–van Creveld syndrome, asphyxiating thoracic dystrophy (Jeune syndrome), Meckel–Gruber syndrome, and trisomy 13.
- All affected infants with short-rib polydactyly syndrome have severe pulmonary hypoplasia that prevents extrauterine survival.
- Chromosomes are usually normal. Genes responsible for these conditions have not yet been identified.

CONDITION

The short-rib polydactyly syndromes comprise a group of rare, generally lethal skeletal dysplasias. Much debate exists within the clinical genetics community as to the appropriate subclassifications, if any, for these conditions. Sonographic characteristics common to all the subtypes of the short-rib polydactyly syndromes include short horizontal ribs and long tubular bone changes that result in severe micromelia. Most of the conditions have associated polydactyly of the feet and hands. A variety of organ anomalies can also accompany this condition (de Sierra et al., 1992).

The short-rib polydactyly syndromes (SRPS) have been divided into four types. Type I SRPS (Saldino–Noonan syndrome) was first described in 1972 (Saldino and Noonan, 1972). It is characterized by extremely short bones with pointed and narrowed metaphyses. The ribs are also extremely short, causing compression of the developing lungs. This eventually results in severe pulmonary hypoplasia. Saldino–Noonan syndrome is also associated with more severe systemic abnormalities than exist in some of the other subtypes. These abnormalities include congenital heart disease, anorectal anomalies, and cysts in the kidneys. Polydactyly is present in more than 95% of cases of type I SRPS (Keating et al., 1989).

Type II SRPS (Majewski syndrome) was first described in 1971 (Majewski et al., 1971). These patients have very short ribs, severe pulmonary hypoplasia, micromelia, and polydactyly. A distinguishing feature of the syndrome is the presence of a median or midline cleft lip with or without cleft palate. These patients also have a very high frequency of central nervous system abnormalities (Lurie, 1994). The most common central nervous system abnormalities seen in Majewski syndrome include pachygyria, small cerebellar vermis, and absent olfactory bulbs (Martínez-Frías et al., 1993). Other central nervous system changes that have been demonstrated in type II SRPS include arachnoid cysts, agenesis of the corpus callosum, and arrhinencephaly (Prudlo et al., 1993). In addition to the midline cleft lip and cleft palate, patients with Majewski syndrome can have a cleft tongue, oral frenulae, natal teeth, and abnormalities of the epiglottis (Knapp et al., 1990).

Type III SRPS (Verma–Naumoff syndrome) was first described in 1977 (Verma et al., 1975; Naumoff et al., 1977). Patients with this subtype clinically resemble patients with type I because of the absence of cleft lip. These patients have the typical long narrow thorax with pronounced rib shortening, shortened long bones, and polydactyly. Their long bones can be distinguished from those in type I by the presence of the metaphyseal spurs (Figures 95-1 and 95-2). In addition to the presence of the spurs, there is a diagnostic shortening of the base of the skull. Patients with type III SRPS have small and poorly ossified vertebral bodies (Naumoff et al., 1977). The chondro-osseous histopathology is qualitatively similar in SRPS types I and III. The essential abnormality is a shortened or absent zone of proliferative chondrocytes with a loss of columnization (Sillence et al., 1987). In SRPS type II, shortening of the proliferative columns and irregularity in the columnization is not as marked as it is in types I and III.

Type IV SRPS (Beemer–Langer syndrome) was described in 1983 (Beemer et al., 1983). It clinically resembles type II SRPS, but the distinguishing feature is the general lack of polydactyly (Chen et al., 1994). Patients with type IV SRPS have the midline cleft lip, but the shape of the tibia differs significantly from that seen in the Majewski syndrome. Pathologic studies from patients with type IV SRPS reveal a disorganized physeal growth zone with a prominent zone

of hypertrophy that is composed of closely arranged large chrondrocytic lacunae (Chen et al., 1994).

Although each has distinguishing clinical symptoms, much overlap exists between the subtypes of SRPS (Figure 95-3) (Sarafoglou et al., 1999). There are multiple case reports in the literature describing patients with features of each subtype that defy definitive classification (Bernstein et al., 1985; Yang et al., 1991; Tsai et al., 1992; Wu et al., 1995). Debate in the literature persists as to whether or not this group of disorders represents one entity with a continuous spectrum of clinical manifestations (Sarafoglou et al., 1999). Controversy also exists about whether the different subtypes of SRPS are the result of point mutations occurring at different loci, different alleles at a single locus, or variability in the expression of the same mutant gene (Martínez-Frías et al., 1993). In one paper, Bernstein et al. (1985) argued that the SRPS subtypes represent a single entity with varying expressivity. It is hoped that when the mutant gene or genes responsible for this condition are identified, the controversy regarding classification will be settled by molecular analysis.

INCIDENCE

The SRPSs are extremely rare skeletal dysplasias. In the database of the Latin-American collaborative study of congenital malformations, representing 349,470 livebirths and stillbirths, no cases of short rib polydactyly were described (Orioli et al., 1986). In another report, evaluating the accuracy of prenatal diagnosis of skeletal dysplasias, there were eight cases of SRPS described in a study population of 226 stillbirths or fetuses with a prenatal diagnosis of skeletal dysplasia (Sharony et al., 1993). SRPS, therefore, is extremely rare in the general population but may represent 4% of fetuses evaluated in a perinatal center for a presumed skeletal dysplasia.

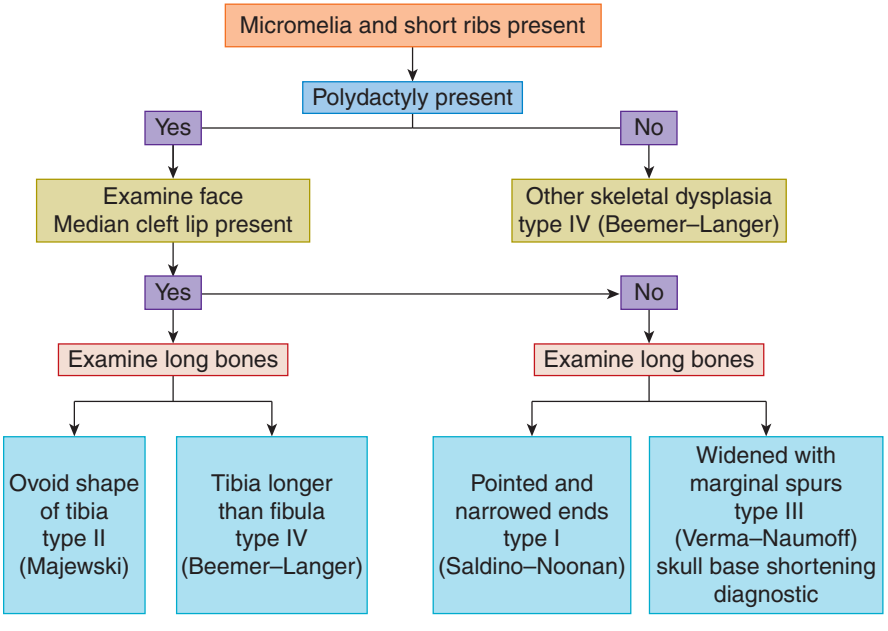

Figure 95-3 Approach to the sonographic diagnosis of the different short-rib polydactyly syndromes.

SONOGRAPHIC FINDINGS

Prenatal diagnosis by two-dimensional sonography has been reported for all of the subtypes of SRPS. Three-dimensional sonographic studies have been described in types II and III (Viora et al., 2002; Chen et al., 2005). Prenatal sonographic studies appear to be highly accurate in the setting of a family history that is positive because of a previously affected child. Prenatal diagnosis has also successfully been performed even in the setting of a negative family history (Meizner and Bar-Ziv, 1985; Benacerraf, 1993).

Prenatal diagnosis of type I SRPS has been described both in the first and early third trimesters (Hill and Leary, 1998; Meizner and Bar-Ziv, 1989). In the case ascertained at 13 weeks, a narrow chest, micromelia, polydactyly, and anasarca were seen on transvaginal sonography (Hill and Leary, 1998). In the case ascertained in the third trimester, a singleton fetus was reported with a markedly narrow thorax, severely shortened long bones with pointed metaphyses, polydactyly on both hands, a markedly bulging forehead, a large ventricular septal defect, a small penis, severe polyhydramnios, mild hydrops, and hypoplastic vertebral bodies (Meizner and Bar-Ziv, 1989). The prenatal diagnosis of type II SRPS is characterized by polyhydramnios, shortened long bones, and very short ribs extending less than halfway around the fetal thorax (Thomson et al., 1982; Gembruch et al., 1985; Benacerraf, 1993). This may give the heart a disproportionately large appearance within the thorax. In one report, the median cleft lip was visualized antenatally. In type II SRPS, the tibias have a diagnostic ovoid shape.

Prenatal diagnosis of type III SRPS consists of the typical findings of severe micromelia, narrowed thorax, short ribs, postaxial polydactyly, and severe polyhydramnios with mild edema (see Figure 95-1). The most useful diagnostic feature for discriminating type III from type I is that the ends of the long bones appear widened, with the presence of marginal spurs (see Figures 95-1 and 95-2). In addition, cases of type III SRPS demonstrate hypoplastic vertebral bodies with increased intervertebral spaces (Meizner and Bar-Ziv, 1985; Meizner and Barnhard, 1995). A fetus with type III SRPS has also been described with complete situs inversus and hypospadias (de Sierra et al., 1992). High airway obstruction due to epiglottal hypoplasia has been reported in type III SRPS (Golombeck et al., 2001; Chen et al., 2005).

Distinguishing type IV from type II SRPS is extremely difficult antenatally. In one case report, a fetus at 23.5 weeks of gestation was visualized with ascites, an extremely narrow thorax, short limbs, a flat midface with a median cleft lip, but no polydactyly. This patient was demonstrated on postmortem examination to have short intestines and pyloric stenosis (Balci et al., 1991). The differentiation between type II and type IV SRPS became even more confused with the report of Yang et al. (1991), who described a 30-week-old fetus with an antenatal diagnosis of SRPS but a postmortem diagnosis of Beemer–Langer syndrome with polydactyly. This fetus also had cerebral anomalies, a small heart, and ambiguous genitalia. Recently, transvaginal sonography has been used to diagnose two fetuses with type IV SRPS in the early second trimester (den Hollander et al., 1998).

Figure 95-3 illustrates a sonographic approach to the identification of the different SRPSs. Once the severe micromelia and short ribs have been demonstrated, the fetal hands and feet should be evaluated for the presence of polydactyly (Meizner and Barnhard, 1995). If polydactyly is absent, this could represent a different skeletal dysplasia, although type IV SRPS (Beemer–Langer syndrome) does not typically include polydactyly. A specific attempt should be made to examine the fetal face, because the presence or absence of a median cleft lip will help to separate types II and IV from types I and III SRPS. If a median cleft lip is present, then the diagnosis is either type II or IV SRPS. If the fetal face is completely normal, then the diagnosis is either type I or III. Examination of the long bones can help to further discriminate type II from type IV and type I from type III, because each of these subtypes has a characteristic long bone appearance on sonography (Cooper and Hall, 1982; Sillence et al., 1987; Yang et al., 1991; Meizner and Barnhard, 1995).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for a fetus with severe micromelia and short ribs with evidence of polydactyly includes chondroectodermal dysplasia (Ellis–van Creveld syndrome) (see Chapter 94), asphyxiating thoracic dystrophy (Jeune syndrome), Meckel–Gruber syndrome, and trisomy 13 (Meizner and Bar-Ziv, 1985) (see Chapter 129). Trisomy 13 can easily be differentiated from the other syndromes by chromosomal analysis. Fetuses with trisomy 13 generally do not manifest severe skeletal dysplasia. Polydactyly may be present, but the long bones are generally within the normal range or minimally shortened as compared with fetuses at the same gestational age. In Meckel–Gruber syndrome, the presence of the large polycystic kidneys and occipital encephalocele may help to distinguish this condition from the SRPSs.

It is important to demarcate the SRPSs from chondroectodermal dysplasia and asphyxiating thoracic dystrophy, because these latter two conditions are sometimes compatible with survival outside the womb. Chondroectodermal dysplasia is characterized by disproportionately short extremities, a small thorax, an atrial septal defect, cryptorchidism, clubfeet, unilateral renal agenesis, and variable pulmonary hypoplasia. In chondroectodermal dysplasia, polydactyly is always present in the hands, but the feet are affected only 10% of the time (Thomson et al., 1982). Asphyxiating thoracic dystrophy is characterized by a milder micromelia, less-shortened horizontal ribs, and the less frequent occurrence of polydactyly (Thomson et al., 1982). (See Table 95-1.)

ANTENATAL NATURAL HISTORY

Little is known about the antenatal natural history for these conditions, although there is an increased incidence of stillbirth, polyhydramnios, and hydrops fetalis in SRPS.

Table 95-1

Differential Diagnosis of Short-Rib Polydactyly Syndromes (SRPS)

	Type I (Saldino–Noonan)	Type II (Majewski)	Type III (Verma–Naumoff)	Type IV (Beemer–Langer)
Short ribs	+	+	+	+
Short long bones	+	+	+ (Spurs present)	+
Pulmonary hypoplasia	+	+	+	+
Polydactyly	+	+	+	–
Cleft lip/palate	–	+	–	+
CNS abnormalities	–	+	–	–
Congenital heart disease	+	–	–	–
Kidney cysts	+	–	–	–
Short skull base	–	–	+	–

MANAGEMENT OF PREGNANCY

Fetuses in which a skeletal dysplasia is suspected should have a targeted anatomic scan in a center with expertise in the diagnosis of fetal anomalies. The sonographic study should include a specific and detailed assessment of the bones (see Figure 95-3). In addition, attention should be paid to the documentation of associated anomalies that frequently occur in SRPS (see Table 95-1). Although the overwhelming majority of cases reported have had normal chromosomes, we recommend that an amniocentesis be performed to rule out trisomy 13 or to diagnose a chromosomal abnormality as the basis for the dysplasia. Many cases of SRPS in male fetuses are associated with absence of the penis or ambiguous genitalia. Therefore, obtaining a karyotype will help to diagnose the true fetal gender. Two case reports have documented chromosomal abnormalities in cases of SRPS. In one, a pericentric inversion of chromosome 4 was identified (Urioste et al., 1994). However, this abnormality was also present in the infant's clinically normal mother. In another case, a de novo pericentric inversion of the long arm of chromosome 17 was demonstrated in a case of Beemer–Langer syndrome. The abnormal karyotype [46, XY/46, XY, inv(17q21;q23)] was present in 8 of 60 cells (13%). This report raised the question of linkage of genes responsible for skeletal development to the long arm of chromosome 17 (Chen et al., 1994). In the past, fetoscopy was used to document the presence of the median cleft lip and polydactyly in families at risk for type II SRPS, Majewski syndrome (Toftager-Larsen and Benzie, 1984). At present, however, targeted sonography is considered to be the gold standard for prenatal diagnosis, but diagnostic fetoscopy may be contemplated when sonographic findings are unclear, and diagnosis will influence further management.

If the fetus is diagnosed as having one of the SRPS conditions, elective termination can be offered to the parents if the diagnosis is made at less than 24 weeks of gestation. The condition is uniformly lethal. To allow a definitive diagnosis, especially of the specific subtype of SRPS, we recommend delivery of an intact fetus to permit a full perinatal autopsy, radiographic studies, and collagen and DNA analysis (Figure 95-4).

FETAL INTERVENTION

There are no fetal interventions for SRPS.

TREATMENT OF THE NEWBORN

If a definitive diagnosis of SRPS has been made antenatally, newborn resuscitation is not indicated because these infants all have severe pulmonary hypoplasia that prevents survival outside the womb. The difficulty is that if the symptoms are due to asphyxiating thoracic dystrophy or chondroectodermal dysplasia, these latter conditions are compatible with survival. Therefore, a neonatologist should be present at the delivery to confirm the presumptive prenatal diagnosis. If the chest circumference is so narrow that severe pulmonary

Figure 95-4 Postmortem appearance of monozygotic twins with SRPS delivered at 29 weeks of gestation each demonstrating polydactyly, short extremities, and an extremely narrow thorax. (*Reprinted, with permission, from Wu M-H, Kuo P-L, Lin S-J. Prenatal diagnosis of recurrence of short rib polydactyly syndrome.* Am J Med Genet. *1995;55:279-284. Copyright 1995 John Wiley & Sons. Reprinted, by permission, of John Wiley & Sons, Inc.*)

hypoplasia is present, the infant will not survive regardless of the underlying diagnosis. The cause of death in this condition is always respiratory insufficiency (Figure 95-5) (Prudlo et al., 1993).

As in the prenatal setting, we recommend that a complete autopsy be performed to permit definitive diagnosis. If the parents refuse an autopsy, postnatal radiographs should always be obtained. A complete radiologic assessment of the

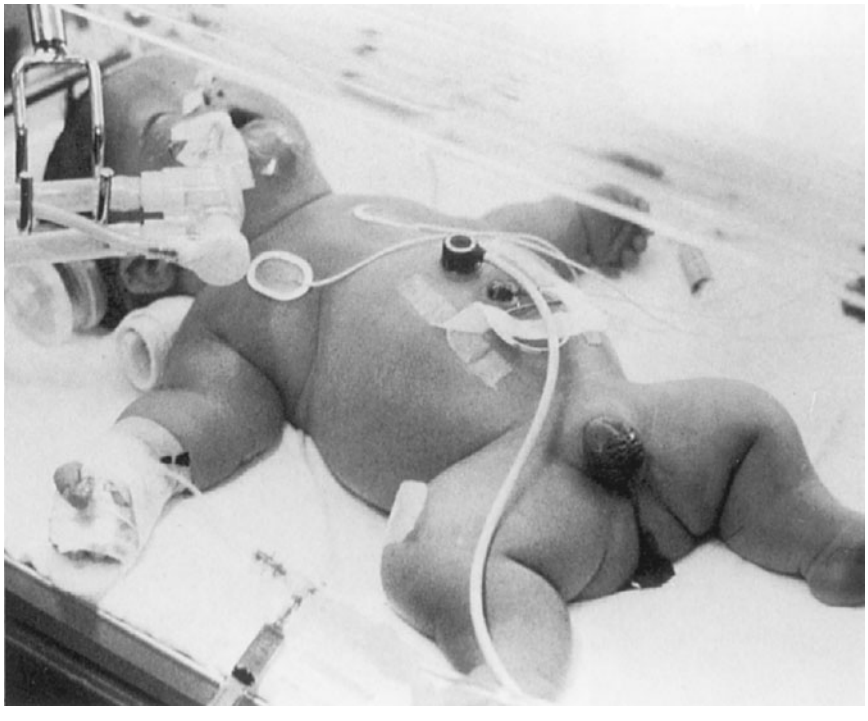

Figure 95-5 Postnatal appearance of an infant affected with SRPS of undetermined type, demonstrating shortened extremities, protuberant abdomen, and absent penis. (*Reprinted, with permission, from Wu M-H, Kuo P-L, Lin S-J. Prenatal diagnosis of recurrence of short rib polydactyly syndrome.* Am J Med Genet. *1995;55:279-284. Copyright 1995 John Wiley & Sons. fetus or infant should include anteroposterior and lateral views of the skull, spine, and chest; lateral view of one ankle; and anteroposterior views of the upper limb, lower limb, and pelvis. While radiographs may be helpful, there is no guarantee that they will contribute to a definitive diagnosis. In addition, a small sample of cartilage should be put into gluteraldehyde for subsequent electron microscopy. A generous amount of cartilage (from one complete long bone) should be frozen at −70°C for collagen and proteoglycan analysis. In addition, 1 cm^3 of tissue from the liver or spleen should be frozen and stored at −70°C for subsequent DNA analysis (Keating et al., 1989). This is important because the molecular bases for many of the skeletal dysplasias are currently being elucidated. Having tissue stored from the affected fetus or infant will permit eventual DNA analysis and definitive diagnosis. Once a DNA mutation is identified, prenatal diagnosis in a subsequent pregnancy is theoretically possible as early as 10 weeks of gestation by chorionic villus sampling.

Before the parents leave the hospital, an appointment should be made for approximately 6 weeks after delivery, when the results of these studies can be discussed.

SURGICAL TREATMENT

There are no surgical treatments for SRPS.

LONG-TERM OUTCOME

There is no long-term outcome for this condition, as it is invariably fatal during the neonatal period.

GENETICS AND RECURRENCE RISK

To date, all types of SRPS have been inherited as autosomal recessive disorders. In the majority of cases described, the chromosomes have been normal. The only two cases of chromosomal abnormalities found in cases of SRPS include a pericentric inversion of chromosome 4 (Urioste et al., 1994), and a de novo 17q pericentric inversion mosaicism (Chen et al., 1994). Thus far, the gene or genes responsible for SRPS have not been mapped. *EVC1*, the gene responsible for some cases of Ellis–van Creveld syndrome has been excluded as a cause of SRPS type III (Takamine et al., 2004). It is hoped that molecular analysis of the DNA obtained from affected fetuses and infants will help to clarify the confusing subclassification of this rare disorder.

Parents who have had a previously affected fetus or infant should be counseled regarding a 25% recurrence risk. Prenatal diagnosis by sonography appears to be highly accurate for diagnosis of recurrent cases within a family.

Jarcho–Levin Syndrome

96 CHAPTER

Key Points

- "Jarcho–Levin" syndrome refers to a group of conditions characterized by short trunk dwarfism, rib and vertebral anomalies, and normal long bones.
- Inheritance may be autosomal recessive, autosomal dominant, or sporadic.
- Chromosomes are normal.
- Delivery should occur in a tertiary center due to increased likelihood of respiratory complications.
- No longer considered to be a lethal condition.
- All affected individuals are developmentally normal.

CONDITION

Jarcho–Levin syndrome is an eponym that refers to a group of conditions characterized by short trunk dwarfism, rib and vertebral anomalies, and normal long bones. The name Jarcho–Levin syndrome was attached to the condition because of an initial report in 1938 by Saul Jarcho and Paul Levin who described a brother and sister with severe malformations of their vertebral columns. In addition, the mother of these children had a minor cervical vertebral anomaly. The infants demonstrated a shortened thorax and a prominent abdomen. Both infants died from respiratory failure during the first year of life.

Subsequently, the classification of genetic syndromes that include rib and vertebral anomalies as their major symptoms has become progressively more confusing. Jarcho and Levin's original disorder was termed "hereditary malformation of the vertebral bodies." Related or identical conditions have also been called familial dwarfism due to hereditary multiple hemivertebrae, spondylothoracic dysostosis,

Table 96-1

Clinical and Genetic Features in the Jarcho–Levin Spectrum

	Spondylothoracic Dysplasia or Dysostosis (STD)	Spondylocostal Dysplasia or Dysostosis (SCD)
Sonographic Findings		
Ribs	Fused posteriorly creating "crablike" or "fan" appearance; no intrinsic malformations	Intrinsic malformations
Spine	Hemivertebrae	Hemivertebrae
	Fused vertebrae	Fused vertebrae
	Lordosis	Scoliosis
Long bones	Normal	Normal
Inheritance pattern	Autosomal recessive	Autosomal dominant or autosomal recessive
Causative gene	Unknown but linkage analysis maps gene to chromosome 2q32.1	Delta-like 3 (*DLL3*) on chromosome 19q13

Adapted from Wong G, Levine D. Jarcho–Levin syndrome: two consecutive pregnancies in a Puerto Rican couple. Ultrasound Obstet Gynecol. *1998;12:70-73.*

spondylocostal dysplasia, spondylocostal dysostosis, costovertebral dysplasia, and occipito-facial-cervical-thoracic-abdominal-digital dysplasia. The nosology of these various conditions is further complicated by the fact that some of them are inherited as autosomal dominant genes and some are associated with autosomal recessive inheritance (Table 96-1). The condition that most clinicians agree is the classical presentation of Jarcho–Levin syndrome is spondylothoracic dysplasia, and consists of multiple rib and vertebral anomalies associated with a "crab-claw" or "fanlike" configuration of the ribs on X-ray (Figures 96-1 and 96-2), with a resultant small thoracic volume and symptoms coincident with respiratory insufficiency. The majority of patients who manifest the classic Jarcho–Levin syndrome can trace their ancestry to Puerto Rico (Perez-Comas and Garcia-Castro, 1974).

INCIDENCE

The incidence of spondylothoracic dysplasia is unknown. It is rare. As previously stated, the disorder occurs most frequently in patients of Puerto Rican ancestry, although there have been multiple reports of familial Jarcho–Levin syndrome in Europeans and at least one report in an Arab family (Romeo et al., 1991; Eliyahu et al., 1997). The incidence of spondylocostal dysplasia is 0.25 per 10^5 livebirths (Martínez-Frias et al., 1994).

SONOGRAPHIC FINDINGS

Spondylothoracic dysostosis should be suspected in any fetus with multiple vertebral anomalies and spina bifida (Cornier et al., 2003). Jarcho–Levin syndrome has been diagnosed in the first trimester through a combination of increased nuchal translucency thickness and spine abnormalities visualized by two-dimensional or three-dimensional sonography (Hull et al., 2001; Kauffmann et al., 2003).

The fetal vertebral bodies can be visualized between 16 and 20 weeks of gestation on a longitudinal section that includes the entire spinal canal. At this point in the pregnancy, the normal parallel line configuration of the fetal spine should be obtainable no matter where the fetal spine is located within the uterus (Miskin et al., 1979). The first prenatal roentgenographic diagnosis of Jarcho–Levin syndrome was made in 1979 and the first prenatal sonographic diagnoses were made in the 1980s (Marks et al., 1989). In 1987, Tolmie et al. described a Scottish couple who had a previous child affected with Jarcho–Levin syndrome. In a subsequent pregnancy, at 20 weeks of gestation, a grossly deformed spine and incomplete rib cage were demonstrated on prenatal sonography. The pregnancy was electively terminated and postmortem study revealed associated anomalies, including an imperforate anus and ectopic adrenal glands. Simultaneously, another report at 22 weeks of gestation described the subtle spacing and

Figure 96-1 Anteroposterior radiograph of a newborn with Jarcho–Levin syndrome, demonstrating deformation of chest with characteristic "crab-claw" appearance.

Figure 96-2 Lateral radiograph of the patient in Figure 96-1, showing the fanlike appearance of ribs.

widening of the fetal vertebrae seen in prenatal sonographic examination of a fetus with Jarcho–Levin syndrome. At 22 weeks of gestation, a slightly smaller than normal chest diameter was appreciated but the diagnosis was unclear. By 28 weeks of gestation, an abnormally shaped chest was appreciated that included slight flattening of the ribs and irregularly spaced vertebrae (Apuzzio et al., 1987). In the third report, a fetus at 23 weeks of gestation was described with a shortened spine, disorganization of the vertebral bodies, posterior fusion of the ribs, with a short thorax but normal thoracic diameter. In a coronal view, narrowing of the lateral laminae in the lower thoracic and upper lumbar region was described. In the sagittal and coronal planes, grossly malaligned vertebrae, disorganization of vertebral bodies, and posteriorly fused ribs were appreciated (Romero et al., 1988). In 1989, Marks et al. reported two fetuses with sonographic findings of Jarcho–Levin syndrome. They described the following sonographic criteria for diagnosis of this condition (Marks et al., 1989):

1. Unpaired and poorly formed vertebral centers resulting in a "pebblelike" appearance of the spine (Figure 96-3);
2. Multiple vertebral body fusion causing an irregular shortened spine;
3. Indistinct or joined ribs posteriorly;
4. A small or shortened thorax;
5. A protuberant abdomen resulting from the shortened thorax;
6. The presence of abdominal hernias;
7. Normal amniotic fluid volume;
8. Normal limb length and biparietal diameter measurements for gestational age.

Subsequent reports have described the utility of prenatal sonographic diagnosis in families known to be at risk because of the prior birth of an affected infant (Lawson et al., 1997; Wong and Levine, 1998). In one study, four affected fetuses were diagnosed as early as 12 weeks of gestation (Eliyahu et al., 1997).

Figure 96-3 Sonographic image demonstrating unpaired and poorly formed vertebral centers resulting in an extremely abnormal appearance of the spine. (*Image courtesy of Prenatal Diagnosis Center, Women and Infants' Hospital.*)

DIFFERENTIAL DIAGNOSIS

The main consideration in the differential diagnosis is the determination of whether the findings are consistent with Jarcho–Levin syndrome or the related spondylocostal dysostoses, or whether the anomalies represent a more serious lethal skeletal dysplasia, such as Jeune syndrome, campomelic dysplasia, or thanatophoric dysplasia. These lethal conditions can be distinguished sonographically from Jarcho–Levin syndrome by the short long bones and narrow chest. In addition, in each of these three conditions there is no fusion of the ribs. Klippel–Feil syndrome can be distinguished from Jarcho–Levin syndrome because it affects the cervical rather than the thoracic ribs. Other conditions in the differential diagnosis include dyssegmental dysplasia and spondyloepiphyseal dysplasia congenita. In dyssegmental dysplasia the limbs are short with reduced mobility. In spondyloepiphyseal dysplasia congenita there is no rib fusion and platyspondyly is present. Any fetus that presents with thoracic vertebral anomalies should be further investigated to rule out the VACTERL association, which consists of vertebral, anal, cardiac, tracheal and esophageal, renal, and radial limb anomalies (Wong and Levine, 1998). The condition that is most similar to Jarcho–Levin syndrome is COVESDEM (costovertebral segmentation defects with mesomelia) syndrome (Wadia et al., 1978). In this condition, however, the thorax is not shortened and mesomelia of the limbs is present, affecting the upper extremities more severely than the lower.

ANTENATAL NATURAL HISTORY

Morphologic studies of affected fetuses have shown that the vertebral bodies are malformed and consist of asymmetrically distributed ossification centers that vary greatly in size and shape and rarely cross the midline (Solomon et al., 1978). Microscopic examination of fetuses with Jarcho–Levin syndrome that were terminated during the second trimester has demonstrated disorganized vertebral endochondral bone formation with a lack of orderly column formation of mature chondrocytes. Although the ribs are characteristically fused, the endochondral bone formation within the ribs is normal (Marks et al., 1989). These defects undoubtedly occur extremely early in gestation, as the paraxial mesoderm undergoes segmentation between 21 and 28 days of gestation (Tolmie et al., 1987). Because certain homeobox genes important in formation of body structure are expressed uniquely in spinal cord, the question has been raised as to whether Jarcho–Levin syndrome could represent a mutation in one of the master homeobox genes that control vertebral development, such as *Pax1* and *Pax9* (Tolmie et al., 1987). Bannykh et al. (2003) performed immunochemical analysis of the levels of Pax1 and Pax9 proteins in chondrocytes from two fetuses with Jarcho–Levin syndrome and found them to be significantly reduced compared to controls.

Approximately one-third of fetuses and infants with Jarcho–Levin syndrome have associated malformations that are outside of the thorax and vertebral bodies (Roberts et al., 1988). Some of the nonskeletal malformations that have been described in Jarcho–Levin syndrome include genitourinary anomalies such as uterus didelphys, bilobed bladder, hydronephrosis, undescended testes, urethral atresia, absent external genitalia, single umbilical artery, cerebral polymicrogyria, and congenital heart defects (Poor et al., 1983; Hatakeyama et al., 2003). Most reports do not emphasize central nervous system malformations, although spina bifida and diastematomelia were described in a patient with Jarcho–Levin syndrome. Spina bifida occulta is reported to occur in 40.6% of patients with Jarcho–Levin syndrome (Giacoia and Say, 1991).

MANAGEMENT OF PREGNANCY

The main consideration in management of pregnancy is an accurate sonographic diagnosis. Prenatal sonograms should be reviewed by an expert in diagnosis of skeletal dysplasias. Both decreased and elevated maternal serum α-fetoprotein levels have been reported in this condition (Apuzzio et al., 1987; Romero et al., 1988). All reports of fetuses and infants affected with this condition have had normal chromosomes (Cantu et al., 1971; Perez-Comas and Garcia-Castro, 1974; Tolmie et al., 1987; Romero et al., 1988; Karnes et al., 1991). Therefore, if the sonographic diagnosis is reasonably certain, there is no indication to obtain a fetal karyotype. The route of delivery should be vaginal unless otherwise indicated for obstetric reasons. It is important for fetuses with Jarcho–Levin syndrome to be delivered in tertiary care centers because most of these infants will require neonatal resuscitation, mechanical ventilation, and postnatal genetic assessment.

FETAL INTERVENTION

There are no fetal interventions for Jarcho–Levin syndrome.

TREATMENT OF THE NEWBORN

A complete and detailed physical examination is indicated. Typical findings of the infant with Jarcho–Levin syndrome include a short neck, prominent occiput, low hairline, and a dysmorphic facial appearance that consists of a broad forehead, wide nasal bridge, prominent philtrum, anteverted nares, and a triangle-shaped mouth (Figure 96-4A). Additional physical findings include a protuberant abdomen, poor muscle tone, abdominal hernias, long tapering fingers and toes, and soft tissue syndactyly.

Because of the abnormally shaped chest, infants with Jarcho–Levin syndrome are likely to have pulmonary hypoplasia and may require resuscitation in the delivery room. Optimal treatment of the newborn with Jarcho–Levin syndrome should include delivery in a tertiary care center with a neonatologist prepared to provide immediate respiratory support and mechanical ventilation.

Consultation with a clinical geneticist is indicated. In the newborn nursery, a complete postnatal skeletal survey should be performed. Radiographs should include the spine, which will demonstrate clefts, hemivertebrae, and abnormal vertebral body fusion and the chest, which may demonstrate hypoplasia and multiple rib fusion as well as a "scrambled" vertebral column (see Figures 96-1 and 96-2) (Herold et al., 1988). Additional bony anomalies that may be diagnosed postnatally include an absent coccyx and a hypoplastic sacrum. The typical posteroanterior chest radiograph will show the rib anomalies in a distribution that appears similar to a crab. The lateral chest radiograph should show the rib fusion anomalies in a manner that appears like a fan (see Figure 96-2). These findings are considered pathognomonic for this condition. In addition, long bone films will be helpful to rule out another skeletal dysplasia.

SURGICAL TREATMENT

The management of the orthopedic anomalies in Jarcho–Levin syndrome is difficult. The crablike rib deformity and consequent pulmonary hypoplasia often require mechanical ventilatory support. This can be compounded by flail segments of the chest wall. In order to optimize respiratory mechanics and improve the affected infant's ability to be weaned from mechanical support, chest wall reconstruction may be necessary. We successfully performed an extensive chest wall reconstruction in an infant with Jarcho–Levin syndrome. In addition to a flail anterolateral right chest wall, he had diaphragmatic insertion at the 6th rib, further compromising ventilation. A prosthetic patch and rib graft were used to stent the flail chest wall segment, and the diaphragm was repositioned at the 12th rib posteriorly. The infant subsequently died from infection. More recently, the use of vertical expandable titanium rib techniques has been advocated to stabilize the chest and prevent pulmonary complications from progressive scoliosis (Vázquez-López et al., 2005).

LONG-TERM OUTCOME

Jarcho–Levin syndrome was considered to be a lethal condition until Cornier et al. (2004) described a cohort of 27 prospectively evaluated patients with spondylothoracic dysplasia and a 56% long-term survival rate. The patients who died in the first 6 months did so due to respiratory insufficiency secondary to pneumonia and pulmonary restriction. Other complications include pulmonary hypertension (Rastogi et al., 2001). Affected infants generally require multiple hospital admissions during the first year of life due to upper respiratory infections, but after 2 years of age, this decreases significantly (Cornier et al., 2004). Approximately half of patients are diagnosed with reactive airway disease. Pulmonary function tests show a severe restrictive pattern. Patients have short stature, averaging at the 2nd percentile for age. They also have a prominent abdomen and recurrent inguinal hernias.

Importantly, mental retardation is not a component of this condition. In Cornier et al.'s (2004) report, all affected individuals were developmentally normal for their age, except for mild delays in their motor milestones during the first 18 months of life. Herold et al. (1988) described 10 cases of Jarcho–Levin syndrome, 8 of whom survived well into childhood and adolescence. One of the patients described in this report included a 14-year-old who had no respiratory problems and had good compensatory movement in the hip joints

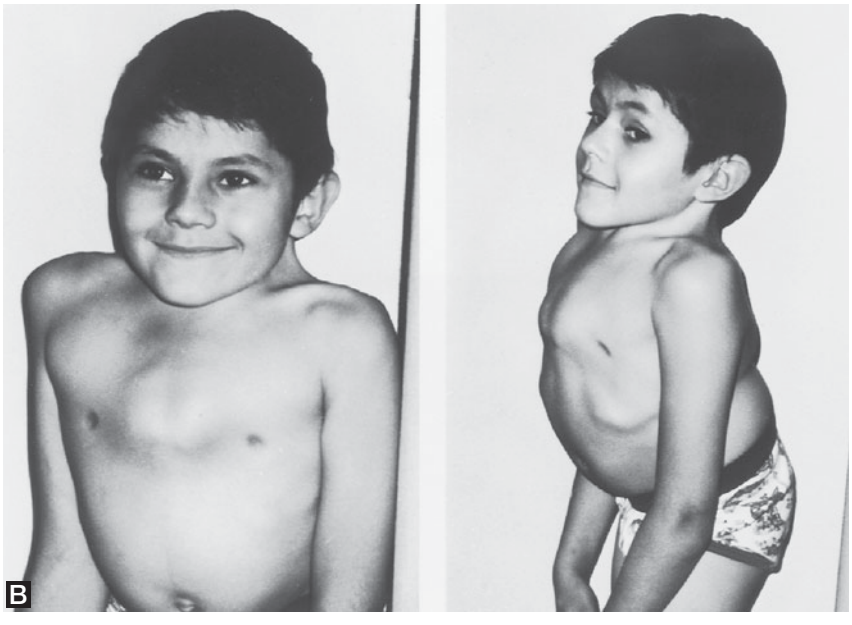

Figure 96-4 **A.** Infant with Jarcho–Levin syndrome who survived postnatally. **B.** Same patient as in (A), at age 7 years 8 months, demonstrating marked thoracic and neck shortness with severe pectus carinatum deformity. (*Reprinted, with permission, from McCall CP, Hudgins L, Cloutier M, et al. Jarcho–Levin syndrome: unusual survival in a classical case.* Am J Med Genet. *1994;49: 328-332.*)

despite marked restriction of the lumbar spine and rigidity of the cervical spine. This patient could bend and touch the floor without bending her knees. She was as active as other children with the exception of having back pain.

A long-term survivor, an 11-year-old Puerto Rican male was described in great detail in 1994 (McCall et al., 1994). This patient had the classic phenotype of Jarcho–Levin syndrome (Figure 96-4B). By 11 years of age, his height was more than 3 SD below the mean and equaled a height-age of 8 years. His weight was between the 5th and 25th percentile for age. His overall health was good, with the exception of recurrent otitis media in childhood and pneumonia at 5 months of age and then again at 3 years 6 months. This individual had normal development and hearing, and was attending a regular fifth-grade class. He was extremely active in sports and was limited only by pulmonary function. His physical examination at age 11 showed an extremely short neck with low hairline and limited neck movement. His arms were long in relation to his body. He had a pectus carinatum deformity and an increased anteroposterior diameter of his chest. He had a dorsal kyphoscoliosis and a lumbar lordosis with a prominent abdomen. His face was normal and he had no other anomalies. Pulmonary function testing at age 11 years revealed a moderately severe restrictive pulmonary disease, with a decreased forced vital capacity and decreased forced expiratory volume. Although his pulmonary function tests are slightly worsening with time, these authors felt that for an individual diagnosed with Jarcho–Levin syndrome, the prognosis was less pessimistic than previously thought (McCall et al., 1994).

GENETICS AND RECURRENCE RISK

The genetics of Jarcho–Levin syndrome are somewhat confused in the medical literature because of the different criteria used to establish the diagnosis. The clinical findings in 42 published patients were separated into three clusters based on their physical findings. The patients were grouped into the severely affected with recessively inherited Jarcho–Levin syndrome, the more mildly affected patients with autosomal recessive or autosomal dominant disorders, and the patients who appeared to have the segmentation defects (Ayme and Preus, 1986). In another study, 172 cases of spondylocostal dysostosis were reviewed for their patterns of inheritance. Of these, 78 appeared to be inherited as recessive disorders, 20 were dominantly inherited disorders, and 78 were new mutations in the family. The gene for autosomal recessive spondylocostal dystostosis is deltalike 3 (DLL3) on chromosome 19q13. More than 17 mutations have been described in DLL3, which is a somitogenesis gene that encodes a ligand for the Notch signaling pathway (Turnpenny et al., 2003).

There is good evidence for autosomal recessive inheritance of the classic phenotype of Jarcho–Levin syndrome. First of all, there is an increased incidence of consanguinity in affected cases (Herold et al., 1988). In a review of 21 patients with Jarcho–Levin syndrome of Puerto Rican or Hispanic ancestry, 43% had evidence of either consanguinity or more than one affected case in the family with normal parents. Linkage analysis in this group has mapped the as yet unknown causative gene to chromosome 2q32.1.

Parents of a fetus or infant identified with features that are likely to represent Jarcho–Levin syndrome should meet with a genetic counselor to have a complete three generation family history taken. Once a clinical diagnosis is established for the fetus or infant, genetic counseling is indicated to discuss recurrence risk. If autosomal recessive inheritance appears likely, the recurrence risk is 25%.

97 CHAPTER Achondrogenesis

Key Points

- Second most common lethal short-limb dysplasia.
- Incidence is 1/40,000 to 1/50,000 livebirths.
- Characterized by severe micromelia, lack of vertebral ossification, and a large head with relatively normal ossification of the calvarium; also associated with polyhydramnios, cystic hygroma, and hydrops fetalis.
- Type I (20% of cases) is more severe and is inherited as an autosomal recessive. Type IB is caused by a mutation in the diastrophic dysplasia sulfate transporter (*DTDST*) gene.
- Type II (80% of cases) is caused by mutations in the *COL2A1* gene, which results in significantly decreased type II collagen. Type II is usually a de novo dominant mutation, with rare reports of recurrence due to germline mosaicism.
- Increased incidence of prematurity and stillbirth. Condition is lethal in perinatal period.

CONDITION

The term achondrogenesis refers to a diverse group of generally lethal chondrodysplasias characterized by a short trunk, severe micromelia, and a disproportionately large cranium. Achondrogenesis is the second most common lethal short-limb dysplasia. The term achondrogenesis is actually a misnomer, as it implies that cartilage is not made. In this condition, cartilage is made but it is profoundly abnormal. A more correct term would be chondrogenesis imperfecta (Eyre et al., 1986).

Subclassification of the different conditions included under the term achondrogenesis has been confusing. Historically, two types of achondrogenesis have been described: type I is referred to in the literature as Parenti–Fraccaro syndrome. This subtype accounts for 20% of cases and is the more severe of the two. Type II achondrogenesis—termed Langer–Saldino syndrome—accounts for 80% of cases. In 1983, Whitley and Gorlin reviewed 79 cases that presented with a lethal neonatal chondrodysplasia. Affected infants had a short trunk, extreme micromelia, and a disproportionately large cranium. Radiographically, they were demonstrated as having deficient spine ossification, short ribs with cupped and flared ends, and absent pubic and ischial ossification. On the basis of this study, they identified four subtypes. These included type I (Parenti–Fraccaro), which was characterized by multiple rib fractures and the most marked limb shortening. Within the type II category (Langer–Saldino), they identified three subtypes, characterized by differences in the severity of the micromelia and ossification of the vertebrae. Although type I achondrogenesis was traditionally called Parenti–Fraccaro syndrome, a review by Borochowitz et al. (1988) revealed that the original case described by Parenti had a well-ossified skull and ossification of the vertebral bodies. This original case, therefore, was more likely to represent a more mildly affected case of achondrogenesis type II.

Borochowitz et al. (1988) attempted to more accurately classify the subtypes of achondrogenesis (Figure 97-1). In this report, they divided achondrogenesis into three subtypes: the most severely affected is lethal achondrogenesis, type IA (Houston–Harris). This condition is characterized by a poorly ossified skull, multiple rib fractures, and a completely unossified spine (Figure 97-2). Type I also includes lethal achondrogenesis, type IB (Fraccaro), which follows the original case description of Fraccaro. These patients are characterized by a poorly ossified skull, absence of rib fractures, and some ossification of the posterior pedicles of the spine (Figure 97-3). The third subtype is known as lethal achondrogenesis, type II (Langer–Saldino), which is characterized by a normally ossified skull and some ossification of the vertebral bodies, which may make the spine appear flat and ovoid. All three types of achondrogenesis are lethal and they are distinguished from a rare nonlethal form, known as Grebe dysplasia that has been described in Brazilian patients.

Affected Bone	Type of Achondrogenesis by Eponym		
	Houston–Harris Achondrogenesis IA	Fraccaro Achondrogenesis IB	Langer–Saldino Achondrogenesis II/Hypochondrogenesis
Skull	Poorly ossified	Poorly ossified	Normally ossified
Ribs	Short & fractured	Short, no fractures Cupped ends	Short
Spine	Completely unossified	Posterior pedicles only	Flat & ovoid (when ossified)
Ilium	Arched	Crenated	Hypoplastic with medial spike
Ischium	*Ossified–hypoplastic	Unossified trapezoid	Ossified–hypoplastic
Femur	Wedged with metaphyseal spike	Crenated unossified	Short & broad with metaphyseal flare
Tibia	Short with metaphyseal flare		Short & broad
Fibula			Short & broad
	*Unossified 30 weeks' gestation		

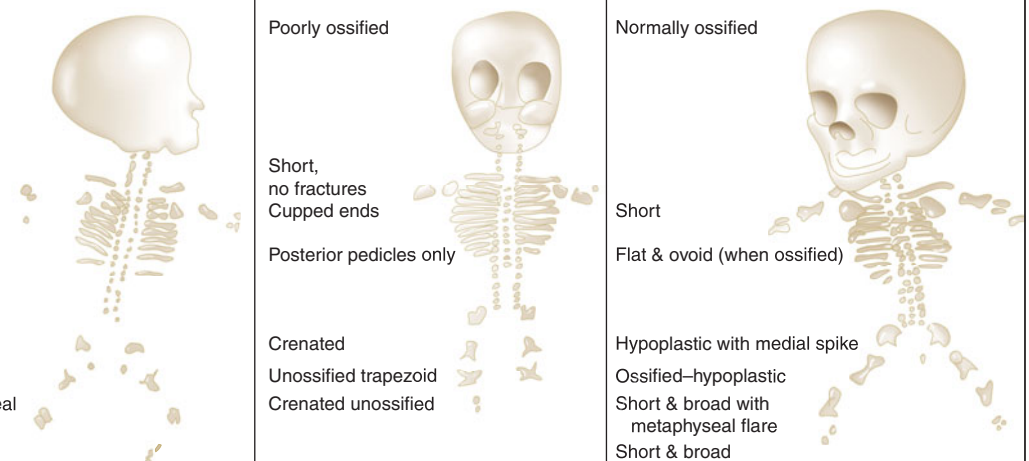

Figure 97-1 Diagrammatic representation of the major radiographic differences seen in the subtypes of achondrogenesis. (*Reprinted, with permission, from Borochowitz Z, Lachman R, Adomain GE, Spear G, Jones K, Rimoin DL. Achondrogenesis type 1: delineation of further heterogeneity and identification of two distinct subgroups.* J Pediatr. *1988;112:28.*)

The molecular basis of the achondrogenesis syndromes affirm the rationale behind the classification of Borochowitz et al. Achondrogenesis type IB is caused by an inborn error of cartilage metabolism and achondrogenesis type II is caused by a defect in type II collagen (Rimoin, 1996). The underlying basis for achondrogenesis type IA is currently unknown.

Achondrogenesis is part of the group of disorders known as osteochondrodysplasias, which highlights the fact that abnormalities of cartilage or bone growth and development are present (Rimoin, 1978). Autopsy studies performed on all patients with achondrogenesis reveal disorganization of the chondrocytes. In some cases, the cartilage matrix stains irregularly for mucopolysaccharides (Jimenez et al., 1973). For all cases of achondrogenesis, chondrocytes fail to align in columns and they are very irregularly distributed. In type IA, intracellular acid Schiff–positive inclusion bodies are seen with vacuolization of cytoplasm of chondrocytes of the growth plate (Jaeger et al., 1994). These intracytoplasmic inclusion bodies are pathognomonic of achondrogenesis type IA. Type IB is characterized by a decrease in type II collagen, with a peculiar arrangement of fibers in the cartilage matrix that form unique or multiple rings around the chondrocytes (Freisinger et al., 1994). In type II achondrogenesis, there are structural abnormalities present in the type II collagen. This results in an abnormal, poorly secreted type II collagen molecule. Ultrastructural studies have shown intracellular retention of type II collagen within vacuolar structures, probably existing within dilated rough endoplasmic reticulum observed in all chondrocytes by electron microscopy (Godfrey et al., 1988). Patients with type II achondrogenesis have increased amounts of type I and type III collagen (Feshchenko et al., 1989). Therefore, definitive diagnosis of the subtype of achondrogenesis is possible with histopathologic studies.

INCIDENCE

The incidence of achondrogenesis is 1 in 40,000 to 1 in 50,000 livebirths (Smith et al., 1981; Orioli et al., 1986; Lachman and Rappaport, 1990). Achondrogenesis accounts for 1 in 650 perinatal deaths (van der Harten et al., 1988).

SONOGRAPHIC FINDINGS

The major sonographic findings in achondrogenesis are that of a severe short-limb dwarfism with lack of vertebral ossification (Table 97-1). Typically, a large head is seen with either normal or decreased ossification of the calvarium. Additional findings include a small thorax, protuberant abdomen, and polyhydramnios or generalized edema (Figure 97-4) (Wenstrom et al., 1989). Large cystic hygromas have been described in association with types I (Özeren et al., 1999) and II (Won et al., 1999). To distinguish between types IA and IB and type II, a specific notation must be made of the degree of skull ossification. Type I is characterized by decreased or absent skull ossification. In addition, type IA is characterized by the presence of rib fractures, which can be visualized sonographically (see Figure 97-2) (Graham et al., 1983). In one report, the most specific finding for the diagnosis of achondrogenesis in a case of short-limb dysplasia was a transverse view

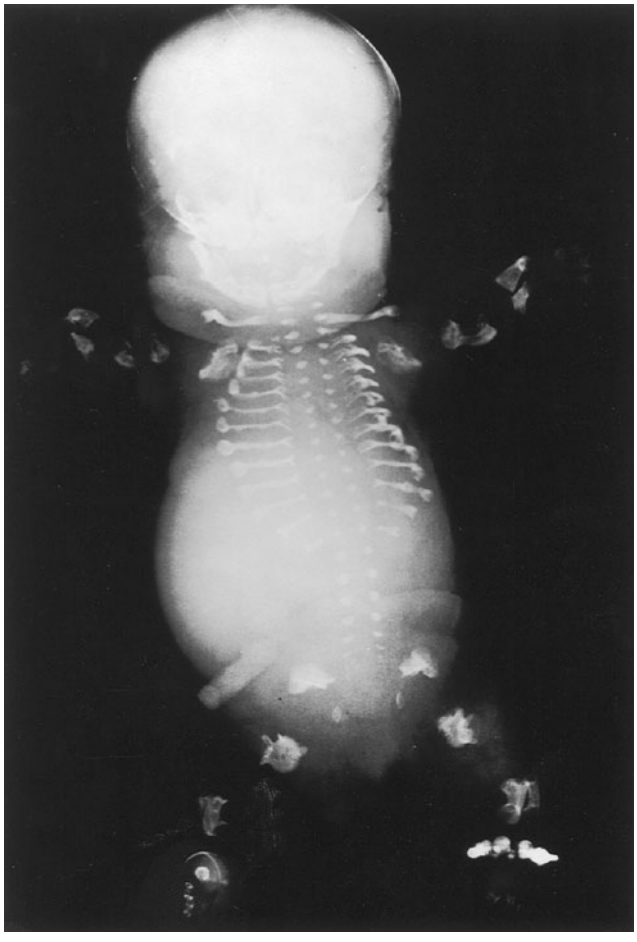

Figure 97-2 Postmortem radiograph of an infant with achondrogenesis, type IA, demonstrating the pathognomonic rib fractures, unossified spine, short long bones, arched ilium, and hypoplastic ischium. (*Reprinted, with permission, from Borochowitz Z, Lachman R, Adomain GE, Spear G, Jones K, Rimoin DL. Achondrogenesis type 1: delineation of further heterogeneity and identification of two distinct subgroups.* J Pediatr. *1988;112:24.*)

of the fetus demonstrating less than three ossification centers per spinal segment (Pretorius et al., 1986). Interestingly, approximately one-third of cases with achondrogenesis are associated with hydrops fetalis. It is postulated that this may be due to the primary collagen defect in type II, which may damage subcutaneous tissue as well as bone and cartilage (Soothill et al., 1993).

In one report of 15 cases of achondrogenesis, all fetuses were demonstrated to have severe micromelia. Of these 15 cases, 6 were detected early in the second trimester (between 15 and 19 weeks of gestation), 13 (87%) showed decreased or absent vertebral body ossification, 6 (40%) showed a narrow thorax, 5 (33%) showed deformed extremities, 7 (47%) had polyhydramnios, and 5 (33%) had hydrops fetalis (Figure 97-5) (Mahony et al., 1984). Multiple case reports exist in the literature in the setting of both positive and negative family histories, in which the diagnosis of achondrogenesis was made easily by sonography (Golbus et al., 1977; Graham et al., 1983; Benacerraf et al., 1984; Glenn and Teng, 1985; Tongsong et al., 1995). Transvaginal sonography has also been used to demonstrate that the pathologic abnormalities in achondrogenesis are present as early as 9 weeks of gestation (Fisk et al., 1991). In one case, a positive family history alerted the sonographer to the potential for achondrogenesis (Fisk et al., 1991). At 9 weeks of gestation, no movement was seen in the fetal limb buds. By 10 weeks of gestation, nuchal and dorsal edema were visualized. At 11 weeks of gestation, the edema was shown to be increased, with upper and lower extremities grossly shortened and held in abnormal and fixed position. Even at this early stage of gestation, the vertebral bodies and long bones were difficult to identify, although the crown-to-rump length was appropriate for gestational age. These early findings were thought to be consistent with a diagnosis of achondrogenesis type II. Of interest in this report was the discussion regarding the nuchal edema, in which cystic hygroma was ruled out because there was no endothelial lining surrounding the fluid-filled areas. These authors postulated that this finding was possibly due to lymphatic stasis, and they also stated that nuchal edema may be an important component in the first trimester sonographic diagnosis of achondrogenesis (Fisk et al., 1991). In an additional case (also in a pregnancy at risk because of a prior family history), a fetus at 12 weeks of gestation was diagnosed with achondrogenesis type II by transvaginal sonography. Even at this early point in gestation, severe hydrops and abnormal bone formation were noted (Soothill et al., 1993). Transvaginal prenatal diagnosis of achondrogenesis IB has also been described in the first trimester (Meizner and Barnhard, 1995). Pertinent findings included severely shortened extremities, thin ribs with fractures, deficient ossification of the vertebral bodies, and underossification of the calvarium. Three-dimensional imaging has also been used to diagnose a case of achondrogenesis type II (Krakow et al., 2003).

DIFFERENTIAL DIAGNOSIS

A multicenter study demonstrated that femur length was the best biometric parameter to distinguish amongst the five most common skeletal dysplasias (thanatophoric dysplasia, osteogenesis imperfecta type II, achondrogenesis, achondroplasia, and hypochondroplasia). Fifty-four percent of fetuses with a femur length measuring less than 30% of the mean for gestational age had achondrogenesis (Mahony et al., 1984). Furthermore, the combination of absent vertebral body ossification with normal skull ossification was shown to differentiate achondrogenesis from most other severe skeletal dysplasias.

The differential diagnosis for the fetus with a severe short-limb dysplasia and apparently absent vertebral bodies also includes hypophosphatasia. However, severe hypophosphatasia results in a diffuse underossification of all bones. The fetal skull in hypophosphatasia is not as well seen as it is in achondrogenesis type II. Other considerations in the setting of a severe short-limb dysplasia documented at less than 20 weeks of gestation include thanatophoric dysplasia, homozygous achondroplasia, and short-rib polydactyly

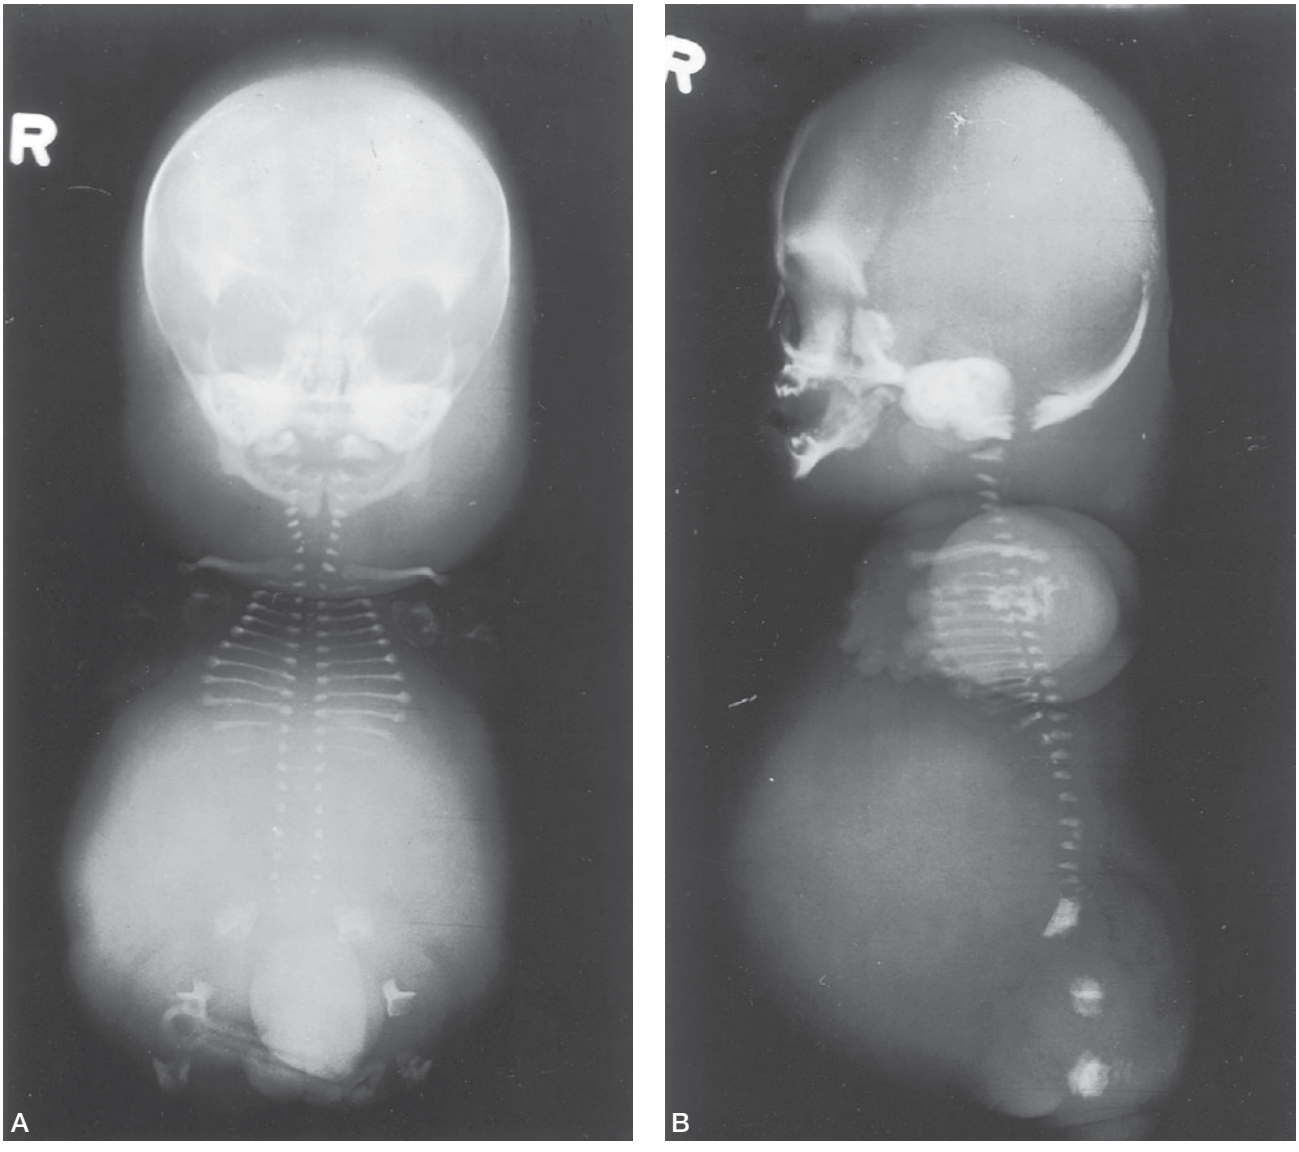

Figure 97-3 **A.** and **B.** Postmortem radiographs of an infant with achondrogenesis, type IB, demonstrating short ribs, ossified posterior spine pedicles, short long bones, crenated ilium, and unossified ischium. Note the absence of rib fractures, in contrast to type IA seen in Figure 97-2. (*Reprinted, with permission, from Borochowitz Z, Lachman R, Adomain GE, Spear G, Jones K, Rimoin DL. Achondrogenesis type 1: delineation of further heterogeneity and identification of two distinct subgroups.* J Pediatr. *1988;112:27.*)

syndrome. In all these conditions, underdevelopment of the vertebral bodies is seen, but there is normal calvarial ossification. In short-rib polydactyly syndrome, the presence of an extra digit can be demonstrated. Other considerations in the differential diagnosis include campomelic dysplasia, chondrodysplasia punctata with proximal limb shortening, Grebe syndrome, and osteogenesis imperfecta, type II (Pretorius et al., 1986).

ANTENATAL NATURAL HISTORY

For all types of achondrogenesis, there is an increased incidence of both prematurity and stillbirth. The condition is frequently complicated by polyhydramnios (Saldino, 1971; Borochowitz et al., 1988; Tongsong et al., 1995). In one study, the authors attempted to delineate the antenatal natural history for the different types of achondrogenesis. Type I was shown to have a 50% incidence of stillbirth. Type II was shown to have fewer stillbirths, a longer antenatal survival time, a longer gestational period, a larger birth weight, longer limbs, and characteristic craniofacial features (Chen et al., 1981).

MANAGEMENT OF PREGNANCY

A major consideration in management of pregnancy is the establishment of a definitive diagnosis. Because the sonographic

Table 97-1

Sonographic Findings in Achondrogenesis

Earliest age at diagnosis 9 weeks
First trimester findings Nuchal and dorsal edema Poor or absent ossification of spine and long bones Absent fetal movement
Second trimester findings Femur length >2 SD below normal Bent long bones Poor or absent ossification of spine, skull, and long bones Hydrops fetalis Polyhydramnios Rib fractures Small thorax

findings in achondrogenesis are so distinctive, a diagnosis of achondrogenesis should be possible on the basis of sonographic features alone. In all cases of achondrogenesis reported to date in which the chromosomes have been analyzed, the fetal karyotype has been normal. In the setting of a positive family history due to a prior affected child, once the definitive diagnosis has been made by sonography, the parents should be offered the opportunity to terminate the pregnancy, if before 24 weeks of gestation. With the possible exception of the mildest form of achondrogenesis, known as Grebe dysplasia, all affected fetuses with achondrogenesis will die during the perinatal period. This should be discussed with the family, as should importance of obtaining a perinatal autopsy to permit definitive histologic diagnosis. Cesarean delivery is indicated only for maternal health considerations.

Figure 97-5 Facial profile of the same fetus shown in Figure 97-4, demonstrating flattened facies and subcutaneous edema.

FETAL INTERVENTION

There are no fetal interventions for achondrogenesis.

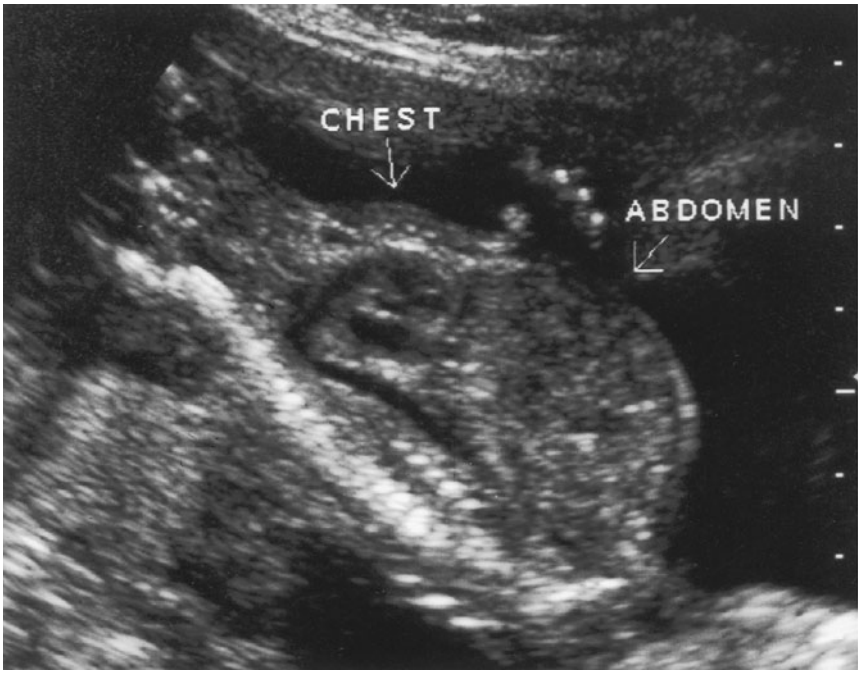

Figure 97-4 Prenatal sonographic image of a fetus with achondrogenesis demonstrating narrow thorax, protruberant abdomen, and absent rib ossification.

Figure 97-6 Post-termination photograph of the fetus shown in Figures 97-4 and 97-5, demonstrating nuchal edema, prominent abdomen, and clubfoot.

The boneless neonate: a severe form of achondrogenesis type I.* Pediatr Radiol. *1994;24:320.*)

TREATMENT OF THE NEWBORN

If the diagnosis of suspected short-limb dysplasia is made during the third trimester, neonatal resuscitation is not indicated for an infant with achondrogenesis. At birth, physical examination findings consistent with a diagnosis of achondrogenesis include a large head, short neck, markedly shortened limbs, and a distended abdomen (Figure 97-6). In addition to the narrow thorax, these infants all have pulmonary hypoplasia, as documented by reduced weight of the lungs on autopsy. For achondrogenesis type II, it has been postulated that the pulmonary hypoplasia is due to the underlying abnormality in type II collagen (Pretorius et al., 1986). All of these infants die from respiratory complications.

If the diagnosis is unknown at birth, a series of radiographs should be obtained, which should include anteroposterior and lateral films of the skull, chest, lateral spine, pelvis, extremities, hands, and feet (see Figure 97-7) (Lachman and Rappaport, 1990). Typical findings will include a large calvarium with wormian bones, but normal suture diastases. The rib cage is bell-shaped and the spine is short and very poorly ossified. What is most striking on the radiographs is the almost complete absence of ossification of the vertebral bodies. The long bones are also shortened and widened and demonstrate a variety of abnormalities (Jimenez et al., 1973). Because the condition is lethal, only comfort measures should be offered for the infant.

LONG-TERM OUTCOME

There is no long-term outcome for this condition, as it is lethal during the perinatal period. The longest survivor with achondrogenesis documented in the literature lived for 10 to 12 days after birth (van der Harten et al., 1988).

GENETICS AND RECURRENCE RISK

Achondrogenesis types IA and IB are typically described as single-gene disorders inherited as autosomal recessive conditions. The possibility also exists that germline mosaicism is present in parents who have more than one affected child. Autosomal recessive inheritance is likely, given the documented

increased incidence of consanguinity in affected families (Ornoy et al., 1976). The underlying abnormality in type II achondrogenesis is decreased type II collagen, which is due to mutations in the *COL2A1* gene (Rimoin, 1996). Although formerly thought to be autosomal recessive, type II achondrogenesis is most commonly a de novo dominant mutation, although at least one case of recurrence within a family due to presumed germline mosaicism has been described (Faivre et al., 2004).

Under normal circumstances, type I collagen is not found in cartilage. However, in most cases of achondrogenesis type II, due to the mutations in the type II collagen gene, only type I collagen is seen in cartilage. Most defined mutations in achondrogenesis type II are single amino acid substitutions for a glycine residue in the type II collagen helix near the carboxyl terminal end of the molecule (Rimoin, 1996). In one study, genomic DNA was extracted from 12 patients with achondrogenesis type II to search for mutations in the *COL2A1* gene (Körkkö et al., 2000). The exons and flanking sequences of all 54 exons in the *COL2A1* gene were amplified by the polymerase chain reaction (PCR). PCR products were then scanned for the presence of a mutation using the relatively simple technique of conformation-sensitive gel electrophoresis. Abnormal products were then sequenced. Mutations in the *COL2A1* gene were found in all 12 affected patients (Körkkö et al., 2000).

Mutations in *SLC26A2*—also known as the diastrophic dysplasia sulfate transporter (*DTDST*) gene—cause abnormalities in the sulfation of chondroitin sulfate-containing proteoglycans, and are the basis for achondrogenesis type IB (Superti-Furga et al., 1996). Individuals with this condition have early stop codon mutations in the *DTDST* gene coding regions on both copies of chromosome 5, at bands q32-q33.1. Achondrogenesis type IB is now known to belong to a family of disorders caused by mutations in the *DTDST* gene. These include two lethal disorders, achondrogenesis type IB and atelosteogenesis II, and two nonlethal disorders, diastrophic dysplasia and multiple epiphyseal dysplasia (see Chapter 93) (Rimoin, 1996; Superti-Furga et al., 1996; Karniski, 2001; Rossi and Superti-Furga, 2001). Although *DTDST* is expressed in many tissues, the only tissue known to be affected by mutations in *DTDST* is cartilage (Haila et al., 2001). The gene product is a sulfate-chloride exchanger in the cell membrane. Inactivation of this exchanger leads to intracellular sulfate depletion and synthesis of undersulfated proteoglycans in chondrocytes and fibroblasts (Rossi and Superti-Furga, 2001). Genotype–phenotype correlations exist within this gene. Mutations that predict a truncated protein or a nonconserved amino acid substitution in a transmembrane domain result in the severe phenotypes, while nontransmembrane amino acid substitutions and splice site mutations result in the milder phenotypes (Rossi and Superti-Furga, 2001).

In one case report, a 17-week-old fetus was suspected of having achondrogenesis due to an abnormal prenatal sonographic examination. The family history was remarkable for two prior affected fetuses with achondrogenesis type IB. This fetus was electively terminated and genomic DNA was extracted from frozen femoral cartilage. Nucleotide sequencing of the *DTDST* gene demonstrated that the fetus was homozygous for both delVal340 and Thr689Ser mutations; the parents and a healthy brother were each heterozygous (Cai et al., 1998). This case demonstrates the importance of DNA analysis in affected fetuses with achondrogenesis type IB. Once the mutations in the *DTDST* gene are identified in a family, prenatal diagnosis by chorionic villus sampling then becomes an option in subsequent pregnancies.

98 CHAPTER Hypophosphatasia

Key Points

- Rare hereditary metabolic bone disorder characterized by deficient activity of the tissue-nonspecific isoenzyme of alkaline phosphatase (TNSALP).
- Incidence is 1 in 100,000 births in most ethnic groups but 1 in 2500 in Canadian Mennonites.
- Two forms present perinatally: severe (lethal) and benign, which resolves spontaneously.
- In the severe form sonographic findings include increased nuchal translucency measurement, undermineralized skull, shortened, bent, fixed limbs with decreased echogenicity, and lack of ossification of vertebral bodies, neural arches, and hands. The benign perinatal form presents with symmetric bowing of long bones.
- Differential diagnosis includes anencephaly, osteogenesis imperfecta types II and III, thanatophoric dysplasia, campomelic dysplasia, achondrogenesis, and cleidocranial dysplasia.
- Amniocentesis should be offered to rule out anencephaly, confirm fetal karyotype, assay alkaline phosphatase activity, and check for DNA mutation(s).
- Causative gene is *TNSALP*.
- Severe form is recessively inherited with two mutations. Milder form is dominantly inherited with one mutation.
- Genetic consultation and counseling are indicated.

CONDITION

The term hypophosphatasia was first used by Rathbun in 1948 to describe an infant with severe rickets and very low alkaline phosphatase activity in serum and tissues (Henthorn and Whyte, 1992; Whyte et al., 1995). Hypophosphatasia is a rare inherited metabolic bone disorder characterized by deficient activity of the liver/bone/kidney isoenzyme of alkaline phosphatase. This isoenzyme is also known as the tissue-nonspecific form of alkaline phosphatase (TNSALP).

Alkaline phosphatase was first discovered in 1923, when Robert Robinson noted a large amount of phosphatase activity within ossifying bone and cartilage in rats and rabbits. He was the first to suggest that this catalytic action was important for mineralization of the skeleton due to hydrolysis of a phosphate ester, which would result in the local increase of inorganic (free) phosphate (Whyte, 1994). He subsequently showed that the enzyme functioned optimally at a distinctly alkaline pH, although he never specifically used the term *alkaline phosphatase*. Later, alkaline phosphatase was also demonstrated in tissues that normally do not mineralize, such as the liver, intestines, and placenta; thus, the role of alkaline phosphatase in skeletal mineralization was questioned. It is now known that at least four distinct genes encode four different human alkaline phosphatase isoenzymes. The TNSALP liver bone kidney form is especially rich in mineralizing bone. The location of this gene is on the short arm of chromosome 1, band p36.1-34 (Henthorn and Whyte, 1992; Whyte et al., 1995). The other three genes are found in a cluster on the end of the long arm of chromosome 2. These include placental, intestinal, and placental-like isoenzymes of alkaline phosphatase. Each of the alkaline phosphatase genes have now been sequenced, and the *TNSALP* gene is the largest of the four (Whyte, 1994).

Hypophosphatasia is a clinically variable condition. Mutations in the *TNSALP* gene are responsible for perinatal hypophosphatasia, in which the severity of the disease usually correlates with the age of onset of symptoms. Fetuses detected in utero generally have the most severe form of hypophosphatasia, also known as the perinatal lethal form. Findings in this condition include profound undermineralization of the skeleton, lack of skull ossification resulting in a caput membraneceum, and shortened deformed limbs. Postnatal survival of affected infants is limited because of associated pulmonary hypoplasia and rachitic disease of the chest. Radiographic studies in the newborn are diagnostic. The infantile form of hypophosphatasia presents before the age of 6 months. The newborn can initially appear normal, but poor feeding subsequently develops, as do inadequate weight gain and symptoms of rickets. Additional problems include the development of craniosynostosis, increased intracranial pressure, hypercalcemia, renal failure, and seizures. Approximately 50% of affected infants die. The childhood form is variable in its clinical expression. It is characterized by premature loss of the deciduous teeth at an age of less than 5 years, resulting from abnormalities of the dental cementum, which is important for connection between the tooth roots and the periodontal ligament (Whyte, 1994). Affected children also have short stature, rickets, deformation of the legs, knees, ankles, and wrists, although some of these improve with age. Affected patients have characteristic abnormalities on radiographs, which include focal bony defects near the ends of the major long bones. These manifest as a tonguelike shape of radiolucency that projects from the growth plate into the metaphysis (Whyte, 1994). The adult form of hypophosphatasia generally presents during middle age. A childhood history of rickets or premature loss of deciduous teeth may or may not be present. In general, affected adults enjoy relatively good health as adolescents and young adults, but then develop recurrent metatarsal stress fractures and early loss of permanent teeth. The mildest form of hypophosphatasia is called "odontohypophosphatasia," which is reserved for patients whose only clinical manifestation is dental disease. Most recently, it has become appreciated that there is another mild form that presents in fetal life with severe symmetric long bone bowing that resolves spontaneously (Moore et al., 1999; Pauli et al., 1999; Comstock et al., 2005). No absolute diagnostic criteria exist for the separation of the various clinical presentations. A continuous spectrum of symptoms exists. This chapter will focus on the two forms that present in the antenatal period.

INCIDENCE

The incidence of hypophosphatasia, based on data from Toronto, is 1 in 100,000 livebirths (Mulivor et al., 1978; Greenberg et al., 1990). Cases of hypophosphatasia have been described throughout the world, occurring in all races (Whyte, 1994). During the years 1977 to 1986, six neonates affected with hypophosphatasia were born in southern Manitoba. After these infants were identified, it was appreciated that Mennonites in southern Canada have a 1 in 25 chance of being a carrier for at least one mutation in the *TNSALP* gene. The birth incidence of affected infants with hypophosphatasia in Mennonites is 1 in 2500 (Chodirker et al., 1990). This unusually high incidence is presumably due to a founder effect with inbreeding.

SONOGRAPHIC FINDINGS

The most striking abnormality described in cases of the severe form of perinatal hypophosphatasia is the absence of a normally formed fetal skull (Kousseff and Mulivor, 1981). The hallmarks for sonographic diagnosis of hypophosphatasia include a fetus that is small for gestational age with decreased echogenicity of the bones, a prominent falx cerebri due to undermineralization of the skull, various skeletal deformities,

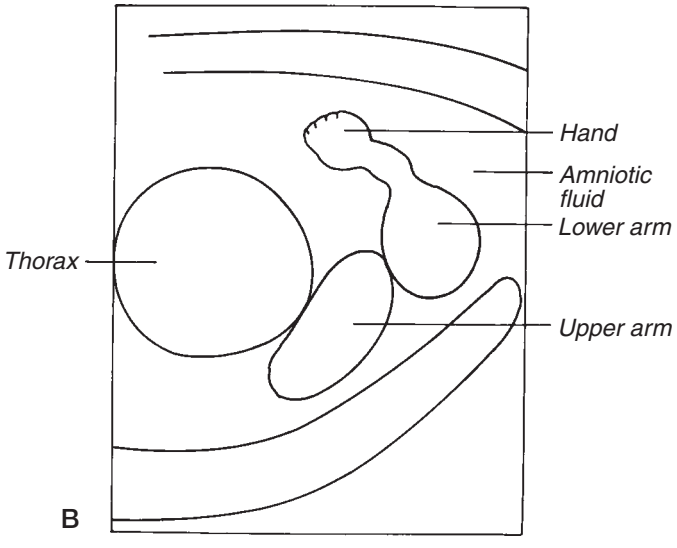

Figure 98-1 **A.** Sonographic image of a fetus at 24 weeks with hypophosphatasia, demonstrating severely shortened and bent forearm. **B.** Diagram of sonographic image in panel (A). (*Reprinted, with permission, from van Dongen PWJ, Hamel BCJ, Nijhuis JG, de Boer CN. Reprinted with the permission of Elsevier Science Ireland Ltd., Bay 15K, Shannon Industrial Estate, Co. Clare, Ireland.*)

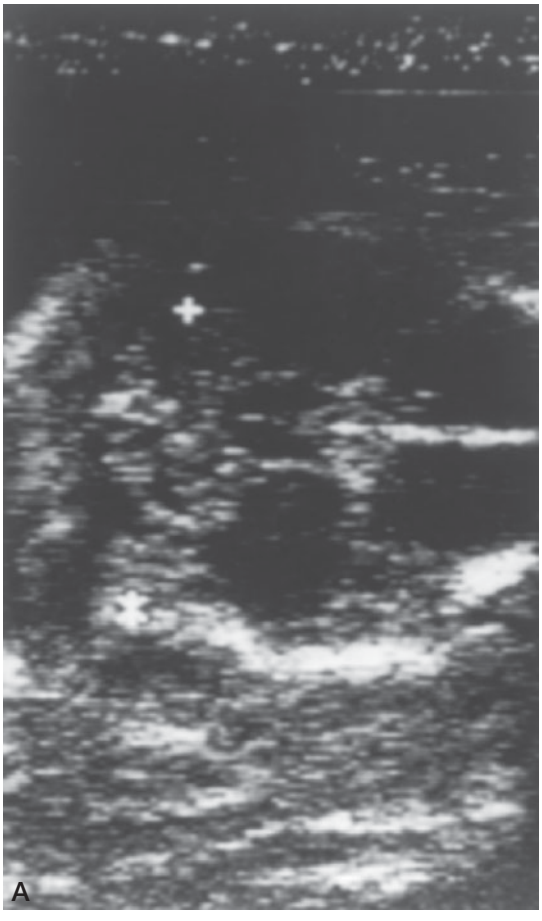
and the presence of polyhydramnios occurring later in gestation (Wladimiroff et al., 1985). Also, pulmonary hypoplasia may be documented as a result of a severely reduced thoracic volume due to abnormal and short ribs. In one report, Van Dongen et al. (1990) described sonographic studies performed in a family with a previously affected child. Even as early as 8 weeks of gestation, the crown-to-rump length was suggestive of a fetus 1.5 weeks younger than the actual gestational age. The family was lost to follow-up until 24 weeks of gestation, when severe polyhydramnios was noted. Other findings included an active fetus with shortened, bent, fixed limbs with markedly decreased echogenicity, which prevented separate visualization of the fingers and toes (Figure 98-1A and 98-1B). The falx cerebri and other central nervous system structures could be distinguished unusually clearly due to the low echogenicity of the skull bones (Figure 98-2A and 98-2B). This was described as being similar to the fetal appearance in hydrocephalus. In another report of prenatal diagnosis in a family at risk for recurrence of hypophosphatasia, the failure to outline a fetal head was noted at 16 weeks of gestation (Rudd et al., 1976). The skull was described as a very thin, faint circular outline. In addition, skip defects were noted in the cervical spine vertebral bodies.

In another case, with a negative family history, but a conception marked by consanguinity, underossification of the skull, facial bones, ribs, and limbs was noted at 27 weeks of gestation (DeLange and Rouse, 1990). In addition, underossification of the metacarpals, neural arches of the spine, and vertebral bodies was present. This group made a presumptive prenatal diagnosis of hypophosphatasia based on (1) the generalized underossification of the fetal bones, (2) shortening of the limbs, and (3) lack of ossification of groups of vertebral bodies, the neural arches, and the hands.

Souka et al. (2002) demonstrated the presence of an increased nuchal translucency measurement in two fetuses with hypophosphatasia from the same family. In the first affected fetus, additional findings were seen at 14 weeks, including fixed flexed upper and lower limbs, hypomineralization of the skull and spine, narrowing of the chest with short ribs, shortening of all of the long bones, and bilateral talipes. In the second affected pregnancy, sonographic examination at 12 weeks showed hypomineralization of the skull



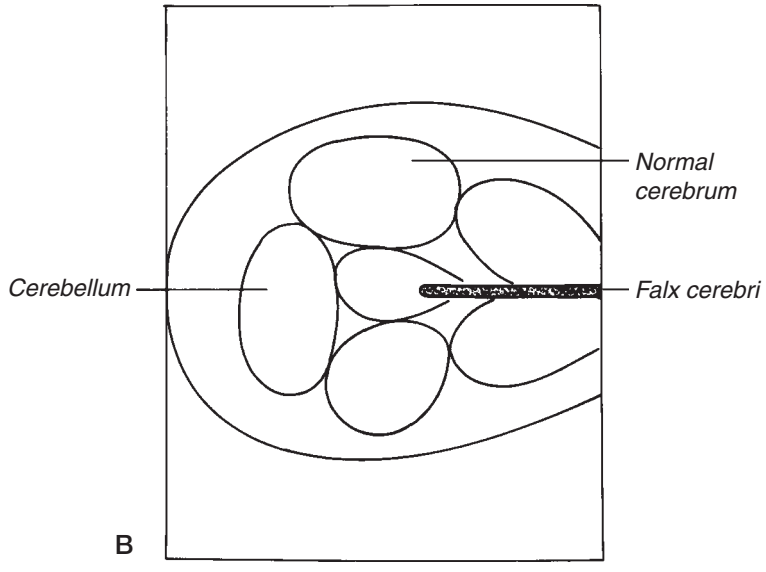


Figure 98-2 **A.** Sonographic image of the fetus seen in Figure 98-1A, demonstrating unusually clear visualization of the falx cerebri. **B.** Diagram of sonographic image in panel (A). (*Reprinted, with permission, from van Dongen PWJ, Hamel BCJ, Nijhuis JG, de Boer CN. Reprinted with the permission of Elsevier Science Ireland Ltd., Bay 15K, Shannon Industrial Estate, Co. Clare, Ireland.*)

and spine, narrowing of the chest, and shortening and bowing of the limbs. This report is the earliest prenatal sonographic diagnosis of specific findings associated with hypophosphatasia.

A dominantly inherited form of mild hypophosphatasia has also been described that presents in utero as severe bowing of the long bones (Moore et al., 1999; Pauli et al., 1999). Interestingly, in this condition, prenatal and postnatal improvement of the bone dysplasia occurs spontaneously although affected children remain short and have premature loss of teeth. Some authors suggest that the condition should be called the "benign prenatal" form of hypophosphatasia.

DIFFERENTIAL DIAGNOSIS

Failure to visualize the fetal skull may lead to an initial presumptive differential diagnosis of hypophosphatasia versus anencephaly. Other conditions that may result in malformation and undermineralization of the bones include osteogenesis imperfecta types II and III, thanatophoric dysplasia, campomelic dysplasia, and achondrogenesis. Achondrogenesis (see Chapter 97) can be distinguished from hypophosphatasia by an ossified calvarium, as well as better ossification of the neural arches with nonossification of the vertebral bodies. Cleidocranial dysplasia can be associated with decreased bone density and low alkaline phosphatase activity and may thus mimic hypophosphatasia (Morava et al., 2002).

ANTENATAL NATURAL HISTORY

Little is known about the antenatal natural history for fetuses affected with hypophosphatasia. There is an increased incidence of stillbirth for the severe perinatal form, although the cause for this is unknown.

MANAGEMENT OF PREGNANCY

The strategies for the definitive prenatal diagnosis of hypophosphatasia have included fetal radiography (in the early 1980s), prenatal sonography, assay of alkaline phosphatase activity in cultured amniocytes, fibroblasts, or chorionic villus samples, measurement of alkaline phosphatase activity in fetal

serum obtained by cordocentesis (Tongsong and Pongsatha, 2000), or analysis of DNA from fetal tissue (Henthorn and Whyte, 1995). Management of pregnancy differs in the setting of a positive family history of hypophosphatasia versus a negative family history. If the family history is positive, ideally DNA has been previously obtained from the affected proband before death. This material, along with parental blood samples, should be sent to a diagnostic reference laboratory with experience in the identification of mutations in the *TNSALP* gene. If the mutation(s) in the family is known, prenatal diagnosis is best performed by chorionic villus sampling (CVS) to identify the presence of parental mutation(s) in the fetus (Mornet et al., 1999).

If mutation analysis has not been performed on a previously affected child, other approaches to prenatal diagnosis may include the use of monoclonal antibody to the TNSALP isoenzyme on fetal material obtained by CVS. In one report of 16 pregnancies at risk for hypophosphatasia, a normal range for the TNSALP levels was established (50–150 μmol activity per minute per gram of tissue; median = 130). In 11 of the 16 at-risk cases, the fetus had greater than 50 μmol per minute per gram of tissue. These values were considered to fall within the normal range. All pregnancies continued to term and all infants were normal. In 5 of the 16 at-risk pregnancies, the TNSALP values were <25 μmol per minute per gram of tissue and all fetuses were terminated. Four of the 5 affected fetuses were confirmed as abnormal either by documenting sonographic abnormalities, autopsy diagnosis of abnormally foreshortened limbs, or by subsequent biochemical confirmation on fibroblast or liver tissue. One family was lost to follow-up (Brock and Barron, 1991). Muller et al. (1991) have cautioned that CVS material should be sampled at less than 12 weeks of gestation and that particular care should be taken to eliminate maternal decidual tissue from the sample. These authors have confirmed the very low activity of the TNSALP in early chorionic villus material in affected fetuses. Placental alkaline phosphatase was never detected by these authors before 9 weeks of gestation. Affected pregnancies have both low total alkaline phosphatase and 0% TNSALP (Muller et al., 1991). Thus, in families with a positive history of hypophosphatasia but with no knowledge of DNA mutation analysis, prenatal diagnosis may be performed in two different ways on chorionic villus material.

In the setting of a fetus with typical sonographic findings suggesting the presence of hypophosphatasia, but a negative or unknown family history, we suggest performing amniocentesis to measure amniotic fluid α-fetoprotein to rule out anencephaly and to confirm the fetal karyotype. The amniocytes may be placed into culture and used for both assay of alkaline phosphatase activity (Mulivor et al., 1978; Kousseff and Mulivor, 1981) and DNA analysis (Mornet et al., 1999). Alternatively, a cordocentesis can be performed to measure alkaline phosphatase levels (Tongsong and Pongsatha, 2000). Normal values are 51 ± 24 IU/L. Affected fetuses have undetectable or very low levels. Consultation with a clinical geneticist is indicated.

FETAL INTERVENTION

There are no fetal interventions for hypophosphatasia.

TREATMENT OF THE NEWBORN

No effective treatment is currently available for the perinatal form of hypophosphatasia. Vitamin D and mineral supplements normally used in the treatment of rickets should be avoided, since circulating levels of calcium, inorganic phosphorus, and the vitamin D metabolites are generally normal in affected patients with hypophosphatasia (Whyte, 1994). Unsuccessful attempts have been made to infuse several types of alkaline phosphatase intravenously (Whyte, 1994). Because perinatal hypophosphatasia is a lethal condition, treatment of the newborn should be directed toward confirming the diagnosis and ensuring that a mechanism is in place for follow-up genetic counseling.

Physical findings at birth include rhizomelic and asymmetric shortening of all four extremities, with very pliable skull bones and possible craniotabes (Kousseff and Mulivor, 1981). The infant's thorax is extremely compliant and a respirator may be required for ventilation. This should be considered only for the time needed to confirm the diagnosis, as the abnormalities in the thorax will not improve. Confirmatory postnatal radiographs may be obtained, which should reveal the extreme hypomineralization that is considered diagnostic of this condition (Figure 98-3). Serum may be obtained to demonstrate the decreased activity of TNSALP and increased urinary excretion of phosphoethanolamine. Serum calcium is typically normal except in infantile cases, in which hypercalcemia is a secondary effect of renal failure (Chodirker et al., 1990).

When the infant dies, an autopsy should be obtained to confirm the diagnosis. This will demonstrate that the cranium has been replaced by connective tissue. The absence of alkaline phosphatase activity in the bones, heart, and liver should be documented (Van Dongen et al., 1990).

SURGICAL TREATMENT

There is no surgical treatment for hypophosphatasia.

LONG-TERM OUTCOME

The long-term outcome is only an issue for infants with the benign perinatal and infantile forms of hypophosphatasia. These infants should be followed carefully for evidence of increased intracranial pressure due to functional or true premature craniosynostosis (Whyte, 1994). Affected infants also

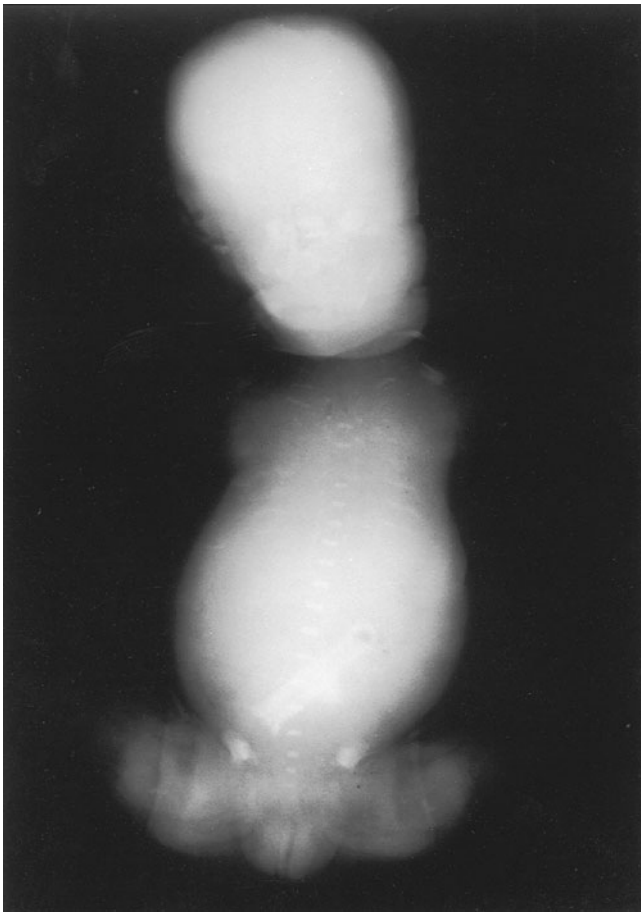

Figure 98-3 Postmortem radiograph of a newborn infant with hypophosphatasia. Note the severely hypomineralized bones. (*Reprinted, with permission, from van Dongen PWJ, Hamel BCJ, Nijhuis JG, de Boer CN. Reprinted with the permission of Elsevier Science Ireland Ltd., Bay 15K, Shannon Industrial Estate, Co. Clare, Ireland.*)

need close follow-up with an orthopedic surgeon and observation for the development and treatment of fractures. These infants need close follow-up with a dentist and careful attention to dental hygiene. Interestingly, adult survivors of infantile hypophosphatasia may have normal stature (Whyte, 1994). Bone marrow transplant has been suggested as a treatment for survivors that have poor growth, fractures, and respiratory problems (Whyte et al., 2003).

GENETICS AND RECURRENCE RISK

The *TNSALP* gene is the gene responsible for perinatal hypophosphatasia. This gene has been localized to chromosome 1p36.1-34 (Greenberg et al., 1990). The *TNSALP* gene is large, consisting of more than 50 kilobases of DNA. The gene contains 12 exons, 11 of which are translated. The nascent enzyme consists of 507 amino acid residues (Whyte, 1994). The tissue-specific (placental, intestinal, and placental-like) alkaline phosphatase genes are smaller and contain shorter exons. There is approximately 87% identity between the sequences of placental and intestinal alkaline phosphatase but only 52% to 56% identity between the tissue-specific isoenzymes and the tissue-nonspecific isoenzymes of alkaline phosphatase. In the placenta, expression of alkaline phosphatase is controlled through the fetal genome (Whyte, 1994).

Molecular studies have determined that the primary genetic defects in hypophosphatasia are missense mutations in the *TNSALP* gene (Henthorn and Whyte, 1992; Henthorn et al., 1992). Hypophosphatasia is molecularly heterogeneous, with a correlation between genotype and phenotype (Zurutuza et al., 1999). More than 128 mutations have been described to date (Gehring et al., 1999; Witters et al., 2004). Individuals with the recessive form of hypophosphatasia have two mutant *TNSALP* alleles. Individuals with the milder, dominant form of hypophosphatasia have only one mutant *TNSALP* allele. Normal biomineralization occurs if a single normal copy of *TNSALP* is present (Hu et al., 2000).

Following the birth of an affected infant, the carrier status of parents can be confirmed by both biochemical and DNA studies. In obligate carriers, the TNSALP isoenzyme is lower than normal and urinary phosphoethanolamine is significantly higher. Carriers also have a relative hyperphosphatemia with normal serum inorganic phosphate (Chodirker et al., 1990). Families that have an affected infant with the perinatal form of hypophosphatasia should have DNA mutation analyses coordinated by a genetic counseling center and sent to a referral laboratory. Genetic counseling is definitely indicated for this condition, and prenatal diagnosis is available for subsequent pregnancies (see "Management of Pregnancy").

Chondrodysplasia Punctata

99 CHAPTER

Key Points

- Chondrodysplasia punctata comprises a group of genetically heterogenous skeletal dysplasias characterized by small calcified densities in the epiphyses of the long bones.
- The rhizomelic form (RCDP) is more severe and inherited as an autosomal recessive condition. Rhizomelic chondrodysplasia punctata is a disorder of the peroxisomes.
- The nonrhizomelic form, also known as Conradi–Hünermann syndrome, can be inherited as an autosomal dominant, X-linked recessive or dominant condition. It is generally milder.
- Sonographic findings include profound humeral and femoral shortening in rhizomelic chondrodysplasia punctata. Multiple hyperechoic foci (puncta), nasal hypoplasia, midface depression, vertebral anomalies, and congenital heart defects are associated with both RCDP and Conradi–Hünermann syndrome.
- Differential diagnosis includes skeletal dysplasias, autosomal trisomies, Zellweger syndrome, disorders of vitamin K metabolism, warfarin exposure, Smith–Lemli–Opitz syndrome, and GM_1 gangliosidosis.

Key Points (cont.)

- Pregnant women carrying fetuses with punctate calcifications should be referred to a tertiary center and to a medical geneticist. Chromosome analysis is indicated to rule out trisomy and deletions of Xp22.3.
- There are three types of RCDP; type 1 is most common, caused by mutations in *PEX7*. Molecular diagnosis is possible for all three types.
- Prognosis is poor for RCDP. Only 50% of affected infants survive past the age of 6 years. All affected infants have severe failure to thrive, mental retardation, joint contractures, and cataracts.
- Infants affected with Conradi–Hünermann syndrome have milder symptoms, generally normal intelligence and, with the exception of the X-linked dominant form in males, a fairly normal lifespan.

CONDITION

Chondrodysplasia punctata denotes a group of skeletal dysplasias characterized by locally disordered bone mineralization that results in bone stippling observed on radiographs obtained during the newborn period (Pryde et al., 1993). The areas of punctate calcification were first described by Conradi in 1914. In 1931, Hünermann designated the disorder "chondrodystrophia calcificans congenita." This term was defined as the X-ray finding of small calcified densities in the epiphyses (Hyndman et al., 1976). The disorder recognized by Hünermann also included micromelia, a saddle nose deformity, flexion contractures, cataracts, and a dermopathy. As used today, the term chondrodysplasia punctata comprises a group of genetically heterogeneous disorders (Spranger et al., 1971). Some of these are associated with rhizomelia (proximal limb shortness) and some are not. The rhizomelic form is generally more severe. It has been subdivided into three types, each of which is associated with a mutation in a different gene (see Figure 99-1). All three types are inherited as autosomal recessive conditions. The nonrhizomelic form of chondrodysplasia punctata, also known as Conradi–Hünermann syndrome, is milder and can be inherited as an autosomal dominant, X-linked recessive, or X-linked dominant condition. A rarer form of mild chondrodysplasia punctata, known as the tibia-metacarpal type, is inherited as an autosomal dominant condition.

Rhizomelic chondrodysplasia punctata is a disorder of the peroxisomes. Peroxisomes are intracellular organelles that catalyze a number of metabolic functions (Wanders and Waterham, 2004). These include β-oxidative chain shortening of fatty acids and their derivatives, synthesis of ether phospholipids, and detoxification of glyoxalate (Hoefler et al., 1988; Schutgens et al., 1989; Wanders et al., 1993). Human peroxisomal disorders are subdivided into two categories: those in which the organelle is not normally formed (peroxisome biogenesis disorders) and those that involve a single peroxisomal enzyme (Moser, 1999).

In patients with rhizomelic chondrodysplasia punctata, the peroxisomes are present, but they have lost many of their normal functions. Four distinct abnormalities have been found in patients with rhizomelic chondrodysplasia. These involve deficiency of enzymes important in phospholipid synthesis and phytanic acid oxidation (Hoefler et al., 1988; Schutgens et al., 1989; Wanders et al., 1993). A severe deficiency in plasmalogen synthesis is associated with deficient activities of the peroxisomal enzymes acyl coenzyme A (acyl CoA, dihydroxyacetone phosphate [DHAP] acyltransferase) and alkyl-dihydroxyacteone phosphate synthase. In addition,

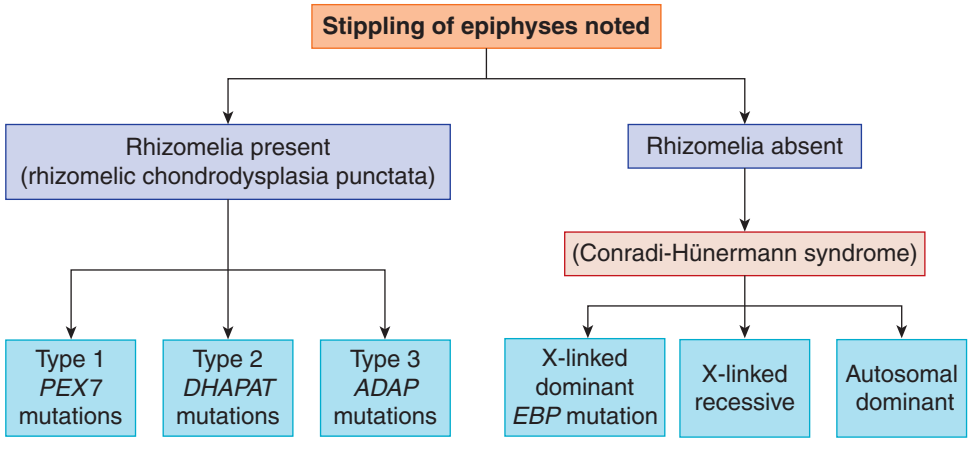

Figure 99-1 Approach to the diagnosis of the conditions characterized by small calcified densities in the epiphyses of the long bones.

there is deficient activity of phytanic acid oxidase, and the enzyme peroxisomal 3-oxo-acyl-CoA thiolase is present in an abnormal unprocessed form (Gendall et al., 1994; Suzuki et al., 1994). Because of these enzyme abnormalities, the characteristic biochemical abnormality in rhizomelic chondrodysplasia punctata is increased phytanic acid levels and decreased plasmalogens (Singh et al., 1988). In rhizomelic chondrodysplasia punctata, unlike in other peroxisomal conditions, the amount of very long-chain fatty acids is normal. In the absence of a known familial DNA mutation, one way to identify rhizomelic chondrodysplasia punctata prenatally is to analyze the plasmalogen levels in chorionic villi and erythrocytes (Wanders et al., 1993).

To date, 32 peroxisomal (peroxins, or *PEX*) genes have been identified (Wanders and Waterham, 2004). Most of them are also found in yeast, indicating their essential importance for cellular metabolism. Thus far, 16 *PEX* genes have been identified in humans (Subramani, 1997; Wanders and Waterham, 2004). Of these, twelve have been implicated in human disorders. Patients with rhizomelic chondrodysplasia punctata are deficient in a subset of peroxisomal enzymes.

INCIDENCE

The incidence of rhizomelic chondrodysplasia punctata is approximately 1 in 100,000 livebirths (Connor et al., 1985; Stoll et al., 1989). Parental consanguinity has been noted in 8% to 10% of recessively inherited cases (Stoll et al., 1989). The incidence of dominantly inherited Conradi–Hünermann syndrome is presumably higher, as clinically the condition appears to be at least twice as common (Stoll et al., 1989). Precise incidence figures are unavailable because many mildly affected patients go unrecognized. The incidence of Zellweger syndrome, another peroxisomal disorder that can be associated with punctate calcifications around the extremities, is 1 in 50,000, with an estimated gene frequency of 1 in 110 individuals in the United States (Zellweger et al., 1988).

SONOGRAPHIC FINDINGS

The major sonographic criterion for a diagnosis of rhizomelic chondrodysplasia punctata includes profound humeral shortening that is less marked than the femoral shortening, without shortening of other bones. In addition, expanded epiphyses are present, which contain multiple hyperechoic foci (the so-called puncta) (Figure 99-2). In normal fetuses, the distal femoral epiphyseal ossification center is never identified before 28 weeks and is more commonly appreciated after 34 weeks (Pradhan et al., 2002). In addition, nasal hypoplasia or midface depression with frontal bossing may be observed in the fetal profile. Approximately 10% of cases have associated congenital heart disease, predominantly pulmonic stenosis, and pulmonary artery and aortic calcifications (Fourie, 1995). In nonrhizomelic chondrodysplasia punctata (Conradi–Hünermann syndrome), the major finding is the long bone epiphyseal calcifications. Similar facial abnormalities to those seen in the rhizomelic form may also be present.

The first prenatal diagnosis of Conradi–Hünermann syndrome was made incidentally, when radiography was performed to assess fetal maturity in a woman who was post-term (Hyndman et al., 1976). The radiograph demonstrated stippling of the epiphyses at the fetal ankles, knees, pubic and ischial bones, and femur. At birth, the infant was noted to have a saddle nose deformity as well as coronal cleft vertebrae in the lumbar spine.

Cases of sonographic prenatal diagnosis of Conradi–Hünermann syndrome have also been described in the

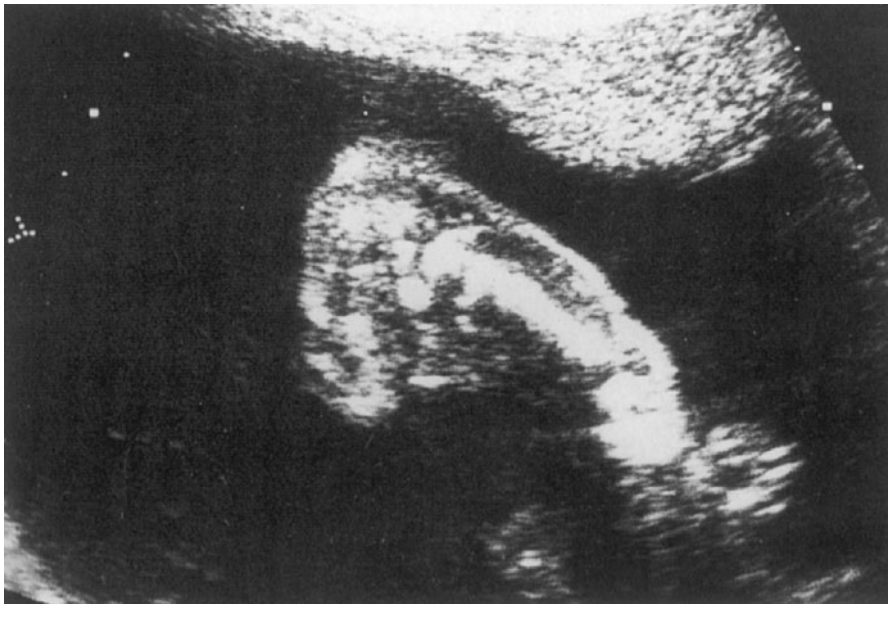

Figure 99-2 Prenatal sonographic image of a fetal femur at 22 weeks of gestation demonstrating proximal shortening and increased echogenicity due to punctate epiphyseal calcification. *(Reprinted, with permission, from Sastrowijoto SH, Vandenberghe K, Moerman P, Lauweryns JM, Fryns JP. Prenatal ultrasound diagnosis of rhizomelic chondrodysplasia punctata in a primigravida. Prenat Diagn. 1994;14:770-776. Copyright 1994 John Wiley & Sons. Reprinted, by permission, of John Wiley & Sons, Ltd.)*

literature. In one report, Tuck et al. (1990) described a 21-year-old primigravida with a known diagnosis of Conradi–Hünermann syndrome. She had ichthyosis; sparse, dry hair; and asymmetrical limb shortening. She had surgery performed on her right hip at 6 years of age and subsequently had operations to lengthen her right femur at the age of 9 years. As an adult, she had short stature (144 cm) and a pronounced limp. When she became pregnant, sonographic survey of fetal anatomy was performed at 17 weeks of gestation and revealed a 3 mm asymmetry between the lengths of the right and left fetal femora and humeri. This asymmetry persisted on prenatal sonograms performed at 21, 24, 32, and 35 weeks of gestation. At birth, radiographs of her infant demonstrated epiphyseal stippling that was missed on prenatal sonogram. Physical examination also revealed a low nasal bridge, malar hypoplasia, and ichthyotic skin (Tuck et al., 1990).

As shown in the case above, the diagnosis of Conradi–Hünermann syndrome is more straightforward when it is known that one of the parents is affected. In one report, Pryde et al. (1993) described a pregnant woman, who herself had been diagnosed with Conradi–Hünermann syndrome at birth, who presented with scoliosis, punctate calcifications of the spine and femoral epiphyses, asymmetric limb shortening, postaxial polydactyly, cataracts, and irregular macular skin hyperpigmentation. In her first pregnancy, her fetus was noted to have asymmetrical short limbs, scoliosis, and mild ventriculomegaly. In her second pregnancy, at 16 weeks of gestation a 5 mm difference was noted between the right and left femoral lengths. At 32 weeks, severe polyhydramnios developed. At birth, the diagnosis was confirmed by the presence of a saddle nose, ichthyotic skin, and epiphyseal stipplings seen on radiographs. In this report, an affected fetus with a negative family history was also described. Prenatal sonograms were characterized by severe disorganization of the fetal spine observed at 18 weeks of gestation, represented by malsegmentation of the vertebrae along the entire length of the spine. No definitive scoliosis or short long bones was observed. At 21 weeks, the fetal profile demonstrated a flat nasal bridge. In addition, hyperechoic regions were observed at the femoral epiphyses that suggested premature calcification. In the same fetus, polyhydramnios was observed at 30 weeks (Pryde et al., 1993).

The diagnosis of rhizomelic chondrodysplasia punctata is easier to make than Conradi–Hünermann syndrome because of the severe shortening of the extremities in combination with premature ossification and stippling of the ephiphyses (Hertzberg et al., 1999). Since the condition is inherited in an autosomal recessive manner, there will be a negative family history for most cases. The prenatal sonographic findings reveal bilateral symmetric proximal shortening of the humeri and femora (less than the 3rd percentile for gestational age), along with marked epiphyseal echogenicity that suggests the presence of the punctate epiphyseal calcifications (Sastrowijoto et al., 1994). Additional fetal findings may include brachycephaly, hydrocephalus, scalp edema, hypertelorism, hypoplastic nose, and coronal clefts of the vertebral bodies. Bilateral cataracts have been detected by sonogram in a fetus with rhizomelic chondrodysplasia, type 1, at 30 weeks of gestation (Başbuğ et al., 2005). Congenital heart disease has also been reported in the rhizomelic form of chondrodysplasia punctata (Sastrowijoto et al., 1994).

Duff et al. (1990) described the sonographic diagnosis of rhizomelic chondrodysplasia punctata at 28 weeks of gestation in a woman with a previous affected infant. These investigators demonstrated stippling at the proximal end of the right humerus and both femurs over an 8-week period. The tibia consistently measured at the 20th percentile for gestational age, but both the femur and humerus were consistently at less than the 5th percentile. Over the period observed, a progressively more mottled appearance of the proximal end of the right humerus was demonstrated. The bone became more and more attenuated, irregular, and stippled in appearance, making it difficult to precisely define the end of it (Duff et al., 1990). In another report, a set of dichorionic twins was described, in which one was noted to have rhizomelic limb shortening at 25 weeks of gestation. In this fetus, the humeri were shaped like dumbbells and multiple hyperechoic foci were noted in the humeral epiphyses and the proximal femoral epiphyses. A 15-week sonogram was reanalyzed retrospectively; it revealed that the profound humeral shortening had previously been missed. Even at 15 weeks of gestation, flared humeral metaphyses and widened hyperechoic proximal ends of the humeri were visible (Gendall et al., 1994). After postmortem examination, the diagnosis of rhizomelic chondrodysplasia punctata was confirmed in this twin by demonstration of absent alkyl-dihydroxyacetone phosphate synthase activity in cultured skin fibroblasts.

Although two-dimensional ultrasound is adequate for diagnosis, at least one report exists that demonstrated enhanced resolution of pathologic findings in rhizomelic chondrodysplasia punctata using three-dimensional sonography and three-dimensional helical computer tomography (Ruano et al., 2004).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of conditions that result in limb shortening with punctate epiphyses is given in Table 99-1. The conditions include skeletal dysplasias, other genetic or metabolic disorders, disorders of vitamin K metabolism, and teratogens. To distinguish among the conditions grouped under the term chondrodysplasia punctata, fetal limb length must be measured. The humeri are the shortest in the rhizomelic form of chondrodysplasia punctata. The presence of polydactyly may suggest the more mildly X-linked dominant form of Conradi–Hünermann syndrome (Poznanski, 1994). The major consideration in the differential diagnosis is to distinguish between the rhizomelic form of chondrodysplasia punctata and the milder, Conradi–Hünermann type.

The other major condition that can present with punctate epiphyses is Zellweger (cerebrohepatorenal) syndrome,

Table 99-1

Differential Diagnosis of Punctate Epiphyses

Vitamin K epoxide reductase deficiency
Teratogens
Fetal alcohol effects
Hydantoin exposure
Phenacetin intoxication
Maternal febrile illness

Source: Poznanski AK. Punctate epiphyses: a radiological sign, not a disease. Pediatr Radiol *1994;24:418-424.*

which is also characterized by lack of peroxisomes. In this condition, fetal limb length should be appropriate for gestational age, but additional antenatal findings may include hepatomegaly, hypotonia, and cystic changes in the liver and kidney. The calcifications in Zellweger syndrome tend to be centered around the patella. A number of other metabolic conditions, such as Smith–Lemli–Opitz syndrome and GM_1 gangliosidosis, can also present with punctate epiphyses (see Table 99-1).

Fetal exposure to warfarin, an anticoagulant, or the presence of a vitamin K epoxide reductase deficiency can result in stippled epiphyses. Warfarin exerts its effect on the developing fetus by inhibiting vitamin K–dependent posttranslational carboxylation of certain bone proteins. Vitamin K is normally converted to vitamin K epoxide. The enzyme vitamin K epoxide reductase then converts this metabolite back to vitamin K. Warfarin inhibits this reductase, so vitamin K–dependent carboxylases do not have their cofactor. The vitamin K disorders can result in fetal findings that are very similar to chondrodysplasia punctata, including nasal hypoplasia, calcification of the trachea, and brachytelephalangic changes of the digits (Poznanski, 1994; Tongsong et al., 1999). The effects of warfarin and other coumarin derivatives are most significant when the fetus is exposed during the sixth to ninth week of gestation (Poznanski, 1994). In both fetal alcohol exposure and the autosomal trisomies, the puncta are characteristically seen in the tarsal bones.

ANTENATAL NATURAL HISTORY

The underlying bone abnormalities that result in the chondrodysplasia punctata phenotype are present in the early second trimester. In studies of fetuses from pregnancies that have been terminated, extensive characteristic calcifications have been noted in the sites of endochondral bone formation in the limbs and trunk. The calcifications are distinct from endochondral bone. Ossification appears delayed in areas where calcifications are most prominent (Silengo et al., 1980). In rhizomelic chondrodysplasia punctata, histopathologic studies reveal that the abnormal areas of calcification are characterized by irregular distribution of cartilage cells, mucoid degeneration, presence of cystic spaces, increased vascularity, and proliferation of fibroblasts (Duff et al., 1990). The growth plates of the long bones are normal and the chondrocytes are arranged in normal columns (Sastrowijoto et al., 1994).

In fetuses with Zellweger syndrome, stippled calcifications of the patella, femur, and humerus are all observed by 20 weeks of gestation. In addition, the renal microcysts and macrocysts are also present. This condition is also characterized by neuronal migrational abnormalities. Cortical plate defects and heterotopias that are apparent at the light microscope level are associated with lipid inclusions at the ultrastructural level (Powers, 1995). These abnormalities are all because of the absence of peroxisomes.

MANAGEMENT OF PREGNANCY

Fetuses that are suspected of having punctate calcifications or rhizomelic limb shortening should be referred to a center capable of detailed anatomic scanning. Once the suspected diagnosis of chondrodysplasia punctata has been confirmed, it is prudent to refer the parents to a medical geneticist, who could then examine both of them for mild signs of Conradi–Hünermann syndrome. This is extremely important, as the prognosis for the infant will differ depending on the cause of the puncta. If one of the parents is affected, as opposed to neither parent being affected, the prognosis will be considerably improved. It is critical that the person who examines the parents looks for nonskeletal manifestations of Conradi–Hünermann syndrome. As an example, Silengo et al. (1980) reported that a 27-year-old woman presented for genetic counseling because her 32-month-old daughter had Conradi–Hünermann syndrome. Despite the fact that the mother walked with a limp, was short, had patches of alopecia, and had follicular atrophoderma, she herself had not been

diagnosed as having Conradi–Hünermann syndrome. A slit-lamp examination revealed the presence of early lenticular cataracts in the mother. This woman had no abnormalities in her long bones or spine, but because of her hip dysplasia and eye and skin abnormalities, she was retrospectively diagnosed as affected. Therefore, for any fetus in which chondrodysplasia punctata is suspected, parents and close relatives should be specifically examined for the presence of a hypoplastic nose, cataracts, optic atrophy, alopecia, or pigmentary skin changes.

In addition, a chromosome analysis should be performed on the fetus to evaluate for the X-linked recessive form of chondrodysplasia punctata, which may be due to a deletion of chromosome X at band p22.3 (Bick et al., 1992). Several investigators have described the existence of a contiguous gene syndrome at Xp22.3 that consists of chondrodysplasia punctata, steroid sulfatase deficiency, and X-linked Kallman syndrome, which includes hypogonadism due to hypothalamic gonadotropin-releasing hormone deficiency and anosmia secondary to absence of the olfactory bulbs and tracts (Bick et al., 1992).

For families who have had previously affected children with the rhizomelic form of chondrodysplasia punctata, prenatal diagnosis can be performed by biochemical analysis of either chorionic villi or amniocytes, although the recent identification of DNA mutations in the *PEX7, DHAPAT*, and *ADAPS* genes (see "Genetics and Recurrence Risk") should facilitate prenatal DNA diagnosis.

No specific indication exists for cesarean delivery. Fetuses in which chondrodysplasia punctata is suspected should be delivered at a tertiary care center because of the risk of respiratory distress.

FETAL INTERVENTION

There are no fetal interventions for chondrodysplasia punctata.

TREATMENT OF THE NEWBORN

Treatment of the newborn begins with an extensive and detailed physical examination. A list of the comparative clinical findings associated with nonrhizomelic chondrodysplasia punctata is given in Table 99-2. For many of the conditions associated with chondrodysplasia punctata, nasal hypoplasia is commonly seen (Seguin et al., 1993). This finding may be associated with a small and/or calcified airway. In one study, 29% of affected infants had respiratory distress syndrome during the newborn period that was attributed to the small airway (Seguin et al., 1993). The airway obstruction improves with age, as it is not typically found in older children (see Figure 99-3).

Many of the typical radiographic findings that aid in obtaining the diagnosis are best observed during the newborn period, as they tend to disappear with age. These include the punctate epiphyses and vertebral clefts. A diagnosis of Conradi–Hünermann syndrome may be presumptively made by the characteristic facial appearance that consists of a flattened face due to malar hypoplasia, a small nose with a flat nasal bridge, a prominent forehead, wide-set eyes, and upslanting palpebral fissures. Cataracts are seen in 18% of affected infants (Poznanski, 1994). Infants affected with Conradi–Hünermann syndrome may have ichthyosiform erythroderma or systemic atrophoderma. They may also have patches of alopecia and contractures of the extremities. The limb shortening is usually mild but it can be asymmetric. Polydactyly may be observed in the X-linked dominant form.

Infants affected with rhizomelic chondrodysplasia punctata have much more marked shortening of the upper limbs. The metaphyses are generally flared. Radiographs demonstrate the puncta less commonly than in Conradi–Hünermann syndrome (see Figure 99-4). The physical examination reveals the presence of full cheeks, giving the infant the appearance of a chipmunk (see Figure 99-3). The skin changes are much less commonly observed in rhizomelic chondrodysplasia punctata. Cataracts are present in 75% of infants affected with this disorder (Poznanski, 1994). Developmental abnormalities are typical of the rhizomelic form of chondrodysplasia punctata. Magnetic resonance imaging (MRI) may reveal the presence of migrational disturbances in the brain. An additional helpful radiographic finding is the presence of coronal clefts that can be seen on lateral films of the lumbar and thoracic vertebrae.

There are several milder forms of chondrodysplasia punctata, characterized by abnormalities of the extremities. In the tibia-metacarpal type of chondrodysplasia punctata, short third and fourth metacarpals are observed. These children also have a hypoplastic midface and a flattened nasal bridge. In later life, they have a height that is 2 to 4 SD below normal. The brachytelephalangic type of chondrodysplasia punctata is characterized by an extremely small, anteverted, grooved nose that resembles the one in infants affected with Binder syndrome. On radiographs, the distal phalanges have a characteristic triangular appearance. This condition may be associated with a terminal deletion of the short arm of the X chromosome.

Another important consideration during the newborn period is the diagnosis of Zellweger syndrome, characterized by calcification of the patella. These infants are much more severely hypotonic than other infants. Renal sonography may also indicate the presence of cortical cystic changes. These infants also have progressive hepatic failure.

SURGICAL TREATMENT

For more mildly affected patients with Conradi–Hünermann syndrome, orthopedic surgery may eventually be needed to correct limb length asymmetry.

Table 99-2

Comparative Manifestations of Nonrhizomelic Chondrodysplasia Punctata Subtypes by Inheritance Patterns

Inheritance	Synonyms	Punctate Calcifications	Limb Shortness	Saddle Nose Deformity	Skin Changes (Ichthyosiform Erythroderma)	Cataracts	Mental Retardation	Other	Overall Prognosis
Autosomal dominant	Chondrodystrophia calcificans congenita	Variable severity asymmetric	Mild or none	Present	Present in 28% of cases	Symmetric, present in 17% of cases	None or minimal	Skeletal dysplasia	Good
X-linked recessive without chromosome deletion	Brachytelephalangic chondrodysplasia punctata	Mild severity, symmetric	Mild overall growth lag	Variable severity	No changes	None	None or mild	Uniform distal phalangeal hypoplasia	Good
X-linked recessive with Xp deletion	CPXR	Extensive bilateral symmetric	Shortness of stature	Typically severe with nasal hypoplasia	Marked skin changes	Occasional	IQ range, 50–70	Steroid sulfatase deficiency, and frequent distal phalangeal hypoplasia	Survival good, but neurodevelopmentally impaired
X-linked dominant	CPXD	Variable asymmetric	Proximal variable, asymmetric	Present	Marked cicatrical "patchy" changes	Asymmetric	Normal	Occasional scoliosis	Lethal in hemizygous males
Teratogenic phenocopy	Vitamin K–dependent coagulation defect, warfarin embryopathy	Irregular asymmetric pattern, variable severity	Moderate to severe	Moderate to severe with frequent nasal hypoplasia	None	None	Mild or none	Common mild distal phalangeal hypoplasia	Good

LONG-TERM OUTCOME

The long-term outcome is related to the underlying condition. The rhizomelic form of chondrodysplasia punctata is the most severe, with a poor prognosis. A recent review of 97 affected cases reported that survival is better than previously reported, with 90% of infants surviving up to 1 year and 50% surviving up to 6 years (White et al., 2003). All infants with rhizomelic chondrodysplasia have severe failure to thrive, profound mental retardation, joint contractures, and bilateral cataracts. Surgical removal of cataracts is recommended to increase visual stimulation and environmental interaction. Seizures are common. Death is usually due to respiratory complications.

Patients affected with Conradi–Hünermann syndrome are shorter than normal at birth and remain so throughout life. The typical calcific stippling disappears by 3 to 4 years of age (Poznanski, 1994). During infancy and early childhood, these infants may have cataracts, growth failure, or feeding problems. Affected infants are very susceptible to respiratory infections, generally because of the airway abnormalities. The laryngeal and tracheal calcifications usually resolve within the first 3 years of life (Seguin et al., 1993). Laryngoscopy and bronchoscopy can be considered electively during the first year of life to identify any lower airway abnormalities (Seguin et al., 1993).

For infants who survive the first year of life, the skeletal deformities eventually become less pronounced and the contractures may disappear. The clinically unrecognized adults with Conradi–Hünermann syndrome described in the literature have had normal intelligence.

GENETICS AND RECURRENCE RISK

To adequately calculate the recurrence risk, the definitive diagnosis must be known. For infants affected with rhizomelic chondrodysplasia punctata, the condition is inherited in an autosomal recessive fashion and parents should be counseled

that there is a 25% recurrence risk. Prenatal diagnosis is available as early as 10 weeks of gestation by demonstration of decreased plasmalogen synthesis and decreased phytanic oxidation in chorionic villi. In addition, immunoblot studies of the peroxisomal 3-oxo-acyl-CoA thiolase can also definitively diagnose the presence of an affected fetus with rhizomelic chondrodysplasia punctata (Hoefler et al., 1988). If the biochemical studies of the chorionic villi or cultured amniocytes are normal, prenatal sonography can be used as additional confirmation of fetal status (Schutgens et al., 1989; Gray et al., 1990).

Mutations in the human *PEX7* gene are the molecular basis for rhizomelic chondrodysplasia punctata type 1 (Braverman et al., 1997; Motley et al., 1997; Purdue et al., 1997; Braverman et al., 2002; Motley et al., 2002). The *PEX7* gene maps to human chromosome 6q22–24 and consists of eight exons spanning more than 40 kb of DNA. In one study, 26 of 36 patients with rhizomelic chrondrodysplasia punctata had a single inactivating mutation known as L292X. This mutation was seen exclusively in patients of northern European descent because of a founder effect (Braverman et al., 1997) Type 1 rhizomelic chondrodysplasia punctata is the most common of the rhizomelic forms (Motley et al., 2002). In type 2, there is an isolated deficiency of DHAP acyltransferase because of mutations in the acyl CoA: dihydroxyacetone phosphate acyltansferase (*DHAPAT*) gene. Type 3 is caused by mutations in the alkyl-dihydroxyacetone phosphate synthase (*ADHAPS*) gene.

Once a mutation is identified in a particular family, DNA diagnosis by molecular studies of chorionic villi in subsequent pregnancies is definitive. Therefore, arrangements should be made to establish fibroblast cell cultures from affected fetuses or infants who are electively terminated or die during the perinatal period in order to identify the familial mutation.

Similarly, Zellweger syndrome is inherited as an autosomal recessive condition. This condition can be diagnosed definitively during the newborn period by measurement of plasma very long-chain fatty acids. Prenatal diagnosis in subsequent pregnancies can demonstrate the very long-chain fatty acid abnormalities and the absence of peroxisomes in cultured chorionic villus cells.

The diagnosis of Conradi–Hünermann syndrome depends on a complete examination of both parents as well as taking a complete family history to rule out the autosomal dominant, X-linked dominant, and X-linked recessive forms. Parents who are retrospectively diagnosed as being affected with Conradi–Hünermann syndrome, such as in the case of Silengo et al. (1980), will be counseled that their fetuses have a 50% risk of recurrence. If possible, DNA diagnosis should be performed on an affected parent to permit prenatal diagnosis. In one case, a pregnant woman with a mild form of X-linked dominant chondrodysplasia punctata (Conradi–Hünermann syndrome) was shown to have a mutation in the emopamil binding pathway (*EBP)* gene (Whittock et al., 2003). This allowed molecular prenatal testing on her male fetus, who was shown to be unaffected.

Gene mapping studies have suggested that another form of chondrodysplasia maps to chromosome 4p16 (Dimmick et al., 1991) and that the X-linked dominant form maps to Xq28. The X-linked recessive and brachytelephalangic forms map to Xp22.3.

Amniotic Band Syndrome

100
CHAPTER

Key Points

- Amniotic band syndrome is a group of congenital anomalies involving limbs, craniofacial region, or trunk.
- Amniotic band syndrome can range from constrictive bands involving a digit to thoracoabdominoschisis, encephalocele, or the limb–body wall complex.
- The incidence ranges widely from 1 in 1200 to 1 in 15,000 livebirths depending on how it is defined.
- Ultrasound examination is the mainstay of diagnosis.
- Amniotic bands can occur spontaneously or as a result of instrumentation of the pregnancy.
- Fetoscopic release of amniotic bands may prevent limb amputation when it involves an extremity or may be lifesaving if they involve the umbilical cord.
- Almost all cases of amniotic band syndrome deliver prematurely.

CONDITION

The amniotic band syndrome (ABS) is a group of sporadic congenital anomalies that involve the limbs, craniofacial regions, and trunk, ranging from constrictive bands, pseudosyndactyly to amputation, as well as multiple craniofacial, visceral, and body wall defects (Torpin, 1965; Jones et al., 1974; Higginbottom and Jones, 1979; Seeds et al., 1982; Ray et al., 1988; Lockwood et al., 1989; Seidman et al., 1989; Kulkarni and Gopal, 1990). The term *amniotic band syndrome* encompasses many congenital anomalies, including amniotic band disruption complex (Higginbottom and Jones, 1979), amniochorionic mesoblastic fibrous strings (Torpin, 1965), aberrant tissue bands (Jones et al., 1974), amniotic deformity, adhesion and mutilation (ADAM) complex (Keller et al., 1978; Orioli et al., 2003), amniotic adhesion malformation syndrome (Herva and Karkinen-Jaaskelainen, 1984), and the limb and/or body wall defect (Bamforth, 1992).

Several theories have been advanced to explain the occurrence of these anomalies but two are most commonly held. In 1930, Streeter proposed that a disruption in embryogenesis at the time of formation of the germ disk and the amniotic cavity initiated a chain of events leading to the multiple defects. He suggested that amniotic bands were the result, not the cause, of the pathologic process. In 1992, Bamforth reviewed this theory in a series of 54 cases of ABS and concluded that it may be caused by a localized disturbance in establishment of basic embryonic organization. The most widely accepted theory was proposed by Torpin in 1965. He examined the placenta and fetal membranes in a number of affected individuals and concluded that the disorder was caused by primary rupture of the amnion early in gestation (Keller et al., 1978; Higginbottom and Jones, 1979; Seeds et al., 1982; Herva and Karkinen-Jaaskelainen, 1984).

More recently, Moerman et al. (1992) proposed that the ABS is a collection of three distinct entities that can reconcile

both Streeter's and Torpin's hypotheses. They suggested that ABS consists of three distinct lesions: (1) constrictive tissue bands; (2) amniotic adhesions; and (3) the more complex pattern of anomalies designated the limb–body wall complex (LBWC) (see Chapter 60). In this report of the fetopathologic evaluation of 18 cases of ABS, 4 had clearly constrictive bands, which formed as a result of the amnion rupture sequence. The bands that resulted from amnion rupture encircled the limbs, resulting in annular constrictions, secondary syndactyly, and intrauterine amputations. In addition, constriction of the umbilical cord is a recognized cause of fetal death (Hong and Simon, 1963; Torpin, 1965). These authors distinguish cases caused by constrictive bands from those caused by broad amniotic adhesions. Moerman et al. (1992) suggested that adhesive amniotic bands were morphologically and pathogenetically different from constrictive bands. Adhesive amniotic bands are usually associated with severe defects such as encephalocele and facial clefts. This group demonstrated pathologically that cranioplacental adhesions are broad adhesions, with the fetal skin fused to the amnion at the margins of the cranial defect. They speculated that the amnion covering the placenta or membranes seals the cranial defect separating the protruding brain from the chorion. Van Allen et al. (1987) proposed that the amnion becomes adherent to the embryo in areas of ischemic necrosis following vascular disruption. In short, the amniotic adhesions are secondary to fetal defects.

Moerman et al. (1992) considered the LBWC to be due to both band-related and non–band-related defects. The band-related defects include limb defects such as clubfoot. Non–band-related defects occur as a result of vascular disruptions or from compression (Miller et al., 1981). The thoracoabdominoschisis of LBWC is characterized by an anterolateral body wall defect with evisceration of abdominal and/or thoracic organs. The eviscerated organs are in an extra-amniotic sac bounded by the chorionic plate, a persistent extraembryonic coelom. The amnion is continuous with the skin. The umbilical cord is extremely short, with umbilical vessels running in the amniotic sac, often with an absent umbilical artery. The severe scoliosis is a postural deformity caused by abnormal fixation of the fetus to the placenta. They also cite the high incidence of internal structural defects such as cardiac anomalies, unilateral absence of a kidney, or intestinal atresia, which do not fit with simple amnion rupture.

The fetal malformations that can occur as a result of ABS can be categorized into neural tubelike defects, craniofacial anomalies, limb anomalies, and constrictive bands (Seeds et al., 1982; Lubinsky et al., 1983; Ho and Liu, 1987; Seidman et al., 1989). The neural tubelike defects include cases of anencephaly and encephalocele, which may be asymmetric or multiple. The craniofacial anomalies include facial clefts, nasal deformity, asymmetric microphthalmia, and abnormal cranial calcification. Limb anomalies may be multiple and asymmetric, including limb or digital amputation, pseudosyndactyly, abnormal dermatoglyphics, and some cases of clubbed feet. Abdominal wall and thoracic wall defects can occur, and some cases are mistaken for gastroschisis or omphalocele with rupture.

The most puzzling component of the ABS is its association with visceral anomalies, including bladder exstrophy, vertebral hypoplasia, and other renal, gonadal, cardiac, and pulmonary defects (Bamforth, 1992). Constrictive bands involving the extremities are the most common defect associated with the ABS (Huang et al., 1995).

The variation in manifestations of the ABS are thought to be due to differences in timing of amniotic rupture and the degree to which the fetus becomes entangled by strands of amnion (Higginbottom and Jones, 1979; Seeds et al., 1982). The effects the amniotic bands have on the developing fetus have been classified into malformation, disruption, and deformation (Higginbottom and Jones, 1979). Amniotic bands that interrupt the normal sequence of embryologic development lead to malformations such as cleft lip and palate, and abdominal wall defects. In contrast, bands may tear normally developed structures, leading to disruption such as central nervous system or calvarial defects, acrosyndactyly, amputations, and nonanatomical facial clefts (Lockwood et al., 1989). The effects of fetal compression and tethering may lead to deformations such as clubbing of the feet and angulation of the spine.

The timing of amnion rupture has been suggested to occur between 28 days after conception to 18 weeks of gestation. If amnion rupture occurs prior to 45 days of gestation, the results are likely to be devastating, including severe skull defects and major visceral defects (Huang et al., 1995). Rupture occurring after 45 days of gestation is likely to result in more limited defects.

The cause of amnion rupture and band formation is not well understood, but it has been observed following amniocentesis (Rehder, 1978). Late gestation bands, even in the absence of an amniocentesis, can also occur. Lage et al. (1988) reported ABS presenting at birth with multiple abnormalities of the extremities despite a normal sonographic appearance at 21 weeks of gestation. There have also been cases of ABS associated with underlying disease. Young et al. (1985) reported two cases in fetuses with Ehlers–Danlos syndrome type IV and one with osteogenesis imperfecta. They speculated that the premature amnion rupture may have been due to reduced or abnormal collagen in the amnion. There have been rare familial cases of ABS, and some teratogens, such as lysergic acid diethylamide and methadone, have been reported in association with the syndrome (Chemke et al., 1973; Lubinsky et al., 1983; Daly et al., 1996). Other significant exposures include misoprostol and maternal fever (Orioli et al., 2003; Ribeiro et al., 2004).

Chorioamniotic separation, occurring spontaneously or as a consequence of invasive procedures, is a potential cause of the ABS. The incidence of chorioamniotic separation diagnosed by ultrasound is reported to range from 1 in 187 to 1 in 4333 births (Kaufman et al., 1985; Borlum, 1989). The natural history of chorioamniotic separation occurring in normal pregnancies was initially thought to be benign. However, Graf et al. (1997) reported a case of chorioamniotic

separation that resulted in the formation of amniotic bands involving the umbilical cord, resulting in fetal death. The incidence of chorioamniotic separation may be even higher in cases of fetal surgery. In the same report, Graf and colleagues described 5 cases of chorioamniotic separation occurring in a series of 40 patients undergoing open fetal surgery. Three of the five fetuses had amniotic bands involving the umbilical cord, leading to fetal death in one. This report speculated that because the amnion is adherent and fixed to the umbilical cord, once formed amniotic bands may retract to the cord, causing strangulation. Heifetz (1984), in a review of ABS, reported that as many as 10% of cases had umbilical cord strangulation.

ABS is often misdiagnosed, especially in cases of early amniotic band rupture. Infants affected by early amniotic rupture present with anencephaly, encephalocele, abdominal or thoracic wall defects, and severe limb abnormalities. The severity of the anomalies obscures the cause, especially if the amniotic bands are not evident at birth. It has been estimated that a correct neonatal diagnosis of ABS is made in only 24% to 50% of patients without specialized genetic consultation (Seeds et al., 1982).

INCIDENCE

Because of difficulties in accurately diagnosing ABS, the estimates of its incidence vary widely. The reported incidence ranges from 1 in 1200 to 1 in 15,000 livebirths (Chemke et al., 1973; Seeds et al., 1982; Ho and Liu, 1987; Ray et al., 1988). More recent estimates place the incidence of ABS at 1 in 1200 because of the more frequent recognition of an amniogenic cause for congenital anomalies (Ossipoff and Hall, 1977; Seeds et al., 1982; Moerman et al., 1992). In a retrospective analysis of 3173 autopsies performed during a 14-year period, Czichos et al. (2005) found 744 cases of malformations of which 14 had anomalies thought to be a consequence of amnion rupture. This series yielding an incidence of 1:226 among fetuses and newborns undergoing autopsy suggested that it may be a more common cause of anomalies than generally appreciated.

Hands are more frequently affected than feet, with the largest fingers (third, fourth, and second) more commonly afflicted (Ribeiro et al., 2004).

SONOGRAPHIC FINDINGS

ABS is associated with numerous antenatal sonographic features, as there are numerous forms of the syndrome and these features may occur as isolated problems or in combination. The earliest that amniotic bands have been seen is at 12 weeks of gestation, by endovaginal probe. The bands can be extremely difficult to detect sonographically and ABS is more often diagnosed by the effect that they have on fetal anatomy

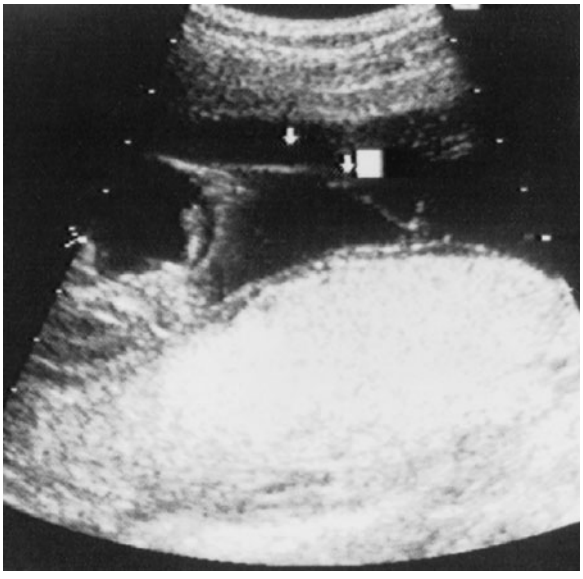

Figure 100-1 Sonographic image demonstrating an amniotic band attached to the fetus and floating in the amniotic fluid.

(Figure 100-1). The effect of amniotic bands on the extremities may be manifested by absent digits or portions of limbs, or a swollen distal arm or leg resulting from constrictive amniotic bands (Paladini et al., 2004) (Figure 100-2). ABS may affect the face with cleft lip or palate, asymmetric microphthalmia, or severe nasal deformity. Encephalocele may be a manifestation of ABS, especially when eccentrically placed (Figure 100-3). Abdominal wall defects can be the result of ABS, typically with large defects with free-floating intestine herniated outside the abdomen. The characteristic appearance of an aberrant sheet or band of amnion attached to the fetus with resultant deformity and restriction of motion allows a diagnosis of ABS to be made (Figure 100-3). However, prenatal diagnosis is the exception rather than the rule.

The findings in ABS may be limited to isolated defects, including isolated facial cleft, digital amputation, or mild elephantiasis of an extremity beyond a constrictive band (Sentilhes et al., 2004; Dyson et al., 2000). These isolated features may be difficult to diagnose sonographically because the detailed fetal visualization required is beyond the scope of routine obstetrical ultrasound examinations. At the worst end of the spectrum, the fetus may be so severely deformed by the amniotic bands that the spine is contracted and organs are formed in perplexing and bizarre proportions. The head may be completely misshapen or absent. The bands responsible for these deformities are rarely seen and a presumptive diagnosis of ABS is made based on the commonly associated deformities.

The spinal deformities in ABS can be severe, manifesting as kyphotic lordosis or scoliosis as well as severe rotational abnormalities and even spinal amputation (Chen, 2001). While spinal deformity can be seen in other syndromes, severe spinal deformity should suggest ABS.

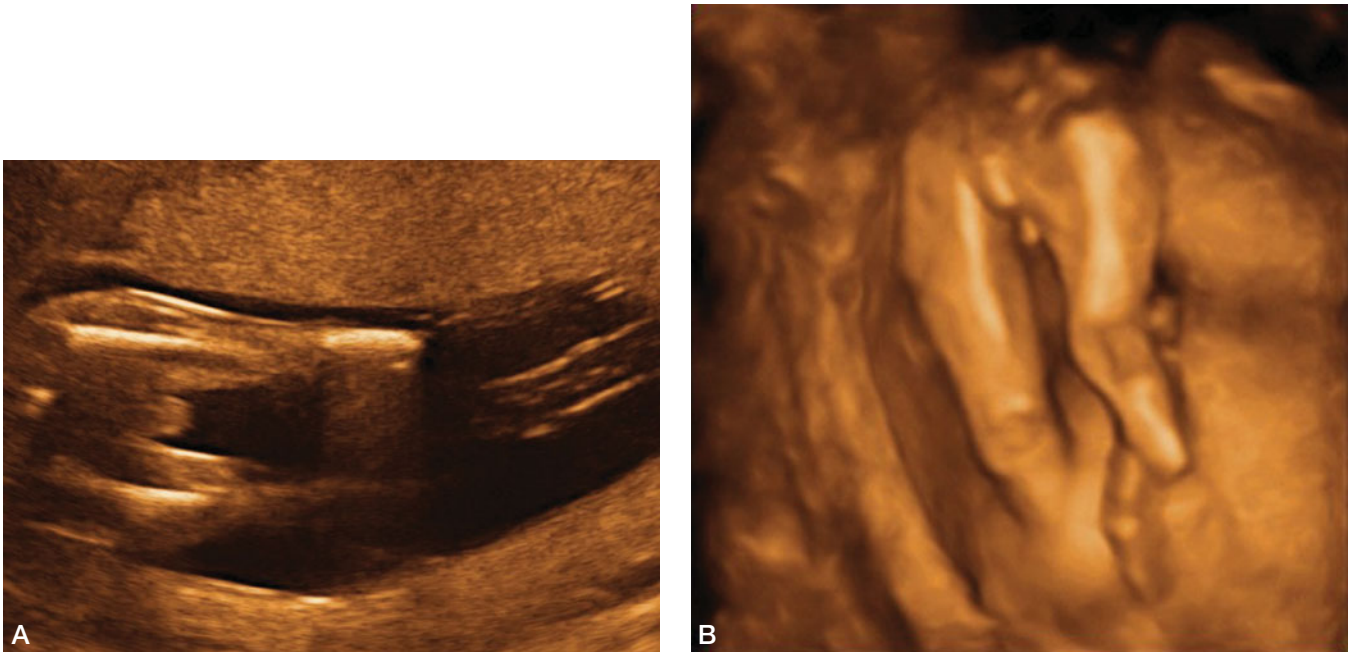

Figure 100-2 Sonographic image of a fetus with a constricting amniotic band of an extremity. **A.** 2-D image depicting amputation of the distal portion of both lower extremities as a result of amniotic bands. **B.** 2-D image of the same fetus showing bilateral limb reduction defects.

Spinal deformity associated with an abdominal wall defect is particularly suggestive of ABS. While the typical appearance of an omphalocele is possible, the more common defect is a large slashlike defect of both the thoracic and abdominal cavities with evisceration. These defects are associated with exteriorized bowel, liver, and sometimes heart without an enveloping membrane. When associated with limb abnormalities, this is characteristic of the LBWC form of ABS (Figure 100-4).

Deformation of the calvarium is another group of anomalies characteristic of ABS. If complete, the fetus may appear anencephalic or to have acrania (Chen et al., 2004). If partial, the fetus may appear to have an encephalocele. The distinguishing features that characterize these defects as

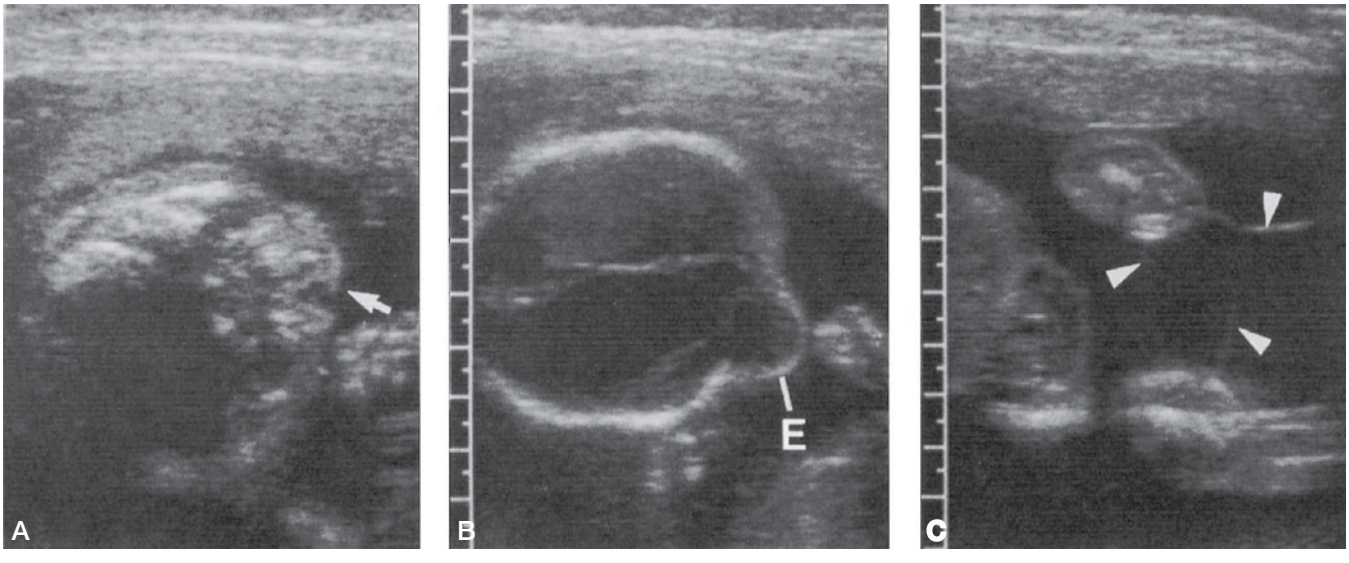

Figure 100-3 Sonographic image of a fetus with amniotic band syndrome manifesting as **A.** a "slash" defect in the maxillary region, and **B.** an eccentric encephalocele. **C.** Amniotic bands were also noted to be attached to the extremities (*arrowheads*). *(Reprinted, with permission, from Filly RA, Golbus MS. The fetus with amniotic band syndrome. In: Harrison MR, Golbus MS, Filly RA, eds. The Unborn Patient. 2nd ed. Philadelphia, PA: WB Saunders; 1991:440-447.)*

ABS are their asymmetric nature and associated spinal deformity or abdominal wall defects. In classic anencephaly, the calvarial bones are symmetrically absent (see Chapter 7). In anencephaly caused by ABS there is some portion of calvarium present, usually near the base of the skull or near one other orbit. Similarly, classic encephaloceles occur near the midline, while ABS causes encephaloceles off the midline.

The presence of bands is unnecessary for the diagnosis of ABS in the presence of characteristic fetal anomalies. The sonographic detection of bands is helpful in confirming the diagnosis of ABS as the cause of fetal deformity. However, observation of these bands without fetal abnormality is not ABS. It is important for the sonographer to distinguish amniotic bands from other membranes and separations within the amnion. Separation of amnion and chorion is normal in early pregnancy until fusion occurs at approximately 16 weeks of gestation (Sauerbrei et al., 1980; Burrows et al., 1982; Patten et al., 1986).

Chorioamniotic separation may occur as a result of amniocentesis or fetal surgery, and extrachorionic hemorrhage may separate the chorioamniotic membrane from the uterine wall (Spirit et al., 1979; Burrows et al., 1982; Graf et al., 1997). In both of these instances, a membrane may be observed sonographically. Other causes of membranes in the developing fetus include septate uterus, blighted twin, and circumvallate placenta (Fillyand Golbus, 1991).

Adhesions that form in the uterus as a result of curettage, cesarean section, or myomectomy may cause sheets of amnion that protrude into the lumen of the amniotic cavity (Asherman, 1948; Comninos and Zourlas, 1969; Mahony et al., 1985; Randal et al., 1988; Filly and Golbus, 1991). Randal et al. (1988) found that 76% of patients with amniotic sheets had undergone prior instrumentation. This results in an adhesion that becomes covered by chorion and amnion and has a thickness similar to the intertwin membrane of dichorionic diamniotic twins. These amniotic sheets do not adhere to the fetus because the amnion is intact (Tan et al., 2005). The uterine adhesion may rupture with growth of the fetus. Filly and Golbus (1991) have described the sonographic appearance of these synechiae as having a thickened base and a fine edge that undulates. There may be a bulbous edge, presumably due to the synechiae. There are no associated fetal abnormalities and there is free fetal movement around the sheet. The synechiae may not be seen in the third trimester, because of rupture or compression by the growing fetus.

In the LBWC there is a constellation of abnormalities, including myelomeningocele or caudal regression, thoracoabdominoschisis, or abdominoschisis and limb defects (see Figure 100-4). At least two of the three abnormalities listed above are necessary to make a diagnosis of LBWC. The umbilical cord is usually short or absent, with the placenta attached to the fetus. If present, there may be only a two-vessel cord. The limbs may be missing or the feet clubbed. The spine is often short and curved and sacral regression is common. There may be Arnold–Chiari malformation and hydrocephalus associated with the meningomyelocele. There may be ectopia cordis as part of the thoracoabdominoschisis. Facial clefts may also be seen in LBWC.

ABS involving the umbilical cord can be recognized by abnormal clustering of loops of umbilical cord, which may be adherent to a bend fixed to a limb. These findings may be subtle and should be sought in any case of ABS as umbilical cord involvement may result in fetal demise (Figure 100-5).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis in ABS depends on the sonographic findings. In isolated constrictive amniotic bands associated with distal limb edema, possible lymphatic or vascular malformations should be considered. However, color Doppler studies should closely show the flow characteristics of a vascular malformation. Constrictive bands involving the upper extremity should suggest the possibility of the VACTERL association if the radius is affected, and Fanconi anemia if radial

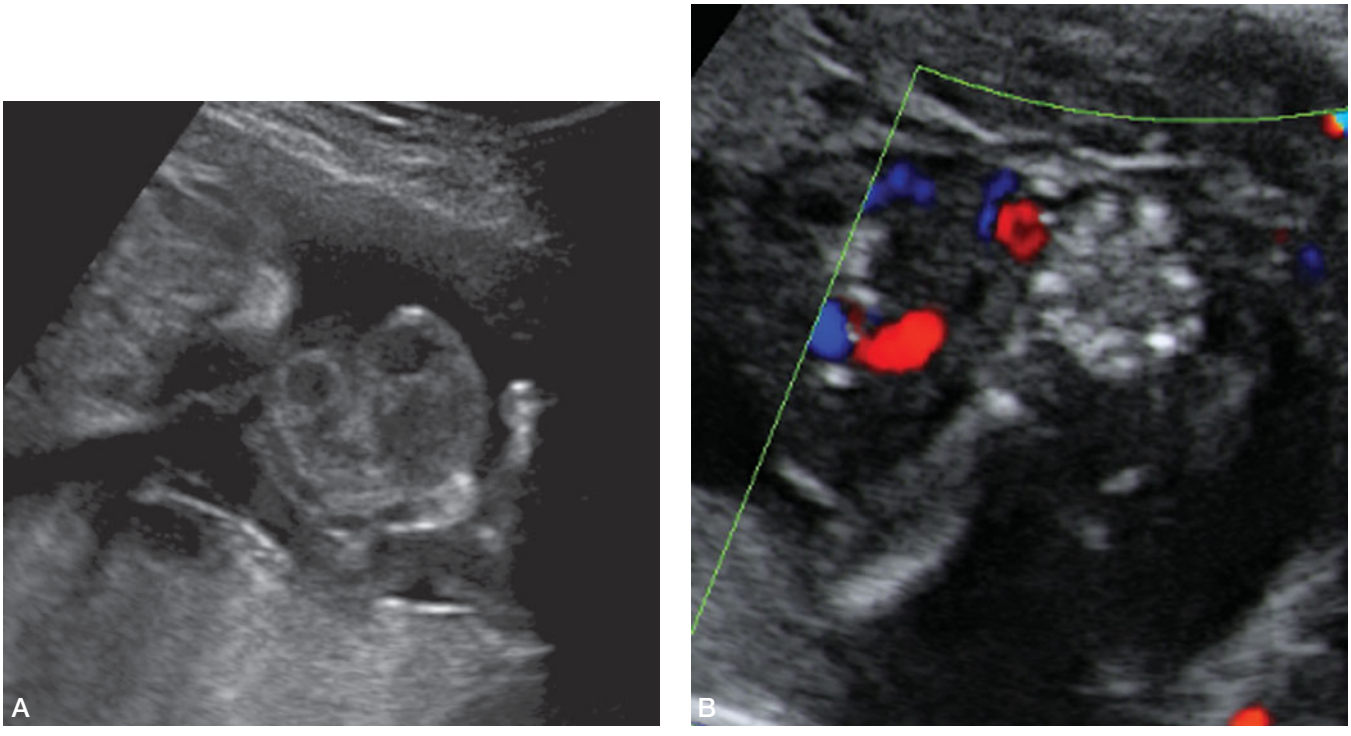

Figure 100-5 **A.** Sonographic image of amniotic bands involving the umbilical cord and the right upper extremity. **B.** Color doppler of the same patient.

hypoplasia or absent thumbs are observed. Amniotic membranes within the amniotic cavity without associated fetal anomalies may be amniotic sheets secondary to intrauterine synechiae or remnant of a blighted twin, or secondary to amniocentesis or chorionic villus sampling.

A diagnosis of LBWC requires two of three of the following abnormalities: (1) myelomeningocele or caudal regression, (2) abdominal or thoracoabdominal wall defect, or (3) limb defects. The main differential diagnoses are cases of isolated neural tube defects or ruptured omphalocele, which do not meet the criteria for LBWC. The body stalk anomaly has a similar constellation of anomalies but the placenta is attached to the trunk of the fetus.

ANTENATAL NATURAL HISTORY

There is great controversy about the pathogenesis of the various forms of ABS. Part of this controversy involves the timing in gestation of the development of amniotic bands. However, in constrictive amniotic bands of the extremities, the progression of constriction combined with fetal growth has resulted in extremity amputation (Figures 100-2, 100-6, and 100-7) (Hill et al., 1988). ABS can be associated with either polyhydramnios or oligohydramnios. Despite the severity of some forms of ABS, there are no adverse maternal consequences for this diagnosis. The incidence of intrauterine fetal death from ABS involving the umbilical cord is not known but numerous cases have been reported (Torpin, 1965; Kanayama

Figure 100-6 3D image demonstrating absence of the left fetal hand in a pregnancy complicated by amniotic bands.

Figure 100-7 Plain radiograph of the right leg of a newborn who sustained amputation in utero of the right leg and foot from amniotic bands. *(Courtesy of Benjamin Alman, MD)*

et al., 1995; Graf et al., 1997). However, the poorly characterized pathogenesis of this syndrome and limited sonographic surveillance, limit our understanding of its prenatal natural history.

ABS is a relatively common, if underappreciated, cause of fetal and neonatal morbidity and mortality. The fetal lamb model of ABS will be useful to better define the pathophysiology of ABS and to provide a tool to understand the unique fetal response to tissue injury, repair, and regeneration. Sonographic identification of ABS affecting the umbilical cord may be an indication for fetoscopic surgical intervention. In the future, intervention for nonlethal limb deformation may also be considered if maternal risk is sufficiently lowered. ABS is another in a growing list of conditions for which fetal surgery may be considered in the future.

Constrictive bands most commonly affect the extremities, but can also involve the umbilical cord, with resulting fetal death. Kanayama et al. (1995) described the reversal of diastolic flow observed in a fetus with umbilical cord constriction due to amniotic bands. Graf et al. (1997) similarly reported a case of amniotic bands involving the umbilical cord following the development of chorioamniotic separation. Despite initially normal umbilical artery Doppler waveforms, this fetus died within 2 weeks from a constrictive amniotic band of the umbilical cord. Reports have described constrictive amniotic bands as a cause of fetal death (Torpin, 1965; Moerman et al., 1992). However, until the reports by Kanayama and Graf and their colleagues, this was a diagnosis made pathologically after the fact. It is in cases like these that fetoscopic lysis of amniotic bands could be lifesaving (see "Fetal Intervention").

Cases of ABS, by definition, have ruptured membranes and typically deliver prematurely with an average gestational age of 32 weeks.

MANAGEMENT OF PREGNANCY

In managing a pregnancy with suspected ABS, it is essential to have a detailed sonographic fetal survey to accurately assess any anomalies present. Fetal echocardiography is indicated in cases of abdominal wall or abdominothoracic wall defects because of the increased incidence of associated cardiac defects. Amniocentesis is not necessary in clear-cut cases of ABS, as these are sporadic deformations with no association with chromosomal abnormalities. However, in instances in which the diagnosis is uncertain, genetic amniocentesis should be considered. For example, in cases of abdominal wall defects in which a ruptured covered omphalocele cannot be excluded, genetic amniocentesis is indicated.

A fetus with ABS should pose no increased risk for the mother in the management of the pregnancy. There is no indication for cesarean section, except for obstetrical indications. In severe cases of ABS, such as LBWC, in which survival is not anticipated, conventional labor and vaginal delivery without intervention for fetal distress should be considered.

FETAL INTERVENTION

The indications for fetal surgery are, with few exceptions, only for life-threatening conditions such as congenital pulmonary airway malformation (CPAM) with hydrops, diaphragmatic hernia with a low lung-to-heart ratio, bladder outlet obstruction with oligohydramnios, or sacrococcygeal teratoma with placentomegaly (see Chapters 35, 37, 38, 82, and 115). However, as experience with the techniques of fetal surgery has grown and the natural histories of certain non–life-threatening conditions have been better defined, the indications for fetal surgery have been extended. Two examples of this are in utero repair of meningomyelocele to prevent the devastating neurologic injury to the spinal cord (Adzick et al., 1998) and fetoscopic cord ligation in monochorionic twins with imminent death of one twin to prevent neurologic injury in the surviving twin (Crombleholme et al., 1996). The indications for fetal surgery in the ABS may be either for a life-threatening condition if it involves constriction of the umbilical cord or, more commonly, threatened limb amputation due to amniotic band constriction (Torpin, 1965; Ashkenazy et al., 1982; Kanayama et al., 1995; Quintero et al., 1997; Tadmor et al., 1997; Crombleholme, 2001; Keswani et al., 2003).

Torpin (1965) reported 36 cases of fetal death due to cord constriction from amniotic bands. In each case, the diagnosis was made retrospectively. Recognition of amniotic bands constricting the umbilical cord has been reported by Kanayama et al. (1995), who were able to document fetal compromise by reversal of diastolic flow in the umbilical

artery by color Doppler. It is in cases like the one reported by Kanayama et al. that fetoscopic lysis of amniotic bands could be lifesaving.

On the basis of their experience with fetoscopy for cord ligation in TRAP sequence and the experimental work by Crombleholme et al. demonstrating the potential for functional recovery of banded extremities once released, Quintero et al. performed the first fetoscopic lysis of amniotic bands in human fetuses (Crombleholme et al., 1995; Quintero et al., 1997). Their first case was a fetus at 21 weeks of gestation with bilateral cleft lip and bands attached to the face and left upper extremity with distal limb edema. In order to avert limb amputation, fetoscopic lysis of bands was attempted at 22 weeks of gestation using a two-port technique. However, because of bleeding encountered on insertion of the second operating port, it was removed. The endoscissors were passed through the port used for the fetoscope, and the lysis was performed under ultrasound guidance. There was resolution of the distal edema within 6 days of the procedure. At 32 weeks, microphthalmia and anophthalmia of the right orbit were first noted at the site of the previously attached amniotic band. The infant was delivered at 39 weeks and was found to have a type IV Tessier craniofacial cleft and right microphthalmia. The extremity showed minimal residual scarring where the band had been attached and lysed. The infant's hand had radial paresis and mild hypoplasia.

The second case was a fetus at 23 weeks of gestation with a thick amniotic band constricting the left ankle of the fetus. There was marked edema distal to the band and minimal blood flow to the foot was observed by color and pulsed Doppler. Fetoscopy was performed using a 2.7-mm 5-degree endoscope and confirmed the sonographic findings. Again, bleeding was encountered on insertion of the operating port, necessitating its removal. Attempts at ultrasound-guided lysis using endoscissors were unsuccessful. A 2.4-mm 0-degree operating scope with a 400-μm contact YAG laser fiber was used to lyse approximately 85% of the band. Complete lysis of the band was not achieved for fear of injury to "important elements in the ankle." Postoperatively, the edema markedly improved, as did distal arterial blood flow, and there was return of flexion and extension on follow-up sonographic examination. The mother was hospitalized 8 weeks postoperatively at 31 weeks of gestation with premature rupture of membranes and delivered at 34.5 weeks of gestation. The infant underwent Z-plasties for residual effects of the amniotic band, and full functional recovery was anticipated.

The rationale for performing fetoscopic lysis of constricting extremity amniotic bands is based on the hypothesis that progressive compromise of fetal growth leads to amputation. However, this assumes that the procedure can be accomplished with no maternal morbidity and minimal fetal morbidity. This procedure would be hard to justify in the face of a serious maternal complication or a fetal death due to severely premature delivery at 21 or 23 weeks of gestation, even in the face of certain fetal limb amputation.

The experience reported by Keswani et al. (2003) similarly supports the use of fetoscopic release of amniotic bands for limb salvage. However, the sequelae of the ABS may not completely remove or may result in secondary lymphedema. It is worth noting that the cases reported that all had additional amniotic bands encircling limbs not appreciated by ultrasound examination that were also lysed. Crombleholme has experience with fetoscopic release of amniotic bands involving the umbilical cords in five fetuses (Crombleholme TM, unpublished observation, 2009). All were successfully lysed with all three fetuses surviving the procedure.

While extremity ABS may have devastating morphologic and functional effects on a limb, possibly resulting in amputation, it is not lethal. Extremity ABS is not an indication for fetoscopic surgery unless maternal risks and incidence of preterm labor are fully appreciated by the mother. However, there are forms of ABS that are lethal or have devastating neurologic sequelae that may justify the current risks of intervention. Torpin (1965) has reported 36 cases of constrictive amniotic bands of the umbilical cord, which were uniformly fatal. Although rarer than other forms of ABS, umbilical cord constriction, once diagnosed sonographically, may be amenable to fetoscopic release to avert fetal death as shown by Crombleholme (unpublished observation, 2008).

TREATMENT OF THE NEWBORN

A fetus known to have ABS should be delivered in a tertiary care center with neonatologists, pediatric surgeons, and pediatric plastic and orthopedic surgeons available. Treatment depends on the nature of the ABS and the severity of the deformation. In cases of umbilical cord involvement, early or even emergency delivery may be indicated if there are signs of fetal compromise (Kanayama et al., 1995). After delivery, a careful physical examination should assess the severity of the ABS. Often there will be no evidence of the amniotic band at the time of delivery. In the case of extremity amniotic bands, treatment is dictated by the severity of the deformation. The severity of deformity can range from a mildly constrictive band, requiring release, to near amputation, requiring debridement. More often there is a bandlike deformation that requires Z-plasties to surgically correct it (Dyer and Chamlin, 2005; Findik et al., 2006) (Figure 100-8).

In cases of amniotic bands involving the face and head, there may be severe facial clefts, anophthalmia, and encephalocele. These deformities may require many extensive reconstructive procedures to achieve an acceptable cosmetic result. Cases of the LBWC form of ABS are always fatal, and no reconstructive procedures are indicated.

LONG-TERM OUTCOME

The outcome in ABS depends on the severity of the deformation. Cases of extremity ABS usually have an excellent long-term outcome. Even in cases of limb amputation, ambulation

Figure 100-8 **A.** Postnatal appearance of the leg of a newborn with extremity amniotic band syndrome. **B.** Postnatal appearance of the hand of a newborn with extremity amniotic band syndrome.

is possible with the aid of a prosthesis. The cosmetic results following extensive craniofacial reconstructive surgery are often acceptable, but the severity of these defects may leave these children permanently disfigured. ABS in which fetoscopic release was performed may show evidence of secondary lymphedema, which may require multiple surgical procedures to provide an acceptable functional result (Marler et al., 2002).

GENETICS AND RECURRENCE RISK

Most cases of ABS are sporadic and there is no risk of recurrence in subsequent pregnancies. There have been cases of ABS associated with underlying disease, such as Ehlers–Danlos syndrome type III or osteogenesis imperfecta. Similarly, ABS has been reported in association with teratogens such as methadone and lysergic acid diethylamide (Chemke et al., 1973; Daly et al., 1996). While associated maternal disease or teratogenic exposure may predispose to recurrence, these are rare causes of the ABS.

101 CHAPTER

Arthrogryposis

Key Points

- Descriptive term that refers to the presence of congenital contractures in two or more joints. Does not necessarily represent a syndrome but is a compensatory connective tissue response.
- Causes include abnormal muscle tissue, abnormal nerve function, abnormal connective tissue, and mechanical limitation of fetal movement.
- Incidence is 1 in 3000 livebirths.
- Sonographic findings include malpositioned limbs, limited fetal movements, hypoechogenicity of long bones. May be associated with increased nuchal translucency, polyhydramnios, and cystic hygroma.
- Differential diagnosis includes more than 150 conditions. Amyoplasia is the most common. Chromosome abnormalities are unlikely, but should consider trisomy 18 and mosaic trisomy 8.
- Examine both prospective parents for signs of distal arthrogryposis, which is dominantly inherited and associated with 10 conditions.
- Treatment of newborn focuses on whether only limbs are affected or if there are abnormalities of nervous or muscular systems.
- Treatment for isolated joint abnormalities begins with plaster casts in newborn period. Surgery, if performed, occurs at 3 to 12 months.

CONDITION

The term arthrogryposis, a mixture of Latin and Greek words, means curved or crooked joint (Hageman et al., 1988). This term was first used in 1923 by Stern. The first medical description of arthrogryposis occurred in 1841, when Otto described an infant with multiple congenital contractures and referred to the condition as "congenital myodystrophy" (Swinyard and Bleck, 1985).

Arthrogryposis refers to a symptom complex characterized by multiple joint contractures that are present at birth. The muscles in the affected area or areas are replaced by fat and fibrous tissue (Shapiro and Specht, 1993). Although the term arthrogryposis is in wide use, the preferred descriptive term is multiple congenital contractures. These contractures do not represent a syndrome but a compensatory connective tissue response (Swinyard and Bleck, 1985).

Clinical features of arthrogryposis include rigidity of several joints, resulting from short, tight muscles and capsular contractures, dislocation of joints, "featureless" extremities (normal skin creases are absent and there is an increase in the amount of subcutaneous fat), presence of deep skin dimples in the vicinity of affected joints, absence or fibrosis of muscles, and normal intellectual development (Williams, 1978).

According to Hall (1981), the term arthrogryposis multiplex congenita was coined to describe infants with multiple congenital contractures. Confusion has arisen because the term was used as a diagnosis. The term is descriptive, and the

presence of congenital contractures only indicates a clinical sign with multiple underlying causes. In general, anything that decreases intrauterine movement may lead to limitation of joint movement and the subsequent formation of contractures. The earlier in development it occurs and the longer the duration of limitation of movement, it will result in more severe contractures at birth.

There are four major causes of congenital contractures (Hall, 1981):

1. *Abnormal muscle tissue:* Examples of this are muscular dystrophy, congenital myopathies, and congenital absence of muscle (amyoplasia).
2. *Abnormal nerve function:* This includes central nervous system malformations, congenital neuropathy, failure of the nerves to form or myelinate, or exposure to toxins that affect nerve function.
3. *Abnormal connective tissue:* This interferes with the normal development of tendons, bone, cartilage, or joint tissue.
4. *Mechanical limitation to movement in utero:* This includes uterine fibroids, oligohydramnios, amniotic bands, or the presence of a multiple gestation.

INCIDENCE

The incidence of multiple congenital contractures is approximately 1 in 3000 livebirths (Hall, 1985). In one study of 66 cases of arthrogryposis multiplex congenita, the mothers were significantly older than average (Wynne-Davies and Lloyd-Roberts, 1976). Davis and Kalousek (1988) identified 16 cases of fetal akinesia deformation sequence in 948 not yet viable fetuses at 9 to 20 weeks of gestation. The fetal akinesia deformation sequence was defined as joint contractures with or without formation of webs, with intrauterine growth restriction, pulmonary hypoplasia, micrognathia, short umbilical cord, and a short gut (Davis and Kalousek, 1988). In addition, arthrogryposis multiplex congenita has been described in association with cases of failed termination of pregnancy (Hall, 1996). These authors hypothesized that the contractures were due to vascular compromise during attempted termination with a secondary loss of functional neurons leading to fetal akinesia and subsequent contractures. A rupture of membranes with continuous leakage of amniotic fluid after attempted termination may have worsened the existing contractures.

SONOGRAPHIC FINDINGS

Detailed examination of the fetal extremities is not listed in the most recent American College of Obstetricians and Gynecologists or American Institute of Ultrasound and Medicine (AIUM) guidelines, but it is a critical adjunct to fetal imaging and is needed to diagnose conditions such as arthrogryposis

Figure 101-1 Sagittal sonographic image of a fetal lower extremity with contractures at the knee and ankle.

(Bromley and Benacerraf, 1995; ACOG, 2008). The sonographic diagnosis of arthrogryposis is made by observation of the malposition of the limbs (Figure 101-1). The morphologic aspects of the bones are normal but the range of movements is limited (Deschamps et al., 1992). Increased nuchal translucency, polyhydramnios, and cystic hygroma are often observed in association with arthrogryposis (Goldberg et al., 1986; Bui et al., 1992; Hyett et al., 1997; Scott et al., 1999).

Murphy et al. (2002) described three cases of fetal arthrogryposis with severe hypoechogenicity of the long bones that was noted after 30 weeks' gestation. They speculated that fetal osteoporosis developed as a consequence of absent fetal movement.

Baty et al. (1988) reported the prenatal diagnosis of distal arthrogryposis by sonographic examination at 18 weeks of gestation in a family with two other affected members. Real-time sonographic evaluation demonstrated a flexed position of the fingers and extension of the right wrist, which did not change despite active motion of the shoulders and elbows. The fetal hands were in a fist and the fingers did not extend (Figure 101-2). These authors described the following important variables in the sonographic diagnosis of fetal joint contractures (Baty et al., 1988):

1. The gestational age of the fetus.
2. The timing of the development of the joint contractures.
3. The severity of the joint contractures.
4. The index of suspicion of the ultrasonographer.
5. The skill, patience, and previous experience of the sonographer.
6. The divergence of the affected joints from the neutral position.
7. The amount of joint movement.
8. The presence of other sonographically detectable anomalies.
9. The persistence of findings over time.

Amyoplasia is the most common cause of joint contractures. Sepulveda et al. (1995) diagnosed a case of fetal

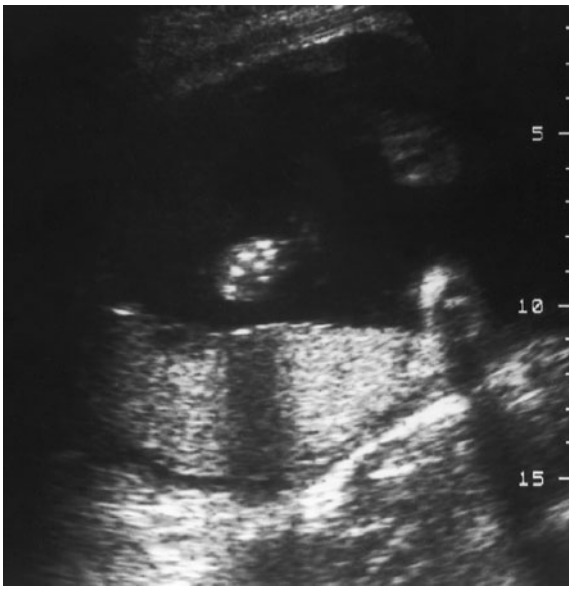

Figure 101-2 Sonographic image of a fetal hand demonstrating fixed flexion of all digits.

amyoplasia at 19 weeks of gestation with absent fetal movements, severe multiple congenital contractures, hydrops fetalis, and polyhydramnios. No spontaneous fetal movements were seen over a 40-minute period of observation. Autopsy of this affected fetus revealed small groups of poorly developed muscle fibers within areas of fat. These authors noted that fetal movements were absent during intrahepatic venous sampling in the fetus with amyoplasia. This was in contrast to their previous observations that second trimester fetuses normally react with vigorous movements during fetal blood sampling.

Stoll et al. (1991) studied two children born to a mother with myasthenia gravis. Her first pregnancy was a 33-week-old fetus with multiple flexion contractures, which died 1 hour after birth from respiratory insufficiency. Her second pregnancy was remarkable for an abnormal ultrasound examination at 20 weeks, which showed decreased fetal movements and multiple flexion contractures. In myasthenia gravis, a maternal factor is transferred to the fetus, which affects the fetal joints. This has been confirmed in an animal model by injecting pregnant mice with plasma from women who have antibodies to the acetylcholine receptor (Jacobson et al., 1999). Many pups were stillborn and showed fixed joints.

Goldberg et al. (1986) described a case of fetal arthrogryposis at 30 weeks of gestation in a fetus with scalp edema but no ascites. Moderate polyhydramnios was present. In this fetus, the lower extremities were tightly flexed and crossed in a squatting position. No normal limb activity was noted. These authors stated that late identification of arthrogryposis was valuable in minimizing the birth trauma associated with the vaginal delivery of an infant with fixed joints.

More recently, three-dimensional (3D) surface-rendering images were used to show the fixed postural abnormalites of the fetal extremities (Ruano et al., 2003). When viewed in real time, the authors were able to show that there was absence of fetal movement, leading to a diagnosis of fetal akinesia deformation sequence.

DIFFERENTIAL DIAGNOSIS

More than 150 conditions are known in which multiple congenital contractures are a predominant sign (Hall, 1985). In a review of 155 patients with arthrogryposis, Sarwark et al. (1990) noted that 43% of patients had amyoplasia, 35% had other contracture syndromes, 7% had the dominantly inherited form of distal arthrogryposis, 6% had multiple congenital anomalies, and 2% had chromosomal abnormalities.

Amyoplasia is the single most common cause of multiple congenital contractures. A very specific limb positioning exists in this condition. There is a marked decrease in muscle mass. Contractures are symmetric, with all four limbs affected. Affected patients have a round face with a mild micrognathia and a midline hemangioma. Intelligence is normal in this condition.

Distal arthrogryposis refers to syndromes in which there are congenital distal contractures but the proximal joints are largely spared (Beals, 2005). There is a lesser degree of involvement of the extremities and preservation of good muscle tone and bulk. Affected patients have a clenched-fist deformity of the hand, occasional congenital dislocation of the hip, mild to severe positional deformities of the foot, and normal intelligence (Baty et al., 1988). In most distal arthrogryposis conditions, the function of the hands improves with time, use, and physical therapy.

Currently, there are 10 different syndromes described that have a common pattern of distal congenital contractures, minimal proximal contractures, and other findings (Bamshad et al., 1996; Beals, 2005). All are inherited as autosomal dominant conditions with variable expression. This group of conditions includes Freeman–Sheldon syndrome, (also known as distal arthrogryposis type 2A), which presents with a distintive facies, flexion, and ulnar deviation of the fingers and vertical talus. Congenital contractural arachnodactyly (Beals syndrome), also known as distal arthrogryposis type 9, presents with ear deformities and finger contractures. This condition is in the differential diagnosis for Marfan syndrome.

Another consideration in the differential diagnosis is Pena–Shokeir syndrome, which manifests as severe intrauterine growth restriction, a short umbilical cord, pulmonary hypoplasia, micrognathia, and facial anomalies. The overall appearance, however, is somewhat nonspecific.

Only a small percentage of patients with arthrogryposis will have a chromosomal abnormality. The most common abnormalities associated with this condition are trisomy 18 and mosaic trisomy 8. In one study, approximately a fourth of the cases of trisomy 18 (23/89) were associated with arthrogryposis (Chen, 2005).

In Scandinavia, a lethal congenital contracture syndrome is inherited as an autosomal recessive condition. This

condition is lethal in utero at a mean gestational age of 29 weeks. Affected fetuses present with hydrops fetalis and malpositioning of the hips and knees with webbing of the neck and elbows. The muscles are hypoplastic, and there is severe thinning of the ventral half of the spinal cord (Kirkinen et al., 1987; Herva et al., 1988).

Maternal myasthenia gravis is in the differential diagnosis, as neonatal myasthenia develops in 12% of babies born to mothers with this condition. In the subgroup of patients with contractures due to neurogenic abnormalities, spinal muscular atrophy is a consideration. DNA analysis of 12 unrelated patients with congenital contractures, generalized muscle weakness, evidence of denervation on electromyographic studies, and muscle biopsy evidence of denervation, revealed that 50% of affected patients lacked the survival motor neuron gene (Börglen et al., 1996). The survival motor neuron (*SMN*) gene is absent or interrupted in 90% to 100% of patients with spinal muscular atrophy.

ANTENATAL NATURAL HISTORY

Joint development starts at 5.5 weeks of gestation, and by the 8th week, the first movement of the limbs can be observed (Ajayi et al., 1995). Absence of motion leads to stiff joints, pterygium formation, pulmonary hypoplasia, and a short umbilical cord. The primary underlying problem in arthrogryposis is due to degeneration of the anterior horn cells, occurring during the early months of gestation (Williams, 1978). Early destruction of muscle fibers in utero will result in certain muscles being affected earlier or more severely. Affected muscles tend to lose tone and fail to counterbalance the tone of the normally developed antagonist muscles. This further restricts the normal movements of the muscles and joints during periods of rapid fetal growth (Williams, 1978). According to Hall (1996), an ischemic event occurring during a critical period of anterior horn development may result in contractures. Handling of the pregnant uterus disturbs uterine blood flow, which may result in temporary hypoxia and bradycardia of the embryo. Disruption or decreased flow in the anterior spinal arteries or decreased uterine vessel blood flow will lead to damage or loss of neurons or muscles. The anterior horn cells are particularly susceptible to hypoxic damage or loss at 8 to 14 weeks of gestation (Hall, 1996). The subsequent lack of normal anterior horn cell function leads to fetal akinesia and secondarily to multiple joint contractures.

Moessinger (1983) developed an animal model of fetal akinesia deformation sequence by paralyzing rat fetuses with injections of curare. The anomalies noted at the time of delivery included multiple joint contractures, pulmonary hypoplasia, micrognathia, intrauterine growth restriction, short umbilical cord, and polyhydramnios. The polyhydramnios in association with fetal akinesia is mediated by lack of swallowing activity.

Clarren and Hall (1983) studied the neuropathologic findings in the spinal cords of 10 infants with neurogenic arthrogryposis and compared them to 8 infants with spinal muscular atrophy type I and II age matched controls. The numbers of α-motor neurons were reduced in affected patients with arthrogryposis and spinal muscular atrophy. Abnormal histology was seen in patients with arthrogryposis. In five patients, the pathologic pattern was consistent throughout the entire spinal cord. In five patients there was an unequal distribution across the spinal cord and this correlated with the muscle groups involved clinically.

MANAGEMENT OF PREGNANCY

The pregnant patient should be asked whether there is a history of decreased fetal movement. This may be difficult to ascertain in a first pregnancy. She should also be asked whether there is a history of infection, fever or hypothermia, or exposure to teratogens. Additional considerations include the exclusion of uterine masses, the presence of a twin gestation, placental abnormalities, or oligohydramnios. The diagnoses of myotonic dystrophy or myasthenia gravis should be ruled out in the pregnant patient. The pregnant woman should be specifically asked whether she has any history of use of phenytoin, insulin, ethanol, or phencyclidine (PCP or angel dust) (Thompson and Bilenker, 1985). A prenatal karyotype should be obtained to rule out an associated chromosomal abnormality. Prenatal factors that potentially predict severe respiratory insufficiency at birth include decreased fetal movements, presence of polyhydramnios, micrognathia, and thin ribs (Bianchi and Van Marter, 1994). If the fetus appears to have arthrogryposis and has a strong likelihood of respiratory insufficiency at birth, the prospective parents can be offered termination of pregnancy. If the diagnosis is made later than 24 weeks of gestation, or if the parents do not desire termination, the fetal position should be checked close to term. There is an increased incidence of breech positioning associated with arthrogryposis. Delivery can be complicated by abnormal fetal position and lack of flexibility of the limbs (see Figure 101-1) (Hall, 1981). Therefore, an elective cesarean section may be necessary for safe delivery. We recommend delivery in a tertiary care center because of the potential for respiratory difficulties at birth and the potential need for mechanical ventilation. The pregnant patient and her partner should be examined for any signs of distal contractures that might suggest a dominantly inherited condition.

FETAL INTERVENTION

There are no fetal interventions for arthrogryposis.

TREATMENT OF THE NEWBORN

The primary consideration in the treatment of the newborn is to determine if only the limbs are affected, if there is

evidence of central nervous system dysfunction, or if there is evidence of additional organs being affected (Hall, 1981). A complete and detailed physical examination should be performed, including specific notation of the appearance and position of the joints and the passive range of motion of the joints. The physical examination should specifically rule out the presence of a "whistling face," micrognathia, cleft palate (including the submucous isoform type), scoliosis, muscular imbalance, hemivertebrae, or a covered neural tube defect. Common skin defects associated with arthrogryposis include scalp defects, amniotic bands, and dimples over the joints with limitation of movement. Midline hemangiomas are particularly common in amyoplasia.

Laboratory tests that are recommended for diagnosis include cranial imaging by computed tomographic or magnetic resonance imaging scan (Hageman et al., 1988), chromosome analysis if not performed antenatally, electroencephalography, electromyography with nerve conduction velocity studies (Thompson and Bilenker, 1985), and radiography. Thin ribs are associated with congenital muscular disease (Chassevent et al., 1978). Creatine kinase levels are nonspecifically elevated and are not useful in confirming a diagnosis (Bianchi and Van Marter, 1994). A muscle biopsy can be performed as early as days 6 to 15 of postnatal life (Bianchi and Van Marter, 1994).

Physical examination findings consistent with a diagnosis of amyoplasia include a round face with a midline hemangioma (Figure 101-3), the presence of bilateral clubfeet, hands that are always flexed at the wrists, and shoulders that are internally rotated. The elbows are usually straight and the hand is rotated posteriorly in what is known as the "waiter's tip" position. Affected children with amyoplasia have decreased muscle mass. It is important to mobilize the joints as soon as possible after birth. Physical therapy for children with amyoplasia should be initiated during the newborn period. Treatment includes a mixture of application of plaster casts with periods of vigorous therapy (Figure 101-4).

A neuromuscular work-up may be warranted in cases of arthrogryposis. Patients should be closely examined for the occurrence of perinatal fractures. This can be suspected if a localized deformity, soft tissue swelling, or irritability occurs. Rigid joints and hypotonia contribute to the occurrence of fractures at delivery (Shapiro and Specht, 1993).

Figure 101-3 Postnatal photograph of a newborn infant with amyoplasia, demonstrating typical round face and a midline hemangioma on forehead and tip of nose.

SURGICAL TREATMENT

The goal of surgical treatment is to achieve the maximum function possible for each involved joint. Major surgery is generally performed between 3 and 12 months of age (Mennen et al., 2005).

Clubfoot is the most common abnormality in arthrogryposis. Ninety percent of children with arthrogryposis have severe bilateral clubfeet (Solund et al., 1991). Treatment of the foot is the dominant orthopedic problem throughout the first year of life. Solund et al. (1991) treated 10 children with 17 affected feet for a mean follow-up period of 13 years. Fourteen of the 17 feet were satisfactorily treated, defined as painless and plantigrade at the time of examination. These authors recommended performing a talectomy (removal of the talus) before the expected age of walking.

Knee contractures are generally treated with physical therapy to extend the range of motion. If operative correction is necessary, this is performed with lengthening of the hamstrings with a posterior capsulotomy. Thomas et al. (1985) reported on 104 patients treated between 1952 and 1982. Seventy-four of the 104 had significant knee contractures, and they were followed for a period of 2 to 20 years. Of the 74, 43 had nonoperative treatment, which included physical therapy, bracing, or serial casting. Thirty-one patients had operative procedures, and these authors stated that the most useful procedure in the growing child was a posterior capsule release with hamstring tenotomy.

Affected patients can also have hip dislocation. The characteristic deformity is flexion abduction–external rotation contractures, accompanied by unilateral or bilateral hip dislocation (Shapiro and Specht, 1993).

Scoliosis often occurs in patients with arthrogryposis due to contractures of the muscles of the trunk. This almost invariably responds to stretching and orthopedic management. Most patients have a history of uterine malposition.

Figure 101-4 Postnatal appearance of same infant in Figure 101-3, demonstrating early treatment with plaster casts. At the time the photograph was taken, the left clubfoot was receiving a new cast. Symmetric contractures of all four extremities are found in amyoplasia.

Surgical correction is recommended for curves of greater than 15 degrees (Sarwark et al., 1990).

Treatment options for contractures that involve the upper extremity include passive joint stretching, serial casting, and surgical intervention. In one study of 17 infant patients with both distal and classical arthrogryposis, outcome was analyzed with an average follow-up of 6 years (Smith and Drennan, 2002). For both groups, the maximal gain in wrist motion occurred after the first casting session. Infants with distal arthrogryposis had the largest improvement in passive wrist motion, had no recurrence, and were more functionally independent at final follow-up. Infants with classic arthrogryposis had more rigid contractures that were more likely to recur after casting and interfere with daily living. These authors suggested that repeat serial casting is unlikely to improve wrist extension and that surgical options should be considered in the absence of improvement (Smith and Drennan, 2002).

LONG-TERM OUTCOME

Bianchi and Van Marter (1994) performed a retrospective medical review and identified 15 newborns over a 10-year period that had arthrogryposis multiplex congenita and required ventilatory support at birth. Fourteen of the 15 patients died; 13 were electively extubated after a variable time course (2 hours to 64 days). All were totally apneic without respiratory support. Autopsies were performed on all 14 nonsurvivors and revealed an approximately equal distribution of central nervous system malformations, peripheral neuropathies, and peripheral myopathies. The single patient who survived had a different clinical course from the other infants. She was weaned spontaneously from the ventilator at age 7 days and was ultimately diagnosed with myasthenia gravis. These authors recommended performing an edrophonium challenge test prior to elective extubation of any infant with arthrogryposis multiplex congenita and inability to breathe. However, most infants with arthrogryposis do not have respiratory problems, and their prognoses are considerably better.

Amyoplasia is an example of a severe birth defect that can improve with appropriate intervention. Sarwark et al. (1990) described a better than expected prognosis in amyoplasia. The size of the limbs at birth and presence or absence of pterygia (webs) can be used to predict response to therapy. Sells et al. (1996) reviewed the outcome of 38 children with amyoplasia, diagnosed by a medical geneticist. Eighty-four percent of the 38 had symmetrical four-limb involvement. Affected patients had an average of 5.7 orthopedic procedures performed. By age 5 years, 85% of affected children were ambulatory, although mobility aids were used by a large proportion of them. Most of the children were relatively or completely independent in their activities of daily living. Most were in regular classrooms at the appropriate grade level. Although infants with amyoplasia have pronounced musculoskeletal involvement at birth and require orthopedic and rehabilitative interventions during childhood, the authors concluded that functional outcome in physical and education areas is excellent (Sells et al., 1996). Of note, 11.6% of the children with amyoplasia had anomalies suggesting a vascular

compromise in utero, including gastroschisis, bowel atresia, or abdominal wall defects.

Carlson et al. (1985) identified a different population of 52 patients who were at least 16 years old with arthrogryposis. The mean age was 27.3 years (range, 17–42 years). Although these patients had limitation in shoulder motion they had no significant functional handicaps despite the presence of elbow deformities. Fifty-two percent had wrist deformities, and approximately half of them were not treated. Fifteen of the 27 patients with wrist deformities had serial casts and splints and 7 required subsequent surgical correction. Following carpectomy or wrist fusions patients had no pain and had satisfactory wrist function. Seventy-one percent of the 52 patients had knee involvement and 85% had foot involvement, mainly clubfoot. Twenty-six patients required surgery and an average of 4.9 procedures on each foot. Fifty-six percent of patients had hip problems but functioned well as adults. The majority of patients had normal intelligence and 50% of adults were married. In this mixed population of patients with arthrogryposis, half walked independently, nine walked with crutches or other mobility aids, and only eight were nonambulatory. Most of the patients had no limitations in their activities of daily living.

GENETICS AND RECURRENCE RISK

The recurrence risk for arthrogryposis depends on the underlying cause for the condition. Amyoplasia is sporadic with little or no recurrence risk. Distal arthrogryposis types 1 to 10 are autosomal dominant conditions with a 50% risk of recurrence. The gene for one of the subtypes of distal arthrogryposis type 1 maps to the pericentromeric region of chromosome 9 (Bamshad et al., 1994). The Scandinavian form of lethal congenital contracture syndrome is an autosomal recessive condition with a 25% risk of recurrence (Vuopala and Herva, 1994).

There is an increased incidence of clubfeet, dislocated hips, and hyperextensibility in children with multiple contractures (Hall, 1981). Hall (1985) personally studied a group of more than 350 children with congenital contractures. Twenty-eight percent of these cases had a known recognizable genetic disorder caused by a single gene, chromosomal, or multifactorial condition. Six percent were the result of an environmental insult or exposure to a teratogen. Forty-six percent of cases had known diagnoses (such as amyoplasia) with no risk of recurrence. In only 20% of cases there was no diagnosis made. In situations where there was no diagnosis or cause for the arthrogryposis, Hall stratified the recurrence risk. If the limbs are primarily affected, there is a recurrence risk of 4.7%. If the limbs are affected in addition to other malformations, there is a recurrence risk of 1.4%. If the limbs and the central nervous system are both affected, there is a recurrence risk of 7%. However, Hall cautioned that these numbers should be used only if a specific diagnosis has not been made for the index case with arthrogryposis.

102 CHAPTER Clinodactyly

Key Points

- Medial deviation of finger at distal interphalangeal joint. Fifth finger most commonly affected.
- Not an anomaly. Usually due to developmental delay or arrest.
- Present in 1% of normal individuals, but also found in 60% of newborns with Down syndrome.
- Associated with many genetic syndromes.
- A detailed fetal ultrasound evaluation should be performed. If clinodactyly is isolated, karyotype is not indicated. If an additional anomaly is found on a detailed scan, obtain a fetal karyotype.
- Isolated clinodactyly can be inherited as an autosomal dominant trait.

CONDITION

The term clinodactyly derives from the two Greek words—*kleinin*, meaning "to bend," and *dactylos*, which means "finger." Clinodactyly is a descriptive term that refers to incurving or medial deviation of the finger at the distal interphalangeal joint (Figure 102-1). The fifth finger is most frequently affected. Usually, this is due to wedging of the middle phalanx so that the planes of the proximal and distal ends are not parallel but converge toward the radial side (Birkbeck, 1975). Clinodactyly is frequently accompanied by brachymesophalangy, which means that the middle phalanx of the fifth finger is short and has increased breadth. There have been several attempts to provide an objective definition of clinodactyly. In one approach, clinodactyly is defined as the relationship between the length of the fifth middle phalanx to the length of the fourth middle phalanx (Birkbeck, 1975). Other authors have used an angle of greater than 8 degrees between the long axis of the distal phalanx and the middle phalanx (Birkbeck,

Figure 102-1 Photograph of a child's hand demonstrating medial incurving of the fifth finger consistent with a clinical diagnosis of clinodactyly.

1975). Yet other groups use a more stringent definition of a distal phalanx deviation of at least 15 degrees (Skvarilova and Smahel, 1984).

Clinodactyly may be isolated or part of a syndrome. It may be a sporadic developmental event or it may be familial (Poznanski et al., 1969). Approximately 60% of newborns with Down syndrome have bilateral fifth finger clinodactyly (Hall, 1970). The association between clinodactyly and Down syndrome has been known for more than 100 years (see Chapter 131). In 1896, Smith published the first X-ray illustrating fifth finger clinodactyly in a patient with Down syndrome (Smith, 1896).

INCIDENCE

Several large population studies have addressed the incidence of clinodactyly in healthy infants and children. In Czechoslovakia, Skvarilova and Smahel (1984) studied 911 healthy children from Prague, age 6 to 18 years. They defined clinodactyly as the presence of any distal phalanx axis deviation of greater than 15 degrees on clinical examination. Affected children underwent radiography and the hands of their immediate family members were examined. Clinodactyly of the fifth finger was seen in 10 individuals (1.1%). Of these, 6 individuals also had brachymesophalangy. In 9 of the 10 affected cases at least one parent was confirmed as being similarly affected. In the remaining case, the father was unavailable for examination. Affected children had considerable bilateral symmetry. The ratio of boys to girls affected was 3:2. An incidence of clinodactyly of approximately 1% in the normal population was confirmed in a study of healthy white newborns, in which clinodactyly of the fifth finger was seen in 0.99% of cases (Marden et al., 1964). Poznanski et al. (1969) have noted significant racial and ethnic differences in fifth finger clinodactyly. For example, they cite an incidence of 3.4% in a Guatemalan population and an incidence of 5% in a population from Hong Kong. Clinodactyly is not an anomaly, per se, but rather a developmental delay or arrest. Mehes et al. (1973) reported that 0.5% of normal full-term Hungarian newborns had clinodactyly, but that this percentage increased to 0.9% in full-term small for gestational age infants. This study also noted an increased incidence of clinodactyly in preterm infants at less than 25 weeks of gestation, in which the incidence was 2.56%. Clinodactyly is seen in 12% of newborns with other major congenital anomalies (Marden et al., 1964).

SONOGRAPHIC FINDINGS

Although ossification of the middle phalanx of the fifth finger occurs normally early during the second trimester of pregnancy, the major concern when fifth finger clinodactyly is detected on a prenatal sonogram is its potential association with trisomy 21 (Deren et al., 1998). In one study of ultrasound markers of chromosomal disease, 3 of 21 cases of Down syndrome had postmortem or postnatal findings of fifth finger clinodactyly (Twining and Zuccollo, 1993).

In 1988, Benacerraf et al. demonstrated hypoplasia of the middle phalanx of the fifth digit in four of five fetuses with Down syndrome examined at 17 to 20 weeks of gestation. They described a radial curve to the fifth digit. One of the five affected fetuses had no visible ossification of the middle phalanx of the fifth digit (Figure 102-2). These authors suggested that fifth finger clinodactyly could be used in addition to other sonographic signs in screening for trisomy 21. This observation was followed by a prospective study examining the middle phalanx of the fourth and fifth digits in

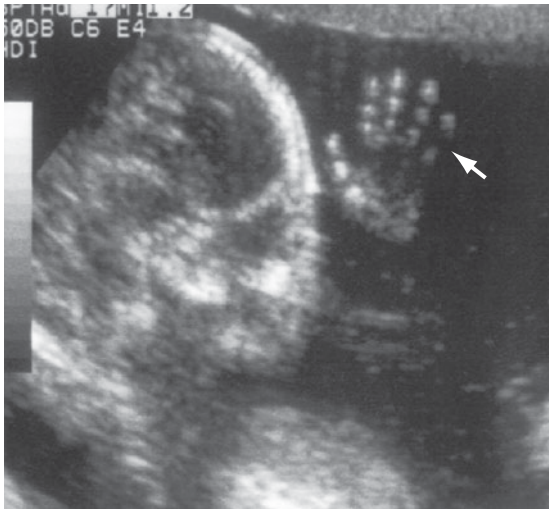

Figure 102-2 Prenatal sonographic image demonstrating absent ossification of the middle phalanx of the fifth finger (*arrow*) with radial incurving, suggesting a diagnosis of clinodactyly.

1032 fetuses between 15 and 20 weeks of gestation prior to routine genetic amniocentesis (Benacerraf et al., 1990). These authors constructed a ratio of the middle phalanx of the fifth digit divided by the middle phalanx of the fourth digit and obtained a median value for normal fetuses of 0.85. In eight fetuses with trisomy 21, the median ratio was 0.59. These authors suggested a cutoff value of 0.70, which would identify 75% of the Down syndrome fetuses and 18% of normal fetuses at the same gestational age. This gave a positive predictive value of this finding of 3.2%. These authors noted that the ratio appeared to rise slightly between 15 and 16 weeks of gestation and at greater than 17.5 weeks of gestation in normal fetuses, implying that the ratios would be affected by normal developmental maturation of this bone. Ossification of the middle phalanx was completely absent in 65 (6.3%) of normal fetuses, although 50% of these fetuses were between 15 and 16 weeks of gestation. Thus, ossification of the middle phalanx of the fifth finger is a gradual process that is not normally complete at 15 weeks of gestation. This has also been confirmed by other investigators (Birkbeck, 1975). The conclusion of this report was that measurement of the middle phalanx of the fourth and fifth digits may be useful as an adjunct to sonographic screening for Down syndrome (Benacerraf et al., 1990).

Deren et al. (1998) examined whether the detection of subtle sonographic abnormalities, including clinodactyly, improved screening efficiency for fetal trisomy 21. Clinodactyly alone had a 28.6% detection rate. Clinodactyly, when seen in association with increased nuchal thickness or short humerus, increased the detection rate of trisomy 21 from 53.3% to 63.2%.

Bahado-Singh et al. (2002) compared the performance of different sonographic markers for fetal Down syndrome detection at 14 to 16 weeks versus 16 to 24 weeks of gestation. As an individual sonographic marker, clinodactyly had a 59.1% sensitivity for detection of Down syndrome with a false-positive rate of 6.2% at <16 weeks' gestation. After 16 weeks the sensitivity decreased to 28.2% and false-positive rate was 2.9%.

DIFFERENTIAL DIAGNOSIS

Clinodactyly has been observed in 1% of normal individuals. Therefore, the most likely diagnosis is a normal fetus. However, the finding should elicit some concern, as clinodactyly is a component of many genetic syndromes, including Down syndrome (clinodactyly observed in 60% of cases), Russell–Silver dwarfism (76% of cases), Cornelia de Lange syndrome (88% of cases), Klinefelter syndrome (84% of cases), oto-palatal-digital syndrome, oro-facial-digital syndrome, oculo-dento-digital syndrome, Holt–Oram syndrome, Prader–Willi syndrome, Alagille syndrome, and Turner syndrome (Poznanski et al., 1969). Many of these syndromes will be characterized by the presence of additional anomalies or a chromosomal abnormality.

ANTENATAL NATURAL HISTORY

Birkbeck (1975) examined radiographs of the silver-stained hand bones of 210 human fetuses obtained between 8 and 20 weeks of gestation. In 179 (85%) of fetuses studied, clinodactyly of the fifth finger was demonstrated. He suggested that clinodactyly and brachymesophalangy of the fifth finger were both normal developmental stages that diminished with advancing age and bone development. He demonstrated that a normal transition occurs from the characteristic wedge shape of the middle phalanx of the fifth finger to the more typical postnatal form with a series of radiographs taken at different gestational age intervals.

Thus, demonstration of clinodactyly and brachymesophalangy in the fetus after 16 weeks of gestation should be considered examples of subtle developmental delays and not malformations.

MANAGEMENT OF PREGNANCY

The documentation of fifth finger clinodactyly mandates that a targeted fetal sonographic scan should be performed to screen for additional anomalies typical of Down syndrome, including increased nuchal fold measurement, cystic hygroma, atrioventricular canal defect of the heart, duodenal atresia, polyhydramnios, and an increased gap between the first and second toes (see Chapters 2, 3, and 131). We do not advocate karyotyping for isolated fifth finger clinodactyly, especially if both parents have been examined and at least one has fifth finger clinodactyly. In the setting of both fifth finger clinodactyly and an additional fetal anomaly, we would recommend obtaining a prenatal chromosome analysis, as there are many reports in the literature of abnormal karyotypes associated with this combination of findings.

FETAL INTERVENTION

There are no fetal interventions for clinodactyly.

TREATMENT OF THE NEWBORN

No treatment is required for isolated fifth finger clinodactyly. However, a thorough physical examination of the newborn is indicated to elicit subtle anomalies that may have been missed on the prenatal sonographic examination. If not examined prior to their infant's birth, an attempt should be made to examine the hands of both parents. If a hand of one of the parents demonstrates clinodactyly on physical examination, radiographic studies are not necessary. Parental hand films might be helpful to detect subtle abnormalities of the phalanges.

SURGICAL TREATMENT

For most cases of fifth finger clinodactyly, there is no indication for surgical treatment. However, rare case reports exist in which the clinodactyly has been treated surgically (Godunova, 1982). In most of these case reports, additional hand anomalies, such as the absence of the fifth metacarpal, have also been present, creating a more serious hand deformity.

LONG-TERM OUTCOME

For isolated clinodactyly, the long-term outcome is expected to be excellent. The presence of the clinodactyly seldom impairs manual dexterity.

GENETICS AND RECURRENCE RISK

For a discussion of the genetics of trisomy 21, see Chapter 131. Most cases of clinodactyly are isolated or are due to an autosomal dominant trait with variable expressivity (Skvarilova and Smahel, 1984; Leung and Kao, 2003). There are multiple reports of three and four generation pedigrees in which clinodactyly is inherited as an asymptomatic autosomal dominant trait, as summarized in Leung and Kao (2003). Clinodactyly may be one feature of the syndromes listed under "Differential Diagnosis." In addition, it can be one component of rarer syndromes, such as the dominantly inherited syndrome of characteristic facial appearance, preauricular pits, fifth finger clinodactyly, and tetralogy of Fallot (Jones and Waldman, 1985). When clinodactyly occurs as part of a genetic syndrome, or if it is due to a chromosome abnormality, the recurrence risk is that of the specific syndrome or chromosome abnormality.

103 CHAPTER Ectrodactyly

Key Points

- Developmental malformation that consists of missing digits, a deep median cleft, and fusion of remaining digits.
- Occurs as either a nonsyndromic split hand/foot malformation or as a syndromic condition with associated anomalies.
- Most syndromic ectrodactylies are inherited as autosomal dominant conditions and are due to mutations in the *p*63 gene.
- Incidence is 1/18,000 in newborns.
- Fetuses with ectrodactyly should be referred for detailed fetal sonographic anatomic evaluation due to the high incidence of associated anomalies.
- Parents should be examined by a medical geneticist to specifically rule out subtle malformations such as missing teeth.
- Fetal karyotype is indicated.
- Intelligence is generally normal and functional outcome of the hands is good following surgical repair.

CONDITION

The term ectrodactyly derives from the Greek *ektroma*, meaning "abortion," and *daktylos*, meaning "finger." Ectrodactyly is a human developmental malformation that consists of missing digits, a deep median cleft, and fusion of remaining digits, all of which result in clawlike extremities (Scherer et al., 1994). A central ray defect is the hallmark of the split hand and split foot malformation. This deformity was first reported in the medical literature in 1575, when Ambroise Paré described a 9-year-old boy with a right split hand and an absence deformity of the long bones of the legs (cited in Temtamy and McKusick, 1978) (Figure 103-1).

Although the common usage of the term ectrodactyly is as a descriptive term for the split hand or foot malformation, the term was actually first used in 1832 by St. Hilaire to denote "absence of fingers." According to Temtamy and McKusick (1978), ectrodactyly refers to a specific hand deformity with a partial or total absence of the distal segments of the hand and normal proximal segments. In this broader definition, ectrodactyly may involve certain phalanges (aphalangia), only the digits (adactylia), or the full hand (acheiria). More recently, it has become clear that ectrodactyly occurs in two clinical settings—the split nonsyndromic hand/foot malformation, a single-gene defect that is transmitted as an autosomal dominant disorder in families; and the syndromic ectrodactylies that include split hand and split foot as one component of a group of anomalies, which occur in approximately 40% of cases (Czeizel et al., 1993; Evans et al., 1994).

The syndromic ectrodactylies encompass many different conditions, such as ectrodactyly ectodermal dysplasia cleft syndrome (EEC syndrome). Many of these syndromic ectrodactylies are due to mutations in the *p*63 gene (Brunner et al., 2002). *P*63 is specifically expressed in embryonic ectoderm. The *p*63 knockout mouse dies at birth and has absent epidermis, prostate, breast, and urothelial tissues as well as limb anomalies.

INCIDENCE

The incidence of split hand malformation is 1 in 18,000 newborns (Czeizel et al., 1993; Evans et al., 1994)

SONOGRAPHIC FINDINGS

The characteristic sonographic findings in ectrodactyly are the absence of the central digits of the hand with normal or enlarged digits at the lateral aspects (Figure 103-2) (Leung et al., 1995). Prenatal diagnosis of ectrodactyly was first reported

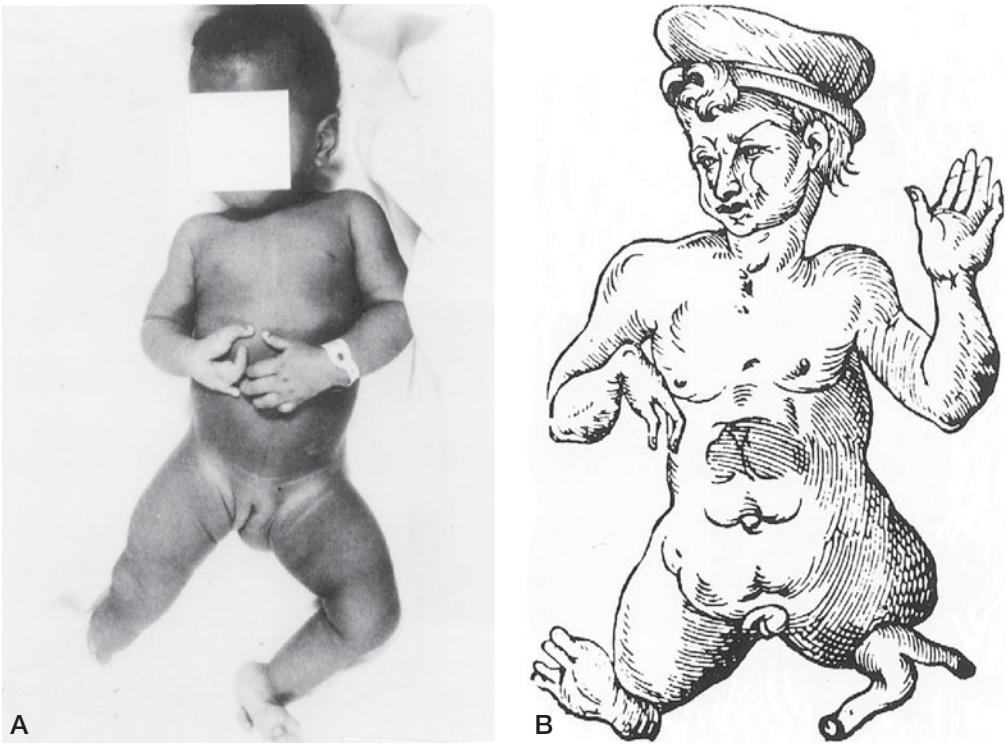

Figure 103-1 Similarities occurring between two cases of split hand/split foot malformation in cases separated by four centuries. **A.** Affected infant with ectrodactyly of the right hand. **B.** Nine-year-old affected boy described by Ambroise Paré in 1575. (*Reprinted, with permission, from Temtamy S, McKusick V.* The Genetics of Hand Malformations. *New York : Liss, 1978. Copyright 1978 Alan R. Liss. Reprinted, by permission, of John Wiley and Sons, Inc.*)

in 1980, when a fetus studied at 16 and 19 weeks of gestation was noted to have one hand with syndactyly and both feet with lobster-claw deformities. This diagnosis occurred in the setting of a father known to be affected with ectrodactyly. These parents elected to terminate the pregnancy. Examination following termination confirmed bilateral syndactyly of the third and fourth fingers and bilateral lobster-claw deformities of the feet (Henrion et al., 1980). Kohler et al. (1989) described the detection of a 30-week appropriate-for-gestational-age male fetus with cleft palate, syndactyly, and lobster-claw deformity and no family history of ectrodactyly.

Figure 103-2 Prenatal sonographic image of a fetal hand with ectrodactyly. Note the absence of central digits.

Transvaginal sonography has also been used to diagnose bilateral cleft lip with lobster-claw deformities of the hands and feet in a fetus with an apparently negative family history at 14 weeks of gestation (Figure 103-3). Post-termination studies confirmed the diagnosis of EEC syndrome. The mother was a healthy 24-year-old woman who had sonography performed as an anatomic screen without a specific clinical indication. After diagnosis of EEC syndrome in this fetus, the mother was more closely examined and was found to have microdontia of two lateral upper incisors. This was not apparent initially because cosmetic dental work had been performed. The authors suggested that the dental anomalies could represent an extremely mild form of EEC syndrome in the mother. She was advised to have transvaginal sonography after the 10th week of gestation in a subsequent pregnancy, when fetal fingers and toes can be visualized (Bronshtein and Gershoni-Baruch, 1993). Approximately 8% of patients with EEC syndrome also have urologic anomalies. Chuangsuwanich et al. (2005) described a fetus with EEC and a large nephrogenic cyst that resulted in bladder and pulmonary hypoplasia.

We described a case of ectrodactyly in all four fetal extremities observed on a sonogram performed for assessment of pre-eclampsia at 33 4/7 weeks (O'Brien et al., 2002). The father of the fetus had bilateral foot and right hand

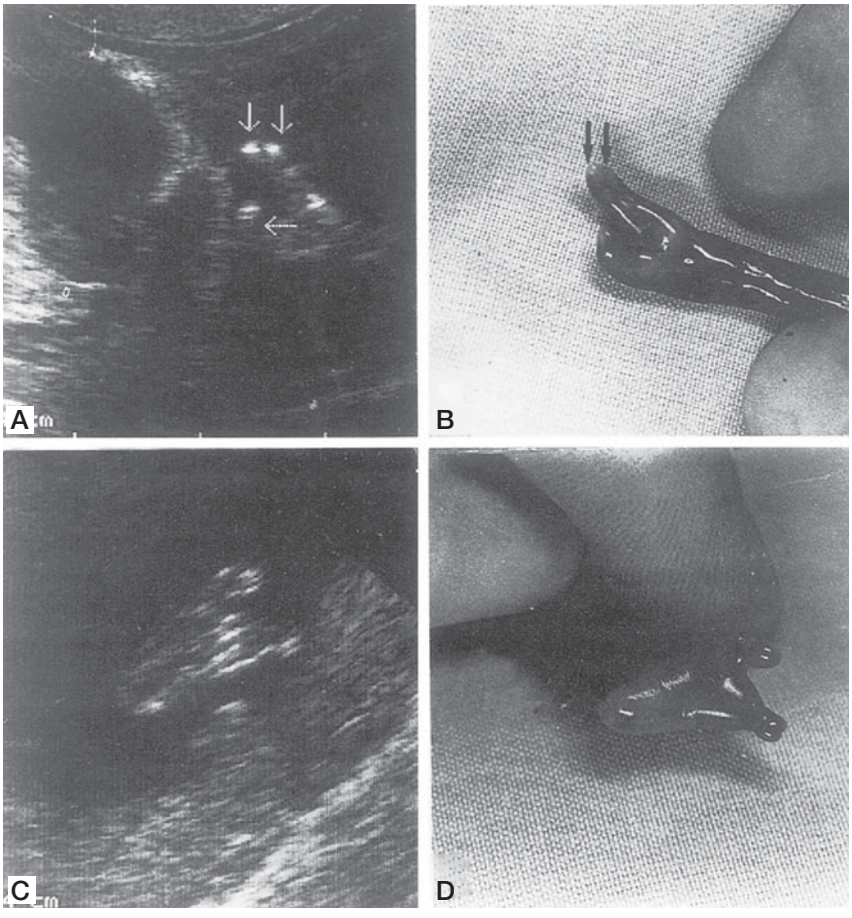

Figure 103-3 Corresponding transvaginal sonographic and pathologic views at 14 weeks of gestation of the fetal hand, demonstrating absent digits and symphalangism (panels **A** and **B**) and the fetal foot, showing absent digits and split foot malformation (panels **C** and **D**). (*Reprinted, with permission, from Bronshtein M, Gershoni-Baruch R. Prenatal transvaginal diagnosis of the ectrodactyly, ectodermal dysplasia, cleft palate (EEC) syndrome.* Prenat Diagn. *1993;13:519-522. Copyright 1993 John Wiley and Sons. Reprinted, by permission, of John Wiley and Sons, Inc.*)

ectrodactyly, small peg-shaped teeth, microretrognathia, nail dysplasia, and a history of lacrimal duct blockage requiring surgery during his infancy. This prompted a diagnosis of acro-dermato-ungual-lacrimal-tooth (ADULT) syndrome, a dominantly inherited condition. Remarkably, the father had never been seen by a geneticist, and was told by his primary care physician that his condition would not affect his offspring. Following publication of the sonographic findings (O'Brien et al., 2002) the father and son were shown to have mutations in the *p*63 gene.

Ectrodactyly has also been described in association with autosomal recessively inherited disorders, such as Smith–Lemli–Opitz syndrome (de Jong et al., 1998), bilateral tibial agenesis with ectrodactyly (Witters et al., 2001), and acro-cardio-facial syndrome (Guion-Almeida et al., 2000).

DIFFERENTIAL DIAGNOSIS

The main consideration in the prenatal diagnosis of ectrodactyly is the distinction between the nonsyndromic split hand and foot malformation, inherited as a single-gene autosomal dominant disorder, versus the syndromic ectrodactylies. Some of the clinical features of the various ectrodactyly syndromes are described in Table 103-1. The most well known of the syndromic ectrodactylies is the EEC syndrome (ectrodactyly, ectodermal dysplasia, cleft lip and palate). In the EEC syndrome, the ectodermal dysplasia is manifested by lightly pigmented, sparse and wiry hair, a decreased number of hairs in the eyelashes and eyebrows, hypopigmented skin with numerous pigmented nevi in the head and neck region, abnormalities of the primary and permanent teeth, including hypoplasia of the enamel, severe caries, brittle or dystrophic nails, atretic lacrimal puncta, a decrease or absence of the orifices of the meibomian glands, and corneal vascularization and scarring, which results in limitation of visual acuity or functional blindness (Bystrom et al., 1975). A conductive sensorineural hearing loss may be a complication of the cleft palate seen in EEC syndrome (Anneren et al., 1991). In one large study of 123 affected patients, 100% had ectodermal dysplasia, 84% had tear duct anomalies, 83.7% had ectrodactyly, 72.4% had cleft lip and/or palate, 33.3% had genitourinary anomalies, and 14% had deafness (Rodini and Richieri-Costa, 1990). EEC syndrome is characterized by variability in clinical expression. A variety of other disorders overlap the EEC syndrome.

The EE syndrome (Wallis, 1988) is a distinct autosomal dominant disorder that manifests as ectrodactyly and ectodermal dysplasia. Wallis (1988) described six members of a four-generation Mauritian family with ectrodactyly and ectodermal dysplasia but with no evidence of cleft lip and/or palate, no abnormalities in the nasolacrimal ducts or sac, and no abnormalities of the scalp. Similarly, families have

Table 103-1

Clinical Features of the Ectrodactyly Syndromes

Condition	Mode of Inheritance	Ectrodactyly	Ecto-dermal Dysplasia	Cleft Lip/ Palate	Tear Duct Abnormality	Genito-urinary Abnormality	Hearing Loss	Dysmor-phic Facies
EEC	Autosomal dominant	+	+	+	+	+	+	+
EE	Autosomal dominant	+	+		+

been described with ectrodactyly and cleft lip (ECP syndrome) but no evidence of ectodermal dysplasia. To further confuse matters, there is another autosomal dominant disorder that presents as ectrodactyly and absent or hypoplastic long bones of the extremities (Hoyme et al., 1987; Genuardi et al., 1990). In this latter condition, approximately 68% of patients have hand malformations and 64% have foot malformations. The associated defects observed in affected kindreds include craniosynostosis, a bifid xiphoid process, and kidney stones. The other abnormalities characteristic of EEC syndrome are not observed in this unique disorder. Patients have also been described with ectrodactyly and hearing loss (E-HL syndrome). The lacrimo-auriculo-dental-digital (LADD) syndrome is characterized by tear duct abnormalities, nasolacrimal duct obstruction, ear anomalies, deafness, small and peg-shaped teeth with hypoplastic enamel, and renal anomalies. These patients are distinguished from patients with EEC by the lack of characteristic lobster-claw deformities (Rodini and Richieri-Costa, 1990). The ADULT syndrome is another dominantly inherited disorder characterized by hypodontia, early loss of permanent teeth due to weak fixation, ectrodactyly, obstruction of the tear ducts, onychodysplasia, and excessive freckling (Propping and Zerres, 1993). In this unique disorder, intelligence is normal and skin pigmentation with sun exposure is normal. Patients have some overlap with EEC syndrome. In Goltz–Gorlin syndrome, affected patients are female. This disorder is inherited as an X-linked dominant condition with lethality in males. Affected patients have ectodermal dysplasia, facial clefts, limb abnormalities, (but not typically ectrodactyly), tear duct and genitourinary abnormalities, and hearing loss. These patients also typically exhibit growth and neuropsychomotor delay, which is not a characteristic of EEC syndrome or the split hand and foot malformation. In patients with Goltz–Gorlin syndrome, the presence of characteristic focal dermal hypoplasia facilitates the diagnosis (Rodini et al., 1992). A relatively recently appreciated genetic disorder, limb–mammary syndrome, consists of mammary gland abnormalities and nipple hypolasia, ectrodactyly, and cleft palate but not cleft lip (van Bokhoven et al., 1999).

ANTENATAL NATURAL HISTORY

Little is known about the antenatal natural history of the ectrodactyly syndromes. Pregnancy loss is not a characteristic feature of these syndromes.

MANAGEMENT OF PREGNANCY

Fetuses ascertained to have ectrodactyly on a prenatal sonographic examination should be referred to a perinatal center capable of performing a complete anatomic study, due to the high incidence of associated anomalies. Particular attention should be paid to the diagnosis of cleft lip and/or palate (see Chapter 23), genitourinary abnormalities, and other anatomic defects. Once ectrodactyly has been diagnosed, it is important to examine both parents and to obtain a complete family history. The ectrodactyly syndromes are characterized by extreme variation in clinical expression. Thus, it is important to be aware of extremely mild manifestations of these disorders such as missing teeth in the parents. A number of ectrodactyly conditions have been associated with chromosomal abnormalities, particularly involving chromosome 7q22 (Naritomi et al., 1993; Scherer et al., 1994; McElveen et al., 1995). Therefore, prenatal karyotyping is recommended when ectrodactyly is observed in the fetus. Furthermore, consideration should be given to obtaining amniocytes for DNA analysis of mutations in the *p*63 gene (South et al., 2002).

Patients with EEC syndrome have been described with low birth weight and a slightly increased incidence of prematurity (Anneren et al., 1991).

There is no indication for delivery by cesarean section solely for the diagnosis of ectrodactyly. Decisions regarding route of delivery should proceed according to standard obstetrical management. There is no indication for delivery in a tertiary care center, as many of the malformations characteristic of the ectrodactyly syndromes generally present with symptoms later in life. However, arrangements should be made for postnatal referral to a clinical genetics unit and a plastic surgeon. Infants with severe cleft lip and cleft palate may need to have a feeding team evaluation.

FETAL INTERVENTION

There are no fetal interventions for ectrodactyly.

TREATMENT OF THE NEWBORN

Infants affected with split hand/foot malformation or one of the ectrodactyly syndromes generally do not have difficulty with their cardiopulmonary systems and do not require neonatal resuscitation. A thorough postnatal physical examination is mandatory. Infants diagnosed prenatally with ectrodactyly should have a complete examination of the palate, including the soft palate and the uvula. Given that these infants are at a reasonably high risk for underlying genitourinary abnormalities, we recommend administration of prophylactic antibiotics until renal anatomy can be studied postnatally. In addition, an early audiologic investigation should be performed, as there is also a significant risk of associated hearing loss. For further management of cleft lip and cleft palate, see Chapter 23. If evidence of decreased lacrimal secretion is present, consideration can be given to administration of artificial tears.

SURGICAL TREATMENT

Surgical treatment for affected patients with EEC syndrome includes functional improvement of the hands, repair of cleft lip and/or cleft palate, and removal of lacrimal duct blockage. None of these surgical procedures are performed during the newborn period. Although the hands will never appear normal, the main surgical consideration is the successful establishment of opposition between two digits.

LONG-TERM OUTCOME

Functional impairment of the hands of affected patients with ectrodactyly is not usually very significant, provided that opposition of two digits can be obtained (Buss et al., 1995). Surgical procedures are directed mainly toward closing an exceptionally wide cleft of the hands and separating syndactylous digits. Patients with ectrodactyly also have difficulty finding proper-fitting shoes. For patients with split hand/foot malformation or EEC syndrome, there is little evidence that intelligence is affected. In one study of 24 cases of patients with EEC syndrome, there was no evidence of mental retardation or developmental delay (Buss et al., 1995). In this study, every affected patient attended a normal school and each patient had normal language milestones despite some of them having problems with hearing loss.

The major difficulties associated with EEC syndrome with regard to long-term outcome include visual difficulties resulting from corneal scarring due to meibomian gland dysfunction and recurrent blepharitis. This latter condition has been ameliorated by operations that improve lacrimal drainage. Orofacial clefting, seen in 14 of 24 patients described with EEC syndrome, may also affect hearing (Buss et al., 1995).

Since the major complications of EEC syndrome are related to repeated infections of the eyes, upper respiratory tract, teeth, and urogenital system, the question has been raised as to whether these patients have an underlying immunodeficiency. In one report, four patients with EEC syndrome were studied and shown to have normal immunoglobulin production, complement activity, and lymphocyte and granulocyte function. These authors concluded that the recurrent infections in EEC syndrome were due to the predisposing anatomic abnormalities and recommended surgical repair of the nasolacrimal duct and extraction of hypoplastic teeth to reduce the frequency of infections (Obel et al., 1993). They also recommended prophylactic use of antibiotics to prevent deafness and ophthalmic sequelae.

GENETICS AND RECURRENCE RISK

The split hand/foot malformation and the ectrodactyly syndromes are characterized by wide variability of clinical expression. Autosomal dominant inheritance of ectrodactyly was first suggested in 1908 (Temtamy and McKusick, 1978). Families with pedigree evidence of autosomal dominant inheritance have a 50% risk of recurrence.

The autosomal dominant form of nonsyndromic split hand/foot malformation was mapped to chromosome 7q21.3-q22.1 by studying multiple patients with cytogenetic rearrangements (Naritomi et al., 1993; Scherer et al., 1994; McElveen et al., 1995) Ectrodactyly is present in 41% of patients who have a deletion of 7q21.2-7q22.1. Based on cytogenetic information, molecular mapping has identified a critical region of DNA for a locus designated as *SHFM1* (split hand/foot malformation number 1). There are at least two other separate genetic loci for isolated split hand/foot malformation. There is an X-linked gene that maps to Xq26.1, known as *SHFM2*, and an additional locus, *SHFM3*, that maps to chromosome 10q24, (Nunes et al., 1995; Roscioli et al., 2004).

Mutations in the *p63* gene have been found in four syndromes associated with ectrodactyly to date (Brunner et al., 2002; Duijf et al., 2002). In nine unrelated families affected with EEC, mutations were demonstrated in the *p63* gene (Celli et al., 1999). In a larger study, 40/43 individuals with EEC syndrome, 2/3 individuals with limb-mammary syndrome, and 4/35 individuals with isolated split hand/foot malformation were shown to have *p63* mutations (van Bokhoven et al., 2001). There is a genotype–phenotype correlation for the *p63* mutations. EEC syndrome is characterized by missense mutations whereas limb–mammary syndrome is associated with frameshift mutations. Functional data suggest that these mutations are consistent with a partial loss of function in combination with dominant gain or change of function defects (Celli et al., 1999; Brunner et al., 2002). *P63* mutations have also been demonstrated in ADULT syndrome (Amiel et al., 2001; O'Brien et al., 2002).

Families with clear-cut evidence of a dominantly inherited form of ectrodactyly should be encouraged to submit blood samples to one of the laboratories investigating the various ectrodactyly genes. If linkage is documented within an individual family, prenatal DNA diagnosis is possible (South et al., 2002). When the case is isolated or there is no evidence of DNA mutation in one of the previously identified *SHFM* or *p63* loci, prenatal diagnosis of ectrodactyly can be performed by sonography starting at 10 weeks using a transvaginal probe.

104 CHAPTER Polydactyly

Key Points

- Defined as the presence of a hand or foot with more than 5 digits.
- May be "radial/tibial" (formerly preaxial), "ulnar/fibular" (formerly postaxial), or "central".
- Incidence is 1/100 to 1/698 depending on ethnic origin of population studied.
- Major consideration is to determine if isolated or associated with other anomalies. Isolated polydactyly is frequently inherited as an autosomal dominant condition.
- Polydactyly is a component of at least 119 recognized conditions.
- Differential diagnosis includes trisomy 13, Meckel–Gruber syndrome, Bardet–Biedl syndrome, Ellis–van Creveld syndrome, short-rib polydactyly syndrome, and Smith–Lemli–Opitz syndrome.
- Refer for detailed fetal sonographic anatomic evaluation, consider karyotype.
- Surgical outcome and prognosis are good if isolated.
- If associated with other anomalies, consider genetics consultation and DNA mutation testing.
- Recurrence risk depends on underlying diagnosis.

CONDITION

Polydactyly is the presence of a hand or a foot with more than five fingers or toes. Although the medical term polydactyly was first ascribed to the 17th century Amsterdam physician Theodor Kerckring (Blauth and Olason, 1988), the presence of polydactyly was mentioned in the Bible (Nicolai and Schoch, 1986) and is even evident on the left leg of St. Joseph in Raphael's famous 16th century painting of "The Marriage of the Virgin" (Mimouni et al., 2000). Polydactyly is the most frequent congenital anomaly of the human hand (Tsukurov et al., 1994). Polydactyly affecting the thumb or great toe is now classified as "radial/tibial" (formerly preaxial), which refers to a duplication of digits on the radial side of the hand and the tibial side of the foot, or "ulnar/fibular" (formerly postaxial), in which the extra digits occur on the

ulnar and fibular sides of the hand and foot, respectively (Talamillo et al., 2005). Cases in which the three central digits are affected are referred to as "central polydactyly" and are the least common of the three types. In general, radial/tibial polydactyly is more common than ulnar/fibular polydactyly (Temtamy and McKusick, 1978). Polydactyly has been further subclassified on a descriptive basis. In ulnar/fibular polydactyly, type A denotes fully developed extra digits. Type B describes rudimentary extra digits or a pedunculated skin tag that is usually found on the hands and only rarely on the feet. This type is very common among blacks. In radial/tibial polydactyly, when the thumb is polydactylous it is known as type I, when a triphalangeal thumb is present it is known as type II, when the index finger is polydactylous it is type III, and when polysyndactyly occurs it is known as type IV.

Morphogenetically, the hand and foot malformations can be considered as a process of bifurcation of one or several finger or toe rays in the longitudinal axis progressing from peripheral to central. Segment polarity genes initially identified in *Drosophila*, such as sonic hedgehog (*SHH*), play a critical role in this process.

INCIDENCE

Notable differences exist in the incidence of polydactyly according to race and gender. In a 1963 study performed in New York City, the incidence of ulnar/fibular polydactyly in blacks was 10.7 in 1000 livebirths, whereas in a comparable white population, the incidence was 1.6 in 1000 livebirths. In this study, polydactyly was noted to be twice as common in males as in females (Mellin, 1963). In general, there is a 1% incidence of ulnar/fibular polydactyly of the hand in black individuals. This is inherited as an autosomal dominant trait. There is also a high frequency of ulnar/fibular polydactyly in some Latino populations (Orioli, 1995). In one Japanese study, radial/fibular polydactyly was demonstrated in the hand and ulnar/fibular polydactyly in the foot (Masada et al., 1986). Affected females predominated when the foot was involved and males predominated when the hand was involved. In this study of 523 cases, associated anomalies were seen in 5% of patients (Masada et al., 1986). In another Japanese study of 330 feet in 265 patients affected with foot polydactyly, a 10% incidence of a positive family history was noted (Watanabe et al., 1992). More recently, in a sonographic study of 17,760 consecutive Israeli women, Zimmer and Bronshtein (2000) detected 26 fetuses with polydactyly. This equated to an incidence of 1 in 698 women. Most of the examinations in this study were performed at 14–16 weeks of gestation.

Maternal smoking increases the chance of fetal limb defects (Hampton, 2006; Man and Chang, 2006).

SONOGRAPHIC FINDINGS

The phalanges are identifiable as early as the 13th week of gestation by transabdominal sonographic examination (Figures 104-1 and 104-2) (Deschamps et al., 1992), and by 11 weeks of gestation by transvaginal scan (Hobbins et al., 1994). The major consideration in the prenatal sonographic examination is to determine whether the polydactyly is isolated. As polydactyly is a component of many genetic syndromes, it is especially important to perform a thorough anatomic survey to look for associated anomalies. Specific associations that should be ruled out include skeletal dysplasia, polycystic kidneys, and encephalocele. Once polydactyly is identified it is especially important to note the length of the long bones (Bromley and Benacerraf, 1995). Polydactyly of the hand is easier to diagnose than that of the foot (Figures 104-3 and 104-4). An ulnar/fibular skin tag can be easily overlooked, whereas a normally formed extra digit will be more easily visualized. Triphalangeal thumbs are also considered within the diagnostic spectrum of polydactyly. Three dimensional (3D) sonography may provide improved resolution of

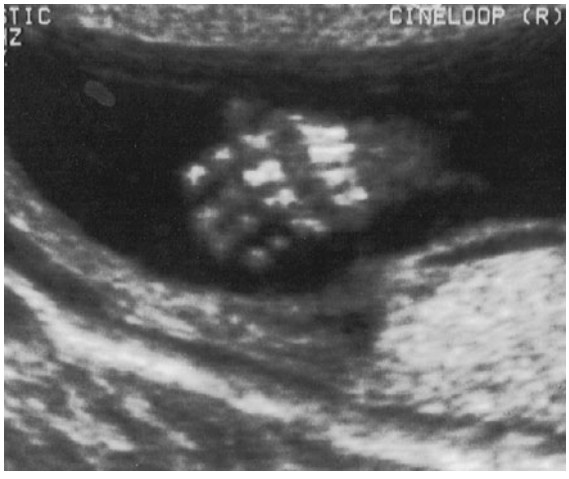

Figure 104-1 Prenatal sonographic image of a fetus with five normal digits. In this image two phalangeal bones are demonstrated in the thumb, whereas the other digits each have three clearly visualized phalangeal bones.

Figure 104-2 Prenatal sonographic image of a fetus with ulnar/fibular polydactyly. Note the presence of a single phalanx that appears to be on the ulnar side of the fifth digit.

Figure 104-3 Sonographic image of the base of a normal fetal foot indicating the great toe and four additional smaller toes.

the fingers and toes, especially when using transparent mode reconstruction (Kos et al., 2002).

DIFFERENTIAL DIAGNOSIS

The majority of antenatally diagnosed cases of polydactyly will be isolated and associated with a normal prognosis (Bromley et al., 2000). The major consideration in the differential diagnosis is to determine whether the condition is isolated and familial or due to a syndrome. Isolated polydactyly is also considered to be a manifestation of the heterozygote (carrier) state for Ellis–van Creveld and Meckel–Gruber syndromes (Goldblatt et al., 1992; Nelson et al., 1994; Wright et al., 1994). Trisomy 13, which manifests as polydactyly in 75% of affected patients (Tsukurov et al., 1994) should be ruled out by prenatal karyotyping if additional sonographic abnormalities are present (see Chapter 129). Fetuses with trisomy 13 have polydactyly, cardiac defects, central nervous system defects including holoprosencephaly, and other major organ abnormalities. If the chromosomes are normal but the fetus is noted to have polydactyly and holoprosencephaly, a possible diagnosis is pseudotrisomy 13, which is inherited as an autosomal recessive condition (Verloes et al., 1991). For patients to receive this diagnosis, the karyotype must be normal and holoprosencephaly must be present with polydactyly or other anomalies.

Figure 104-4 Sonographic view of a fetus with polydactyly of the foot, indicating the presence of six well-formed toes.

Alternatively, polydactyly with other serious central nervous system defects can be present (Lurie and Wulfsberg, 1993). The constellation of brain abnormalities in the setting of polydactyly suggests Meckel–Gruber syndrome, which is also inherited as an autosomal recessive trait (Gershoni-Baruch et al., 1992). Fetuses with Meckel–Gruber syndrome characteristically have an occipital encephalocele, polycystic kidneys, and polydactyly. This condition was first described in 1822 (Ueda et al., 1987). Isolated polydactyly has been questioned in carriers of the Meckel–Gruber syndrome. Nelson et al. (1994) described a family in which three boys were affected. Their father and paternal first cousin had bilateral ulnar/fibular polydactyly, which raised the question of whether they were manifesting heterozygotes. One hundred percent of patients affected with Meckel–Gruber syndrome have cystic renal dysplasia and 55% of these patients have polydactyly.

The constellation of ulnar/fibular polydactyly, obesity, progressive retinal dystrophy, hypogonadism, renal dysfunction, and learning difficulty suggests the diagnosis of Bardet–Biedl syndrome, which is also inherited as a recessive trait. Bardet–Biedl syndrome is genetically heterogenous, and eight genes have been identified to date (*BBS1-BBS8*) (Karmons-Benailly et al., 2005). In cases of Bardet–Biedl syndrome, prenatal sonographic findings such as polydactyly and cystic kidneys may initially suggest a diagnosis of Meckel–Gruber syndrome. In one study, 13 fetuses that presented with these findings and did not have encephalocele, but were diagnosed as having Meckel–Gruber syndrome, underwent DNA sequencing for *BBS1–8* mutations (Karmons-Benailly et al., 2005). In six of the 13 cases, recessive mutations in *BBS* genes were identified. Thus, the antenatal presentation of Bardet–Biedl syndrome mimics Meckel–Gruber syndrome.

The combination of short-limb dysplasia, thoracic hypoplasia, multiple visceral abnormalities, and polydactyly suggest a diagnosis of short-rib polydactyly syndrome (see Chapter 95). Ellis–van Creveld syndrome (see Chapter 94) presents with polydactyly and a skeletal dysplasia, along with cardiac malformations. If a midline abdominal cyst is seen in association with the polydactyly, the underlying diagnosis could be McKusick–Kaufman syndrome (Chitayat et al., 1987). Smith–Lemli–Opitz syndrome, a recessive condition that is due to deficiency of 7-dehydrocholesterol reductase, presents antenatally as growth restriction with polydactyly and ambiguous genitalia in males (Goldenberg et al., 2004). The findings of radial/tibial polydactyly and club hands with hypoplastic first metacarpal have been described in DiGeorge syndrome and 22q11.2 deletion (see Chapter 139) (Cormier-Daire et al., 1995; Fryer, 1996). Additional considerations in the differential diagnosis are given in Table 104-1.

Table 104-1

Differential Diagnosis of Polydactyly

Condition	Major Associated Prenatal Findings
Bardet–Biedl syndrome	Cystic kidneys, micropenis
Cephalopolysyndactyly (Greig syndrome)	Craniosynostosis, syndactyly
Chondrodysplasia punctata (X-linked)	Skeletal, midface anomalies
DiGeorge syndrome	Cardiac, renal anomalies
Ellis–van Creveld syndrome	Skeletal dysplasias, cardiac anomalies
Holt–Oram syndrome	Cardiac anomalies
Isolated (familial)	None
McKusick–Kaufman syndrome	Cystic abdominal mass (hydrometrocolpos)
Meckel–Gruber syndrome	Encephalocele, renal dysplasia, liver cysts
Pallister–Hall syndrome	Midline central nervous system anomalies
Pseudotrisomy 13	Holoprosencephaly
Short-rib polydactyly syndromes	Skeletal dysplasia
Smith–Lemli–Opitz syndrome	Intrauterine growth retardation, holoprosencephaly, ambiguous genitalia
Trisomy 13	Central nervous system, cardiac, renal anomalies

ANTENATAL NATURAL HISTORY

The antenatal natural history depends entirely on the underlying associated diagnosis. Isolated polydactyly has no apparent effect on the antenatal natural history. Conditions such as trisomy 13 have a profound effect on the antenatal natural history and may result in miscarriage. Autoamputation of extra digits has been observed in utero (Zimmer and Bronshtein, 2000).

MANAGEMENT OF PREGNANCY

Fetuses in which polydactyly is suspected should be referred to a tertiary care center capable of detailed fetal anatomic diagnosis. A complete family history should be obtained regarding the occurrence of polydactyly in other family members. Occasionally, parents are unaware of the fact that they themselves had small digits removed during infancy. Both parents should be examined for the presence of scars on the ulnar sides of their hands. For fetuses with isolated polydactyly, there is no indication for delivery at a tertiary care center, especially in light of a positive family history. However, if the fetus is shown to have associated abnormalities, consideration should be given to delivery in a tertiary care center, where clinical geneticists are available for syndromic diagnosis. Consideration should be given to performing antenatal karyotyping to specifically rule out trisomy 13. As stated earlier, sonographic attention should be paid to the length of the long bones, the central nervous system, the heart, and the kidneys as these are the organs that are abnormal in major conditions that are associated with polydactyly. For families known to be at risk for a single-gene disorder associated with polydactyly, embryofetoscopy has been performed successfully to diagnose polydactyly (Quintero et al., 1993). In one report, in a family at risk for recurrence for Meckel–Gruber syndrome, ulnar/fibular polydactyly was observed on both the hands and feet of a fetus at 10 menstrual weeks (Dumez et al., 1994). In addition, bilateral cystic lesions in the mesonephros and metanephros were visualized. The fingers and toes can be observed as early as 9 weeks of gestation by embryoscopy in fetuses at high risk for an inherited abnormality (Dumez et al., 1994). Given the advances in high frequency transvaginal ultrasound transducers, it is unlikely that embyrofetoscopy offers any advantages for diagnosis in contemporary practice.

FETAL INTERVENTION

There is no fetal intervention for polydactyly.

TREATMENT OF THE NEWBORN

Newborns who are delivered with polydactyly should have a thorough physical examination by a clinical geneticist to rule out associated findings (Figures 104-5 and 104-6A). If karyotyping has not been performed prenatally, it should be considered at the time of birth to rule out trisomy 13. A case of 22q11 deletion has been associated with polydactyly (Fryer, 1996). If evidence of polysyndactyly is present, radiographs may be obtained to document the underlying bony anatomy (see Figure 104-6B). A pediatric orthopedic surgeon should be consulted.

In cases of ulnar/fibular polydactyly that consist of a small skin tag, consideration can be given to their removal. Pediatricians are commonly taught to ligate the base of these lesions with suture material as a simple, inexpensive form of

Figure 104-5 Postnatal photograph of a newborn infant at term with six well-formed fingers. This patient has radial/tibial polydactyly of the index finger (type III). At 3 months of age this infant was diagnosed with Pallister–Hall syndrome.

removal (Frieden, 1995). However, because these supernumerary digits may vary in size and internal contents, consultation with a pediatric orthopedic surgeon may be advisable. Extra digits with a wide pedicle at the base are at increased risk for infection, scarring, or incomplete removal. Frieden, (1995) suggest infiltrating the base of the extra digit with a local anthestic and removing the lesion with sterile iris scissors. They suggest that hemostasis will occur with firm, direct pressure for several minutes, or with 20% ammonium chloride or ferric subsulfate solution or a silver nitrate stick.

SURGICAL TREATMENT

For well-formed digits that interfere with hand function, consultation with a hand surgeon is advisable. The goal of surgical treatment is to achieve optimal function and as normal an appearance as possible. In one report, Ganley and Lubahn (1995) performed a follow-up study of 21 patients with radial/tibial polydactyly who were treated between 1979 and 1994. There were 26 thumbs affected. Of their patients, 9 were boys and 12 were girls. Of the 26 thumbs, 6 were treated with ablation alone, 10 were treated with ablation and radial collateral ligament reconstruction and shaving of the metacarpal, 5 thumbs were treated with the Bilhaut–Cloquet procedure (see below), and 5 thumbs were treated conservatively with only observation. Of the 6 thumbs treated with ablation alone, 5 required subsequent radial collateral ligament reconstruction. Patients who underwent ablation with ligament

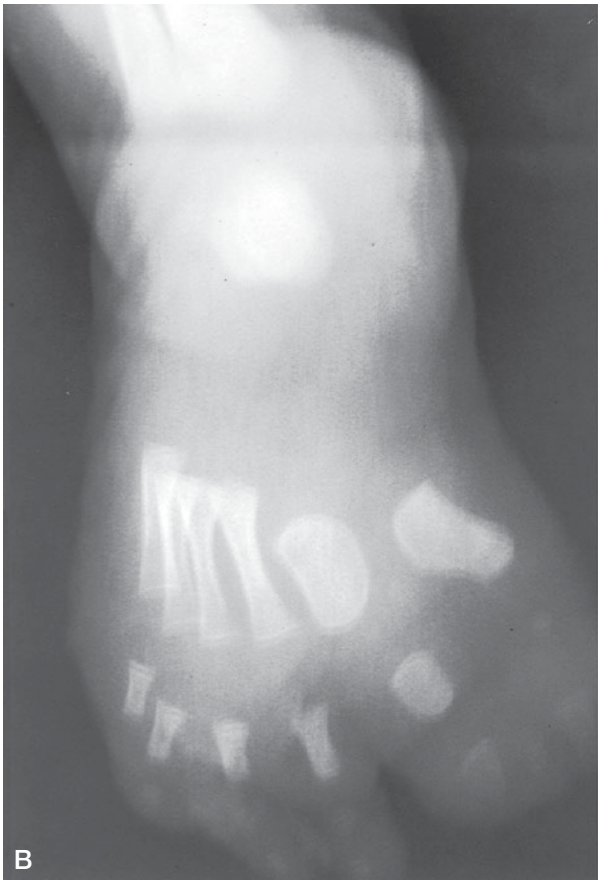

Figure 104-6 **A.** Postnatal photograph of the same infant in Figure 104-5 with polysyndactyly of the toes. **B.** Radiograph of this foot.

reconstruction showed improvement in clinical alignment and stability of the thumbs, but they did not have normal joint motion. The Bilhaut–Cloquet procedure involves removing the middle portions of the two adjoining thumbs; the remaining thumbs are sewn together, resulting in a narrower single digit. Patients who underwent this procedure had improved cosmetic appearance and function, however, they did not have normal joint motion. These authors recommended that ablation be performed only in the context of reconstruction of the radial collateral ligament. They also cautioned that no surgical techniques guarantee ultimately normal joint motion. However, all of their patients were satisfied that the postoperative thumb was significantly improved as compared with their preoperative condition (Ganley and Lubahn, 1995).

LONG-TERM OUTCOME

See under "Surgical Treatment."

GENETICS AND RECURRENCE RISK

There are at least 119 human disorders associated with polydactyly (Biesecker, 2002). Of these, 97 are syndromic and 22 are nonsyndromic. Mutations in at least 26 genes have been identified. The major genes involved are *GLI3* (Greig cephalopolysyndactyly, Pallister–Hall syndrome), *MKS* (McKusick–Kaufman syndrome), *EVC* (Ellis-van–Creveld syndrome), and *DHCR7* (Smith–Lemli–Opitz syndrome). The genes that have been identified to date in association with polydactyly are all critical for normal mammalian development (Biesecker, 2002). They consist of transcription factors, DNA repair genes, signal transduction molecules, chaperonins, and growth factors.

Several of the genes responsible for polysyndactyly have been mapped to chromosome 7q36 (Roberts and Tabin, 1994; Zguricas et al., 1999). Hing et al. (1995) described a six-generation North American white kindred with radial/tibial polydactyly; they showed linkage to chromosome 7q36. In addition, genes responsible for polysyndactyly and radial/tibial polydactyly types II and III have also been mapped to the same region (Tsukurov et al., 1994; Zguricas et al., 1999). Interestingly, both *EN2,* the human homologue of the engrailed gene of Drosophila, which is important for axial patterning, and *SHH,* sonic hedgehog, map to the same region of the human genome.

Greig cephalopolysyndactyly syndrome is a rare autosomal dominant disorder characterized by craniofacial abnormalities, polydactyly, as well as syndactyly of the hands and feet. Point mutations in the human *GLI3* gene, as well as cytogenetic rearrangements of chromosome 7p13 that disrupt the *GLI3* gene, are the underlying basis of this condition (Wild et al., 1997).

Patients with isolated polydactyly generally inherit this trait as an autosomal dominant condition. In one report, Radhakrishna et al. (1993) described a five generational pedigree of 71 affected members of an Indian family in Gujarat. All affected family members had radial/tibial polydactyly manifesting as a well formed, articulated digit of the hand or foot. An additional 20 family members had triphalangeal thumbs or duplication of the great toe. The digital anomalies were isolated. Patients had no other abnormalities, and the polydactyly did not interfere with their work as agricultural laborers. There was no effect of this gene on reproductive fitness. This autosomal dominant gene was manifested by three different phenotypes: radial/tibial polydactyly, duplication of the thumbs or great toes, or the presence of triphalangeal thumbs.

The recurrence risk for isolated familial polysyndactyly is 50%. The recurrence risk for many of the associated conditions depends on the specific condition. Many of these conditions are inherited as autosomal recessive genes, which carry a 25% recurrence risk. Trisomy 13 has a 1% recurrence that is independent of maternal age. Prenatal diagnosis is possible as early as 11 weeks of gestation by transvaginal sonography, or possibly earlier by fetoscopy. If a specific condition has been identified in a prior affected fetus DNA mutation information may be available. If this is the case, prenatal diagnosis will be most accurate if a CVS is performed to obtain fetal DNA.

105 CHAPTER Syndactyly

Key Points

- Syndactyly refers to apparent fusion of digits, either osseous or cutaneous.
- Prenatal ultrasound examination reveals an inability to distinguish separate digits of fingers or toes or to demonstrate independent movement of fingers.
- May be isolated or syndromic.
- Many syndromes are associated with craniosynostosis.
- Fetuses with syndactyly should undergo detailed fetal sonographic examination to look for associated anomalies.
- Review results of estriol levels in maternal serum screen, as low levels are present in triploidy and Smith–Lemli–Opitz syndrome.
- Consider karyotype to rule out triploidy. Obtain complete family history. Review results of estriol levels in maternal serum screen.
- A complete physical examination of infant at birth is essential.

CONDITION

The term syndactyly comes from the Greek *syn,* meaning together and *daktylos,* meaning finger. It describes an apparent fusion of the digits. Syndactyly can be osseous, which refers to fusion of the bones, or cutaneous, defined as webbing of the skin between two digits. In fetal life, the limb buds may be recognized sonographically as early as 8 weeks of gestation, but the digits become visible only at 11 to 12 weeks (Bromley and Benacerraf, 1995). After the 12th week, the hand is fully formed, but separate movements of the digits are not easily observed until 15 weeks of gestation (Deschamps, et al., 1992). Absence of digital dissociation implies a diagnosis of syndactyly.

Although mild cutaneous syndactyly, or webbing, of the toes is a common familial trait, it is generally too subtle to be appreciated on a prenatal sonogram. Syndactyly severe enough to interfere with digital movement suggests a more serious pathology, such as one of the acrocephalosyndactyly syndromes. These syndromes are generally associated with abnormalities of the skull shape due to craniosynostosis (Chapter 10).

INCIDENCE

Mild syndactyly is relatively common. It has an incidence of 1 in 1650 to 1 in 3000 livebirths (Temtamy and McKusick, 1978). Syndactyly severe enough to interfere with fetal digital movement is rare. Triploidy, which is associated with syndactyly, has an incidence of 1 in 10,000 livebirths. The incidence of Apert syndrome, which includes syndactyly as one component, is 1 in 160,000 livebirths. There is an associated high neonatal mortality rate in this condition, which results in a 1 in 2 million incidence in the general population (Hill et al., 1987; Filkins et al., 1997; Boog et al., 1999).

SONOGRAPHIC FINDINGS

Syndactyly is suggested by the inability to distinguish separate digits of the fingers and toes or to demonstrate independent movement of the fingers. Syndactyly is excluded if the fetus splays or interdigitates the fingers (Ginsberg et al., 1994).

Syndactyly may be one component of a syndrome. To make a syndromic diagnosis, the sonographer needs to decide if all four limbs are involved and what associated anomalies are present. Many of the syndromes associated with syndactyly also have synostosis of the cranial sutures. This may appear as acrocephaly, a tall, peaked skull shape with a high forehead, frontal bossing, and a prominent metopic suture.

One of the better known acrocephalosyndactyly syndromes is Apert syndrome. In Apert syndrome, complete syndactyly of the second through fourth digits is present, which leads to the characteristic "mitten-like" hands and feet (Figures 105-1 and 105-2). This condition also frequently involves the fifth finger. Multiple case reports have appeared in the literature regarding the prenatal sonographic diagnosis of Apert syndrome (Kim et al., 1986; Hill et al., 1987; Narayan and Scott, 1991; Parent et al., 1994; Filkins et al., 1997; Boog et al., 1999). The hallmark of the sonographic diagnosis of this condition is that despite prolonged observation, the fetus is never noted to have distinct or separate finger movements. The hands are never seen to open in this condition (Figure 105-1A). In addition, the toes appear fused (Figure 105-2A). Additional abnormalities characteristic of Apert syndrome include polyhydramnios and an acrocephalic calvarium (Hill et al., 1987), ventriculomegaly, partial agenesis of the corpus callosum (Parent et al., 1994), hydrocephalus (Kim et al., 1986), and dysmorphic features, including a high forehead, hypertelorism, and a depressed nasal bridge (Parent et al., 1994). Prenatal sonographic diagnosis of Apert syndrome has been made in both the setting of an affected mother with a fetus at 50% risk for inheriting the condition (Narayan and Scott, 1991), as well as in the setting of a negative family history with the disorder presumably due to a spontaneous mutation (Filkins et al., 1997; Hill and Grzybek, 1994; Parent et al., 1994). Three dimensional sonography improves visualization of both cranial and extremity anatomy (Esser et al., 2005).

Prenatal sonographic diagnosis of Carpenter syndrome has been reported in a twin gestation first studied at 17 weeks (Ashby et al., 1994). In this case report, one twin was noted to have clublike fetal hands, with the fingers maintained permanently in a flexed position. At 20 weeks of gestation, an abnormal, diamond-shaped head was noted in the axial plane along with preaxial polydactyly of the feet and duplication of the great toe. The fingers were described as being "pulled together," and they never spread normally, which was noticed easily because the other twin had normal digital movements (Ashby et al., 1994).

Synpolydactyly is a rare dominantly inherited malformation of the distal limbs (Goodman, 2002). Its severity can range from partial cutaneous syndactyly to complete duplication of the digits.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of syndactyly is listed in Table 105-1. Syndactyly can be isolated or syndromic. Fetuses with triploidy (see Chapter 132) have characteristic, pathognomonic cutaneous syndactyly of the third and fourth digits. Fetuses with triploidy also have second trimester growth restriction, cystic and/or small placentae, ventriculomegaly, and congenital heart defects (Mittal et al., 1998). The differential diagnosis also includes Apert syndrome (acrocephalosyndactyly type I). Patients with acrocephalosyndactyly type II (Carpenter syndrome) have acrocephaly, with variable synostoses of the sagittal lambdoid, and coronal sutures

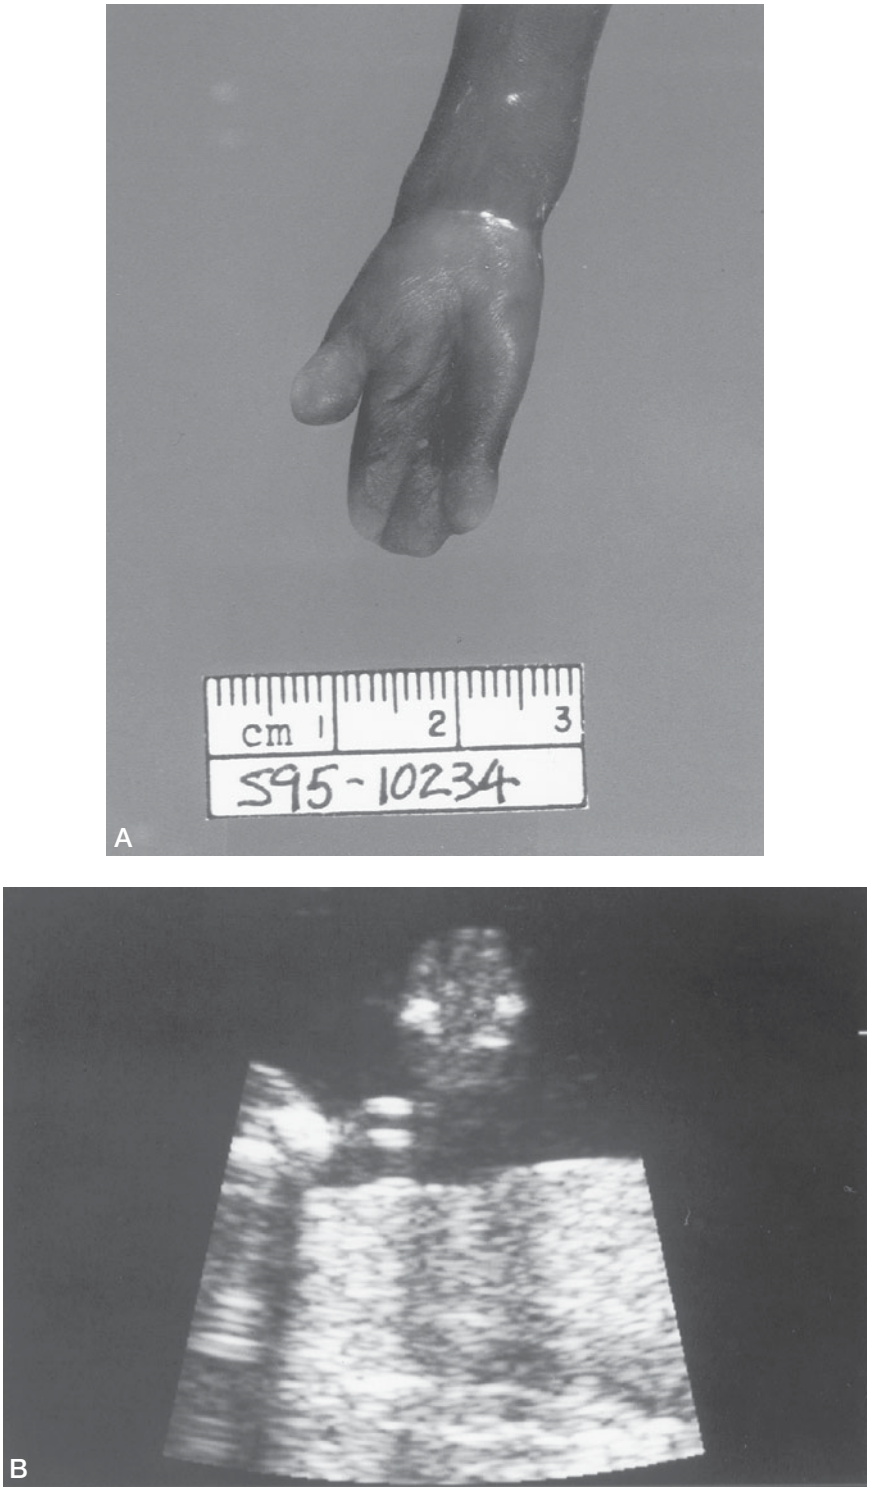

Figure 105-1 **A.** Postmortem photograph of a hand from a fetus at 21 weeks of gestation demonstrating the "mitten-like" appearance due to syndactyly of the second, third, and fourth digits. **B.** Corresponding prenatal sonographic image obtained from the fetus shown in (A), showing syndactyly. *(Courtesy of Dr. Joseph Semple.)*

(see Chapter 10). They also have syndactyly, preaxial polydactyly of the toes, and brachydactyly of the hands and feet with short or absent middle phalanges. One of the difficulties in the prenatal diagnosis of Carpenter syndrome is that marked variability exists even within a family. Pfeiffer syndrome, another acrocephalosyndactyly syndrome, is characterized by craniosynostosis, hydrocephalus, large thumb, and partial cutaneous soft-tissue syndactyly of the hands and feet (Hill and Grzybek, 1994). Magnetic resonance imaging may be helpful in demonstrating both the syndactyly and the broad thumbs that are characteristic of this condition (Itoh et al., 2006). Syndactyly that occurs between the second and third digits is a major manifestation of Smith–Lemli–Opitz syndrome, a recessively inherited disorder of cholesterol metabolism. Fraser syndrome (see Chapter 29) is characterized by cryptophthalmos and syndactyly (Fryns et al., 1997). Patients with Fraser syndrome also have renal agenesis, laryngeal stenosis or atresia, abnormalities of the ears and external genitalia, and other minor anomalies (Rousseau et al., 2002). Syndactyly is a major feature of Fraser syndrome.

Figure 105-2 **A.** Postmortem photograph of the fetus in Figure 105-1 demonstrating syndactyly of all of the toes. The pregnancy was terminated due to a diagnosis of Apert syndrome. *(Courtesy of Dr. Joseph Semple.)* **B.** Corresponding prenatal sonographic image obtained from the same fetus shown in (A), showing fusion of the toes.

It occurs in 77% of patients with this condition (Ramsing et al., 1990). The syndactyly in Fraser syndrome is always cutaneous and most often involves fingers and toes. Its severity may vary from slight interdigital webbing to complete syndactyly. Another consideration in the differential diagnosis of syndactyly is short-rib polydactyly syndrome (SRPS) type II, Majewski (see Chapter 95). In type II SRPS, patients have polysyndactyly, short ribs, cleft lip, and short tibiae (Thomson et al., 1982).

ANTENATAL NATURAL HISTORY

Syndactyly is due to deficiency in the normal pattern of preprogrammed cell death that occurs with the radial grooves of the hand and foot plates (Ramsing et al., 1990). Under normal developmental circumstances, differentiation of the metacarpal bones and phalanges occurs in the fifth to sixth week of fetal life (Hill et al., 1987). Persistent digital fusion

Table 105-1

Differential Diagnosis of Fetal Syndactyly

Isolated
Triploidy
Acrocephalosyndactyly Type I (Apert syndrome)
Acrocephalosyndactyly Type II (Carpenter syndrome)
Fraser syndrome
Pfeiffer syndrome
Short-rib polydactyly syndrome Type II Smith–Lemli–Opitz syndrome (Majewski syndrome)
Synpolydactyly

results from failure of the tissue between the digits to degenerate at between 40 and 44 days of gestation (Schauer et al., 1990).

The *HOX* genes code for a highly conserved family of transcription factors that are essential for normal morphogenesis during embryonic life. Like most vertebrates, humans have 39 *HOX* genes that are organized into four separate clusters, known as *HOXA*, *HOXB, HOXC*, and *HOXD*. Each cluster contains 9 to 11 genes and is oriented in the same 5′ to 3′ direction (Goodman, 2002). The parts of the *HOXA* and *HOXD* gene clusters that are nearest the 5′ end are important in limb development. Synpolydactyly results from mutations in the *HOXD13* gene (Muragaki et al., 1996).

MANAGEMENT OF PREGNANCY

When syndactyly is suspected, the pregnant patient should be referred to a center with expertise in sonographic diagnosis. The fetus should undergo a thorough examination to screen for the possibility of other anatomic abnormalities. A complete family history should be obtained by a genetic counselor or geneticist. The results of second trimester maternal screening tests, if performed, should be reviewed, with particular inspection of the estriol levels, which may be low in cases of Smith–Lemli–Opitz syndrome and triploidy. A prenatal chromosome analysis should be considered to rule out a diagnosis of triploidy. It is important to diagnose triploidy, as this condition is lethal, and it carries a maternal risk of preeclampsia.

Fetal chromosomes are normal in the acrocephalosyndactyly syndromes. Craniosynostosis and abnormalities of skull shape should be specifically ruled out. Prospective parents may benefit from discussing the fetal anomalies observed with a genetic counselor and/or medical geneticist. If a diagnosis of one of the acrocephalosyndactyly syndromes is made before 24 weeks of gestation, the parents should be given the option of terminating the pregnancy. It may be helpful for the parents to see photographs of infants and children with the acrocephalosyndactyly syndromes. Care should be taken when discussing the long-term implications of the diagnosis.

Delivery by cesarean section should be reserved for standard obstetric reasons. Consideration may be given to delivering the patient at a tertiary care center to permit immediate postnatal consultation with a clinical geneticist and pediatric plastic and orthopedic surgeons.

TREATMENT OF THE NEWBORN

The newborn with prenatally diagnosed syndactyly should have a complete physical examination at birth. Consideration should be given to obtaining postnatal radiographs of the extremities and skull if clinical suspicion exists that the child has craniosynostosis. Consultation with a dysmorphologist is indicated. Typical physical features of Apert syndrome include craniosynostosis, turricephaly (a towerlike skull), a flat occiput, midface hypoplasia, ocular hypertelorism, proptosis, a parrot-beaked nose, maxillary hypoplasia, and mandibular prognathism (Narayan and Scott, 1991). In Apert syndrome, one of the characteristic features is that symmetrical syndactyly is present in all four limbs. Subcutaneous or osseous syndactyly always exists in the second through fourth digits, presenting as a large bony mass with a common nail. Partial separation may be present for the first and fifth digits.

The infant with triploidy will be severely growth restricted but may not have markedly dysmorphic features. Often infants with triploidy are mistakenly thought to have trisomy 18.

FETAL INTERVENTION

There are no fetal interventions.

SURGICAL TREATMENT

Affected children with syndactyly may require plastic surgery to improve their appearance. Consultation with a plastic or orthopedic surgeon is recommended because these children eventually require hand surgery to create a pincer grasp.

Patients affected with one of the acrocephalosyndactyly syndromes may require neurosurgical repair of the prematurely fused sutures during infancy (see Chapter 10).

LONG-TERM OUTCOME

Acrocephalosyndactyly syndromes are compatible with survival outside the womb, although the infant mortality rate is greater than 10% for Apert syndrome (Kim et al., 1986). Hydrocephaly is considered to be one of the more common associations in Apert syndrome. Approximately 48% of patients with Apert syndrome have normal or borderline intelligence (Narayan and Scott, 1991). There is no long-term outcome for triploidy because it is not compatible with extrauterine survival.

GENETICS AND RECURRENCE RISK

In general, triploidy is due to double fertilization and has a negligible recurrence risk. Apert syndrome is inherited as an autosomal dominant condition, with a 50% recurrence risk in affected individuals. Most cases represent a new mutation, possibly associated with increased paternal age (Tolorova et al., 1997). New mutations in Apert syndrome are exclusively paternal in origin (Maloney et al., 1996). Phenotypically normal individuals have given birth to more than one affected child, which implies that gonadal mosaicism exists for this condition (Parent et al., 1994). Patients affected with Apert syndrome have reproduced (Leonard et al., 1982; Narayan and Scott, 1991). Apert and Pfeiffer syndromes are associated with fibroblast growth factor receptor type 2 *(FGFR2)* mutations (see Chapter 10), so if the affected person has been genotyped, DNA diagnosis is possible in the first trimester in at-risk families (Chang et al., 1998).

First trimester prenatal diagnosis of disorders associated with syndactyly are also amenable to the diagnosis by fetoscopy (Ginsberg et al., 1994).

Carpenter and Fraser syndromes are both inherited as autosomal recessive conditions with a 25% risk of recurrence. Pfeiffer syndrome is an autosomal dominant trait with a 50% risk of recurrence. Synpolydactyly is inherited as an autosomal dominant condition, with a 50% recurrence risk. The disorder is due to expansion of polyalanine tracts within the gene. There is a genotype phenotype correlation in that the larger the expansion, the greater the number of limbs involved and more complete extent of digital duplication (Goodman, 2002).

Patients who have previously had affected fetuses or infants with syndactyly should have targeted sonographic studies in future pregnancies.

106 CHAPTER Radial Aplasia

Key Points

- Defect occurs on the radial (formerly preaxial) side of the forearm. Findings may include absence or hypoplasia of the radius, absence or hypoplasia of the scaphoid and trapezium bones of the wrist, or abnormalities of the thumb and the first metacarpal.
- Radial deformities may be associated with hematologic abnormalities.
- Incidence is 1 in 30,000. Occurs bilaterally in 50% of cases.
- May be diagnosed as early as 14–15 weeks. Sonographically, a single forearm bone is seen with radial deviation of the hand.
- Differential diagnosis includes chromosome abnormalities, single-gene (dominant or recessive) disorders, teratogen exposure, and multiple congenital anomaly syndromes.
- Should exclude trisomy 18 by performing a karyotype.
- Delivery is recommended at a tertiary center to permit consultation with genetics, radiology, and orthopedics.
- Recurrence risk depends on underlying condition.

CONDITION

Radial aplasia is one manifestation of a spectrum of anomalies known as radial ray malformations. These may occur unilaterally or bilaterally, and either as isolated malformations or in association with other birth defects (Figure 106-1). In radial aplasia, the defect occurs on the radial (thumb) side of the forearm. Skeletal findings in radial ray malformations may include absence or hypoplasia of the radius, with associated absence or hypoplasia of the scaphoid and trapezium bones of the wrist, with or without first metacarpal and thumb abnormalities (Lamb, 1972; Brons et al., 1990).

Radial aplasia results from arrest of radial longitudinal development, which may be secondary to damage at the apical ectoderm of the limb bud occurring between 6 and 12 weeks of gestation. One hypothesis regarding its etiology is that radial aplasia may result from abnormal blood vessel development, which causes an abnormal gradient of nutrients important for the differentiation of mesenchyme into bone or muscle (Van Allen et al., 1982). In radial aplasia, bones as well as associated muscles, nerves, and joints may be affected. Other causes for the developmental arrest of the radius include maternal infectious agents and local biochemical abnormalities secondary to maternal diabetes or medication.

In many cases, a correlation exists between the specific type of radial deformity and associated hematologic abnormalities (Bay and Levine, 1988). For example, absence of the radius with presence of the thumb affects the platelets and is a characteristic finding in the thrombocytopenia–absent radius (TAR) syndrome. If both the radius and thumb are absent, the hematologic findings are more severe; aplastic anemia generally results (Bay and Levine, 1988).

INCIDENCE

The incidence of radial aplasia is approximately 1 in 30,000 livebirths (Brons et al., 1990; Sofer et al., 1983). The condition is bilateral in approximately 50% of cases (Bay and Levine, 1988).

SONOGRAPHIC FINDINGS

In radial aplasia, a single fetal forearm bone is identified, with acute radial deviation of the hand (Figure 106-2). The single forearm bone can be identified as an ulna by comparison

Figure 106-1 Postnatal photograph of a newborn infant with bilateral radial aplasia and absent thumbs.

with standard tables of ulnar lengths (Ylagan and Budorick, 1994). Published standards exist for normal humeral, radial, and ulnar bone lengths at different points in gestation (Jeanty et al., 1985). Detailed examination of the fetal extremities is not listed in current American College of Obstetricians and Gynecologists or American Institute of Ultrasound in Medicine (AIUM) guidelines for standard obstetric sonography (ACOG, 2008). However, examination of the extremities is critically important in the diagnosis of many genetic syndromes. The fetal limb buds may be seen sonographically as early as 8 weeks of gestation, with the limb articulations and digits becoming visible by 11 to 12 weeks of gestation (Bromley and Benacerraf, 1995).

The diagnosis of radial aplasia may be made as early as 14 to 15 weeks of gestation by noting the absence of the radius and the hand in varus position. Prolonged observation of the fetus will reveal that malposition of the hand persists during the entire sonographic examination. When the fetus moves its arms, the hand remains flexed but not rigid (Deschamps et al., 1992). More recently, three-dimensional ultrasound examination has been used to demonstrate radial agenesis in a male fetus with trisomy 18 (Huang et al., 2004).

Figure 106-2 Prenatal sonographic image of a fetal right forearm, demonstrating the presence of a single bone, the ulna.

In one report, Meizner et al. (1986) described the prenatal diagnosis of an affected fetus with absence of the radius and thumb at 18 weeks of gestation. They noted shortening and bowing of the ulna. The fetal hands were clubbed and deviated laterally. An additional finding included crossed renal ectopy of the right kidney. The family history was notable for an affected father and sibling (Sofer et al., 1983; Meizner et al., 1986). In a retrospective study of seven affected fetuses and infants with radial aplasia diagnosed during the perinatal period at the University Hospitals of Amsterdam and Rotterdam, six affected patients were noted to have associated abnormalities of the central nervous system, gastrointestinal tract, kidneys, or heart (Brons et al., 1990). Three of these affected fetuses had trisomy 18. A high degree of perinatal lethality was noted in this report; however, there may have been bias of ascertainment. These authors recommended both longitudinal visualization and transverse scanning of the bones of the extremities to clearly delineate the ulna from the radius. They recommended that the best time for visualization and separate measurements of the radius and ulna was approximately 13 to 16 weeks of gestation. Many of the cases in this report were complicated by abnormalities in amniotic fluid, including both oligohydramnios and polyhydramnios. These authors emphasized, however, that special attention

should be paid to the central nervous system, heart, kidneys, vertebral column, and monitoring of fetal growth.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for conditions associated with radial aplasia is listed in Table 106-1. The conditions comprise four different categories: single-gene disorders, multiple congenital anomaly syndromes of unknown or sporadic cause, chromosomal abnormalities, and teratogen exposures. The most common chromosomal abnormality associated with radial aplasia is trisomy 18, although radial abnormalities are generally uncommon in trisomy 18 (Sepulveda et al., 1995). More commonly, a shortened radial ray is present. However, in one case of trisomy 18, upper limb defects (bilateral radial aplasia, and absent first metacarpals and thumbs) were the only sonographic abnormalities detected (Makrydimas et al., 2003). Although many authors list trisomy 13 as potentially being associated with radial aplasia, the much more common skeletal abnormality in trisomy 13 is polydactyly (see Chapter 129). In one report, a case of mosaic trisomy 22 was associated with radial aplasia (Dulitzky et al., 1981). In another case report, a translocation occurring between chromosomes 1 and 7 was associated with the presence of Wilms tumor and bilateral radial aplasia (Hewitt et al., 1991).

With regard to maternal teratogen exposure, valproic acid is the biggest concern (Verloes et al., 1990). Valproic acid is the most effective antiepileptic drug for simple petit mal seizures, which is the most commonly occurring type of epilepsy in women of childbearing age. Unfortunately, valproic acid is associated with a higher prevalence of fetal anomalies than other antiepileptic agents (Ylagan and Budorick, 1994). The risk of neural tube defects with valproic acid exposure during pregnancy is on the order of 1% to 2%. Valproic acid crosses the placenta, and the fetal serum concentration is greater than the maternal serum concentration. Limb anomalies have been reported in 47% to 65% of mothers exposed to valproic acid. These figures, however, include even minor abnormalities of the nails such as hypoplasia (Ylagan and Budorick, 1994).

In one case, a fetus with radial ray aplasia was described in a mother with a petit mal seizure disorder who took valproic acid from 2 to 8 menstrual weeks. After 8 weeks, when it was determined that she was pregnant, her therapy was changed to carbamazepine for the remainder of the pregnancy (Ylagan and Budorick, 1994). Multidrug therapy has been noted to be a primary factor associated with an increased incidence of malformations in offspring of women with epilepsy (Delgado-Escueta and Janz, 1992).

A complete family history is essential for any fetus diagnosed with radial ray aplasia. Several disorders characterized by autosomal dominant patterns of inheritance are associated with radial ray malformations. These include Holt–Oram syndrome, the acrorenal syndrome, and acrofacial dysostosis (Nager syndrome) (Paladini et al., 2003) (see Table 106-1). Many of the autosomal recessive conditions associated with radial aplasia are also associated with hematologic disturbances. The major disorders in this category include Fanconi anemia, thrombocytopenia–absent radius (TAR) syndrome, and Aase syndrome. In the TAR syndrome, thrombocytopenia results in symptomatic bleeding in more than 90% of affected cases during the first 6 months of life (Bhargava et al., 1972; Adeyokunnu, 1984; O'Flanagan et al., 1989). Cordocentesis results documenting the presence of thrombocytopenia will diagnose this condition (Boute et al., 1996; Shelton et al., 1999). The Baller–Gerold syndrome is distinguishable by the hallmark findings of craniosynostosis, short stature, and radial aplasia. In this condition, cases are divisible into two groups: those who do not have additional malformations and those who have a broad range of additional abnormalities. In Baller–Gerold syndrome, the chromosomes are normal and most patients are intellectually normal (Greitzer et al., 1974; Feingold et al., 1979; Anyane-Yeboa et al., 1980; Boudreaux et al., 1990; Galea and Tolmie, 1990). Juberg–Hayward syndrome is an autosomal recessive condition characterized by growth restriction, microcephaly, cleft lip and palate, and radial abnormalities (Couvreur-Lionnais et al., 2005). The acronym RAPADILINO stands for radial aplasia, patella absent, diarrhea, dislocated joints, little size/limb malformations, nose long, normal intelligence. To date, affected patients have been of Finnish ancestry (Kaariainen et al., 1989).

The finding of associated vertebral, cardiac, renal, or tracheoesophageal abnormalities may also lead to a presumed diagnosis of VACTERL association (Tongsong et al., 1999).

ANTENATAL NATURAL HISTORY

At 6 weeks of gestation, the upper limb buds are recognized as small bumps on the lateral side of the embryo's body. Embryonic mesenchyme induces a thickening of the covering ectoderm. This ectoderm secondarily induces mesenchymal differentiation. The proximal segment of the limb bud develops first (Deschamps et al., 1992). At 7 weeks the limb buds first become visible sonographically (Bromley and Benacerraf, 1995). At 8 weeks, the distal limb buds flatten to become the hand and foot plates. The limbs subsequently develop and flex. Development of the upper limb occurs approximately 2 days ahead of the lower limbs (Bromley and Benacerraf, 1995). By 9 weeks the fetal forearms can raise progressively above the shoulder level. The hands are often observed to cover the mouth and nose. At this point, however, sonographic differentiation of the digits is still not possible (Deschamps et al., 1992). At 10 weeks of gestation, posterior rotation of the upper limb occurs, and for the first time, individual digits can be identified. At 12 weeks, primary ossification centers of the long bones are present. By 14 weeks of gestation, the whole hand is fully formed and one can observe full movements of the fetal arm, including abduction, flexion, scratching, and movements toward the mouth. By 15 weeks of gestation, differentiation of the carpal

Table 106-1

Differential Diagnosis of Radial Aplasia

Condition	Associated Findings in Addition to Radial Aplasia	Mode of Inheritance
Single-Gene Disorders		
Aase syndrome	Cleft lip and/or palate, hypoplastic anemia	Autosomal Recessive
Acrofacial dysostosis (Nager syndrome)	Malar and mandibular hypoplasia, deafness, coloboma of lower eyelids	Autosomal Dominant
Acrorenal syndrome	Crossed renal ectopy, single kidney, ear malformations	Autosomal Dominant
Baller–Gerold syndrome	Craniosynostosis, short stature	Autosomal Recessive
Cornelia de Lange syndrome	Dwarfism, microcephaly, synophrys	Autosomal Dominant, X-linked
Fanconi anemia	Pancytopenia, microcephaly, hyperpigmentation, increased chromosome breakage	Autosomal Recessive
Holt–Oram syndrome	Cardiac abnormalities	Autosomal Dominant
IVIC (oculo-oto-radial syndrome)	Hearing impairment, external opthalmoplegia, thrombocytopenia, urogenital anomalies	Autosomal Recessive
Juberg–Hayward syndrome	Growth restriction, microcephaly, cleft lip and palate	Autosomal Recessive
Lacrimo-auriculo-dental-digital syndrome	Lacrimal duct stenosis, cupped external ear, dental anomalies	Autosomal Dominant
RAPADILINO syndrome	Absent patellae, dislocated joints, diarrhea, short stature, long nose	Autosomal Recessive
Roberts syndrome	Cardiac anomalies, cleft lip and/or palate, tetraphocomelia	Autosomal Recessive
Seckel syndrome	Dwarfism, microcephaly, mental retardation, prominent nose	Autosomal Recessive
Thrombocytopenia-absent radius (TAR)	Thrombocytopenia	Autosomal Recessive
Multiple anomalies, unknown cause		
Poland anomaly	Breast and chest wall deformities on affected side	Vascular accident
VACTERL association	Vertebral, anal, cardiac, tracheoesophageal, renal, and limb defects	Sporadic
Chromosomal abnormalities		
46,XY,t(1:7)(q42;p15)	Wilms' tumor	Chromosomal (familial)
Mosaic trisomy 22	Ectopic kidney, mental retardation	Post-meiosis nondisjunction
Trisomy 13	Polydactyly, central nervous system abnormalities, cardiac and renal abnormalities	Chromosomal
Trisomy 18	Intrauterine growth restriction, micrognathia, cardiac anomalies, clenched hand	Chromosomal
Teratogen exposure		
Thalidomide	Tetraphocomelia	Environmental
Valproic acid	Neural tube defects, vertebral and cardiac abnormalities	Environmental

bones is possible and individual phalanges are identifiable (Deschamps et al., 1992).

Any disruption in the process of limb development occurring between 6 and 12 weeks of gestation will result in a limb defect (Bay and Levine, 1988). Vascular differentiation may have a role in this process. The radial artery is the last major vessel of the arm to appear, at 39 days of embryonic life. The radial bone develops later than the ulna. The difference in timing may contribute to the increased frequency of radial versus ulnar defects observed in humans (Van Allen et al., 1982). Vasculogenesis precedes differentiation of the mesenchyme into muscle and bone. The formation of arteries does not require the presence of bone. Van Allen et al., (1982) described three different patterns of vascular abnormalities in spontaneously miscarried fetuses with radial aplasia. In type 1 cases, a single midline superficial vessel was observed, with no radial or ulnar artery. This pattern of malformation was characteristic of fetuses with acardia. In type 2 cases, absence of the radial artery was seen with or without persistence of the median artery. Other vessels were within normal limits. This pattern was observed in fetuses with multiple malformations of unknown cause. In type 3 cases, the radial artery was present but had an abnormal course. All other vessels were normal. This pattern was characteristic of TAR syndrome. These authors hypothesized that the morphogenesis of the entire limb was determined by a previously established pattern of blood vessels. They hypothesized that radial aplasia may be the result of abnormal vessel development. The early capillaries form a three dimensional network that gives the appearance of a humerus, radius, and ulna even before chondrogenesis ensues. The existing vasculature establishes gradients that are important in the determination of mesenchymal differentiation into bone or muscle. Therefore, it is not unreasonable to imply that abnormalities in vessel development will have important consequences for subsequent bone and muscle development.

FETAL INTERVENTION

There are no fetal interventions for radial aplasia.

MANAGEMENT OF PREGNANCY

Fetuses in which radial aplasia is ascertained need to have a detailed anatomic survey to specifically delineate the presence of other anatomic abnormalities. Areas of concern include the central nervous system, heart, vertebral column, gastrointestinal system, and kidneys. A complete family history should be obtained, ideally by a genetic counselor, to specifically rule out consanguinity, which may predispose the fetus to an autosomal recessive disorder. The parents should be examined for subtle malformations such as ear abnormalities (present in the acrorenal syndrome) or minor, clinically subtle hand abnormalities that may occur in the Holt–Oram syndrome. A history of teratogen exposure should be obtained from the mother, specifically with regard to valproic acid treatment during the pregnancy. Maternal diabetes should be ruled out. An amniocentesis should be performed to study the fetal karyotype. The most likely underlying chromosomal abnormality is trisomy 18. Microarray analysis should be considered to rule out the microdeletion on chromosome 1q21.1 that is associated with thrombocytopenia-absent radius syndrome (Klopocki et al., 2007). If Fanconi anemia is a consideration, karyotyping should be performed, with specific documentation of the presence of chromosomal breaks and the formation of quadriradial figures. To rule out Fanconi anemia, the chromosomes must also be studied after exposure to the clastogenic agent diepoxybutane. This is best performed by a specialty laboratory with experience in the prenatal diagnosis of Fanconi anemia.

In the setting of a positive family history for TAR syndrome, or to rule out associated hematologic abnormalities, consideration should be given to cordocentesis. Cordocentesis can provide both chromosome analysis and diagnosis of hematologic abnormalities. It is potentially useful in ruling out thrombocytopenia or early signs of aplastic anemia, such as an increased mean corpuscular volume for gestational age.

Consideration should be given to delivery of the infant by cesarean section because of the presence of bilateral flexion contractures at the elbow, which might result in dystocia. Delivery is recommended at a tertiary care center to permit early consultation with experts in clinical genetics, orthopedic surgery, and pediatric radiology.

TREATMENT OF THE NEWBORN

A complete physical examination is essential at birth. The newborn should be evaluated by individuals with experience in clinical genetics, pediatric orthopedic surgery, pediatric hematology, and pediatric radiology. Confirmatory skeletal radiography of the extremities should be performed (Figure 106-3). If a chromosome analysis was not performed prenatally, full-scale banded karyotyping with observation for chromosome breaks and a diepoxybutane study should be performed postnatally. A complete blood count with a differential and platelet counts should also be obtained to rule out Fanconi anemia, and TAR, and Aase syndromes. A subtle manifestation of aplastic anemia during the newborn period is an increased elevation in the mean cellular volume as compared with normal reference values for neonates.

SURGICAL TREATMENT

The child with radial aplasia will have displacement of the wrists and hand to the radial side of the ulna, producing a characteristic deformity (see Figure 106-1). This is initially

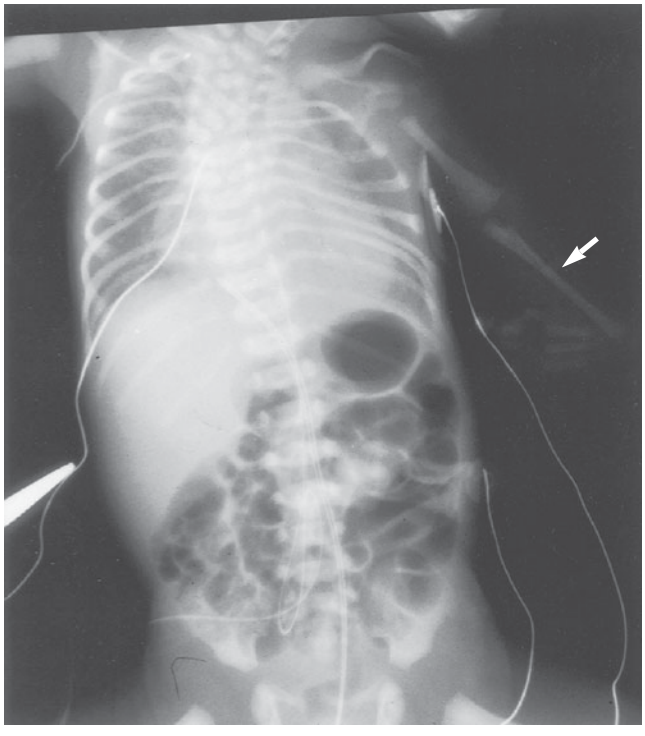

Figure 106-3 Postnatal radiograph of an infant with VATER association. Note the presence of vertebral malformations. The arrow indicates a single left forearm bone with clubbed hand.

correctable with manipulation by casts or by splinting. The soft tissues of the wrists can be tight and contracted on the radial side. This is generally due to the presence of a strong, fibrous band that replaces the absent radius. With subsequent long-bone growth, bowing of the ulna increases. Therefore, splinting is an essential part of the early treatment of radial aplasia (Lamb, 1972). The two digits on the ulnar side of the hand are almost always normal in appearance and function. The two digits on the radial side of the hand usually have some impairment in joint structure and function. Most affected children prefer to use the ulnar two digits for prehension (Lamb, 1972).

Surgical treatment depends on whether the affected patient has unilateral or bilateral radial aplasia. If the case is unilateral, the normal arm will be the functional one and the affected arm will serve only as an aid. In this case, the major goal is to improve the appearance of the affected arm. Functional outcome is a secondary consideration. In bilateral cases, the goal is to improve function to permit independent living. In general, treatment begins during the newborn period and operative intervention occurs within the first year of life. All therapies are designed to improve mobility, strength, and stability of the forearm and wrist, and to improve the dexterity of the hand and fingers (Bay and Levine, 1988). The four basic principles of treatment are (Lamb, 1972):

1. Prevent soft-tissue contractures by short casts or by creating splints for the patient to wear at night.
2. Excise the fibrous band that causes radial contractures.
3. Centralize the carpus over the ulna. This produces wrist stability with a limited range of wrist movement.
4. Pollicize the index finger (creating a thumb from the index finger by surgically migrating to the position of the thumb).

LONG-TERM OUTCOME

In one report, 10 patients were described with congenital anomalies of the radius diagnosed at birth. None of the cases were isolated. Two of the patients had TAR syndrome, 1 had VACTERL association, 1 had Holt–Oram syndrome, and 1 had Poland anomaly. All patients had concomitant abnormalities of the ulna. Four patients had associated congenital cardiac disease. Three patients had vertebral defects and 2 had abnormalities of the sacrum. Seven of the 10 cases were bilateral. Three patients had a positive family history and 2 were infants of diabetic mothers. Of the 10 patients, 5 required surgery: 3 had centralization of the carpus over the ulna, 1 had pollicization of the index finger, and 1 had local reconstructive hand surgery. In all 5 cases, the limb function improved to some degree (Bay and Levine, 1988).

GENETICS AND RECURRENCE RISK

The genetics and recurrence risk of radial aplasia depends on the underlying condition responsible for this bony abnormality. If a chromosomal abnormality was diagnosed, the recurrence risk for a condition such as trisomy 18 will be the maternal age–related risk or 1%, whichever is greater. If an unbalanced chromosomal abnormality was diagnosed, both parents need to be studied to determine whether a parental translocation was responsible for the unbalanced situation in the offspring. If a single-gene disorder was diagnosed, the recurrence risk will be 25% or 50%, depending on whether the condition is inherited as an autosomal recessive or autosomal dominant condition, respectively (see Table 106-1). The VACTERL association is considered to be sporadic, with a negligible recurrence risk. If maternal valproic acid exposure has been determined to be the underlying cause for the radial aplasia, consideration should be given to stopping the antiepileptic medication prior to conception after consultation with a neurologist. If necessary, medication can be restarted during the second trimester.

Thrombocytopenia-absent radius (TAR) syndrome has recently been shown to be the result of homozygosity for a common interstitial microdeletion of 200 kb of DNA on chromosome 1q21.1 using microarray analysis (Klopocki et al., 2007). If, following microarray analysis, a microdeletion is found in the fetus, parental studies should be performed to determine if the deletion is inherited or de novo. About 25% of TAR cases arise from de novo deletions.

In the event that the fetus or infant dies from associated malformations, a perinatal autopsy is strongly recommended to determine the underlying diagnosis.

107 Clubfoot

CHAPTER

Key Points

- Positional abnormality of the fetal foot that results in it being fixed in adduction, supination, and varus, with concomitant soft-tissue abnormalities.
- Incidence is 1 in 1000 livebirths.
- Early amniocentesis (11–14 weeks of gestation) is associated with an increased incidence of clubfoot.
- Fetuses with clubfoot should be referred to a facility capable of performing detailed fetal sonographic anatomic evaluation. Such a targeted scan should include measurement of amniotic fluid volume, observation for presence of amniotic bands, masses or abnormalities that could crowd the fetus, and assessment of fetal movement.
- Associated abnormalities are seen in 23% to 61% of cases. More than 250 syndromes include clubfoot as one component.
- If associated anomalies are seen, consider obtaining a karyotype. If clubfoot is isolated, a karyotype is not needed.
- Treatment consists of stretching exercises, serial casting, and/or surgery. Surgery, if performed, is done at 2 to 12 months.
- Recurrence risk depends on whether a syndrome is present. If clubfoot is isolated, complete family history information is needed to quote a risk.

CONDITION

The term clubfoot refers to a positional abnormality of the fetal foot, resulting in it being fixed in adduction, supination, and varus, with concomitant soft-tissue abnormalities (Drvaric et al., 1989). The Latin term *talipes equinovarus* (*tali* = ankle, *pes* = foot, *equino* = horse, *varus* = bent inward) (abbreviated as TEV) is used interchangeably with clubfoot.

Two general categories of clubfoot are recognized. Intrinsic clubfoot describes a foot that is rigid at birth with marked atrophy, fibrosis, and abnormal bony relationships. This form of clubfoot is generally treated by surgical intervention. Extrinsic clubfoot refers to a foot that is flexible at birth, although bony relationships may be abnormal. This type of clubfoot may be corrected conservatively, with manipulation and stretching (Kawashima and Uhthoff, 1990).

Even today, the cause of clubfoot is not precisely known. Most investigators agree that clubfoot is the result of an intrauterine developmental deformity, although controversy exists as to whether the cause is primarily muscular or neurologic in origin. The chief anatomic abnormality is the deformity of the talus, which is smaller than normal. Plantar and medial deviation of the head and neck of the talus also exists. Bony malposition and subsequent development of contractures serve to keep the foot in a fixed position, resulting in forefoot adduction, midfoot supination, and hindfoot supination or equinus deformity (Drvaric et al., 1989). One hypothesis proposed for the cause of clubfoot involves a potential arrest in fetal development. The evidence for this relates to studies performed by Kawashima and Uhthoff (1990), who demonstrated that during normal embryologic development of the lower limb bud, the foot is first adducted in a position that resembles the clubfoot deformity at approximately 8 to 9 weeks of gestation (Figure 107-1) (Kawashima and Uhthoff, 1990). Movements of the fetal lower limb begin between 9 and 11 weeks of gestation. Thus, if neurologic or muscular abnormalities impede limb movement, the joints will eventually become stiff and contracted. Flexion of the fetal foot occurs to the point at which by 11 weeks of gestation it reaches a normal position (Kawashima and Uhthoff, 1990). Therefore, some investigators believe that anything that arrests development of the fetal foot at approximately 8 to 9 weeks will eventually result in a clubfoot deformity. Other theories regarding the cause of clubfoot include primary bony abnormalities, either intrinsic or because of exogenous forces acting on the bone, primary muscle imbalances, ligamentous contractures with fibrosis, peroneal nerve weakness, peroneal dorsiflexor

weakness, collagen abnormalities, neurogenic abnormalities, or the presence of subcellular retractile elements (Drvaric et al., 1989), excessive fibrous tissue resulting in a retracting fibrosis, contracture of myofibroblastlike cells enhanced by histamine release from mast cells, anomalous insertion of the Achilles tendon, tibialis anterior or peroneal tendons (Bleck, 1993), or relative delay in the growth of the tissues of the posteromedial foot and leg (Dietz, 1985).

Early amniocentesis, at 11 to 14 weeks of gestation, is associated with an increased incidence of clubfoot (Sundberg et al., 1997; Canadian Early and Mid-Trimester Amniocentesis Trial Group, 1998; Cederholm et al., 2005). Pediatric orthopedic surgeons who reviewed the data from the Canadian Early and Midtrimester Amniocentesis Trial group (CEMAT) concluded that the increase in foot deformities seen in the early amniocentesis group suggested that the period between 11 and 16 weeks is a vulnerable time (Tredwell et al., 2001). Weeks 12 to 16 are a period of maximal foot growth velocity and also a time when the fetus is developing coordinated movements, which are necessary for the development of normal synovial joints. During this period the amniotic fluid volume is also increasing exponentially. The orthopedists proposed that the loss or leakage of amniotic fluid induces a temporary fetal akinesia, which results in joint and limb deformities. The underlying mechanism is at present unknown, but has been speculated to be either a physical response or a result of maternal humoral and local microcellular response to the loss of amniotic fluid (Tredwell et al., 2001).

INCIDENCE

The incidence of clubfoot is approximately 1 in 1000 liveborn infants (Wynne-Davies, 1964a; Bakalis et al., 2002). In a study that encompassed a period of 45 years (1946–1990) in Malmö, Sweden, Danielsson (1992), determined that there were more than 128 cases of clubfoot in 137,614 livebirths that occurred over this period, yielding an incidence of 0.93 case per 1000 livebirths. In one study, the incidence of prenatally diagnosed clubfoot was 0.43% of cases (Treadwell et al., 1999). The incidence of clubfoot depends on the ethnic background of the patient. The highest incidence of clubfoot occurs in individuals of Polynesian ancestry, specifically Hawaiians and Maoris of New Zealand, who have an incidence of 6.5 to 7 cases of clubfoot per 1000 livebirths (Wynne-Davies, 1972; Drvaric et al., 1989). In all published studies, the incidence of clubfoot is more common in males than in females, with an approximate 2:1 ratio (Wynne-Davies, 1964a). In Danielsson's study, 79% of affected patients were males (the range in other studies was 64%–76%) (Danielsson, 1992). Forty-four percent of cases are bilateral (range 40%–59%) (Danielsson, 1992). When the clubfoot is unilateral, there is a slight right-sided predominance (Drvaric et al., 1989). The incidence of clubfoot is not increased with advanced maternal age (Yamamoto, 1979). In one study, a seasonal variation was demonstrated, with an increased incidence of milder forms of clubfoot occurring in babies born between November and April (Pryor et al., 1991).

SONOGRAPHIC FINDINGS

Prenatal sonographic detection of clubfoot is now common. The first prenatal diagnosis of clubfoot was reported in 1985 by Benacerraf and Frigoletto, who described five affected fetuses. Of the five fetuses, four had other associated malformations (Benacerraf and Frigoletto, 1985). These authors recommended examining the fetal lower extremity in a transverse section, in which the plantar aspect of the foot can be seen perpendicular to the shaft of the tibia (Figures 107-2 and 3). They made a diagnosis of clubfoot deformity when the foot was oriented in the same plane as the lower leg and

Figure 107-2 Prenatal sonogram demonstrating the visualization of the fetal foot and tibia and fibula in the same plane.

was visualized only in a plane or section parallel to the lower leg rather than perpendicular to it. Transvaginal sonography has been used to diagnose the presence of bilateral clubfeet in a female fetus at 13 weeks of gestation (Bronshtein and Zimmer, 1989). In this case, the family history was notable for maternal congenital hip dysplasia and a maternal uncle with orthopedic problems in one of his ankles during infancy. This case highlights what has been noted previously in a genetic epidemiologic study of clubfoot: A high frequency of associated connective tissue disorders, such as hernia, congenital hip dislocation, and generalized joint laxity are observed in families that have at least one affected member (Wynne-Davies, 1964a).

Figure 107-3 Three-dimensional surface rendered image of a fetus at 24 weeks of gestation showing bilateral clubfoot.

The presence of a clubfoot deformity may not be apparent on an early sonographic scan. For example, intrauterine progression of a clubfoot deformity was demonstrated concurrent with the worsening of hydrocephalus observed by transvaginal scanning over a period between 11 and 16 weeks of gestation (Bronshtein et al., 1992). Similarly, in a fetus with trisomy 18, early scans performed at 14 and 17 weeks of gestation did not reveal the presence of a clubfoot deformity (Bar-Hava et al., 1993). At 21 weeks of gestation, multiple sonographic abnormalities, including clubfoot, were easily observed.

The targeted anatomic scan for a fetus with clubfoot should include measurement of amniotic fluid volume; observation for the presence of amniotic bands; detailed observation for the presence of masses within the uterus that could result in an abnormal, fixed position of the fetus; evidence for uterine abnormalities that might similarly crowd the fetus, resulting in a positional deformation; and a careful observation for the presence of associated anomalies.

Using this approach, a number of studies have looked at outcome for fetuses diagnosed with clubfoot (see Table 107-1). The relatively high percentage of associated anomalies (23%–62%) reflects the fact that most of these studies were performed in high-risk referral centers. Studies involving large numbers of liveborn infants quote a 10% incidence of associated anomalies (Yamamoto, 1979). Also of note is the fact that there is a significant false-positive rate for the diagnosis of clubfoot (Bar-On et al., 2005; Mammen and Benson, 2004). While three-dimensional sonography (see Figure 107-3) is not usually needed to make or clarify the diagnosis of clubfoot, in one case it was used to help a couple visualize the problem and better understand it (Mohammed and Biswas, 2002).

DIFFERENTIAL DIAGNOSIS

Most cases of clubfoot are isolated and idiopathic. When considering the differential diagnosis, it is important to determine whether this is a familial trait, part of a syndrome, or as a result of a positional deformity. More than 250 nonchromosomal syndromes include clubfoot as one component (Rebbeck et al., 1993) (Table 107-2). Chromosomal abnormalities that are associated with clubfoot deformity include trisomy 18 (Bar-Hava et al., 1993) and deletion of chromosomes 18q, 4p, 7q, 9q, and 13q. Possible causes of positional deformity include uterine constriction due to a multiple gestation, large uterine fibroid, or severe oligohydramnios. Consideration must also be given to underlying neuromuscular disorders in the fetus, including neural tube defects, spinal muscular atrophy, muscular dystrophy, and arthrogryposis multiplex congenita (see Chapter 101). Dominantly inherited Mendelian disorders, such as Freeman–Sheldon syndrome, can be associated with clubfoot. Similarly, recessively inherited syndromes such as Smith–Lemli–Opitz, Larsen, and multiple pterygium (Ramer et al., 1988) can all be associated with clubfoot. Some of the skeletal dysplasias, for example, diastrophic dysplasia

Table 107-1

Clubfoot: Characteristics of Prenatally Diagnosed Cases

Study	Number of Fetuses with Clubfoot	Percent Bilateral	Mean age at Diagnosis (wk)	Percent Associated with Anomalies	Percent with No or Mild Treatment (Less than Casting)
Katz et al., 1999	13	69	23.6	23	0
Tillett et al., 2000	14	64	20	NG	21
Bakalis et al., 2002	107	60	18–23	48	NG

Bar-On et al., 2005	51	61	22.1	39	NG

NG, not given in article.

(Gollop and Eigier, 1987) are also associated with the presence of clubfoot (see Chapter 93).

The presence of clubfoot has also been reported after in utero treatment of maternal tetanus with tubocurarine. This finding has been duplicated experimentally in chickens. Clubfoot has also been documented following failed abortion attempts using sodium aminopterin (Drvaric et al., 1989).

ANTENATAL NATURAL HISTORY

The antenatal natural history for a lower extremity affected by a clubfoot deformity includes atrophy of the leg, resulting from a decrease in the size of the individual muscle fibers. Tendon sheaths in the affected extremity are frequently thickened, especially around the peroneal and tibialis posterior tendons. Eventually, during fetal life, the joint capsules become contracted at the ankle, subtalar, talonavicular, and calcaneocuboid joints (Bronshtein et al., 1992). Involved ligaments eventually become contracted. Contractures of the fascial planes and plantar fascia may also occur. The end result is that in cases of unilateral clubfoot, the entire lower limb may be shorter than the normal limb on the affected side.

There is no evidence for increased loss of pregnancy in cases of isolated clubfoot. When the clubfoot deformity is part of a more generalized syndrome, there may be an increased chance of spontaneous pregnancy loss.

MANAGEMENT OF PREGNANCY

When a diagnosis of fetal clubfoot is made antenatally, referral to a center with expertise in targeted fetal anatomy scanning is indicated. We recommend that associated abnormalities, oligohydramnios, and uterine deformities be specifically ruled out. We also recommend consultation with a genetic counselor or medical geneticist, who can obtain a complete family history and examine the parents for evidence of discrepancies in leg length and width. The presence of associated anomalies may suggest an underlying syndromic diagnosis. Controversy exists about whether to offer genetic amniocentesis for fetal karyotype when the clubfoot is isolated (Benacerraf, 1986). In one study, follow-up of 68 fetuses identified prenatally with clubfoot showed that four had abnormal karyotypes: 47, XXY, 47, XXX, trisomy 18, and trisomy 21 (Shipp and Benacerraf, 1998). However, the two fetuses with trisomy 18 and 21 had additional abnormal sonographic findings, so the clubfoot was not isolated. As described in Chapters 135 and 136 on the XXY and XXX syndromes, clubfoot is not considered part of the phenotype associated with these karyotypes. In another study performed at Tufts-New England Medical Center, we reviewed 51 cases of prenatally diagnosed isolated clubfoot (Malone et al., 2000). No cases of aneuploidy were found on either fetal karyotype evaluation or newborn physical examination. Our findings and subsequently, those of others (Bakalis et al., 2002; Mammen and Benson, 2004) suggest that invasive testing for fetal karyotype is not necessary if the fetal anatomy has been studied by an appropriately detailed sonographic anatomy survey and found to be otherwise normal.

In a study performed at the Royal Women's Hospital, Melbourne, 17 fetuses were diagnosed with isolated clubfoot (Woodrow et al., 1998). Sixteen of the seventeen had a normal karyotype and the remaining case was phenotypically normal. Six infants did not have clubfoot at birth, two infants did not require further treatment, and nine infants required casting, orthotics, and/or surgery. All infants had excellent results at 2 years of age.

Table 107-2

Conditions Associated with Clubfoot

Type of Condition	Pattern of Inheritance
Chromosome Abnormalities	Chromosomal
Neuromuscular Disorders	
Meningomyelocele	Multifactorial
Amyoplasia congenita	Sporadic
Arthrogryposis multiplex congenita	Many etiologies
Moebius sequence	Sporadic
Pena Shokeir phenotype	Many etiologies
Skeletal Dysplasias	
Campomelic dysplasia	Autosomal recessive
Diastrophic dysplasia	Autosomal recessive
Chondrodysplasia punctata, rhizomelic	Autosomal recessive
Ellis-van Creveld syndrome	Autosomal recessive
Single-gene Disorders	
Escobar syndrome	Autosomal recessive
Multiple pterygium syndrome	Autosomal recessive
Freeman–Sheldon syndrome	Autosomal dominant
Hecht syndrome	Autosomal dominant
Larsen syndrome	Autosomal recessive and dominant
Smith–Lemli–Opitz syndrome	Autosomal recessive
Meckel–Gruber syndrome	Autosomal recessive
Zellweger syndrome	Autosomal recessive

If the clubfoot is an isolated abnormality, there is no indication for delivery at a tertiary care hospital. Similarly, cesarean section should be performed only for standard obstetric indications. The parents may benefit from antenatal consultation with a pediatric orthopedic surgeon, who can counsel them regarding the expected treatment for the condition.

FETAL INTERVENTION

There is no fetal intervention for clubfoot.

TREATMENT OF THE NEWBORN

For the fetus diagnosed antenatally with clubfoot, we recommend that a complete and detailed physical examination be performed during the newborn period. We also recommend consultation shortly after birth with a pediatric orthopedic surgeon. Initial therapy consists of gentle stretching and manipulation of the affected foot or feet, followed by taping, casting, or a Denis Browne splint, which consists of adhesive strapping of shoes to a metal plate that is rotated laterally and attached to a transverse bar. The infant corrects the foot abnormality by constant kicking, which forces the foot into eversion and dorsiflexion (Bleck, 1993). With conservative management, the clubfoot that results from uterine deformation will be corrected in most cases. In cases that are due to an underlying neurologic or neuromuscular disorder, approximately one-third to one-half of cases will be corrected with physical manipulation (Drvaric et al., 1989). Casting of the foot prevents further tightening of contracted structures prior to surgery. Other authors have described even more optimistic results from conservative management. In one clinic's experience, satisfactory functional results were achieved in 89% of cases by manipulation and serial application of casts, supported by limited operative intervention (Ponseti, 1992). This author suggested that a successful nonoperatively treated clubfoot results in much better long-term function than the successfully surgically treated foot (Ponseti, 1992).

Some authors recommend obtaining an anteroposterior radiograph of the foot (Bleck, 1993). In the newborn, one can visualize only the ossification centers of the major tarsal bones, but not the key indicator of prognosis, the navicular ossification center. Other authors recommend that magnetic resonance imaging (MRI) may be more helpful to study the foot anatomy (Downey et al., 1992). MRI produces excellent images of the tendons, cartilage, and bone in the infant's hindfoot. In one study, the T_2-weighted image was demonstrated to be useful in delineating articular surfaces, but the intermediate weighting image gave the best overall image of the cartilaginous structures. Downey et al. (1992) studied the feet of 10 infants with clubfoot by MRI. This was the first study to look in great detail at the relationships between the bones in the in vivo setting. These authors observed medial angulation of the talar neck and rotation of the calcaneus with the anterior portion of the calcaneus shifting medially and the posterior portion of the calcaneus shifting laterally. They thought that the primary problem in clubfoot was a talar head and neck deformity, which resulted in the anterior calcaneus following the deformed anterior talus, thus causing a pivot about the interosseous ligament so the posterior calcaneus is forced laterally (Downey et al., 1992).

SURGICAL TREATMENT

Many different surgical approaches have been described for the treatment of clubfoot. In many ways, however, little has changed since Felix Würtz, a Basel surgeon, published the following treatment for clubfoot in 1563: "It hapneth that a child is born with crooked feet . . . Let no man be neglective if his child be thus crooked, as not to ask counsel about it; though all be not recovered which are in such cases, yet many

are cured, if not perfectly, yet may they be mended in some sort. Observe whether that joint both lie and turn easily to the place where it should be, then bind it that way, and cure it" (Würtz, cited in Dunn, 1992). All authors agree that the initial management should be nonoperative with manipulation and casting. The optimal age for initial surgical intervention is 3 to 6 months (Drvaric et al., 1989). There appears to be no advantage for surgery performed at less than 2 months of age. Ideally, however, surgery should be performed at less than 12 months of age because up to this time, the tarsal bones are still cartilaginous. Thus, maximal potential for remodeling of the joint still remains. The goal of surgery is that the patient ends up with a functional, pain-free, plantigrade foot with good mobility and no calluses and no need for modified shoes (Ponseti, 1992). Precise surgical goals consist of accurate bone realignment, resulting in talonavicular articulation and proper alignment of the bimalleolar axis with normal range of motion. Most surgical techniques consist of soft-tissue release with lengthening of the tendons. Some authors use wires to stabilize the talonavicular and talocalcaneal joints (Drvaric et al., 1989). In one approach, the contracted joint capsules are cut, the tendons are lengthened, and the bones are repositioned correctly in one stage. Specifically, this consists of a posterior ankle capsulotomy and tendon lengthenings to correct the equinus deformity, and capsulotomy of the talonavicular joint with posterior tibial tendon lengthening to shift the navicular bone laterally onto the head of the talar neck to correct the varus deformity (Bleck, 1993).

LONG-TERM OUTCOME

Prospective parents of a fetus with isolated clubfoot should be counseled that successful results of treatment, consisting of complete correction and no recurrence of the deformity with manipulation, serial casting, or surgery, varies from 60% to 95% of cases (Bleck, 1993). A good clinical prognosis exists for a female infant with a unilateral clubfoot, clinical evidence at birth of increased joint laxity, or an age at diagnosis and treatment of less than 9 months. A relatively poorer prognosis exists for an infant older than 9 months of age at the time of diagnosis and treatment. Also, the presence of a deep medial crease in the plantar arch because of a cavus deformity or evidence of marked atrophy of the leg on the affected side indicate an underlying neurologic or neuromuscular disorder.

Prospective parents should be counseled that eventual correction can be achieved with manipulation and surgery in the majority of cases, although recurrences will occur in some. Surgery is generally successful for most patients who require operative intervention, but 25% of cases may require revision surgery (Atar et al., 1992). Prospective parents should also be counseled that in unilateral cases, the corrected clubfoot will remain smaller than the normal foot. Similarly, the circumference of the calf on the affected side will be smaller than that of the contralateral calf. This will be variable in severity but will persist into adult life (Bleck, 1993; Ponseti, 1992). In general, children with corrected clubfeet can participate in almost all athletic activities and there appears to be no long-term apparent functional disability.

To document long-term outcome for patients with clubfoot, Wynne-Davies (1964b) reported on her clinical outcome studies of 84 patients (representing 121 feet) at age 10 through 35 years of life. This study was performed to determine residual disability and deformity in patients with clubfoot. These individuals were treated with casting, splinting, Denis Browne shoes with a cross bar, and eventual surgical correction if conservative management failed. She concluded that very few of these patients limited their activities because of the clubfoot. Extremely few of the patients reported any symptoms at all. Only after extensive questioning, the commonest complaint was the presence of calluses on the lateral border of the affected foot or feet. In unilateral cases, some patients had shortening of the affected leg, which on an average was 2.5 cm shorter than the contralateral leg. Nearly all the patients with the unilateral deformity had a smaller foot on the affected side (average difference 2.5 cm), but interestingly, the patients did not buy shoes of unequal size. Dr. Wynne-Davies also measured the extent of the equinus deformity, which was measured as the distance between the heel and the ground when the tibia was vertical. In 51 of 121 feet studied, there was greater than a 1.25-cm distance, but this was not described as a practical problem for the patient when the individual was wearing shoes. Overall, this long-term study indicated that there was very little residual morbidity associated with the clubfoot deformity (Wynne-Davies, 1964b).

GENETICS AND RECURRENCE RISK

The traditional teaching has been that clubfoot is inherited as a multifactorial trait (Yamamoto, 1979) or as polygenic inheritance with a threshold effect (Wynne-Davies, 1972). Evidence for the presence of a genetic background effect was demonstrated in one large-scale study of twins, in which the incidence of clubfoot was compared between monozygous and dizygous twins. In 4 of 134 (2.9%) dizygotic twins, there was concordance of the clubfoot deformity. This was greatly increased above the background incidence of 0.1% in the general population. In the monozygous twins, there was an even higher incidence of both twins being affected, 13 of 40 (32.5%) twins. Because of the increased incidence in monozygous as opposed to dizygous twins, genetic factors must have a cause in the inheritance of clubfoot; however, the trait cannot be solely genetic or the incidence in monozygous twins would have been closer to 100% (Wynne-Davies, 1972).

Using complex segregation analyses, Rebbeck et al. (1993) demonstrated that the probability of having idiopathic clubfoot was explained by Mendelian segregation of a single gene with two different alleles in the population, plus effects of other unmeasured factors shared by siblings (Rebbeck et al., 1993). This study suggests that a search for an underlying DNA abnormality in a single gene as the molecular basis of the disorder is warranted.

At present, the appropriate recurrence risk counseling for parents is as follows: If both parents are normal, and the initially affected fetus or child was male, the risk for a subsequent sibling to be affected is 2%. If both parents are normal and the original affected fetus or child was female, the risk for a subsequently affected sibling is higher, in the order of 5%. However, if one parent has a clubfoot deformity and one previous fetus or child has been affected with clubfoot, the risk for a subsequent sibling to be affected is 25% (Wynne-Davies, 1972). The appropriate prenatal diagnostic method for detection of clubfoot is antenatal sonographic examination.

Umbilical Cord Abnormalities

108 CHAPTER

Key Points

- A variety of umbilical cord abnormalities may be sonographically detected, including short cord, lack of coiling, and cystic and vascular malformations.
- Sonographic examination of the cord should include counting the number of vessels, Doppler studies, notation of coiling, and observation of the presence of cysts, masses, and vascular malformations.
- Umbilical cord diameter increases with age.
- The major consideration in the differential diagnosis is to determine if cord abnormality is isolated or associated with anomalies or aneuploidy.
- The umbilical cord grows by tension generated by fetal movement. Short cords are associated with trisomy 21 and neuromuscular abnormalities.
- Other findings associated with aneuploidy include lack of coiling, umbilical vein varix, aneurysms, and pseudocysts. Abnormal umbilical cord diameter measurements are not currently thought to be accurate markers of aneuploidy.

CONDITION

A variety of umbilical cord abnormalities may be detected by prenatal sonography. These conditions include a short cord, lack of coiling, umbilical cord ulceration, a knot in the umbilical cord, umbilical artery hypoplasia, supernumerary vessels, and a variety of cystic and vascular malformations (Table 108-1) (Persutte and Hobbins, 1995). The most common abnormality, single umbilical artery, is discussed in Chapter 109.

INCIDENCE

An absolutely short cord (≤35 cm at term) occurs in 0.78% of pregnancies (Skupski et al., 1992). A relatively short cord (≤54 cm at term) occurs in 16.8% of pregnancies (Skupski et al., 1992). Noncoiled umbilical vessels occur in 4.3% (38 of 394 pregnancies) (Strong et al., 1993). Umbilical cord ulceration is a rare abnormality. Four umbilical vessels have been noted in 0.4% (2 of 444 pregnancies) (Aokio et al., 1997). Umbilical artery hypoplasia occurs in 1.9% of pregnancies (6 of 310 high-risk patients) (Sepulveda et al., 1992). A knot occurs in the umbilical cord in 0.3% to 2.1% of pregnancies (Sepulveda et al., 1995). Vascular malformations are rare. Tumors of the umbilical cord are extremely rare.

SONOGRAPHIC FINDINGS

Sonographic examination of the umbilical cord includes documentation of the number of vessels, Doppler velocimetry studies, and observation of coiling and looping of the cord (Figure 108-1). The umbilical cord is routinely examined in three locations: at the insertion site in the anterior abdominal wall of the fetus, at some point along the cord to determine

the number of vessels, and at the segment floating within the cavity during assessment of amniotic fluid volume (Sepulveda et al., 1995). The umbilical cord diameter can be measured. Its diameter increases with gestational age (Ghezzi et al., 2002; Rembouskos et al., 2004). An increased umbilical cord diameter was originally thought to be a marker for aneuploidy (Ghezzi et al., 2002) but this finding was disproven in a later study (Rembouskos et al., 2004).

In extremely short umbilical cords, the cord appears to be stretched tautly across the uterine cavity (Skupski et al., 1992). Color Doppler has greatly enhanced the ability to visualize abnormalities in the umbilical cord (see Figure 108-1) (Jauniaux et al., 1989). Vascular abnormalities include umbilical artery aneurysm (Siddiqui et al., 1992), umbilical vein varix (Estroff and Benacerraf, 1992; Mahony et al., 1992;

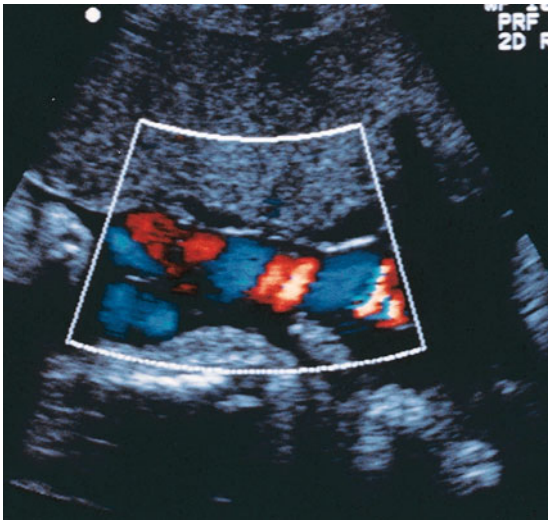

Figure 108-1 Color Doppler velocimetry studies showing the normal coiling of the umbilical cord.

Rahemtullah et al., 2001), and persistent right umbilical vein (Jeanty, 1989; Hill et al., 1994; Wolman et al., 2002). The distance between spirals (helixes) in the umbilical cord can be measured. Normally, this distance is 2 to 2.5 cm. If the distance decreases to less than 2 cm between helixes, acute torsion of the cord is possible (Collins et al., 1993). Umbilical cord knots are difficult to identify prospectively; as many as 72% of cases are missed on third trimester color Doppler studies (Sepulveda et al., 1995). Umbilical cord cysts are found in 3% of pregnancies in the first trimester; most resolve spontaneously (Weissman and Drugan 2001). When found in the second or third trimester, there is a high incidence of structural or chromosome abnormalities (Smith et al., 1996).

DIFFERENTIAL DIAGNOSIS

The major consideration in the differential diagnosis is to determine if the umbilical cord abnormality is a false-positive finding and if it is associated with other sonographically detectable abnormalities. Many umbilical cord abnormalities are descriptive. Sensitivity and specificity of diagnosis is improved by the concurrent use of Doppler studies. The differential diagnosis for umbilical cord tumors includes hemangioma and teratoma. The differential diagnosis for cystic masses includes true cysts, pseudocysts, allantoic cysts, and hematomas.

ANTENATAL NATURAL HISTORY

The umbilical cord grows by tension generated by fetal movement; Naeye (1985) has measured umbilical cord lengths of 35,779 singletons and determined that a length of at least 32 cm is necessary to prevent traction on the cord during a

vaginal delivery. The majority of umbilical cord growth occurs during the first and second trimesters. Walker and Pye (1960) demonstrated that the cord length of premature babies is similar to that of full-term babies. The mean length of a full-term newborn's umbilical cord is 60 cm. There is no correlation between umbilical cord length and parity, maternal age, maternal weight or height, presence of preeclampsia, or fetal gender, weight, length, or presenting part (Walker and Pye, 1960).

Short umbilical cords are significantly associated with low IQ values and neuromuscular abnormalities, such as the fetal akinesia deformation sequence or severe infantile spinal muscular atrophy (Naeye, 1985). In infants with trisomy 21, the average cord length is 45 cm; this is almost certainly due to in utero hypotonia, which causes decreased tension to be placed on the cord (Moessinger et al., 1982). Miller et al. (1981) studied infants with a variety of pathologic conditions. They found the most dramatically shortened cords in patients with early evidence of amnion rupture. Restriction of fetal movement was thought to be the effect of tethering by amniotic bands. The lesser degree of cord shortening seen in renal agenesis is presumably due to a later decrease in intrauterine space resulting from oligohydramnios.

Experiments on rat fetuses have confirmed that early oligohydramnios affects the cord length by limiting the intrauterine environment. Conversely, rat fetuses allowed to develop in the maternal abdomen have a cord length that is 147% greater than controls. In addition, rat fetuses with movements that are paralyzed by curare have cord lengths that are 85% of control values (Moessinger et al., 1986; Skupski et al., 1992).

Umbilical vascular coiling is established by the end of the first trimester. A sinistral (counterclockwise) rotation is present in most pregnancies (Fletcher 1993; Strong et al., 1993). The absence of the normal coiling of the umbilical cord has been identified as an antenatal risk factor for perinatal morbidity and mortality. This finding occurs in approximately 5% of fetuses (Weissman and Drugan, 2001). This so-called straight cord may be structurally weaker and more susceptible to external tension (Figure 108-2) (Strong et al., 1993). Lacro et al. (1987) noted a 10% stillbirth rate in newborns with absent umbilical coiling. In a prospective study, 38 fetuses with noncoiled umbilical vessels were identified. As compared with normal control fetuses, the noncoiled group had a significantly increased incidence of intrauterine death, preterm delivery, repetitive intrapartum fetal heart rate decelerations, operative delivery for fetal distress, meconium staining, and anatomical and karyotype abnormalities (Strong et al., 1993). Other investigators have calculated an umbilical coiling index by dividing the total number of coils observed by the length of the cord. Subjects with below the 10th percentile and above the 90th are defined as hypocoiled and hypercoiled, respectively. In one study of 635 placentas from deliveries of at least 24 weeks of gestation, Rana et al. (1995) found that subjects with hypocoiled cords had increased rates of fetal heart rate disturbances and interventional delivery. Fetuses with hypercoiled cords had a higher rate of premature delivery as compared with fetuses with normally coiled cords.

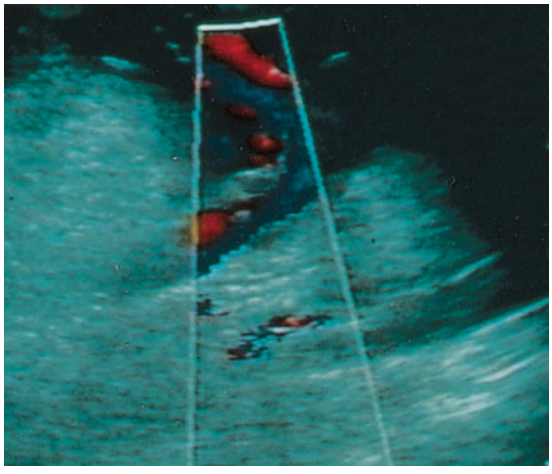

Figure 108-2 Color Doppler velocimetry studies demonstrating a straight umbilical cord. Note the lack of coiling as compared with Figure 108-1.

To our knowledge, prospective outcome studies related to a sonographic finding of umbilical cord ulceration have not yet been performed. The finding is described here because of the reported association of umbilical cord ulceration noted at birth with intestinal atresia in two infants and one stillborn fetus (Bendon et al., 1991). In two of three cases, severe in utero hemorrhage occurred from the ulcers. The intestinal atresia is the primary problem, with umbilical cord ulceration occurring as a secondary phenomenon. The following hypotheses have been proposed to account for this association: vascular reactivity, gastric reflux, and epithelial abnormalities (Bendon et al., 1991).

In one case report, an infant with four umbilical arteries and one vein was described (Beck and Naulty, 1985). The infant had multiple medical problems due to *Escherichia coli* sepsis, but ultimately survived with age-appropriate growth and development. There were no associated anomalies. The patient was shown to have triplication of the right umbilical artery.

Umbilical artery hypoplasia has been defined as a difference in the diameter between both umbilical arteries of $\geq$2 mm (Sepulveda et al., 1992). The umbilical arteries have discordant blood flow velocity waveforms in the absence of associated placental pathology. In one series, two of six affected fetuses with this finding had an adverse perinatal outcome (Dolkart et al., 1992). In another case report with pathologic follow-up of the umbilical cord after birth, no adverse effect was seen (Sepulveda et al., 1992).

Vascular malformations of the umbilical cord, such as umbilical vein varix and umbilical artery aneurysm, are rare. In one study, 25 cases of intra-abdominal umbilical vein varix were identified over a 10-year period (Rahemtullah et al., 2001). Follow-up information was available for 23 of 25 cases. Eleven of 23 cases (48%) had normal pregnancies, full-term deliveries, and normal neonatal outcome.

Three cases (13%) had preterm deliveries, and one had Kell isoimmunization. In the remaining 8 cases (35%) structural anomalies were identified. These authors recommended that a thorough fetal survey and echocardiogram be performed if an umbilical vein varix is observed. Umbilical artery aneurysm is potentially lethal in utero because of umbilical venous compression (Siddiqui et al., 1992). One case of umbilical cord aneurysm and arteriovenous fistula has been reported in association with a case of trisomy 18 (Berg et al., 2001). Cystic dilatation of the umbilical vein has been variously associated with both an increased incidence of in utero death (Mahony et al., 1992) and a normal outcome (Estroff and Benacerraf, 1992). Umbilical cord cysts develop from the remnants of the allantois or omphalomesenteric duct (Weissman and Drugan, 2001). They are usually located near the fetal insertion end of the cord and range from 4 to 60 mm in size. Pseudocysts have no epithelial lining and represent localized edema of Wharton's jelly (Kiran et al., 2003). Allantoic cysts originate from an extra-abdominal urachal system (Bunch et al., 2006).

MANAGEMENT OF PREGNANCY

When a short cord is diagnosed, detailed level II sonography is indicated to look for evidence of oligohydramnios, amniotic bands, body wall defects, neuromuscular abnormalities, and arthrogryposis. A short cord in the setting of abnormalities such as increased nuchal translucency measurement and a decreased ratio of femur to foot length may suggest trisomy 21. Fetuses with noncoiled umbilical cords may also be at increased risk for aneuploidy. In one study of 48 consecutive liveborn neonates with noncoiled umbilical vessels, four cases of trisomy (8.3%) and one case of mosaic trisomy (2.1%) were identified (Strong, 1995). However, all of these fetuses had additional anomalies detected with sonography. It is therefore unclear at present whether amniocentesis is indicated for an isolated noncoiled cord. Umbilical cord pseudocysts, if detected with other sonographic abnormalities, are strongly associated with aneuploidy and, in particular, trisomy 18 (Sepulveda et al., 1999). A good general principle is that cord abnormalities, when found with other malformations, are an indication for fetal karyotyping.

Fetuses with noncoiled umbilical cords are at increased risk for perinatal mortality; antepartum testing and early documentation of fetal lung maturity should be considered. Fetuses with evidence of bowel atresia should be monitored for sonographic findings consistent with umbilical cord ulceration and resulting hemorrhage.

Fetuses with vascular malformations such as umbilical artery aneurysm may need to be delivered as soon as lung maturity is present (Siddiqui et al., 1992). Fetuses with true knots of the umbilical cord ascertained prenatally may need to be delivered by cesarean section. In one report, a fetus with umbilical cord cysts underwent magnetic resonance imaging (MRI). The MRI suggested that the diagnosis was actually an allantoic cyst (Bunch et al., 2006).

FETAL INTERVENTION

There are no fetal interventions for umbilical cord abnormalities.

TREATMENT OF THE NEWBORN

For all of the conditions discussed here, a thorough physical examination of the newborn and the umbilical cord is indicated. Umbilical cord hemangioma is associated with a high (40%) incidence of vascular birthmarks, such as port wine stains (Daniel-Spiegel et al., 2005).

In the setting of the short cord, observation of newborn movements, with particular emphasis on the neurologic examination, is important. Tables of normal values exist for the measurement of periumbilical skin length in the newborn. These standards are useful in the neonatal diagnosis of syndromes that include umbilical dysmorphology (O'Marcaigh et al., 1992).

SURGICAL TREATMENT

There is no surgical treatment indicated for most umbilical cord abnormalities. Allantoic cyst is the prenatal presentation of patent urachus (Van der Bilt et al., 2003; Bunch et al., 2006). These umbilical cords are often grossly edematous from reflux of urine via the patent urachus. The cord is usually clamped well away from the edematous segment of cord. In the newborn period, the urachus can be surgically closed and cord remnants debrided away. Postnatally, the patent urachus needs to be resected.

LONG-TERM OUTCOME

The isolated umbilical cord findings do not need follow-up. Follow-up is indicated for associated abnormalities.

GENETICS AND RECURRENCE RISK

None of the conditions discussed, when present as an isolated finding, have implications for familial recurrence.

109 CHAPTER Single Umbilical Artery

Key Points

- Single umbilical artery (SUA) is one of the most common malformations found in humans.
- Color Doppler techniques have improved the ability to visualize vessels in the umbilical cord, particularly in a transverse view through the fetal bladder.
- Detailed sonographic evaluation of fetal anatomy is important to determine if SUA is isolated or associated with other anomalies.
- If isolated, fetal echocardiography should be considered, but karyotype is not indicated.
- If associated anomalies are present, fetal karyotype should be obtained, with trisomy 18 being the most commonly associated aneuploidy.
- SUA is associated with increased perinatal mortality, increased chance of IUGR, and slightly increased prematurity.
- If no additional anomalies are detected, postnatal urologic radiographic investigations are not indicated.
- For surviving infants, long-term prognosis is excellent.

CONDITION

The normal umbilical cord consists of three vessels—two arteries and one vein (Figure 109-1). Single umbilical artery (SUA) refers to the congenital absence of one of the arteries. The condition was originally described by Vesalius in 1543, Fallopio in 1561, and by Bauhin in 1621 (Persutte and Hobbins 1995). The first prenatal diagnosis of SUA was made in 1980 (Jassani et al., 1980). SUA is one of the most common malformations found in humans.

INCIDENCE

In prospective studies of liveborn infants, the incidence of SUA varied from 344 in 39,773 (0.9%) to 782 in 372,066 (0.48%) births in the United States National Collaborative Perinatal Project and a Swedish registry, respectively (Froehlich and Fujikura, 1973; Lilja, 1991). The incidence was twofold to threefold higher in a survey of spontaneous abortuses (Byrne and Blanc, 1985). In most studies, the gender distribution is equal. In the National Collaborative Perinatal Project, SUA was noted in 1.2% of white infants and 0.5% of black infants (Froehlich and Fujikura, 1973). SUA occurs three to four times more frequently among twins than among singletons (Heifetz, 1984). Other conditions associated with SUA include maternal diabetes, epilepsy, hypertension, antepartum hemorrhage, polyhydramnios, and oligohydramnios (Persutte and Hobbins, 1995). Maternal age does not affect the incidence of SUA (Prucka et al., 2004).

SONOGRAPHIC FINDINGS

The normal umbilical cord contains two arteries and one vein (see Figure 109-1). SUA is easiest to demonstrate in cross-sectional images (Figure 109-2) but may also be visualized longitudinally (Figure 109-3). The most reliable technique is to use color Doppler to visualize both umbilical arteries on either side of the dome of the fetal bladder. SUA can be diagnosed in the first trimester (Rembouskos et al., 2003). Fetuses with SUA have an increased diameter of the umbilical artery with no changes in diameter of the umbilical vein (Sepulveda et al., 1996b). There may, however, be a reduction in the amount of Wharton's jelly present (Raio et al., 1999). Color flow Doppler techniques have greatly enhanced the ability to both visualize the umbilical cord (Jauniaux et al., 1989; Catanzarite et al., 1995) and measure its flow velocity waveforms (Sepulveda et al., 1996a; Ulm et al., 1997). Fetal umbilical arteries should be examined near the bifurcation of

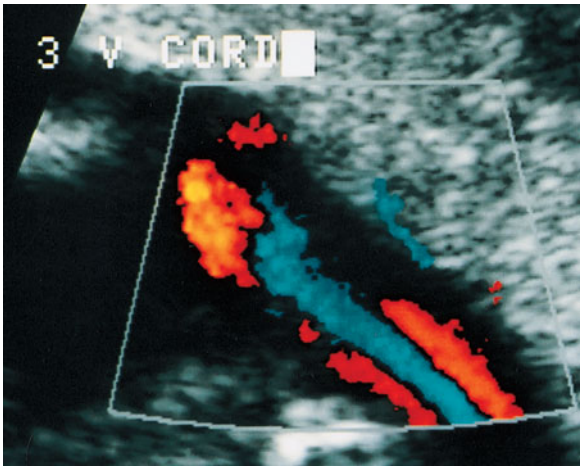

Figure 109-1 Color Doppler study demonstrating the presence of two umbilical arteries and one umbilical vein.

the aorta with color Doppler (see Figure 109-3). The intrafetal portion of the umbilical arteries may be easier to visualize than the free-floating cord. A SUA may have a diameter that approaches that of the umbilical vein. Diagnosis of SUA by sonography has a sensitivity of 64.9%, a specificity of 99.9%, and a positive predictive value of 64.9% (Jones et al., 1993).

Rembouskos et al. (2002) performed a prospective study in 717 consecutively examined singleton pregnancies undergoing chorionic villus sampling at 11 to 14 weeks to determine the incidence of SUA. Color flow mapping was used to visualize the umbilical arteries on either side of the bladder. The overall incidence of SUA was 5.9% (42/712), which is much higher than the liveborn incidence. In the 21 fetuses with SUA and normal chromosomes, 6 had major anomalies detected, including omphalocele, diaphragmatic hernia, megacystis, and scoliosis. In the 21 fetuses with SUA and an abnormal karyotype, 14 had trisomy 18, 5 had trisomy 21, and 2 had other abnormalities. In this study, the incidence of associated chromosome abnormalities in fetuses with SUA

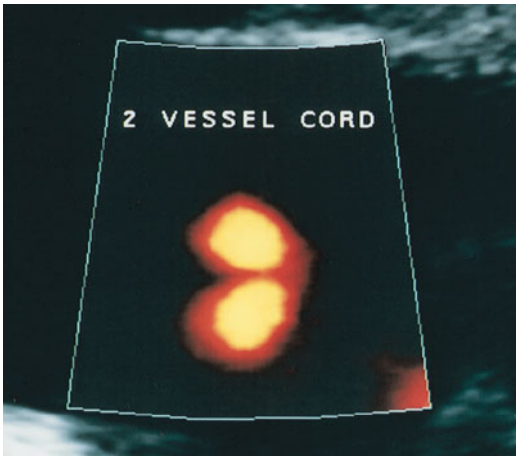

Figure 109-2 Cross-sectional view of the umbilical cord demonstrating the presence of two umbilical vessels.

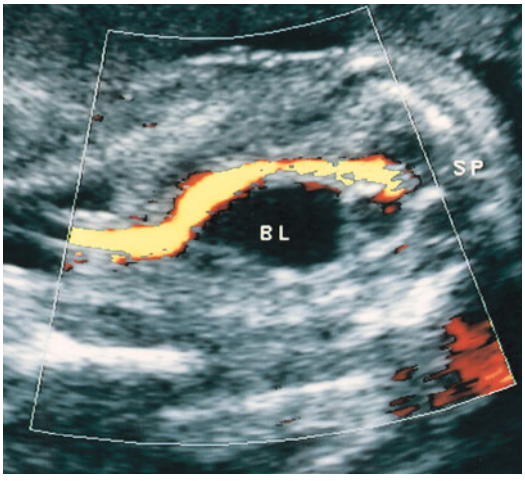

Figure 109-3 Longitudinal view of the umbilical arteries at the bifurcation of the aorta, demonstrating the presence of a single umbilical artery. BL, bladder.

was much higher (50%) than in studies performed in the second and third trimester.

DIFFERENTIAL DIAGNOSIS

Nonvisualized second umbilical artery should be ruled out. False-positive diagnoses are more likely to occur before 22 weeks of gestation.

ANTENATAL NATURAL HISTORY

The umbilical arteries develop from the allantois, a diverticulum of the yolk sac. Between 3 and 5 weeks of gestation, a transient common umbilical artery is normally present in all embryos, replacing a plexus of arteries around the allantois. Subsequently, the common umbilical artery becomes shorter, and right and left umbilical arteries advance within the body stalk (Monie, 1970). SUA can result from one of three mechanisms: primary agenesis of one of the definitive umbilical arteries, a secondary atrophy or atresia of a previously normal umbilical artery, or persistence of the common allantoic or umbilical artery. In several prospective studies of fetuses with antenatally diagnosed SUA, the left artery was absent 69% to 73% of the time. In addition, the presence of multiple anomalies and/or abnormal karyotype were seen more commonly with absence of the left artery (Abuhamad et al., 1995; Geipel et al., 2000). However, other studies do not demonstrate an association between the side of the single artery and presence of malformations (Blazer et al., 1997; Budorick et al., 2001). The risk of perinatal mortality increases when SUA is diagnosed. Much of this is due to the presence of associated congenital malformations. Independent of the presence of malformations, several studies have documented an increased chance of intrauterine growth restriction (with an

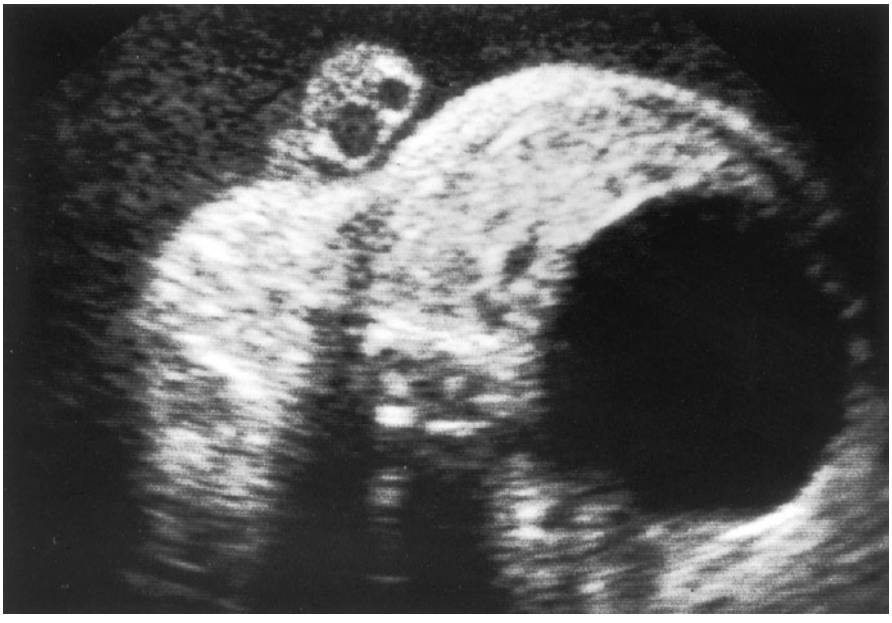

Figure 109-4 Cross-sectional view of an umbilical cord with two vessels, in association with a large simple ovarian cyst. *(Courtesy of Dr. Wolfgang Holzgreve.)*

average birth weight of less than 2.5 kg) and preterm delivery (with an average gestation of 35.9 weeks) for infants with SUA (Heifetz, 1984; Leung and Robson, 1989; Lilja, 1991; Jones et al., 1993; Gornall et al., 2003).

MANAGEMENT OF PREGNANCY

The key determinant of prognosis for a fetus with SUA is to detect the presence of associated anomalies (Table 109-1, Figure 109-4) (Csecsei et al., 1992). For this reason, detailed fetal sonographic evaluation is recommended for all cases of SUA. Some groups advocate fetal echocardiographic studies even for cases of apparently isolated SUA (Abuhamad et al., 1995; Persutte and Hobbins, 1995; Budorick et al., 2001). Other groups have not found abnormalities on echocardiography in fetuses with isolated SUA (Gossett et al., 2002). In newborns, the incidence of major malformations ranges from 17.5% to 44% (Leung and Robson, 1989). These malformations affect a wide variety of organ systems, including heart, brain, skeletal, gastrointestinal, and genitourinary systems (Table 109-1) (Froehlich and Fujikura, 1989). In fetuses with SUA, prospective studies indicate a 26% to 31% chance of associated structural anomalies (Abuhamad et al., 1995; Chow et al., 1998). The distribution of anomalies in fetuses differs from newborns in that genitourinary and cardiac anomalies are more common (Martínez-Payo et al., 2005) (Table 109-1). The documentation of associated anomalies puts the fetus at a significant risk for a chromosomal abnormality (Byrne and Blanc, 1985; Nyberg et al., 1991, 1988); prenatal karyotyping is recommended. Trisomies 13, 18, and 21 and Turner syndrome have all been reported in association with SUA (Saller et al., 1990), although trisomy 18 is the most common aneuploidy (Rembouskos et al., 2003). If the karyotype is normal but there are associated anomalies, consideration should be given to planned delivery in a tertiary care center capable of newborn resuscitation and sophisticated syndrome diagnosis. If the karyotype reveals a diagnosis incompatible with prolonged extrauterine survival, the infant can be delivered in a community hospital with pediatric consultation and

Table 109-1

Anomalies Associated with a Single Umbilical Artery

Fetuses*	**Newborn Malformations†**

an antenatal agreement not to perform heroic resuscitative efforts.

Many questions arise regarding the appropriate subsequent management of a fetus with an isolated SUA. On the basis of our experience and review of the literature, prenatal karyotype is not indicated once the detailed fetal anatomical survey reveals no other abnormalities (Nyberg et al., 1991; Budorick et al., 2001). Many groups now recommend that fetal echocardiography be performed as part of the evaluation of SUA. In addition, careful attention to fetal growth during the third trimester with serial ultrasound examinations is warranted. (Nyberg et al., 1991; Khong and George, 1992; Catanzarite et al., 1995).

FETAL INTERVENTION

There are no fetal interventions indicated for SUA.

TREATMENT OF THE NEWBORN

As discussed above, the newborn with associated malformations needs delivery, treatment, and diagnostic evaluation in a tertiary care center. The newborn with isolated SUA needs no immediate treatment other than a thorough physical examination.

A somewhat controversial area has been the need for a renal workup following the demonstration of SUA. This originated from a study by Feingold (1964), who performed intravenous pyelography on 24 children with isolated SUA at birth and found genitourinary tract abnormalities in one-third of cases. These findings were confirmed by an Irish study of 112 infants who were found to have isolated SUA at delivery. In this study, 19 infants were documented with abnormal postnatal renal sonography; 8 of 112 (7.1%) had significant persisting abnormalities, with vesicoureteric reflux found in five infants (Bourke et al., 1993). The morphologic abnormalities found in three patients included megaureter, pelvic kidney, and dilation of the collecting system. These anomalies, however, would be visible on a contemporary sonographic scan. Therefore, if a detailed fetal sonographic anatomic evaluation is normal, we do not advocate confirmatory postnatal renal screening in the absence of clinical symptoms.

A more recent meta-analysis of 37 postnatal studies on SUA published over a 40-year period confirms this approach (Thummala et al., 1998). The mean incidence of associated anomalies in liveborn infants with SUA was 27% (range 22%–32%). Additional urologic studies were performed on 204 infants with apparently isolated SUA. Of these, 33 (16.2%) had some form of renal anomaly, but more than half of these anomalies were minor or self-limiting. Thummala et al. concluded that current data do not justify extensive urologic radiographic investigations for asymptomatic newborns with isolated SUA.

SURGICAL TREATMENT

There is no surgical treatment for isolated SUA. If a genitourinary abnormality is detected, consultation with a pediatric urologist is warranted. Postnatal follow-up may include renal sonography and voiding cystourethrography.

LONG-TERM OUTCOME

For surviving infants, the prognosis is excellent. The National Collaborative Perinatal Project noted that growth-restricted infants caught up with their peers (Froehlich and Fujikura, 1973). Intelligence was in the normal range. The one surprising finding was the increased incidence of inguinal hernias in survivors.

GENETICS AND RECURRENCE RISK

Isolated SUA is thought to be a developmental anomaly, with no risk for familial recurrence. In the setting of associated anomalies, it is important to make an accurate diagnosis to permit proper genetic counseling.

Cervical Teratoma

110
CHAPTER

Key Points

- Cervical teratomas are often large, solid, and cystic lesions with calcifications.
- Polyhydramnios occurs from esophageal compression, predisposing to preterm delivery.
- Vascular malformations, including lymphangiomas and arteriovenous malformations, are the main differential diagnoses.
- The EXIT procedure is indicated to secure the airway.
- Delivery should occur in a tertiary center with expertise in the EXIT procedure.
- Cervical teratomas can arise in the thyroid. Postoperative hypothyroidism or hypoparathyroidism can occur.
- Close follow-up after resection is indicated, as residual or recurrent teratoma is at risk for malignant transformation.

CONDITION

Cervical teratoma is a rare tumor. Approximately 300 congenital cases have been described (Riedlinger et al., 2005; Oka et al., 2007). Since the first prenatal diagnosis of fetal cervical teratoma in 1978, there have been only a few dozen published reports of cervical masses detected in utero (Schoenfeld et al., 1978; Patel et al., 1982; Suita et al., 1982; Kagan, 1983; Thurkow et al., 1983; Trecet et al., 1984; Pearl et al., 1986; Cunningham et al., 1987; Hitchcock et al., 1987; Holinger and Birnholz, 1987; Roodhooft et al., 1987; Jordan and Gauderer, 1988; Kelly et al., 1990; Zerella and Finberg, 1990; Baumann and Nerlich, 1993; Liechty et al., 1997; O'Callaghan et al., 1997).

As in other teratomas, cervical teratomas are composed of tissues foreign to their normal anatomic sites. All three germ layers are represented within the tumor. Neural tissue is the most common histologic component, with cartilage and respiratory epithelium also observed (Schoenfeld et al., 1982). Thyroid tissue occurs in 30% to 40% but it is uncertain whether this represents actual involvement of the gland or ectopic thyroid tissue (Jordan and Gauderer, 1988). Theories regarding the origin of cervical teratoma include derivation from totipotential germ cells or abnormal development following cleavage of monozygous twins with fetus in feta (Ashley, 1973; Hitchcock et al., 1987).

INCIDENCE

Cervical teratomas are rare with an incidence ranging from 1 in 20,000 to 1 in 40,000 livebirths (Azizkhan et al., 1995). Cervical teratomas account for 3% to 6% of teratomas (Azizkhan et al., 1995, Jordan and Gauderer, 1988). There is no apparent relationship to maternal age or parity (Hitchcock et al., 1987). Unlike other teratomas, males and females are equally affected (Batsakis et al., 1964; Tapper and

Figure 110-1 Sagittal image demonstrating cervical teratoma. Note the solid and cystic areas.

Figure 110-2 3D image revealing a mass arising from the right side of the fetal face.

Lack, 1983) and there is no racial predilection (Suita et al., 1982).

SONOGRAPHIC FINDINGS

On ultrasound examination, cervical teratomas are typically asymmetric, unilateral, mobile, and well demarcated (Figures 110-1 to 110-3). Most are multiloculated, irregular masses with solid and cystic components (Figure 110-1). As many as 50% have calcifications present (Gundry et al., 1983; Kelly et al., 1990). Calcifications may be difficult to appreciate on ultrasound examination and are more easily seen on plain radiographs (Goodwin and Gay, 1965; Hajdu et al., 1966; Suita et a1., 1982). Calcifications, when present in a partially cystic and solid neck mass, are virtually diagnostic of cervical teratoma (Gundry et al., 1983).

Cervical teratomas are usually large and bulky, typically measuring 5 to 12 cm in diameter (Silberman and Mendelson, 1960; Batsakis et al., 1964; Liechty et al., 1997; Liechty and Crombleholme, 1999; Crombleholme and Albanese, 2001). Tumor masses greater than the size of the fetal head have also

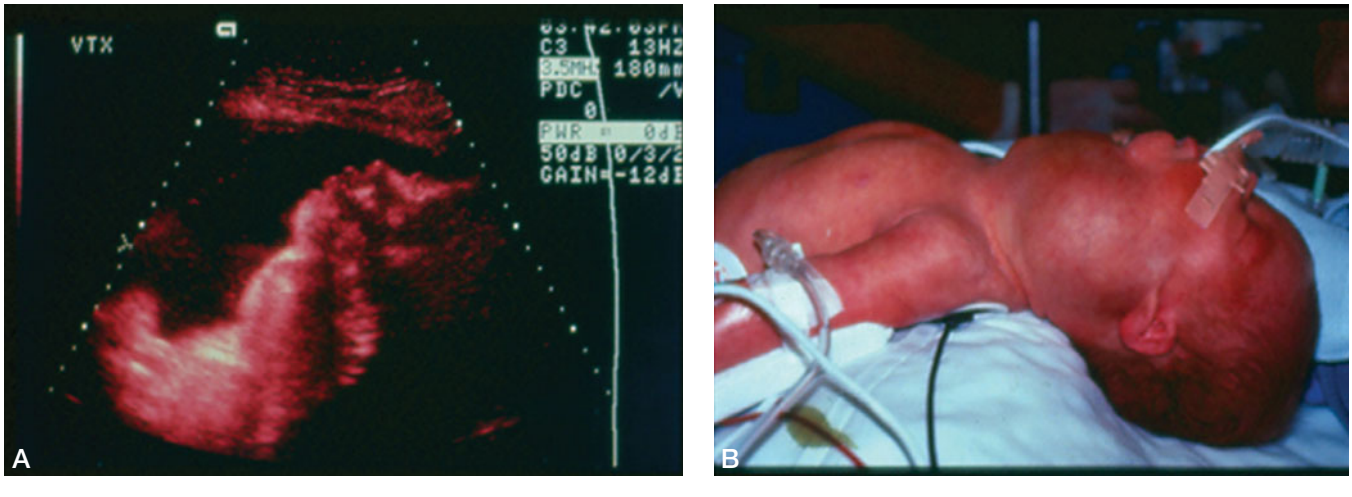

Figure 110-3 **A.** Prenatal sonographic image of a fetus in sagittal section demonstrating a complex cervical mass resulting in hyperextension of the neck due to a cervical teratoma. This has been referred to as the "flying fetus" sign, as the head extension is similar to that observed in ski jumpers when they fly off the ski jump. **B.** Postnatal appearance of the same patient.

Figure 110-4 Fetal magnetic resonance image (MRI) showing a giant cervical teratoma with a huge cystic component. The cervical teratoma was larger than the fetus. *(Reprinted, with permission, from Liechty KW, Crombleholme TM, Flake AW, et al. Intrapartum airway management for giant fetal neck masses: the EXIT procedure (ex-utero intrapartum treatment). Am J Obstet Gynecol. 1997;177:870-874.)*

been reported (Figure 110-4) (Batsakis et al., 1964; Owor and Master, 1974; Jordan and Gauderer, 1988). These tumors usually extend to the mastoid process and body of the mandible, superiorly displacing the ear. Inferiorly they can extend to the clavicle and suprasternal notch or extend into the mediastinum. Posteriorly, they can extend to the anterior border of the trapezius. Involvement of the oral floor, protrusion into the oral cavity (epignathus), and extension into the superior mediastinum have also been noted in cervical teratomas (Jordan and Gauderer, 1988).

Polyhydramnios will complicate 20% to 40% of the prenatally diagnosed cases and is more commonly observed in large tumors (Bale, 1949; Lloyd and Clatworthy, 1958; Hajdu et al., 1966; Trecet et al., 1984). Polyhydramnios is thought to be due to esophageal obstruction, as has been demonstrated by contrast amniography (Rosenfeld et al., 1979; Mochizuki et al., 1986). An empty stomach may be the first sonographic clue to esophageal obstruction from cervical teratoma (Rosenfeld et al., 1979; Suita et al., 1982). Other anomalies have been reported in association with cervical teratomas, including one case each of chondrodystrophia fetalis and imperforate anus (McGoon, 1952). Hypoplastic left ventricle and trisomy 13 have also been reported in association with cervical teratoma (Gundry et al., 1983; Dische and Gardner, 1987), as has agenesis of the corpus callosum (Goldstein and Drugan, 2005). Mandibular hypoplasia may also be seen as a direct result of mass effect on the developing mandible (Liechty et al., 1997).

The fetus with a large cervical teratoma often has a marked extension of the neck due to mass effect. The cervical teratomas are deeper than the strap muscles of the neck, thus causing severe compression of the larynx, trachea, and esophagus. As noted above, esophageal compression results in polyhydramnios, and compression of the larynx and trachea can result in not only deviation and distortion of the airway, but also marked laryngotracheomalacia. The hyperextension of the fetal neck may also result in profound pulmonary hypoplasia. The hyperextended neck pulls the fetal trachea cephalad, and in severe cases the carina can be found above the level of the thoracic inlet. This pulls the lungs into the cupola of the thoracic cavities, preventing normal lung growth. Several cases of death due to profound pulmonary hypoplasia have been reported despite successful EXIT (ex utero intrapartum treatment) procedures to secure the airway (Liechty and Crombleholme, 1999; Crombleholme and Albanese, 2001).

DIFFERENTIAL DIAGNOSIS

Cystic hygroma is the most likely entity to be mistaken for cervical teratoma in cases detected prenatally (see Chapter 32). The similarities in size, sonographic findings, clinical characteristics, location, and gestational age at presentation make this distinction difficult (Batsakis et al., 1964). Cystic hygromas are typically multiloculated cystic masses with poorly defined borders that infiltrate the normal structures of the neck. This contrasts with the usually well-defined borders of cervical teratomas. Furthermore, cystic hygromas tend to be smaller than cervical teratomas, are unilateral, and more frequently involve the posterior triangle (Pearl et al., 1986).

Many other entities may resemble a cervical teratoma on sonographic imaging (Table 110-1). Amniotic fluid α-fetoprotein (AFP) has been suggested as an aid in the differential diagnosis of a cervical mass. However, maternal and fetal AFP levels may be either elevated or normal in cervical teratomas. Because fewer than 30% of cervical teratomas have an elevated AFP (Schoenfeld et al., 1982; Trecet et al., 1984), this assay is not particularly helpful in the differential diagnosis of fetal cervical masses. An elevated serum AFP level in the newborn, however, may be helpful in following the patient for signs of teratoma recurrence after successful resection. The preoperative values may be difficult to interpret, as AFP levels are high in normal newborns

Vascular malformations are another important condition in the differential diagnosis. These lesions may be both cystic and solid, like cervical teratomas, but do not have

Table 110-1

Differential Diagnosis of Cervical Teratoma

Congenital goiter

Lymphangioma
Parotid tumor
Neural tube defects, such as occipital encephalocele or cervical myelomeningocele

calcifications. These lesions are often quite vascular and color flow Doppler images often reveal the extensive vascularity of these lesions. Flow through either cervical teratomas or vascular malformations can result in high-output failure, and echocardiographic assessment of combined ventricular output is indicated in all cases.

Fetal MRI has proven particularly useful in distinguishing the complex, septic, and solid teratoma from lymphangioma (see Figure 110-2) (Liechty et al., 1997; Hubbard et al., 1998). An MRI allows a larger field of view than an ultrasound and may show better tissue contrast (Figure 110-4). The T_1 and T_2-weighted imaging may allow fat to be identified within the lesion, which is more consistent with a diagnosis of cervical teratoma than cystic hygroma or vascular malformation (Hubbard et al., 1998).

ANTENATAL NATURAL HISTORY

The antenatal natural history of fetal cervical teratomas is not well defined. Although they are most often malignant in adults, the vast majority of cervical teratomas in fetuses and infants are benign (Mochizuki et al., 1986). However, rare cases of malignancies in this age group have been described with estimates of fewer than 10% of cases being malignant (Heys et al., 1967; Schoenfeld et al., 1982; Thurkow et al., 1983; Touran et al., 1989; Baumann and Nerlich, 1993; Azizkhan et al., 1995). The true malignant potential of a cervical teratoma is uncertain (Batsakis et al., 1964; Owor and Master, 1974; Watanatittan et al., 1981; Gundry et al., 1983; Pupovac, 1986; Cunningham et al., 1987). Despite the existence of primitive tissue types in the tumor and metastases to regional lymph nodes, many infants have remained free from recurrence following complete resection of a cervical teratoma. These cases suggest that malignant biologic behavior is uncommon in this population (Batsakis et al., 1964; Gundry et al., 1983; Dunn et al., 1992). Immature tissue seen on histologic examination may merely represent the immaturity of the host; thus, pathologic studies are not completely reliable in predicting the prognosis (Batsakis et al., 1964; Tapper and Lack, 1983). This is an unusual tumor that may have "benign" metastases to regional lymph nodes detected after resection of the cervical teratoma (Rothschild et al., 1994; Azizkhan et al., 1995; Oka et al., 2007).

A fetus with a cervical teratoma is at increased risk for intrauterine fetal demise and stillbirth. It has been estimated that as many as 17% die in utero and 35% die prior to surgery (Mochizuki et al., 1986; Berry, 1997; Berge et al., 2004). Because of esophageal compression, the majority of the fetuses with cervical teratoma will have polyhydramnios. The notable exceptions are small lesions and those that extend to one side without severe compression of the esophagus. The presence of a large cervical mass may result in compression of the cranial nerves. This results in loss of function, most notably the mandibular branch of the facial nerve with an attendant drop of the corner of the mouth, of the hypoglossal nerve with deviation of the tongue to the contralateral side with protrusion, and of the recurrent laryngeal nerve with paresis or paralysis of the ipsilateral vocal cord. The large cervical teratomas may compress or displace the mandible, causing hypoplasia or flaring out of the mandible from the face at odd angles, causing marked facial asymmetry.

In some cases, cervical teratomas may result in nonimmune hydrops due to the highly vascular nature of some of these lesions. In this rare circumstance, fetal demise would be anticipated without fetal surgical resection (Hirose et al., 2003).

MANAGEMENT OF PREGNANCY

Fetal cervical teratoma can profoundly affect the course of pregnancy. Repeated ultrasound examinations are indicated to monitor amniotic fluid volume, tumor size, and fetal well-being. In cases followed by serial sonography, rapid tumor growth has been noted (Hitchcock et al., 1987; Baumann and Nerlich, 1993). Stillbirth rates of 10% to 50% have been reported (Silberman and Mendelson, 1960; Hajdu et al., 1966; Hawkins and Park, 1972; Trecet et al., 1984; Roodhooft et al., 1987). There is a high incidence of preterm labor and preterm delivery, thought to be secondary to the increase in uterine size due to polyhydramnios and/or tumor. Because of the hyperextension of the neck, the so-called "flying fetus" sign (see Figure 110-1) and the often large tumor size, there is an increased incidence of malpresentation and dystocia (Owor and Master, 1974; Gonzalez-Crussi, 1982). Cesarean

section is often recommended because of the abnormal fetal position (Kagan et al., 1983; Chervenak et al., 1985; Rempen and Feige, 1985; Levine et al., 1990). Stabilization of the newborn's airway at delivery is facilitated by the assembly of a team qualified to obtain a bronchoscopic or surgical airway, if orotracheal intubation is unsuccessful (Zerella and Finberg, 1990). Currently, a fetus with cervical teratoma is best managed by the EXIT procedure, which provides time for laryngoscopy, bronchoscopy, tracheostomy, or tumor resection, if necessary, to secure the airway (Liechty et al., 1997; Crombleholme and Albanese, 2001; Marwan and Crombleholme, 2006).

Airway obstruction and respiratory compromise at birth can be life-threatening and accounts for up to 45% of the mortality seen with this abnormality. Consequently, delivery should occur at a tertiary care center with significant experience with the EXIT procedure. There have been anecdotal reports of intrapartum laryngoscopy or bronchoscopy in cases of fetal neck masses in which the fetus is delivered but the cord is not clamped (Kelly et al., 1990). Unfortunately, this procedure offers no advantage over standard cesarean section, as the removal of the fetus from the womb results in uterine contraction and cessation of the uteroplacental gas exchange (McNamara and Johnson, 1995; Liechty et al., 1997; Crombleholme and Albanese, 2001; Bouchard et al., 2002; Marwan and Crombleholme, 2006).

FETAL INTERVENTION

The ex utero partum treatment, or EXIT, procedure was specifically designed to provide time to secure an airway while preserving uteroplacental gas exchange (Figure 110-5). While Langer and Schwartz and their colleagues had each reported a case using this approach, the technique was not fully developed until it was applied in diaphragmatic hernia (Langer et al., 1992; Schwartz et al., 1993; Mychalishka et al., 1997). When tracheal clip application was applied in human fetuses with diaphragmatic hernia, it was necessary to develop a technique to allow time for neck dissection, clip removal, bronchoscopy, and intubation. Several individual case reports have described "operating on placental support" for fetal airway management, but none presented a systematic approach and correlated cord blood gases with time or placental support (Catalano et al., 1992; Langer et al., 1992; Schwartz et al., 1993; Tanaka et al., 1994; Skarsgard et al., 1996). Crombleholme et al., (1997) applied the lessons learned from use of the EXIT procedure in diaphragmatic hernia to the management of giant fetal neck masses in a small series of five patients, three with cervical teratomas and two with lymphangioma (Crombleholme et al., 1997; Liechty et al., 1997). The mean duration of the EXIT procedure was 28 minutes, with a range of 8 to 54 minutes. Direct laryngoscopy was performed in all five cases. Although orotracheal intubation was possible in two of the five, but one of the two intubations was possible only after drainage of 1800 ml of cyst fluid. In one case, massive involvement of the chest, neck, and face by the lymphangioma precluded orotracheal intubation and, in accordance with the family's wishes, a surgical airway was not attempted. In the remaining two patients, who had teratomas, there was severe distortion of the airway, rendering intubation by direct laryngoscopy impossible. In each of these cases bronchoscopy and tracheostomy were required to secure the airway. In both cases the mass effect of the tumor had pulled the thoracic trachea into the neck. In the first case this resulted in a tracheostomy 1.5 cm above the carina, and in the second case the tracheostomy was performed between the 8th and 10th tracheal rings, as this was the only available site because of mass effect of the tumor (Figure 110-6). This infant subsequently underwent resection of the mass closure of this distal tracheostomy and creation of a new tracheostomy between the 2nd and 3rd tracheal rings.

Figure 110-5 EXIT procedure being performed on a fetus with a cervical teratoma. Only the head and the upper chest are removed from the uterus to maintain uterine volume. A pulse oximetry probe is on the right hand and a bronchoscope is inserted into the airway of the fetus.

Unlike a conventional cesarean section, the EXIT procedure maintains uteroplacental blood flow and fetal gas exchange by keeping the uterus relaxed with the use of inhalational agents and the maintenance of uterine volume, by only partially exposing the fetus (Bouchard et al., 2002; Marwan and Crombleholme, 2006). This is apparent in the relatively normal venous cord blood gases seen after up to 54 minutes of uteroplacental support (Liechty et al., 1997). By preserving uteroplacental blood flow, the EXIT procedure allows for adequate time to perform multiple procedures such as direct laryngoscopy, bronchoscopy, tracheostomy, surfactant administration, and cyst decompression, some or all of which may be required to secure the airway (Figures 110-5 and 110-6).

There are a number of potential risks to the mother who undergoes an EXIT procedure. Because inhalational agents keep the uterus very relaxed, there is a risk of increased hemorrhage because of uterine atony. The risk of uterine atony and hemorrhage can be minimized through coordination between the surgeon and the anesthesiologist to decrease the concentration of inhalational anesthetic and administer oxytocin at the time of umbilical cord ligation. The use of the uterine stapling device and coordination with the anesthesiologist keeps the average intraoperative blood loss at 950 ml,

Figure 110-6 The same patient in Figure 110-5 during the EXIT procedure. The cervical teratoma had so distorted the airway that an endotracheal tube had to be tunneled through the soft tissue of the neck and entered the trachea between the 8th and 10th tracheal rings.

well within the accepted range for traditional cesarean section (Hood and Holubec, 1990).

Lower uterine segment hysterotomy is preferred for the EXIT procedure, as it allows the possibility of future vaginal delivery. However, a low anterior placenta or extremely large neck mass may make lower uterine segment section impossible. In such cases, a classical hysterotomy is necessary. This approach necessitates cesarean delivery for all future deliveries because of the risk of uterine rupture during labor. Prior to an EXIT procedure, mothers should be counseled about the possibility that future pregnancies would require cesarean delivery. In rare cases, hydrops resulting from a cervical teratoma in a fetus less than 30 weeks' gestation may necessitate open fetal surgery to resect the teratoma. To date this has been performed successfully in only one case (Hirose et al., 2003).

TREATMENT OF THE NEWBORN

Airway obstruction at birth is life-threatening and associated with a high mortality rate (Azizkhan et al., 1995). In giant fetal neck masses, this mortality is usually associated with a delay in obtaining an airway and an inability to ventilate the infant effectively. This delay can result in hypoxia and acidosis and, if the delay is greater than 5 minutes, anoxic injury may occur (Dawes, 1968). This complication is all the more tragic as most of these children have an isolated benign tumor and do well after postnatal resection.

Mortality can be as high as 80% to 100% in untreated infants, regardless of the tumor size (Silberman and Mendelson, 1960; Batsakis et al., 1964; Goodwin and Gay, 1965; Hurlbut et al., 1967; Gundry et al., 1983; Garmel and Crombleholme, 1985). Delaying surgery can result in retention of secretions, atelectasis, and/or pneumonia due to interference with swallowing (Batsakis et al., 1964; Gonzalez-Crussi, 1982). In addition, precipitous airway obstruction may occur due to hemorrhage into the tumor (Silberman and Mendelson, 1960; Batsakis et al., 1964; Hurlbut et al., 1967; Gundry et al., 1983) even in minimally symptomatic newborns. For this reason, orotracheal intubation is indicated in all patients regardless of the presence or absence of symptoms. Mortality decreases to between 9% and 17% in infants treated surgically (Silberman and Mendelson, 1960; Batsakis et al., 1964; Goodwin and Gay, 1965; Hajdu et al., 1966; Hurlbut et al., 1967; Gundry et al., 1983).

SURGICAL TREATMENT

These tumors tend to be large, disfiguring masses that displace or envelop vital structures in the neck. Extensive neck dissection and multiple procedures are often necessary to achieve the goals of complete extirpation of the tumor with acceptable functional and cosmetic results.

In a review of 18 cases of cervical and orofacial teratomas, Azizkhan and colleagues reported that life-threatening airway obstruction occurred in 7 infants (39%), 2 of whom died without ever having a secure airway (Azizkhan et al., 1995). Two neonates with prenatally diagnosed tumors, survived because tracheostomies were performed in the delivery room by an attending pediatric surgeon. Survival was observed in 15 of the 18 cases (83%). One neonate required multiple surgeries to achieve complete tumor removal. Morbidity included two cases with recurrent laryngeal nerve injury, two with hypothyroidism, and two with developmental delay and mental retardation secondary to airway obstruction and asphyxia at birth.

LONG-TERM OUTCOME

Infants with cervical teratoma are at risk for transient or permanent hypoparathyroidism and hypothyroidism. Cervical teratoma may completely replace the thyroid gland and tumor resection may result in permanent hypothyroidism. More commonly, thyroid tissue may be preserved but may not be adequately functioning and an interval of thyroxine supplementation may be necessary. Because of the massive nature

of these tumors and the difficulty in identifying parathyroid glands, transient or even permanent hypoparathyroidism may be observed. Calcium and vitamin D supplementation may be needed postoperatively. A pediatric endocrinologist should be consulted if these complications are encountered. In approximately one-third of the cases, cervical teratomas produce markedly elevated levels of AFP. However, an elevated AFP level obtained immediately postoperatively must be interpreted with caution. AFP levels in normal newborns have an enormous range, with some as high as 20,000 units during the first month of life. The AFP values progressively fall during infancy until levels of less than 10 units are obtained at the age of one. While an elevated AFP level may not necessarily be abnormal, the levels should progressively decrease during infancy. A rising AFP should alert the clinician to the possibility of teratoma recurrence. While cervical teratoma is generally a benign tumor, there is the possibility of malignant transformation, and close surveillance for tumor recurrence is essential. We recommend following AFP levels at 3-month intervals in infancy and yearly thereafter, with CT or MRI scanning twice a year for the first three years of life.

GENETICS AND RECURRENCE RISK

There has been one report of congenital cervical teratoma occurring in siblings, but no other familial cases have been described (Hurlbut et al., 1967).

111 Liver Tumors

CHAPTER

Key Points

- Liver tumors account for only 5% of fetal and neonatal tumors.
- The most common tumor is hemangioma followed by mesenchymal hamartoma and hepatoblastoma.
- Hemangiomas can be hypoechoic, hyperechoic, or undetectable and can result in high-output failure polyhydramnios and hydrops.
- Mesenchymal hamartomas tend to be cystic lesions.
- Hepatoblastomas are typically solid and echogenic and occasionally have calcifications.
- Hepatoblastoma can be associated with Beckwith–Wiedemann syndrome, familial adenomatous polyposis coli, and rarely, trisomy 18.

Key Points (cont.)

- Alpha-fetoprotein levels may be markedly elevated in mesenchymal hamartoma and neuroblastoma.
- In utero cyst decompression, rare mesenchymal hamartomas with extremely large cysts may be considered.
- Transplacental steroids may be helpful in large hemangiomas associated with high-output cardiac failure or hydrops.
- There is increased risk of intrauterine demise and stillbirth in primary hepatic tumors.
- Neonatal management of primary hepatic tumor is complicated and should be performed at centers with appropriate expertise.

CONDITION

Tumors of the liver are rare during the perinatal period. They account for only 5% of all neoplasms that occur in the fetus and the newborn (Campbell et al., 1987; Borch et al., 1992; Broadbent, 1992; Werbe et al., 1992; Isaacs, 1997). The most common primary hepatic tumor is hemangioma, followed by mesenchymal hamartoma and hepatoblastoma (Stocker and Ishak, 1983; Isaacs, 1985; Davis et al., 1988; Davenport et al., 1995; von Schweinitz, 2003; Laberge et al., 2005; Christison-Lagay et al., 2007; Isaacs, 2007). Each has been detected prenatally by ultrasound examination and can be detected postnatally by palpation of an abdominal mass (Romero et al., 1988; Garmel et al., 1994; Isaacs, 1997; Isaacs, 2007). However, metastatic lesions are more common than primary liver tumors (Dehner, 1978; Coffin and Dehner, 1992). The most common tumor that metastasizes to the liver in the fetus and newborn is neuroblastoma, followed by leukemia, yolk sac tumor from sacrococcygeal teratoma, and rhabdoid tumor of the kidney (Dehner, 1978; Isaacs, 1985, Isaacs, 1997). The majority of hepatic hemangiomas are diagnosed before the age of 6 months and almost 50% appear within the first week of life (Dehner et al., 1975; Laird et al., 1976; Stanley et al., 1977, Dehner, 1978, Dehner, 1981, Ehren et al., 1983; Miller and Greenspan, 1985a and Miller and Greenspan, 1985b; Golitz et al., 1986; Dehner, 1987; Davis et al., 1988; Luks et al., 1991; Drut et al., 1992; Werbe et al., 1992). There have been multiple reports in the literature of hepatic hemangiomas diagnosed by prenatal sonographic examination (Nakamoto et al., 1983; Platt et al., 1983; Horgan et al., 1984; Petrovic et al., 1992; Sepulveda et al., 1993; Chou et al., 2005; Isaacs, 2007). In the report by Isaacs, reviewing reported cases in the literature and experience at Children's Hospital San Diego and Children's Hospital Los Angeles, he found that of the 194 fetal and neonatal tumors, 29% presented antenatally (Isaacs, 2007). The most common of these were hepatic hemangiomas, accounting for 117 of the 194 tumors, with 28% presenting antenatally. The most common antenatal presentation was the sonographic detection of a hepatic mass followed by anemia, hydrops, polyhydramnios, heart failure, thrombocytopenia, and disseminated intravascular coagulation (Isaacs, 2007). It is likely that more hemangiomas occur in the liver than are actually recognized, because many are asymptomatic or silent conditions that regress or are discovered as only an incidental finding on clinical imaging or postmortem examination (Dehner, 1978). Some hemangiomas, in contrast, present with hepatomegaly or a mass lesion and high-output cardiac failure, while others may be life-threatening during the perinatal period because of rupture of the hemangioma and hemoperitoneum during delivery (Dehner, 1981; Larcher et al., 1981; Miller and Greenspan, 1985a and Miller and Greenspan, 1985b; Weinberg and Finegold, 1986; Dehner, 1987; Romero et al., 1988; Stanley et al., 1989; Berry, 1993; Davenport et al., 1995). Hemangiomas have been associated with consumptive coagulopathy resulting from disseminated intravascular coagulation (DIC), sequestration of platelets causing a bleeding diathesis (Kasabach–Merritt syndrome), and anemia (Dehner, 1987; Slopeck and Lakatau, 1989; Isaacs, 1991; Berry, 1993; Isaacs, 2007). High-output cardiac failure leading to in utero demise as a result of hepatic hemangioma has been described by (Nakamoto et al. (1983); Isaacs, 2007). In a report from Stanley et al. (1989) a palpable abdominal mass and cardiac failure were the most frequent presenting findings in 20 infants diagnosed with hepatic hemangiomas. Hepatic hemangiomas can be focal or multifocal. Most focal hemangiomas occur in the right lobe of the liver (Isaacs, 2007). Associated extrahepatic hemangiomas most often occur in skin, brain, placenta, lungs, and eyes. In about 50% of newborns, hepatic hemangiomas are associated with hemangiomas of the skin and other organs (Dehner, 1978; Shturman-Ellstein et al., 1978; Larcher et al., 1981; Isaacs, 1985; Golitz et al., 1986; Dehner, 1987; Stanley et al., 1989; Berry, 1993; Leonidas et al., 1993; Davenport et al., 1995; Isaacs, 2007). The fatal combination of cutaneous and hepatic hemangiomas, hydrops fetalis, hydramnios, and premature delivery has been reported by Shturman-Ellstein et al. (1978). This case was also notable for associated placental edema and chorioangioma, with a terminal clinical course complicated by thrombocytopenia and DIC in the Kasabach–Merritt syndrome that was further compromised by respiratory distress syndrome (Shturman-Ellstein et al., 1978).

Congenital malformations may also be observed in association with hepatic hemangiomas. Werbe et al. (1992) described two such cases in stillborn infants. One infant had a 4-cm hemangioma and an encephalocele, while the other had two liver lesions in addition to encephalomyelitis, partial

gut malrotation, and single umbilical artery. In another report, congenital heart disease and prune belly syndrome, respectively, occurred with hepatic hemangiomas in two other neonates (Ehren et al., 1983). Shah et al. (1987) reported a 6-hour-old full-term female infant who died during surgery for repair of a left congenital diaphragmatic hernia and was found to have hemangioma rising from the lobe of the liver in the left thorax. Hepatic hemangiomas have also been described in association with the Beckwith–Wiedemann syndrome, placental chorioangioma, and dysmorphic kidneys (Drut et al., 1992). In the review by Isaacs, capillary and cavernous hemangioma was the most common histology, accounting for 39% of cases, followed by type I hemangioendothelioma (31%), infantile hemangiomas (24%), and angiosarcoma (7%) (Isaacs, 2007).

The second most common benign hepatic tumor that occurs during the perinatal period is mesenchymal hamartoma (Dehner, 1978; Dehner, 1981, Isaacs, 1983; Stocker and Ishak, 1983; Weinberg and Finegold, 1986; Davis et al., 1988; De Maioribus et al., 1990; Isaacs, 1991; Isaacs, 2007;). Over 33% of cases of mesenchymal hamartomas are diagnosed in infants and about 25% are in newborns. In the review by Isaacs, 23% of hepatic tumors were mesenchymal hamartomas (Isaacs, 2007). In a report by Keeling (1971), five of seven patients with this condition were of the age of 2 months or younger. The lesion was an incidental postmortem finding in three newborns, including one stillborn infant.

The pathogenesis of mesenchymal hamartoma is incompletely understood and, as the name *hamartoma* implies, it is of a developmental rather than a neoplastic origin (Dehner, 1978, Weinberg and Finegold, 1986). Lennington et al. (1993) have suggested that mesenchymal hamartomas result from anomalous blood supply to a liver lobule, leading to ischemia and subsequent cystic change and fibrosis. Consistent with this premise is the observation that some hamartomas have necrotic centers and are attached to the liver by a pedicle (Lennington et al., 1993). In addition, neither recurrence following complete resection nor malignant transformation has been reported in mesenchymal hamartomas (Dehner, 1978; Isaacs, 1983; Stocker and Ishak, 1983; Stanley et al., 1989). Mesenchymal hamartomas can readily be detected by prenatal sonographic examination (Foucar et al., 1983; Hirata et al., 1990; Wienk et al., 1990; Mason et al., 1992; Garmel et al., 1994; Isaacs, 2007). Most mesenchymal hamartomas are multicystic (70%), with the remainder being either solid or a combination of solid and cystic (Isaacs, 2007). In general, mesenchymal hamartomas are not associated with other congenital malformations (Weinberg and Finegold, 1986), but occasional exceptions have been noted, including Keeling's (1971), report of excessive oral mucus secretions and an abdominal mass. This infant was found to have a tracheoesophageal fistula with an annular pancreas in addition to the hamartoma. Stocker et al., reported that 5 of their 30 patients with mesenchymal hamartoma had various anomalies and associated conditions (Stocker and Ishak, 1983). Most mesenchymal hamartomas occur in the right lobe of the liver (90%) but up to 10% can be bilateral (Dehner, 1978; Weinberg and Finegold, 1986; Dehner, 1987; Isaacs, 2007). Hepatoblastoma is the leading primary hepatic malignant tumor occurring during the first year of life (Isaacs , 1997; Isaacs, 2007). Over half of all hepatoblastomas are diagnosed in infants, but less than 10% are found in newborns (Keeling, 1971; Exelby et al., 1974; Gonzalez-Crussi et al., 1982; Weinberg and Finegold, 1983; Weinberg and Finegold, 1986; Campbell et al., 1987; Isaacs, 1991). Among the 32 cases of fetal and neonatal hepatoblastomas reported by Isaacs, 9 were diagnosed prenatally (Isaacs, 2007).

Typically, hepatoblastoma presents as an upper abdominal mass arising from a single area, more often from the right lobe of the liver than the left (Figure 111-1). Hepatoblastoma

Figure 111-1 Intraoperative view of a newborn with congenital hepatoblastoma arising from the right lobe of the liver.

can be detected by antenatal sonography (van de Bor et al., 1985; Orozco-Florian et al., 1991; Garmel et al., 1994; Isaacs, 2007). In one prenatally detected case, a hepatoblastoma was responsible for compression of the inferior vena cava, leading to fetal hydrops and intrauterine death at 36 weeks of gestation (Benjamin et al., 1981). Kazzi et al. (1989) described a similar case in a newborn with hepatoblastoma that was diagnosed antenatally. Hydrops fetalis, consumptive coagulopathy associated with massive hemorrhage into the tumor, and anemia were present at birth in this fetus. Orozco-Florian et al. (1991) reported a fetus with hepatoblastoma detected antenatally that had associated nephromegaly and pancreatic nesidioblastosis consistent with the diagnosis of Beckwith–Wiedemann syndrome; however, the affected neonate did not have either macroglossia or omphalocele. In addition to neuroblastoma and leukemia, hepatoblastoma is one of the rare perinatal malignancies that can metastasize to the placenta and cause fetal death (Bond, 1976; Robinson and Bolande, 1985; Dinmick, 1991). A broad range of congenital anomalies and malformation syndromes have been reported to occur in association with hepatoblastoma. Hemihypertrophy can occur in as many as 2% to 3% of affected patients. Beckwith–Wiedemann syndrome and familial intestinal adenomatous polyposis (FAP) are the most common associated syndromes (Geiser et al., 1970; Landing, 1976; Fraumeni et al., 1978; Dehner, 1981; Weinberg and Finegold, 1986; Li et al., 1987; Kazzi et al., 1989; Hartley et al., 1990; Giardiello et al., 1991; Orozco-Florian et al., 1991; Greenberg and Filler, 1993; Rubie et al., 1993). Hepatoblastoma, in addition, has been described in siblings in a variety of clinical settings, including in fetal alcohol syndrome, in association with the maternal use of contraceptives, in trisomy 18, in patients with Wilms tumor, and in newborns with adenomatoid malformation of the renal epithelium (Landing, 1976; Khan et al., 1979; Knowlson and Cameron, 1979; Mamlok et al., 1989; Riikonen et al., 1985; Greenberg and Filler, 1993). Aicardi syndrome (infantile spasms, agenesis of the corpus callosum, and multiple ocular malformations) has been described in a 2-month-old female infant with hepatoblastoma (Tanaka et al., 1985).

No clearly defined factors have been implicated in the development of these tumors and the causes of these entities are unknown. Because of the rarity of these lesions, much remains to be learned about the prenatal sonographic findings, natural history, and optimal pregnancy management for these unusual cases.

INCIDENCE

Tumors of the liver presenting during the perinatal period are rare. Primary hepatic neoplasms account for only 0.5% to 2% of pediatric tumors (Alagille and Odievre, 1979). They comprise 5% of total neoplasms occurring in the fetus and neonate (Dehner, 1978; Wu et al., 1981; Lack et al., 1982; Stocker and Ishak, 1983; Weinberg and Finegold, 1986; DeMaioribus et al., 1990; Samuel and Spitz, 1995; von Schweinitz, 2003; Sallam et al., 2005). Hemangiomas are relatively common, occurring in as many as 1 in 100 newborns and in 1 in 5 premature infants with a birth weight less than 1000 grams (Folkman, 1984; Enjorlas et al., 1990). The specific incidence of hepatic hemangioma is not known. The annual incidence of hepatoblastoma in the United States is estimated to be 0.9 in 1 million children, with a 2:1 male predominance (Young and Jr Miller, 1975; Fraumeni et al., 1978). However Isaacs found a 1.6:1 female ratio in fetal and neonatal hepatoblastomas (Isaacs, 2007). The incidence of mesenchymal hamartoma is uncertain, but there appears to be a male predominance. The prenatal incidence of each of these hepatic tumors is unknown.

SONOGRAPHIC FINDINGS

There have been multiple reported cases of hepatic hemangiomas diagnosed prenatally by ultrasound examination (Nakamoto et al., 1983; Platt et al., 1983; Horgan et al., 1984; Petrovic et al., 1992; Sepulveda et al., 1993; von Schweinitz, 2003; Christison-Lagay et al., 2007). These lesions can be single or multiple and can appear hypoechogenic, hyperechogenic, or mixed in appearance depending on the degree of fibrosis and the stage of evolution (Nakamoto et al., 1983; Horgan et al., 1984; Gonen et al., 1989). The reported sizes of hemangiomas have ranged from 1.1 × 0.9 cm to 7.8 × 6.4 cm (Petrovic et al., 1992; Sepulveda et al., 1993). Hepatomegaly may also be seen. Polyhydramnios has been noted occasionally, which is thought to be due to either a hyperdynamic state induced by this vascular tumor or gastrointestinal tract compression secondary to mass effect (Nakamoto et al., 1983; Petrovic et al., 1992). In addition, fetal hydrops has been reported in one case by Shturman-Ellstein et al. (1978).

Mesenchymal hamartomas have also been described prenatally (Foucar et al., 1983; Stocker and Ishak, 1983; Hirata et al., 1990; Mason et al., 1992; Laberge et al., 2005). Hamartomas typically appear as an irregular cyst on ultrasound examination (Nyberg et al., 1990). Both oligohydramnios and polyhydramnios have been reported in association with mesenchymal hamartomas (Mason et al., 1992).

Hepatoblastoma develops in fetal life and is the most common primary liver malignancy in infancy and childhood, yet only rarely are cases detected prenatally (van de Bor et al., 1985; Garmel et al., 1994; Isaacs, 1997; Shih et al., 2000; von Schweinitz, 2003; Aviram et al., 2005; Catanzarite et al., 2008). Neonatal hepatoblastomas are typically solid and echogenic and calcifications may be present. Two-thirds involve only one lobe (Exelby et al., 1974). Associated anomalies have been reported in the neonate, including hemihypertrophy, Down syndrome, cardiovascular defects, and genitourinary anomalies (Gonzalez-Crussi et al., 1982). Whether most of these are chance associations is not clear. In van de Bor et al.'s (1985) case report of hepatoblastoma, polyhydramnios was

noted in association with hepatomegaly; this was because of a gastrointestinal obstruction.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of fetal hepatomegaly also usually involves splenomegaly and includes hydrops, fetal infection, anemia, metabolic abnormalities (e.g., hypothyroidism) and genetic syndromes such as Beckwith–Wiedemann and Zellweger (Schutgens et al., 1985; Nyberg et al., 1990). The differential diagnosis of prenatally diagnosed hepatic masses should include isolated nonparasitic cysts (Chung, 1986), cysts associated with polycystic kidney disease, and metastatic neuroblastoma. Gonen et al. (1989) prenatally confirmed the vascular nature of hemangioma with pulsed Doppler studies showing drainage into an enlarged hepatic vein. This technique may prove useful in a differential diagnosis of prenatally detected hepatic lesions. In addition to hemangioma, hepatoblastoma, and mesenchymal hamartomas, one should also consider the possibility of hepatic adenoma. There has been one reported case of prenatally diagnosed hepatic adenoma. Marks et al. (1990) noted a 4-cm × 4-cm hypoechoic liver mass with no associated anomalies. An autopsy confirmed the diagnosis of hepatic adenoma. Hepatic hemangioendothelioma has also been diagnosed prenatally as a cystic and solid lesion with Doppler imaging, confirming the vascular nature of the tumor (Gonen et al., 1989). While this fetus progressed to nonimmune hydrops, another case was noted to spontaneously regress (Horgan et al., 1984).

Alpha-fetoprotein (AFP) levels are markedly elevated in neonatal cases of hepatoblastoma and mesenchymal hamartoma (Exelby et al., 1974; Ito et al., 1984; Pollice et al., 1992). AFP levels can be difficult to interpret in the newborn, as this value is normally quite high. This has not yet been reported with prenatal lesions, and the usefulness of maternal serum AFP levels in the diagnosis and management of prenatally detected hepatic tumors is unknown.

ANTENATAL NATURAL HISTORY

Because of the rarity of these lesions, little is known about the antenatal natural history of hepatic tumors. Hemangiomas are histologically benign. Postnatally, the natural history tends toward spontaneous regression after infancy. However, there is great variability in severity and complications (Larcher et al., 1981). Occasionally, hemangiomas are associated with arteriovenous shunting and subsequent congestive heart failure. Heart failure and hydrops, with resultant intrauterine neonatal death, has been reported (Berdon and Baker, 1969; Nakamoto et al., 1983; Gonen et al., 1989). These cases may represent the prenatal correlate of infants with hemangiomas and arteriovenous shunting, resulting in congestive heart failure. Others have reported either no change or spontaneous resolution (Platt et al., 1983; Horgan et al., 1984; Sepulveda et al., 1993). Once the diagnosis of hemangioma is confirmed postnatally, by computed tomographic (CT) or magnetic resonance imaging (MRI) scans, the asymptomatic neonate can be treated conservatively with counseling to alert the family of potential complications (Platt et al., 1983; Horgan et al., 1984). In the absence of complications, such as heart failure, the prognosis is good (Slovis et al., 1975).

The report by van de Bor et al. (1985) of prenatally detected hepatomegaly, later found to be hepatoblastoma, described neonatal death from liver rupture. Benjamin et al. (1981) reported hepatoblastoma as a cause of intrauterine fetal death. Similarly, Robinson and Bolande (1985) reported a stillborn infant with metastases to the lungs, placenta, and cord from hepatoblastoma. Experience with infants and children is slightly more encouraging. In patients in whom complete resection is possible, the long-term survival rate is 60% (Exelby et al., 1974). However, local extension and recurrence occurs in more than 40% of patients with hepatoblastoma. Hepatoblastoma is usually fatal if it cannot be completely resected, despite preoperative chemotherapy (Gonzalez-Crussi et al., 1982).

There is one reported case of stillbirth associated with mesenchymal hamartoma, and no other fetal abnormalities potentially responsible for fetal death were noted at autopsy (Foucar et al., 1983). Laberge et al., have reported fetal demise because of mesenchymal hamartoma that was associated with placental changes of mesenchymal stem villous hyperplasia of the placenta. They noted that among 11 such cases diagnosed prenatally, 4 had died in utero. Two other fetuses with prenatally diagnosed hamartomas did well after surgical resection. This last scenario is more consistent with neonatal mesenchymal hamartoma, in which the prognosis is favorable following tumor resection (Hirata et al., 1990). However, Isaacs reported that among 45 fetuses and neonates with mesenchymal hamartoma that underwent surgery, only 76% survived. Some patients were not treated and only one-third survived, yielding an overall survival rate for mesenchymal hamartoma of 65% (Isaacs, 2007).

MANAGEMENT OF PREGNANCY

A pregnant woman carrying a fetus in which a hepatic tumor is suspected should undergo an extensive prenatal evaluation. This should include a detailed sonographic examination to define the nature of the mass, location, blood supply, and any associated anomalies. Color Doppler studies may be helpful in distinguishing hemangioma from hepatoblastoma, mesenchymal hamartoma, or adenoma. Evidence of other hemangiomas should be sought. While mesenchymal hamartoma is usually an isolated finding, associated anomalies such as tracheoesophageal fistula and annular pancreas have been reported (Keeling, 1971; Stocker and Ishak, 1983). Hepatoblastoma has been reported in Beckwith–Wiedemann

syndrome and a fetus with a hepatic tumor should be examined for evidence of organomegaly or macroglossia. Hepatoblastoma also occurs in the Aicardi syndrome, and care should be taken to rule out agenesis of the corpus callosum (Jones, 1997). Every fetus with a hepatic mass should undergo echocardiography to obtain baseline values and be followed for development of high-output cardiac physiology. Serial scans in fetuses with hepatic tumors are indicated because of the potential for the development of oligohydramnios, polyhydramnios, nonimmune hydrops, and intrauterine fetal death. Fetal MRI scanning may be helpful in establishing a diagnosis of a liver tumor as well as defining the anatomic relationship with intrahepatic structures and adjacent organs.

Pregnancies complicated by hepatic tumors should be delivered in a tertiary care center, with neonatologists, pediatric surgeons, and pediatric oncologists available. Depending on the size of the lesion, cesarean section may be necessary. Tumor rupture at the time of delivery has been reported with mesenchymal hamartoma and hepatoblastoma. Because of the vascular nature of these lesions, every effort should be made to minimize the risk of tumor rupture.

FETAL INTERVENTION

There are few indications for fetal interventions for liver tumors. However, in case of fatal fetal mesenchymal hamartomas, decompression of large cystic components was suggested as a last ditch effort to prevent fetal death from tumor growth (Laberge et al., 2005). In the case of large hepatic hemangiomas that result in high-output failure and hydrops, maternal steroid treatment should be considered.

TREATMENT OF THE NEWBORN

Once an infant with a hepatic tumor is born, attention should focus on establishing a definitive diagnosis. In the case of hepatic hemangiomas, more than 50% will have associated cutaneous hemangiomas. The infant's platelet count, fibrinogen, and fibrin split products should be checked to exclude DIC and platelet trapping. Follow-up echocardiography should be performed to exclude high-output cardiac physiology. An initial bedside ultrasound examination may be helpful in establishing the diagnosis; however, CT or MRI scans are usually indicated to more fully define these lesions.

In the newborn with a hepatic mass suspected of being a hepatoblastoma, the serum AFP level should be measured. However, values in normal term infants may be between 20,000 and 120,000 ng/mL, which may make interpretation difficult in the newborn, but even more markedly elevated AFP levels are usually seen in hepatoblastoma. Ultrasound examination is helpful in differentiating solid from cystic masses. Hepatoblastoma usually shows a large hyperechoic mass. Color Doppler imaging is also helpful in evaluating the involvement of the portal vein, hepatic veins, and the inferior vena cava.

CT or MRI scanning of the liver is helpful in defining the extent of the tumor and assessing its resectability (Figure 111-2). MRI scans give detailed information not only on

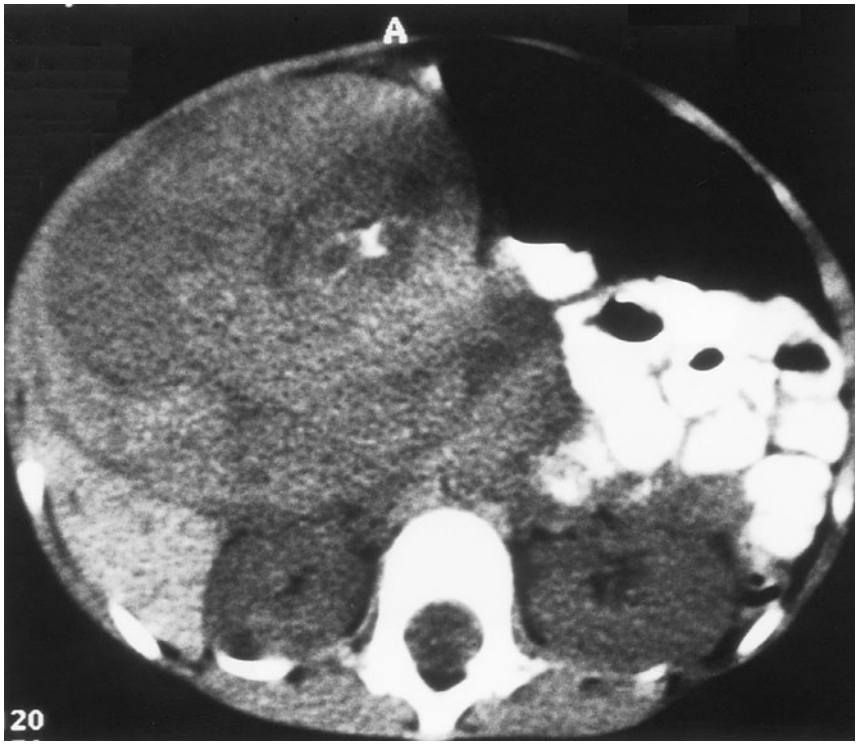

Figure 111-2 CT scan of a patient with a hepatoblastoma largely replacing the right lobe of the liver.

segmental anatomy of a hepatic tumor, but also on the vascular anatomy of the liver, making angiography unnecessary.

The distinction between hepatic hemangioma and arteriovenous malformations is an important one. Hepatic arteriovenous malformations require embolization or surgical resection and do not respond to corticosteroids or interferon gamma.

SURGICAL TREATMENT

In the experience with 34 hepatic hemangiomas causing congestive heart failure, the mortality associated with surgical resection of solitary lesions was 25%, and it was 45% when embolization was used for solitary and multiple lesions (Folkman, 1984). The mortality rate was only 20% when corticosteroids were used. Eleven patients who did not respond to corticosteroids received interferon gamma, resulting in a mortality rate of only 9%. Currently, interferon gamma is restricted to treatment of serious or life-threatening hemangiomas that fail to respond to corticosteroids, develop complications of corticosteroid administration, or have a contraindication to long-term corticosteroids (gastrointestinal bleeding, vomiting, infection), or if there is parental refusal of corticosteroids. An initial 2-week course of oral corticosteroids at 2 to 3 mg per kilogram of body weight per day is given. If the hemangioma responds, as evidenced by shrinkage, decreased turgor, pallor, or arrest of growth, then steroids are continued for 4 weeks before beginning a slow taper over 8 to 10 months (Folkman et al., 1997).

Interferon gamma is not without potential complications; recognized toxicities include fever, elevated liver function tests, transient neutropenia, and anemia. These toxicities are reversible. One worrisome complication associated with interferon gamma is the development of long tract signs and increased motor tone in the lower limbs.

The survival among fetuses and neonates with hemangiomas reported by Isaacs depended on treatment and histology. Only 78% of the 41 patients with multifocal hemangiomas were treated. Twenty-two percent were untreated, with survival rates of 75% and 56%, respectively. Among the 5 patients with type II hemangioendothelioma or angiosarcoma, 2 of the 5 operated on survived. Corticosteroids were a frequent choice of therapy for multifocal hemangiomas; all 10 patients who received them survived. Hepatic artery ligation was used successfully in 11 of 12 patients with or without steroids. In large type I hemangioendotheliomas, even biopsy can precipitate a consumptive coagulopathy, and medical therapy using steroids or even chemotherapy to shrink the lesion may be safer than surgery alone (Isaacs, 2007).

In cases of mesenchymal hamartoma, definitive treatment consists of a frozen section to confirm the diagnosis and exclude the possibility of malignancy. This is followed by complete resection of the mass. In the review by Isaacs, surgery was performed in 29 of 45 patients (64%) with 76% survival. Only one-third of those not treated survived. The fetal and neonatal survival with mesoblastic nephroma was 64% and 65%, respectively (Isaacs, 2007).

Surgical resection is the primary mode of treatment in hepatoblastoma. However, in tumors that are found to be unresectable at operative staging, a biopsy is performed to make a diagnosis and chemotherapy is begun. Reexploration for evidence of tumor regression with consideration of definitive resection occurs after several cycles of chemotherapy. In some centers a decision on resectability is made on the basis of imaging studies, and a percutaneous biopsy is obtained to make a tissue diagnosis before starting chemotherapy.

Surgical resection of liver tumors, whether hemangioendotheliomas, mesenchymal harmatomas, or hepatoblastomas, should be undertaken by experienced pediatric surgeons. In the case of hemangioendotheliomas, the involvement of multiple specialists from a Vascular Malformation and Tumor service is advisable. In the case of hepatoblastoma, the survival of the 32 cases compiled by Isaacs were stage dependent, with survival rates of 50%, 50% and 0% for stages I, III, and IV, respectively (Isaacs, 2007).

LONG-TERM OUTCOME

In hepatic hemangiomas in the absence of complications such as congestive heart failure, platelet trapping, or rupture at the time of delivery, a good prognosis can be anticipated. Most hepatic hemangiomas are asymptomatic and go unrecognized and do not develop complications. Even in the face of complications there has been significant improvement in survival because of the treatment of hepatic hemangiomas with corticosteroids and interferon gamma (Folkman et al., 1997). The natural history of hemangiomas is to progress during infancy and then to steadily regress thereafter (Folkman et al., 1997).

The long-term prognosis in mesenchymal hamartoma is excellent following complete resection. These tumors are not associated with malignant transformation and do not recur following complete resection.

There has also been steady progress in the outcome of patients treated for hepatoblastoma. The combination of surgery, chemotherapy, and liver transplantation has achieved disease-free survival rates of 100% for stage I, 75% for stage II, and 67% for stage III disease (Tagge and Tagge, 1997; Sallam et al., 2005; Tiao et al., 2005). Unfortunately, no disease-free survival has been achieved with stage IV disease.

GENETICS AND RECURRENCE RISK

Most of the hepatic lesions discussed in this chapter develop sporadically, without an associated risk for recurrence in subsequent pregnancies. There are, however, three notable exceptions associated with hepatoblastoma. Hepatoblastoma occurs in up to 10% of children with Beckwith–Wiedemann

syndrome, which is inherited as an autosomal dominant condition (see Chapter 27). There is also an increased risk of hepatoblastoma in kindreds with familial adenomatous polyposis (FAP). This is an autosomal dominant condition that predisposes to colonic adenomas and carcinomas. It is estimated that the risk of hepatoblastoma in children of patients with FAP is 0.42% (Li et al., 1987, Tagge and Tagge, 1997). DNA mutation analysis of the *APC* gene is clinically available for families with symptoms that suggest FAP. Lastly, hepatoblastoma has been reported in 4 individuals with trisomy 18 (Bove et al., 1996).

112 CHAPTER

Mesoblastic Nephroma

Key Points

- Most common congenital renal tumor.
- Sonographically, mesoblastic nephroma is most often a unilateral solid mass with nodular densities.
- Differential diagnosis includes hydronephrosis, multicystic dysplastic kidney, and nephroblastoma (Wilms' tumor).
- Mesoblastic nephroma can be cystic in areas due to hemorrhage with cystic degeneration.
- There are 3 histologic variants: classic, cellular, and mixed.
- 50% deliver prior to 34 weeks of gestation and are associated with polyhydramnios; 23% are hypertensive.
- Surgical resection is curative – local recurrence and metastases usually associated with the cellular variant.

CONDITION

Although in general, congenital renal tumors are rare, mesoblastic nephroma is among the most common to present during the first few months of postnatal life, accounting for 50% of all renal masses in the neonate (Campagnola et al., 1998; Jones and Cohen, 2007). Mesoblastic nephroma is also known as fetal renal hamartoma, lyomyomatous hamartoma, and mesenchymal hamartoma (Wigger, 1975; Slasky et al., 1982). These tumors are composed of mesenchymal tissue, in the form of interlacing bundles of ovoid or spindle-shaped cells. Since this "classical" form of mesoblastic nephroma was reported, a cellular variant has been described that may account for a large proportion of cases. Both types can coexist in distinct areas in a given tumor; this is known as a mixed type (Joshi et al., 1986; Pettinato et al., 1989). The cellular type of mesoblastic nephroma accounts for 42% to 63% of all cases (Knezevich et al., 1998; Furtwaengler et al., 2006). The cause of mesoblastic nephroma is unknown, but it has been suggested that mesoblastic nephroma is a differentiated form of Wilms' tumor (Bolande, 1974) or a derivative of secondary mesenchyme (Wigger, 1975). Current opinion favors classification of mesoblastic nephroma as a distinct, usually benign neoplasm arising from renal mesenchyme.

There is much debate as to the nature of mesoblastic nephroma and its biologic behavior. It is estimated that 95% of patients with mesoblastic nephroma do not relapse. The majority of those that either recur locally or metastasize have the cellular variant of mesoblastic nephroma (Bolande, 1974; Howell et al., 1982). The cellular variant has the strongest evidence, given the rarity of this tumor, for associated poor prognosis with a recurrence-free survival of 85% in contrast to 100% for the classic variant (Furtwaengler et al., 2006). This biologic behavior in the cellular variant may be due to a chromosome translocation, which results in the *ETV6* sequence on chromosome 12p13 fusing with the *NTRK3* sequence on chromosome 15q25 (Argani and Beckwith, 2000; Anderson et al., 2006). These genes are thought to result in constitutive dimerization of activating tyrosine kinase mediated growth signals. This translocation is not present in the classic variant and is variably present in the mixed type (Argani and Beckwith, 2000; Anderson et al., 2006; Ahmed et al., 2007).

INCIDENCE

A mesoblastic nephroma is a rare tumor, but accounts for 3% to 10% of all pediatric renal tumors and is the most common renal tumor in infants under three months of age (Glick et al., 2004; Ahmed et al., 2007). Ninety percent of mesoblastic nephromas are diagnosed in the first year of life (Glick et al., 2004). It has been estimated that fewer than 50 cases have been described in utero (Chen et al., 2003; Jones and Cohen, 2007). The rarity of this tumor makes estimates of the incidence of this lesion difficult. In one report, there was a male predominance of 2 to 1 (Furtwaengler et al., 2006). Another

report of 29 cases found a female predominance of 1.6 to 1 (Sanstedt et al., 1985).

SONOGRAPHIC FINDINGS

Ehman et al. (1983) described the first case of mesoblastic nephroma detected prenatally by ultrasound examination—a 4-cm solid mass in the left upper quadrant of a twin fetus at 35 weeks of gestation. They also noted mild-to-moderate polyhydramnios. A nephrectomy performed after birth confirmed the diagnosis of mesoblastic nephroma. Since then, other authors have described the detection of these tumors prenatally with ultrasound imaging during the third trimester (Giulian, 1984; Romano, 1984; Geirsson et al., 1985; Howey et al., 1985; Walter and McGahan, 1985; Appuzio et al., 1986; Yamboa et al., 1986; Burtner and Willard, 1988; Boulot et al., 1989; Kuo et al., 1989; Ohmichi et al., 1989; Rempen et al., 1992; Matsumura et al., 1993; Irsutti et al., 2000; Chen et al., 2003; Won et al., 2002; Yamamoto et al., 2006). However, some of these authors did not consider the diagnosis of mesoblastic nephroma prenatally. Mesoblastic nephroma can present as a large (4 to 8 cm), unilateral renal mass with nodular densities or as diffuse renal enlargement (Figure 112-1). These tumors are predominantly solid, but cystic areas are occasionally seen (Slasky et al., 1982), most likely due to hemorrhage with subsequent cystic degeneration. Unlike Wilms' tumor, there is no well-defined capsule.

Many fetal mesoblastic nephromas are initially detected by ultrasound examination because of a discrepancy between uterine size and gestational dates due to associated polyhydramnios. Polyhydramnios has been detected in most of the published cases of mesoblastic nephroma (Giulian, 1984; Romano, 1984; Geirsson et al., 1985; Howey et al., 1985; Walter and McGahan, 1985; Appuzio et al., 1986; Yamboa et al., 1986; Burtner and Willard, 1988; Boulot et al., 1989; Ohmichi et al., 1989; Rempen et al., 1992). The mechanism of polyhydramnios is unclear (Favara et al., 1968; Howey et al., 1985; Walter and McGahan, 1985). Theories regarding cause include impaired gastrointestinal obstruction due to mass effect of the tumor (Geirsson et al., 1985; Howey et al., 1985) and increased renal blood flow or impaired renal concentrating ability (Perlman et al., 1976; Geirsson et al., 1985), with subsequent increase in fetal urine production (Ohmichi et al., 1989). No matter the cause, over 70% of fetal mesoblastic nephromas will present with polyhydramnios, which may predispose to preterm labor and delivery (Haddad et al., 1996; Glick et al., 2004; Yamamoto et al., 2006).

Figure 112-1 Transverse sonographic image of a fetal mesoblastic nephroma demonstrating the complex solid and cystic components of the tumor completely replacing the normal renal structure.

Figure 112-2 Fetal MRI demonstrating the anatomic relations of this very large mesoblastic nephroma elevating the ipsilateral liver and diaphragm, crossing the midline with the ureter visible along the medial and inferior border of the tumor.

Fetal MRI has been reported to aid in the accurate prenatal diagnosis of mesoblastic nephroma (Figure 112-2) (Matsumura et al., 1993; Irsutti et al., 2000; Won et al., 2002; Yamamoto et al., 2006). The advantages of MRI include better tissue contrast and definition of the relationship of the tumor to adjacent structures (Yamamoto et al., 2006). However, the overlap in imaging findings between mesoblastic nephroma and Wilms' tumor often preclude a definitive diagnosis without tissue histology (Toma et al., 1990; Geller et al., 1997; Applegate et al., 1999).

Associated anomalies have been reported with congenital mesoblastic nephroma; these include neuroblastoma (Blank et al., 1978) and central nervous system (Howell et al., 1982; Werb et al., 1992), genitourinary, gastrointestinal, and limb abnormalities (Howell et al., 1982).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of mesoblastic nephroma includes hydronephrosis and multicystic dysplastic kidney, which are both more common than mesoblastic nephroma and appear typically cystic on ultrasound examination. The more malignant nephroblastoma, or Wilms' tumor (see Chapter 116), may be indistinguishable from mesoblastic nephroma antenatally (Giulian, 1984; Walter and McGahan, 1985; Toma et al., 1990; Geller et al., 1997; Applegate et al., 1999). Wilms' tumor usually has a well-defined capsule and, although an embryonic tumor, is more likely to be seen in the infant or young child. Focal renal dysplasia should also be considered in the differential diagnosis (Gordillo et al., 1987; Sanders et al., 1988). In addition, diffuse nephroblastomatosis should be considered, in which case both kidneys are involved and can be seen as acoustic shadowing due to calcifications (Ambrosino et al., 1990). Infantile polycystic kidney disease can be recognized by nonvisualization of the bladder, oligohydramnios, and bilaterally enlarged echogenic kidneys (Rempen et al., 1992). Adult polycystic kidney disease can be presumed in the presence of a positive family history of this condition (see Chapter 79). Kidney enlargement in other inherited disorders, such as Meckel–Gruber syndrome, is usually bilateral.

In the differential diagnosis, one must also rule out masses extending from adjacent organs such as the adrenal gland or the liver. Solid tumors, such as neuroblastoma of the adrenal or extraadrenal neuroblastoma and extrathoracic bronchopulmonary sequestration, may be mistaken for mesoblastic nephroma. Careful sonography can usually distinguish the normal-appearing kidney adjacent to these external tumors.

Other conditions that should be considered in the differential diagnosis include rhabdoid tumor, clear cell sarcoma, angiomyolipoma and ossifying renal tumor of infancy (Marsden and Lawler, 1983; Pinto and Guignard, 1995; Lowe et al., 2000; Glick et al., 2004).

ANTENATAL NATURAL HISTORY

Mesoblastic nephromas are usually benign. In the vast majority of cases, total nephrectomy is curative. However, infiltration of adjacent structures, local recurrence, and metastases have been reported (Fu and Kay, 1973; Joshi et al., 1973; Walker and Richard, 1973; Bolande, 1974; Gonzalez-Crussi et al., 1980; Shen and Yunis, 1980; Howell et al., 1982; Steinfeld et al., 1984). These unusual cases may be due to incomplete excision (Slasky et al., 1982; Beckwith and Weeks, 1986). However, mesenchymal tumors are a heterogeneous group, with malignant tumors comprising one end of the spectrum and the majority (the benign tumors) at the other end (Gonzalez-Crussi et al., 1981; Beckwith and Weeks, 1986; Joshi et al., 1986).

Most of the tumors that recur locally or with distant metastasis fall into the cellular variant of mesoblastic nephroma (Fu and Kay, 1973; Howell et al., 1982; Ahmed et al., 2007). Recurrent disease can be local (Fu and Kay 1973) or due to distant metastases to lung (Gonzalez-Crussi et al., 1980), liver (Patel et al., 2003), heart (Vujanic et al., 1993) or brain (Heidelberger et al., 1993).

MANAGEMENT OF PREGNANCY

Because of the benign nature of most mesoblastic nephromas, if ultrasound examination convincingly shows a renal lesion, it is recommended to allow the pregnancy to go to term (Giulian, 1984). There appears to be a higher incidence of preterm labor and/or preterm rupture of membranes in pregnancies complicated by mesoblastic nephroma, as a result of associated polyhydramnios (Walter and McGahan, 1985; Haddad et al., 1996). In a review of prenatally diagnosed mesoblastic nephroma, 9 of 13 (69%) cases were complicated by preterm labor and/or preterm rupture of membranes as early as 26 weeks of gestation (Appuzio et al., 1986; Rempen et al., 1992). LeClair et al. found that almost half of newborns with mesoblastic nephroma delivered before 34 weeks' (LeClair et al., 2005). In addition, 25% of fetuses showed evidence of fetal distress prompting Cesarean section delivery. Not only were these infants delivered prematurely, but 8 required ventilatory support either due to respiratory distress syndrome or an abdominal mass that compressed the diaphragm. Therefore, due to the risks of prematurity and potential for complications related to mesoblastic nephroma, we recommended delivery of these patients in tertiary care centers to optimize care of the neonate.

Dystocia may complicate these deliveries due to the large size of these renal tumors (Yamboa et al., 1986). There has also been one report of hydrops in association with a large mesoblastic nephroma. Possible mechanisms include obstruction of the portal vein or inferior vena cava circulations, increased vascularity with subsequent arteriovenous shunting, massive hemorrhage into the tumor with resultant anemia, or some combination of these factors (Gray, 1989). Serial ultrasound examinations should be performed to monitor tumor size, amniotic fluid volume, and fetal well being. The prospective parents should be advised that the prognosis for cases of fetal mesoblastic nephroma is excellent with current surgical techniques and close postoperative surveillance for possible recurrence.

FETAL INTERVENTION

There is no fetal treatment for mesoblastic nephroma.

TREATMENT OF THE NEWBORN

The main differential diagnosis in an infant with a large heterogeneous renal mass is between mesoblastic nephroma and

malignant neoplasms, such as Wilms' tumor, clear tumor, clear-cell sarcoma of the kidney, and malignant rhabdoid tumor and ossifying renal tumor of infancy. The infant should be delivered in a tertiary care setting, with consideration given to cesarean section delivery to obviate the potential for dystocia or hemorrhage into the tumor. Once the infant has been stabilized, further preoperative evaluation should include an ultrasound examination with color flow Doppler studies to evaluate for the presence of tumor thrombus within the renal veins or inferior vena cava, as is commonly seen with Wilms' tumor, but is uncommonly associated with mesoblastic nephroma. Computed tomographic scanning of the abdomen is useful to best define the extent of the tumor and plan the surgical resection.

Careful blood pressure monitoring is indicated, as up to 23% of cases of mesoblastic nephroma will have significant hypertension due either to renin production within the tumor or altered renal perfusion by the tumor, inducing renin production by the native kidney (Malone et al., 1989). This will need to be controlled preoperatively. Hypercalcemia may also occur in mesoblastic nephroma as a paraneoplastic phenomenon due to tumor production of parathyroid hormone-like peptides or prostaglandins causing hypercalcemia (Shanbhogue et al., 1986; Jayabose et al., 1988; Yokomori et al., 1988; Tsuchida et al., 1993).

SURGICAL TREATMENT

Radical resection of the tumor is the therapy of choice, and it is usually curative (Bolande, 1974; Wigger, 1975). Although resection alone is usually curative for mesoblastic nephroma, a small percentage may have local recurrence or present later with metastases. It is thought that these local recurrences are due to inadequate resection during the primary procedure. It was observed by Beckwith and Weeks (1986) that many of the specimens of patients in whom metastases subsequently developed showed either focal or diffuse increases in cellularity, with high mitotic rates. Some have suggested that the so-called cellular or atypical congenital mesoblastic nephroma should be treated as a potentially malignant tumor (Joshi et al., 1986). However, a review of all cases of recurrent or metastatic mesoblastic nephroma demonstrated that the cellular variant is not associated with adverse outcome in infants younger than 3 months, with the exception of one instance in which incomplete removal of the tumor was documented (Beckwith and Weeks, 1986).

Because of the tendency to extend into perirenal tissues and subsequently recur, appropriate treatment of mesoblastic nephroma includes a radical surgical approach with efforts to secure wide margins of uninvolved tissue on all aspects of the specimen. In addition, the cellular variant of mesoblastic nephroma carries no adverse prognostic significance in infants younger than three months of age. However, in older infants the demonstration of increased cellularity and high mitotic rate is of some concern because a few patients with such lesions will experience local recurrence or distant metastases. Infants older than 3 months of age with the cellular variant of congenital mesoblastic nephroma should probably receive adjuvant chemotherapy, whereas in infants younger than 3 months of age, resection alone is adequate therapy (Beckwith and Weeks, 1986; Berry, 1987). The proper role for adjuvant chemotherapy mesoblastic nephroma remains controversial (Jones and Cohen, 2007) especially in infants less than 3 months of age in the presence of tumor spillage with the cellular variant. It is believed that cellular variants with genetic characteristics like *ETV-6-NTRK3* gene fusion associated with translocation between chromosomes 12 and 15 may respond better to chemotherapy (Jones and Cohen, 2007). In the setting of recurrent disease, combinations of vincristine, doxorubicin and cyclophosphamide or ifosfamide, carboplatin and etoposide have been used successfully (Ahmed et al., 2007). Chemotherapy can be used either alone or in combination with radiation therapy (Howell et al., 1982; Loeb et al., 2002).

LONG-TERM OUTCOME

Because of the potential in a small percentage of patients with these tumors for local recurrence or distant metastases, these patients need to be followed closely for evidence of recurrence so that they can be treated aggressively. It has been suggested that monthly postnatal ultrasound examinations be used to screen for local recurrence. In addition, if a patient is hypercalcemic preoperatively, calcium levels can be followed as an indicator of recurrent disease. The majority of recurrences, either local or metastatic, occur within one year.

GENETICS AND RECURRENCE RISK

Mesoblastic nephroma is not known to be familial and there is no known risk of recurrence in subsequent siblings.

113 CHAPTER Neuroblastoma

Key Points

- Most common solid tumor in infants.
- Neuroblastomas are generally diagnosed by sonography in the third trimester, and can be cystic, solid, or both.
- The differential diagnosis includes hydronephrosis, multicystic kidney, obstructive duplex collecting system, Wilms' tumor, mesoblastic nephroma, and adrenal hemorrhage.
- Neuroblastoma in situ may be responsible for many prenatally diagnosed cystic neuroblastomas, and may be due to delayed regression of neuroblasts.
- 83% of prenatally diagnosed neuroblastomas will be localized stage I or II disease.
- Neuroblastoma is stage III or IVS in only 16% of cases.
- Poor prognostic signs, such as N-myc amplification, occur in less than 5% of cases.
- Prenatal complications such as fetal hydrops, hepatomegaly, and maternal hypertension occur rarely.

CONDITION

Neuroblastomas arise from undifferentiated neural tissue of the adrenal medulla (40% to 70%), or extraadrenal sympathetic ganglia (30% to 60%), in the abdomen, thorax, pelvis, or head and neck (Birner, 1961; Beckwith and Perrin, 1963; Schneider et al., 1965; Janetschek et al., 1984; Ferraro et al., 1988). Neuroblastic nodules appear to be normal fetal structures within the adrenal gland that regress or differentiate throughout gestation. Greater numbers of these nodules are present early in gestation than at birth or during early infancy (Turkel and Habashi, 1974; Ikeda et al., 1981; Grosfeld et al., 1993). Neuroblastic nodules were found in 100% of the adrenal glands studied in second trimester abortuses (Turkel and Habashi, 1974; Ikeda et al., 1981) (Figure 113-1). Postnatal autopsy studies of newborn and young infants who died of unrelated causes reveal nodules to be present in 0.5% to 2.5% of carefully sectioned specimens (Beckwith and Perrin, 1963; Guin et al., 1969; Grosfeld et al., 1993). These figures contrast with the incidence of symptomatic neuroblastoma of 1 in 10,000 to 1 in 30,000 children. This calls into question the clinical significance of these early lesions and the need for treatment. It is also of interest that adrenal cysts are more commonly seen in fetal neuroblastoma, but are relatively uncommon in postnatal life (Turkel and Habashi, 1974). Cystic change may also represent a phase of normal adrenal development, thus accounting for prenatal detection of sonographically apparent but possibly clinically insignificant tumors (Tubergen and Heyn, 1970) (Figure 113-2). Although these tumors may represent rests of neural tissue with persistence

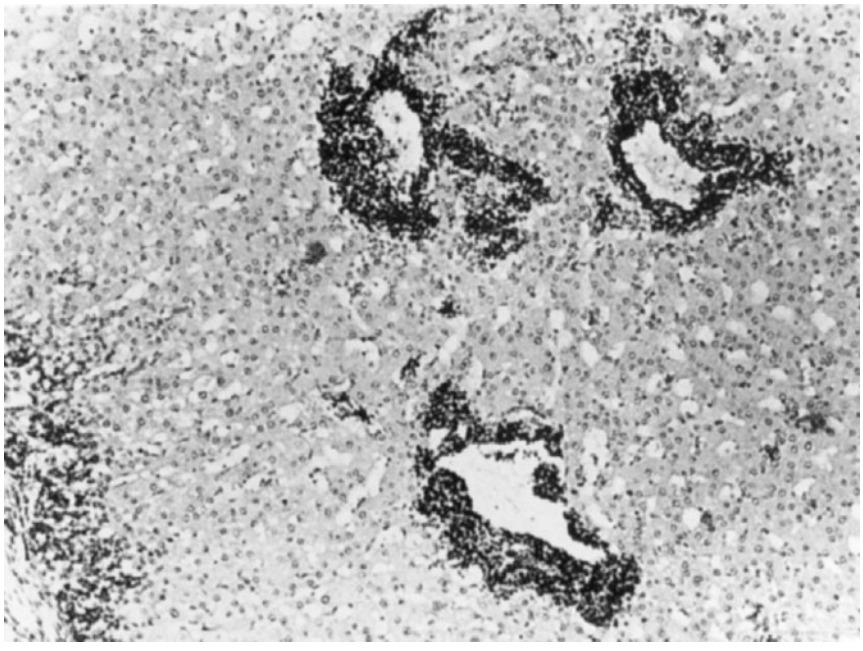

Figure 113-1 Histologic section demonstrating fetal neuroblastic nodules, or rests.

into neonatal life, the potential for malignant transformation due to defective regression or differentiation must be considered (Turkel and Habashi, 1974; Grosfeld et al., 1993). Beckwith referred to these lesions as "neuroblastoma in situ" because these aggregates of neuroblasts exhibited mitotic figures and infiltration of the adult cortex (Beckwith and Perrin, 1963).

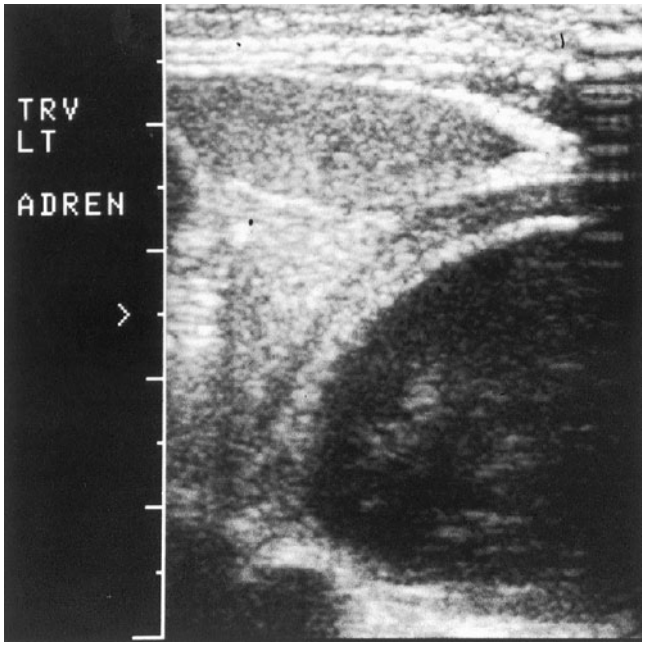

Figure 113-2 Prenatal sonographic image of an adrenal cyst from a fetal neuroblastoma. *(Reprinted, with permission, from Garmel SH, Crombleholme TM, Semple JP, et al. Prenatal diagnosis and management of fetal tumors.* Semin Perinatol. *1994b;18:350-365.)*

The results of mass infant screening programs in Japan and Canada using urinary vanillylmandelic acid (VMA) and homovanillic acid (HVA) support the view that neuroblastoma in situ may not represent clinically significant disease (Bessho et al., 1991; Murphy et al., 1991; Grosfeld et al., 1993; Woods et al., 2002). Screening infants at 6 months of age has resulted in a doubling of the incidence of neuroblastoma detected in infants. However, the expected fall in the incidence of more advanced stage neuroblastoma detected in older age groups was not seen. Furthermore, survival in the screened groups has approached 100%. The asymptomatic cases detected by screening may represent a subset of tumors destined to regress or differentiate without posing any clinical risk. This would explain both the high incidence in infants detected by screening programs and their excellent survival. The group detected by newborn screening may be the same subset of tumors detected prenatally with ultrasound examination.

In contrast, there is a subset of neuroblastoma diagnosed in utero or in newborns that does display an aggressive biologic behavior. Among the 300 cases of fetal or perinatal neuroblastoma reported, 83% were stage I or II, but there were also one each with stage III and IV disease (Fenart et al., 1983; Gadwood and Reynes, 1983; Sones, 1983; Newton et al., 1985; Atkinson et al., 1986; deFilippi et al., 1986; Giulian et al., 1986; Tovar et al., 1988; Kurtz and Hilbert, 1989; Pley et al., 1989; Forman et al., 1990; Hosoda et al., 1992; Suresh et al., 1993; Crombleholme et al., 1994a; Goldstein et al., 1994; Garmel et al., 1994b; Acharya et al., 1997; Granata et al., 2000; Sauvat et al., 2002; Nuchtern, 2006) and five with stage IVS disease (Hainaut et al., 1987; Ho et al., 1993). All children affected with stage IV disease died. In a review of congenital neuroblastoma reported between 1985 and 1991, Jennings et al. (1993) found 14 stillbirths, 44 neonatal deaths, and 2 late deaths, with only 10 survivors. Eight cases were associated with metastases to the placenta, and 1 had umbilical cord

metastases. This subset of aggressive tumors associated with such poor outcomes may be quite different from the subset detected by the Japanese screening programs (Grosfeld et al., 1993) or by prenatal ultrasound examination.

The cause of neuroblastoma is unclear, although most cases appear sporadically (Behrman, 1992). At least one hypothesis is that antenatal factors play a role, with some adverse stimulus or stimuli occurring in late pregnancy. Preterm delivery is protective, while growth restricted term infants are at risk (Johnson and Spitz, 1985). There have been reports of congenital neuroblastoma in association with maternal phenytoin and phenobarbital use (Sherman and Roizen, 1976; Allen et al., 1980). The causative effect of phenytoin in neuroblastoma has been questioned and this is most likely a coincidental finding. In addition, some epidemiologic studies have suggested an association with maternal diabetes (Chow et al., 2007) and antenatal exposure to codeine (Cook et al., 2004).

INCIDENCE

Neuroblastoma is one of the most common tumors of infancy and childhood, with a clinical incidence of between 1 in 10,000 and 1 in 30,000 individuals (Janetschek et al., 1984; Fowlie et al., 1986; Goodman et al., 1999). Gurney et al., estimated the rate of neuroblastoma in the U.S. at 58 per 1,000,000 infants per year (Gurney et al., 1997). Neuroblastoma may be more common in white children than in other ethnic groups, and more common in male than in female children (Miller et al., 1968; Turkel and Habashi, 1974; Askin and Geschickter, 1985; Behrman, 1992). It is estimated that 16% of infant neuroblastomas are diagnosed in the first month of life and 41% within the first three months (Goodman et al., 1999).

SONOGRAPHIC FINDINGS

Since the first case of prenatally detected neuroblastoma was reported by Fenart et al., 300 cases of neuroblastoma have been suspected or diagnosed by prenatal ultrasound examination (Nuchtern, 2006; Fenart et al., 1983). All have been visualized during the third trimester of pregnancy (Fenart et al., 1983; Gadwood and Reynes, 1983; Sones, 1983; Janetschek et al., 1984; Newton et al., 1985; Atkinson et al., 1986; deFilippi et al., 1986; Fowlie et al., 1986; Giulian et al., 1986; Hainaut et al., 1987; Ferraro et al., 1988; Tovar et al., 1988; Kurtz and Hilbert, 1989; Pley et al., 1989; Forman et al., 1990; Hosoda et al., 1992; Liyanage and Katoch, 1992; Ho et al., 1993; Jaffa et al., 1993; Jennings et al., 1993; Suresh et al., 1993; Crombleholme et al., 1994a; Garmel et al., 1994b; Goldstein et al., 1994; Acharya et al., 1997; Granata et al., 2000; Sauvat et al., 2002). The sonographic findings described by these studies were quite variable. The primary tumor is often small (only a few millimeters or centimeters in greatest diameter). Ninety percent of cases involve the adrenal gland, creating difficulties in distinction between the mass itself and the upper pole of the ipsilateral kidney. Cystic and solid areas within the mass are typically seen, which may be related to hemorrhage and necrosis of the tumor (Atkinson et al., 1986). Purely cystic lesions have also been reported in fetal neuroblastoma and may indicate a more favorable prognosis (Atkinson et al., 1986; Kurtz and Hilbert, 1989; Crombleholme et al., 1994a; Garmel et al., 1994b; Hamada et al., 1999; Petit et al., 2001; Lopez Alvarez-Buhilla et al., 2002; Tanaka et al., 2003; Athanassiadou et al., 2005). Occasionally, calcifications can be seen within the tumor (Potter, 1961; Fowlie et al., 1986; Giulian et al., 1986). Calcifications within neuroblastomas are often described as microcalcifications with acoustic shadowing (Kurtz and Hilbert, 1989; Gorincour et al., 2003). The tumor is usually well encapsulated and may displace the kidney inferiorly and laterally but preserves the renal outline (Figure 113-3A and B). If arising in the sympathetic ganglia, the mass may be seen in the chest, cervical region, or intra-abdominal paravertebral locations. Cervical lesions sufficiently large to compromise the fetal airway have been reported (Gorincour et al., 2003), as have large retroperitoneal masses presenting as flank masses that are readily palpable on physical examination (Nagasako et al., 2004).

Occult neuroblastomas are rarely metastatic, but prenatal detection of liver metastases has been reported (Liyanage and Katoch, 1992; Jaffa et al., 1993; Nagasako et al., 2004). A suprarenal mass associated with hepatomegaly is highly suggestive of the diagnosis of neuroblastoma. Likewise, if a liver mass is seen on prenatal ultrasound examination, one needs to carefully examine all neural crest regions, especially in the renal and suprarenal areas, to rule out a primary tumor locus (Jaffa et al., 1993). Several cases have been reported with neuroblastoma metastatic to the placenta and umbilical cord. Careful imaging of the placenta and umbilical cord is also indicated because of reports of metastases to these areas. Fetoplacental metastases have been also reported in monochorionic twins with a primary tumor detectable in only one twin, with both having simultaneous evidence of metastatic disease (Adaletli et al., 2006).

Occasionally, ultrasound examination may also reveal polyhydramnios and/or hydrops (Falkinburg and Kay, 1953; Forman et al., 1990). Although the underlying mechanism is unknown, numerous hypotheses have been proposed, including hepatomegaly with subsequent mechanical obstruction of the umbilical vein or vena cava (Moss and Kaplan, 1978; Van der Slikke and Balk, 1980), compromised liver function with resultant hypoproteinemia (Adzick and Harrison, 1994); metastatic involvement of the placenta with placentomegaly and hydrops (Janetschek et al., 1984), tumor infiltration of bone marrow with subsequent anemia and heart failure (Moss and Kaplan, 1987), or arrhythmia and heart failure due to catecholamine release (Moss and Kaplan, 1987).

Malformations have occasionally been noted in association with neuroblastoma in children, including microcephaly, hydrocephaly, absence of the corpus callosum,

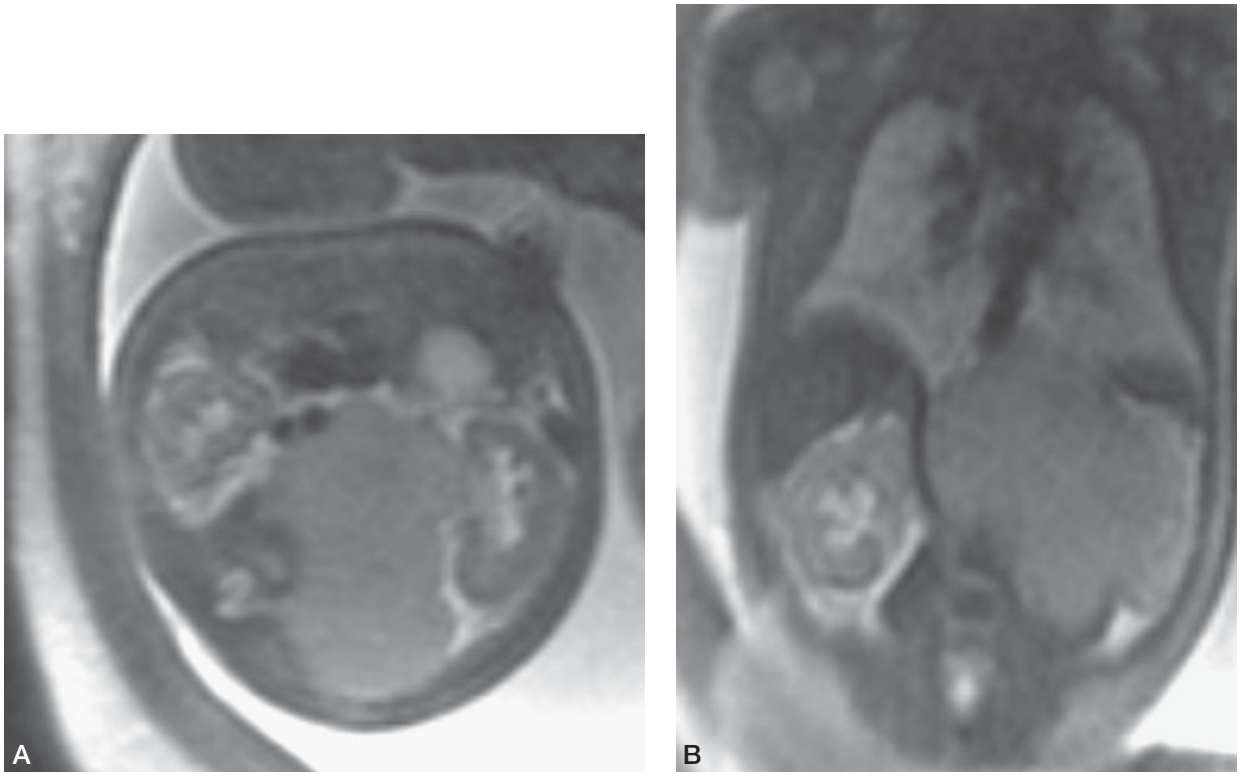

Figure 113-3 **A.** Axial image on fetal MRI of a large neuroblastoma arising from the retroperitoneum. **B.** Coronal image of same fetus demonstrating very large neuroblastoma.

cleft lip and palate, tracheoesophageal fistula, heart defects, skeletal abnormalities, genitourinary abnormalities, polydactyly, and single umbilical artery (Potter and Parrish, 1942; Kouyoumdjian and McDonald, 1951; Bodian, 1963; Berry et al., 1970; Andersen and Hariri, 1983). A consistent pattern of associated anomalies has not been demonstrated however, and the majority have been isolated cases of fetal neuroblastomas (Miller, 1966; Sy and Edmonson, 1968; Berry et al., 1970).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis in neuroblastoma is extensive, as these tumors can be found in the adrenal gland and elsewhere along the sympathetic ganglia. The involvement of the adrenals can be mistaken for hydronephrosis, multicystic kidney, or upper-pole cystic dysplasia seen in obstructive duplex collecting systems, Wilms' tumor or mesoblastic nephroma unless a clear distinction from the adjacent kidney is made. Less common entities are outlined in Table 113-1. Demonstration of low-impedance waveforms by color Doppler studies and flow mapping may be helpful in differentiating neuroblastoma from adrenal hemorrhage (Goldstein et al., 1994). If the liver is involved, hamartoma, hepatoblastoma, and hemangioma must be considered. Subdiaphragmatic extralobar pulmonary sequestrations are predominantly left-sided, solid, with echogenic appearance and occur only one-third

Splenic cyst

as frequently as neuroblastomas (Curtis et al., 1997). A case report of a solid neck mass seen prenatally on ultrasound examination was found postmortem to be consistent with either primary or metastatic cervical neuroblastoma (Gadwood and Reynes, 1983). In this case, the differential diagnosis included cystic hygroma, neural tube defect, cervical teratoma, and goiter. In one case report of cerebral neuroblastoma, the differential diagnosis included teratoma, glioblastoma, and craniopharyngioma. Prenatal tumor biopsy confirmed the diagnosis of neuroblastoma (Suresh et al., 1993).

ANTENATAL NATURAL HISTORY

Our understanding of the antenatal natural history of prenatally diagnosed neuroblastoma is still evolving, and much remains uncertain. The incidence of adrenal neuroblastoma in situ at neonatal autopsy has been reported to occur in 1 of 40 patients dying from unrelated causes (Grosfeld et al., 1993). The majority of occult neuroblastomas are most likely developmental variants, which regress spontaneously before becoming clinically evident, or differentiate into benign ganglioneuromas (Beckwith and Perrin, 1963; Miller et al., 1968; Turkel and Habashi, 1974; Pley et al., 1989).

Among the 300 reported cases of fetal or perinatal neuroblastoma, the vast majority developed in the adrenal glands, with rare cases of intrathoracic, intracranial tumor, or an unknown primary site (Gadwood and Reynes, 1983; deFilippi et al., 1986; Jaffa et al., 1993; Ho et al., 1993; Suresh et al., 1993; Acharya et al., 1997; Granata et al., 2000; Sauvat et al., 2002). Eighty-three percent of these neuroblastomas were stage I or II, only 16.6% were stage III, IV, or IVS (Gadwood and Reynes, 1983; Newton et al., 1985; Hainaut et al., 1987; Kurtz and Hilbert, 1989; Liyanage and Katoch, 1992; Ho et al., 1993; Jaffa et al., 1993; Suresh et al., 1993; Acharya et al., 1997; Granata et al., 2000; Sauvat et al., 2002). It is interesting that in two patients initially diagnosed and treated as stage I postnatally, hepatic metastases developed and later evolved to stage IV (Fenart et al., 1983; Ferraro et al., 1988). One patient with neuroblastoma initially diagnosed and treated as stage II later had hepatic and bone marrow metastases, which evolved into stage IVS (Ho et al., 1993). These cases underscore the need for close postoperative surveillance, even in patients with stage I disease. Hydrops developed in three fetuses with stage IV or IVS and liver metastases (Gadwood and Reynes, 1983; Newton et al., 1985; Hainaut et al., 1987). In addition, hypertension and preeclampsia reportedly developed in three pregnant women, thought to be induced by catecholamines secreted from functional tumors although it was not documented (Newton et al., 1985; Pley et al., 1989; Jennings et al., 1993).

The two most important factors in the prognosis of clinical neuroblastoma are the age of the patient at diagnosis and the stage of the disease. The overall survival is only 10% to 20% in children presenting after 1 year of age, but is greater than 90% in patients younger than 1 year of age at the time of diagnosis (Estroff et al., 1991; Grosfeld et al., 1993). Patients with disease at an earlier stage and well-differentiated tumors have a better prognosis than those with disease at a more advanced stage and poorly differentiated tumors. Early diagnosis is important in identifying patients prior to 1 year of age and at an early stage of disease. The increasing use of prenatal ultrasound imaging may allow diagnosis at a younger age and earlier stage with the hope of improved survival. The caveat is that the clinical significance of fetal neuroblastoma remains unknown. It is not clear that the natural history of fetal neuroblastoma parallels that of clinical neuroblastoma presenting later in life. The true prenatal natural history of fetal neuroblastoma may never be determined because potentially malignant tumors are rarely managed expectantly. The Children's Oncology Group is conducting a clinical trial of expectant observation for infants with small stage I neuroblastomas diagnosed either prenatally or within the first 6 months of life (Nuchtern, 2006). Because of this we may be subjecting neonates, many of whom have biologically benign lesions, to unnecessary risks of surgery and chemotherapy.

MANAGEMENT OF PREGNANCY

Serial ultrasound examinations to assess tumor size, amniotic fluid volume, and fetal well-being play an important role in pregnancy management. A search should also be made for evidence of metastatic spread. An attempt should be made to stage the disease prenatally by sonographic examination. The presence of extensive hepatic metastases places the fetus at markedly increased risk for the development of hydrops. Significant and rapid tumor growth has been noted in at least two reports and may not be predictable (Janetschek et al., 1984; Fowlie et al., 1986). Others have reported an association with placentomegaly and hydrops, with subsequent death in utero or during early neonatal life (Potter and Parrish, 1942; Birner, 1961; Anders et al., 1973; Van der Slikke and Balk, 1980; Gadwood and Reynes, 1983; Newton et al., 1985; Hainaut et al., 1987; Jaffa et al., 1993). Because of the poor prognosis, delivery is recommended if hydrops develops. In one case, the rapid growth of the component of the neuroblastoma extending into the spinal canal resulted in irreversible paralysis (Nagasako et al., 2004). The authors speculated that early delivery to prevent cord compression might have prevented paralysis.

Dystocia at delivery has been reported due to liver enlargement with capsule rupture and subsequent hemoperitoneum (Hagstrom, 1929; Askin and Geschickter, 1985; Birner, 1961; Potter, 1961). Cesarean section should be considered to avoid tumor hemorrhage during labor when the neuroblastoma is large, as has been reported by Murthy, Weinberg, and others (Weinberg and Radman, 1943; Murthy et al., 1978; Jaffa et al., 1993). However, Ho et al. (1993) reported no peripartum delivery complications in their series. We recommend an ultrasound examination late in gestation to evaluate the likelihood of dystocia and the need for cesarean section.

Maternal symptoms related to fetal catacholamine production, including sweating, flushing, palpitations and hypertension, have been reported during the third trimester of pregnancy (Voute et al., 1970; Newton et al., 1985). Development of hypertension is a potential complication in pregnancies associated with either a functioning fetal adrenal tumor or a hydropic fetus (Nicolay and Gainey, 1964; Voute et al., 1970; Newton et al., 1985). Early delivery may be indicated if maternal health is jeopardized. Delivery should take place at a tertiary care center, with neonatologists, pediatric surgeons and oncologists available.

It has been suggested that a 24-hour maternal urine assay or amniocentesis for fetal urinary catecholamine metabolites (VMA, HVA) may be helpful when the prenatal diagnosis of neuroblastoma is unclear or the cause of maternal hypertension is suspected (Zambotti et al., 1975; Newton et al., 1985; Crombleholme et al., 1994a; Garmel et al., 1994b). However, most neuroblastomas are nonfunctional, and thus far, amniotic fluid catecholamine studies have not been helpful in establishing the prenatal diagnosis of neuroblastoma (Hosoda et al., 1992). Therefore, in the absence of maternal or fetal complications, no invasive diagnostic testing is warranted, but serial examinations of the mother and fetus are recommended (Crombleholme et al., 1994a; Garmel et al., 1994b).

FETAL INTERVENTION

There is currently no indication for fetal intervention in fetal neuroblastoma. However, if fetal or maternal complications arise, early delivery should be considered in cases of catecholamine-induced hypertension or fetal hydrops. Early delivery may be warranted if ultrasound or MRI demonstrates intraspinal extension of the tumor. If the neuroblastoma is rapidly growing, the spinal extension may cause cord compression and urgent delivery may be warranted.

TREATMENT OF THE NEWBORN

An infant with a prenatal diagnosis of suspected fetal neuroblastoma should undergo a detailed physical examination. In cases of stage IVS disease, bluish subcutaneous nodules (the so-called "blueberry muffin" sign) from metastatic neuroblastoma may be seen all over the infant's body. The blood pressure should be noted prior to and during palpation of the suspected tumor mass. Among postnatal neuroblastomas, approximately 20% may release vasoactive peptides on palpation. The abdomen should be gently palpated to discern an abdominal mass and its relationship to other viscera. The liver should be assessed for size and evidence of metastases. Similarly, gentle palpation of a cervical mass will offer clues to histology and relationship to adjacent structures.

The newborn with suspected congenital neuroblastoma should have plain radiography of the abdomen, chest, or neck region (depending on tumor location). Neuroblastoma has characteristic finely stippled calcifications. A postnatal ultrasound examination may be useful to correlate with prenatal findings. Chest radiography should be performed to exclude pulmonary metastases. In most instances a computed tomographic (CT) scan is indicated to more accurately stage the disease and define the extent of the primary tumor (Figure 113-4).

Urine should be collected for spot measurement of catecholamines and tumor metabolites, including epinephrine, norepinephrine, dopamine, VMA, and HVA. Baseline liver function tests should be determined in all patients even without evidence of hepatic metastases. Serum ferritin and neuron-specific enolase should be assayed, as they have

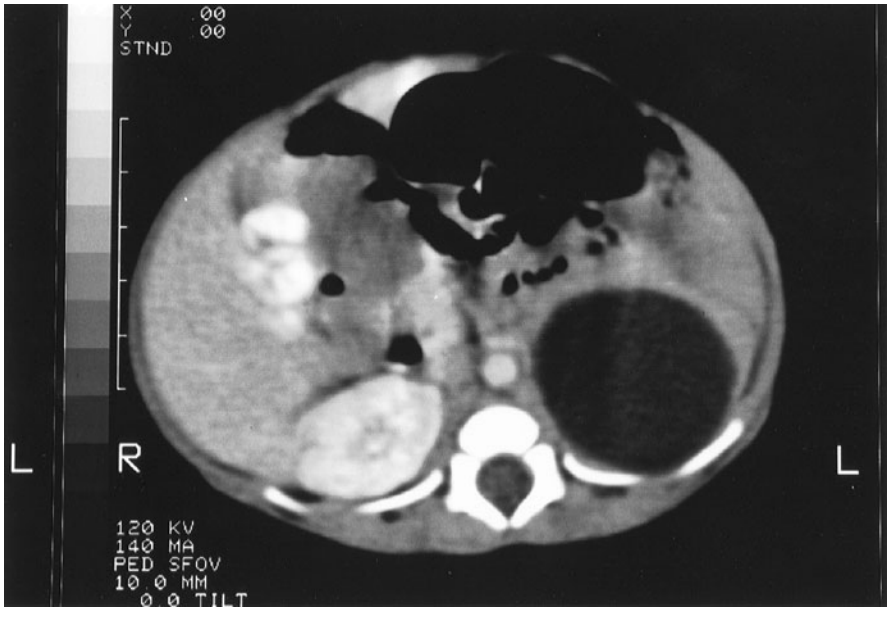

Figure 113-4 CT of newborn diagnosed with fetal neuroblastoma.

prognostic significance in patients less than 1 year of age. As part of the preoperative staging, a technetium-99m bone scan, and bone marrow aspiration and biopsy should be performed. ^{123}I-MIBG and ^{99m}Tc-MDP scintigraphy can be useful in identifying metastatic disease (Sauvat et al., 2002; Kushner, 2004).

The child should undergo surgery for biopsy, staging, and resection of the primary tumor, if possible without jeopardizing adjacent structures. Similarly, in stage IVS disease, resection of the primary tumor is indicated. This will provide tissue for determination of N-*myc* amplification and DNA ploidy. In stage IVS disease, with the presence of diploid DNA complement and N-*myc* amplification, chemotherapy is indicated. In the absence of these findings, observation alone is indicated. The treatment of neuroblastoma depends on the clinical staging. In stage I (primary with regional or distant metastases) or stage II (regional lymph node metastases but no distant metastases), surgery alone is sufficient. But in stage III (tumor extends beyond midline and bilateral lymph nodes may be involved) or stage IV (distant metastases) preoperative chemotherapy is indicated.

LONG-TERM OUTCOME

The newborn with congenital neuroblastoma may initially present with stage I disease that subsequently progresses. This does not represent disease recurrence but rather a delayed presentation of metastases, which results in restaging to stage IVS or IV, which requires chemotherapy. As with all pediatric oncology patients, close long-term follow-up is essential even after completion of therapy to ensure early detection of recurrence. Overall, the long-term survival in prenatally diagnosed neuroblastoma is over 90% (Nuchtern, 2006).

GENETICS AND RECURRENCE RISK

Several cytogenetic abnormalities can be seen in neuroblastoma, including deletion of the short arm of chromosome 1, abnormal chromosome fragments known as "double minutes" (DMs, N-*myc* amplification), and integrated homogeneously staining regions (HSRs) (Brodeur et al., 1981; Brodeur and Fong, 1989). The chromosome 1p deletion may represent loss of a tumor suppressor gene involved in neuroblastoma, while the DMs and the HSRs may represent gene amplification. Neuroblastomas can be familial, but no characteristic genetic syndrome or congenital anomaly is associated with a predisposition for this tumor. The proto-oncogene N-*myc* was found initially because it was amplified in neuroblastoma cell lines (Schwab et al., 1983). N-*myc* amplification (3- to 300-fold) is found in primary neuroblastoma and is associated with advanced stages of disease, rapid progression, and poor outcome (Brodeur et al., 1984; Seeger et al., 1985; Brodeur, 1990). Neuroblastomas with favorable prognoses are diagnosed early in life, at an early stage, with hyperdiploid karyotypes, and without abnormalities of chromosome 1p or N-*myc* amplification (Jennings et al., 1993). More than 90% of perinatal neuroblastomas have a DNA index of >1, which is associated with a better prognosis in infants (Acharya et al., 1997; Granata et al., 2000; Sauvat et al., 2002). In addition, less than 5% of perinatal neuroblastomas have N-*myc* amplification (Acharya et al., 1997; Granata et al., 2000; Sauvat et al., 2002).

Familial cases of neuroblastoma have been observed in siblings, identical twins, and one case in which the mother and child were both affected (Pendergrass and Hanson, 1976; Emery et al., 1983; Grotting et al., 1983; Gorincour et al., 2003). Neuroblastoma has also been reported in patients with the Beckwith–Wiedemann syndrome, pancreatic islet-cell dysplasia, and infants born to mothers taking phenytoin. There have also been occasional reports of familial neuroblastoma. One report involved four or five siblings, which suggests that some neuroblastomas may be inherited as an autosomal dominant trait (Dodge and Benner, 1945; Chatten and Voorhees, 1967). There is also an increased incidence of neuroblastoma in infants with the fetal alcohol syndrome (Seeler et al., 1979; Kinney et al., 1980). Neuroblastoma has also been reported in infants with both rectosigmoid and total colonic Hirschsprung's disease (Carachi et al., 1982; Michna et al., 1988).

114 CHAPTER Retinoblastoma

Key Points

- Most common intraocular tumor of childhood, with only a few cases diagnosed antenatally.
- Retinoblastoma develops in cells that have mutations in both copies of the gene *RB1*, which is located on chromosome 13q14.
- Retinoblastoma may be nonheritable or heritable. When familial, a single RB1 mutation is inherited as an autosomal dominant condition. Tumor formation then requires a second mutation. Heritable forms are predisposed to second malignancies, such as sarcoma.
- Prenatal sonography is an extremely insensitive screening technique for families at risk for recurrence. DNA diagnosis is definitive if the RB1 mutation is known.
- In fetuses with a suspected retinoblastoma and negative family history, work-up should include chromosome analysis with FISH probes for 13q14 deletion, level II sonography, and delivery in a tertiary setting.
- Many postnatal treatment options exist, including radiation, enucleation, and chemotherapy.

CONDITION

Retinoblastoma is the most common intraocular tumor of childhood (Donaldson et al., 1993). It is a malignant tumor that arises from the embryonic neural retina. This tumor is thought to be congenital, although it may not be recognized at birth. Although it usually presents during early childhood, there has been at least one report of retinoblastoma diagnosed in utero (Maat-Kievit et al., 1993). Retinoblastoma occurs in both sporadic and inherited forms, with the hereditary type predisposing to other malignant tumors (Abramson et al., 1984; Murphree and Benedict, 1984; Roarty et al., 1988; Wilson et al., 1996). Retinoblastoma is usually characterized by rapid growth, enlarging over a period of only weeks to destroy increasing amounts of the retina. The tumor can fill the eye, either by direct enlargement or by growth of tumor seeds. Once the globe is filled by the tumor, orbital and intracranial extension may occur. Retinoblastoma has been said to have a spontaneous regression rate of 1%, but this figure is sometimes confused with two separate processes (Gallie and Phillips, 1982). In the first process there is true regression after an enlarged intraocular tumor becomes totally necrotic. The tumor subsequently atrophies, resulting in a small, disorganized blind eye. The second process occurs in a functional eye as a benign variant of retinoblastoma, which has been termed "retinocytoma" or "retinoma" (Gallie and Phillips, 1982; Marga et al., 1983; Zimmerman, 1985). These tumors are usually composed of viable, benign-appearing tumor cells with a high degree of photoreceptor differentiation. On ophthalmoscopic examination, retinomas have an appearance similar to retinoblastomas that have undergone regression following radiotherapy. Despite the presence of the retinoma, vision is usually normal, but the genetic implications are the same as for retinoblastoma.

The majority of cases of retinoblastoma are diagnosed while the tumor remains confined to the eye. In contrast, in prenatal diagnosis, because of the insensitivity of sonographic evaluation of the eye, to be detected there must be gross extension to the orbit (Maat-Kievit et al., 1993). The most common postnatal sign in retinoblastoma is leukokoria of one or both eyes, which has been termed the "cat's-eye reflex" but which parents described as an unusual appearance of the eye (Donaldson et al., 1993). The next most common presenting sign is strabismus, which occurs when the tumor arises in the macula, causing loss of central vision and, therefore, loss of the fusional reflex so that the eye may drift, resulting in esotropia or exotropia. Other less common signs are orbital inflammation, hyphema, fixed pupil, and heterochromic irides. Vision loss is not a typical symptom at presentation because young children do not report unilaterally decreased vision. In addition, intraocular tumors are not painful unless secondary glaucoma or inflammation is present. Between 20% and 30% of cases are bilateral at the time of initial diagnosis. In these cases the disease is often multifocal, with several tumors in each eye. The presentation in utero is that of a sonographically detected ocular mass, which is irregular and echogenic, with extension beyond the orbit itself.

INCIDENCE

The incidence of retinoblastoma is estimated to be 1 in 15,000 to 1 in 34,000 livebirths (Devesa, 1975; Shields and Shields, 1990; Salim et al., 1998). The estimated frequency of bilateral cases of retinoblastoma in children is between 20% and 30% (Donaldson et al., 1993). There is no known racial or gender predisposition for this tumor. Retinoblastoma is a congenital tumor and is present at birth, although it is not often recognized at that time. Eighty percent of cases are diagnosed before the age of 3 to 4 years, with a mean time of presentation at 2 years of age. Bilateral retinoblastoma typically becomes clinically apparent earlier; the average age at diagnosis is 12 months (Shields and Shields, 1990). In rare cases, multiple congenital anomalies may be seen in association with retinoblastoma. However, these cases represent only 0.05% of cases of retinoblastoma reported in the United States (Jensen and Miller, 1971). The reported anomalies include congenital heart disease, cleft palate, Bloch–Sulzberger syndrome, infantile corital hyperasthosis, dentinogenesis imperfecta, incontinentia pigmenti, and familial congenital cataracts (Green, 1985).

SONOGRAPHIC FINDINGS

Only a few cases of retinoblastoma have been antenatally diagnosed (Maat-Kievit et al., 1993; Salim et al., 1998; Kodzov et al., 2002; Lehman, 2003). In the case reported by Maat-Kievit et al. (1993), a fetus at 21 weeks of gestation had an oval-shaped mass protruding from the right side of the face (Figure 114-1). The tumor was an irregular echogenic mass measuring 8 × 6 × 3 cm. The tumor was covered by a thin membrane with an echolucent rim between the membrane

Figure 114-1 Fetus at 22 weeks of gestation with a large tumor originating from the right eye. (*Reprinted from Maat-Kievit JA, Oepkes D, Hartwig NG, et al. A large retinoblastoma detected in a fetus at 21 weeks of gestation.* Prenat Diagn. *1993;13:377-384. Copyright John Wiley & Sons Limited. Reproduced with permission.*)

Table 114-1

Differential Diagnosis of Facial/Orbital Tumors Detected by Prenatal Sonographic Studies

Epignathus Sonolucent and (highly) echogenic areas Irregular shape Localization: nasopharyngeal area
Cephalocele Intracranial abnormalities, hydrocephaly, skull defect Smooth, rounded shape Localization: skull
Hemangioma Echogenic or sonolucent areas Pulsations, flow (Doppler) Localization: oral cavity
Myoblastoma Echogenic with small sonolucent areas Multilobular shape Localization: oral cavity
Dacryocystocele Sonolucent Small cyst Localization: inferomedial to the orbit
Retinoblastoma Irregular, echogenic, surrounded by sonolucent area Oval shape, covered by membrane Localization: eye

and the tumor. The majority of the face was obscured by the tumor. The tumor deformed the normal anatomy of the facial bones, and the contralateral orbit could not be seen. The differential diagnosis of a facial tumor detected by prenatal ultrasound examination and the features that distinguish them are listed in Table 114-1. It should be noted that ultrasound examination is an extremely insensitive screening technique for heritable retinoblastoma in families at risk for recurrence. In these cases, percutaneous umbilical blood sampling, CVS, or amniocentesis to obtain fetal tissue is recommended, as DNA-based prenatal diagnosis is available.

DIFFERENTIAL DIAGNOSIS

The case of retinoblastoma diagnosed at 21 weeks of gestation was found to have a very large oval-shaped mass protruding from the right side of the fetal face (Maat-Kievit et al., 1993). Histologic studies confirmed the diagnosis of retinoblastoma with extension beyond the orbit with an 8 × 6 × 3-cm mass rounded by a transonic area covered by a thin membrane. Because of the location and the size of this tumor the differential diagnosis included most causes of facial tumors (see Table 114-1). Epignathus is a tumor that grows through the floor of the mouth, is usually quite irregular in shape, and is localized primarily in the nasopharyngeal area. Although it has a heterogeneous appearance, with sonolucent and highly echogenic areas, its location usually distinguishes it from retinoblastoma. Encephalocele (see Chapter 12) is usually associated with intracranial abnormalities, such as hydrocephalus and calvarial defects. It is usually smooth, contoured, round in shape, and localized to the skull. In contrast, hemangiomas are usually readily identified by color flow Doppler studies, which show significant blood flow within the tumor mass. Myoblastomas are ordinarily localized to the oral cavity and tend to be echogenic, with other sonolucent areas within it. Dacryocystocele may be more difficult to distinguish from retinoblastoma because of its proximity to the eye. It is usually localized in the inframedial aspect of the orbit. Retinoblastoma is an irregular echogenic mass that may be surrounded by the sonolucent area that arises specifically from the eye (see Figure 114-1).

ANTENATAL NATURAL HISTORY

Retinoblastoma is a congenital tumor that arises from embryonic neural crest cells. In most newborns, as well as fetuses, retinoblastomas remain undetected until ophthalmologic symptoms arise during childhood (Liebman and Gellis, 1966; Gallie and Phillips, 1982; Abramson et al., 1983). It is thought that the onset of retinoblastoma must be after the transformation and first differentiation of the nervous layer of the pars optica of the retina in the fifth to eighth weeks of embryogenesis (England, 1983). In the case reported by Maat-Kievit et al. (1993), the fetus presented at 21 weeks with a large mass extending beyond the orbit. This suggests that the tumor cells must have undergone enormous mitotic activity to create such a large tumor in a brief time. This is not the usual presentation of retinoblastoma, which may not be detected for the first several years of life. Whether the natural history of retinoblastoma presenting prenatally is distinct from more typical cases that present in early childhood is unknown.

MANAGEMENT OF PREGNANCY

Fetuses in which retinoblastoma is suspected should be referred to a tertiary care center capable of anatomic sonographic diagnosis of the fetus. Level 2 sonograms should be obtained to exclude the possibility of associated congenital anomalies, including cleft palate and congenital heart disease. Because of the potential for associated congenital heart disease, if any abnormalities are detected on four-chamber view of the heart, or the outflow tracts or abnormalities in

cardiac axis are detected, formal echocardiography is indicated. Chromosome analysis should be considered to look for deletions in chromosome band 13q14. FISH probes are available specifically for this region. If a deletion is found, the parental chromosomes also need to be analyzed.

If retinoblastoma is detected prior to 24 weeks of gestation, the parents should be counseled about the option of terminating the pregnancy. No treatment options are currently available in utero, and the parents should be informed that a retinoblastoma of a sufficient size to be detected sonographically places the fetus in a very poor prognostic category. Postnatal survival with tumors of this nature is poor, with only a third of the eyes being salvageable, and the cure rate is less than 25%.

Although data regarding the management of the pregnancy are scarce, as few cases have been diagnosed prenatally, consideration should be given to delivery at lung maturity for immediate postnatal therapy. It is unclear if cesarean section is warranted and should be based on an assessment of the size of the tumor close to the time of delivery. Delivery should be planned in a tertiary care setting, with pediatric ophthalmologists, oncologists, and radiation therapists available to plan the treatment of the newborn.

FETAL INTERVENTION

There is no fetal treatment for retinoblastoma. However, in a fetus with an RB1 mutation that had sonographically detected tumors, preterm delivery was induced to initiate postnatal treatment (Gallie et al., 1999).

TREATMENT OF THE NEWBORN

The neonate should be carefully examined for the presence of associated anomalies. An ophthalmologic consultation should be obtained to assess the extent of the tumor, as well as the contralateral eye. Molecular genetic testing should be performed on peripheral blood to identify the two RB1 mutations that inactivated both *RB1* alleles. If no mutations are detected in the blood and the eye(s) requires enucleation, tumor DNA should also be studied.

SURGICAL TREATMENT

The goals of treatment are first, to preserve life and second, to preserve sight. Retinoblastoma cure rates exceed 90% with current treatment methods (Shields and Shields, 1990). Specific treatment approaches vary from center to center, and increasing attention is now focused on preservation of visual function. Enucleation of the eye is considered when there is no hope for useful vision, even if the tumor is thought to be eradicated. A cosmetic disadvantage of this approach is that in children younger than 3 years of age the orbit ceases to grow normally after the eye is removed, and as the face of the infant grows the orbit looks increasingly sunken (see Chapter 29). External beam radiation therapy produces the same appearance due to inhibition of bone growth. The indication for cryotherapy and photocoagulation are similar; however, both techniques can successfully treat only small lesions, less than 3 mm in diameter and 2 mm thick. Episcleral plaque radiotherapy may be superior to external beam irradiation in delivering a higher local tumor radiation dose with considerably lower orbital and facial radiation and may be used in solitary tumors less than 8 mm in thickness.

Retinoblastomas are considered radiosensitive. The purpose of radiation therapy for retinoblastomas is control of local disease while preserving vision. Because the majority of patients will have multiple tumors in one or both eyes and these tumors may be multifocal in origin, radiation fields must include the entire geographic extent of the retina, the anterior border of which is the ora serrata. In an attempt to preserve vision, external beam or episcleral plaque radiotherapy has become the treatment of choice for the majority of children with retinoblastoma. Any eye that has a chance for useful vision should be considered for radiation therapy rather than enucleation. The results of chemotherapy treatment for intraocular retinoblastoma have been disappointing because intraocular penetration of systemic drugs is poor and tumors often express the membrane glycoprotein p170 and become drug-resistant (Chan et al., 1989). Adjuvant chemotherapy has been tested in children with group V disease (tumors involving more than half the retina or with vitreous seeding) after enucleation, with no survival advantage over enucleation alone (Abramson, 1985). Chemotherapy is best restricted to patients with extraocular disease or regional or distant metastases (Pizzo et al., 1985).

After initial treatment, patients must be examined closely for tumor regrowth, extraocular extension, and/or vitreous seeding, and additional radiation, laser, cryotherapy, or adjuvant chemotherapy may be indicated in these cases.

Coordinated follow-up between the ocular oncologist and the primary care specialist is essential because of the likelihood of retinoblastoma recurrence, treatment-associated morbidity, and development of a second tumor that is not retinoblastoma.

LONG-TERM OUTCOME

Patients with heritable retinoblastoma have an increased risk for developing other malignancies (Abramson et al., 1984; Roarty et al., 1988; Wilson et al., 1996). In one study, 13% of patients with retinoblastoma, treated by radiation therapy, had second malignancies. Seventy percent of these tumors were in and 30% outside the irradiation field (Abramson et al., 1984). In the same study, there were 23 patients who did not receive radiation therapy and 5 of these had second malignant tumors. These tumors were predominately sarcomas, with osteosarcoma the tumor most frequently reported. The incidence of second malignant tumors appears to increase with time, with a 20% incidence after 10 years. This rises to 50% at 20 years, and at 30 years it approaches 90% (Abramson et al., 1984).

There is considerable controversy regarding the true rate of second malignancy in retinoblastoma survivors. Long-term follow-up studies vary widely with respect to long-term incidence, with reported rates of second malignancy between 25% and 90% at 30-year follow-up. Because of the increasing risk of the development of a second tumor, patients should be examined periodically by the primary care physician. In particular, patients with bilateral retinoblastoma are always at risk for the development of second tumor; the longest reported interval is 57 years between primary retinoblastoma diagnosis and second tumor presentation (Wilson et al., 1996).

GENETICS AND RECURRENCE RISK

Retinoblastoma develops in cells that have mutations in both copies of *RB1*, the retinoblastoma locus, which is located on chromosome 13q14 (Sparkes et al., 1980). Cytogenetic analysis has revealed that there is a deletion of band 13q14 in 5% to 10% of patients with retinoblastoma (Howard, 1982; Lemieux and Richer, 1990). Genetic and physical mapping indicates that the retinoblastoma gene is closely linked to the genetic locus for esterase D, which maps exactly to this region (Sparkes et al., 1983; Lee and Lee, 1986; Squire et al., 1986).

RB1 is the only gene known to be associated with retinoblastoma. *RB1* is 200,000 base pairs in size and it encodes a protein of 928 amino acids. The *RB1* gene product is a nuclear phosphoprotein with DNA-binding activity that is expressed in many different types of cells (Lee et al., 1987). RB1 protein forms complexes with viral oncoproteins of several DNA tumor viruses (DeCaprio et al., 1988; Whyte et al., 1988). Many studies have suggested that the RB1 protein plays a role in the regulation of cell growth (Chan et al., 1989).

Retinoblastoma may be either nonheritable or of the heritable type that shows an autosomal dominant inheritance pattern with a high degree of penetrance (Nussbaum and Puck, 1976; Vogel, 1979). If there is a positive family history, genetic counseling becomes more straightforward because this is clearly a heritable case of retinoblastoma (Cavenee et al., 1986; Yandell et al., 1989; Draper et al., 1992). In sporadic cases, which include the majority of patients, this may be either heritable or nonheritable. Bilateral sporadic cases are always heritable, and each child of the affected patients who survive will have a 50% risk of having retinoblastoma. Unilateral sporadic cases may be either heritable or nonheritable, with empiric risk studies revealing a 10% to 12% risk of having heritable type and that the first child of a survivor has a 5% to 6% chance of having the disease (Vogel, 1979). If normal parents have one affected child, the risk of their next child having a retinoblastoma is approximately 1% if the first child has a unilateral tumor and 6% if the child has bilateral tumors. To rule out the possibility that one parent is silently clinically affected with an unsuspected retinoblastoma, both parents should have ophthalmologic examinations to facilitate accurate genetic counseling.

DNA-based prenatal diagnosis is available for families in which one parent is affected with a heritable RB1 mutation (Wiggs et al., 1988). For these families a 50% recurrence risk exists. DNA analysis is much more accurate than prenatal sonography (Dryja et al., 1989; Gallie et al., 1991; Naumova and Sapienza, 1994). Preimplantation genetic diagnosis of retinoblastoma is also available for families at risk for the disease to screen embryos prior to embryo transfer (Girardet et al., 2003; Xu et al., 2004; Thornhill, 2005).

115 CHAPTER

Sacrococcygeal Teratoma

Key Points

- Sacrococcygeal teratomas (SCTs) arise from a totipotent stem cell in Henson's node.
- Most SCTs are large, complex, solid, and cystic masses but may have intrapelvic or intra-abdominal extension.
- Ultrasound alone will make the diagnosis, but fetal MRI will help define anatomic relations, and echocardiographs will evaluate high-output state.
- SCTs that are >10 cm, solid, highly vascular, or rapidly growing are at highest risk for hydrops.
- Fetal surgery may be an option in cases that develop early signs of hydrops.
- Cesarean section is usually indicated for large SCTs due to risk of rupture and exsanguination.
- SCTs are usually benign but can have immature elements or rests of malignant yolk sac tumor.
- Close serial follow-up for at least 3 months for tumor recurrence is indicated with serial α-fetoprotein levels, physical exam, and imaging studies.

CONDITION

Sacrococcygeal teratoma (SCT) is defined as a neoplasm composed of tissues from either all three germ layers or multiple foreign tissues lacking an organ specificity arising in the sacrococcygeal region (Gross et al., 1951; Mahour et al., 1975). Because of the multiple cell lineages that characterize these tumors, it was previously suggested that SCT was of germ cell origin or a form of fetus in fetu (Theiss et al., 1960; Linder et al., 1975). Early theories suggested a "twinning accident" with incomplete separation during embryogenesis and abnormal development of one fetus (Waldhausen et al., 1963; Ashley, 1973; Cousins et al., 1980). In support of this theory, several authors have noted a family history of twinning in many SCT patients (Hickey and Layton, 1954; Grosfeld et al., 1976; Gross et al., 1987). However, more recently, SCT has been thought to arise from a totipotent somatic cell originating in Hensen's node (Gross et al., 1987). This node is a caudal cell mass in the embryo that appears to escape normal inductive influences (Bale, 1984). Others hypothesize that SCT is derived from totipotent cells in reproductive gland anlage (Abbott et al., 1966).

SCT has been classified by the relative amounts of presacral and external tumor present [American Academy of Pediatrics Surgery Section (AAPSS) Classification (Table 115-1 and Figure 115-1)] (Altman et al., 1974). The utility of this classification scheme lies in the relationship between stage and timing of diagnosis, ease of resection, and malignant potential. Type I SCT is evident at birth, is usually easily resected, and has a low malignant potential. Similarly, types II and III SCT are recognized at birth, but resection may be difficult, requiring both an anterior and a posterior approach. In type IV SCT, the diagnosis may be delayed until it becomes symptomatic at a later age. Malignant transformation has frequently occurred by the time a type IV SCT is diagnosed.

Table 115-1

AAPSS Staging Classification of Sacrococcygeal Teratomas

Type	Description
I	Completely external; no presacral component
II	External component and internal pelvic component
III	External component and internal component extending into abdomen
IV	Completely internal and no external component

Adapted from Altman RP, Randolph JG, Lilly JR. Sacrococcygeal teratoma: American Academy of Pediatrics Surgical Section Survey 1993. J Pediatr Surg. *1974;9:389-398.*

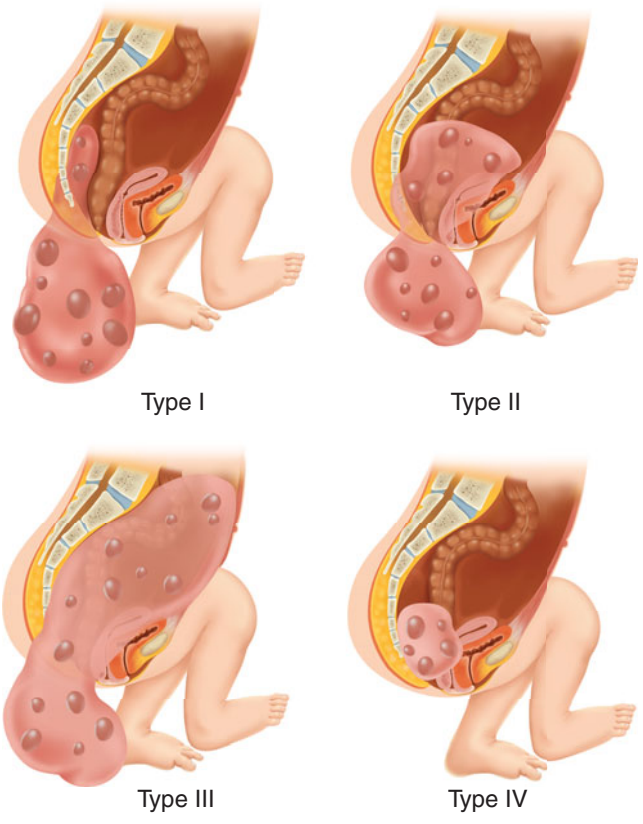

Figure 115-1 AAPSS classification of the different types of sacrococcygeal teratoma, based on the location of the tumor. (*Reprinted, with permission, from Holzgreve W, Flake AW, Langer JC. The fetus with sacrococcygeal teratoma. In: Harrison MR, Golbus MS, Filly RA, eds.* The Unborn Patient. *Philadelphia: WB Saunders; 1991:461*).

INCIDENCE

SCT is one of the most common tumors in newborns; however, it is still rare, occurring in 1 in 23,000 to 1 in 40,000 livebirths (Schiffer and Greenberg, 1956; Altman et al., 1974; Tapper and Lack, 1983; Forrester and Merz, 2006). Females are four times more likely to be affected as males, however, malignant change is more frequently observed in males (Abbott et al., 1966; Conklin and Abell, 1967; Carney et al., 1972; Fraumeni et al., 1973; Altman et al., 1974).

SONOGRAPHIC FINDINGS

Retrospective prenatal diagnosis of SCT was first made in the mid-1970s, and the first prospective prenatal diagnosis was reported by Horger and McCarter in 1979. They described a 13-cm complex mass at the caudal end of the fetus, with solid and cystic areas and bizarre internal echoes associated with polyhydramnios. This typical prenatal sonographic appearance has been confirmed by other authors (Figure 115-2) and approximately 60 cases of prenatally diagnosed SCT have been reported (Seeds et al., 1982; Grisoni et al., 1988; Bond et al.,

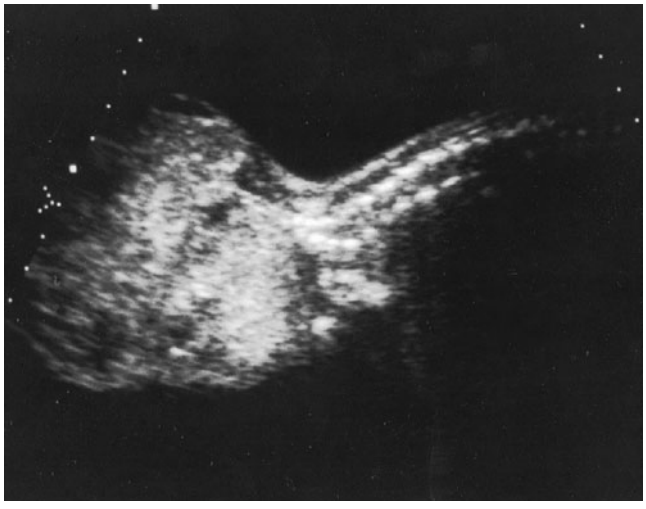

Figure 115-2 Prenatal sonographic image demonstrating large type II sacrococcygeal tumor in a 23-week-old fetus. In this view, the intrapelvic extent of the tumor cannot be seen.

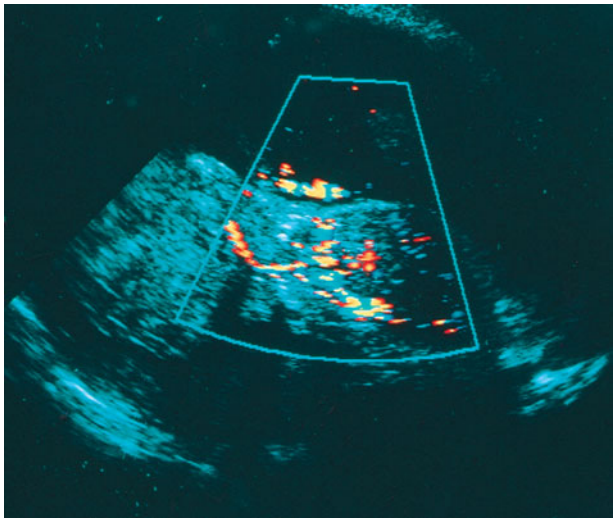

Figure 115-3 Color flow Doppler study of the same fetus shown in Figure 115-1 demonstrating the vascularity of the tumor.

1990). The most common clinical presentation is uterine size greater than dates, initiating an ultrasound examination (Seeds et al., 1982). To date, the earliest diagnosis of SCT that has been made is 12 3/7 weeks of gestation (Roman et al., 2004).

SCTs can grow at an unpredictable rate to tremendous dimensions. Several case reports note fetal tumors as large as 25 by 20 cm (Heys et al., 1967; Weiss et al., 1976). These tumors are generally exophytic (AAPSS type I), but may extend retroperitoneally displacing pelvic (type II) or abdominal structures (type III) (Litwiller, 1969).

Most SCTs are solid or mixed solid and cystic, consisting of randomly arranged irregularly shaped cysts (Seeds et al., 1982; Chervenak et al., 1985). Purely cystic SCT has also been described prenatally (Seeds et al., 1982; Hogge et al., 1987). Calcifications can be seen microscopically, although the majority are not visible on prenatal ultrasound examination. Most prenatally diagnosed SCTs are extremely vascular, which is easily demonstrated with the use of color flow Doppler studies (Figure 115-3). Three-dimensional power Doppler has been suggested to demonstrate the large vascular volume in SCT (Sciaky-Tamir et al., 2006). Polyhydramnios has been noted in most cases of prenatally diagnosed SCT, and—although the mechanisms for this are not known—it is likely secondary to renal hyperfiltration occurring as a result of high-output state (Chervenak et al., 1985).

Hepatomegaly, placentomegaly, and nonimmune hydrops have also been seen in association with SCT and appear to be secondary to high-output cardiac failure (Heys et al., 1967; Cousins et al., 1980; Gergely et al., 1980; Kapoor and Saha, 1989; Bond et al., 1990; Flake, 1993; Hedrick et al., 2004). High-output failure may be due to tumor hemorrhage or arteriovenous shunting within the tumor (Cousins et al., 1980; Flake et al., 1986; Alter et al., 1988; Schmidt et al., 1989; Bond et al., 1990). Some authors have attributed heart failure with subsequent hydrops to severe fetal anemia secondary to tumor hemorrhage (Alter et al., 1988). However, normal fetal hematocrits have also been reported, suggesting that congestive heart failure is more often due to high-output cardiac failure from arteriovenous shunting within the tumor (Schmidt et al., 1989). The demonstration of heart failure or hydrops on ultrasound examination is usually a preterminal event (Flake et al., 1986; Kuhlmann et al., 1987; Bond et al., 1990).

Controversy exists regarding the presence of associated anomalies and the need for chromosome analysis. The incidence of coexisting anomalies is 11% to 38%, primarily involving the nervous, cardiac, gastrointestinal, genitourinary, and musculoskeletal systems (Hickey and Layton, 1954; Schiffer and Greenberg, 1956; Carney et al., 1972; Fraumeni et al., 1973; Altman et al., 1974; Izant and Filston, 1975; Gonzalez-Crussi et al., 1978; Ein et al., 1980; Holzgreve et al., 1985; Kuhlmann et al., 1987; Werb et al., 1992). Several authors postulate that at least some of these anomalies are related to tumor development. Others have reported an increased incidence of spinal deformities (Ewing, 1940; Gruenwald, 1941; Alexander and Stevenson, 1946; Bentley and Smith, 1960; Wilson et al., 1963; Carney et al., 1972). Most authors agree with Berry et al.'s (1970) observation that local abnormalities such as rectovaginal fistula and imperforate anus are thought to be directly related to tumor growth during fetal development. Aneuploidy has not been reported with SCT and we do not recommend amniocentesis for karyotype analysis unless there are multiple anomalies, advanced maternal age, or fetal surgery is contemplated.

Fetal MRI has emerged as an adjunctive imaging modality that can provide important anatomical detail in cases of SCT (Avni et al., 2002; Hedrick et al., 2004; Nassenstein et al., 2006). MRI may be particularly useful in defining the pelvic component of SCT and impact on other pelvic structures (Garel et al., 2005). In cases in which fetal surgery is being considered, fetal MRI provides a broader field of view than

ultrasound and may be helpful in operative planning. In cases in which SCT has a pelvic component or there is polyhydramnios, oligohydramnios, hydronephrosis or hydrocolpos, fetal MRI may provide additional information on the anatomical relationships not apparent on ultrasound alone (Danzer et al., 2006). Fetal MRI in cases of cystic SCT may be particularly helpful in excluding myelomeningocele from the differential diagnosis (Yoon and Park, 2005; Danzer et al., 2006).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of SCT includes lumbosacral myelomeningocele, which invariably demonstrates a spinal defect. Myelomeningoceles have a cystic or semicystic rather than a solid appearance and do not contain calcifications. Examination of the fetal brain is helpful in establishing the diagnosis, as most fetuses with lumbosacral myelomeningocele will have associated cranial findings. Rarer entities that mimic SCT include neuroblastoma, glioma, hemangioma, neurofibroma, cordoma, leiomyoma, lipoma, melanoma, and any of 50 tumors or malformations reported in the sacrococcygeal region (Table 115-2) (Lemire and Beckwith, 1982; Sebire et al., 2004; Tanaka et al., 2005).

Biochemical markers such as α-fetoprotein (AFP) and acetylcholinesterase are not reliable in distinguishing SCTs from other abnormalities (Holzgreve et al., 1987). It has been suggested, however, that AFP can be used to differentiate benign from malignant tumors, as marked elevations of AFP may reflect the presence of a malignant endodermal sinus component to the tumor (Tsuchilda et al., 1975; Grosfeld et al., 1976; Gonzalez-Crussi et al., 1978; Gonzalez-Crussi, 1982). AFP levels can be extremely high in normal newborns, limiting the utility of this marker to distinguish benign from malignant lesions (Ohama et al., 1997).

** This table lists reported tumors and malformations of the sacrococcygeal region in postnatal patients. Not all have been diagnosed prenatally. Source: Lemire RJ, Beckwith JB. Pathogenesis of congenital tumors and malformations in the sacrococcygeal region.* Teratology *1982;25:201-213.*

ANTENATAL NATURAL HISTORY

The antenatal natural history of prenatally detected SCT is not as favorable as that of SCT presenting at birth. Well-defined prognostic factors for SCT diagnosed postnatally, as outlined in the AAPSS classification system, do not necessarily apply to fetal cases (Altman et al., 1974; Bond et al., 1990) (see Table 115-1). While the mortality rate for SCT diagnosed in the newborn is at most 5%, the mortality rate for fetal SCT approaches 50% (Flake et al., 1986; Bond et al., 1990; Flake, 1993; Hedrick et al., 2004).

Most SCTs are histologically benign. The incidence of malignant elements present in fetal SCT has ranged from 7% to 30% (Hedrick et al., 2004; Heerema-McKenny et al., 2005). Malignancy appears to be more common in males, especially with solid versus complex or cystic tumors (Schey et al., 1977). The presence of histologically immature tissue does not necessarily signify malignancy (Carney et al., 1972; Gonzalez-Crussi, 1982). Calcifications occur more often in benign tumors but may also be seen in malignant tumors and are unreliable indicators of malignant potential (Hickey and Layton, 1954; Waldhausen et al., 1963; Grosfeld et al., 1976; Schey et al., 1977; Horger and McCarter, 1979). Although there is one reported case of malignant yolk sac differentiation in a fetal SCT, there has not been a case of metastatic teratoma in a neonate with a prenatally diagnosed SCT (Holzgreve et al., 1985; Flake, 1993).

The prenatal history of SCT is quite different from the postnatal natural history. Flake et al. (1986) reviewed 27 cases of prenatally diagnosed SCT. Five cases were electively terminated and 15 of the remaining 22 died, either in utero or shortly after delivery. The majority of these patients presented between 22 and 34 weeks of gestation with a uterus large for gestational age secondary to severe polyhydramnios. The presence of hydrops and/or polyhydramnios was associated with intrauterine fetal death in seven of seven cases. The International Fetal Medicine and Surgery Society reported a mortality rate of 52% among cases of prenatally diagnosed

SCT (Bond et al., 1990). When SCT was seen in association with placentomegaly or hydrops, all affected fetuses died in utero. The indication for ultrasound examination was also found to be a predictive factor. If SCT was an incidental finding, the prognosis was favorable at any gestational age. However, if the ultrasound examination was performed for maternal indications, 22 of 32 fetuses died. In addition, diagnosis prior to 30 weeks was associated with a poor outcome.

Sheth et al. (1988) also reported significant perinatal mortality associated with SCT, with only 6 survivors among 15 cases diagnosed prenatally. Three of four cases associated with hydrops were rapidly fatal. The sole survivor was salvaged by emergency cesarean section at 35 weeks. This series was unusual because three cases had severe obstructive uropathy and secondary renal dysplasia. A more favorable outcome was reported by Gross et al. (1987) in which 8 of 10 fetuses with prenatally diagnosed SCT survived. However, no fetus had hydrops or placentomegaly, and the two nonsurvivors were electively terminated.

Hydrops in SCT is usually, but not always, fatal. Nakoyama et al. (1991) reported survival in two fetuses with SCT presenting with hydrops at 27 and 30 weeks of gestation. In addition, Robertson et al. (1995) were able to salvage a hydropic fetus at 26 weeks of gestation by staged resection of the SCT in the neonatal period (Figure 115-4). In this case, acute rapid growth of the SCT led to polyhydramnios and preterm delivery. After delivery, the newborn was noted to be in a high-output state from shunting through the tumor. In a staged resection, the tumor was initially devascularized by ligation of both internal iliac arteries. Twenty-four hours later, the external portion of the mass was resected. The infant subsequently underwent resection of the intrapelvic portion of the tumor at 3 months of age, and did well.

Hedrick et al. (2004) reviewed their experiences with 30 cases of prenatally diagnosed SCT and reported 4 terminations, 5 fetal deaths, 7 neonatal deaths, and only 14 survivors (47%). Among the 26 patients continuing the pregnancy, 81% experienced obstetric complications including polyhydramnios ($n = 7$), oligohydramnios ($n = 4$), preterm labor ($n = 13$), pre-eclampsia ($n = 4$), gestational diabetes ($n = 1$), HELLP syndrome ($n = 1$), and hyperemesis ($n = 1$).

Sonographic features of SCT such as size, AAPSS classification, solid or cystic composition, or presence or absence of calcifications have not been predictive of either fetal survival or future malignant potential (Altman et al., 1974; Flake, 1993). One exception to this may be the unilocular cystic form of SCT, which has a relatively favorable prognosis because of benign histology and limited vascular and metabolic demand (Horger and McCarter, 1979; Mintz et al., 1983). The growth of the SCT in relation to the size of the fetus is also unpredictable and may increase, decrease, or stabilize as gestation proceeds. However, a rapid phase of tumor growth usually precedes the development of placentomegaly and hydrops.

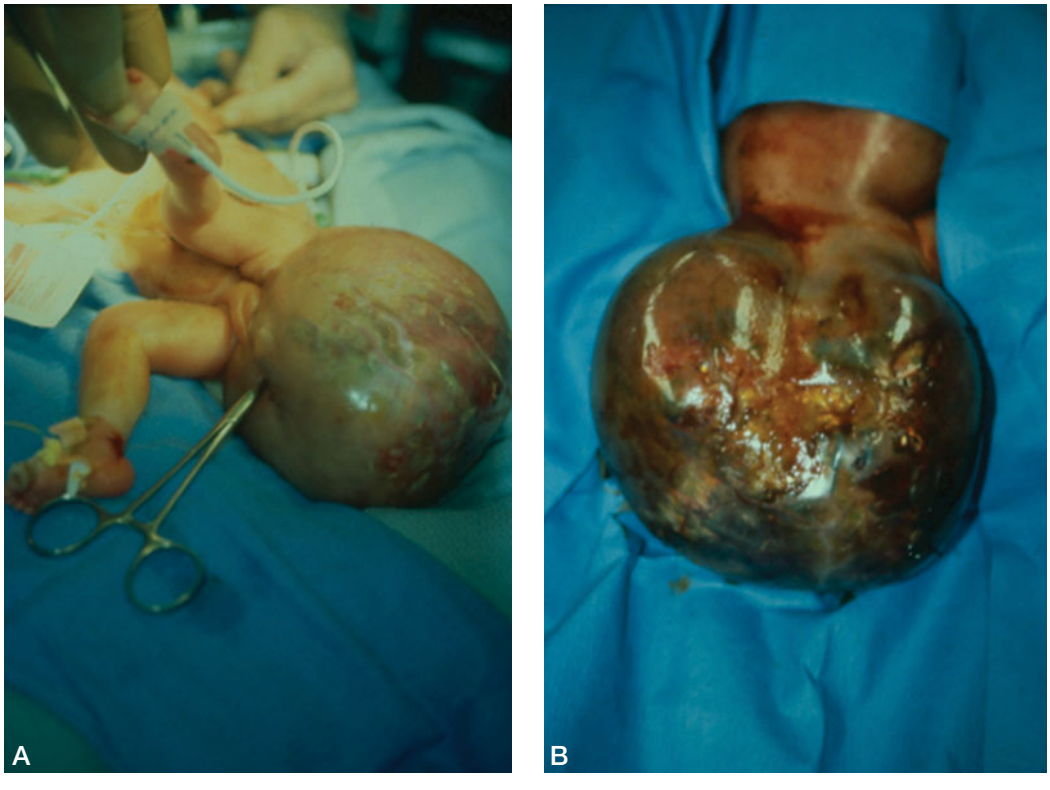

Figure 115-4 Postnatal photograph of a 26-week-gestation premature newborn with a large SCT. **A.** The SCT has distorted the perineum so that the anus is in a plane anterior to the genitalia. The tip of the clamp is in the anal orifice. **B.** The same tumor following devascularization.

Highly vascular lesions are more likely to undergo rapid tumor growth and to be associated with the development of placentomegaly and hydrops. The prenatal mortality, unlike postnatal mortality, is not due to malignant degeneration, but to complications of tumor mass or tumor physiology (Flake et al., 1993). The tumor mass may result in malpresentation or dystocia, which in turn may result in tumor rupture and hemorrhage during delivery. Dystocia has been reported in 6% to 13% of cases in postnatal series (Giugiaro et al., 1977; Musci et al., 1983; Gross et al., 1987). SCTs may also spontaneously rupture in utero leading to significant fetal anemia or death (Sy et al., 2006). The most important benefit of prenatal diagnosis is prevention of dystocia by elective or emergency cesarean section. Tumor mass effect may also result in uterine instability and preterm delivery because of uterine distention (Flake et al., 1986; Bond et al., 1990). Massive polyhydramnios is frequently seen in large fetal SCT, which also predisposes to uterine irritability and preterm delivery.

SCT may occur in twins further complicating the prenatal management. In Hedrick et al.'s series, 10% of the cases occurred in twin gestations (Hedrick et al., 2004). The presence of SCT in a twin gestation increases the risk of preterm delivery. Because SCT is associated with an increased risk of fetal death, intrauterine demise of a monochorionic twin with SCT places the surviving unaffected co-twin at risk of adverse neurologic outcome (Ayzen et al., 2006).

The physiologic consequence of fetal SCT depends on the metabolic demands of the tumor, blood flow to the tumor, and the presence and degree of anemia. The features of the SCT—whether cystic or solid, size, and rate of growth—all affect the metabolic demands of fetal SCT. While classically thought to derive its blood supply from the middle sacral artery (Smith et al., 1961), these large tumors often parasitize blood supply from the internal and external iliac systems. This may result in vascular "steal" from the umbilical artery blood flow to the placenta. As an SCT outgrows its blood supply, tumor necrosis may occur leading to tumor rupture and hemorrhage. The high-output cardiac failure in fetal SCT can be diagnosed by fetal echocardiography and Doppler study (Flake et al., 1986; Langer et al., 1989; Schmidt et al., 1989). When hydrops develops in fetuses with SCT, all have dilated ventricles and dilated inferior venae cavae due to increased venous return from the lower body (Flake, 1993). Serial sonographic examinations in fetal SCT often show progressive increases in combined ventricular output and descending aortic flow velocity. In general, placental blood flow is decreased by the vascular steal by the SCT (Schmidt et al., 1989; Flake, 1993) and may lead to the finding of end-diastolic flow reversals in the umbilical artery.

Benachi et al. (2006) have suggested a prenatal prognostic classification system based on tumor diameter, vascularity, and rapidity of growth. In a group of 44 fetal SCTs divided into group A (tumor <10 cm, absent or mild vascularity and slow growth), group B (tumor ≥ 10 cm, pronounced vascularity or high output cardiac failure and rapid growth), and group C (tumor ≥ 10 cm, predominantly cystic lesion with absent or mild vascularity and slow growth). Groups A and C did well with gestational age at delivery of 38 and 37 weeks, respectively while group B delivered prematurely at 31 weeks of gestation. There was no mortality in either group A or C but was 52% for group B. The newborns in group B also have a much longer length of stay postnatally (Benachi et al. 2006). Postnatal measurements of umbilical arterial blood gases before and after removal of a large SCT demonstrate that the tumor acts as a large arteriovenous shunt.

MANAGEMENT OF PREGNANCY

Although the primary cause of death in neonatal SCT is malignant invasion, in prenatal SCT the complications of prematurity or exsanguinating tumor hemorrhage at delivery predominate (Flake et al., 1986; Bond et al., 1990; Adzick and Harrison, 1994). Weekly sonographic examinations should be performed during pregnancy to assess amniotic fluid index, tumor growth, fetal well-being, and early evidence of hydrops (Chervenak et al., 1985; Langer et al., 1989). Serial Doppler echocardiographic evaluations should be performed in all patients to detect early signs of high-output state, as evaluated by an increased diameter of the inferior vena cava (should be >1 cm), increased descending aortic flow velocity (>120 cm/s) (Alter et al., 1988; Flake, 1993; Bahlmann et al., 2001), or increased combined ventricular output (>500 mL/kg/min for CVO) (Bahlmann et al., 2001). Evidence of the earliest signs of heart failure, placentomegaly, and/or hydrops should be sought, as these may progress rapidly and are harbingers of preterminal events (Langer et al., 1989). Bond et al. (1990) reported a uniformly fatal outcome when SCT was associated with placentomegaly and/or hydrops. Flake et al. (1986) reported seven of seven fetal deaths in pregnancies complicated by placentomegaly and hydrops.

Weekly amniocenteses to determine pulmonary maturity are recommended by some physicians after 36 weeks of gestation, with delivery once fetal lung maturity is established (Adzick and Harrison, 1994). Many pregnancies complicated by SCT do not reach this gestational age however. Warning signs and symptoms of preterm labor should be stressed at prenatal visits, and limitation of activity, treatment, and cervical checks may be indicated (Garmel et al., 1994).

The recommended mode of delivery is determined by the size of the tumor. Vaginal delivery may be possible with some small tumors (Grisoni et al., 1988; Flake, 1993). Complications of vaginal delivery, however, have included fetal death after rupture, avulsion, or asphyxia (Schiffer and Greenberg, 1956; Heys et al., 1967; Grosfeld et al., 1976; Giugiaro et al., 1977; Chervenak et al., 1985; Holzgreve et al., 1987; Werb et al., 1992). Cesarean delivery is recommended to avoid trauma-induced hemorrhage or dystocia, especially in large (>5–10 cm) tumors (Chervenak et al., 1985; Gross et al., 1987; Hogge et al., 1987; El-Qarmalaui et al., 1990; Flake, 1993). The size of the tumor may also influence the type of uterine incision. A large tumor may warrant a classical uterine incision, especially in a preterm infant (Chervenak et al., 1985).

Dystocia has been reported when the diagnosis of SCT was unsuspected in as many as 6% to 13% of cases (Hickey and Layton, 1954; Schiffer and Greenberg, 1956; Seidenberg and Hurwitt, 1958; Lowenstein et al., 1963; Hickey and Martin, 1964; Abbott et al., 1966; Lu and Lee, 1966; Heys et al., 1967; Desai, 1968; Kowalski and Sokolowska-Pituchowa, 1968; Werner and Swiecicka, 1968; Litwiller, 1969; Weiss et al., 1976; Seeds et al., 1982; Tanaree, 1982; Edwards, 1983; Mintz et al., 1983; Musci et al., 1983; Varga et al., 1987; El-Shafie et al., 1988; Johnson et al., 1988). Transabdominal and transvaginal aspirations of large cysts have been attempted with variable results to facilitate delivery in the face of significant dystocia (Abbott et al., 1966; Desai, 1968; Litwiller, 1969; Weiss et al., 1976; Tanaree, 1982; Edwards, 1983; Mintz et al., 1983; Musci et al., 1983; El-Shafie et al., 1988; Johnson et al., 1988). Cyst decompression has also been used to treat maternal discomfort, and in one case cyst amniotic shunting was used to treat bladder outlet obstruction due to tumor compression (Garcia et al., 1998; Kay et al., 1999; Jouannic et al., 2001). It is hoped that prenatal detection of SCT will prevent such unforeseen emergencies (Musci et al., 1983).

Fetal SCT is sometimes associated with maternal complications. The mother should be observed for signs and symptoms of pre-eclampsia, such as the "mirror syndrome" described by Nicolay et al. in association with SCT and hydrops (Nicolay and Gainey, 1964; Cousins et al., 1980; Flake et al., 1986; Coleman et al., 1987; Langer et al., 1989; Bond et al., 1990). Delivery should be performed in a tertiary care center, with neonatologists and pediatric surgeons available.

FETAL INTERVENTION

The uniformly dismal outcome in fetuses with SCT complicated by placentomegaly and hydrops has been the impetus for resection of this tumor in utero. Harrison was the first to attempt antenatal resection of an SCT (Langer et al., 1989). In this first case, a fetus was noted to be markedly hydropic with a significantly elevated combined ventricular output (972 mL per kilogram of body weight per minute) at 24 weeks (Langer et al., 1989; Flake, 1993). In addition, the mother had mild hypertension, edema, and proteinuria. Preterm labor developed that was controlled with tocolytic agents. At surgery, the exophytic portion of the tumor was dissected free of the anus and rectum and amputated at its base with a stapling device. Despite the resection, the fetus remained hydropic, with an elevated combined ventricular output of 869 mL per kilogram of body weight per minute. Percutaneous umbilical cord blood sampling showed the fetal hematocrit to be only 16%. This was increased to 27% by blood transfusion. The fetus subsequently improved significantly, with sonographic resolution of hydrops, and a decrease in descending aortic flow to 524 mL/kg of body weight per minute. However, the maternal mirror syndrome progressed to pulmonary edema and on postoperative day 12 a 26-week-gestation fetus was delivered by cesarean section and died of pulmonary immaturity at 6 hours of age. The mother's illness resolved within 2 days. Autopsy showed no evidence of hydrops and no residual tumor.

A second case was attempted at 26 weeks of gestation, when dramatic enlargement of the tumor resulted in early hydrops, elevated combined ventricular output, and severe polyhydramnios (Flake, 1993). The surgery went uneventfully, and the base of the tumor was stapled to excise the exophytic portion and reverse the hyperdynamic state. The fetus did well until postoperative day 8, when irreversible preterm labor developed and the fetus was delivered by emergency cesarean section. Because the histology of the resected specimen was interpreted as an immature teratoma grade III/III, with predominance of neuroepithelial elements and foci of yolk sac differentiation, resection of residual tumor was attempted on the 13th day of postnatal life. During dissection of the presacral space the baby experienced complete cardiovascular collapse due to a paradoxical air embolism. The histology of the tumor revealed grade III/III immature teratoma, but the residual tumor was more mature than the previous tumor specimen and contained no foci of yolk sac differentiation.

The first successful resection of fetal SCT with long-term survival was reported by Adzick et al. (1997). At 25 weeks of gestation a type II SCT had rapid enlargement and development of polyhydramnios and placentomegaly, with associated maternal tachycardia and proteinuria suggesting impending maternal mirror syndrome (Figure 115-5). At surgery, the exophytic portion of the tumor was dissected free of the anus and rectum and the base of the tumor excised with a thick tissue stapling device (Figure 115-6). The mother and fetus did well postoperatively, with resolution of hydrops and placentomegaly within 10 days. Pathology of the tumor showed grade III/III immature teratoma without evidence of yolk sac differentiation. At 29 weeks of gestation preterm labor prompted cesarean delivery. Postnatally, the female infant underwent resection of the coccyx and surrounding tissue at 2 months of age, but no residual tumor was found. She did well until 1 year of age when AFP levels became elevated to 22,000 ng/mL and she presented with pleural effusions, lung nodules, and a recurrent buttock mass from a metastatic yolk sac tumor. She has had an excellent response to chemotherapy. Hedrick et al. subsequently reported their experience with four open fetal surgeries for SCT with all four surviving the procedure to delivery at an average gestational age of 29 weeks (range 27.6–31.7 weeks). There was one neonatal death due to premature closure of the ductus arteriosus thought to be secondary to indomethacin exposure as a tocolytic following fetal surgery. Other complications experienced in these fetal surgery patients included embolism resulting in renal infarction and multiple jejunal atresias ($n = 1$), chronic lung disease ($n = 1$), and development of metastatic endodermal yolk sac tumor ($n = 1$) (Hedrick et al., 2004).

While clinical experience remains limited, there have been other cases of SCT successfully resected in utero at the University of California, San Francisco and at Cincinnati Children's Hospital. For the fetus with a large SCT associated

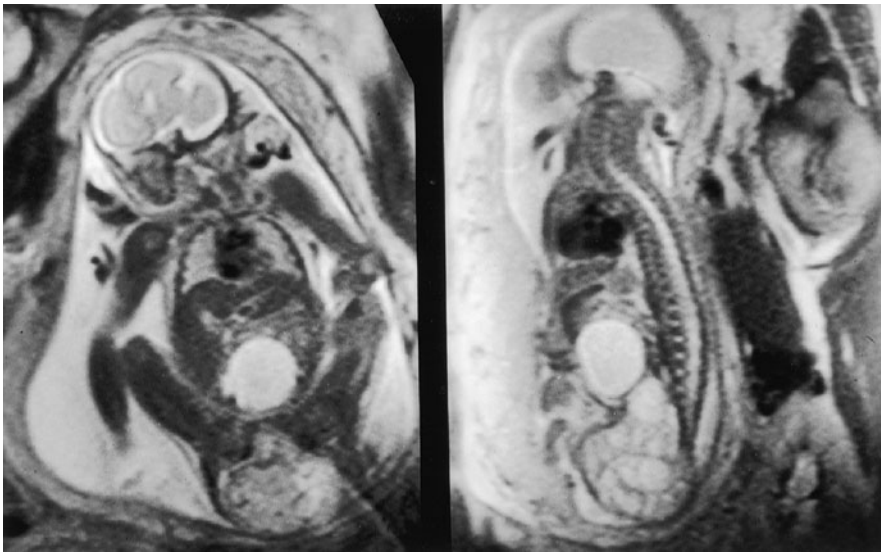

Figure 115-5 Fetal magnetic resonance imaging scan demonstrating in coronal (*left*) and sagittal (*right*) sections a fetus at 25 weeks of gestation with type II SCT. The large intrapelvic portion of tumor has completely blocked the bladder outlet, causing megacystis. The fetal urine is detectable by the presence of contrast dye. (*Reprinted, with permission, from Quinn TM, Hubbard AM, Adzick NS. Prenatal magnetic resonance imaging enhances fetal diagnosis.* J Pediatr Surg. *1998;33:553-558.*)

with early signs of hydrops or placentomegaly, resection in utero remains a viable option. Primary resection of the external portion of the tumor was performed with interval resection of the pelvic extension of SCT. This approach may be useful in managing the common association of prematurity, large tumor, and hyperdynamic state. Because the primary cause of fetal mortality and morbidity is the vascular shunting through the tumor, there have been attempts to embolize or devascularize the tumor using radiofrequency ablation (Paek et al., 2001; Lam et al., 2002). In a report of four patients

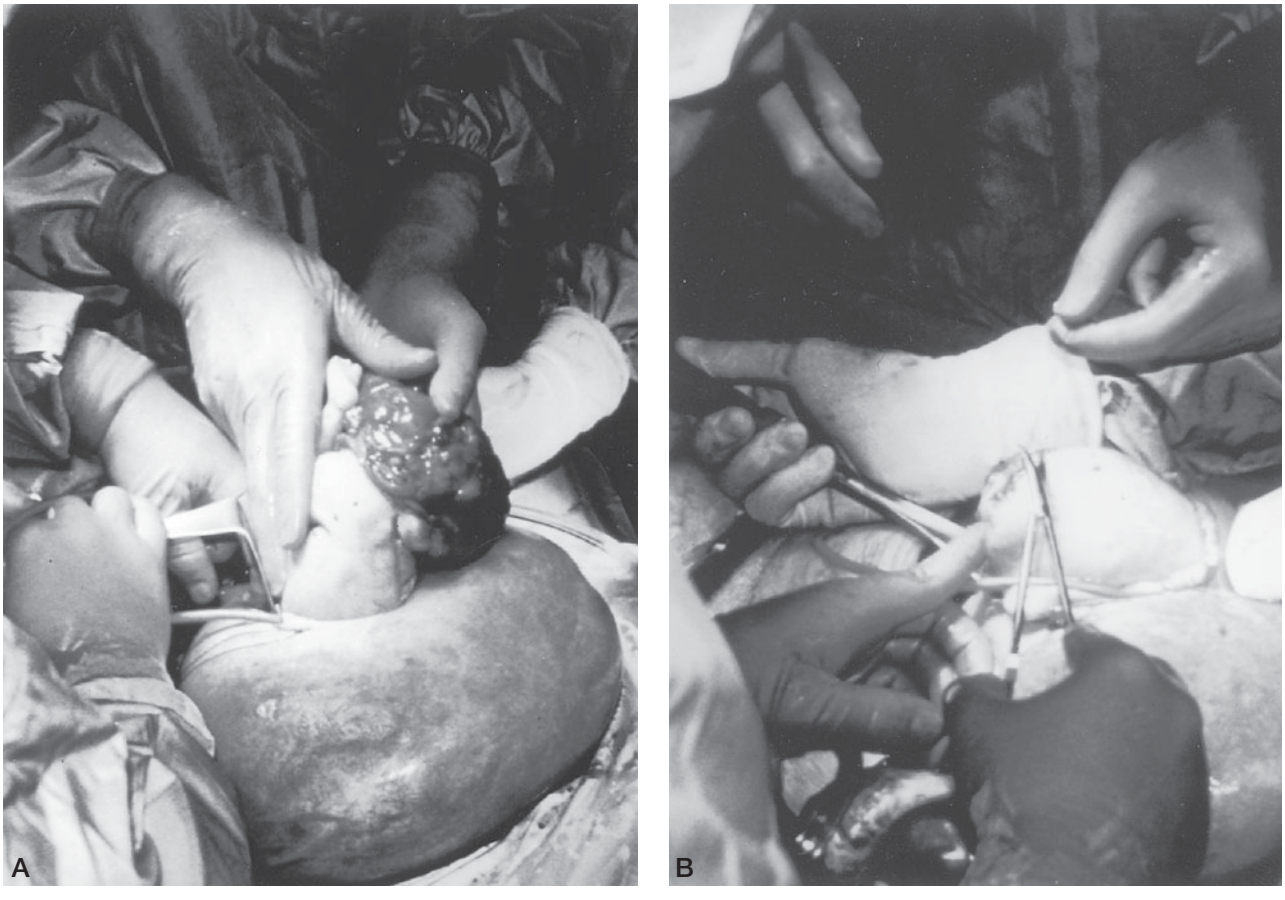

Figure 115-6 Intraoperative view of a 25-week-gestation fetus undergoing resection in utero. **A.** The ruptured tumor and lower extremities of the fetus are delivered from the wound. **B.** The fetal buttock wound is closed immediately following resection. (*Reprinted, with permission, from Adzick NS, Crombleholme TM, Morgan MA, Quinn TM. A rapidly growing fetal teratoma.* Lancet. *1997;349:538.*)

treated with radiofrequency ablation, two fetuses died secondary to hemorrhage after a significant portion of the tumor mass was ablated. The remaining two fetuses delivered at 28 and 31 weeks gestation with evidence of extensive necrosis of pelvic and perineal structures, necessitating extensive reconstructive surgery (Ibrahim et al., 2003). The uncontrolled nature of the energy delivered by the radiofrequency ablation device prevents its safe application in SCT, and this treatment modality has been abandoned.

TREATMENT OF THE NEWBORN

A neonatologist should attend the delivery and be prepared to provide respiratory support. Careful handling of the infant is important to prevent exsanguinating hemorrhage into the tumor. Excellent venous access is paramount should hemorrhage in the tumor occur, and umbilical artery and umbilical venous catheters should be placed. The infant should be started on pressor agents such as dopamine or dobutamine to support the heart in its hyperdynamic state. Transfusion may be necessary immediately postnatally because hemorrhage into the tumor may have occurred during the delivery.

Severely premature infants should be intubated and treated for respiratory distress with surfactant-replacement therapy. Echocardiography should be obtained to assess the cardiac status of the newborn. Abdominal ultrasound examination can be performed at the bedside to assess the intrapelvic extent of tumor. If there is no high-output state then there is no urgency to resect the tumor, and attention should focus on the treatment of respiratory distress and correction of anemia. If a hyperdynamic state exists with an elevated cardiac output, attention should focus on supporting the newborn heart with inotropic agents and urgent resection of the SCT.

SURGICAL TREATMENT

The goal of this resection is reversal of the high-output state, and this can usually be accomplished by resection of the exophytic portion of the tumor. Aortic occlusion by vessel loop to minimize hemorrhage when resecting an SCT in a severely premature infant has been effective in this setting (Robertson et al., 1995). Preoperative angiography and embolization and radiofrequency ablation have been used successfully as adjuncts to surgical resection of large vascular SCTs (Cowles et al., 2006). As with fetal resection of SCT, SCT resection in a premature infant should focus on eliminating the cause of the high-output state, not necessarily complete tumor resection. This can be accomplished by utilization of a thick tissue stapling device at the base of the SCT. If residual pelvic tumor remains, the urgency of resection can be guided by the pathology. The presence of yolk sac differentiation would necessitate earlier resection. In the absence of yolk sac differentiation, however, several months of growth of the infant can facilitate subsequent resection of the coccyx and the intrapelvic portion of the tumor. An abdominoperitoneal approach may be required for resection of the pelvic tumor. The operating table should be kept in a slight reverse Trendelenburg position to prevent air embolism (Seeds et al., 1982).

Staged resection may also be considered. In one report, a fetus in a high-output state due to an SCT 1.5 times its size underwent initial devascularization via ligation of the middle sacral and internal iliac arteries that eliminated the hyperdynamic high-output state and returned cardiac output to normal (Robertson et al., 1995). Thirty-six hours later, primary resection of the residual tumor was performed. The infant subsequently underwent resection of the intrapelvic portion of the tumor at 2 months of age, and is now 4 years of age and free of disease.

Massive hemorrhage is an important cause of neonatal death in large vascular SCTs undergoing resection. Coagulapathy resulting from massive hemorrhage may be an important contributing factor. Recombinant factor VIIa has been used successfully in this setting (Girisch et al., 2004).

LONG-TERM OUTCOME

The long-term outcome in newborns with SCT is generally excellent. The most important prognostic factor for SCT appears to be the age at diagnosis (Conklin and Abell, 1967). When the diagnosis is made prior to 2 months of postnatal age, or excision is performed prior to 4 months of age, the malignant potential is only 5% to 10% (Gross et al., 1951; Hickey and Layton, 1954; Waldhausen et al., 1963; Donnellan and Swenson, 1988). This increases to 50% to 90% if the diagnosis is delayed until after 2 to 4 months of age (Hickey and Layton, 1954; Altman et al., 1974).

The mortality in a newborn with SCT is, however, not primarily due to malignant potential, but rather from difficulty in resection, and possibility of tumor hemorrhage (Altman et al., 1974; Schey et al., 1977; Alter et al., 1988; Grisoni et al., 1988). Gestational age at diagnosis may also affect prognosis, as fetuses diagnosed with SCT after 30 weeks of gestation tend to fare better than those diagnosed earlier (Schey et al., 1977; Flake et al., 1986; Kuhlmann et al., 1987). Cystic tumors may carry a better prognosis, most likely because of the lower incidence of tumor hemorrhage or vascular steal (Hogge et al., 1987). Prompt excision of both the tumor and the coccyx is thought to be essential to prevent recurrence (Gross et al., 1987). Delay may result in infection, hemorrhage, pressure necrosis, and malignant degeneration (Holzgreve et al., 1985).

Although SCTs are usually benign, they are prone to recurrence and have malignant potential. Surveillance for tumor recurrence is essential postoperatively. In SCTs, AFP levels are a useful marker for possible recurrence; a consistent downward trend in values should be observed until normal levels are reached by 1 year of age. We currently recommend that all newborns with SCT have serum AFP levels measured and physical examinations performed, including digital

rectal examinations every 3 months. Such surveillance is recommended for at least 3 years (Barreto et al., 2006). If the SCT was nonfunctional, postnatal pelvic sonographic examinations should be obtained at similar intervals. Once the serum AFP level normalizes, usually by 1 year of age, then MRI should be obtained on at least a yearly basis. Any increase over previous AFP values should prompt investigation for possible recurrence.

Factors that were thought to increase risk of recurrence of SCT or malignant yolk sac tumor were immature and malignant histology or incomplete resection. The chances of this recurrence was estimated at 11% by Derikx et al. (2006). Recurrence of the tumor does not necessarily indicate recurrence of malignancy. It should be treated as a premalignant lesion and excised. Even with malignant transformation of SCT, results with current chemotherapeutic regimens have achieved excellent survival rates. Misra et al. (1997) reported survival rates of 88% with local disease and 75% even in the face of distant metastases.

If the pathologic examination of the SCT reveals microscopic rests of endodermal sinus tumor it remains controversial as to whether chemotherapy is indicated (Heerema-McKenney et al., 2005). Older studies suggested any amount of yolk sac tumor presaged a poor prognosis and aggressive treatment was indicated (Valdiserri and Yunis, 1981; Rescorla et al., 1998). More recent studies suggest the presence of yolk sac tumor, foci of fetal lines, and immature endodermal glands in the SCT are associated with an increased risk of recurrent yolk sac tumor (Hawkins et al., 1993; Heifetz et al., 1998). Those recurrences however are amenable to modern combination chemotherapy with excellent survival (Rescorla et al., 1998; Marina et al., 1999; Huddart et al., 2003; Heerema-McKenney et al., 2005; De Backer et al., 2006). As there is no consensus on this issue, the decision to treat microscopic rests of yolk sac tumor with combination chemotherapy will vary from institution to institution.

There is limited long-term outcome data in SCT patients. Fortunately, with benign SCT, there is usually no serious bowel or bladder dysfunction after surgery and most neonates do well following resection (Litwiller, 1969; Tapper and Lack, 1983; Gross et al., 1987). Neurogenic bladder, however, is not an uncommon sequela in SCTs with a large pelvic component. Ozkan et al. reported a series of 14 cases of neurogenic bladder with high grade reflux with abnormal bladder and urethral function following resection of SCTs (Ozkan et al., 2006). Similarly postoperative urologic sequelae in SCT have been ranged from 20% to 30% (Kirk and Lister, 1976; Lahdenne et al., 1992; Carr et al., 1997). Urologic functional recovery has been documented with increasing age (Engelskirchen et al., 1987; Carr et al., 1997). Bittmann and Bittman found 33% had impaired bowel and bladder function. The frequency of anorectal dysfunction has ranged up to 40% (Engelskirchen et al., 1987; Malone et al., 1990; Wooley, 1993; Boemers et al., 1994). The most common long-term complication after SCT resection was cosmetic dissatisfaction with operative closure (Bittmann and Bittmann, 2006). Some children may experience subtle gait abnormalities as a result of SCT and its resection (Zaccara et al., 2004).

GENETICS AND RECURRENCE RISK

Some cases of SCT appear to be familial, with a suggestion of an autosomal dominant inheritance (Hunt et al., 1977; Gonzalez-Crussi, 1982). Familial SCTs are more often type IV SCTs and can be easily missed (Gopal et al., 2007). While only 10% of nonfamilial SCTs are presacral, 100% of familial SCTs are presacral. Familial cases have a male to female rate of 1:1 compared to 1:3 ratio in nonfamilial cases. Familial cases can be associated with anorectal malformations, most commonly anal stenosis, and can present as part of Currarino's triad (presacral tumor, anorectal malformation, and sacral anomaly) (Currarino et al., 1981). The familial cases are more likely to be associated with a "scimitar sacrum" and are usually benign (Gopal et al., 2007).

There have been rare cases of chromosomal abnormalities reported in patients with SCT including distal 10q trisomy syndrome (Batukan et al., 2007), mosaic trisomy of the long arm of chromosome 1 (Wax et al., 2000), and de novo translocation between chromosome 2 and 7 (Le Caignec et al., 2003).

116 Wilms' Tumor

CHAPTER

Key Points

- Wilms' tumor is a common cause of renal neoplasms in children but is rarely diagnosed in utero.
- The main differential diagnosis in Wilms' tumor is mesoblastic nephrosis.
- Wilms' tumor may present in utero as part of Perlman syndrome (ascites, polyhydramnios, hepatomegaly, macrosomia, and Wilms' tumor).
- Wilms' tumor may present as part of recognized genetic conditions including Beckwith–Wiedemann syndrome, Denys–Drash syndrome, WAGR syndrome, Fanconi anemia, and Simpson–Golabi–Behmel syndrome.
- Excellent survival is achieved with current therapies including surgery, chemotherapy, and in some cases radiation therapy.

CONDITION

Renal neoplasms account for approximately 10% of all malignant tumors in children (Breslow and Beckwith, 1982). Nephroblastoma (Wilms' tumor) accounts for 80% of renal neoplasms in children, while other tumor types, such as anaplastic sarcoma, clear cell sarcoma, rhabdoid tumor, and renal cell carcinoma account for the rest. Wilms' tumor has a peak incidence at 2 to 3 years of age, but it can present from fetal life to adulthood (Breslow et al., 1988a,b). However, neonatal Wilms' tumor is unusual, with only 5 cases reported to the National Wilms' Tumor Study among 3340 reported between 1969 and 1984 (Hrabovsky et al., 1986; Ritchey et al., 1995). Several cases now have been diagnosed in utero (Giulian, 1984; Ritchey et al., 1995; Applegate et al., 1999; Vadeyar et al., 2000; Cavicchioni et al., 2005).

Nephroblastoma is a tumor that arises within the kidney and consists of a variety of embryonic tissues such as glomeruli and tubules, spindle cells, smooth and skeletal muscle fibers, cartilage, and bone. Wilms' tumor is associated with

many genetic conditions, including Beckwith–Wiedemann, Denys–Drash, Klippel–Trenaunay syndromes and neurofibromatosis and the WAGR complex (Wilms' tumor, aniridia, genitourinary malformations, and mental retardation) (King, 1993), suggesting a genetic predisposition to Wilms' tumor (Jadresic et al., 1990). However, the most common presentation of Wilms' tumor is an asymptomatic abdominal mass. Abdominal pain, hematuria or malaise, weakness, anorexia, and weight loss may also be presenting symptoms.

Fetal Wilms' tumor may present as part of Perlman syndrome, which is characterized by familial nephroblastomatosis, fetal ascites, polyhydramnios, hepatomegaly, macrosomia, and Wilms' tumor (Greenberg et al., 1986; Perlman, 1986). Wilms' tumor in Perlman syndrome occurs in the absence of chromosomal abnormalities, enzymatic defects, or somatic conditions known to be associated with Wilms' tumor. Nephroblastomatosis may present as either diffuse or discrete rests of abnormally persistent embryonic renal blastema. In some instances, this condition is believed to be a premalignant precursor of Wilms' tumor (Kulkarni et al., 1980; Stone et al., 1990). Nephroblastomatosis has been defined by Ambrosino et al. (1990) as either persistent metanephric blastema in infants over 36 weeks of gestation or the presence of persistent metanephric blastema in an abnormal location and/or quantity in younger fetuses. Nephrogenic rests occur as two main types, perilobar and intralobar (Beckwith et al., 1990). Nephroblastomatosis occurs in four patterns: perilobar only, intralobar only, combined, and universal or panlobular (Beckwith et al., 1990). The diffuse, panlobar type is characterized by diffuse superficial blastemal tissue that surrounds and compresses the normal parenchyma. In contrast, in the multifocal, perilobar, or intralobar types, nodular renal blastoma is found in the subcapsular cortex and in the deep cortex above the columns of Bertin. In autopsy series of infants younger than 3 months of age, perilobular nephrogenic rests were observed in 0.87% and intralobular in 0.1% (Beckwith et al., 1990). In contrast, 41% of unilateral Wilms' tumors are associated with nephrogenic rests and 99% of synchronous bilateral Wilms' tumors were associated with nephrogenic rests (Beckwith et al., 1990). Nephroblastomatosis is considered a precursor of Wilms' tumor, especially when it is of the multifocal type (Kulkarni et al., 1980; Ambrosino et al., 1990, Stone et al., 1990). Diffuse hyperplastic perilobar nephroblastomatosis is a distinct entity presenting as massively enlarged kidneys or kidneys that maintain their normal architecture and lack necrosis (Shamberger, 2005). A third of these will go on to develop Wilms' tumor (Barbosa et al., 1998).

INCIDENCE

Relatively few cases of Wilms' tumor have been diagnosed prenatally. However, our current understanding of the disease suggests that at least the predisposition to developing Wilms' tumor is present before birth. The incidence of Wilms' tumor is thought to be 1 in 8000 to 10,000 livebirths, with an estimated 8 cases in 1 million children younger than the age of 15 years (Kramer, 1985; Breslow et al., 1993; Miller et al., 1995). The fetal and neonatal incidence of the disease is unknown. In 50% of cases the left kidney is affected, in 45% of the cases the right is affected, and in 5% the tumor is bilateral. The tumor can be seen in association with specific anomalies, including aniridia (8.5 in 1000 cases), hemihypertrophy (25 in 1000 cases), cryptorchidism (28 in 1000 cases), and hypospadias (18 in 1000) (Breslow et al., 1988a,b).

SONOGRAPHIC FINDINGS

The sonographic features of Wilms' tumor may be indistinguishable from those of mesoblastic nephroma. Both present as complex masses that arise from or may completely replace the normal kidney. These tumors are predominantly solid, but cystic areas also can be seen. There may be a well-defined pseudocapsule in Wilms' tumor as opposed to mesoblastic nephromas (Figure 116-1A) (Giulian, 1984; Walter and McGahan, 1985). In mesoblastic nephroma, polyhydramnios is a feature of most cases that have been reported (Yambao et al., 1986). Few antenatally detected cases of Wilms' tumor have been described thus far, so it is uncertain if polyhydramnios may also occur in association with Wilms' tumor. Magnetic resonance imaging (MRI) may be used to enhance anatomic delineation of a renal mass (Figure 116-1B) (Tomá et al., 1990). Fetal MRI provides a larger field of view with better appreciation of the impact of a large Wilms' tumor on adjacent structures (Figure 116-1A and 116-1B). Three cases of prenatally diagnosed nephroblastomatosis have been reported (Ambrosino et al., 1990; Gaulier et al., 1993). One was the stillborn product of a 28-week gestation complicated by polyhydramnios, ascites, pleural effusion, nephromegaly, and calcific foci in one kidney. The second case similarly showed polyhydramnios, homogeneous nephromegaly, and calcific foci within the kidney. The lungs of both fetuses were hypoplastic. The kidneys at autopsy showed diffuse nephroblastomastosis and were thought to represent Perlman syndrome. The third case occurred within a multicystic dysplastic kidney.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a fetal renal mass includes hydronephrosis (see Chapters 80–83) and multicystic dysplastic kidney (see Chapter 78). While far more common, the typical cystic appearance of hydronephrosis and multicystic dysplastic kidney easily distinguishes them from Wilms' tumor. However, mesoblastic nephroma (see Chapter 113) may be indistinguishable from Wilms' tumor (Giulian, 1984; Walter and McGahan, 1985; Garmel et al., 1994). Focal renal dysplasia should also be considered in the differential diagnosis (Gordillo et al., 1987; Sanders et al., 1988) as well as masses

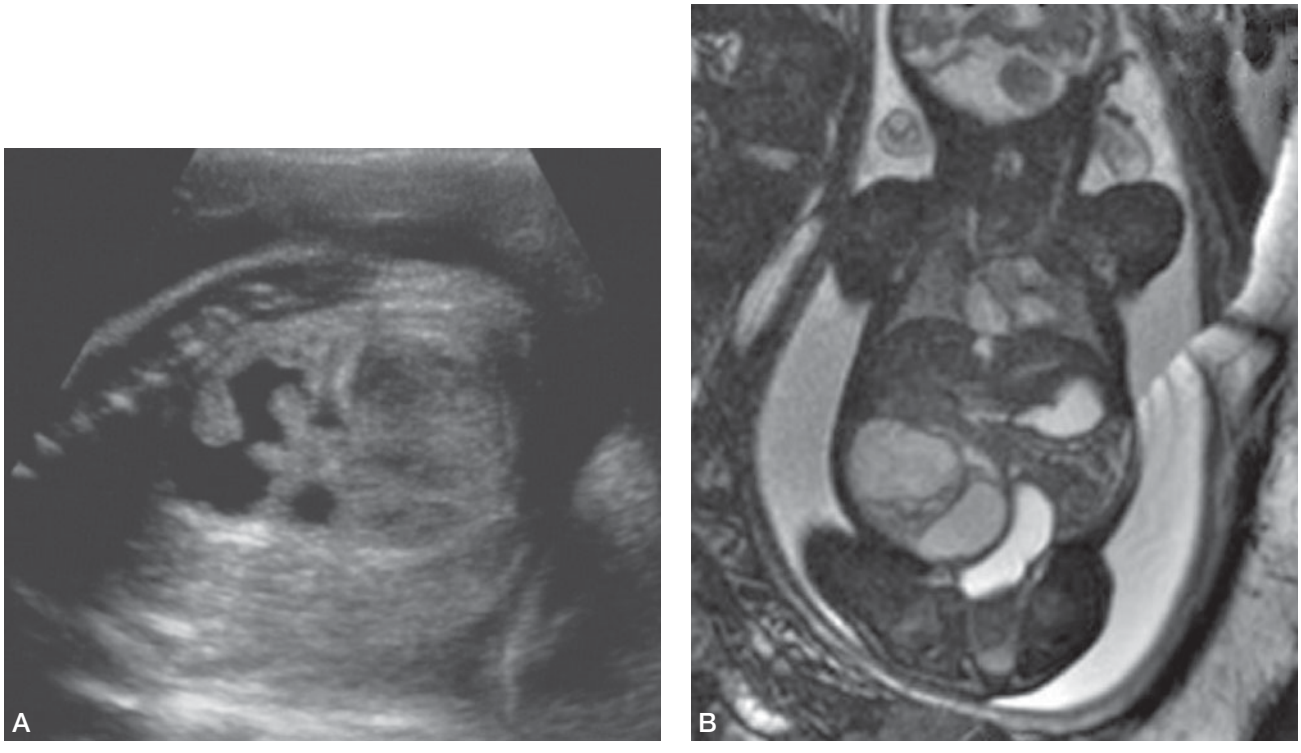

Figure 116-1 **A.** Fetal saggital sonographic image at 33 weeks of gestation demonstrating a large complex echogenic mass with well-defined borders arising from the right renal fossa displacing the bladder and extending across the midline with large cystic components. **B.** Coronal T_1-weighted MRI image of the same fetus, showing the mass to be hypointense relative to the liver, displacing the liver superiorly and the bladder to the left. The contrast in signal intensity in solid and cystic components is apparent.

extending from adjacent organs such as the adrenal gland or liver. In addition, nephroblastomatosis occurring in multicystic dysplastic kidney was detected by prenatal ultrasound examination as a renal mass may be difficult to distinguish from a Wilms' tumor (Gaulier et al., 1993). Nephroblastomatosis tends to maintain more normal renal architecture, and there are no cases of necrosis or cystic degeneration (Barbosa et al., 1998).

ANTENATAL NATURAL HISTORY

The antenatal natural history of Wilms' tumor remains undefined because of the infrequent prenatal ascertainment of these tumors.

MANAGEMENT OF PREGNANCY

The fetus with a suspected renal tumor should undergo a detailed sonographic evaluation to detect associated anomalies and clues to the cause of the mass. The features of Perlman syndrome, including fetal ascites, hepatomegaly, macrosomia, and polyhydramnios should be sought. A family history of Wilms' tumor should also be excluded. The contralateral kidney should be closely examined for anomalies or masses.

Because of the possibility of polyhydramnios in mesoblastic nephroma (the main consideration in the differential diagnosis) as well as in Perlman syndrome, these pregnancies should be followed closely, as polyhydramnios may precipitate preterm labor and premature birth. These tumors seldom achieve a size that might preclude vaginal delivery; however, an ultrasound examination should be done close to term to assess this possibility. Fetal MRI may be helpful in defining the anatomy and potentially in assisting in the differential diagnosis (Figure 116-1B).

FETAL INTERVENTION

No fetal intervention is necessary in Wilms' tumors.

TREATMENT OF THE NEWBORN

Physical examination of the newborn should confirm the presence of an abdominal mass. The affected newborn's blood pressure should be monitored, as 50% of Wilms' tumors may have associated hypertension. Associated anomalies (aniridia, cryptorchidism, and hypospadias) or physical signs of Beckwith–Wiedemann syndrome (macrosomia and macroglossia) should be excluded. A diagnostic work-up for

the presence of metastases should include chest radiography and abdominal computed tomographic (CT) scanning. Abdominal ultrasound should be obtained to evaluate tumor thrombus within the renal vein and the inferior vena cava.

A newborn with suspected Wilms' tumor should undergo an exploratory laparotomy for radical nephroureterectomy and exploration of the contralateral kidney to exclude synchronous bilateral lesions. If a complete resection is achieved and the histology reveals mesoblastic nephroma, no further treatment is indicated. In the National Wilms' Tumor Study-5 protocol, in cases of stage I Wilms' tumors that weigh less than 550 g in a patient younger than 2 years of age, a complete surgical resection is all that is necessary (Larsen et al., 1990; Green et al., 1994; Ritchey, 1998). In other tumors, adjuvant treatment with chemotherapy and radiation therapy is planned according to stage of disease and histology as defined by the National Wilms' Tumor Study. Expected long-term survival rates of >90% for localized cancers and approximately 70% for metastatic disease are achieved with current treatment regimens (Pritchard-Jones, 2002).

LONG-TERM OUTCOME

The long-term outcome for infants with Wilms' tumor depends on histology and stage of the tumor. In general, the 4-year survival of all patients with favorable histology approaches 90% (Haase and Ritchey, 1997; Pritchard-Jones, 2002). Unfavorable histology includes Wilms' tumors with anaplasia, and two other distinct renal tumors—clear cell sarcoma of the kidney and malignant rhabdoid tumor of the kidney. Anaplasia is present in approximately 4.5% of tumors and is more common in older children, with a peak incidence of 5 years. Stage I anaplastic tumors have a biologic behavior similar to stage I patients with a favorable histology with similar survival and relapse rates (Shochat, 1997). The survival rate in patients with focal anaplasia, stages II to IV, was 100%. However, this is a small percentage of patients with anaplasia. The 4-year survival of patients with diffuse anaplasia was only 52% (Shochat, 1997). The 4-year survival is 75% for patients with clear cell sarcoma of the kidney, and 25% for malignant rhabdoid tumors (D'Angio et al., 1989).

One concern for patients undergoing treatment for Wilms' tumor is the potential for the development of second malignant neoplasms. Li et al. (1983) reported that in 11 (2%) of 487 children treated at the Dana–Farber Cancer Institute second primary malignancies developed 7 to 34 years after treatment. The National Wilms' Tumor Study has reported similar findings, with 1% of survivors having a second malignancy at 10 years (Breslow et al., 1988b). These malignancies ranged from leukemia or lymphoma to hepatocellular carcinoma and soft tissue sarcomas. Children with Wilms' tumor who are long-term survivors require ongoing surveillance for the development of a second malignant neoplasm during their adult life.

Other late effects in Wilms' tumor survivors are problems with hypertension, fertility and pregnancy, and low birth weight infants. Haddy et al. (2007) found that as many as 70% of Wilms' tumor patients develop hypertension or prehypertension. Green et al. (1982) reviewed the reproductive histories of 36 Wilms' tumor survivors and found a significant increase (6.7%) in the perinatal mortality of their offspring. This was thought to be primarily the result of prematurity and the low birth weight of infants born to mothers who had previously undergone abdominal radiation. The risk of low birth weight infants in this group of patients was 30%. Li et al. (1987) observed similar problems in 34 of 114 pregnancies in female Wilms' tumor survivors who underwent radiation. Because of the increased risk in mothers who are Wilms' tumor survivors, prenatal counseling and referral to a maternal and fetal medicine specialist is recommended when pregnancy is contemplated (Byrne et al., 1988).

GENETICS AND RECURRENCE RISK

Recent advances suggest that there are hereditary and nonhereditary forms of Wilms' tumor, depending on whether the initial mutational event occurred in a germ cell or a somatic cell (Knudson and Strong, 1978) (Table 116-1). Younger patients; those with aniridia, genitourinary anomalies, and bilateral disease; and familial cases have been considered to be in the hereditary group. It has been estimated that this group accounts for 20% of cases of Wilms' tumors. Of the patients registered with the National Wilms' Tumor Study, 1% of the cases have at least one family member similarly affected (Breslow and Beckwith, 1982).

Patients with Wilms' tumor and aniridia, genitourinary anomalies, and mental retardation (WAGR) syndrome frequently demonstrate a deletion of band 11p13 (Francke et al., 1979; Kofous et al., 1984). The loss of function of a recessive tumor suppressor gene located in the 11p13 region may be responsible for the development of Wilms' tumor. Call et al. (1990) have identified a *WT1* (Wilms' tumor) gene from the 11p13 region. *WT1* invades a zinc finger transcription factor then acts by binding to other DNA sequences that control the expression of renal genes. *WT1* acts as a classic tumor suppressor gene and the XXXX type allele is somatically inactivated in tumors occurring in individuals with constitutional *WT1* mutations or deletions (Haber et al., 1991). *WT1* appears to be essential for normal development of the kidney and genitourinary tract. However, *WT1* mutations occur in fewer than 10% of cases. A second gene, *WT2*, has been identified at the end of chromosome 11p in association with the Beckwith–Wiedemann syndrome locus. In addition, a third Wilms' tumor locus has been suggested by lack of linkage to either *WT1* or *WT2* in the rare families affected with Wilms' tumor (Grundy et al., 1988; Strong et al., 1988). Other genes and chromosomal abnormalities have been identified at the 11p15 locus and on chromosome 16q (Waley et al., 1990; Maw et al., 1992). The sporadic form of Wilms' tumor is not

Table 116-1

Conditions with an Increased Risk of Wilms' Tumor

High Risk (>20%)
- WT1 deletions (including WAGR syndrome)
- Truncating and pathogenic missense WT1 mutations (including Denys–Drash syndrome)
- Familial Wilms' tumor
- Perlman syndrome
- Mosaic variegated aneuploidy
- Fanconi anemia D1/biallelic BRCA2 mutations

Moderate Risk (5–20%)
- WT1 intron 9 splice mutations (Frasier syndrome)
- Beckwith–Wiedemann syndrome caused by 11p15 Uniparental disomy, isolated H19 hypermethylation, or of unknown cause
- Simpson–Golabi–Behmel syndrome caused by GPC3 mutations/deletions

Low Risk (<5%)
- Isolated hemihypertrophy
- Bloom syndrome
- Li–Fraumeni syndrome/Li–Fraumeni-like syndrome
- Hereditary hyperparathyroidism-jaw tumor syndrome
- Mulibrey nanism
- Trisomy 18
- Trisomy 13
- 2q37 deletions

Adapted from Scott H, Stiller CA, Walker L, et al. Syndromes and constitutional chromosomal abnormalities associated with Wilms' tumour. J Med Genet. 2006;43:705-715.

associated with recurrence in subsequent pregnancies. However, approximately 20% of patients with Wilms' tumor are at risk for recurrence in a sibling. These pregnancies should be closely observed by ultrasound examination and amniocentesis should be considered for genetic testing.

Familial cases of Wilms' tumor account for 1% to 2% of cases. Putative tumor genes have been identified in some of these cases as FWT1 with a link to chromosome 17q12-21 (Rahman et al., 1996) and FWT2 linked to chromosome 19q13.3-q13.4 (McDonald et al., 1998). Grundy et al. (1994) have found that loss of heterozygosity on chromosome 16q in Wilms' tumor, which occurs in 15% to 20% of cases, is associated with 3.3-fold greater rate of relapse and 12-fold greater incidence of mortality compared to cases without these changes.

Most Wilms' tumors diagnosed in the newborn or infant are stage I or II and the long-term prognosis appears to be excellent, with a survival rate of 95% (Ritchey et al., 1995). Not only is survival influenced by the early stage of neonatal Wilms' tumor, but also unfavorable histology is rare in patients younger than 2 years of age (Isaacs, 1997). It is important to emphasize, however, that the rarity of neonatal Wilms' tumor precludes definitive statements regarding survival.

Malformations in Twins

117
CHAPTER

Key Points

- Congenital malformations occur more commonly in twins as compared with singleton gestations and are an important contributor to the increased perinatal mortality associated with multiple gestations.
- The incidence of congenital anomalies is thought to be more common in monozygotic compared with dizygotic twin pregnancies.
- Antenatal ultrasound examination is used to detect malformations in twin pregnancies.
- The antenatal natural history will depend on the malformation diagnosed, whether or not it is discordant, and the chorionicity of the pregnancy.
- The management will be influenced by the type of abnormality, whether or not it is concordant, the gestational age when diagnosed, and chorionicity.
- Counseling of parents depends on the type of abnormality and the prognosis for the anomalous twin as well as on the likely outcome for the normal co-twin.
- Three management options are available in this situation: expectant management, selective termination of the anomalous fetus, and termination of the entire pregnancy.
- Expectant management of a twin pregnancy discordant for an abnormality is associated with an increased risk for preterm delivery.
- The method chosen for selective termination will depend on chorionicity. Intracardiac injection of potassium chloride is safe in dichorionic twins, while cord occlusive techniques are necessary for monochorionic pregnancies.
- Treatment of neonatal twins with malformations will depend on the particular malformation.
- The recurrence risk for malformations seen in twin pregnancies will depend on the specific abnormality.

CONDITION

When congenital malformations occur in a multiple gestation, management decisions can be difficult for both parents and physicians because the fates of such sibling fetuses are necessarily linked. Given that the incidence of multiple gestations is increasing in industrialized countries, primarily because of assisted reproductive technologies (Jewell and Yip, 1995), the management dilemma for twins with malformations will also inevitably increase. Congenital malformations occur more commonly in twins as compared with singleton gestations and are an important contributor to the increased perinatal mortality associated with twin gestation. Some malformations in twins are inherent to the monozygotic twinning process, such as acardiac twinning, conjoined twins, and twin-to-twin transfusion syndrome. These

malformations are discussed separately (see Chapters 119–121). Other malformations in twins are deformation abnormalities, such as clubfoot, which result from the crowding of the intrauterine environment.

INCIDENCE

Using data from the British Columbia Health Surveillance Registry, the incidence of congenital malformations in twin pairs was estimated at 6% (Schinzel et al., 1979). In this series, the incidence of congenital anomalies was 2.5 times more common in monozygotic twins than in dizygotic twins or singletons. The incidence of chromosomal abnormalities is increased twofold in dizygotic twins as compared with age-matched singleton pregnancies, but the incidence of nonchromosomal abnormalities is not increased (Drugan et al., 1996).

In one series of 1424 twin pairs, 445 pairs were monozygotic, 26 of which (6%) had congenital malformations (Cameron et al., 1983). Even among monozygotic twin pairs with malformations, however, the majority of fetuses will be discordant for the abnormality, with only 6 of the 26 twin pairs (23%) concordant (Cameron et al., 1983). In another registry of 4490 twins, there was a 50% increase in incidence of congenital malformations among twins as compared with singletons, 4.9% versus 3.3%, respectively, with this increase almost entirely limited to same sex—and therefore presumably monozygotic—twin pairs (Layde et al., 1980).

The incidence of open neural tube defects in twins is controversial. In one study from California and Norway, anencephaly and encephalocele, but not meningomyelocele, were found more commonly in twins as compared with singletons (Windham et al., 1982). In a national survey from England and Wales, there was a threefold increased incidence of anencephaly in twins as compared with singletons, while the incidences of encephalocele and meningomyelocele were similar in twins and singletons (Doyle et al., 1991). In a further study from Spain, the incidence of anencephaly was 0.1% for twins as compared with 0.03% for singletons, and this increase was almost entirely in same-sex twin pairs (Ramos-Arroyo, 1991). However, in a study from Northern Ireland, the incidence of anencephaly was decreased in twins, while the incidence of meningomyelocele was similar to that of singletons (Little and Nevin, 1989a). The incidence of congenital cardiovascular malformations was also found to be modestly increased in twins as compared with singletons, 0.9% versus 0.7%, with the increase again being confined to same-sex twin pairs (Little and Nevin, 1989b).

SONOGRAPHIC FINDINGS

The ability of sonographic examination to detect congenital malformations in twin pregnancies has not been adequately evaluated, with no large patient series available for review. In one series of 33 fetuses from twin pregnancies with anomalies, none of the 8 cardiac anomalies were diagnosed prenatally, while 11 of 20 (55%) other major anomalies and none of the 12 minor anomalies were diagnosed prenatally (Allen et al., 1991). In another series of 24 fetuses with anomalies, it was concluded that by using serial ultrasonography in a tertiary care center it may be possible to achieve an 88% detection rate, with 100% specificity, in the prenatal diagnosis of anomalies in twin pregnancies (Edwards et al., 1995). However, almost 40% of fetuses with anomalies in this series were not diagnosed until 24 weeks of gestation or later, when options for management are more limited. It has also been suggested that up to 88% of cases of Down syndrome in twin pregnancies could be detected by combining risks derived from maternal age and sonographic nuchal translucency thickness measurement at 10 to 14 weeks of gestation (Sebire et al., 1996).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis following the prenatal diagnosis of a congenital malformation in a twin pregnancy is extensive and is dependent on the particular abnormality that is suspected. For differential diagnoses for individual malformations, the corresponding chapters in this textbook should be consulted. Judging from the few published series of sonographic diagnosis of congenital malformations in twins, there is a high degree of specificity involved in the correct prenatal identification of anomalies (Allen et al., 1991; Edwards et al., 1995).

ANTENATAL NATURAL HISTORY

Specific information on the antenatal natural history of individual malformations is available in the corresponding chapters in this textbook. The history of such pregnancies becomes even more complicated when, as in the majority of cases, there is discordance for the malformation in question. In a series of 14 expectantly managed twin gestations in which only one fetus had a congenital malformation, Malone et al. (1996) found a significantly increased (20%) risk of preterm delivery in such pregnancies, in addition to the baseline risk of prematurity already seen with normal twin gestations. This was attributable to the presence of a fetus with an anomaly. Birth weight was significantly lower, and both cesarean delivery rate and perinatal mortality rate were increased in anomalous twin pregnancies as compared with control twins. These data were subsequently confirmed by Alexander et al. (1997) and Gul et al. (2005), both of whom found both lower gestational age at delivery and lower birth weight in their small series of expectantly managed anomalous twin pregnancies as compared with control twins.

MANAGEMENT OF PREGNANCY

When both fetuses in a twin pregnancy are concordant for malformations, subsequent management of that pregnancy

is straightforward and should involve both the usual obstetric management of twin gestations and any required interventions for the particular malformation. However, pregnancy management becomes considerably more complex when one twin has a congenital malformation but the co-twin is normal. Counseling of parents depends on the type of abnormality and the prognosis for the twin with the anomaly as well as on the likely outcome for the normal co-twin. Three management options are available in this situation: expectant management, selective termination of the anomalous fetus, and termination of the entire pregnancy (Malone and D'Alton, 1997; Rustico et al., 2005). Selective termination of an anomalous twin is described in detail under "Fetal Intervention."

For pregnancy management, we recommend karyotyping for twins with malformations. As already described, parents should be counseled that expectant management of an anomalous twin pregnancy is associated with an increased risk of preterm delivery. In addition to the risk of prematurity, expectant management can also be complicated by intrauterine death of the anomalous fetus, which can have profound implications for the well-being of the normal co-twin, especially in a monochorionic twin gestation. If one fetus in a monochorionic twin pair dies, there may be a greater than 20% risk to the remaining co-twin of developing multicystic encephalomalacia, leading to profound neurologic handicap (Pharoah and Cooke, 1997; Pharoah and Adi, 2000). This risk is present from the moment of the death of the first twin, and may not be predictable, even by intensive surveillance with sonographic examination or fetal heart rate monitoring. Therefore, serious consideration should be given to delivering the twins if an anomalous fetus in a monochorionic gestation appears to be in a premorbid condition. This decision will depend on the gestational age, so that the risks of neurologic morbidity associated with expectant management are balanced against the iatrogenic risk of prematurity associated with delivery. If an anomalous twin in a monochorionic twin pair has already died in utero, close fetal surveillance for the surviving co-twin is recommended, although it must be realized that this may not prevent neurologic morbidity, which may already have occurred. Similarly, delivery immediately after diagnosis of the intrauterine death of one twin may not protect against neurologic morbidity in the surviving co-twin. Delivery at 37 weeks, or after measuring lung indexes consistent with maturity, is reasonable in such situations.

Antenatal surveillance of twin gestations complicated by congenital malformations should follow the usual recommended fetal surveillance practices for normal twin pregnancies. This includes serial sonographic examinations every 3 to 4 weeks, from approximately 18 weeks for fetal growth, or every 2 weeks if growth restriction or growth discordance greater than 20% is present. More intensive fetal surveillance with nonstress tests and Doppler velocimetry is recommended for cases of growth restriction or significant growth discordance. Additional fetal testing may also be indicated depending on the particular type of congenital malformation present.

The decision on location of delivery will depend entirely on the nature of the congenital malformation, presence of associated anomalies, and availability of postnatal therapies. With regard to mode of delivery, the choice between vaginal and cesarean delivery will also be dictated by the individual malformation and fetal prognosis. This is described in detail in the appropriate section in the chapters describing each abnormality. In addition, the usual obstetric indications for determining mode of delivery of normal twin gestations may also apply. Typically, all vertex/vertex twins are candidates for vaginal delivery, while most obstetricians perform a cesarean delivery if the presenting twin is nonvertex. When the presenting twin is vertex and the second twin is nonvertex, a vaginal breech delivery of the second twin is generally acceptable if the estimated fetal weight is greater than 1500 g. There are insufficient data to confirm the optimal mode of delivery when a nonvertex second twin weighs less than 1500 g.

FETAL INTERVENTION

The main fetal intervention available for twin gestations in which one fetus has a congenital malformation is selective termination. Whether selective termination is considered a reasonable option will depend on the severity of the anomaly, the chorionicity of the gestation, and the moral and ethical beliefs of the parents (Table 117-1). Selective termination may appear unreasonable in the case of minor congenital malformations. It has also been argued that selective termination should not be performed in cases of lethal anomalies, because it is difficult to justify the additional risk to the normal fetus of an invasive procedure designed to terminate a co-twin that is already nonviable (Stone and Berkowitz, 1995). An exception may be the presence of polyhydramnios in a twin gestation discordant for anencephaly because such pregnancies are at much higher risk of preterm delivery than are normal twin pregnancies (Sebire et al., 1997). Another option in the case of twins discordant for anencephaly is to perform serial amnioreduction if polyhydramnios develops, with the goal of reducing the risk of preterm delivery (Sebire et al., 1997).

Table 117-1

Common Indications for Selective Fetal Reduction in Monochorionic, Diamniotic Twin Gestations

1. TRAP sequence
2. Severe fetal malformations in one twin
3. Early severe intrauterine fetal growth restriction in one twin
4. Early severe TTTS when laser therapy not an option
5. Chromosomal abnormality in heterokaryotypic twins

Determining chorionicity is vital prior to considering selective termination of an anomalous fetus in a twin pregnancy. This can be determined sonographically by identifying fetal gender, observing the thickness of the dividing membranes, or observing separate placentae. Alternatively, at the time karyotyping is performed, the amniocyte culture can also be used as a source of fetal DNA for zygosity testing (Norton et al., 1997). Monozygous twins will have identical DNA polymorphisms at all loci analyzed, whereas dizygous twins will differ.

Before performing the termination procedure, it is essential to confirm that the targeted fetus has the abnormality in question. This identification is fairly straightforward if a structural abnormality is present. However, in cases of chromosomal abnormality without obvious structural malformation, there may be some doubt about correct identification of the anomalous fetus, especially if some time has passed since karyotyping or if careful intrauterine mapping was not performed initially. In cases in which there is some doubt regarding fetal identification, it is recommended to perform repeat chromosomal analysis using rapid techniques (such as fluorescence in situ hybridization or fetal blood sampling) immediately before selective termination.

Several techniques have been successfully used to perform selective termination in the second trimester. These include cardiac puncture, removal of the anomalous twin at hysterotomy, cardiac puncture with intracardiac injection of calcium gluconate, air embolization through the umbilical vessels with fetoscopic guidance, and intracardiac injection with potassium chloride (Aberg et al., 1978; Beck et al., 1981; Kerenyi and Chitkara, 1981; Rodeck et al., 1982; Antsaklis et al., 1984; Chitkara et al., 1989). The latter has gained widespread acceptance for both selective termination and multifetal pregnancy reduction procedures in dichorionic twins due to its proven safety and efficacy (Evans et al., 1999).

Evans et al. reported the outcome of 402 selective termination procedures from four countries and eight centers using ultrasound-guided intracardiac injection of potassium chloride (Evans et al., 1999). The overall results were excellent, with delivery of one or more viable infants in more than 90% of cases. Similarly, Eddelman and colleagues reported favorable outcomes in 200 selective termination cases performed in one institution (Eddelman et al., 2002). This study included 164 twins, 32 triplets, and 4 quadruplets. The average gestational age at the time of the procedure was 19 2/7 weeks, with a range of 12 to 23 6/7 weeks. The indications for selective termination included chromosomal abnormalities, structural anomalies, Mendelian disorders, placental insufficiency, and cervical incompetence. The overall unintended pregnancy loss rate was 4%, with losses being fivefold higher in triplets than in twins. The average gestational age at delivery was 36 1/7 weeks and 84% delivered after 32 weeks of gestation.

Selective termination by potassium chloride injection is contraindicated with monochorionic gestations because death of the unaffected twin occurs in 80% to 100% of cases within several days of termination of the anomalous fetus (Golbus et al., 1988; Evans et al., 1994; Challis et al., 1999). Other methods of performing selective termination of an anomalous fetus in a monochorionic twin pair have been described, but all are considered experimental at this time. Each of these experimental techniques must ensure rapid occlusion of the umbilical vessels of the anomalous fetus to prevent acute hypotension and subsequent mortality or neurologic morbidity in the normal fetus (Malone and D'Alton, 1997). Successful techniques that have been described to date include hysterotomy (Robie et al., 1989), fetoscopic cord ligation (Figure 117-1) (Crombleholme et al., 1996; Quintero et al., 1996), fetoscopic laser ablation of umbilical vessels (Hecher et al., 1996), and percutaneous injection of absolute alcohol (Denbow et al., 1997) into the intra-abdominal umbilical vessels (Tables 117-2 and 117-3; Figures 117-1 to 117-4).

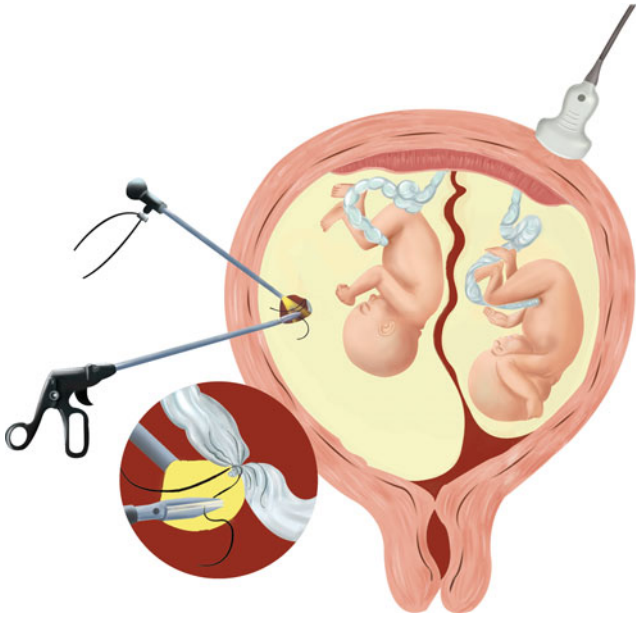

Figure 117-1 Diagram of fetoscopic cord ligation technique used in the selective termination of a twin fetus with a malformation.

TREATMENT OF THE NEWBORN

The treatment of neonatal twins with malformations is entirely dependent on the type of abnormality and is described for each abnormality under the appropriate "Treatment of the Newborn" section in this textbook.

SURGICAL TREATMENT

As with treatment of the newborn, neonatal surgery is also entirely dependent on the type of abnormality and is described for that abnormality under the appropriate "Surgical Treatment" section in this textbook.

LONG-TERM OUTCOME

No data are available on the long-term outcome of normal co-twins following selective termination of an anomalous twin. The long-term outcome of anomalous fetuses that are managed expectantly is also entirely dependent on the type of abnormality and is described for each abnormality under the appropriate "Long-Term Outcome" section in this textbook.

GENETICS AND RECURRENCE RISK

The recurrence risk for malformations seen in twin pregnancies varies greatly depending on the particular abnormality. For deformations such as clubfoot that probably occur as a result of crowding of the intrauterine environment, the risk of recurrence is relatively small. For malformations such as acardiac twinning and twin-to-twin transfusion syndrome, which occur secondary to vascular communications across a monochorionic placenta, the recurrence risk is also relatively small. Recurrence risks for other abnormalities are described under the "Genetics and Recurrence Risk" sections in the relevant chapters in this textbook.

118 CHAPTER Intrauterine Death in One Twin

Key Points

- Intrauterine fetal death (IUFD) of one twin in the first trimester is common and is known as a "vanishing twin."
- Although a "vanishing twin" may be associated with vaginal spotting, it is not associated with adverse perinatal outcomes for the surviving twin.
- Single IUFD in the second and third trimester is less common and is more likely to be associated with complications for the surviving co-twin.
- When single IUFD occurs in a monochorionic pregnancy, it is associated with a worse prognosis, including up to 20% incidence of significant neurologic morbidity for the surviving co-twin, such as multicystic encephalomalacia.
- Sonographic assessment of a single IUFD in a twin pregnancy should include determination of chorionicity, the accuracy of which may be limited in the second and third trimesters.

Key Points (cont.)

- If a certain diagnosis of chorionicity is needed for pregnancy management, DNA studies on amniocytes may be needed.
- Management of a case of single IUFD depends on gestational age and chorionicity.
- Preterm labor and delivery is often associated with single IUFD. Otherwise, expectant management is suggested if the gestational age is less than or equal to 37 completed weeks and there are no indications for delivery.
- Surviving co-twins in a monochorionic pregnancy should be evaluated postnatally for neurologic sequelae.

CONDITION

The intrauterine fetal death (IUFD) of one twin occurs most commonly during the first trimester. This phenomenon is known as a "vanishing twin" (Landy and Weingold, 1989). Although this may be associated with vaginal spotting, the loss of one conceptus is often not clinically recognized, and the prognosis for the surviving twin is excellent (Landy et al., 1986; Samuels, 1988; Prompeler et al., 1994).

Single IUFD in the second or third trimesters is much less common. Single IUFD is observed more often in association with monochorionic than with dichorionic placentation. When it occurs in a monochorionic gestation it may be associated with a worse outcome for the surviving co-twin.

The etiology of IUFD in a multiple pregnancy may be similar to singletons or unique to the twinning process. IUFD may be caused by genetic or anatomical anomalies, abruption, placental insufficiency, cord abnormalities such as a velamentous cord insertion, infection, and maternal disease including diabetes and hypertension (Ogunyemi et al., 1998; Collins, 2002; Craven and Ward, 2002; Simpson, 2002). In monochorionic pregnancies, IUFD may result from complications of the twin-to-twin transfusion syndrome (TTTS). Most often, the smaller, donor twin dies, but IUFD can occur in the larger recipient twin (D'Alton and Simpson, 1995). In addition, monoamniotic twins are at increased risk of cord entanglement and subsequent IUFD (Colburn and Pasquale, 1982). Similar to singletons, the etiology of IUFD often remains elusive (Santema et al., 1995).

Single IUFD in a multiple gestation can adversely affect the surviving fetus or fetuses in two ways: (1) risk for multicystic encephalomalacia and multiorgan damage in monochorionic pregnancies and (2) preterm labor and delivery in both dichorionic and monochorionic twins resulting in prematurity.

Multicystic encephalomalacia (cystic lesions in the cerebral white matter distributed in areas supplied by the anterior and middle cerebral arteries) is associated with profound neurologic handicap. The risk of multicystic encephalomalacia following single IUFD in a monochorionic pregnancy may be as high as 20% for the surviving co-twin (Melnick, 1977; Wessel and Schmidt-Gollwitzer, 1988; Yoshida and Matayoshi, 1990; Dudley and D'Alton, 1986; Eglowstein and D'Alton, 1993; D'Alton and Simpson, 1995; Pharoah and Cooke, 1997; Pharoah and Adi, 2000).

Two theories have been suggested to explain the pathophysiology of multiorgan damage in surviving monochorionic twins. One theory is based on the premise that the retained demised fetus produces thromboplastic materials that traverse the anastomoses between the placentas resulting in disseminated intravascular coagulation. This would lead to infarction and cystic change in numerous organ systems including the kidneys, lungs, spleen, liver, and brain (Bulla et al., 1987). Although several autopsy reports have supported this hypothesis (Moore et al., 1969; Yoshioka et al., 1979; Szymonowicz et al., 1986), this mechanism of injury is no longer thought to be plausible.

The current widely accepted theory suggests that blood from the surviving twin may rapidly "back-bleed" into the demised twin through placental anastomoses, a form of acute fetofetal transfusion (Fusi et al., 1991). The demised twin may become congested while the surviving twin may become anemic. If the hypotension is significant, the surviving twin is at risk for ischemic damage to vital organs (D'Alton et al., 1984; Fusi et al., 1991; Okamura et al., 1994).

In 1991, Fusi et al. reported a case where cerebral and renal lesions were pathologically confirmed in a deceased neonate who had experienced IUFD of a co-twin. Autopsy demonstrated acute blood transfusion from the surviving twin to the IUFD. Hematocrit at delivery was consistent with anemia (Fusi et al., 1991). Fusi's case suggests the need for intervention before IUFD in monochorionic twins to avoid permanent multiorgan damage. Nicolini et al. further supported this concept when they described eight monochorionic pregnancies complicated by a single IUFD (Nicolini et al., 1998). Five of the eight pregnancies underwent blood sampling prior to IUFD. Four of these five who had died were not anemic prior to death and neither were their co-twins. All survivors sampled within 24 hours following the death of their co-twin were anemic.

Since the injury seems to occur at the time of IUFD, immediate delivery of the co-twin following single IUFD in a monochorionic pregnancy does not seem to improve outcomes but rather adds to the risk of prematurity. Perfectly timed intravascular transfusion of blood or fluid immediately prior to the death of the moribund twin has been suggested as a therapeutic intervention to improve outcomes (Fusi

Figure 118-1 Sonographic image of monochorionic twins showing absence of "twin peak" and thin dividing membrane.

et al., 1991; Nicolini et al., 1998; Nicolini and Poblete, 1999). In our opinion, this is unproven and very unlikely to have any significant clinical role.

It is unclear at which gestational age IUFD in a monochorionic pregnancy may result in adverse sequelae for the surviving co-twin. It is often taught that the risk for multicystic encephalomalacia begins in the late second and third trimesters (D'Alton and Simpson, 1995). Neuropathology has not been able to pinpoint the exact timing of insult (D'Alton and Dudley, 1989). According to Pharoah et al., it is possible that early demise ("vanishing twin") in a monochorionic pregnancy secondary to acute and early TTTS could be an explanation for a portion of cases of unexplained cerebral palsy (Pharoah and Cooke, 1997; Pharoah and Adi, 2000). Until further research is completed, this theory can neither be supported nor refuted (Blickstein, 1998).

Of note, we recently reported a case of an IUFD of one twin at approximately 13 weeks in a monochorionic gestation that resulted in multicystic encephalomalacia in the surviving twin. Ultrasound and Magnetic Resonance Imaging (MRI) were performed at approximately 21 weeks demonstrating the neuroradiological pathology (Figures 118-1 and 118-2). The patient was counseled regarding the poor prognosis and opted for termination. The multicystic encephalomalacia was confirmed by pathology, although the exact timing of the injury could not be determined (Weiss et al., 2004).

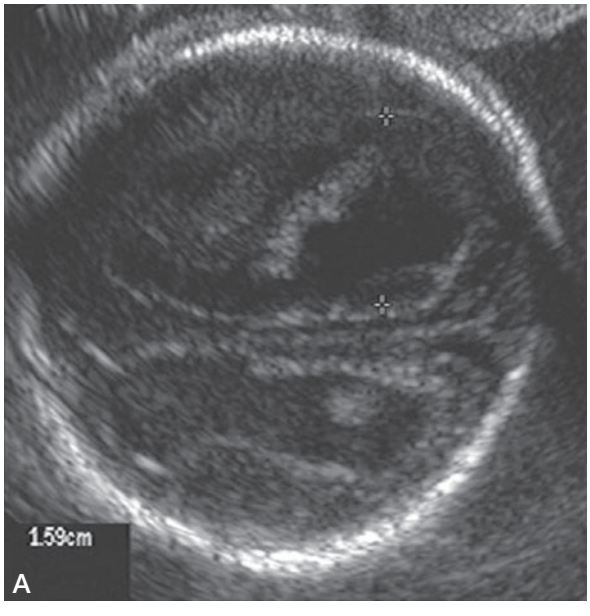

Figure 118-2 A case of monochorionic diamniotic twins, in which co-twin demise occurred at 13 weeks; follow-up ultrasound at 21 weeks demonstrating mild ventriculomegaly. (*With permission Weiss, et al. Multicystic encephalomalacia after first trimester intrauterine fetal demise in monochorionic twins.* Am J Obstet Gynecol. *2004;190:563-565.*)

In addition, studies have demonstrated that IUFD of one twin can result in preterm delivery in both monochorionic and dichorionic pregnancies (Carlson and Towers, 1989; Peterson and Nyholm, 1999). In a study by Carlson and Towers of 17 twin pregnancies complicated by IUFD, 76% of these pregnancies were delivered before 37 weeks. Eighty-six percent of the patients delivering prematurely presented in active labor (Carlson and Towers, 1989). This is almost double the background incidence of reported preterm delivery in twins.

Besides fetal risks, there is a theoretical possibility for maternal consumptive coagulopathy in twin pregnancies complicated by single IUFD (Anderson et al., 1990). It has been established that retention of a dead fetus for 4 to 5 weeks in a singleton pregnancy results in an increased risk of maternal consumptive coagulopathy (Pritchard and Ratnoff, 1955; D'Alton and Simpson, 1995). It was originally estimated that there was a 25% incidence of maternal disseminated intravascular coagulation when fetal death occurred in multiple gestations (Landy and Weingold, 1989). However, only a few cases of laboratory evidence rather than clinical evidence of coagulopathy have been reported under these circumstances, and the 25% incidence is likely an overestimation (Anderson et al., 1990; Carlson and Towers, 1989; D'Alton and Simpson, 1995). In one series of 16 pregnancies complicated by IUFD of one twin, no cases of maternal disseminated intravascular coagulation were found (Fusi and Gordon, 1990). In another series, transient fibrin-split products and hypofibrinogenemia were found in 2 of 20 cases of single IUFD in twins, neither of which was clinically apparent or required medical therapy (Eglowstein and D'Alton, 1993). It is also reassuring to note that no cases of clinically significant coagulopathy have been reported in the extensive literature on selective termination and multifetal pregnancy reduction.

INCIDENCE

Ultrasound during the first trimester has demonstrated that the incidence of twins is greater than previously presumed (Landy and Weingold, 1989). Single IUFD in the first trimester may occur in up to 50% of cases of twin pregnancies (Varma, 1979).

Single IUFD of one fetus in a multiple gestation in the second or third trimesters is much less common complicating approximately 0.5% to 6.8% of twin pregnancies (Benirschke, 1961; Litschgi and Stucki, 1980; D'Alton et al., 1984; Hanna and Hill, 1984; Enbom, 1985; Carlson and Towers, 1989; Fusi and Gordon, 1990; Kilby et al., 1994; Johnson and Zhang, 2002). Monochorionic twins are at increased risk for single IUFD compared to dichorionic twins. It is estimated that there is a threefold to fourfold increase in intrauterine death with monochorionic twins as compared with dichorionic twins (Burke, 1990; Kilby et al., 1994). It is interesting to note that because of increasing use and success of assisted reproductive technologies, the incidence of monochorionic twins is increasing and may be greater than 10 times the spontaneous rate (Blickstein, 2005).

In addition, a single fetal death is also more common among twins with a structural abnormality (Kilby et al., 1994). Demise of both fetuses in a twin pregnancy has been reported infrequently (Rydhstroem, 1996). In high-order multiples, however, demise of a single fetus may be more common. Studies have indicated single IUFD rates ranging from 4.3% to 17% in triplet pregnancies (Gonen et al., 1990; Borlum, 1991; Johnson and Zhang, 2002).

SONOGRAPHIC FINDINGS

The sonographic findings in single IUFD in twin pregnancy vary, depending on whether there is an identifiable cause for the death and on the interval between the death and performance of the ultrasound examination. Sonographic assessment should include complete biometric and anatomic assessments of the dead and surviving twins, an assessment of amniotic fluid volume, evaluation of the cord insertion sites, and determination of chorionicity. If the fetal death is due to placental insufficiency associated with maternal medical disease, there may be evidence of intrauterine growth restriction. Sonographic examination may reveal a fetal abnormality or a placental abruption as a causative factor. Sonographic features of TTTS should also be searched for, as described in Chapter 119.

The determination of chorionicity is important for the counseling and treatment of patients with single IUFD. It is optimal if chorionicity was established early in pregnancy. If chorionicity has not been documented previous to the IUFD, an attempt at determining chorionicity by ultrasound is necessary. If two separate placentas are visualized or the fetuses are of unlike gender, the pregnancy is dichorionic. If only one placenta is identified and the fetuses are of the same sex, the separating membrane should then be examined. If two layers are present the placentation is monochorionic. If three or four layers are visualized, the placentation is dichorionic (D'Alton and Dudley, 1989). Membrane thickness has been used to assess chorionicity, with a thin membrane indicating monochorionicity and a thick membrane indicating dichorionicity (Barss et al., 1985). However, there is some concern that a membrane may appear both thin and thick at different times during the same ultrasound examination and at different gestational ages (Hertzberg et al., 1987; Samuels, 1988; D'Alton and Dudley, 1989). The "twin peak" sign, identified on ultrasound examination by the presence of a triangular projection of placental tissue between the layers of the separating membrane, has been suggested to provide reliable evidence of dichorionicity (Figure 118-3). The absence of the twin peak sign does not help to determine chorionicity, which limits its usefulness as a clinical marker.

Sonographic examination may not establish the diagnosis of chorionicity with absolute certainty in a portion of cases. If an accurate diagnosis of chorionicity is needed, in

Figure 118-3 Sonographic image of dichorionic twins demonstrating "twin peak" sign.

the presence of a single placenta and same-sex fetuses, DNA studies on amniocytes may be considered (Norton et al., 1997).

DIFFERENTIAL DIAGNOSIS

There is no differential diagnosis for this condition.

ANTENATAL NATURAL HISTORY

An accurate assessment of the antenatal natural history of multiple pregnancies complicated by single IUFD is hampered by the lack of a large prospective study (Landy and Weingold, 1989). Most of the available data are biased by either case reports or small retrospective series dealing with unfavorable outcomes (Enbom, 1985). Many cases will not pose a management problem because labor will already have begun by the time the diagnosis is made. However, some patients will remain pregnant with one or more surviving fetuses, which may create a management dilemma. Elective delivery is not recommended before 37 weeks of gestation for the surviving co-twin of a stillbirth in utero unless antenatal surveillance is suggestive of fetal compromise. Similarly, close fetal surveillance after the diagnosis of single IUFD in monochorionic twins cannot guarantee a good outcome for the surviving fetus.

In 14 cases in Landy and Weingold's (1989) series, expectant management was instituted in an attempt to delay delivery in order to benefit the surviving co-twin. The interval between diagnosis of fetal death and delivery ranged from 2 to 12 weeks. One of the survivors had neurologic deficits, and 11 of the 14 pregnancies were delivered before 37 weeks of gestation. In addition to the 14 cases identified by Landy, Santema et al. identified from 8 reports 123 cases that were managed expectantly (Santema et al., 1995). The overall incidence of neurologic morbidity was 12%, and the mortality rate for the surviving twin was 4.3%.

MANAGEMENT OF PREGNANCY

Referral to a tertiary care perinatal unit is advised when single IUFD in a multiple gestation is diagnosed. In many cases, labor will already have started, and in others coexisting maternal illness or placental abruption may make it necessary to deliver the surviving fetus or fetuses (D'Alton et al., 1984). Clinical management depends on gestational age, fetal lung maturity, and detection of in utero compromise of the surviving twin. The goal is to optimize outcome for the surviving twin while avoiding prematurity and its potential adverse sequelae. The optimal treatment for IUFD in multiples is not well established due to the paucity of cases. Recommendations are based on case reports, case series, and expert opinion (Enbom, 1985; Landy and Weingold, 1989; Eglowstein and D'Alton, 1993; Johnson and Zhang, 2002). Management protocols can be divided into (1) pregnancies complicated by IUFD prior to viability and (2) pregnancies complicated by IUFD once viability has been achieved.

If IUFD occurs in a viable pregnancy, management is similar for both dichorionic and monochorionic pregnancies. Patients with monochorionic pregnancies should be counseled about the risk for multicystic encephalomalacia, but no interventions are available to impact on this risk.

It is difficult to predict in utero which cases of surviving monochorionic twin will have cerebral injury. The nonstress test and the biophysical profile give insight into the physiological status of the fetus as reflected in the autonomic nervous system. Although ultrasound may be suggestive of multicystic encephalomalacia, ultrasound of the fetal brain cannot make the definitive diagnosis (D'Alton and Simpson, 1995). MRI, however, may have a role in detecting multicystic encephalomalacia antenatally (D'Alton and Dudley, 1989; Weiss et al., 2004). We recommend that an MRI is scheduled approximately 2 to 3 weeks after the diagnosis of IUFD in a monochorionic pregnancy. Patients in the late second trimester who may be considering pregnancy termination may request an MRI earlier than the usual 2- to 3-week interval to allow for radiological changes to become evident. While it is uncertain if a normal MRI soon after diagnosis of IUFD definitively rules out brain pathology, it provides some reassurance, in our opinion.

We suggest that IUFD in monochorionic and dichorionic twin pregnancies is managed utilizing a straightforward protocol. A single course of antenatal corticosteroids is administered if delivery is anticipated within 7 days and the gestational age is between 24 and 34 completed weeks (Hashimoto et al., 2002). In monochorionic pregnancies, surviving fetuses are monitored with weekly biophysical profiles and nonstress tests (D'Alton and Simpson, 1995).

Antenatal surveillance for dichorionic pregnancies complicated by IUFD is controversial. We monitor these pregnancies weekly with nonstress tests and biophysical profiles since they have a history of unexplained stillbirth. If other abnormalities such as intrauterine growth restriction or oligohydramnios are concomitant, fetal testing is intensified.

In most cases, elective delivery is scheduled at approximately 37 weeks of gestation. If lung maturity is documented, delivery may be scheduled earlier. Nonreassuring fetal status results in immediate delivery. Vaginal delivery is not contraindicated, and cesarean delivery is reserved for routine obstetric indications (Fusi and Gordon, 1990). At delivery, umbilical cord blood gas and hematocrit measurements are performed. Autopsy is offered for the stillborn fetus. The placenta is sent for pathological examination. In addition, the pregnancy history is communicated to pediatric colleagues. Careful pediatric follow-up is suggested for the offspring of monochorionic pregnancies complicated by IUFD. It is recommended that these neonates be followed for any signs or symptoms of cerebral impairment and for any indications of other vital organ damage (Rydhstroem and Ingemarsson, 1993).

If IUFD occurs in a previable dichorionic pregnancy, the patient is managed expectantly until 37 weeks of gestation. Fetal surveillance and a single course of antenatal steroids are considered once viability is achieved.

Monochorionic pregnancies complicated by IUFD before viability are challenging. It is recommended that patients be counseled regarding the risk of multiorgan injury including multicystic encephalomalacia. Ultrasound imaging and fetal MRI may be helpful. Some patients may opt to terminate the entire pregnancy, while others may desire expectant management. Once the surviving co-twin reaches viability, these patients should be managed according to the recommendations described above.

In addition to fetal risks, IUFD in a multiple gestation may lead to maternal complications. When IUFD occurs in a multiple pregnancy, baseline maternal hematological laboratory results are obtained including a prothrombin time (PT), partial thromboplastin time (PTT), fibrinogen level, and platelet count. If these values are within normal limits, further laboratory surveillance is not performed. Of note, mothers with IUFD in one twin do not appear to be at increased risk of infection due to a retained twin (Carlson and Towers, 1989). Dystocia secondary to the demised fetus has been reported infrequently. Cesarean delivery rates seem to be increased in patients with single IUFD because of nonreassuring fetal status (Carlson and Towers, 1989).

It is well known that IUFD in singleton pregnancies may cause feelings of loss, sadness, anxiety, and guilt (Hughes et al., 2002). The psychological impact of fetal loss in multiple pregnancies has not been well studied (Bryan, 2003). In fact, bereavement may be underestimated because there is a shift in focus to the living offspring (Bryan, 1995, Bryan, 2002). As a result, we suggest that patients with a multiple pregnancy complicated by IUFD are offered psychological and/or bereavement counseling.

FETAL INTERVENTION

No fetal intervention is recommended in cases diagnosed before 37 weeks in cases in which a single IUFD has already been documented.

In known monochorionic pregnancies with impending death of one twin, preterm delivery may be indicated in order to prevent neurologic injury to the survivor or potentially to salvage both twins. In a monochorionic twin pregnancy with a gestational age of greater than 28 weeks, the risk of neurologic handicap to the surviving twin in the case of death of the co-twin may be higher than the risk of prematurity. Delivery should be considered if it appears likely that one fetus is about to die in utero. If chorionicity is unclear and the death of one twin seems imminent, it is necessary to weigh the risks and benefits to each twin of expectant management versus early delivery. If dichorionicity can be clearly demonstrated, there is no benefit to the healthy, appropriately grown co-twin of elective preterm delivery in cases in which the smaller twin is likely to die.

In addition, selective termination of a fetus that has a significantly increased risk of demise in a monochorionic gestation may be considered, in an effort to protect the healthy co-fetus or fetuses (Crombleholme et al., 1996). The usual method of intracardiac KCl injection is contraindicated in monochorionic pregnancies. Alternative cord occlusive methods should be considered, such as fetoscopic cord ligation or fetoscopic ablation of communicating placental vessels. We have reported a case of radiofrequency cord ablation in one member of a monochorionic twin pregnancy discordant for a cystic hygroma, hydrops, and Turner's syndrome, which was thought to be at significant risk of IUFD. The normal co-twin was delivered at term and had a normal neonatal course (Shevell et al., 2004). At 2-year follow-up, the surviving co-twin was neurologically intact.

Indications for considering a fetoscopic cord ligation procedure to prevent neurologic handicap in twins include anomalies incompatible with life in monochorionic pregnancies at a previable gestational age or significant growth discordance in monochorionic gestations at a previable gestational age. Fetoscopic cord occlusive techniques in monochorionic pregnancies are further explored in Chapter 117.

The optimal gestational age at which to deliver uncomplicated monochorionic twin pregnancies to prevent single IUFD is an unanswered question, which remains an area of controversy. Barigye et al. recently reported the prospective risk of fetal death in uncomplicated monochorionic diamniotic twin pregnancies managed at a single tertiary care referral center (Barigye et al., 2005). Patients were excluded from the study if the pregnancy was complicated by TTTS, monoamnionicity, IUGR, growth discordance, structural anomalies, and TRAP. Conjoined twins and high-order multiples were

also excluded. The prospective risk of fetal death was calculated by determining the number of IUFDs that occurred within a 2-week block divided by the number of continuing uncomplicated monochorionic twin pregnancies during that same time period. There were 10 unexpected deaths (3 double IUFDs and 4 single IUFDs) for a total of 7 (4.6%) of the 151 seemingly uncomplicated monochorionic diamniotic pregnancies. These IUFDs occurred predominantly during the late preterm gestation, at a median gestational age of 34 weeks and 1 day. There were no significant differences between the IUFD affected pregnancies and the unaffected pregnancies with regard to antenatal indicators of IUGR and TTTS. The authors concluded that despite intensive fetal surveillance, uncomplicated monochorionic diamniotic twin pregnancies are at risk for unexpected intrauterine death. As a result, the authors suggested that after 32 weeks of gestation, the prospective risk for fetal death in these pregnancies might be eliminated by elective preterm delivery. Nonetheless, the risks of prematurity are not negligible at 32 weeks of gestation. Balancing the risk of iatrogenic preterm birth in an *apparently* uncomplicated monochorionic twin pregnancy with the risk of double IUFD or single IUFD with the concomitant risk of multicystic encephalomalacia for the surviving co-twin is challenging (Cleary-Goldman and D'Alton, 2005). One option may be to offer delivery of these *apparently* uncomplicated monochorionic twins at approximately 34 to 35 weeks of gestation following antenatal corticosteroid administration and thorough counseling regarding the risks of expectant management versus elective preterm delivery. This may be a reasonable approach to this dilemma until larger, prospective observational studies have been conducted to better elucidate the natural history of these high-risk pregnancies.

TREATMENT OF THE NEWBORN

All surviving infants of a monochorionic pregnancy following single IUFD should be evaluated postnatally for neurologic injury, and a thorough neurological assessment should be performed. Pediatric follow-up to assess growth and development is advisable. Otherwise, no additional special precautions or investigations are required.

SURGICAL TREATMENT

There is no requirement for neonatal surgical evaluation for surviving infants of multiple gestations following single IUFD, unless additional anomalies are present in the survivors.

LONG-TERM OUTCOME

The literature regarding the clinical significance of single IUFD in twins spans more than 40 years and includes more than 500 cases, most of which do not address long-term outcome for the survivor. In one series of 188 confirmed monozygous twin pairs, there were 7 in utero deaths (Melnick, 1977). Five of the seven co-twin survivors had normal head circumference and psychomotor development. Head circumferences ranged between the 35th and 97th percentiles, and the IQs were all within 1 SD of the mean for sex, race, and zygosity. One co-twin died at 2 months, and postmortem studies revealed necrosis of the white matter of the cerebellum. A different co-twin had a head circumference at the third percentile from 1 to 7 years of age, but psychomotor development at 1, 4, and 7 years was normal (Melnick, 1977).

In another series of 206 pregnancies with death of at least one twin before delivery, follow-up for 8 years or more after birth revealed that three twins (5%) had cerebral palsy or mental retardation (Rydhstroem and Ingemarsson, 1993). All three were second twins and of the same sex as their co-twins.

In a more recent study reviewing birth certificate data from United Kingdom, 434 gender-concordant twin pregnancies were found in which intrauterine demise of one fetus had occurred (Pharoah and Adi, 2000). The prevalence of cerebral palsy among surviving fetuses was 10.6% and the prevalence of other neurologic injury was 11.4%. The main limitation, however, of such birth certificate data is the inability to be sure of the prevalence of monochorionicity among the gender-concordant pairs. In a literature review of 119 monochorionic twin pregnancies complicated by a single intrauterine fetal demise, 9% of surviving fetuses subsequently died in utero, a further 10% subsequently died in the neonatal period, and 24% had serious neonatal morbidity, including porencephaly, multicystic encephalomalacia, renal cortical necrosis, and small bowel atresia (Nicolini and Poblete, 1999).

GENETICS AND RECURRENCE RISK

There is unlikely to be an increased risk above the baseline risk of single IUFD if future pregnancies involve multiple gestations.

119 CHAPTER Twin-to-Twin Transfusion Syndrome

Key Points

- The twin-to-twin transfusion syndrome (TTTS) is a complication of monochorionic multiple gestations resulting from vascular communications in the placenta (chorangiopagus), such that one twin is compromised and the other is favored.
- The prognosis is poor, with a perinatal mortality rate ranging from 60% to 100% for both twins.
- TTTS is almost exclusively found in monochorionic twins and is estimated to occur in 5% to 15% of monochorionic twin pregnancies.
- Sonographic criteria for the diagnosis of TTTS include: (1) like sex, (2) monochorionic twins, (3) polyhydramnios in one sac, oligohydramnios in the other sac with or without characteristic Doppler or echocardiographic changes.
- Expectant management is not recommended due to poor perinatal outcomes associated with the disorder.
- Treatment depends on the gestational age and severity at diagnosis.
- Current treatment options for severe TTTS include: (1) serial reduction amniocentesis, (2) amniotic septostomy, (3) laser ablation of the anastomoses, and (4) intrafetal radiofrequency ablation.
- Laser ablation appears to be a promising treatment for severe TTTS diagnosed in the midtrimester. Nonetheless, further studies are still needed to assess long-term pediatric outcome.

CONDITION

The twin-to-twin transfusion syndrome (TTTS) is a complication of multiple gestation resulting from imbalanced blood flow through vascular communications in the placenta (chorangiopagus), such that one twin is compromised and the other is favored. The prognosis is poor, with a perinatal mortality rate ranging from 60% to 100% for both twins (Rausen et al., 1965; Cheschier and Seeds, 1988; Gonsoulin et al., 1990).

The earliest description of TTTS may have been in the book of Genesis. At the birth of Esau and Jacob it was recorded that "the first one came out red," possibly describing the birth of a polycythemic twin. In 1752, William Smellie reported the injection of the umbilical artery of one twin with the injection material flowing out of the vessel of the co-twin.

Research in the area of vascular anastomoses in twin placenta in the late 1800s was dominated by the German obstetrician Friedreich Schatz, who described four types of vascular connections within monochorionic placentas:

1. Superficial connections between capillaries.
2. Superficial arterial connections between large vessels.
3. Superficial venous connections between large vessels.
4. Vascular communications between capillaries in the villi.

He described three circulatory systems in monochorionic twins. The first two were the circulations in either twin. The third circulation consisted of the arteriovenous communications bridging the two fetal circulations below the placental surface (Schatz, 1882).

Schatz proposed that when superficial artery-to-artery and vein-to-vein anastomoses are absent or insufficient, imbalances may occur in the common circulation of the twins. Such imbalances favor the transfer of blood from one twin to the other and result in TTTS. A study demonstrating fewer anastomoses from placentas complicated by TTTS (Bajoria et al., 1995) confirms Schatz's observations from the late 1800s. Ten placentas from pregnancies with evidence of midtrimester TTTS diagnosed using ultrasound criteria were compared with 10 placentas from pregnancies without TTTS. Placentas from pregnancies with TTTS had significantly fewer anastomoses than did those without TTTS, both overall and for each of the different types (arterioarterial, venovenous, and arteriovenous). Whereas multiple anastomoses were present in all controls, only one TTTS placenta

had more than a single communication. Anastomoses in the TTTS group were more likely to be of the deep than the superficial type.

Because of the putative major role of intertwin anastomoses, most investigations of TTTS have been directed toward study of the monochorionic diamniotic placental vasculature. Studies generally have identified a paucity of anastomoses as a prominent risk factor in the development of TTTS. Paucity, especially of deep anastomoses, leads to fewer chances for volumetric balance in cross-circulation between the twins. Larger numbers of superficial chorionic anastomoses, particularly arterioarterial (A-A) connections, appear to confer relative protection against the development, early onset, or severity of TTTS (De Lia et al., 2000; Umur et al., 2002a; De Paepe et al., 2005; Harkness and Crombleholme, 2005; Lewi et al., 2007). However, the "protective effect" of these A-A anastomoses remains somewhat controversial. Venovenous (V-V) connections comprise a lower percentage of anastomotic types found in monochorionic diamniotic gestations and have been associated with poorer perinatal outcome. V-V anastomoses are seen in 20% of monochorionic diamniotic placentas, A-A in 75%, and A-V in 70% by clinical and pathologic studies, but fetoscopic studies have shown that 95% of anastomoses are A-V (De Lia et al., 2000; Crombleholme et al., 2007). However, some investigators have proposed that V-V anastomoses may provide compensatory reversal of blood flow in some situations (De Lia, 2000). Presumably, as the recipient's central venous pressure rises with hypervolemia and ensuing congestive failure, the V-V anastomoses may be "protective" to both twins by helping to alleviate right ventricular failure in the recipient and theoretically shunting blood back to the venous system of the donor. The relatively fewer numbers of V-V connections, in addition to their anatomy and lower pressure differential, may be determinants of how effectively they contribute to balancing intertwin blood flow.

Some researchers' observations that the average numbers of superficial vascular connections are not significantly different between gestations involving severe TTTS and those that do not (Bermudez et al., 2002) and the fact that 80% to 90% of monochorionic diamniotic twins do *not* develop TTTS has led other investigators to propose that more than quantitative differences in the number of anastomoses is involved in the pathogenesis TTTS. Recent evidence suggests that vascular diameter and resistance and the pattern of chorionic plate vascular branching are important factors. Umur et al. (2002a,b) using a complex mathematical computer model, determined that, for a given radius, an A-A anastomosis has lower resistance than the equally sized afferent artery of an A-V anastomosis, which might explain the apparent protective effect of A-A anastomoses noted in most studies of TTTS. By their calculations, blood flow could be balanced more efficaciously through an A-A anastomosis than through oppositely directed A-V anastomoses, even though the pressure gradient in the A-V anastomoses was greater.

De Paepe et al. (2005) studied the chorionic plate branching pattern in monochorionic diamniotic placentas from gestations without TTTS and those affected by severe TTTS. They found that gestations involving severe TTTS were more likely to exhibit magistral pattern (a chorionic vascular pattern composed of relatively large caliber, sparsely branching vessels that extended from the cord insertion site to the placental periphery without significant diminution in diameter), or a mixed magistral and diffuse pattern than unaffected gestations (60% vs. 44%). The presence of a magistral pattern, even when mixed with the more favorable disperse pattern, was also associated with higher incidences of other placental anatomic features implicated in the development of TTTS, such as unequal distribution of vascular territory and marginal or velamentous cord insertions. In addition, donor twins were more than twice as likely to have the magistral or mixed pattern as recipients, and when one or both twins had the magistral or mixed pattern, the average number of intertwin anastomoses was fewer. These investigators suggested that the predominance of magistral and mixed patterns in the donor twins' placentas may be related to the observations that magistral patterns in singleton placentas are associated with absent end-diastolic blood flow (AEDF) in the umbilical arteries (UAs). AEDF has been attributed to the effects of a smaller peripheral vascular tree that results in increased vascular resistance to forward flow from the UAs. The low end-diastolic flow in the donor's UAs combined with the magistral/mixed pattern might result in preferential routing of blood flow through anastomoses to the recipient twin. Thus, evidence supplied by the various placental structural studies of TTTS indicates vascular resistance, cross-sectional area, and other hemodynamic factors are contributing elements in the development, timing of clinical onset, and severity of TTTS (Luks et al., 2005).

Unequal sharing of the placental disc is an additional risk factor for the development of TTTS (Benirschke et al., 2006; Lewi et al., 2007). However, when and how disk inequality develops is unclear. The early developing chorionic villous tree may connect preferentially to the vasculature of the umbilical cord of one twin over that of the other. With unequal division of the inner cell mass, one embryo may develop a larger heart and, thereby, greater stroke volume and cardiac output such that its perfusion of the developing villous tree is initially more robust (Benirschke et al., 2006). However, others have proposed that unequal sharing may reflect abnormalities of placentation. Not all twin pairs that have TTTS exhibit significant growth discordance, and there is evidence that abnormalities of placentation may be relatively more responsible for the growth discordance in TTTS than imbalances in intertwin transfusion (Wee et al., 2006). Approximately 20% of cases of TTTS have concomitant evidence of placental insufficiency that usually, but not always, affects the donor twin (Habli et al., 2008). The combination of placentation anomalies, flow inequalities, and fetal response may determine whether the donor's placental territory appears grossly pale and bulky [with edematous large villi containing increased Hofbauer (chorionic villous macrophage) cells and nucleated fetal erythrocytes characteristic of fetal anemia] or whether it is pale and atrophic-appearing with small villi (Kraus et al., 2005; Faye-Petersen et al., 2006; Kaplan, 2007). Conversely, the recipient's

parenchymal territory usually is deep red-brown and firm due to villous congestion, but it also may show microscopic villous edema if the fetus is in congestive failure.

Marginal and velamentous cord insertions and single UA are associated with increased risks of the development and severity of TTTS (Fries et al., 1993; De Paepe et al., 2005; Benirschke et al., 2006; Kaplan, 2007). Of note, although diamniotic monochorionic twins comprise 20% of twin gestations, they have significantly increased rates of cord anomalies over diamniotic dichorionic twins, with more than 50% of marginal cord insertions, more than 40% of velamentous cord insertions, and nearly 50% of all single UA cases occurring in monochorionic diamniotic twins (Redline et al., 2001). Diamniotic monochorionic twins, therefore, are at constitutively increased risks for the underlying morbidity and mortality associated with cord compression, cord accident with thrombosis, and vessel rupture. Such cord events could compound any underlying risks of chorangiopagus, especially for the donor twin. Donor twins are more likely to have velamentous cord insertion than are recipients (Mari et al., 2000).

The asymmetric, bidirectional intertwin exchange of blood and its biochemical components results in hemodynamic, osmotic, and physiologic changes in the fetuses (Jain and Fisk, 2004; Harkness and Crombleholme, 2005; Luks et al., 2005; Benirschke et al., 2006). Hypovolemia and decreased renal blood flow in the donor may cause a number of renal structural and functional aberrations, especially in severe TTTS, including renal tubular degeneration and cellular apoptosis, loss of glomeruli or reduction in tubular number, and maldevelopmental progression to renal dysgenesis (Kilby et al., 2001; De Paepe et al., 2003). Renal hypoperfusion also has been linked to activation of the renin-angiotensin system (RAS) (Mahieu-Caputo et al., 2000; Kilby et al., 2001; Mahieu-Caputo et al., 2001) and elevated antidiuretic hormone concentrations (Bajoria et al., 2004) in the donor. Donors have hyperplasia of juxtaglomerular apparatuses, with increased numbers of renin-secreting cells (Kilby et al., 2001) and upregulation of renin synthesis (Mahieu-Caputo et al., 2000), which are presumed to represent adaptive responses to restore euvolemia. However, in severe TTTS, activation of the RAS and associated elevations in angiotensin II (AT II) likely result in AT II-mediated fetal vasoconstriction that further compromises renal blood flow, leading to worsening oliguria and oligohydramnios. Increased fetal adrenal production of aldosterone may play a contributing role (Mahieu-Caputo et al., 2000; Kilby et al., 2001; Mahieu-Caputo et al., 2001; Bajoria et al., 2004). Bajoria et al. (2004) recently found that donors' plasma and amniotic fluid concentrations of vasopressin were threefold higher than those of their co-twin recipients (monochorionic diamniotic twins that did not have TTTS had higher concentrations than the recipients in TTTS, but they were not discrepant or as elevated as the donors in TTTS). Thus, good evidence suggests that the oligohydramnios of the donor twin is a consequence of poor renal perfusion due to net hypovolemia, but it is exacerbated by vasoconstriction, mediated by AT II/vasopressin. Fetal vasoconstriction also may reduce placental blood flow to the villous tree, which may contribute to growth restriction in the donor (Mahieu-Caputo et al., 2000, 2001; Kilby et al., 2001).

In severe cases of TTTS, hypervolemic recipients have renomegaly and glomerulomegaly consistent with increased renal blood flow, and immunohistochemical studies have revealed they have downregulation of the RAS, with markedly reduced numbers of renin-secreting cells and renin synthesis (Mahieu-Caputo et al., 2000, 2001; Kilby et al., 2001). However, they have paradoxically high concentrations of renin and aldosterone, and the cardiomegaly, cardiomyopathy, hypertension, and nephrosclerosis seen in recipients in TTTS are insufficiently explained by hypervolemia alone. Such observations are supportive evidence for transfer of these and possibly other vasoactive effectors from the donor to the recipient across placental anastomoses. The hemorrhagic necrosis and microangiopathic lesions seen in kidneys from recipients in severe TTTS also may be related to transanastomotic passage of hormones from the donor (Mahieu-Caputo et al., 2001, 2005). Low concentrations of antidiuretic hormone in the recipient, together with elevated renin concentrations secreted by the donor, are likely responsible for worsening hypervolemia and polyuria/polyhydramnios in recipients. Maternal sequelae of fetal elevations in vasoactive substances have been appreciated recently. Elevated fetal renin-AT II values have been associated with maternal pseudoprimary hyperaldosteronism (Gussi et al., 2007), and it is possible that these contribute to changes in maternal perfusion of the placental bed.

In addition to anastomotic transfer of vasoactive mediators, increased cardiac synthesis and secretion of natriuretic peptides (NPs) have been linked to the progression of TTTS. NPs are a family of biochemical mediators that normally regulate blood pressure and body fluid homeostasis through their diuretic, natriuretic, and vasodilatory effects as well exerting antiproliferative effects on cardiovascular/mesenchymal tissue. Exploration of their role in the pathogenesis of adult cardiac hypertrophy and cardiomyopathy has led to greater appreciation of their importance in normal embryofetal development and their role in cardiomyopathy in the recipient twin in TTTS. In the fetus, in contrast to the adult, both atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP) hormones are normally at high circulating concentrations and are expressed at high concentrations in the ventricles (in the normal adult, they are expressed at low concentrations in cardiac atria and ventricles, respectively). Their release is stimulated primarily by increased myocardial stretch and volume overload, hyperosmolality, and hypoxia, and vasoconstrictors, such as AT II, vasopressin, and endothelin-1 (ET-1), have been shown to result in their increased expression and secretion. ANPs and BNPs appear to be integral to embryonic fetal salt and water and blood pressure regulation, and the peptide system is likely functional by midgestation. ANP and BNP also appear to be important mediators of cardiogenesis because of their inhibitory effects on myocardial and fibroblast cell proliferation. Their effects on fetal aldosterone concentrations are unknown, but they suppress aldosterone synthesis in the adult. A third NP, c-type natriuretic peptide

(CNP), which is found in adult genitourinary, pituitary, and brain tissues, is not produced in any significant quantity in the fetal or adult heart, although it is secreted by the placenta. Placental production of NPs (ANP, BNP, CNP) affects vasorelaxation in the fetoplacental vasculature and likely helps regulate blood supply to and within the fetus.

Bajoria et al. (2002, 2003) demonstrated that recipient twins in TTTS have higher concentrations of ANP, BNP, and ET-1 than their co-twin donors or monochorionic diamniotic twins without TTTS and that high concentrations of BNP and ET-1 are particularly correlated with cardiac dysfunction in the recipient. They suggested that these compounds might be used as early markers of cardiac compromise. It is plausible that the immaturity of the fetal kidney and its inability to concentrate urine may be exacerbated by the vasodilatory and diuretic effects of BNP and ANP released due to hypervolemia and contribute to polyuria/polyhydramnios or be compounded by BNP stimulation due to AT II transferred from the donor. Increased ANP concentrations in blood and amniotic fluid have been detected in recipients in TTTS, greater than donor twin's and uncomplicated monochorionic diamniotic twin pair's values. Increases in ANP also are related directly to increases in amniotic fluid volumes, and markedly increased immunostaining for ANP localizes predominantly to the heart and cytoplasm of the distal convoluted tubules of the kidneys of recipients when compared with measurements for donor twins. These data are supportive evidence that polyhydramnios in the recipient twin occurs as a consequence of ANP-mediated increases in fetal urine output due to ANP expression in both cardiac and renal tissues (Bajoria et al., 2001).

Cardiac hypertrophy with cardiac dilatation is seen in recipients in TTTS and likely is due to the increased cardiac preload and increased afterload pressures due to hypertension (Mahieu-Caputo et al., 2001, 2003). Of note, ventricular hypertrophy predominates and dilatation is comparatively "mild," with right ventricular compromise preceding and generally exceeding that of the left ventricle (Harkness and Crombleholme, 2005). Although the right ventricle is the primary "workhorse" of the fetal heart, and fetal myocardium can proliferate, other developmental factors likely contribute to the myocardial mural thickening detected by ultrasonography. Fetal myocardium is "stiffer" than the adult heart. The fetal myocardium has a greater percentage of noncontractile elements (60% vs. 30% in the mature heart) and relatively delayed removal of calcium from troponin C, and the ventricles have a shorter phase of early passive diastolic filling and a greater reliance on atrial contraction. Fetal lamb studies have shown that after 4 to 5 mm Hg, further atrial preload does not result in increased stoke volume. Thus, the fetal heart is inherently and mechanically less efficient, is less able to increase stroke volume, and displays impaired relaxation (Szwast and Rychik, 2005). These effects may represent, in part, disruption of the NP system, which has been shown to be NP receptor-dependent in murine models. NP receptor-deficient, Npr1−/− knockout mice develop hypertension, cardiac hypertrophy, and fibrosis. The absence of the receptor effectively inhibits vasorelaxation despite elevated concentrations of BNP and ANP. Moreover, cardiac hypertrophy can result independently of the presence of hypertension because the lack of receptor does not permit inhibition of myocardial proliferation/enlargement and fibroplasia.

Recipient twins are at increased risk for right ventricular outflow tract obstruction and pulmonary valvar stenosis/atresia with intact ventricular septum (Harkness and Crombleholme, 2005). The progressive hypertrophy, reduced systolic function, and tricuspid valvar insufficiency lead to progressive decline in flow across the pulmonary valve. In a case in which the infant underwent surgical repair, the trileaflet semilunar valvar anatomy was identified as normal except for adhesions of the coapted leaflets. Thus, the pulmonary valvar stenosis/atresia in recipient twins seems to represent a unique form of "acquired congenital heart disease" and not a primary malformation (Harkness and Crombleholme, 2005). ANP/BNP signaling interruption may play a significant role in the generation of cardiac hypertrophy and dysfunction (Cameron and Ellmers, 2003). The right and left ventricular myocardium have embryologic differences, and the number of NP receptors in the right ventricle may be inherently lower; once proliferation and hypertrophy ensue, the right ventricle may become progressively more vulnerable to the effects of preload, afterload, and pressors.

Although cardiac dysfunction is more common and more dramatic in recipients, decreased cardiac performance and injury also may occur in donor twins in TTTS (Harkness and Crombleholme, 2005; Luks et al., 2005). Protracted increase in cardiac demands and energy expenditure, due to continued transfusion of the co-twin, and hypoxemia and acidemia, due to the anemia and probable shrinking efficiency of placental function, contribute to reduced cardiac function and growth restriction in the donor (Luks et al., 2005). Umbilical arterial end-diastolic forward (AEDF) blood flow diminishes to become absent (Mahieu-Caputo et al., 2003; Umur et al., 2003; Jain and Fisk, 2004; Luks et al., 2005; Wee et al., 2006). Hydrops from high-output cardiac failure can ensue in the donor due to loss of oncotic pressure from chronic transfusion (Luks et al., 2005) and hypoproteinemia due to passive hepatic congestion and reduced hepatic synthesis that reflects reduced blood delivery to the liver (due to splanchnic vasoconstriction and relative preservation of blood shunting through the ductus venosus with effective bypass of the liver) and placental insufficiency with reduced nutritional supply.

INCIDENCE

Vascular communications occur in all monochorionic but rarely in dichorionic placentas. TTTS is therefore almost exclusively found in monochorionic twins. TTTS is estimated to occur in 5% to 15% of monochorionic twin pregnancies (Rausen et al., 1965; Benirschke and Kim, 1973). Lage et al. (1989) described a case of TTTS resulting from vascular anastomoses within a fused dichorionic twin placenta. Robertson

and Neer (1983) reported two cases of TTTS in dichorionic pregnancies.

The true incidence of TTTS is difficult to ascertain. TTTS may occur very early during the second trimester, with loss of both fetuses; in midgestation or at term. It is of most concern to the perinatologist when it occurs in midsecond trimester, when the syndrome results in polyhydramnios, often with spontaneous rupture of membranes, or in spontaneous labor that leads to premature delivery. Because TTTS can have such a wide spectrum of clinical presentation, in many cases the diagnosis may go unrecognized.

SONOGRAPHIC FINDINGS

Wittmann et al. (1981) and Brennan et al. (1982) have suggested the sonographic criteria for the diagnosis of TTTS, including: (1) significant size disparity in fetuses of the same sex, (2) disparity in size between two amniotic sacs, (3) disparity in size of the umbilical cords, (4) single placenta, and (5) evidence of hydrops in either fetus or findings of congestive cardiac failure in the recipient. However, discordant growth is a common complication of twin pregnancies, and causes other than TTTS exist for discordant amniotic fluid volumes. The criterion of a birth weight difference of greater than 20% for the diagnosis of TTTS is based on the belief that the donor twin becomes growth restricted as a result of anemia and hypoalbuminemia. However, Sherer et al. (1994) reported a case of acute intrapartum TTTS so severe as to cause the death of both twins. In this report, the birth weights of the infants differed by only 2%.

In some cases, the discordance in amniotic fluid volume is so great that the amnion adheres to the smaller baby, so that it appears "stuck" to the wall of the uterus (Figure 119-1). In this situation it may be extremely difficult to visualize the dividing membrane between the twins. The "stuck twin" phenomenon is not pathognomonic for TTTS; it may also result from structural fetal anomalies, congenital infection, chromosomal abnormalities, or ruptured membranes (Patten et al., 1989). In contrast, the co-twin moves freely in a normal or increased amniotic fluid volume (see Figure 119-1). On ultrasound examination, signs of hydrops fetalis are occasionally found in the recipient (Brennan et al., 1982), rarely in the donor (Rausen et al., 1965), and exceptionally in both (McCafee et al., 1970).

In addition to measuring biometry and amniotic fluid volume, Doppler velocimetry can be used to confirm the diagnosis of TTTS. Nonetheless, studies have provided conflicting results. Farmakides et al. (1985) reported two cases in which UA waveforms of the twins were discordant and concluded that simultaneous observation of high- and low-resistance UA systolic/diastolic (S/D) ratios was suggestive of TTTS. Meanwhile, Giles et al. (1985) found no difference in interpair S/D ratios in eight cases where the diagnosis was documented or strongly suspected. Pretorius et al. (1988) also reported eight cases of TTTS and found no consistent pattern in Doppler studies. Five of the eight pregnancies resulted in fetal or neonatal death of both twins. In these cases of perinatal loss, one or both of the twins had either absent or reversed diastolic flow. The authors concluded that, while abnormal Doppler studies are not helpful in identifying the donor from the recipient twin, it invariably predicts a poor outcome. Data from the Australian and New Zealand TTTS Registry support these observations (Dickinson and Evans, 2000). Ishimatsu et al. (1992) were also unable to identify any distinctive findings in the UA blood flow velocity waveforms in patients with TTTS. However, the presence of cardiomegaly in five recipient

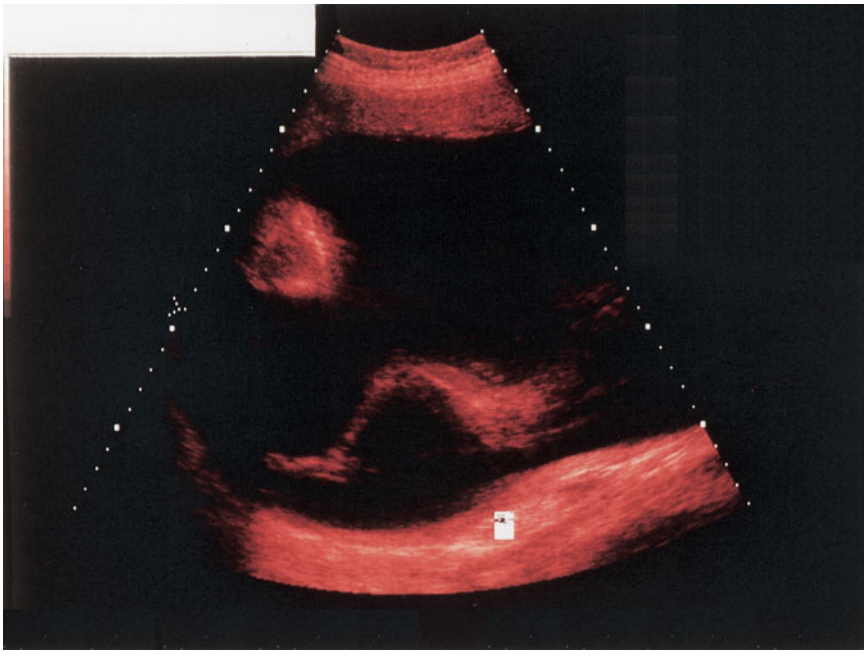

Figure 119-1 Prenatal sonographic image demonstrating a "stuck" twin in the upper left section of the image and the co-twin in a sac with polyhydramnios.

twins, with tricuspid regurgitation and a biphasic umbilical vein waveform in three others, led these authors to suggest that these findings may be more diagnostic than UA Doppler velocimetry and representative of the hemodynamic changes that occurring in TTTS. It is interesting to note that AA anastomoses can be identified using Doppler ultrasound as early as the first trimester, and absence of these anastomoses has been found to be associated with an increased risk for TTTS (Jain and Fisk, 2004).

A staging system for TTTS has been developed by Quintero et al. (1999) for the purpose of categorizing disease severity and standardizing comparison of different treatment results. In Stage I there is oligohydramnios, but the donor twin bladder is visible; in Stage II the bladder of the donor twin is no longer visible; in Stage III abnormal Doppler studies are evident (i.e., absent/reversed end-diastolic velocity in the UA, reversed flow in the ductus venosus, or pulsatile flow in the umbilical vein); Stage IV is complicated by hydrops; and in Stage V one or both fetuses have died.

Taylor et al. (2000) applied the Quintero staging system to a population treated with serial amnioreduction (AR), septostomy, and selective reduction alone or in combination and found no significant influence of staging at presentation on survival in their conservatively treated group. Survival was significantly poorer when stage increased rather than decreased. These authors concluded that the Quintero staging system should be used cautiously for determining prognosis at the time of diagnosis, suggesting that it may be better suited for monitoring disease progression. A subsequent larger study from the same institution, however, showed that Quintero stage at presentation, at first treatment, and at worst stage did, in fact, predict both perinatal (overall number of fetuses surviving of the total number of fetuses treated) and double survival (number of pregnancies with two survivors), but not survival of any twin (number of pregnancies with survival of one or both twins) (Taylor et al., 2002). Duncombe et al. (2003) also showed a correlation of Quintero stage at initial presentation and perinatal survival.

The Quintero staging system, although useful in describing the progression of TTTS along the clinical spectrum of severity, has potential limitations in guiding therapy. For patients who present at Stage I with only amniotic fluid discordance, it may be difficult to know with certainty if they actually have TTTS. Patients who have Stage II presentation usually are believed to be in the early stages of the disease. The use of echocardiography to identify findings of recipient TTTS cardiomyopathy can confirm the diagnosis in Stage I cases when it may be in doubt. In addition, echocardiographic findings can alert the clinician to more advanced disease than the Quintero Stage suggests. The largest group of patients tends to fall into Stage III, but this stage comprises a very broad spectrum of severity. At one end are patients whose only hemodynamic derangement is abnormal UA Doppler velocimetry, and at the other end of the spectrum are patients in whom the recipient twin has severe, end-stage, twin–twin cardiomyopathy. These latter patients may be premorbid but without the development of hydrops (Stage IV disease). The Quintero staging system is heavily weighted toward findings in the donor twin. The absence of a visible bladder in the donor upstages the case to Stage II. The critical Doppler abnormalities that are required for Stage III almost always are observed in the donor twin. Critical Doppler waveform abnormalities in the recipient twin are rare until end-stage TTTS has been reached. In addition, there is no assessment of the TTTS cardiomyopathy, which only occurs in the recipient and has a profound impact on survival of the recipient (Harkness and Crombleholme, 2005; Michelfelder et al., 2007; Habli et al., 2008).

The Fetal Care Center of Cincinnati has used fetal echocardiographic assessment of the recipient twin to stage patients (Table 119-1). This is in keeping with the view that TTTS is a fundamentally hemodynamic derangement. Fetal echocardiography can distinguish degrees of severity among the broad spectrum of severity in Stage III TTTS and identify sicker patients in Stages I and II. Echocardiographic features include the presence and severity of atrioventricular valvar incompetence, ventricular wall thickening, and ventricular function, as assessed by the Tei Myocardial performance index (Barrea et al., 2005; Ichizuka et al., 2005). In recent reviews of experience with the Cincinnati staging system, 20% to 55% of Quintero Stage I and II patients were upstaged to Stage III disease based on echocardiographic findings (Michelfelder et al., 2007; Habli et al., 2008). The impact of TTTS cardiomyopathy on recipient twin survival had been demonstrated by Shah et al. (2008) in patients treated by fetoscopic laser who were stratified by cardiovascular profile score and in the National Institutes of Health TTTS trial in which echocardiographic findings of TTTS were the single most important predictor of adverse recipient survival (Crombleholme et al., 2007; Shah et al., 2008). The upstaging of patients from Stage II to Stage III may influence counseling about treatment options. These echocardiographic features also are used to assess response to therapy. If a patient is treated initially with AR or microseptostomy, fetal echocardiography can be used to assess progression of TTTS despite therapy and as an indication for selective fetoscopic laser photocoagulation (Crombleholme et al., 2006, 2007; Habli et al., 2008).

Intrauterine cardiac dysfunction and hemodynamic derangements lead to ischemic brain lesions, including white matter infarction and leukoencephalopathy, intraventricular hemorrhage, hydranencephaly, and porencephaly, which can be detected by prenatal ultrasonography (Denbow et al., 1998; De Lia et al., 2000; Mari et al., 2000; Taylor et al., 2000; Kline-Fath et al., 2007). Up to 8% of TTTS cases have evidence of CNS injury on fetal magnetic resonance imaging (MRI) at the time of presentation prior to treatment. Such CNS findings range from ischemic or hemorrhagic changes in the brain to marked dilation of the cerebral venous sinuses due to central venous hypertension. The latter has been shown to correlate with worse survival when detected in TTTS (Kline-Fath et al., 2007). When these lesions are seen in surviving twins of instances of co-twin death [66% of cases

Table 119-1

Cincinnati Modification of the Quintero Staging System and the Sequence of Progressive Events in Untreated TTTS

Stage	Donor	Recipient	Recipient Cardiomyopathy
I	Oligohydramnios (DVP <2 cm)	Polyhydramnios (DVP >8 cm)	No
II	Absent bladder	Bladder seen	No

with intrauterine death involve demise of the donor twin (Weisz et al., 2004)], they have been attributed to sudden acute TTTS (De Lia et al., 2000; Kraus et al., 2005) through arterioarterial (A-A) anastomoses (De Lia et al., 2000). Due to the shared placental circulation, if one co-twin dies, there is an acute fall in blood pressure that causes placental resistance to decrease. This decrease in resistance across the placental vascular connections can result in reduced cerebral perfusion pressure and ischemic injury in the brain of the surviving twin. Quintero et al. (2002) reported endoscopic evidence of fetofetal hemorrhage from a recipient to donor twin within 3 hours of the spontaneous demise of the donor, noting endoscopic and middle cerebral artery Doppler evidence of paradoxic anemia in the recipient and erythrocythemia in the donor. TTTS can result in significant neurologic damage, with 5% to 27% of surviving twins having evidence of CNS sequelae on postnatal MRI or ultrasonography (De Lia et al., 1995; Ville et al., 1995; Hecher et al., 1999; Senat et al., 2004; Kraus et al., 2005). Brain injury, however, can occur in TTTS even when both twins survive. When both twins survive, neurologic damage in the recipient may be related to secondary polycythemia and venous stasis. In the donor, neurologic injury may be due to anemia and hypotension.

Multiorgan ischemic sequelae also are seen. Renal failure occurs in 48% of survivors compared with 14% of aged-matched controls (Jain and Fisk, 2004). Renal cortical necrosis, intestinal atresia, and cutis aplasia may be seen in one or both twins (Denbow et al., 1998; Luks et al., 2001; Carr et al., 2004). Limb necrosis and other ischemic lesions and hemolytic jaundice in the surviving recipient twin may be related to hyperviscosity (erythrocythemia) (Carr et al., 2004) or thromboembolic phenomena due to placental chorangiopagus vessels (Margono et al., 1992).

Diamniotic monochorionic twins are at increased risk for structural cardiac anomalies in at least one twin; 7% of monochorionic diamniotic twins have congenital heart defects (CHD) (Manning and Archer, 2006) compared with the overall prevalence of 0.5% seen in neonates (Bahtiyar et al., 2007). Bahtiyar et al. (2007), in their multistudy review of the prevalence of CHD in monochorionic diamniotic twins, found an overall ninefold increased risk for CHD over singletons, a 15- to 23-fold higher risk of CHD with TTTS over that of singletons, and a 2.78 times more frequent occurrence of CHD in the setting of TTTS compared with no TTTS. These overall and relatively increased risks are probably related to the greater frequency of abnormalities of placentation and the umbilical cord in monochorionic diamniotic gestations and their relative predominance in TTTS, respectively. However, the etiopathogenesis of cardiovascular malformations is poorly understood, even in singletons. Thus, the increased prevalence of cardiac malformations in monochorionic diamniotic twins, and especially in those pairs affected by TTTS, probably represents a complex interaction among many variables such as fetal blood flow fluctuations, vascular endothelial growth factors (VEGFs) and other mediators, the process of twinning itself, unequal sharing of the placenta, and inherent genetic factors.

The most common defects in monochorionic diamniotic twins are ventricular septal defect (VSD), pulmonary

stenosis, and atrial septal defect. The prevalence of VSDs in TTTS, although higher, is not remarkably different from that in uncomplicated monochorionic diamniotic gestations (0.024 and 0.019, respectively). The detection of VSDs may represent sites of ischemic necrosis or excessive natriuretic proteins during early embryonic life. However, the membranous septum is a complex structure that has numerous embryologic components effecting its closure and VSDs, together with patent ductus arteriosus, are the most common cardiac defects in infancy. The pathogenesis of VSD is unclear, but its mildly increased incidence in TTTS infants may be related to a combination of factors, including its relatively greater general frequency and the increased risk of ischemia in TTTS due to abnormal placentation or ischemia due to hypovolemia. Bahtiyar et al. (2007) postulated that because recent studies indicate that the cause of CHD is partly due to aberrant angiogenic factors such as VEGF, the increased prevalence of CHD in TTTS may represent the deleterious effects of angiogenic factors. VEGF is upregulated in ischemia, and Dor et al. (2001) found that VEGF is specifically upregulated during normal heart development in the atrioventricular field of the heart, soon after the onset of endocardial cushion formation. Premature induction of myocardial VEGF prevents formation of endocardial cushions in animal models.

The prevalence of pulmonary stenosis is fourfold greater in gestations involving TTTS compared with those not involving TTTS (0.028 vs. 0.007), and atrial septal defects (0.024) are seen only in twins who have experienced TTTS (Bahtiyar et al., 2007). However, these summations do not specify co-twin status (donor or recipient), although pulmonary stenosis presumably represents the recipient population. The original studies also do not separate donor or recipient twin status, so it is difficult to assess the potential relationship of atrial septal defects to fetal volume status or circulating mediators and angiogenic factors. Presumably, high-output failure in the donor twin or right ventricular outflow tract obstruction in the recipient both could result in increased shunting through the foramen ovale and acquired incompetence of the interatrial septum (passive enlargement such that the septum primum does not adequately cover the foramen ovale). It is unclear whether the clinically diagnosed "atrial septal defects" represent a true primary deficiency of tissue (due to ischemic necrosis, increased apoptosis, mesenchymal failure) or excessive secondary dilatation of the foramen due to shunt overload as the right ventricle fails. Recently, transposition of the great arteries has been identified in a recipient twin, but the donor additionally had a vein of Galen malformation. Although the coexistence of the lesions might reflect a common causal mechanism, their etiopathogenesis(es) is unclear (Steggerda et al., 2006).

CHD in donor twins appears to be very rare, but left-sided obstructive lesions might be expected due to complications of hypovolemia. However, of the 830 monochorionic diamniotic gestations reviewed by Bahtiyar et al. (2007), the only instances of coarctation of the aorta or hypoplastic left ventricle (left-sided obstructive lesions) were isolated to two cases that did not have TTTS. Thus, although the prevalence theoretically would be expected to be higher in donor twins in TTTS and small twin size correlates with the presence of structural defects in monochorionic diamniotic twins (Bahtiyar et al., 2007), the pathogenesis of these rarely encountered lesions appears to represent more than unusual sequelae of diminished blood flow.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for TTTS includes discordant severe IUGR, discordant structural fetal anomalies, congenital infection, chromosomal abnormalities, and ruptured membranes. The antenatal diagnosis is based on ultrasound findings. Nevertheless, there have been attempts to devise more definitive diagnostic techniques. Fisk et al. (1990) described fetal blood sampling in six cases compromised by TTTS. Difference in hemoglobin concentration of 5 g per deciliter was found in only one pregnancy. Confirmation of a shared circulation was achieved in two pregnancies by transfusing adult Rh-negative red cells into the smaller fetus and then detecting them by Kleihauer–Betke testing in blood aspirated from the larger fetus. Bruner and Rosemond (1993) further reported successful fetal blood sampling in six of nine cases with the ultrasonographic diagnosis of TTTS. Hemoglobin difference was present in only one case. Shared circulation was demonstrated and confirmed in four (44%) of those initially identified by ultrasonographic criteria through the transfusion of O-negative red cells into the small twin and the performance of Kleihauer–Betke analysis on blood obtained from the larger twin. The author concluded that the currently accepted prenatal criteria are insufficient for the diagnosis of TTTS and suggested that the sonographic findings of marked growth discordance with oligohydramnios, polyhydramnios, monochorionic placenta, and like gender should more accurately be described as the twin oligohydramnios/polyhydramnios sequence.

The injection of intravascular pancuronium bromide has been suggested as an alternative to the injection of adult red cells to confirm TTTS (Tanaka et al., 1992). Paralysis of both fetuses can be detected through the examination of fetal heart rate tracings. There is an absence of accelerations noted with a reduction in fetal heart rate variability and a persistent tachycardia seen following pancuronium injection.

TTTS is generally diagnosed during the neonatal period by demonstration of a hemoglobin difference of greater than 5 g per deciliter (Rausen et al., 1965; Tan et al., 1979) and a difference in birth weight between twins of greater than 20% (Tan et al., 1979). Untimely umbilical cord clamping of either donor or recipient, erythropoietic changes, and reversed intrapartum shunting may result in false-positive and false-negative diagnosis when the determination is based on hemoglobin disparity alone. The cutoff value between normal and abnormal intertwin birth weight differences also remains controversial (Blickstein, 1990). In fact, all the classically accepted neonatal criteria of discordant hemoglobin, hematocrit, and weight have been challenged.

Danskin and Neilson (1989) found that hemoglobin differences of greater than 5 g per deciliter occur at similar rates in twins with dichorionic and monochorionic placentation. They reported birth weight differences greater than 20% equally in monochorionic and dichorionic pregnancies. Wenstrom et al. (1992) reviewed 97 cases of pathologically proven monochorionic twin pregnancies and observed all combinations of weight and hemoglobin/hematocrit discordance. Of 97 twin pairs, 34 were discordant for weight, and in half of these the hemoglobin and hematocrit were concordant. In 18% of cases the smaller twin had the higher hematocrit, and in 32% the smaller twin had the lower hematocrit. The authors concluded that weight and hemoglobin/hematocrit discordance is common in monochorionic twins and in itself is not sufficient for a diagnosis of TTTS. Conflicting information regarding both the fetal and neonatal hematologic criteria for the diagnosis of TTTS, together with the potential risk inherent in fetal blood sampling, has led us to avoid this procedure at our institution for the definitive diagnosis of TTTS.

ANTENATAL NATURAL HISTORY

TTTS occurs in acute and chronic forms. In early pregnancy an acute transfusion may result in an early fetal death, resulting in the so-called vanishing twin syndrome. Later in pregnancy, TTTS may cause death of one or both twins (Figure 119-2). Sometimes, a rapid transfer of blood from one twin to the other occurs during delivery. In such cases the twins are similar in weight and length, but one is polycythemic and hypervolemic and the other is anemic and hypovolemic.

In the chronic form of TTTS, the transfusion of blood from one twin to the other occurs over an extended period during the pregnancy. In chronic TTTS, the donor twin is generally hypovolemic and shows varying degrees of growth restriction. TTTS and placental insufficiency occur together in up to 20% of cases. In severe cases, the donor may die in utero and present at delivery as a fetus papyraceous. The recipient twin is hypervolemic, often larger than the donor, and may develop cardiac hypertrophy and congestive heart failure. Because of increased urine output, severe polyhydramnios frequently develops in the recipient twin that may predispose to premature delivery. Oligohydramnios is generally associated with the donor twin. The organ changes seen in donor twins in chronic TTTS resemble abnormalities observed in malnourished singletons. Weights of the heart, liver, spleen, thymus, and fetal adrenal cortex are proportionately smaller in the donor than in the recipient twin and suggest antenatal malnutrition (Naeye, 1965) (Figure 119-3). A much higher concentration of atriopeptin (atrionatriuretic peptide) has been reported in the serum from the recipient twin as compared with the donor twin in two cases of severe transfusion syndrome. More recently, Habli et al. have found that brain atrial natriuretic peptide (BNP) is significantly elevated in 130 cases of TTTS (Habli and Crombleholme, 2009). The

Figure 119-2 Death of both twins in midgestation as a result of twin-to-twin transfusion syndrome. The smaller, growth-restricted donor twin is on the left and the larger recipient twin on the right. (*Courtesy of Dr. Joseph Semple.*)

elevated BNP levels were found to correlate with Cincinnati stage of TTTS cardiomyopathy (Habli and Crombleholme, 2009). One may infer from this that atriopeptin plays a role in the pathophysiology of the syndrome (Nageotte et al., 1989). Atriopeptin, produced by mammalian atria and BNP produced by the ventricles, are peptides that promote diuresis and vascular changes. In TTTS, atriopeptin and BPN released from the heart of the recipient may lead to increased urine output that results in polyhydramnios and vascular changes that in turn lead to hydrops (Nageotte et al., 1989, Habli and Crombleholme, 2009). Untreated, the natural history of TTTS is associated with a 60% to 100% mortality rate for both twins in severe or chronic cases (Benirschke and Kim, 1973; Cheschier and Seeds, 1988).

MANAGEMENT OF PREGNANCY

In the assessment of discordant growth in twins in utero it is important to differentiate TTTS from isolated growth failure

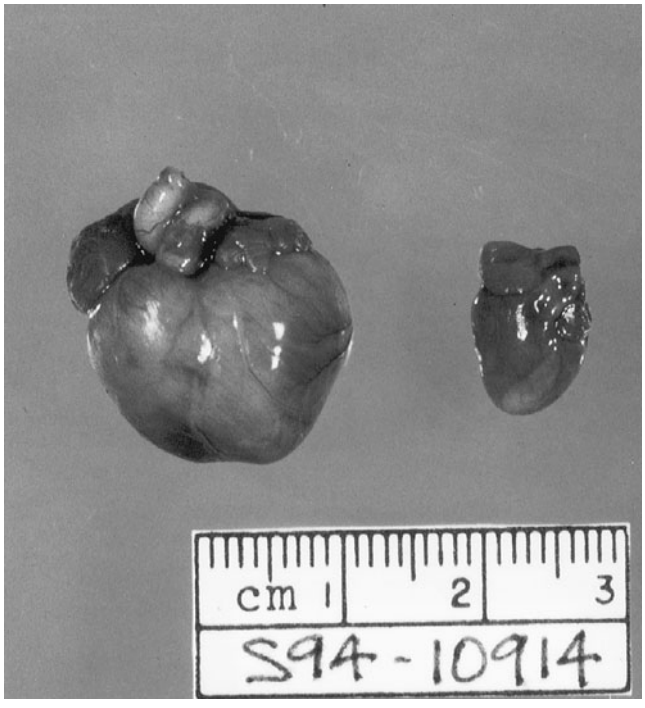

Figure 119-3 At the right is the paler, smaller heart of the donor fetus. At the left is the plethoric, larger heart of the recipient fetus.

of one twin. The cause of stuck twin syndrome includes twin-to-twin transfusion, fetal anomalies, placental insufficiency, and possibly abnormal cord insertion. A detailed anatomic survey is recommended to rule out any associated congenital abnormalities. Such a survey may be difficult if the fetus is stuck because of substantial oligohydramnios, which impairs ultrasonic visualization. Color Doppler studies are useful to visualize where the cord inserts into the placenta. In cases of TTTS, echocardiographic assessment of both donor and recipient twins is recommended and the Cincinnati staging system can be used to stratify TTTS cardiomyopathy into mild moderate and severe. In addition, we routinely perform ultrafast fetal MRI to evaluate the fetal brains for signs of ischemia, hemorrhage or dilated venous sinuses that may be present in up to 8% of cases of TTTS at presentation (Kline-Fath et al., 2007). It is our practice to perform amniocentesis to exclude a chromosomal abnormality. Amniotic fluid is also sent for cytomegalovirus culture because of the reported association of stuck twin syndrome with viral infections. The definitive antenatal diagnosis is one of exclusion, and therapy is usually based on a presumptive diagnosis. It is our practice to inform patients of the various available treatment options, summarized in Table 119-2.

Delivery should be performed at a tertiary care center because most cases deliver less than 32 weeks' gestation. Vaginal delivery may be attempted in cases in which TTTS has been diagnosed. It is critical to monitor the heart rates of both fetuses. A sinusoidal pattern on the fetal heart rate tracing may be a sign of fetal anemia. Of eight cases of TTTS monitored through labor by Goldberg et al. (1986), two pairs experienced severe fetal distress requiring emergency cesarean section. In another case, the recipient died of presumed intrapartum TTTS (Goldberg et al., 1986). The incidence of cesarean delivery in TTTS was reported to be 44% in Reisner et al.'s series (1993), but this has not been reported in other recent series.

Cord hematocrits should be measured at the time of delivery. Initial examination of the placenta should be performed by the obstetrician after delivery. Classically, the placenta of the donor twin looks pale and atrophied in comparison to that of the recipient twin that is red and hypertrophied. Because postnatal demonstration of transplacental vascular connections is an important criterion for the definitive diagnosis of TTTS, the placenta should be sent to the pathology department for further studies. Because many cases involve deep vascular shunts rather than superficial connections, vascular injection is necessary to exclude such connections (Blickstein, 1990).

Table 119-2

Options Available for the Treatment of TTTS

Observation only
Medical therapy Indomethacin Digoxin Nifedipine
Serial amniocentesis with echocardiographic surveillance
Amniotic septostomy
Selective reduction by radiofrequency ablation or cord coagulation
Fetoscopic laser treatment Selective fetoscopic laser photocoagulation Nonselective fetoscopic laser photocoagulation

FETAL INTERVENTION

Due to the poor perinatal outcomes associated with the disorder, expectant management of TTTS is not recommended except in incipient cases that do not meet criteria for TTTS (Fox et al., 2005). Treatment depends on the gestational age at diagnosis. Patients with early onset TTTS may opt for selective termination of one twin (usually the donor) or termination of the entire pregnancy. If TTTS develops later in pregnancy, treatment may be less aggressive depending on the disease severity and gestational age.

In the midtrimester, aggressive management is recommended. Medical management with digoxin has been

attempted but has not shown to be effective (De Lia et al., 1985). Indomethacin is contraindicated due to reports of fetal demise (Jones et al., 1993). Current treatment options for severe TTTS include: (1) serial reduction amniocentesis, (2) amniotic septostomy, and (3) laser ablation of the anastomoses.

In serial reduction amniocentesis, an 18-gauge spinal needle is placed into the polyhydramniotic sac under ultrasound guidance (Malone and D'Alton, 2000; Johnsen, 2004). Provided the patient can tolerate the procedure, amniotic fluid is withdrawn until the fluid level returns to normal (DVP <5 cm). Amnioreduction is repeated as often as necessary to maintain a near normal amniotic fluid volume. The mechanism by which this procedure restores the amniotic fluid balance has not been elucidated. Removing excess fluid from the sac with polyhydramnios may result in decreased pressure on the other sac or the placenta. This, in turn, may result in increased placental perfusion to the stuck twin with secondary improvement in its amniotic fluid. Studies have cited perinatal survival rates of 37% to 83% following this procedure (Malone and D'Alton 2000). The wide range in perinatal survival may be due to reporting bias, small sample sizes, and variation in the timing and amount of fluid removed. Large registries of TTTS pregnancies however, have reported survivals of 60% to 65% (Dickenson and Evans, 2000; Mari et al., 2001).

Amniotic septostomy is another option (Malone and D'Alton, 2000; Johnson et al., 2001). In this procedure, a 20-gauge spinal needle is inserted through the dividing membrane under ultrasound guidance. The amniotic fluid, then, sometimes equilibrates across the disrupted membrane. Similar to serial AR, the mechanism of action of this technique is unknown. It is possible that the defect in the membranes allows the donor to swallow a sufficient volume of fluid to augment its circulating blood volume, secondarily increasing its urine output. Studies regarding the effectiveness of this treatment modality have been conflicting. In one report of 12 cases, pregnancy was prolonged by 8 weeks with an 83% survival rate (Saade et al., 1998). In another report of 14 patients (7 managed by serial AR and 7 with amniotic septostomy) no differences in overall survival were noted. The septostomy patients, however, delivered significantly later. In another report, all three of the treated pregnancies were lost within 5 days secondary to preterm premature rupture of membranes (Pistorius and Howarth, 1999). In a more recent study by Saade et al., 32 patients were randomized to septostomy and 31 to AR. Similar outcomes were noted between the groups. Both groups had 65% survival (Saade et al., 2002). Because septostomy can result in an iatrogenic monoamniotic pregnancy that has its own inherent complications and risks, the procedure has been criticized. Likewise, comparing AR to septostomy is challenging because both procedures utilize AR, and, serial AR can be complicated by inadvertent septostomy.

Laser ablation of placental anastomoses is another invasive treatment option that has been utilized to correct the underlying pathophysiology of TTTS. Reported perinatal survival rates have ranged from 53% to 69% (Malone and D'Alton, 2000). De Lia et al. (1990) developed the technique for intrauterine ablation of vascular communications in the placenta with a fetoscopically directed neodymium-YAG laser. Three women who were carrying twins and who were at risk of pregnancy loss from acute hydramnios underwent the procedure at 18, 22, and 22.5 weeks of gestation. Four of the six infants survived. De Lia et al. subsequently reported 26 patients with a mean gestational age of 20.8 weeks at the time of treatment. One patient has surviving triplets, eight have surviving twins, nine have a single survivor (two neonatal and seven fetal deaths occurred in this group and eight have no survivors). The cases with survivors were delivered for obstetric indications at a mean of 32.2 weeks. Fifty-three percent of the fetuses survived with 96% (27 of 28) developing "normally" at a mean age of 35.8 months. An identical survival rate of 53% was reported in a second series involving 45 cases of TTTS (Ville et al., 1995). The median interval between the endoscopic laser procedure and the delivery was 14 weeks. De Lia et al.'s surgical technique consisted of laparotomy (7- to 10-cm skin incision) under general anesthesia and insertion of a 3.85 × 2.9-mm fetoscope sleeve into the uterus. The technique has not gained widespread acceptance because of its invasive nature. Ville et al. (1995) described the percutaneous insertion of a 2-mm fetoscope into the amniotic cavity using continuous ultrasound visualization under local anesthesia.

The goal of coagulation of all superficial placental vessels is to interrupt the vascular communication between the circulation of the two fetuses (Figure 119-4). This direct treatment of the underlying pathophysiology of TTTS has been cited as a major advantage over other techniques (De Lia et al., 1995; Ville et al., 1995).

In a series of 132 pregnancies with TTTS managed by fetoscopic laser ablation of placental vessels, 55% of infants survived, and there was at least one survivor in 73% of the cases (Ville et al., 1998). The rate of neurologic handicap after 12 months of follow-up was 4%, which was lower than the authors' previous experience with serial reduction amniocentesis. The authors concluded that serial reduction amniocentesis appears to provide similar overall survival results, but there was less neurologic morbidity in the laser group.

In a study of TTTS from Germany, 73 patients at a single center were prospectively treated with fetoscopic laser ablation, while 43 patients at a separate center were prospectively treated with serial reduction amniocentesis (Hecher et al., 1999). Patients in the fetoscopic laser group had a higher proportion of pregnancies with at least one survivor, fewer fetal deaths, higher gestational age at delivery, and fewer cases of abnormal sonographic findings in the brain of survivors. It was therefore concluded that fetoscopic laser ablation is a more effective treatment for TTTS than serial reduction amniocentesis.

Senat et al. (2004) recently published the results of the European prospective multicenter randomized controlled study of endoscopic laser (semiselective technique) versus

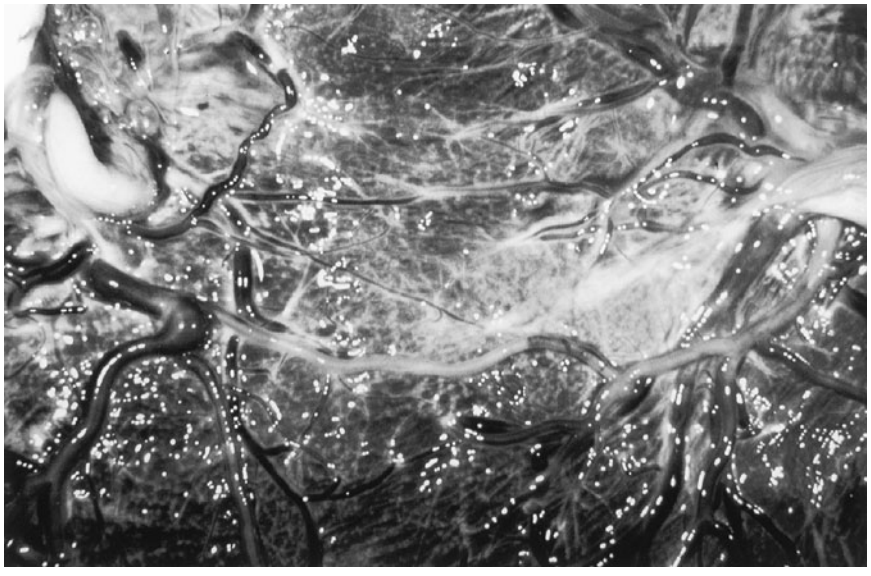

Figure 119-4 Vascular anastomoses in monochorionic twins. (*Courtesy of Dr. Joseph Semple.*)

serial AR for the treatment of severe TTTS. All patients were between 15 and 26 weeks' gestation. Interim analysis demonstrated a significant benefit to the laser group. As result, the study was stopped after 142 patients had been randomized. Compared to the AR group, the laser group had a higher likelihood of survival of at least one twin to 28 days of life (76% vs. 56%) and 6 months of age (76% vs. 51%). The median gestational age at delivery was significantly greater in the laser group than in the AR group (33.3 weeks vs. 29.0 weeks). Thirty patients in the laser group (42%) and 48 in the AR group (69%) delivered before 32 weeks. Neonates from the laser group also had a lower incidence of periventricular leukomalacia and were more likely to be free of neurologic imaging abnormalities at 6 months of age (52% vs. 31%).

The overall survival in the laser arm was 57%, which was consistent with survival rates in previous reports of nonselective fetoscopic laser treatment (53%) (De Lia et al., 1995; Ville et al., 1995). This rate is significantly lower, however, than the survival reported with selective fetoscopic laser photocoagulation (SFLP) (64–68%) (Hecher et al., 1999; Dickinson and Evans, 2000). Of particular concern is the poor survival observed in the AR arm of 39%, which is significantly lower than previously reported (60–65%) (Elliott et al., 1991; Pinette et al., 1993; Dickinson and Evans, 2000; Mari et al., 2001). Antenatal, peripartum, and neonatal care was provided by the referring hospital, and lack of standardization may explain some of these differences (Fisk and Galea, 2004). The decreased survival in the AR group may reflect the higher pregnancy termination rate in the AR group (16 vs. 0 in the laser group). The terminations were requested after the diagnosis of severe fetal complications. It would be instructive to know whether these women were offered cord coagulation as a means of rescuing one baby (Dickinson and Evans, 2000). Reliable assessment of neurologic outcome is critical when assessing efficacy of treatment for TTTS. Although the rate of abnormality on neurologic imaging was lower in the laser group (7% vs. 17%), long-term neurodevelopmental assessment has revealed no difference in outcome between survivors treated by fetoscopic laser and those treated by AR (Ortqvist et al., 2006).

The National Institutes of Health (NIH)-sponsored TTTS trial is the only other prospective randomized trial comparing survival among those receiving AR versus SFLP (Crombleholme et al., 2007). This trial differed from the Eurofoetus trial in several important aspects. First, to qualify for the NIH Trial, the TTTS had to fail to respond to a qualifying amniocentesis. The rationale for this requirement was to eliminate those who were more likely to respond to AR, the so-called "single amnio paradox." Second, patients were candidates only if the TTTS presented earlier than 22 weeks of gestation, and no Stage I patients were candidates for the trial. These two requirements were substantially different from the Eurofoetus trial in which women were randomized into the trial up to 26 weeks of gestation, and 52% of those entered were Stage I (Senat et al., 2004).

The NIH study was stopped early, after 42 women were randomized, when the Trial Oversight Committee detected a trend in adverse outcome affecting the recipient twin in one treatment arm and recommended to the Data Safety Monitoring Board that the trial be stopped to allow biostatistical analysis of the adverse trend. Results of the NIH TTTS trial showed no statistically significant difference in overall neonatal survival to 30 postnatal days (60% vs. 43% p = NS) or neonatal survival of one or both twins in the same pregnancy (75% vs. 65%, p = NS) in cases of severe TTTS treated by either AR or SFLP. Despite these overall results, a statistically significant worse fetal survival was observed among recipient twins in pregnancies treated by SFLP compared with those treated by AR. This apparent conundrum can be accounted for by recipient fetal losses in the SFLP arm being balanced by increased treatment failures among recipients in the AR arm. These results suggest that, in these highly selected cases of

severe TTTS, neither treatment is superior to the other. Once TTTS reaches this degree of severity, the mortality among recipients is considerable, but the losses may occur at different times, depending on treatment. The impact of TTTS severity on fetal survival is supported further by the significantly worse fetal survival among recipient twins in Stages III and IV compared with those in Stage II. One of the strongest predictors of recipient demise is echocardiographic evidence of TTTS cardiomyopathy. The losses of fetal recipients treated by SFLP usually occur within 24 hours of the procedure. In contrast, the recipients treated by AR are not lost following the procedure, but there is progressive TTTS cardiomyopathy, as reflected by more recipients in the AR arm meeting criteria to be declared treatment failures. Taken together, these data suggest a disproportionate impact of TTTS cardiomyopathy on recipient survival in advanced stages of TTTS no matter what treatment they receive.

Recently, Rossi and D'Addario (2008) reported a Cochrane review of TTTS with a meta-analysis that included data from both the Eurofoetus and NIH trials. The conclusion drawn from this analysis was that SFLP of TTTS is preferred over AR when it is available and AR is preferred when SFLP is not available. The results of this analysis likely are skewed toward fetoscopic laser based on the small numbers of individuals included from the NIH trial ($n = 42$) compared with the number included from the Eurofoetus trial ($n = 142$).

AR is readily available, less costly, and less invasive; laser therapy is only available at select institutions and requires specialized training. Although it makes sense to use AR where treatment options give similar results, it would be prudent to move promptly to laser therapy if rigorous studies can prove that this therapy has better short- and long-term outcomes in the setting of advanced disease.

For patients who respond to AR, the overall survival rate has been 88% (Crombleholme et al., 2006). In those cases in which echocardiographic progression is detected despite AR, the overall survival rate when SFLP is performed is 80%. The difference in survival between responders to AR and those who progress to SFLP is not statistically significantly different, suggesting that survival was not compromised by an initial trial of AR before progressing to SFLP.

TREATMENT OF THE NEWBORN

Both acute and chronic cases of TTTS must be managed expeditiously by trained neonatologists. Because the incidence of prematurity is so high, many complications of prematurity are present, including the need for respiratory support, transfusion, and supplemental glucose. Specific problems unique to newborn cases of TTTS include severe anemia in the donor and severe polycythemia and hypervolemia in the recipient newborn. Either one or both twins may have hydrops. Exchange transfusions may be necessary to correct the anemia and polycythemia. If TTTS cardiomyopathy is present, ionotrophic support may be indicated for the recipient twin. Echocardiographic assessment should be performed in any recipient with TTTS cardiomyopathy.

SURGICAL TREATMENT

No surgical treatment has been described for newborns with TTTS.

LONG-TERM OUTCOME

One of the concerns associated with in utero treatment for TTTS is that prolongation of pregnancy might produce survivors with excessive neonatal or infant complications (Mahony et al., 1990). If one fetus dies in utero, the surviving twin is at risk for multiorgan damage including severe neurologic compromise. Even if both twins survive, the pathophysiology of TTTS can result in adverse neurological sequelae to one or both (Cincotta et al., 2000; Dickinson and Evans, 2000; Mari et al., 2001; Sutcliffe et al., 2001; Banek et al., 2003; Lopriore et al., 2003; Dickinson et al., 2005).

In older literature, thrombocytopenia has been suggested as a cause of cataracts, impaired hearing, and growth restriction of the donor twin (Corney and Aherne, 1965). Intrauterine growth deficiency of the brain (Naeye, 1963) and profound neonatal hypoglycemia (Reisner et al., 1965) have been implicated as a cause for cerebral impairment of the donor, resulting in subsequent lower intelligence as compared with the recipient twin. Cardiomyopathy and associated cardiac dysfunction has been reported (Mahony et al., 1990; Elliott, 1992). In one study, five of five recipient twins were found to have cardiomegaly and tricuspid regurgitation prenatally; four had cardiac dysfunction after birth (Zosmer et al., 1994). In Elliott's (1992) experience there were two cardiac abnormalities in 12 fetuses (one critical aortic stenosis, one cardiopathy). Renal cortical necrosis (Dimmick et al., 1971; Feingold et al., 1986) and brain infarction have been reported in the donor twin (Mahony et al., 1990). These complications have also been described in the surviving co-twin of intrauterine fetal death in utero. The mechanism may be hypovolemia and ischemic injury in the smaller donor twin (Elliott, 1992).

Although much attention has focused on the effect of treatment on survival in TTTS, the neurologic morbidity among survivors frequently is underappreciated. The International Amnioreduction Registry tracked 223 women who had TTTS diagnosed before 28 weeks' gestation and were treated with serial aggressive AR (Mari et al., 2001). Of those infants who survived to 4 weeks of age and underwent clinically indicated cranial ultrasonography, 24% of recipient (26/109 scanned) and 25% of donor twins (22/88 scanned) had abnormal findings. Findings included severe intraventricular hemorrhage, ventricular dilation, cerebral echogenic foci, cerebral cysts, and periventricular leukomalacia among

other less common lesions. Eighty infants died before reaching 4 weeks of age, and how many of these would have had abnormal imaging if cranial ultrasonography had been performed is unknown. Among patients in the TTTS Registry from Australia and New Zealand, most of whom had been treated with AR, the rate of abnormal cranial ultrasonography findings was similar at 27.3% (Dickinson and Evans, 2000). The rate of periventricular leukomalacia in this group was 10.8%, which is particularly important due to the association of this lesion with cerebral palsy. In another small series of patients treated with AR, the rate of abnormal neonatal cranial ultrasonography findings was as high as 58% (Denbow et al., 1998). It is important to recognize, however, that neuroimaging does not always correlate with neurodevelopmental outcome. An infant who has normal findings on head ultrasonography and MRI can be neurodevelopmentally devastated, and an infant who has evidence of leukoencephalomalacia on imaging studies can be neurodevelopmentally intact.

Only a few studies have reported longer-term neurodevelopmental outcome. When interpreting these studies, it is important to appreciate the neurodevelopmental outcome in monochorionic twins who do not have TTTS. The incidence of severe neurodevelopmental abnormalities in monochorionic twins without TTTS is 6% (Lopriore et al., 2003). TTTS survivors who develop neurologic handicap and mental retardation do not always have abnormal neonatal ultrasonography results. Similarly, not all children who have abnormal ultrasonography findings have clinically significant neurodevelopmental deficits. In one small study that followed TTTS survivors for a mean of 6.2 years (range, 4–11 years), the incidence of cerebral palsy was 26% (5/19 infants) in the group treated by serial AR. All of these children had abnormal mental development in addition to motor deficits. Of note, three of the five children had normal findings on neonatal head ultrasonography. In the combined cohort of children whose mothers had been treated with AR or conservative treatment, 22% (5/23) who did not have cerebral palsy or abnormal mental development had mild speech delay and required special education. One limitation to this and other studies is the lack of a comparable conservatively treated cohort group. Given the improved survival of TTTS babies who receive AR and other treatment modalities, however, it is unlikely that such a cohort ever will be available for comparison.

Studying infants from pregnancies complicated by TTTS and treated with AR, Mari et al. (2001) detected a rate of cerebral palsy of 4.7% (2 of 42 infants) in those children who survived to more than 24 months of age. One reason for the lower incidence of cerebral palsy than in the study by Lopriore et al. (2003) may be related to the latter study group having more severe disease, with all the patients diagnosed before 28 weeks' gestation versus up to 33 weeks' gestation in the study by Mari et al. Of note, in the Mari study, nine survivors had mild speech or motor delay.

Wee et al. (2005) studied the long-term neurologic outcome of 52 children from 31 TTTS pregnancies who survived to more than 18 months, most of whose mothers had been treated with AR. The comparison was a regional cohort of term and preterm infants, with most born very preterm. In addition, the TTTS babies were compared with matched singleton and twin control groups. The mean intelligence quotient (IQ) of TTTS survivors was significantly lower than the comparison cohort, due primarily to a 13-point IQ reduction in those children born before 33 weeks' gestation. There was no difference in the rate of cerebral palsy (5.8% for TTTS vs. 4.9% for very preterm twins vs. 3.3% for very preterm singletons) or behavioral test results in the TTTS survivors. This was a small study, however, and not sufficiently powered to demonstrate differences in cerebral palsy. Still, these researchers appropriately raise the issue that studies evaluating long-term neurologic outcome in TTTS need to consider that most TTTS pregnancies are delivered very preterm as well as the fact that twins generally are more likely to experience neurologic compromise.

Even fewer studies have examined the long-term outcome of survivors of TTTS treated with intrauterine laser photocoagulation therapy. Banek et al. (2003) reported that in 89 such children, 78% showed normal development at a median age of 22 months. Eleven percent had minor neurologic abnormalities, including strabismus, mildly delayed motor development, or mildly abnormal speech. The remaining 11% suffered significant neurologic deficiencies, including cerebral palsy, hemiparesis, and spastic quadriplegia. Of note, significantly more children in the neurologically impaired groups were born very preterm. Also of importance, two infants from the most severely affected group had abnormal brain scan results before laser treatment. The findings of this study are consistent with those of Sutcliffe et al. (2001) who reported a cerebral palsy rate of 9% in children after in utero treatment with laser therapy for TTTS. Graef et al., (2006) in a report of 167 TTTS survivors who had been treated by fetoscopic laser, found normal neurodevelopmental testing results in 86.8% of cases, with 7.2% of infants having minor neurologic deficiencies and 6% having major neurologic deficiencies such as cerebral palsy, hemiparesis, and quadriplegia. These findings were not unlike those in follow-up of monochorionic twins without TTTS (Adegbite et al., 2004), and the most severely affected children were delivered prior to 28 weeks' gestation, suggesting an important influence of gestational age on neurodevelopmental outcome. Similarly, Ortqvist et al. (2006) reported the neurodevelopmental outcome of 114 survivors treated in the Eurofoetus trial in which 13.2% had evidence of a major neurodevelopmental abnormality. However, there was no difference between those who had been treated by laser and those treated by AR. Perinatal factors, including gestational age at delivery and Apgar score, correlated with adverse outcome.

Of note, earlier and more sensitive antenatal detection of central nervous system injury (Crombleholme, 2003; Quarello et al., 2007) has been reported recently with the adjunct use of MRI techniques. MRI has enabled the detection of cerebral venous sinus dilatation and more clearly delineated central nervous system lesions. The improvements in antenatal detection may result in further improvements in clinical

management (Crombleholme, 2003) and reduced morbidity and its severity in survivors.

GENETICS AND RECURRENCE RISK

There are no reports of recurrence of TTTS in the literature.

Twin Reversed Arterial Perfusion Sequence

120 CHAPTER

Key Points

- Twin reversed arterial perfusion (TRAP) sequence, also known as acardia, is a rare anomaly unique to multiple gestation in which one twin has an absent, rudimentary, or nonfunctioning heart (acardiac twin) and the other twin is normal (pump twin). TRAP sequence has been associated with adverse perinatal outcomes.
- The placentation in the majority of acradic twins is monochorionic diamniotic.
- The fundamental requirement for the TRAP sequence is the development of arterial-to-arterial vascular anastomoses between the umbilical arteries of twins early in embryogenesis.
- The diagnosis is made with ultrasound. The features useful in the diagnosis of acardia include absence of normal cardiac structure and cardiac movement and variable structural abnormalities.
- The malformations found in cases of acardia include growth abnormalities, partial or complete absence of the cranial vault, anencephaly, holoprosencephaly, absent or rudimentary facial features, absent or rudimentary upper and/or lower limbs, absent lungs and heart, gastrointestinal atresia, omphalocele, gastroschisis, and absent liver, pancreas, spleen, and kidneys.
- The pump twin is usually morphologically normal, and the risk of aneuploidy is 9%.
- The goal of antepartum management of a pregnancy complicated by the TRAP sequence is to maximize outcome for the structurally normal pump twin.
- In the absence of poor prognostic features (twin weight ratio >0.70, elevated combined ventricular output, elevated cardiothoracic ratio, congestive cardiac failure, polyhydramnios), expectant management with serial sonographic evaluation is reasonable.
- Intrafetal radiofrequency ablation of the cord of the acardius when indicated by above criteria is associated with 95% pump twin survival.

CONDITION

Twin reversed arterial perfusion (TRAP) sequence, also known as acardia, is a rare anomaly unique to multiple gestation in which one twin has an absent, rudimentary, or nonfunctioning heart. Schatz (1898) classified acardia into two main groups: hemiacardius (imperfectly formed heart) and holoacardius (absence of heart). Das (1902) subdivided acardia into four groups: acardius acephalus, acardius amorphus or anideus, acardius acormus, and acardius anceps or paracephalus (Table 120-1). Simonds and Gowen (1925) added a further subgroup: acardius myelacephalus.

Contemporary authors have considered these classifications meaningless because the pathogenesis is probably similar for all cases (Benirschke and Kim, 1973; Van Allen et al., 1983). Van Allen et al. recommended *twin reversed arterial perfusion sequence* to describe all acardiac fetuses. The TRAP sequence denotes a common pathophysiology for all forms and leads to an explanation of how a gradation of abnormalities can be produced (Van Allen et al., 1983). The fundamental requirement for the TRAP sequence is the development of arterial-to-arterial vascular anastomoses between the umbilical arteries of twins early in embryogenesis. The importance of vascular arterial anastomosis as the pathophysiology for acardia was first elucidated in 1879 by Ahlfeld. The embryo with the hemodynamic advantage becomes the pump twin. The pump twin retrogradely perfuses the other twin with deoxygenated blood along the umbilical artery/arteries to the iliac artery/arteries to the abdominal aorta. The lower limbs and abdominal organs supplied by the iliac arteries and

Table 120-1

Classification of the Conditions of Acardia

Acardius acephalus: This is the most frequent variety, responsible for 60% to 75% of cases (Lachman et al. 1980). The head is absent but the trunk and limbs are more or less well developed (Das 1902; Robie et al. 1989; Simonds and Gowen 1925).
Acardius acormus: This is a very rare type of acardia in which there is development of the fetal head only (Robie et al. 1989). The head is usually directly attached to the placenta via a cord arising in the cervical region (Das 1902; Kappelman 1944; Simonds and Gowen 1925).
Acardius amorphus or anideus: This type of acardia occurs in about 20% of cases (Lachman et al. 1980). The defect consists of an irregular, skin-covered mass of bone, muscle, fat, and connective tissue without the external form of a fetus (Das 1902; Kappelman 1944). The umbilical cord is inserted anywhere on the surface.
Acardius anceps or paracephalus: The head is poorly formed, but trunk and limbs are fairly well developed (Das 1902; Simonds and Gowen 1925). This form is sometimes included with the acephalus group.
Acardius myelacephalus: This form consists of an amorphous mass, with some development of one or more limbs (Kappelman 1944; Simonds and Gowen 1925).

abdominal aorta preferentially receive a better blood supply and usually develop better than the upper part of the body (Van Allen et al., 1983). TRAP occurs in monochorionic pregnancies, and previous theories of polar body fertilization to explain acardius in sex discordant twins have been discounted (Bieber et al., 1981; Fisk et al., 1996). In addition, the TRAP sequence is more common in monozygotic triplets than in monozygotic twins (James, 1977; Healey, 1994). Some authors have suggested a slight female preponderance in acardiac twins while other studies have not supported this idea (James, 1977; Healey, 1994).

The members of a TRAP sequence are known as the perfused twin and the pump twin. The perfused twin in a TRAP sequence is an example of the impact of vascular disruption on morphogenesis. Multisystem malformations, as well as unusual body form, are found in the perfused twin. Figure 120-1 illustrates the gradation of loss of normal body form ranging from an amorphous appearance to an individual with more severe abnormalities found in the upper part of the body. The malformations found in cases of acardia include growth abnormalities, partial or complete absence of the cranial vault, anencephaly, holoprosencephaly, absent or rudimentary facial features, absent or rudimentary upper and/or lower limbs, absent lungs and heart, gastrointestinal atresia, omphalocele, gastroschisis, and absent liver, pancreas, spleen, and kidneys (Van Allen et al., 1983). Of 33 acardiac fetuses with a known karyotype, 11 (33%) were abnormal (Healey, 1994). The karyotypic abnormalities included monosomy, trisomy, deletions, mosaicism, and polyploidy. The pattern of structural abnormalities found in the perfused twins with abnormal karyotypes is not appreciably different from those with normal karyotypes (Van Allen et al., 1983). Van Allen et al. suggested that the abnormal karyotype is not responsible for the malformation complex, but rather that it contributes to the discordant development between twins, increasing the likelihood of reversal of arterial blood flow if an anastomosis occurs.

The presence of an acardiac twin requires a "pump" twin to provide circulation for itself as well as its acardiac co-twin. In many cases the acardiac twin is almost equal in size to the normal twin (Figure 120-2). The pump twin is usually morphologically and genetically normal. In a review of 34 pump fetuses with a known karyotype, 3 (8.8%) were abnormal as a result of trisomy (Healey, 1994). The pump twin may show evidence of the physiologic consequence of fetal cardiac overload and congestive heart failure with hepatosplenomegaly. The principal perinatal problems associated with acardiac twinning are pump twin congestive heart failure, polyhydramnios, and preterm delivery (Moore et al., 1990).

The reported fetal/neonatal mortality in the pump twin is substantial ranging from 50% to 75% (Gillim and Hendricks, 1953; Napolitani and Schreiber, 1960; Van Allen et al., 1983; Moore et al., 1990; Sogaard et al., 1999). One factor thought to be contributing to the high perinatal mortality rate is the increased cardiac demands placed on the pump twin to perfuse the acardiac twin (Sullivan et al., 2003).

Premature delivery is another important factor determining the prognosis for the pump twin (Figure 120-2) (Van Allen et al., 1983; Moore et al., 1990; Healey, 1994). In one study where approximately 55% of acardiac pregnancies resulted in fetal or neonatal death, approximately one quarter of the pregnancies delivered after 36 weeks. Preterm delivery and the attendant long-term morbidities complicated the remaining quarter (Moore et al., 1990).

INCIDENCE

The incidence of the TRAP sequence is estimated as 1% of monozygotic twins, with birth estimates ranging from 1/35,000 to 1/50,000 births (Gillim and Hendricks, 1953; Napolitani and Schreiber, 1960; D'Alton and Simpson, 1995). Acardia was observed in 1 of 606 twin pregnancies, and the rate of twins was calculated at 1 in 86.5 births in the United States (Gillim and Hendricks, 1953). Van Allen et al. (1983) have suggested these figures to be a gross underestimate of

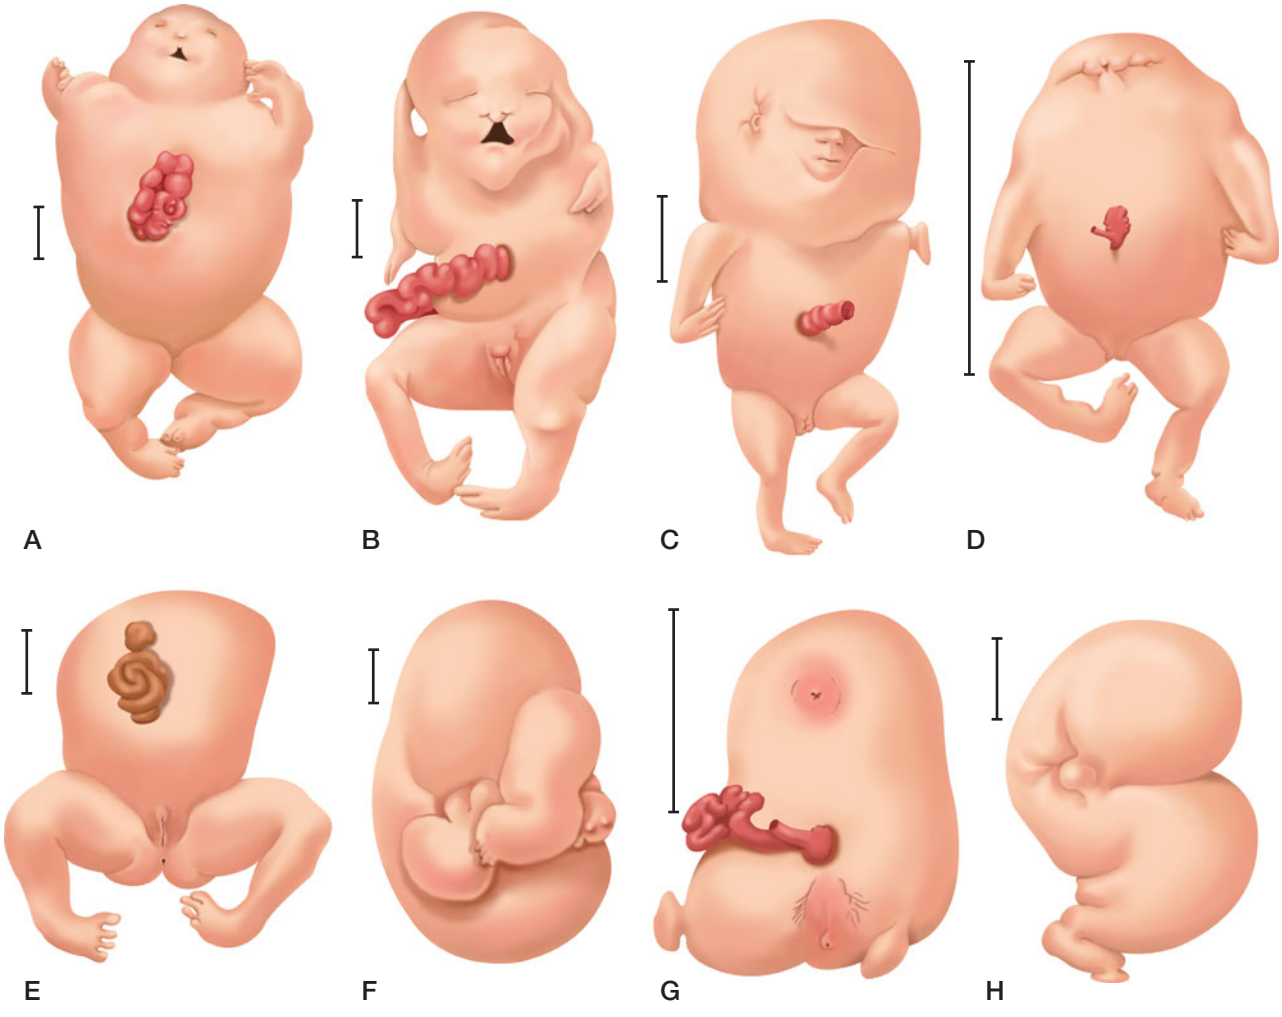

Figure 120-1 Gradation of loss of normal body form in acardia.

Figure 120-2 An acardiac fetus and its pump twin delivered at 26 weeks of gestation following spontaneous premature labor.

the true frequency of the TRAP sequence because most cases go unrecognized due to early pregnancy loss. In contrast, an analysis of data from the Eurocat Network (European Registration of Congenital Anomalies and Twins) gave a prevalence of acardia of 0.064 in 10,000 births, which is much lower than were previous estimates in the literature (Haring et al., 1993).

SONOGRAPHIC FINDINGS

Antenatal diagnoses of the TRAP sequence have been reported in the literature since 1980. Ultrasonographic features useful in the diagnosis of acardia include absence of normal cardiac structure and cardiac movement and variable structural abnormalities. Common structural abnormalities identified in the acardiac fetus include anencephaly, omphalocele, and absence of upper limbs. Most cases have edematous soft tissue, and large cystic hygromalike spaces are commonly identified in the skin (Mack et al., 1982).

The placentation is most commonly monochorionic diamniotic (74%), in which a thin membrane will be seen dividing the sac of the acardiac fetus from the pump fetus (Healey, 1994). Monoamnionicity is present in approximately 24% of cases (Healey, 1994). In exceptional cases, dichorionicity may be diagnosed (Healey, 1994). Polyhydramnios is common as are abnormalities in the umbilical cord or in its insertion (Dashe et al., 2001). The umbilical cord will demonstrate a single umbilical artery in approximately two thirds of cases, and in one-third the number of cord vessels will be normal (Healey, 1994). A velamentous insertion of the cord or a conjoined cord insertion may be present (Dashe et al., 2001).

Measurement of the acardiac twin should be performed, because the ratio of the weight of the acardiac twin to that of the pump twin is useful to predict pregnancy outcome. Because of the structural abnormalities, the biometric parameters of biparietal diameter, abdominal circumference, and femur length may not be available or reliable in an acardiac fetus. This problem of the antenatal determination of the acardiac twin's weight has been addressed by Moore et al. (1990). The dimensions and weights of 23 acardiac twins were used for the analysis. A second-order regression equation (weight [g] $= -1.66 \times$ length $+ 1.21 \times$ length^2) was computed and was predictive of acardiac weight with the use of its longest linear measurement ($r = 0.79$; $P < 0.001$; SEE $= 326$ g). When the actual and equation-predicted weights were compared, the mean error ($\pm$SE) in prediction was 240 ± 156 g. Careful Doppler examination of the acardiac fetus may also demonstrate reversal of flow in the umbilical artery of the acardiac fetus, with flow going from the placenta toward the acardiac fetus (Figure 120-3) (Benson et al., 1989; Malone and D'Alton, 2000).

The pump twin should have a detailed structural survey performed because trisomy has been reported in up to 9% of cases (Healey, 1994) and sonographic features typical

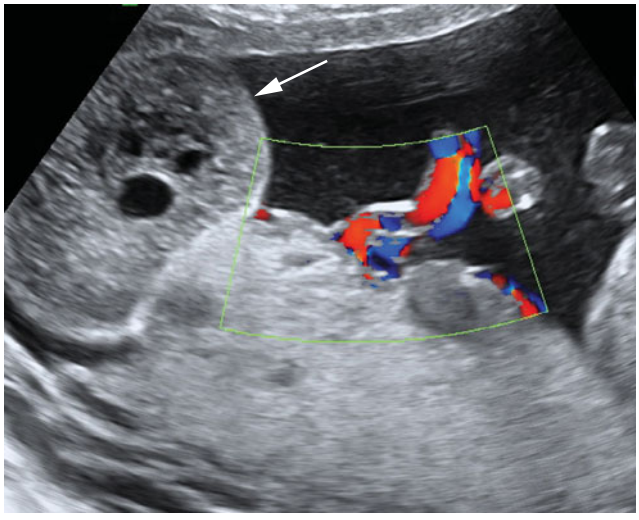

Figure 120-3 Prenatal ultrasound image of TRAP pregnancy at 22 weeks with amorphous mass (*arrow*) connected through placental surface vessel from umbilical cord of pump fetus.

of a trisomic fetus may be identified. Fetal echocardiography is helpful in detecting early signs of in utero congestive heart failure in the pump twin. Atrial and ventricular enlargement can be an initial feature of impending cardiac decompensation and can be measured using M-mode by obtaining a transverse view through the cardiac chambers (Allan, 1986; DeVore, 1987). The ventricular fractional shortening capacity can also be calculated using M-mode with the formula $(D - S)D \times 100$, where D is the diastolic and S is the systolic ventricular size. A low value is indicative of poor cardiac contractility. A pericardial effusion may be present and is a sign of congestive heart failure. Tricuspid regurgitation, demonstrated by Doppler studies of the tricuspid valve, is also a sign of congestive heart failure (Silverman et al., 1985; Shenker et al., 1988). Combined ventricular output (CVO) can be measured to determine if the pump twin is in a high output state. In TRAP sequence at a gestational age too early to determine CVO, Kinsel-Ziter et al. have demonstrated a good correlation of increased CVO with increased cardiothoracic ratio (Kinsel-Ziter et al., 2009).

Doppler studies should be performed in both the acardiac and pump twins. Verification of circulatory reversal by pulsed Doppler sonography of the acardiac twin can be documented with reversed direction of flow in the umbilical artery and vein (Pretorius et al., 1988; Sherer et al., 1989; Benson et al., 1989; Donnenfeld et al., 1991; Langlotz et al., 1991; Dashe et al., 2001). In one recent study by Dashe et al., between, 1990 and 1997, Doppler studies were performed in 6 monochorionic pregnancies complicated by the TRAP sequence. Pulsatile vessels in the umbilical vessels of the acardiac and pump twins were insonated. Reversal of flow was demonstrated in all cases. Resistive index values were calculated, and the difference in resistive index between the pump and acardiac twin was evaluated. In the acardiac twins, no

ratio of systolic to diastolic velocity or resistive index value was associated with a good or with a poor prognosis for the pump twin. In the pump twins, resistive index differences >0.20 between the pump and the acardiac twins were associated with good outcomes, while resistive index differences <0.05 were associated with poor outcomes (Dashe et al., 2001).

DIFFERENTIAL DIAGNOSIS

The acardiac fetus may be mistaken for an anencephalic fetus. The sonographic features of absent trunk region in addition to increased soft tissue in the body aid in the correct diagnosis (Billah et al., 1984).

The TRAP sequence has been mistaken for intrauterine fetal death (IUFD) of one twin in a multiple gestation (Malone and D'Alton, 2000). Evidence of growth in the "dead" fetus and a "twitching" noted on repeat ultrasound examination has allowed the diagnosis of an acardiac twin to be made (Cardwell, 1988). In a severely macerated fetus, the skeletal and visceral forms are more differentiated, and the soft-tissue edema is less advanced than in a case of acardia (Mack et al., 1982). The use of color flow Doppler can assist in differentiating between single IUFD in a co-twin and the TRAP sequence (Malone and D'Alton, 2000). Pulsed Doppler examination has been used to demonstrate reversed flow through the umbilical artery of the acardiac twin (Pretorius et al., 1988).

ANTENATAL NATURAL HISTORY

The principal perinatal problems associated with acardiac twinning are pump twin congestive heart failure, maternal polyhydramnios, and preterm delivery. The antenatal diagnosis of TRAP can be made only through sonographic examination and has been reported in the literature only since 1980. Large series of acardiac twins have attempted to identify factors prognostic of favorable outcome for the pump twin (Moore et al., 1990; Healey, 1994).

In the series of 49 cases reported by Moore et al. (1990), one third of fetuses were delivered before they were viable. In this study, viability was defined as delivery at or beyond 25 weeks of gestation. Of the potentially viable 33 cases, 4 (12%) ended in death of the pump twin in utero. The overall perinatal mortality was 55% and was primarily associated with prematurity (Table 120-2).

Polyydramnios was a major maternal complication, occurring in 46% of all acardiac pregnancies, and it was strongly associated with preterm labor and congestive heart failure in the pump twin. Eighty-two percent of patients with polyhydramnios experienced preterm labor requiring hospital admission and treatment, as compared with 22% of pregnancies with normal amniotic fluid ($P < 0.01$). Polyhydramnios was observed in 78% of pump twins with congestive heart failure as compared with 13% of those in whom congestive heart failure was not confirmed ($P < 0.001$). The perinatal outcome was strongly related to the ratio of the weight of the acardiac twin to that of the pump twin. The mean overall ratio of the twin weights was 52 ± 42%. The twin weight ratio was more than 70% in 25% of cases. When this characteristic was present, the incidence of preterm delivery was 90%, polyhydramnios 40%, and congestive cardiac failure in the pump twin 30%, as compared with 75%, 30%, and 10%, respectively, when the ratio was less than 70% (Moore et al., 1990).

In the series by Healey (1994), of 5 cases at Monash Medical Centre and a review of 184 case reports in the literature from 1960 to 1991, the overall perinatal mortality for the pump fetus was 35% in twins and 45% in triplets. Factors associated with a significant increase in perinatal mortality for the pump fetus included delivery before 32 weeks of gestation, the acardius anceps form of acardia, and the presence of arms, ears, larynx, trachea, pancreas, kidney, or small intestine in the acardiac fetus.

Nonetheless, a more recent study questioned the poor prognosis associated with pregnancies complicated by TRAP

Table 120-2

Perinatal Complications of 49 Pregnancies with Acardiac Twinning

Delivery mode	
Spontaneous abortion	18%
Elective	14%
Cesarean section, all cases	38%
Cesarean section, potentially viable cases	58%
Pump twin	
Male/female	57%/43%
Malpresentation	29%
Major structural anomaly	9%
Hydramnios	46%
Congestive heart failure	53%
Previable	32%
Liveborn	59%
Premature (<37 wk)	35%
Gestational age at delivery (wk)	29 ± 7
Birth weight (g)*	
Acardiac	651 ± 571
Pump twin	1378 ± 1047

and explored the role of expectant management (Sullivan et al., 2003). Ten cases of antenatally diagnosed acardiac twins delivered between 1994 and 2001 in one community were evaluated. All cases were managed expectantly. Nine women delivered a healthy pump twins. There was one neonatal death. The mean gestational age at delivery was 34.2 weeks and the mean weights of the pump and acardiac twins were 2279 g and 1372 g, respectively. The authors concluded that neonatal mortality of pump twins in antenatally diagnosed acardiac twin pregnancies may be considerably less than reported, and expectant management with close antepartum surveillance may be an option.

MANAGEMENT OF PREGNANCY

The goal of antepartum management of a pregnancy complicated by the TRAP sequence is to maximize outcome for the structurally normal pump twin. Management of acardiac twin gestations is controversial. When the diagnosis is made, the gestational age should be documented by maternal history and standard biometric measurements of the pump fetus. The high and low risk factors for perinatal mortality in the pump fetus must be evaluated through sonographic examination. In the absence of poor prognostic features (twin weight ratio >0.70, elevated CVO, increased C:T ration, congestive cardiac failure, polyhydramnios), expectant management with serial sonographic evaluation is reasonable (Malone and D'Alton, 2000). Additional factors that place the pregnancy at high risk for perinatal mortality include features of acardius anceps demonstrating the presence of arms, ears, larynx, trachea, pancreas, renal tissue, and small intestine. Rapid growth of the acardiac twin may also be a sign of poor outcome (Brassard et al., 1999).

Features that indicate a lower risk include features of acardius amorphous with absence of arms, legs, brain, esophagus, trachea, and omphalocele (Healey, 1994). Karyotyping of the pump twin should be offered because as many as 9% of pump twins have an abnormal karyotype (Healey, 1994).

Various techniques have been used to interrupt the vascular communication between the twins in an effort to improve outcome of the normal pump twin. These methods have included hysterotomy with physical removal of the acardiac twin, ultrasound guided injection of thrombogenic materials into the umbilical circulation of the acardiac twin, ligation of the umbilical cord of the acardiac twin under fetoscopic guidance, and intrafetal radiofrequency cord ablation (Simpson et al., 1983; Van Allen et al., 1983; Robie et al., 1989; Ash et al., 1990; Porreco et al., 1991; Holzgreve et al., 1994; Quintero et al., 1994; Challis et al., 1999; Tsao, 2002; Livingston et al., 2007). Steroids should be given if delivery is expected between 24 and 34 weeks of gestation (NIH Consensus Development Panel, 1995). Preterm labor should be suppressed with tocolytic agents.

Delivery at a tertiary care hospital is recommended because of the risk of preterm delivery and congestive cardiac failure in the pump twin. The vaginal route is the preferred mode of delivery. The indications for cesarean include the standard obstetric reasons. In Moore et al.'s series, abnormal presentation and fetal distress necessitated cesarean delivery in more than half of the potentially viable pregnancies.

Medical management with maternal administration of digoxin or indomethacin has been reported, but there are no significant case series on these management strategies. The use of maternal digitalization to treat cardiac failure in the pump twin was reported by Simpson et al. in 1983. Marked edema of the trunk in the normal twin was present. Fetal ascites, pleural effusion, or cardiomegaly was not demonstrated. Serial ultrasound examinations demonstrated resolution of the edema and continued normal growth of the viable fetus. Delivered at 34 weeks, the normal twin weighed 1860 g. The acardiac twin weighed 1810 g. No subsequent reports of this digoxin therapy for acardia have been reported.

Ash et al. (1990) reported the use of indomethacin in an acardiac pregnancy complicated by polyhydramnios at 21 weeks. No evidence of cardiac failure was visualized in the pump twin. Indomethacin, 50 mg daily, was given to treat the symptomatic polyhydramnios because of the high risk of premature labor. The indomethacin was continued for 8.5 weeks. Oligohydramnios at 34 weeks prompted induction of labor, and spontaneous vaginal delivery occurred. The normal twin weighed 1865 g at birth, and the acardiac twin weighed 785 g (Ash et al., 1990).

FETAL INTERVENTION

Many invasive procedures have been described with the goal of interrupting the umbilical circulation of the acardiac twin. There is a great deal of controversy in the literature concerning which cases are candidates for such procedures. It has been recommended that invasive procedures be performed only after heart failure has developed (Platt et al., 1983). Some have recommended surgical intervention only after medical therapy has failed (Ash et al., 1990). Others have suggested intervening before heart failure is present in the pump twin (Platt et al., 1983). Others consider the diagnosis of TRAP the indication for fetal intervention (Tsao et al., 2002).

Various percutaneous procedures have been described to interrupt the umbilical circulation in acardiac twins, including (1) insertion of a thrombogenic coil into the recipient twin's umbilical cord, (2) injection of silk soaked in alcohol into the cord, (3) injection of absolute alcohol into the cord, (4) fetoscopic ligation of the acardiac fetus's cord, (6) bipolar forceps cautery of the acardiac fetus's cord, (7) thermocoagulation of the aorta of the acradiac fetus, and (8) intrafetal radiofrequency thermablation (Porreco et al., 1991; Holzgreve et al., 1994; Quintero et al., 1994; Sepulveda et al., 1995;

Arias et al., 1998; Rodeck et al., 1998; Challis et al., 1999; Tsao et al., 2002; Livingston et al., 2007).

Injection of coils or slerosants is generally no longer performed because of the unreliability in achieveing complete occlusion. Fetoscopic cord ligation may be associated with a failure rate of 10% together with a 30% risk of preterm rupture of membranes (Challis et al., 1999). Laser and cautery options have the advantage of generally requiring one ccess port in the uterus and therefore may be associated with less morbidity. No comparative studies are available, however, to suggest one optimal method of selective termination in this setting.

Robie et al. (1989) reported a case of selective delivery by hysterotomy of an acardiac acephalic twin fetus at 22.5 weeks of gestation with the subsequent delivery of the normal twin at 33 weeks of gestation. Fries et al. (1992) subsequently reported 5 cases of selective delivery in 1992. In one case, placental abruption occurred shortly after the procedure, leading to fetal death. Two cases delivered at 35 weeks of gestation, and the remaining 2 delivered at 27 and 28 weeks.

Porreco et al. (1991) described the insertion of a helical metal coil under sonographic guidance to induce thrombosis in the umbilical artery of the acardiac twin at 24 weeks. The co-twin delivered at 39 weeks and had a normal course.

Quintero et al. (1994) described a percutaneous fetoscopic procedure that treated this condition at 19 weeks of gestation and was followed by the birth of a normal twin at 36 weeks of gestation. A further case was reported by McCurdy et al. (1993). A trial of maternal digoxin administration failed and was followed by a fetoscopic ligation of the acardiac twin's cord at 19 weeks. Ultrasound examination on the first postoperative day indicated death of the pump twin.

Holzgreve et al. (1994) injected multiple pieces of silk suture soaked in 96% alcohol into the umbilical cord of an acardiac twin at 21 weeks of gestation. This resulted in immediate interruption of flow in the cord and the ultimate delivery at term of a 2780-g healthy newborn. The advantage of this approach in comparison to umbilical cord ligation is the use of a much thinner needle. Less operative time is required, and there is no need for general anesthesia (Holzgreve et al., 1994).

Other methods of interrupting the circulation in the acardiac twin involve direct coagulation of the umbilical vessels or the aorta, using either laser photocoagulation or diathermy themocoaglulation. Laser photocoagulation of umbilical vessels using a neodymium yttrium aluminum garnet laser has been successfully reported, although this approach appears less likely to be successful when performed after 24 weeks' gestation (Arias et al., 1998). This may be because umbilical vessels are too large to adequately photocoagulate when the gestational age is greater than 24 weeks. Thermocoagulation of the aorta of the acardiac fetus using diathermy via a wire passed through an 18-gauge needle has been successfully reported in four cases at 24 weeks' gestation or less (Rodeck et al., 1998). The advantages of this latter approach include avoiding the need for microendoscopic instruments or skills, and avoiding the difficulties in identifying the target umbilical cord. Intrafetal radiofrequency ablation (RFA) has also been utilized in cases of TRAP. RFA causes thermal injury with high frequency radiowaves that denature proteins and initiate cell death through coagulative necrosis. In a series of 23 pregnancies complicated by TRAP and managed with RFA, there was a 91% survival rate with a mean gestational age of 35 weeks at delivery (Lee et al., 2004). Livingston et al. reported a 95% survival rate with an ultrasound-guided technique using a 17-gauge radiofrequency DePrest needle (Boston Scientific) with a mean gestational age at delivery of 36 weeks in a series of 26 patients. Survival rates of 85% have been reported with fetoscopic cord coagulation likely as a consequence of two ports being required (Lewi et al., 2006).

It has been suggested that successful interruption of the acardiac circulation after 24 weeks gestation may require a more invasive approach, such as fetoscopic ligation of the umbilical cord (McCurdy et al., 1993; Quintero et al., 1994; Arias et al., 1998). However, the series reported both by Tsao and Livingston included patients successfully treated after 24 weeks' gestation.

TREATMENT OF THE NEWBORN

A neonatologist should attend the delivery. In Moore et al.'s (1990) series, admission to a newborn intensive care unit was required in 41% of the pregnancies and 59% of those reaching viability. Five of 29 liveborn pump twins died during the newborn period. There is little information in the literature on the neonatal course of the pump twin. The main problems for the pump twin include complications of prematurity and congestive heart failure (Van Allen et al., 1983; Moore et al., 1990).

Other frequent neonatal findings include massive hepatosplenomegaly, ascites with hypoplasia of abdominal musculature, edema, and hypoalbuminemia due to inadequate liver synthesis of albumin (Van Allen et al., 1983).

Respiratory assistance as well as support of myocardial function with inotropic medication may be required. Early administration of surfactant therapy is indicated when premature delivery at less than 30 weeks of gestation is anticipated. Postnatal consultation with a pediatric cardiologist and echocardiography are recommended.

LONG-TERM OUTCOME

There is no information in the literature concerning long-term outcome for the pump twin. Considerations for the long-term prognosis must include the degree of prematurity, the severity of the neonatal course, and the degree of congestive heart failure.

GENETICS AND RECURRENCE RISK

Estimates of the recurrence risk of acardiac twin pregnancy are on the order of 1 in 10,000 (Van Allen et al., 1983). This recurrence risk is calculated from the recurrence risk for monoamniotic twinning, which is 1% (Myrianthopoulos, 1970), multiplied by the frequency of the occurrence of the TRAP sequence, which is approximately 1% of all monozygous twins (Gillim and Hendricks, 1953; Napolitani and Schreiber, 1960).

121 CHAPTER

Conjoined Twins

Key Points

- Conjoined twins are rare, and they may be joined at a variety of sites. The nomenclature in use to describe conjoined twins is derived from the most prominent site of conjunction.
- The most common type of conjoined twins include thoracopagus, xiphagus or omphalopagus, pygopagus, ischiopagus, and craniopagus.
- Conjoined twins can be diagnosed with ultrasound examination, and suspicion should arise when a dividing membrane cannot be visualized.
- Congenital anomalies are common even in organs that are not shared.
- The antenatal natural history of conjoined twins is not well known due to the fact that cases are rare and many patients elect termination.
- Successful surgical separation is possible, and the prognosis for the surgery depends on the type of conjunction.

CONDITION

Although a rare event, the birth of conjoined twins has always fascinated both the physician and the layperson. The first well-documented case was reported in A.D. 1100 and described the Biddenden maids who were joined at the hips and shoulders. In 1134, when the maids had lived together for 34 years, Mary was suddenly taken ill and died. Eliza, her sister, died six hours later (Bondeson, 1992). The most famous conjoined twins were Eng and Chang Bunker, born in Siam in 1811. The inappropriate term "Siamese twins" was coined by P.T. Barnum, who promoted the exhibition of Chang and Eng Bunker. An early medical description of these most famous conjoined twins, who lived unseparated until they died at age 63, can be found in the works of Warren (1829). Many conjoined twins are stillborn. In one series 40% of conjoined twins were stillborn and an additional 35% survived only 1 day (Edmonds and Layde, 1982). Konig recorded the first successful separation of conjoined twins in 1689. These twins were joined at the umbilicus, and the division was accomplished by necrosing the band of tissue between the two children with a constricting ligature. Kiesewetter (1966) reviewed 24 surgical attempts at separation that appeared in the literature from 1689 to 1962. There are now over 100 reports of successful separations in the medical literature or lay press. Conjoined twins may be joined at a variety of anatomic sites,

and classifications have been developed to describe all the possibilities (Guttmacher and Nichols, 1967). The nomenclature in use clinically is derived from the most prominent site of conjunction. The common twin types include thoracopagus, xiphopagus or omphalopagus, pygopagus, ischiopagus, and craniopagus.

Thoracopagus is the most common type of conjoined twin and with omphalopagus (or xiphopagus) represents about 75% of cases reported (Malone and D'Alton, 2000). The two individuals lie face to face and share a common sternum, diaphragm, and upper abdominal wall from xiphoid to umbilicus. An extensive review of the anatomy of thoracopagus twins has been published by Nichols et al. (1967). In data from 32 cases, 75% have conjoined hearts. Because of the abnormal ventricular arrangements and associated anomalies of the great arteries and veins, successful surgical division is usually not possible. In about half of these cases, the intestinal tracts are also joined. Occasionally, the esophagus and stomach are single, but usually the union starts in the distal duodenum and ends in a pouch at the site of a Meckel diverticulum. The biliary tree is joined in 25% of cases.

Xiphopagus or omphalopagus twins usually considered a subgroup of thoracopagus, also face one another and usually have the least complicated union of all conjoined twins. They are joined at the anterior abdominal wall from xiphoid to umbilicus. The peritoneal cavity of one communicates with that of the other, but the upper intestinal tracts are usually separate. A bridge of liver connects the infants in the majority of cases. Evaluation of the single umbilical cord in twins joined at the umbilicus has revealed the presence of two to seven umbilical vessels. An omphalocele is often present at the umbilical cord insertion.

Pygopagus twins represent about 20% of cases. They are joined at the buttocks and perineum, and face away from each other. A significant length of sacrum may be fused, and as a result, the twins often share the sacral spinal canal. A single lower rectum and anus is common, and often the lower genital tract and external genitalia are fused.

Ischiopagus accounts for 5% of cases. These twins are united at a single bony pelvis. Four normal lower extremities (ischiopagus tetrapus) may be attached to the pelvis, but often two of the four lower extremities are fused into one malformed limb (ischiopagus tripus). The intestinal tracts usually join at the terminal ileum, which empties into a single colon.

Craniopagus is the least common type of conjoined twins and accounts for 2% of cases. There is always fusion of the skull, and often the twins share large dural sinuses and vascular structures. A classification into partial or total forms, having a junction at brow, vertex, or parietal bone, has been devised by O'Connell (1976). In the partial forms, the brains are separated by bone or dura and each brain has separate leptomeninges. In the total form, the brains of each twin are connected, or they are separated only by arachnoid. Separation of the total type is extremely difficult, and feasibility is often determined by the presence of a superior sagittal sinus for each brain that will provide adequate venous drainage.

INCIDENCE

The exact incidence of conjoined twins is not known, but estimates have varied from 1 in 25,000 to 1 in 80,000 births (Siegel, 1950; Freedman et al., 1962). Other reports on the frequency of conjoined twinning show the incidence to be from 1 in 2,800 to 1 in 200,000 (Hanson, 1975). Three conjoined twins over a 10-month period among residents of South Glamorgan with approximately 5400 deliveries a year is the highest reported incidence of conjoined twinning so far described (Rees et al., 1993). In Rudolph et al.'s (1967) review, about 70% of conjoined twins were female. Maternal age and parity do not appear to be factors that influence the occurrence of this type of twinning. However, use of assisted reproductive techniques may result in an increased risk for conjoined twins (Goldberg et al., 2000).

SONOGRAPHIC FINDINGS

The first report of conjoined twins diagnosed ultrasonographically was in 1977 (Fagan, 1977). Since then prenatal diagnosis has been reported many times and can be made in the first trimester (Figure 121-1) (Hill, 1997; Hubinot et al, 1997; Lam et al, 1998; Maymon et al, 1998). Three-dimensional ultrasound examination may be a valuable adjunct to two-dimensional ultrasound examination when diagnosing conjoined twins (Figure 121-2) (Johnson et al., 1997; Bega et al., 2000; MacKenzie et al., 2004). A suspicion of conjoined twins should arise when a dividing membrane cannot be visualized. van den Brand et al., (1994) have suggested nine sonographic

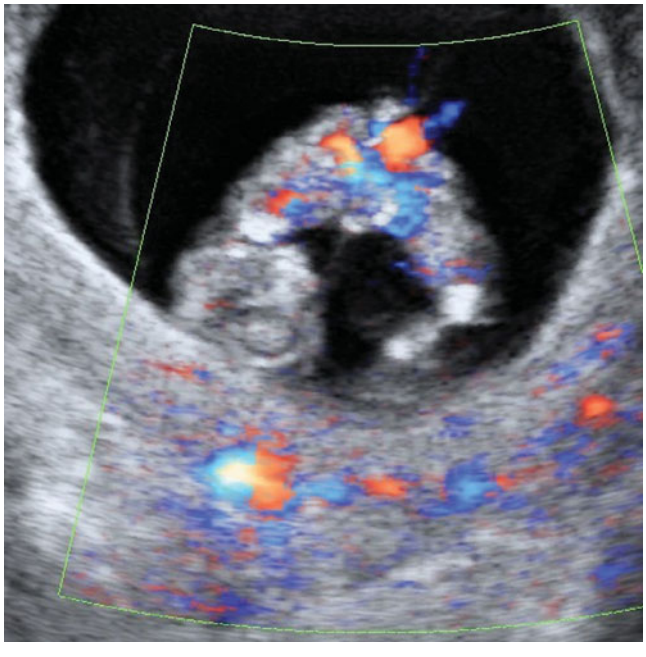

Figure 121-1 First trimester ultrasound demonstrating bifid appearance of the fetal pole consistent with a diagnosis of conjoined twins.

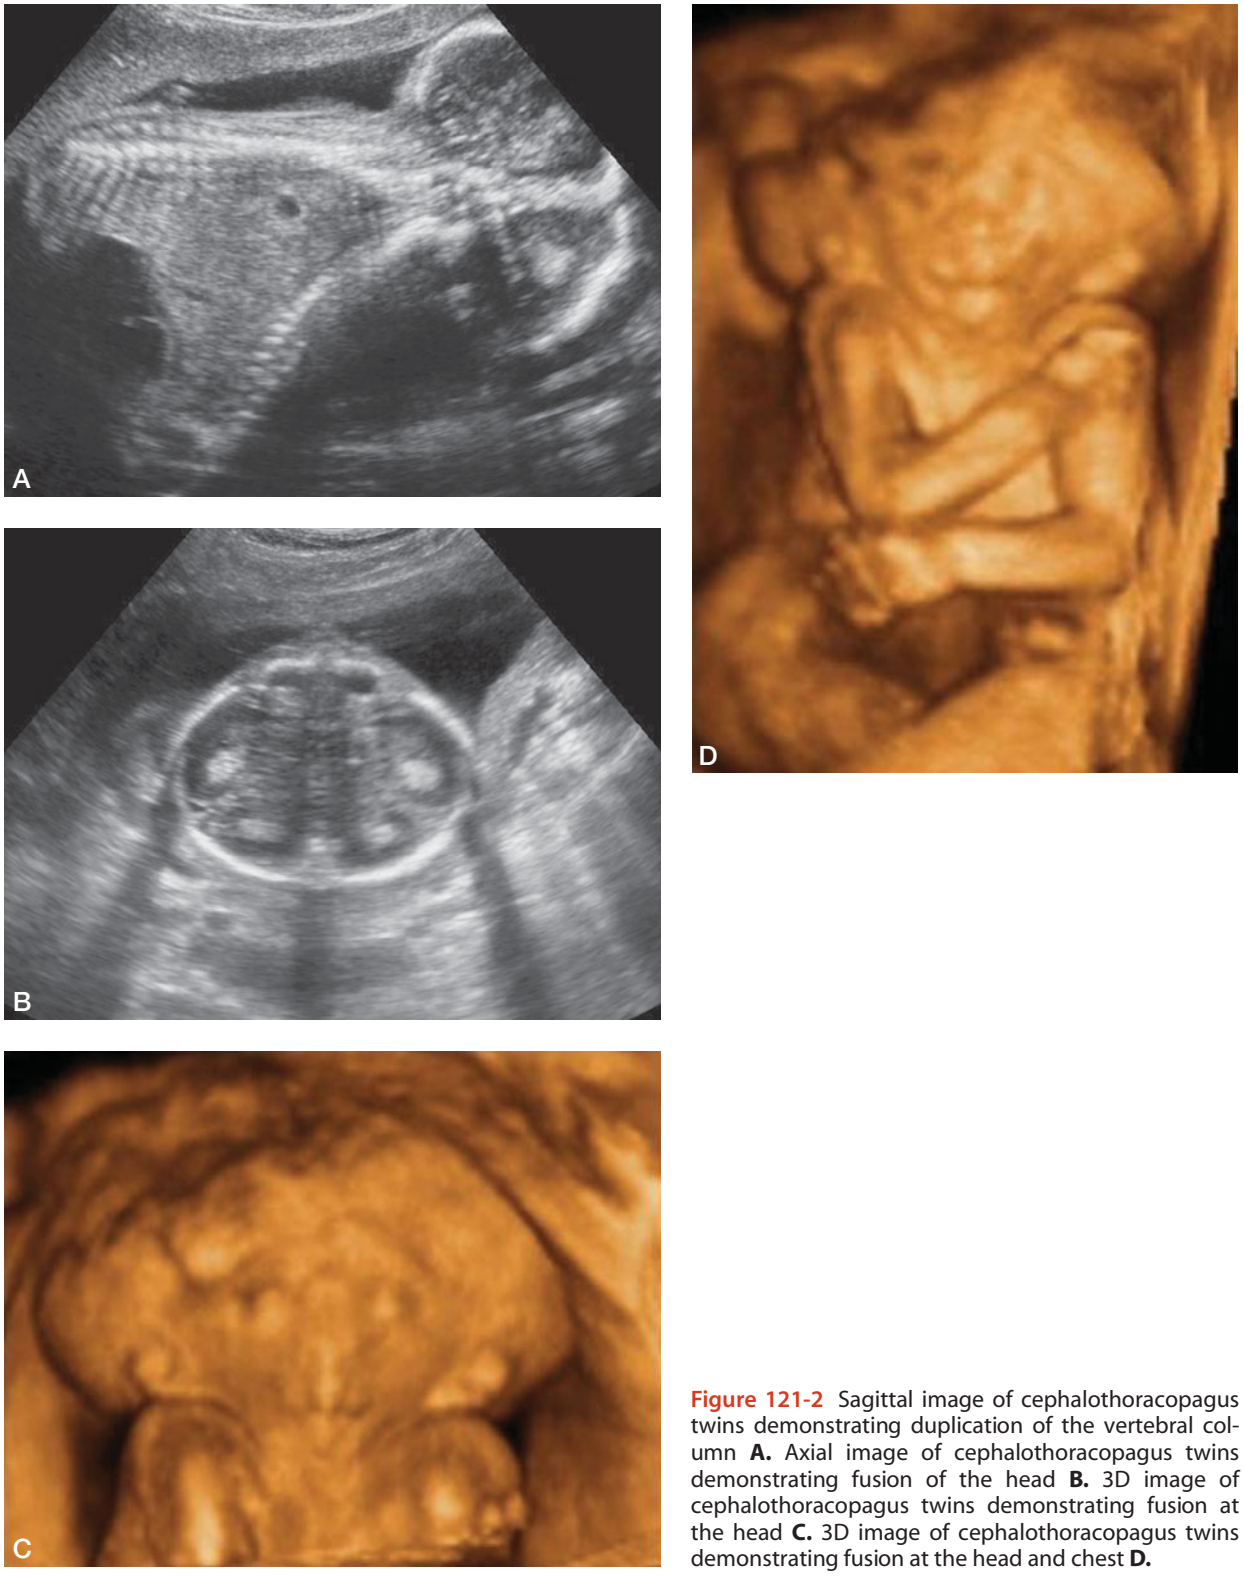

Figure 121-2 Sagittal image of cephalothoracopagus twins demonstrating duplication of the vertebral column **A.** Axial image of cephalothoracopagus twins demonstrating fusion of the head **B.** 3D image of cephalothoracopagus twins demonstrating fusion at the head **C.** 3D image of cephalothoracopagus twins demonstrating fusion at the head and chest **D.**

findings to diagnose conjoined twins (Table 121-1). Polyhydramnios is present in 75% of thoracopagus twins (Harper et al., 1980). Congenital anomalies are common in conjoined twins, even in the unshared organs. Congenital heart disease, renal and genitourinary abnormalities, intestinal duplication, and omphalocele have all been reported.

Ultrasound examination has been found useful in describing the extent of joining of the cardiovascular system in thoracoabdominally joined twins. Sanders et al. (1985) have reviewed their experience in four pairs of thoracoabdominally joined twins and demonstrated that prenatal echocardiography correctly diagnosed major cardiac anomalies, although

Table 121-1

Sonographic Findings used to Diagnose Conjoined Twins

Bifid appearance of the first trimester fetal pole
Lack of a separating membrane between the twins
Inability to separate the fetal bodies
Detection of fetal anomalies
More than three vessels in the umbilical cord
Heads at same level and body plane
Spines unusually extended
Extremities in unusual proximity
Fetuses do not change position relative to one another after movement or manipulation, or with passage of time

Source: van den Brand SFJJ, Nijhuis JG, van Dongen PWJ. Prenatal ultrasound diagnosis of conjoined twins. Obstet Gynecol Surv. *1994;49: 656-662.*

they missed certain important features because of their inability to detect abnormal pulmonary venous connections. In addition, the investigators concluded that conjoined twins were more easily and thoroughly examined in utero because more views could be obtained as compared with the postnatal examination, which is hampered by the conjunction and the associated omphalocele. With the use of ultrasound equipment it is always possible to detect whether bone tissue is interposed between the two brains. However, it is impossible to detect if the two cerebral hemispheres are joined or separated by either the dura or pia mater. Color flow mapping may be useful in craniopagus twins to determine vascular connections (Loverro et al., 1991).

DIFFERENTIAL DIAGNOSIS

There are several pitfalls for the sonographic diagnosis of conjoined twins. Caution should be exercised in making a definite diagnosis of conjoined twins at less than 10 weeks of gestation because false-positive diagnoses have been documented (Usta and Awwaad, 2000; Weiss and Devine, 2002) Three-dimensional ultrasonography may help with the diagnosis (Babinski et al., 1999). Later in gestation, inseparable fetal skin contours must be a persistent finding at the same anatomic level to avoid the false-positive diagnosis of conjoined twins (Barth et al., 1990). Even discordant presentation does not exclude the diagnosis, particularly in omphalopagus twins. The joining bridge may be sufficiently small to allow for rotation of the twins. Finally, with severe conjoining, twins may be melded into a conglomerative tissue mimicking a single pregnancy (Weingast et al., 1984). The diagnosis of conjoined twins does not exclude the presence of other problems unique to twinning. For example, many cases have been reported of conjoined twins coexisting in triplet pregnancies (Sanjaghsaz et al., 1998; Sepulveda et al., 2003).

ANTENATAL NATURAL HISTORY

Little is known about the antenatal natural history of conjoined twins. Polyhydramnios has been reported in 75% of thoracopagus twins (Harper et al., 1980). In the older obstetric literature on the subject, stillbirth occurred in approximately 20% to 40% of cases (Harper et al., 1980). In one recent series of 14 sets of prenatally diagnosed conjoined twin pregnancies from a single center, the combination of prenatal ultrasonography, echocardiography, and magnetic resonance imaging accurately defined the anatomy in all cases. In this series, 3 pregnancies were terminated, 1 resulted in intrauterine demise, and of the remaining 10 pregnancies delivered after viability, 5 individual fetuses survived (Mackenzie et al., 2002). Most of the contemporary literature has concentrated on the subject of surgical separation.

MANAGEMENT OF PREGNANCY

When the diagnosis of conjoined twins is made before viability, the option of pregnancy termination should be discussed with the parents. Since mortality and the ability to separate thoracopagus twins is directly related to the union of two hearts and associated cardiac abnormalities, echocardiography is recommended in all cases and may be of significant value to parents faced with the decision of whether to terminate the pregnancy. Although sonography is a standard technique for evaluation of fetal anatomy, its ability to characterize certain tissues is limited.

Three dimensional ultrasound and magnetic resonance imaging (MRI) improves soft-tissue definition and has been reported to be of additional use in the antenatal evaluation of conjoined twins (Figure 121-3). Zoppini et al. (1993) used MRI following fetal paralysis with pancuronium and identified bowel-to-bowel anastomosis. Prior to the MRI, a solution of gadolinium DTPA was also injected into the stomach of one twin to aid in the diagnosis of bowel-to-bowel anastomosis. Early prenatal diagnosis and precise character relation of conjoined twins are essential for optimal obstetric and postnatal management. Vaginal delivery may be possible for preterm conjoined twins for which postnatal survival is unlikely. Near term cesarean delivery is the delivery method of choice for conjoined twins to maximize survival and prevent birth trauma. Dystocia occurs frequently (Nichols et al., 1967), and in omphalopagus twins it has been reported in

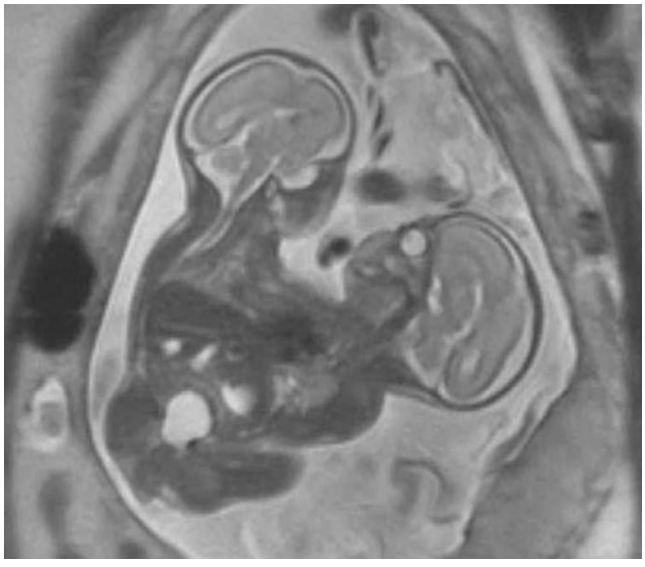

Figure 121-3 Prenatal MRI of thoracopagus twins joined at the chest and abdomen. Note the presence of a single heart, liver, and bladder.

36% of cases (Harper et al., 1980). Delivery at a tertiary care center is recommended for optimal neonatal intensive care and pediatric surgical support.

FETAL INTERVENTION

There are no fetal interventions for conjoined twins.

TREATMENT OF NEWBORN

Except for life threatening emergencies that must be treated by immediate separation of the twins, surgery should be delayed until an accurate assessment of shared structures is completed (Filler, 1986). Table 121-2 lists the important diagnostic studies, the structures that each study will best evaluate, and the type of twin that requires such a study. Comprehensive evaluation of the cardiovascular system is necessary in all thoracopagus twins (Figure 121-4). These studies should be obtained immediately after birth because of the high likelihood of an abnormality in one or both twins. One of the most important factors in prognosis is the degree of separation of the two hearts. Of the conjoined twins who are born alive, the

Table 121-2

Most Useful Diagnostic Studies for Evaluating Different Types of Twins

Test	Evaluation of	Type of Union in Twin
MRI	Nervous system	Cranial and thoracoabdominal
CT scan	Bony unions, kidneys, urinary tract, central nervous system	All types
Ultrasound	Liver, biliary system, pancreas	Thoracoabdominal
Plain films	Extremities	Ischiopagus
Radionuclide scans	Liver, spleen, biliary tract	Thoracoabdominal
Cystography, urethrography	Bladder, urethra	Abdominal and pelvic
Barium studies of gastrointestinal tract	Small bowel, colon	Abdominal and pelvic
Angiography	Heart and major blood vessels	Thoracoabdominal and cranial
Echocardiography*	Heart and great vessels	Thoracoabdominal
Electrocardiography		
Cardiac catheterization

potential long-term survivors fall into two groups. The first group involves children who thrive despite being joined. Pygopagus, ischiopagus, and xiphopagus twins usually fall into this category. In this group there is sufficient time to evaluate organ sharing and to plan operative separation. Separation in these children should probably be delayed several months. The advantages of waiting are that the infants will be larger, important congenital anomalies not obvious at birth will have become apparent, and the risks of surgery and anesthesia should be less. In Filler's (1986) experience with four separations, delay was clearly beneficial. The second group involves twins whose lives are threatened because of the conjunction or coexistent congenital abnormalities. Emergency surgery with or without separation may be required before appropriate diagnostic studies can be completed. Urgent surgery is indicated in three clinical situations: (1) when the existence of one twin threatens the life of the other (Graivier and Jacoby, 1980); (2) when a potentially correctable life-threatening anomaly is present (e.g., severe congenital heart disease or intestinal obstruction); and (3) when surgical intervention is necessary for a traumatic injury to the bridge of tissue and underlying viscera joining the twins.

SURGICAL TREATMENT

Many descriptions of surgical procedures to separate different types of conjoined twins appear in the literature (Koop, 1961; Kiesewetter, 1966; DeVries, 1967; Gans et al., 1968; Kling et al., 1975; James et al., 1985; Kotrikova, 2004). It is beyond the scope of this review to describe the individual operations in detail. However, the surgeon is faced with two general considerations. First, the surgical team must try to separate the shared structures, leaving each child with functional residual organs and limbs whenever possible. Second, the skin, muscle, and bony defect at the site of conjunction must be closed after separation is completed. Closure of defects can be relatively simple when the defect is small, as in the case of omphalopagus twins. When the defect is large, closure can be extremely difficult. In cases of large defects, a flap of skin and muscle may be available for coverage. Silastic tissue expanders have been used to provide additional skin and muscle to aid closure in several cases (Filler, 1986). Teflon mesh and acrylic prostheses have also been described (Wilson, 1957; DeVries, 1967). It is essential to have a coordinated approach of the operating team, consisting of duplicate anesthesiologists, surgeons, and nursing personnel. The anesthesia team should be responsible for setting up methods of physiologic monitoring (Simpson et al., 1967; James et al., 1985). Existing operating tables may need to be modified as the standard tables are not properly designed for the separation of conjoined twins. The modifications required will depend on the type of separation (Savickis, 1984).

Significant ethical considerations arise in cases in which it is not possible to achieve separation without sacrificing the life or the quality of the life of one of the two twins (Pepper, 1967; Raffensperger, 1997; Annas, 2001).

LONG-TERM OUTCOME

The prognosis for surgery depends on the type of conjunction. The results for omphalopagus and xiphopagus twins are particularly good. Even over 30 years ago, in a review of 11 sets of omphalopagus twins, 19 of the 22 children survived (Nichols et al., 1967). When omphalocele is present in

this type of twinning, the prognosis appears to be somewhat worse. Votteler (1986) reviewed the results of separation in seven sets of omphalopagus twins with an associated omphalocele treated between 1963 and 1981. The omphalocele had ruptured in four sets. One twin in three of the four sets died, and one twin from two of the three sets with an intact omphalocele also died.

With the exception of a single case of a successful separation of a set of twins who shared a right atrium (Synhorst et al., 1979), thoracopagus twins sharing hearts have not survived. Survival is more frequent in those sharing a single pericardium (Edmonds and Layde, 1982). The most common causes of death in thoracopagus twins include cardiac abnormalities, infections, and respiratory failure. In many failures, closure of the chest wall has contributed to the poor outcome, either because of tight closure that restricts chest motion or a defect in the sternum that allows paradoxical respiratory motion (Filler, 1986). The outcome for craniopagus twins relates to whether the union is total or partial (Votteler, 1986; Bucholz et al., 1987). In a review of 21 cases of craniopagus, temporoparietal and occipital junctions had a worse outcome than frontal and parietal junctions (Bucholz et al., 1987). In the Votteler series, 50% had residual neurologic abnormalities, whereas in the Bucholz series only one of nine had severe neurologic deficit. The prognosis appears better when surgery is performed during the neonatal period and when craniopagus twins are separated in stages rather than in one procedure (Bucholz et al., 1987).

Successful separations of pygopagus twins have been reported by Koop (1961), Votteler (1982), Cloutier et al. (1979) and Fowler et al. (1999). The prognosis is usually good for pygopagus twins mainly because the joined structures are not essential for life. In most reported cases, both twins have survived (Filler, 1986).

The separation of ischiopagus twins is usually difficult because most of the abdominal viscera are joined. There is only one pelvis and often only three lower extremities. Votteler compiled a list of 12 ischiopagus separations from 1955 to 1981 in which one or both ischiopagus twins survived. Filler (1986), Ross et al. (1985), and Grantzow et al. (1985) have successfully separated four other sets. Albert et al. (1992) further reported on the orthopedic management of four cases treated at Children's Hospital in Philadelphia. Six of the eight infants survived. Significant postseparation orthopedic problems persisted in all of the successful separations. These included but were not limited to hip flexures, clubfoot, recurrent dislocated hip, one functional deformed foot, and quadriceps contractures. In addition to orthopedic problems, successfully separated ischiopagus twins require long-term rehabilitation because of gynecologic, urologic, and intestinal disabilities. In Filler's (1986) series of three cases of ischiopagus twins, one set at age 17 used a prosthesis for an absent lower extremity, and each had a colostomy. In a second set, at age 4 each child had a colostomy and an artificial limb. Because they shared a single set of male genitalia, one child is being raised as a boy and the other as a girl. In a further set reported at age 1.5 years, each had a colostomy, a suprapubic bladder catheter, and normal lower extremities (Filler, 1986).

It is interesting to note that while pregnancy is not recommended, it can occur in female survivors following successful separation. There are two case reports of separated conjoined twins having successful pregnancies themselves (Shan and Chazotte, 1994; Rosemeier et al., 2004). In one recent report, a 23-year-old primigravid woman who was a separated ischiopagus tetrapus twin delivered at 35 weeks of gestation by cesarean. The twins had been separated at 15 months of age but the co-twin died secondary to recurrent pneumonia (Rosemeier et al., 2004).

GENETICS AND RECURRENCE RISK

To our knowledge, the recurrence risk is not increased above background for conjoined twins.

Monoamniotic Twins

122 CHAPTER

Key Points

- Monoamniotic twinning is a rare form of twinning where both twins occupy a single amniotic sac.
- This form of twinning occurs when a single embryo splits during postovulation days 8 to 10.
- The most common way to diagnose monoamniotic twins antenatally is failure to visualize a dividing membrane in the presence of a single placental mass and like-gender twins. During the first trimester, the presence of two embryos in a single sac, but with only one yolk sac, is highly suggestive of monoamnionicity.
- These pregnancies are at risk for significant perinatal morbidity and mortality. This has been attributed to preterm delivery, intrauterine growth restriction, congenital anomalies, vascular anastomoses between twins, and umbilical cord entanglement or cord accidents.
- Intense antenatal surveillance and timed delivery has been shown to improve outcomes. This typically takes the form of elective hospitalization with daily nonstress testing at 24 to 26 weeks' gestation, and increased frequency of testing if variable decelerations are noted.
- Elective delivery at 32 to 34 weeks' gestation is recommended if fetal testing remains reassuring and cesarean delivery is most commonly recommended.

CONDITION

Monoamniotic twinning is an unusual form of twinning in which both twins occupy a single amniotic sac. Monoamniotic twins account for 1% of all monozygotic twin pregnancies (Benirschke and Kim, 1973). This form of monozygotic twinning typically occurs when a single embryo splits between the ninth and twelfth day after fertilization. Splitting before this time gives rise to either dichorionic diamniotic twins (split between the first and third day after fertilization) or to monochorionic diamniotic twins (split between the third and eighth day after fertilization). Splitting later in embryogenesis (after the twelfth day postfertilization) gives rise to conjoined twins (Benirschke, 1998).

Although a rare event, monoamniotic twinning is important because of the high perinatal mortality rate associated with these pregnancies. The first comprehensive review of the world literature was performed in 1935 by Quigley, who found an overall mortality rate of 68% in 94 pregnancies. His opinion was that the poor prognosis was due mainly to twisting and knotting of the umbilical cords with subsequent occlusion of the blood supply to one or both twins. A subsequent review in 1959 added 35 new cases to the world literature and reported a high fetal mortality rate of 30% (Salerno, 1959). More recent series and reviews of prenatally diagnosed cases suggest mortality rates ranging from 10% to 32% (Rodis et al., 1997; Allen et al., 2001; Roque et al., 2003; Demaria et al., 2004; Heyborne et al., 2005). This decrease in perinatal mortality is likely secondary to increased rates of prenatal diagnosis, antenatal steroids, intense fetal surveillance, and timed delivery.

INCIDENCE

It is difficult to ascertain the exact incidence of monoamniotic twins. The incidence has ranged in various studies from 1 in 1650 to 1 in 93,734 livebirths (Simonsen, 1966; Colburn and Pasquale, 1982). Monoamniotic triplets are even more rare (Giannopoulos et al., 2001). Use of in vitro fertilization and embryo transfer may increase the risk for both monochorionic diamniotic twins and for monoamniotic twins (Alikani et al., 2003).

There may be a preponderance of female twins among monoamniotic twin pairs (Derom and Vlietinck, 1988). In

a study of 26 sets of monoamniotic twins, 20 (77%) were female pairs. However, this difference has not been as evident in more recent studies (Carr et al., 1990; Allen et al., 2001). Carr et al.'s (1990) series of 24 sets included 11 (46%) sets of females and 13 (54%) sets of males. Allen et al.'s (2001) series of 25 sets included 12 (48%) sets of females and 13 (52%) sets of males.

SONOGRAPHIC FINDINGS

Prenatal diagnosis is established when a dividing membrane cannot be identified by an experienced sonographer in a twin gestation with a single placental mass and like-gender twins. The diagnosis is confirmed after sonographic identification of entangled umbilical cords using Color flow Doppler (Belfort et al., 1993; Aisenbrey et al., 1995) (Figure 122-1). This feature has been reported in 70% to 100% of cases (Lee, 1992; Rodis et al., 1997). Cord entanglement has been diagnosed using Color Doppler ultrasonography as early as 10 weeks' gestation (Arabin et al., 1999; Sebire et al., 2000; Sherer et al., 2002).

Monoamnionicity may be suspected early in the first trimester. Between the sixth and tenth week, counting the number of gestational sacs is an accurate method of determining chorionicity. Amnionicity can be determined by counting the number of embryonic heartbeats in each gestational sac. A single gestational sac with two embryonic heartbeats can be either monochorionic diamniotic or monochorionic monoamniotic. Two yolk sacs indicate that the pregnancy is diamniotic. One gestational sac with one yolk sac and two embryonic heartbeats suggests monoamnionicity. If monoamnionicity is suspected in the first trimester, a follow-up ultrasound is suggested in the second trimester to reconfirm the diagnosis (Bromly and Benacerraf, 1995). Three-dimensional ultrasound has also been used to visualize monoamniotic fetuses lying in a single amniotic cavity (Su, 2002).

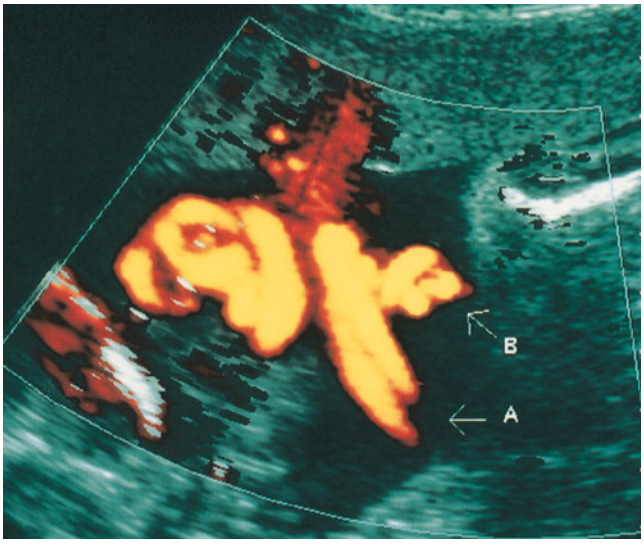

Figure 122-1 Power Doppler imaging of entangled umbilical cords in a case of monoamniotic twins.

It is important to remember that failure to visualize a dividing membrane does not ensure that the pregnancy is monoamniotic (Malone and D'Alton, 2000). Such a membrane may be missed even with well-performed sonography (Blane et al., 1987). As a result, other techniques have been utilized to confirm the diagnosis of monoamnionicity. Ultrasound-guided injection of indigo carmine dye mixed with air into the amniotic sac during genetic amniocentesis has been said to enhance the diagnosis of monoamniotic twins (Tabsh, 1990). If microbubbles are seen around both fetuses, the diagnosis of monoamniotic twinning is made with accuracy. Amniography is another technique, which may increase the accuracy of diagnosis (Lavery and Gadwood, 1990). In this report, 30 mL of 61% iopamidol (Isovue-M 300, Squibb) was injected into the amniotic fluid. Maternal abdominal x-ray films taken 24 hours after the injection revealed that both fetuses had swallowed contrast medium injected into a shared single amniotic sac. Computed tomography following intraamniotic injection of Renografin has also been suggested to confirm the diagnosis of monoamniotic twinning (Carlan et al., 1990; Perkins and Terry, 1992). Such invasive radiological procedures are now mostly of academic interest, and are rarely if ever performed in contemporary clinical practice.

DIFFERENTIAL DIAGNOSIS

A major consideration in differential diagnosis of monoamnionicity is the intrauterine rupture of a diamniotic twin membrane, which can mimic the sonographic appearance of true monoamniotic twins. Actual differential diagnosis between these two conditions is probably not necessary, as intrauterine membrane rupture has a perinatal mortality rate consistent with that of true monoamniotic gestations (Gilbert et al., 1991). This clinical scenario should be suspected when there is failure to visualize a dividing membrane following previous sonographic confirmation of a membrane. Possible causes for intrauterine rupture include trauma during amniocentesis, infection, and developmental disturbances of the membranes (Gilbert et al., 1991).

ANTENATAL NATURAL HISTORY

High intrauterine morbidity and mortality rates have been associated with monoamniotic twins (Quigley, 1935; Salerno, 1959; Raphael, 1961; Simonsen, 1966; Carr et al., 1990; D'Alton and Simpson, 1995). These high rates have been attributed to premature delivery, growth restriction, congenital anomalies, vascular anastomoses between twins, and umbilical cord entanglement and cord accidents. Discordant anatomical abnormalities are common. In a recent series of 25 monoamniotic twin pairs by Allen et al., 28% of the pregnancies had been complicated by fetal structural anatomical abnormalities including two cases of acardiac twinning (Allen at al., 2001). The twin–twin transfusion syndrome (TTTS) is

thought to be rare in monoamniotic twins as the placentas of monoamniotic twins have significantly greater numbers of both superficial and deep anastomoses than uncomplicated monochorionic twins which may be protective against TTTS (Bajoria, 1998; Umur et al., 2003). Cord accidents seem to be the greatest contributor to these high intrauterine mortality rates. In one of the earliest series of monoamniotic twins it was stated that double survival of such twins is a rare event (Quigley, 1935). However, more recent series and reviews of prenatally diagnosed cases suggest mortality rates range from 10% to 32% (Rodis et al., 1997; Allen et al., 2001; Demaria et al., 2004).

Because umbilical cord accidents seem to be the primary cause of fetal death, most management protocols emphasize intense fetal surveillance. Such fetal surveillance should occur from the time of fetal viability because intrauterine fetal demise has been documented in monoamniotic twins throughout gestation (Rodis et al., 1997; Arabin et al., 1999; Beasley et al., 1999). Additionally, surveillance must be repeated frequently because fetal compromise and death have been documented despite frequent testing (Beasley et al., 1999; Rodis et al., 1997).

Many of the older reports on monoamniotic twins are not optimal for guiding contemporary practice because of the fact that in almost all cases the diagnosis of monoamnionicity was only made postnatally. Nonetheless, there have been several recent series of prenatally diagnosed monoamniotic twins, which are helpful for contemporary patient counseling. Rodis et al. (1997) reviewed 13 cases of monoamnionicity at one tertiary care center over a ten-year period. All patients underwent serial ultrasounds and antenatal fetal surveillance 2 to 7 times per week starting at 24 to 26 weeks' gestation. The average gestational age at diagnosis was 16.3 weeks' gestation. All patients received antenatal steroids for fetal lung maturity. The mean gestational age at delivery was 32.9 weeks' gestation with a mean birth weight of 1,669 grams. One hundred percent of the pregnancies exhibited cord entanglement at the time of delivery, with 62% having knotted cords. Sixty-two percent of the pregnancies were delivered for abnormal fetal testing. All sets were delivered by cesarean section by 35 weeks' gestation. There were no fetal deaths. Two neonates died during the perinatal period: one due to a congenital heart defect and the other due to asphyxia and sepsis. The one case of demise secondary to asphyxia received antenatal testing less than two times per week. Perinatal survival was 92% in this series. These 13 cases were compared to 77 sets from the literature that had not been diagnosed prenatally. A 71% reduction in the relative risk of perinatal mortality was observed following prenatal diagnosis and fetal surveillance. Rodis et al., concluded that accurate prenatal diagnosis, intensive surveillance, and appropriately timed delivery all result in improved perinatal survival for monoamniotic twins (Rodis et al., 1997).

In a study by House et al., 22 patients with prenatally diagnosed monoamnionic twins were managed at one tertiary care center over a ten-year period (House et al., 2001). Management included close fetal surveillance with daily nonstress tests commencing at 24 to 26 weeks' gestation. Patients underwent prolonged monitoring if the daily nonstress test demonstrated variable decelerations or any other signs of potential fetal compromise. Frequent growth scans were performed. Management also included steroid administration and elective delivery at 34 to 35 weeks' gestation, provided that the testing was reassuring. Decision to deliver a patient prior to 34 to 35 weeks' gestation took into consideration the patient's gestational age and the frequency and severity of variable decelerations. Nonreassuring fetal status always resulted in emergent delivery. There were no fetal mortalities in this group of patients. While overall outcomes were favorable, monoamniotic twins were more likely to deliver prematurely and had more respiratory problems compared to monochorionic diamniotic and dichorionic diamniotic pregnancies (House et al., 2001).

MANAGEMENT OF PREGNANCY

The optimal management of monoamniontic twins with regards to frequency of fetal surveillance and the optimal timing of delivery is controversial because of the paucity of prospective data. As a result, recommendations are based on case reports, case series, and expert opinion. We acknowledge that the excellent outcomes described in the studies by Rodis et al., and House et al., could be optimistic. Cord accidents may occur without warning, and these studies could have been biased secondary to small patient numbers. Despite these limitations, we recommend that monoamniotic twins be managed with intensive fetal surveillance similar to the above studies. The objective of antenatal testing is to determine the presence and frequency of variable decelerations, as these changes may precede intrauterine fetal death. Further management takes into consideration gestational age, whether or not the patient received antenatal steroids, and overall fetal status.

Daily antenatal testing in the form of the nonstress test is recommended starting between 24 and 26 weeks' gestation. The decision as to whether or not to hospitalize the patient for this daily testing is individualized to the patient. Hospital admission and continuous fetal heart rate monitoring of both twins is recommended if variable decelerations increase in frequency or severity. Delivery may become necessary if fetal heart rate testing becomes nonreassuring. Because biophysical profile testing cannot predict variable decelerations, it is reserved for the evaluation of nonreactive nonstress tests and abnormal fetal growth. Doppler studies of umbilical artery waveforms may be useful in the management of monoamniotic twin pregnancies (Abuhamad et al., 1995). Narrowing of the umbilical vesels secondary to cord entanglement may result in hemodynamic alterations in the fetoplacental circulation and may be manifested as a notch in the umbilical artery waveform (Figure 122-2). Serial ultrasound examinations approximately every 2 to 3 weeks are performed to evaluate fetal growth and to assess amniotic fluid volume.

Antenatal corticosteroid therapy is used to enhance fetal pulmonary maturity because of the high incidence of

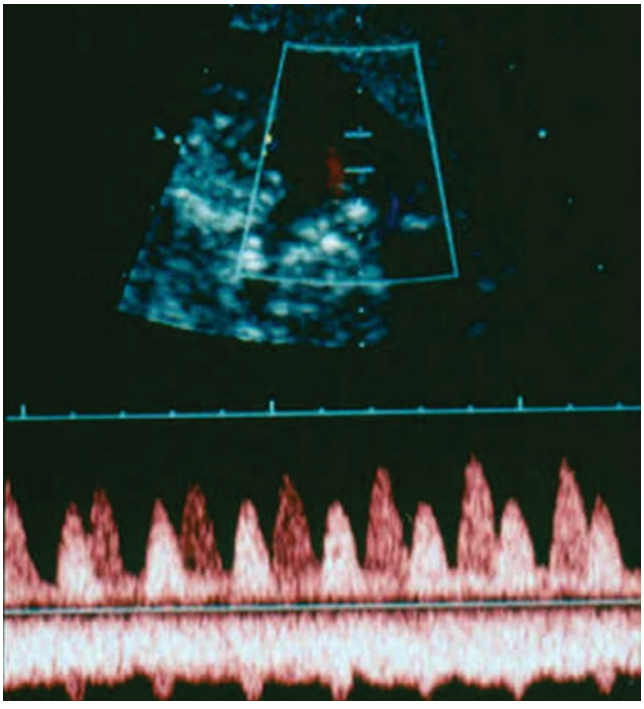

Figure 122-2 Doppler studies in monoamniotic twins. (*Courtesy of Alfred Abuhamad.*)

premature delivery in monoamniotic twins and also because of the significant risk for urgent delivery, secondary to variable decelerations. In general, the delivery of monoamniotic twins requires a tertiary care center setting. However, after 32 weeks of gestation, delivery may be accomplished in a community hospital with appropriate nursery capabilities.

In the absence of nonreassuring fetal testing, the timing of delivery is not well established as the optimal time to deliver monoamniotic twins is unknown (Su, 2002). Some authors have advocated delivery of all monoamniotic twin pregnancies immediately once fetal lung maturity has been demonstrated (Kassam and Tompkins, 1980). Others have recommended elective delivery at 32 weeks of gestation because of a presumed increased risk of cord accidents as the pregnancy progresses (Beasley et al., 1999). Other studies suggest it is unnecessary to deliver monoamniotic twins prematurely. One study by Carr et al., was a retrospective evaluation of 24 sets of mostly postnatally confirmed monoamniotic twin pregnancies (Carr et al., 1990). There were no perinatal deaths after 30 weeks of gestation. As a result, the authors saw no advantage in elective premature delivery. In their series, however, the diagnosis of monoamniotic twins was made prenatally in only 21% of cases, and the diagnosis of twins was known prenatally in only 29% of cases. In a second study by Tessen and Zlatnick, 20 monoamniotic twin pregnancies at the University of Iowa from 1961 to 1989 were reviewed (Tessen and Zlatnik, 1991). In this retrospective series no perinatal death occurred after 32 weeks of gestation. These authors suggested that prophylactic premature delivery might not be indicated. However, in an addendum to the original paper the authors report a double fetal death of 35-week monoamniotic twins just after completion of their study, again demonstrating that the safety of expectant management of monoamniotic twin pregnancies is unproven beyond 34 weeks' gestation.

Provided that the fetal status is reassuring, it is our practice to perform elective delivery following antenatal corticosteroid therapy at 34 weeks' gestation. Delivery at this time carries with it a low risk of neonatal morbidity when weighed against the uncertain risk of continuing the pregnancy. Although some series have questioned the need for early delivery, the double death referred to in the addendum to Tessen's report is particularly troubling (Carr et al., 1990; Tessen and Zlatnik, 1991). In addition, at present we do not have the technology to continuously trace both fetal hearts for a prolonged time. Consequently, it is our preference to perform elective delivery at 34 weeks of gestation. However, it is not unreasonable to manage selected cases of monoamniotic twins expectantly beyond 34 weeks of gestation, with careful fetal surveillance, and to decide on the timing of delivery based on fetal lung maturity.

The optimal mode of delivery of monoamniotic twins also remains uncertain. Cesarean delivery has been recommended by some authors to eliminate the risk of intrapartum cord accidents (Rodis et al., 1987). However, vaginal delivery of monoamniotic twins is not contraindicated. In one series, no fetal deaths and only one case of nonreassuring fetal testing requiring emergency cesarean delivery occurred during labor in 15 monoamniotic twin pregnancies delivered vaginally (Tessen and Zlatnik, 1991). In another series of 24 cases, vaginal delivery was accomplished in 75% of individual neonates and in 48% of liveborn infants, although the antenatal diagnosis of monoamniotic twins was unknown in most cases and could not have influenced management (Carr et al., 1990). Nonetheless, there are data suggesting potential difficulties with vaginal delivery of monoamniotic twins. In one case, a nuchal cord affecting the first twin was cut to facilitate delivery, and on delivery of this twin's body it was noted that the cut cord was actually that of the second twin (McLeod and McCoy, 1981; Kantanka and Buchman, 2001). Given these issues and the high incidence of nonreassuring fetal testing, all monoamniotic twin pregnancies have generally been delivered by elective cesarean delivery.

FETAL INTERVENTION

The only intervention described to reduce the incidence of cord accidents in monoamniotic twins is medical amnioreduction. In one small series, the prostaglandin inhibitor sulindac, 200 mg orally twice daily, was administered to three patients diagnosed with monoamniotic twins, beginning at 24 to 29 weeks of gestation (Peek et al., 1997). In two of the three cases, dose-related reduction in amniotic fluid volume was noted, and in all three cases fetal lie was stabilized. All fetal heart rate tracings remained normal, and all six infants survived. Although this was a very limited study, the authors

pointed out the difficulty of performing a randomized controlled trial given the rarity of the condition. Administration of a medication to deliberately reduce amniotic fluid volume in such pregnancies should therefore be considered experimental and generally not performed.

TREATMENT OF THE NEWBORN

Prematurity is the most important concern, together with growth restriction. Following delivery, a detailed examination should be performed because of the higher incidence of congenital anomalies in monoamniotic twins. No other specific neonatal intervention is required. Placental pathologic tests should be performed in all cases to confirm the prenatal diagnosis.

SURGICAL TREATMENT

No surgical treatments have been described.

LONG-TERM OUTCOME

There are no data available for long-term outcome.

GENETICS AND RECURRENCE RISK

There are no genetics and recurrence risks described in the literature.

Intrauterine Growth Restriction

123
CHAPTER

Key Points

- Intrauterine growth restriction (IUGR) is commonly defined as a birth weight less than the 10th percentile at a given gestational age. It has also been defined as a fetus that has not reached its growth potential at a given gestational age.
- Small for gestational age (SGA) describes a population of fetuses with a weight below the 10th percentile without reference to the cause.
- Prenatal ultrasonography is the imaging method of choice for diagnosing and evaluating possible cases of IUGR. The typical finding is a significant discrepancy in some or all of the fetal biometric parameters as compared with measurements expected based on gestational age alone.
- Because sonographic prediction of fetal weight may vary by up to 20% from actual fetal weight, diagnosis and management of IUGR is generally guided by serial sonographic assessments of the fetus.
- Pregnancy management depends on the gestational age, the etiology of the IUGR, and the results of fetal surveillance. Fetal testing including Doppler studies and serial growth scans are important for determining whether a pregnancy can be continued expectantly.
- Detailed Doppler assessment including umbilical arterial, middle cerebral arterial, ductus venosus, and umbilical venous assessments are used to evaluate fetal status, and may be used to optimize timing of delivery.
- Gestational age at delivery is a strong predictor of neonatal outcome in IUGR cases.
- Elective delivery is recommended for all cases of IUGR reaching 37 weeks of gestation, while expectant management with close fetal surveillance is recommended for cases less than 34 weeks of gestation. For cases between 34 and 37 weeks of gestation, management is individualized depending on overall fetal status.
- A previous pregnancy complicated by IUGR is considered a risk factor for developing IUGR in a subsequent pregnancy. Such cases of recurrent IUGR usually reflect an underlying maternal medical problem, such as chronic hypertension or antiphospholipid antibody syndrome.

CONDITION

Intrauterine growth restriction (IUGR) is commonly defined as a birth weight less than the 10th percentile at a given gestational age (Table 123-1). It has also been defined as a fetus that has not reached its growth potential at a given gestational age, because of one or more causative factors (Lin and Santolaya-Forgas, 1998). The population from which expected fetal growth standards are derived to define the 10th percentile is of major importance. A review of all publications

in the English language literature since 1963 that presented values for the 10th percentile of birth weight for gestational age has been published (Goldenberg et al., 1989). It was found that studies differed in how gestational age was determined, types of infants excluded, populations studied, and whether they were controlled for the sex of the infant as well as the race and parity of the mother. The 10th percentile birth weights at each gestational age from these various published standards differed substantially.

Different standards for fetal growth throughout gestation have been reported. These standards set the normal range of fetal growth as being between 2 SD of the mean (2.5th to 97.5th percentile) or between the 10th and 90th percentiles for gestational age. Fetal growth curves plotting fetal biometric values against gestational age have been published from a variety of populations. One of the earliest set of growth curves was derived from a population in Denver, Colorado (Lubchenco et al., 1966). These Denver curves soon became the standard fetal growth curves used throughout North America. However, these curves underestimate the incidence of small for gestational age (SGA) infants at sea level, especially during the third trimester, and also do not take into account the increase in birth weight noted during the past 30 years. Although many centers report the continued use of the Denver curves, more contemporary standards are available. These include growth standards from the state of California, based on data from more than 2 million singleton births occurring between 1970 and 1976, and also growth standards from Canada, based on data from more than 1 million singleton births and more than 10,000 twin births occurring between 1986 and 1988, as well as from national US standards, based on data from more than 3 million births in 1991 (Williams et al., 1982; Arbuckle et al., 1993; Alexander et al., 1996). Commonly used cutoffs for defining IUGR in male and female fetuses at various gestational ages are shown in Table 123-1. A further problem with the use of such cutoff values for diagnosing IUGR is that they cannot identify a fetus that has failed to reach its own growth potential, but whose weight is not yet below the usual cutoff value, such as the 10th percentile. Such a fetus may be identified through serial sonography, in which sequential weight estimates are associated with decreasing percentile values for gestational age.

The term intrauterine growth restriction is frequently and erroneously used as a substitute for the original term small for gestational age. SGA describes a population of fetuses with a weight below the 10th percentile without reference to the cause. Most SGA fetuses are normal except the small fetuses that simply reflect the normal weight distribution within a population. The use of a particular cutoff value such as the 10th percentile is clearly arbitrary, and will inevitably include a large number of fetuses that are constitutionally small, without any evidence of pathology. Up to 70% of SGA infants are small because of such constitutional reasons as maternal ethnicity, parity, or body mass index (Lin and Santolaya-Forgas, 1998). IUGR describes a subset of these SGA fetuses whose weight is below the 10th percentile as a result of a pathologic process that is due to a diverse group of disorders. The term intrauterine growth restriction is preferred to intrauterine growth retardation, as the word retardation has a tremendously negative influence on patients.

IUGR has classically been subdivided into two patterns: asymmetric and symmetric IUGR. This provides further information on fetal body size and length, rather than a simple reliance on fetal weight. With symmetric IUGR, both the head and abdomen are decreased proportionately, while asymmetric IUGR refers to a greater decrease in abdominal size, which is also referred to as the head-sparing effect (Lin and Santolaya-Forgas, 1998). Approximately 70% to 80% of cases of IUGR are asymmetric, with the remaining 20% to 30% being symmetric. It was commonly believed that asymmetric IUGR represented placental insufficiency, while symmetric

Table 123-2

Risk Factors for Intrauterine Growth Restriction

Fetal Factors	Placental Factors	Maternal Factors
Chromosomal abnormalities:	Abnormal trophoblast invasion	Constitutional factors:
Trisomies 21, 18, 13	Placental infarction	Race
Turner syndrome	Abruption	Height/weight
Chromosomal deletions	Vascular malformations	Nutritional factors:
Uniparental disomy	Velamentous cord insertion	Poor pregnancy weight gain
Confined placental mosaicism	Placenta previa	Low prepregnancy weight
Structural malformations:	Circumvallate placenta	Inflammatory bowel disease
Anencephaly	Chorioangioma	Chronic pancreatitis
Omphalocele/gastroschisis		Gastrointestinal surgeries
Diaphragmatic hernia		Hypoxic conditions:
Renal agenesis/dysplasia		Severe lung disease
Cardiac malformations		Cyanotic heart disease
Multiple malformations		Sickle cell anemia
Multiple pregnancies:		Vascular problems:
Monochorionic gestation		Chronic hypertension
Single anomalous fetus		Preeclampsia
Twin-to-twin transfusion		Collagen vascular disease
Fetal infections:		Insulin-dependent diabetes
Rubella		Antiphospholipid antibodies
Cytomegalovirus		Renal disease:
Varicella-zoster		Glomerulonephritis
		Renal transplantation
		Chronic renal failure
		Environmental factors:
		High altitude
		Cigarette smoking
		Substance abuse
		Medications
		Past obstetric history:
		Previous stillbirth
		Previous IUGR
		Previous preterm birth

Adapted from Lin CC, Santolaya-Forgas J: Current concepts of fetal growth restriction: part I. Causes, classification, and pathophysiology. Obstet Gynecol. *92:1044-55 1998. Reprinted, with permission, from the American College of Obstetricians and Gynecologists.*

IUGR was more likely to be associated with constitutional problems, such as aneuploidy. However, it is now recognized that the timing of the pathologic insult is of more importance than the actual nature of the underlying pathology in determining the pattern of IUGR, thereby calling into question the clinical utility of subdividing IUGR into such patterns (Lin and Santolaya-Forgas, 1998). Symmetric IUGR can be caused by placental insufficiency occurring early in gestation, so that by the time the fetus is examined it has evolved from an initial asymmetric pattern to a pattern of symmetric IUGR. Overall infant body proportions can be described also by using the ponderal index, which is the birth weight in grams divided by the crown-to-heel length in cubic centimeters.

The list of possible causes of IUGR is extensive and is summarized in Table 123-2. These causes can be conveniently divided into fetal, placental, and maternal factors (Lin and Santolaya-Forgas, 1998). The most common fetal factors associated with IUGR include fetal chromosomal abnormalities, structural fetal malformations, fetal infections, and complications related to multiple gestations (Figure 123-1). Chromosomal abnormalities are a major cause of IUGR (ACOG, 2000). Confined placental mosaicism is three times more common in placentas of IUGR fetuses compared with those from appropriately grown fetuses (Wilkins-Haug et al., 1995). Up to one-fourth of all infants with congenital structural malformations will have IUGR, and the incidence of

Figure 123-1 Monozygotic twins in which the twin on the right is severely growth restricted compared to its co-twin.

growth restriction increases significantly as the number of different malformations per infant increases (Khoury et al., 1988). The number of infectious agents proven to cause IUGR is limited; they include rubella and cytomegalovirus, although no known bacterial infections have been linked to IUGR. The importance of defining a subpopulation of fetuses with IUGR lies in its association with adverse pregnancy outcome. The likelihood of perinatal morbidity and perinatal mortality increases significantly as the birth weight percentile decreases, so that once below the third to fifth percentiles, the chances of fetal death increase by as much as 20-fold (Scott and Usher, 1966). For infants weighing less than 1500 grams at term, the perinatal mortality rate is increased at least 70-fold as compared with appropriately grown term infants (Williams et al., 1982). Much of the increased perinatal morbidity and mortality in IUGR fetuses is due to the strong association between aneuploidy and structural fetal malformations with IUGR (Scott and Usher, 1966).

INCIDENCE

The incidence of IUGR varies depending on the population examined and the standard growth curves used to make the diagnosis (Goldenberg et al., 1989). Using the commonly quoted cutoff of the 10th percentile for defining pregnancies at risk for IUGR implies that at least 10% of the entire obstetric population will be labeled as being IUGR. In Europe, the commonly used cutoff for defining IUGR of 2 SD below the mean will include 5% of the total population. Approximately one third of all infants weighing less than 2500 grams at birth are not just small for gestational age, but have sustained IUGR (Lin and Santolaya-Forgas, 1998). Approximately 4% to 7% of all infants born in developed countries and 6% to 30% in developing countries are classified as growth-restricted (Scott and Usher, 1966; Lugo and Cassady, 1971; Galbraith et al., 1979).

SONOGRAPHIC FINDINGS

Prenatal ultrasonography is the imaging method of choice for diagnosing and evaluating possible cases of IUGR. The typical finding is a significant discrepancy in some or all of the fetal biometric parameters as compared with measurements expected based on gestational age alone. The most common biometric parameters evaluated are the biparietal diameter, head circumference, abdominal circumference, and femur length. These measurements can then be used in a variety of formulas to provide an estimate of fetal weight (Hadlock et al., 1984; Shepard et al., 1982). However, it should be noted that sonographic prediction of fetal weight using such formulas may vary by up to 20% from actual fetal weight, thereby calling into question the accuracy of prenatal sonographic diagnosis of IUGR. For this reason, diagnosis and management of IUGR is generally guided by serial sonographic assessments of the fetus.

In cases of symmetric IUGR, measurements of the fetal head, abdomen, and femur should all be below the expected values for a given gestational age. By contrast, with asymmetric IUGR, measurements of the fetal abdomen will be less than expected, while fetal head and femur measurements will be appropriate for gestational age. While it is generally considered that symmetric IUGR represents an intrinsic insult to the fetus (chromosomal abnormality, fetal infection) and asymmetric IUGR represents an extrinsic insult (placental insufficiency), sonographic differentiation of these patterns may not be clinically relevant. Mixed patterns of fetal growth restriction are also possible, which further limits the clinical utility of subdividing IUGR into symmetric and asymmetric types.

Following the diagnosis of IUGR, a careful sonographic survey should be performed to search for some of the possible causes listed in Table 123-2. In cases of severe IUGR associated with placental problems, oligohydramnios is a frequent finding. In cases of severe IUGR but normal or increased amniotic fluid volume, fetal aneuploidy or structural malformation is likely.

Pulsed Doppler sonographic assessment of the umbilical artery may reveal abnormalities of flow in true cases of IUGR. As placental resistance increases, umbilical arterial flow toward the placenta during diastole will decrease, leading to an increase in the ratio of systolic to diastolic flow (SD ratio). The end-diastolic velocity decreases when approximately one-third of the fetal villous vessels are poorly perfused (Vergani et al., 2005). Eventually, umbilical arterial diastolic flow disappears and may even reverse direction toward the fetus, (absent end-diastolic flow and reversed end-diastolic flow). Absent end-diastolic flow is thought to occur when

60% to 70% of the villous vascular tree is damaged (Vergani et al., 2005). (Figures 123-1A to 123-1D) When these changes occur, the frequency of monitoring and the timing of delivery become important management issues. The risks and benefits of delivery versus expectant management must be balanced.

Doppler velocimetry has been used to detect signs of fetal compromise before more traditional tests such as the nonstress test and biophysical profile deteriorate. Doppler studies are thought to change in a consistent and temporal pattern; absent end-diastolic flow in the umbilical artery is present before changes in the fetal heart rate tracing. Compensatory increase in cerebral flow also occurs, which is seen as an increase in end-diastolic flow in the middle cerebral arteries. Changes in venous circulation usually occur just prior to development of an abnormal fetal heart rate tracing, although the reliability of this temporal sequence is still unclear. Such venous changes may be demonstrated by absent or reversed flow during the "a" wave in the ductus venosus (Figures 123-2A to 123-2C) or pulsatile umbilical venous flow.

DIFFERENTIAL DIAGNOSIS

The single most likely alternative cause of apparent IUGR following a single prenatal ultrasound examination is incorrect pregnancy dating. Also, because of the inherent inaccuracy of all forms of prenatal estimation of fetal weight, the differential diagnosis of IUGR should always include a normally grown fetus, which is just physiologically small. In addition, at least 70% of all cases of SGA infants are constitutionally small, and do not reflect a pathologic impairment of fetal growth (Lin and Santolaya-Forgas, 1998). Once a diagnosis of pathologic IUGR is considered likely, the differential diagnosis for the underlying cause is extensive and is listed in Table 123-2.

ANTENATAL NATURAL HISTORY

The antenatal natural history of IUGR is difficult to predict in individual cases. The antenatal natural history of fetuses with IUGR secondary to aneuploidy, structural malformation, or infection will be dictated to a large extent by the nature of the particular abnormality.

In cases of IUGR secondary to placental insufficiency, the typical in utero progression involves redistribution of fetal blood flow away from noncritical organs and maintaining cerebral blood flow (Baschat, 2004). This leads to reduced fetal renal blood flow, which often manifests as worsening oligohydramnios. In addition, further growth of the fetal abdominal dimensions is decreased and subcutaneous fat is no longer deposited. Doppler studies demonstrate decreased umbilical arterial diastolic flow, which may become absent or reversed as the IUGR worsens. In contrast, cerebral end-diastolic blood flow increases and, as the condition worsens, central cerebral vasodilation is lost (Arias, 1994).

Because of this apparent sequence in fetal deterioration with IUGR, many investigators have used intensive fetal surveillance in an effort to predict when a fetus with IUGR is sufficiently compromised that in utero death is likely. Unfortunately, the predictive value of such antenatal surveillance is imperfect. It has been suggested that, in fetuses with IUGR, the development of absent or reversed end-diastolic umbilical arterial flow heralds imminent fetal death, and therefore may warrant elective delivery (Reed et al., 1987). However, the time interval between development of such Doppler abnormalities and fetal heart rate tracing abnormalities and fetal death may be days or even weeks, and therefore abnormal Doppler findings alone cannot be relied on to dictate elective premature delivery of a fetus with IUGR (Lin and Santolaya-Forgas, 1999; Cosmi et al., 2005; Vergani et al., 2005).

The Growth Restriction Intervention Trial (GRIT) was carried out to compare immediate delivery of IUGR fetuses versus expectant management to decrease complications of prematurity (The GRIT Study Group, 2003). Patients (547 mothers and 587 babies) were included if IUGR was diagnosed between 24 and 36 weeks' gestation and the responsible physician was uncertain whether or not to deliver the pregnancy. Umbilical artery Doppler studies were recorded for all patients. Patients were randomized to "immediate delivery" after administration of antenatal steroids or "delay until the physician was no longer uncertain". The median time to delivery for the immediate delivery group was 0.9 days and was 4.9 days for the delayed delivery group. Total perinatal death rate was 10% in the immediate delivery group versus 9% in the delayed delivery group. Thus, there was no difference in the overall mortality rates between the two groups indicating that there was little evidence for choosing immediate delivery over delayed delivery and vice versa. There were however significantly more stillbirths in the delayed delivery group, although this was balanced by a similar increase in neonatal deaths in the immediate delivery group. This study suggests that obstetricians are currently delivering IUGR pregnancies at the correct time to minimize perinatal mortality. At two-year followup, however, the GRIT study group found an increased trend towards disability in the immediate delivery group but no overall difference in the Griffiths developmental quotient (GRIT, 2004). Most of the observed differences were in babies younger than 31 weeks' gestation at randomization. This study emphasizes the important contribution of gestational age at delivery for patients with IUGR.

MANAGEMENT OF PREGNANCY

When the prenatal diagnosis of IUGR is suspected, the patient should be referred to a maternal–fetal medicine physician for targeted ultrasound examination and counseling regarding further pregnancy management. The ultrasound examination should be repeated, with particular attention paid to all biometric parameters, amniotic fluid status, umbilical artery Doppler indices, and the presence of any structural

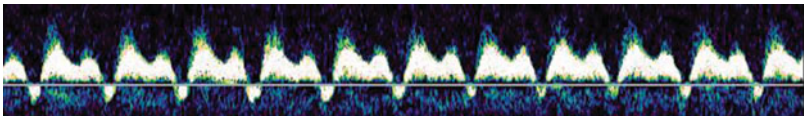

Figure 123-2C Ductus venosus waveform demonstrating reversal of the A-wave.

fetal malformations or stigmata of aneuploidy. Invasive testing for fetal karyotype should be considered (ACOG, 2000). Maternal evaluation should include careful obstetric, medical, family, and genetic histories to evaluate for possible causes of IUGR, as listed in Table 123-2. Maternal serum should be sent for rubella titers, and maternal urine should be evaluated with cytomegalovirus culture. Antiphospholipid antibody testing should be considered in a patient with a history suspicious for this syndrome (ACOG, 2000).

Further pregnancy management will depend on the gestational age and on the presence of additional malformations. If the pregnancy has already reached 37 weeks of gestation, delivery should be considered because of the extremely low risk of pulmonary immaturity. If the pregnancy is at less than 34 weeks of gestation and fetal testing is reassuring, expectant management is generally favored. The frequency of antenatal testing depends on the degree of IUGR, the amniotic fluid status, and umbilical artery Doppler indices (Harman and Baschat, 2003). Periodic fetal assessment using Doppler velocimetry, the fetal nonstress test, and the biophysical profile (traditional or modified) are all considered reasonable monitoring techniques (ACOG, 2000). Expectant management can continue as long as these tests remain reassuring. These tests should be supplemented by daily counting of fetal movements by the mother.

If umbilical artery Doppler indices are abnormal, especially in the presence of absent or reversed end-diastolic flow, more intense surveillance is suggested (Harman and Baschat, 2003). Venous Doppler studies are an independent predictor of adverse perinatal outcomes and should be added if the umbilical artery end-diastolic velocity is absent (Baschat, 2005). The addition of middle cerebral artery Doppler velocimetry also may be a useful predictor for fetuses at risk for neonatal mortality and morbidity (Vergani et al., 2005). Nonetheless, pregnancies may continue for days or weeks with reassuring fetal testing despite the presence of absent or reversed end-diastolic umbilical arterial flow (Lin and Santolaya-Forgas, 1999). Likewise, it is uncertain if delivery because of an abnormal venous Doppler improves outcomes (Hofstaetter et al., 2002; Bilardo et al., 2004). It is important to note that even in cases of IUGR neonatal outcomes are predominantly determined by gestational age at delivery (Cosmi et al., 2005). Thus, managing IUGR in a preterm infant can be a state of clinical equipoise requiring a delicate balance between continuing the pregnancy in a potentially hostile uterine environment versus delivering a neonate who will be confronted with the challenges of prematurity. Both expectant management and preterm delivery have the potential for long-term adverse consequences. Further studies are needed to determine the optimal management protocols for pregnancies complicated by IUGR.

For pregnancies between 34 and 37 weeks of gestation, further pregnancy management should be individualized and may be guided by fetal lung maturity indices. It is not unreasonable to manage all pregnancies with IUGR and reassuring fetal testing expectantly until 37 weeks of gestation, at which time elective delivery is arranged (Craigo et al., 1996). Using this management scheme, delivery before 37 weeks occurs only with nonreassuring fetal testing. If amniocentesis has documented fetal lung maturity during this 34- to 37-week gestational age range, delivery should be arranged promptly.

The mode of delivery for fetuses with IUGR should be based entirely on standard obstetric practices. There is no evidence to support a policy of routine cesarean delivery for all fetuses with IUGR (ACOG, 2000). That being said, it is quite common for IUGR pregnancies to demonstrate significant fetal heart rate changes during labor, most likely due to either oligohydramnios or diminished placental reserve. For this reason, decision on mode of delivery should be individualized depending on obstetric factors such as parity and cervical favorability. If an induction of labor is pursued for an individual fetus with IUGR, continuous electronic monitoring of the fetal heart rate should be conducted. The hospital location of delivery will depend on the gestational age and the presence of additional fetal abnormalities. In general, the optimal site for delivery of a fetus with severe IUGR will be a tertiary care facility with the immediate availability of a perinatologist and neonatologist to guide management.

FETAL INTERVENTION

Many fetal interventions have been evaluated in cases of IUGR to maximize neonatal outcome. These include treating any underlying problems, such as maternal hypertension. Behavior modification for the mother may include smoking cessation and modified bed rest (Lin and Santolaya-Forgas, 1999). More specific therapies for the fetus have included maternal low-dose aspirin therapy. In initial studies, there was a suggestion of increased fetal and placental weight associated with aspirin use (Trudinger et al., 1988). However, this potential benefit was subsequently refuted in a large randomized trial in which the administration of low-dose aspirin to the mother was shown to have no effect on the rate of IUGR or any other perinatal outcome measure (Caritis et al., 1998). Another possible fetal intervention is the antenatal administration to the mother of high-dose oxygen therapy, which in small studies has been shown to, at least transiently, improve umbilical arterial pH and oxygen content (Nicolaides et al., 1987). However, before this intervention can be recommended, larger, well-designed studies need to be completed.

TREATMENT OF THE NEWBORN

Because of their lack of placental reserve, infants with IUGR are more likely to require immediate resuscitation in the delivery room than appropriately grown infants. Problems that may be encountered include neonatal asphyxia, meconium aspiration, hypothermia, polycythemia, hypoglycemia, and other metabolic abnormalities. The infant should be examined carefully for any signs of structural malformation that may have been missed with prenatal ultrasonography,

for dysmorphic features suggestive of chromosomal abnormality, and for signs of perinatal infection with rubella, cytomegalovirus, varicella, syphilis, and toxoplasmosis (Alkalay et al., 1998). If any stigmata of perinatal infection or aneuploidy are present, appropriate serologic titers or karyotype should be obtained. A consultation with a clinical geneticist should also be obtained, if dysmorphic features are noted on examination.

SURGICAL TREATMENT

No surgical treatments have been described.

LONG-TERM OUTCOME

The long-term outcome of infants with IUGR will depend on the underlying cause and on the presence of additional malformations. Considerable data have now accumulated linking IUGR with poor cognitive function and adverse neurologic outcome in later childhood. In one study of 171 children with spastic cerebral palsy, it was found that up to 22% of cases could be attributed to IUGR, although a causal relationship could not be established (Blair and Stanley, 1990). In another study of 218 newborns at high risk, including 77 with IUGR, evaluation of cognitive skills at ages 9 to 11 revealed a significant learning deficit for infants with IUGR (Low et al., 1992). Data also suggest that IUGR infants can be expected to have higher rates of impaired gross motor development, lower intelligence quotient, and speech or reading disabilities (Gembruch and Gortner, 1998).

In a review of the many studies of long-term outcome of infants with IUGR, however, it was shown that after correcting for the effects of prematurity, most of the adverse cognitive outcomes could be diluted by socioenvironmental conditions (Hack, 1998). Therefore, it was suggested that fetal IUGR per se may not have a significant impact on final cognitive outcome in adulthood. Nonetheless, long-term followup has suggested that a history of IUGR may place these patients at risk for adult-onset hypertension and cardiovascular complications (Barker et al., 1989).

GENETICS AND RECURRENCE RISK

As described in Table 123-2, there are many genetic influences that can be associated with IUGR, ranging from genetic abnormalities such as aneuploidy to constitutional factors such as maternal height and weight. A previous pregnancy complicated by IUGR is considered a risk factor for developing IUGR in a subsequent pregnancy. Such cases of recurrent IUGR usually reflect an underlying maternal medical problem, such as chronic hypertension or antiphospholipid antibody syndrome. In the future, routine assessment of first trimester uterine artery Doppler studies might be useful to predict pregnancies at risk for IUGR and perhaps to modify pregnancy management (Dugoff et al., 2005).

124 Overgrowth Syndromes

CHAPTER

Key Points

- Group of conditions characterized by generalized excessive growth for gestational age.
- Incidence between 1 in 10,000 and 1 in 15,000.
- Sonographic findings include overgrowth, polyhydramnios, placentomegaly, and macroglossia.
- Differential diagnosis includes incorrect gestational dating, maternal gestational diabetes, Sotos syndrome, Weaver syndrome, Beckwith–Wiedemann syndrome, and Simpson–Golabi–Behmel syndrome, as well as chromosome abnormalities.
- Management of pregnancy should include level II sonographic examination, high-resolution karyotype, and molecular testing for *NSD1* and *GPC3* mutations. If these tests are negative, imprinting disorders of 11p15.5 should be tested.
- Newborn treatment should include medical genetics consultation, cardiac evaluation, and monitoring for hypoglycemia.
- Some of the overgrowth conditions are associated with a predisposition to childhood cancer.
- Several of the overgrowth conditions have Mendelian patterns of inheritance.

CONDITION

The overgrowth syndromes refer to a heterogeneous group of conditions characterized by generalized excessive growth for gestational age. Many overgrowth syndromes are associated with anomalies, developmental delay, and a propensity for tumor development. Diagnostic characterization has been difficult because of the overlapping clinical features in many of these syndromes (Cytrynbaum et al., 2005). Recent studies using high-resolution cytogenetic techniques, as well as

molecular analysis of several genes, have illustrated the fact that there is substantial clinical as well as molecular overlap amongst the overgrowth disorders (Baujat et al., 2005).

INCIDENCE

The overall incidence of fetal overgrowth is unknown but it is not rare. The incidence of Beckwith–Wiedemann syndrome is about 1 in 13,700 livebirths (Cytrynbaum et al., 2005).Beckwith–Wiedemann syndrome is more common in women who have undergone in vitro fertilization to conceive. It is estimated that Beckwith–Wiedemann syndrome occurs in 1 in 4000 deliveries to women who have used assisted reproductive technology. Another common condition associated with fetal overgrowth is Sotos syndrome, which has an incidence of 1 of 15,000 livebirths (Tatton-Brown and Rahman, 2007). The incidence of some of the other rare genetic conditions, such as Simpson–Golabi–Behmel syndrome (SGBS), is unknown.

SONOGRAPHIC FINDINGS

In the obstetric literature, there has been no prospective study performed to ascertain the outcome of fetuses documented to have overgrowth. There have, however, been reports of prenatal ultrasound findings in fetuses that were postnatally diagnosed as having a specific syndrome. For example, Reish et al. (2002) described three unrelated cases of Beckwith–Wiedemann syndrome and tabulated anomalies that were detected prenatally. The anomalies common to all of the fetuses included overgrowth, polyhydramnios, placentomegaly, macroglossia, and a distended abdomen. In addition, Le Caignec et al., (2004) described a case of Beckwith–Wiedemann syndrome in a 28-year-old *G3P1*-pregnant woman who underwent sonography at 28 weeks of gestation. The fetus was macrosomic, but also had bilateral enlarged echogenic kidneys with a loss of corticomedullary differentiation.

An increasingly appreciated cause of fetal overgrowth is Sotos syndrome. There has been one prenatal description of the findings of Sotos syndrome (Chen et al., 2002). This group described fetal findings at 31 weeks of gestation, which included macrocephaly, an abnormally shaped skull, polyhydramnios, and right hydronephrosis. A subsequent scan at 33 weeks demonstrated the presence of fetal overgrowth. Postnatally, this fetus underwent magnetic resonance imaging (MRI), which showed enlargement of the lateral ventricles, hypoplasia of the corpus callosum, a mega cisterna magna, and a persistent cavum septum pellucidum.

The prenatal sonographic findings in pregnancies affected with SGBS were summarized in Hughes-Benzie et al. (1994). These authors described a case of SGBS in which sonography was performed for an increased maternal serum alpha-fetoprotein measurement. The fetal findings included macrosomia, polyhydramnios, omphalocele, and enlarged or cystic kidneys. Cardiac anomalies are also common in SGBS (Lin et al., 1999), but there have been no prenatal reports of their detection in this condition.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for fetal overgrowth is shown in Table 124-1. The differential diagnosis is complicated by the fact that many of these conditions have substantial clinical overlap. The most common reason for fetal "overgrowth" is incorrect gestational dating. Once this has been ruled out, the second most common cause is hyperinsulinism due to maternal diabetes. Sustained maternal hyperglycemia results in beta cell hyperplasia and fetal hyperinsulinism, which in turn induces fetal macrosomia with a weight that is greater than length.

There are multiple syndromic causes of fetal overgrowth. Sotos syndrome, also known as cerebral gigantism, consists of macrosomia, macrocephaly, a typical postnatal facial appearance, mild developmental delay, and advanced dental maturation. Weaver syndrome is now considered to be allelic with Sotos syndrome. Patients with Weaver syndrome have prenatal overgrowth, advanced skeletal maturation, advanced bone age, a distinctive postnatal facial appearance that consists of micrognathia with a deep horizontal chin crease, deep set nails. Approximately 80% of patients with Weaver syndrome have developmental delay.

Beckwith–Weidemann syndrome is in the differential diagnosis for fetal overgrowth. Affected fetuses have macrosomia, macroglossia (Figures 124-1 and 124-2) (see Chapter 27), and sometimes, an abdominal wall defect. Patients who have Beckwith–Wiedemann syndrome have visceromegaly and ear anomalies (Figure 124-3) that are only detectable postnatally.

Simpson–Golabi–Behmel syndrome (SGBS) overlaps significantly with Beckwith–Wiedemann syndrome. Affected individuals have macroglossia, macrosomia (a characteristic facial appearance that resembles a bulldog), renal and cardiac malformations. Compared with the other overgrowth syndromes, patients with SGBS are more likely to have skeletal abnormalities that include brachydactyly, camptodactyly, clinodactyly, polydactyly, syndactyly, clubfeet, scoliosis and vertebral anomalies (DeBaun et al., 2001). As many as 50% of SGBS patients have cardiac anomalies, which typically include patent ductus arteriosus, atrial septal defect, and ventriculoseptal defect. The distinctive coarse facial features and the presence of cardiac anomalies (Lin et al., 1999) make this condition distinct from Beckwith–Wiedemann syndrome.

Although chromosome abnormalities are typically associated with intrauterine growth restriction or postnatal failure to thrive, increasingly it is being recognized that certain chromosome abnormalities are associated with overgrowth. Most notably, abnormalities of the short arm of

Table 124-1

Differential Diagnosis of Fetal Overgrowth

	Gene Involved	Inheritance Pattern
Incorrect gestational dating	N/A	N/A
Maternal diabetes	N/A	N/A
Sotos syndrome	*NSD1*	Sporadic/AD
Weaver syndrome	*NSD1*	Sporadic/AD
Beckwith–Wiedemann syndrome	Imprinted gene on 11p15	85% sporadic/15% AD
Simpson–Golabi–Behmel syndrome	*GPC3*	X-linked
Bannayan–Riley–Ruvalcaba syndrome	*PTEN*	AD
Chromosome abnormalities	N/A	N/A
Trisomy 4p16.3	N/A	N/A
Trisomy 5p	N/A	N/A
Trisomy 12p	N/A	N/A
Pallister–Killian syndrome (mosaic tetrasomy 12p)	N/A	N/A
Trisomy 15q25	N/A	N/A
Deletion (monosomy) 22q13	N/A	N/A

N/A, not applicable; AD, autosomal dominant.

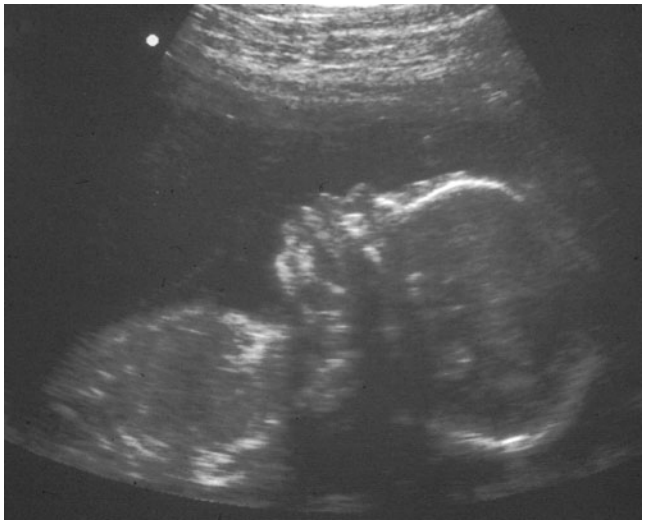

Figure 124-1 Prenatal sonographic image showing mild macroglossia in a fetus subsequently shown to have Beckwith–Wiedemann syndrome. *Image courtesy of Sabrina Craigo, MD.*

chromosome 12, including trisomy 12p and Pallister–Killian syndrome (mosaic tetrasomy 12p), are associated with fetal overgrowth disorders (see Chapter 138). Other chromosome abnormalities associated with overgrowth include trisomy 4p16.3, trisomy 5p, trisomy 11p15.5, and trisomy 15q25. It is also recognized that deletion, or monosomy, of 22q13 leads to overgrowth. There are a number of other rare conditions that are associated with fetal overgrowth, including syndromes such as Perlman, Marshall–Smith, Elejalde, and Bannayan–Riley–Ruvalcaba syndrome. There is no information available on the prenatal clinical manifestations of these conditions.

ANTENATAL NATURAL HISTORY

Little is known about the antenatal natural history of the overgrowth syndromes. Of note, however, is that SGBS has two clinical presentations. The more common presentation is the milder form, which is discussed in the "Genetics and

Figure 124-2 Postnatal image of the same infant as in Figure 124-1, showing mildly prominent tongue.

Figure 124-3 Postnatal image of the same infant with Beckwith–Wiedemann syndrome, showing the mild ear anomalies that are generally not observed by prenatal sonogram. These include a prominent antihelix and vertical creases in the lobe.

Recurrence Risks" section below. It is now appreciated that there is a more severe variant of this condition that is associated with severe neurologic impairment and neonatal death due to pneumonia and sepsis (Terespolsky et al., 1995). This more severe form could potentially be associated with antenatal demise.

MANAGEMENT OF PREGNANCY

When a fetus is demonstrated as being larger than expected for gestational age, the first step is to confirm the gestational dating. Subsequently, maternal diabetes should be ruled out. Assuming the mother does not have diabetes and that the pregnancy is dated correctly, the next step would be to perform a level II sonographic examination, specifically looking for the presence of associated renal or cardiac malformations. For the fetal overgrowth syndromes, we recommend obtaining a karyotype because of the increasingly recognized number of chromosome abnormalities associated with this finding (Faivre et al., 2004). There have been no prospective studies performed to assess the underlying etiology for fetal overgrowth. Based on postnatal studies, such as Baujat et al. (2005), we recommend the following molecular testing. Since amniocentesis would be performed to obtain the karyotype, cells should be grown for subsequent molecular testing including *NSD1* and *GPC3* mutation analysis. *NSD1* is the underlying gene that is responsible for the phenotype of most cases of Sotos syndrome and about half of the cases of Weaver syndrome. *GPC3* (glypican-3) is the gene that is the cause of SGBS. Molecular testing is commercially available for both *NSD1* and *GPC3* mutations. Detection of a mutation in either *NSD1* or *GPC3* is diagnostic and allows accurate genetic counseling regarding prognosis. Beckwith-Wiedemann syndrome is a genetically complex disorder with many underlying etiologies. Karyotype analysis should pay careful attention to the region of 11p15, which is the area involved in its pathogenesis. Beckwith–Wiedemann syndrome is a multigenic disorder that is caused by dysregulation of imprinted genes within the 11p15.5 region. Current molecular testing consists of determining whether uniparental disomy is present or whether there is abnormal methylation of the genes, *H19* or *KVDMR1*. In addition, mutation analysis can be performed in *P*57 or *CDKN1C*. Loss of function due to mutations in these genes will result in Beckwith–Wiedemann syndrome.

Using this strategy of molecular and cytogenetic testing in a postnatal setting, over half of the patients with a clinically diagnosed overgrowth syndrome were given a confirmatory molecular diagnosis (Baujat et al., 2005).

TREATMENT OF THE NEWBORN

There are many similarities in the postnatal presentation of newborns with overgrowth. All newborns should be observed

and tested for the presence of hypoglycemia. A postnatal cardiac evaluation should be performed, including cardiac consultation, echocardiogram, and electrocardiogram (Lin et al., 1999). Although Beckwith–Wiedemann syndrome is rarely associated with cardiac abnormalities, SGBS has a 50% incidence of associated cardiovascular problems. Therefore, a cardiac workup will help to distinguish between these two conditions. In addition, an abdominal ultrasound examination should be performed to look for the presence for underlying renal anomalies as well as vesicoureteric reflux. A medical genetics consultation may be helpful given the differing facial appearances in these overgrowth conditions.

SURGICAL TREATMENT

There is no specific surgical treatment recommended for overgrowth.

LONG-TERM OUTCOME

In general, the overgrowth syndromes are associated with normal intelligence, although in each of the conditions there has been significant variability described. For example, in Sotos syndrome there is a mild-to-moderate learning disability (Tatton-Brown and Rahman, 2007). In Sotos syndrome, interestingly, there is a genotype–phenotype correlation. If a microdeletion is detected in chromosome 5q35, there is a more severe learning disability and less pronounced overgrowth (Tatton-Brown et al., 2005). Childhood follow-up recommendations include screening for renal or cardiac abnormalities, and to check the spine for development of scoliosis.

For Beckwith–Wiedemann syndrome and SGBS, the biggest long-term issue is the increased risk of childhood cancer. Both conditions are associated with an increased risk of Wilms tumor and hepatoblastoma. The recommendations for Wilms tumor screening include ultrasound examinations every four months until the age of 7 to 8, and consideration of blood α-fetoprotein screening to look for hepatocellular carcinoma every 6 to 12 weeks during the first three years of life. SGBS has also been associated with neuroblastoma and testicular gonadoblastoma. Of all of the overgrowth conditions, Sotos syndrome is the least predisposed to neoplasia.

GENETICS AND RECURRENCE RISK

Most individuals with Sotos syndrome are the result of de novo mutations. Affected adults, however, have a 50% risk of having affected offspring. In 2002, haploinsufficiency of the gene *NSD1* was identified as a cause of Sotos syndrome (Kurotaki et al., 2002). Following this report, more than 100 distinct intragenic mutations have been identified (Tatton-Brown et al., 2005). There is also an ethnic difference in the type of mutation. For example, in the Japanese population, microdeletions of 5q35 (a 2.2 megabase sequence) are the most common cause of Sotos syndrome, observed in 50% of patients (Visser and Matsumoto, 2003). In contract, the Caucasian population has intragenic mutations. In both groups the deletions are derived from the paternal copy of chromosome 5 (Miyake et al., 2003). Overall, defects of the *NSD1* gene are present in 80% of individuals with Sotos syndrome (Waggoner et al., 2005). Although *NSD1* was originally associated with Sotos syndrome, subsequent studies have identified that about half of the patients with Weaver syndrome also have *NSD1* mutations, and occasionally patients that were previously classified as having Beckwith–Wiedemann syndrome also have *NSD1* mutations (Rio et al., 2003). *NSD1* is thought to act as a factor that positively and negatively influences transcription.

Simpson–Golabi–Behmel syndrome (SGBS) results from a deletion or point mutation that causes a loss of function in the glypican-3 *(GCP3)* gene on chomosome Xq26 (Pilia et al., 1996). Glypicans modify cellular responses to growth factors and morphogens. Glypican-3 interacts with *IGF2* and forms a complex that modulates *IGF2* action. A defect in *GPC3* results in higher circulating levels of *IGF2*. The condition is X-linked. Female carriers have a milder phenotype.

Of all of the overgrowth disorders, the underlying genetics of Beckwith–Wiedemann syndrome are the most complex. Most cases of Beckwith–Wiedemann syndrome are sporadic and are associated with a normal karyotype (Reish et al., 2002). Twenty percent of cases have paternal uniparental disomy of 11p15. One to two percent of cases have a recognized cytogenetic abnormality at 11p15. A few patients have loss of function mutations in *p*57 or *CDKN1C* genes. There have also been disorders of the maternal imprinting center near the *IGF2* gene associated with Beckwith–Wiedemann syndrome. Also, abnormal methylation of *H19* (Le Caignec et al., 2004) or *KVDMR1* has been proposed as a potential basis for Beckwith–Wiedemann syndrome. The inheritance patterns of these overgrowth conditions are outlined in Table 124-1. Recurrence risk will depend on the diagnosis of the affected proband. Should a cytogenetic abnormality or a molecular abnormality be documented in the affected fetus or newborn, similar testing could be performed by CVS or amniocentesis in a subsequent pregnancy.

125 Oligohydramnios

CHAPTER

Key Points

- Oligohydramnios is a decrease in the volume of amniotic fluid, with the diagnosis usually being made using ultrasound.
- Causes of oligohydramnios include ruptured membranes, placental insufficiency, fetal anomalies, maternal injestion of medications, complications of a multiple gestation, chromosomal abnormalities, and idiopathic.
- Significant oligohydramnios occurring prior to 22 weeks of gestation is associated with a poor prognosis because of a high likelihood of pulmonary hypoplasia and associated malformations.
- Once oligohydramnios is diagnosed, a careful maternal history should be obtained and a physical examination should be performed to evaluate for preterm premature rupture of membranes.
- Whenever a diagnosis of oligohydramnios is made, a careful sonographic anatomical survey should be performed to evaluate for fetal anomalies such as features of urinary tract obstruction or renal malformation.
- Amnioinfusion may assist sonographic visualization of the fetus when severe oligohydramnios is diagnosed in the midtrimester.
- Management of oligohydramnios secondary to preterm premature rupture of membranes depends on the gestational age and on the fetal and maternal status.
- Long-term outcome will depend on gestational age at diagnosis, etiology of the problem, and gestational age at delivery.

CONDITION

Oligohydramnios is a decrease in the volume of amniotic fluid. The diagnosis of oligohydramnios is most frequently made by ultrasound examination. Oligohydramnios was initially defined as a subjective decrease in amniotic fluid volume resulting in fetal crowding as compared with normal values (Crowley et al., 1984). Objective sonographic estimation of amniotic fluid volume involves measuring different dimensions of amniotic fluid pockets. Various definitions of oligohydramnios exist. Oligohydramnios has been defined as a maximal vertical pocket (MVP) of less than 1 cm, but has also been defined as a MVP of less than 2 cm (Manning et al., 1981; Chamberlain et al., 1984). A semiquantitative four-quadrant technique, known as the amniotic fluid index (AFI), is also widely used. Oligohydramnios can be defined as an AFI of less than 5 cm, but has also been defined as an AFI of less than 8 cm (Phelan et al., 1987; Moore, 1993).

Amniotic fluid volume is the result of a balance between inflow and outflow to and from the amniotic cavity. In the first half of pregnancy, the majority of amniotic fluid is a result of active transport of sodium and chloride across the amniotic membrane and fetal skin, with water moving

passively in response (Brace and Resnik, 1999). In the second half of pregnancy, the majority of amniotic fluid is a result of fetal micturition (Underwood et al., 2005). Another major source of amniotic fluid is secretion from the respiratory tract. The average amniotic fluid volume is 30 mL at 10 weeks of gestation, rising to 780 mL at 32 to 35 weeks, after which time a natural decrease in volume occurs (Brace and Resnik, 1999). The amniotic fluid volume is not stagnant, but is completely turned over at least once daily. Fetal urine first appears at 8 to 10 weeks of gestation and reaches a production rate of 700 to 900 mL/d near term (Brace and Resnik, 1999).

Oligohydramnios can occur as a result of decreased urinary production or excretion, or can be a result of fluid loss, such as with premature rupture of membranes. Causes of oligohydramnios include ruptured membranes, placental insufficiency, fetal anomalies, medication use by the mother, abnormalities associated with multiple gestations, chromosomal abnormalities, and idiopathic (Garmel et al., 1997). In the second trimester, premature rupture of membranes accounts for 50% of all cases of oligohydramnios; fetal anomalies, 15%; abruption, 7%; abnormalities associated with multiple gestations, 5%; intrauterine growth restriction, 18%; and idiopathic causes, 5% (Shenker et al., 1991). The presence of oligohydramnios in a twin gestation may be due to twin-to-twin transfusion syndrome, intrauterine growth restriction of one twin, or intrauterine fetal death.

Premature rupture of membranes may be suggested with the sonographic appearance of oligohydramnios and an appropriately grown, structurally normal fetus. A sterile speculum examination demonstrating the absence of pooling following a negative phenaphthazine (nitrazine) test will usually rule out rupture of membranes. Occult rupture of membranes may occur, and amniocentesis with indigocarmine dye infusion may be necessary in some cases to rule out membrane rupture as a causative factor of oligohydramnios. Significant oligohydramnios occurring prior to 22 weeks of gestation is associated with a poor prognosis, most likely because of a high likelihood of pulmonary hypoplasia and also because of a high incidence of associated congenital malformations.

Medication use by the mother, such as prostaglandin synthetase inhibitors and angiotensin-converting enzyme inhibitors, has been reported to cause oligohydramnios. Indomethacin is used to treat preterm labor and can result in oligohydramnios, although this is usually reversible following discontinuation of the drug (Kirshon et al., 1991). Oligohydramnios, prolonged neonatal anuria, and ossification defects in the neonatal skull have been reported with in utero exposure to angiotensin-converting enzyme inhibitors (Cunniff et al., 1990; Barr and Cohen, 1991). The use of angiotensin-converting enzyme inhibitors is absolutely contraindicated during pregnancy. It is interesting to note that oligohydramnios is diagnosed more frequently in pregnancies delivered in the summer months suggesting that maternal dehydration may contribute to this finding (Varner et al., 2005).

INCIDENCE

Because of differing definitions, the reported incidence of oligohydramnios varies from 0.5% to 8% of all pregnancies (McCurdy and Seeds, 1993; Phelan et al., 1987). When an MVP of less than 2 cm is used as a cutoff, the incidence of oligohydramnios is 3% of all pregnancies (Chamberlain et al., 1984). When an AFI of less than 5 cm is used, the incidence of oligohydramnios is 8% (Phelan et al., 1987). Norms for amniotic fluid volume across gestation were established in one report of sonographic amniotic fluid measurements in 791 patients (Moore and Cayle, 1990). The 5th centile for AFI at term was approximately 7 cm. Interobserver variability may account for some of the variations in quoted incidences of oligohydramnios; however, interobserver and intraobserver variability have been reported as reliable and reproducible (Halperin et al., 1985; Moore and Cayle, 1990).

SONOGRAPHIC FINDINGS

A diagnosis of oligohydramnios is almost always made on the basis of sonographic findings. Several methods of sonographic amniotic fluid assessment have been described. The subjective assessment of amniotic fluid volume with ultrasound examination was the earliest technique described (Crowley et al., 1984). This method involved the assessment of the relative amount of amniotic fluid present by comparing the amount of echo-free fluid areas in the uterus with the space occupied by the fetus. Disadvantages of this method include the requirement of a trained observer and the lack of a numerical result that can be used to follow a trend in amniotic fluid volume. Studies of interobserver variability for subjective sonographic assessment of amniotic fluid volume found that among experienced observers subjective estimates had good agreement rates and that this was not improved by the use of an arbitrary amniotic fluid volume classification such as vertical pocket depth (Halperin et al., 1985; Goldstein and Filly, 1988).

However, most clinicians today use some form of objective semiquantitative estimate of amniotic fluid volume, based on the MVP or the AFI. The MVP involves surveying the entire uterus and measuring the depth of the deepest pocket of amniotic fluid in centimeters. Only amniotic fluid pockets free of fetal parts and umbilical cord are measured. The criteria for defining oligohydramnios vary, with some suggesting an MVP of less than 1 cm as an appropriate cutoff for oligohydramnios, while others use a cutoff of less than 2 cm to diagnose oligohydramnios (Manning et al., 1981; Chamberlain et al., 1984).

The AFI involves summing the maximum vertical pockets from each of the four quadrants of the uterus. In a report of sonographic AFI measurements in 197 patients, the mean AFI rose from 7 cm at 12 weeks of gestation to 20 cm at 26 weeks gestation, and then plateaued for the remainder of

gestation at approximately 16 cm (Phelan et al., 1987). In a cross-sectional study of 791 pregnancies with AFI measurements, an AFI of 7 cm was at the 5th centile at term, and only 1% of all pregnancies had an AFI of less than 5 cm at term (Moore and Cayle, 1990).

It is important to measure the AFI with the patient supine, to orient the transducer in the maternal sagittal plane, to measure the sonographic planes perpendicular to the floor, to measure fluid pockets free from umbilical cord or fetal extremities, and to use the umbilicus and linea nigra as landmarks for dividing the uterus into four quadrants (Phelan et al., 1987).

There is no agreement in the obstetric literature as to which method of sonographic measurement of amniotic fluid volume is best. In one study comparing MVP with AFI, the correlation coefficient was 0.51, and the MVP was associated with a lower sensitivity (Moore, 1990). Others have found good correlation between the MVP and AFI methods, with the MVP being better (Magann et al., 1994). Both MVP and AFI should therefore be considered reasonable methods for quantifying the amniotic fluid volume.

Whenever a diagnosis of oligohydramnios is made, a careful sonographic fetal anatomy survey should be performed to evaluate for fetal abnormalities, such as features of urinary tract obstruction or malformation. Absence of bladder filling following a 1-hour period of observation suggests a urinary tract abnormality. Fetal renal anomalies including renal agenesis (see Chapter 86), urethral obstruction (see Chapter 82), and multicystic kidneys (see Chapter 78) account for 11% of cases of oligohydramnios discovered during the second trimester (Shenker et al., 1991).

If severe oligohydramnios is present at less than 24 weeks of gestation, the possibility of pulmonary hypoplasia should be considered. Numerous sonographic criteria to predict pulmonary hypoplasia have been described. Measurements of chest circumference are highly predictive of pulmonary hypoplasia in patients with either severe oligohydramnios or prolonged premature rupture of membranes (D'Alton et al., 1992). Normal values for fetal thoracic circumference and for the ratio of thoracic circumference to abdominal circumference have been established, and this ratio has been found to remain constant throughout pregnancy (D'Alton et al., 1992). A thoracic to abdominal circumference ratio of less than 0.80 in the setting of severe oligohydramnios in the second trimester is suspicious for pulmonary hypoplasia. Fetal compression, including dolicocephaly and clubfeet, may be apparent (Figure 125-1).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for oligohydramnios includes normal pregnancy during the late third trimester, postmaturity, intrauterine growth restriction, premature rupture of membranes, fetal death, fetal renal anomalies (bilateral multicystic dysplastic kidneys, bilateral renal agenesis, bilateral ureteral obstruction, posterior urethral valves, infantile polycystic kidney disease), neural tube defect, chromosomal abnormality, stuck twin, and medication use (such as indomethacin) by the mother.

ANTENATAL NATURAL HISTORY

The antenatal natural history of oligohydramnios depends on the gestational age at diagnosis and the cause of the oligohydramnios. Oligohydramnios accompanies a variety of serious fetal malformations, the most common being fetal renal abnormalities, and the underlying anomaly will dictate the natural history. Cardiac, skeletal, and neurologic malformations, in addition to aneuploidy and a variety of syndromic abnormalities, often coexist with the primary renal abnormality (McCurdy and Seeds, 1993). Bilateral renal agenesis (Potter syndrome) is uniformly lethal because of associated pulmonary hypoplasia and renal failure (Figure 125-2) (see Chapter 86).

The finding of significant oligohydramnios in the second trimester is associated with very high perinatal mortality (Barss et al., 1984; Bhutani et al., 1986; D'Alton et al., 1992). The combination of second trimester oligohydramnios and elevated maternal serum α-fetoprotein (MSAFP) has an extremely poor prognosis. In one report of 21 patients with

Figure 125-2 Severely constricted fetus with oligohydramnios due to bladder agenesis and a single dysplastic kidney. *(Courtesy of Dr. Joseph Semple.)*

midtrimester oligohydramnios and elevated MSAFP, only one infant survived (Dyer et al., 1987). Causes of perinatal loss in the setting of second trimester oligohydramnios include lethal congenital abnormalities, pulmonary hypoplasia, severe prematurity, and neonatal sepsis. Oligohydramnios in cases of chronic abruption appears to be an end-stage manifestation of severe uteroplacental insufficiency and is associated with a high incidence of intrauterine fetal death (Shenker et al., 1991).

Second trimester oligohydramnios following preterm premature rupture of membranes (PPROM) carries a poor prognosis, with up to a 60% fetal loss rate, due mostly to pulmonary hypoplasia (Bhutani et al., 1986; D'Alton et al., 1992). Sequelae of PPROM that contribute to the poor outcome include chorioamnionitis, amnion nodosum (Figure 125-3), neonatal sepsis, neonatal pneumonia, placental abruption, and cord prolapse (Gonen et al., 1989). Neonatal outcome following PPROM can be improved by the routine administration of antibiotics, such as ampicillin and erythromycin (Mercer et al., 1997).

The combination of oligohydramnios and fetal growth restriction is associated with significantly increased perinatal morbidity and mortality rates (Hill et al., 1983; Chamberlain et al., 1984; Seeds, 1984). The perinatal mortality rate ranges from 10% to 19% in these situations (Chamberlain et al., 1984). Close fetal surveillance is indicated to avoid antenatal deterioration of fetal status, and elective premature delivery may be needed.

Postmature pregnancies have increased rates of perinatal morbidity and mortality (Beischer et al., 1969). The finding of oligohydramnios in a pregnancy beyond 41 weeks of gestation identifies a subset of patients who are at significantly increased risk for adverse outcomes. There is a significantly higher risk of abnormal fetal testing, presence of fetal heart rate decelerations during labor, meconium staining, cesarean delivery for nonreassuring fetal testing, and depressed 1- and 5-minute Apgar scores (Rutherford et al., 1987; Sarno et al., 1990; Robson et al., 1992).

Little information exists on the antenatal natural history of oligohydramnios prior to 37 weeks of gestation in the absence of intrauterine growth restriction, PPROM, or fetal anomalies. In one case–control study of pregnancies with unexplained oligohydramnios, there was a significantly higher incidence of premature delivery but no difference in overall neonatal outcomes (Garmel et al., 1997). Oligohydramnios associated with maternal hypovolemia is associated with a good perinatal outcome and is generally reversible with hydration (Sherer et al., 1990).

MANAGEMENT OF PREGNANCY

Following a diagnosis of oligohydramnios, a careful maternal history should be obtained to evaluate for illnesses such as hypertension or chronic renal disease and to assess for use of medications such as prostaglandin synthetase inhibitors. Physical examination should include a sterile speculum examination to evaluate for pooling of amniotic fluid in the vaginal vault, phenaphthazine (nitrazine) paper analysis, and microscopic examination of a vaginal smear on a slide for the presence of ferning. The presence of oligohydramnios should prompt a thorough sonographic survey of the fetal anatomy. Visualization of the fetal anatomy may be extremely difficult in cases of severe oligohydramnios. Administration of furosemide to the mother has been advocated to improve detection of bilateral renal agenesis (Kurjak et al., 1981). Other authors have suggested that fetuses with severe growth restriction may not respond to furosemide administration secondary to decreased renal perfusion and decreased glomerular filtration rate, and therefore extreme caution should be used with this approach (Goldenberg et al., 1984).

Amnioinfusion may assist sonographic visualization of the fetus in pregnancies complicated by severe oligohydramnios. In one report of 13 pregnancies complicated by severe oligohydramnios, amnioinfusion of warmed normal saline was successfully performed in all patients and fluid for karyotype analysis was successfully obtained in 8 patients (Quetel et al., 1992). The use of amnioinfusion, together with indigocarmine dye instillation, allowed subsequent adequate ultrasound examination in 12 of 13 patients, a correct diagnosis of ruptured membranes in 6 patients, and an antenatal diagnosis of Meckel–Gruber syndrome in one case (Quetel et al., 1992). If a structural fetal anomaly is identified, karyotyping should be performed. In cases of severe oligohydramnios prior to 24 weeks of gestation, termination of pregnancy may be discussed with the patient.

The management of pregnancies with oligohydramnios secondary to PPROM depends on the gestational age at presentation. Ruptured membranes beyond 34 weeks of

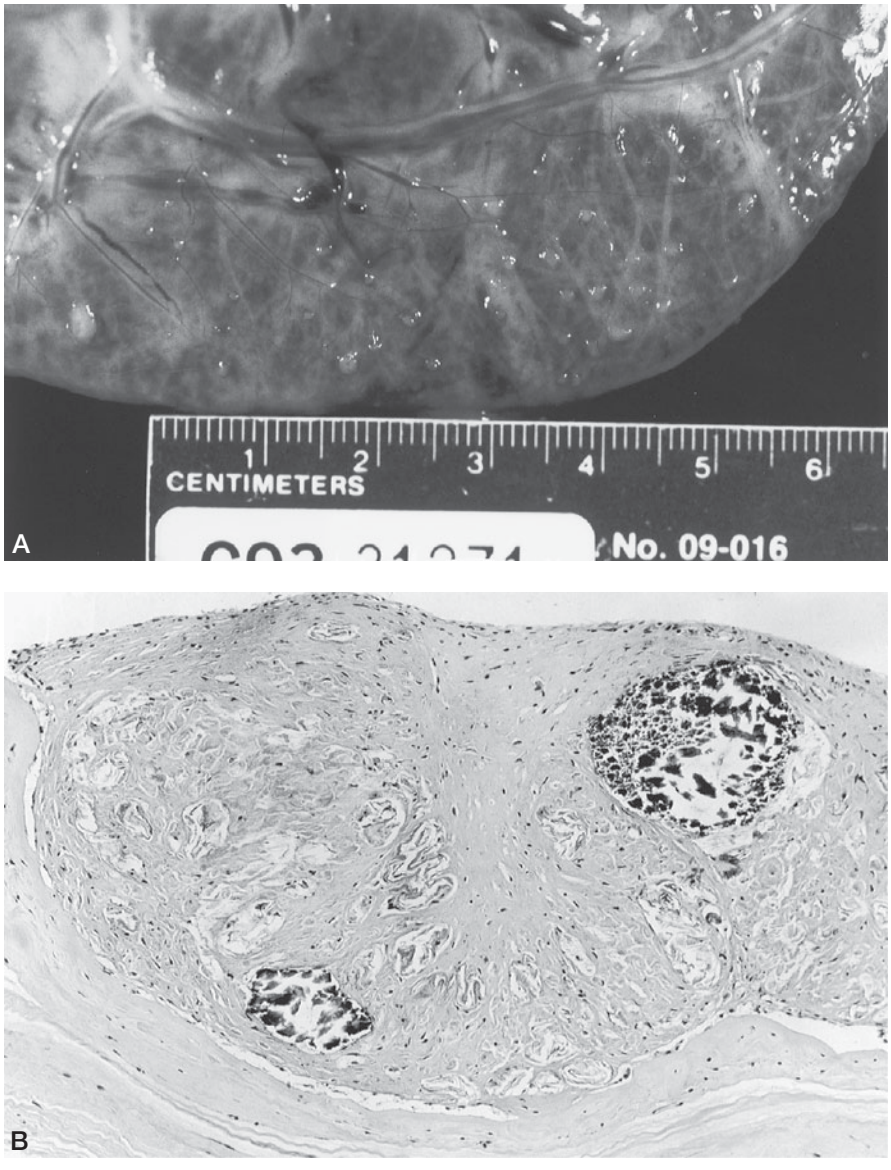

Figure 125-3 Gross (panel **A**) and microscopic (panel **B**) appearances of amnion nodosum in a fetus with oligohydramnios. *(Courtesy of Dr. Joseph Semple.)*

gestation should be managed by prompt induction of labor to minimize infectious maternal and fetal morbidity. In cases of PPROM at less than 34 weeks of gestation, expectant management is reasonable, provided there is no evidence of intrauterine infection, fetal compromise, or preterm labor. Frequent assessment in the form of daily fetal heart rate monitoring is recommended. Administration of betamethasone to the mother is advocated with PPROM prior to 32 to 34 weeks of gestation to reduce complications of prematurity. Although the evidence for improving neonatal outcome is less clear than with the use of corticosteroids in patients with intact membranes, there is an additional benefit in reduction of the incidence of intraventricular hemorrhage (National Institutes of Health, 1995). In cases of PPROM prior to 34 weeks of gestation, administration of antibiotics to the mother, typically ampicillin and erythromycin for 7 days, has been shown to increase the latency period prior to delivery and improves overall neonatal outcome (Mercer et al., 1997). There is no conclusive evidence to support or exclude a benefit from tocolysis in the setting of PPROM. Expectant inpatient management of PPROM is recommended from 24 to 32 weeks of gestation, provided there is reassuring maternal and fetal testing on a daily basis. In cases of PPROM from 32 to 34 weeks of gestation, evaluation of fetal lung maturity may help decide between expectant management and induction of labor.

In cases of fetal growth restriction with oligohydramnios at less than 36 to 37 weeks of gestation, careful fetal assessment is suggested, consisting of nonstress and biophysical testing at least twice weekly. If there is absent end-diastolic flow in the fetal umbilical artery, daily fetal testing is recommended. Delivery is indicated once a gestational age of 36 to 37 weeks is reached or if fetal testing becomes nonreassuring. In cases of oligohydramnios in the presence of an appropriately grown fetus, delivery should be considered once a gestational age of 37 weeks is reached.

The location of delivery will depend on the cause of the oligohydramnios and the gestational age at diagnosis. If a

congenital abnormality is present, delivery at a tertiary care center where appropriately trained personnel are available is recommended. In patients with PPROM, delivery location will depend on the gestational age. For patients at less than 32 weeks of gestation, delivery should occur in a tertiary care center with a neonatal intensive care unit. The mode of delivery should be based on usual obstetric practices; there is no indication to alter the mode of delivery based solely on the presence of oligohydramnios or PPROM. However, there is an increased incidence of cesarean delivery in pregnancies complicated by oligohydramnios, regardless of cause. For this reason, elective cesarean delivery may be reasonable in the setting of significant oligohydramnios with an unfavorable cervix. The significance of oligohydramnios as an isolated finding in the management of labor is difficult to ascertain. In one retrospective case–control study, the frequency of nonreassuring fetal testing, meconium staining, cesarean delivery, and admission to the neonatal intensive care unit were not significantly different when 65 women with oligohydramnios in the absence of IUGR, PPROM, or fetal anomalies were compared with 122 controls matched by indication for sonography (Garmel et al., 1997).

The management of pregnancy complicated by oligohydramnios secondary to PPROM at previable gestational ages (less than 24 weeks) should be individualized. The option of pregnancy termination should be discussed because of the risks of maternal infectious morbidity and the high likelihood of poor perinatal outcome. When expectant management is selected in such cases, inpatient hospitalization is generally not recommended after the initial evaluation, as active fetal intervention is not generally an option. Expectant management should include bed rest at home, daily monitoring of maternal temperature, and observation for the development of regular contractions. In 10% of such patients, leakage of amniotic fluid stops because of membrane resealing, amniotic fluid reaccumulates, and perinatal outcome is significantly improved (Johnson et al., 1990).

FETAL INTERVENTION

Amnioinfusion has been described to reduce the incidence of pulmonary hypoplasia in patients with severe oligohydramnios who are remote from term (Nakayama et al., 1983; Hansmann et al., 1991). However, this treatment remains experimental. The instillation of an isotonic antibiotic solution via the cervix has been used for treating patients with PPROM, but should also be considered experimental (Ogita et al., 1984). Amnioinfusion has also been described for patients with PPROM (Garzetti et al., 1997; Locatelli et al., 2000, Tranquilli et al., 2005). Because of the invasive nature of such approaches and the possibility for adverse maternal and perinatal outcomes, appropriately controlled clinical trials are necessary before these techniques can be recommended.

Another potential intervention for midtrimester PPROM is attempting to correct the defect. It is hoped that this treatment can increase the latency time to delivery, restore amniotic fluid volume to decrease the risk for lung hypoplasia as well as limb and muscular contracture defects, and decrease infectious morbidity.

Amniotic membrane patching has been suggested in carefully selected patients without evidence of intramniotic infection and confirmed PPROM. Transabdominal intraamniotic injection of platelets and cryoprecipitate has been used as a therapy for midtrimester PPROM. In a preliminary study, Quintero et al. treated 7 patients with iatrogenic PPROM (all cases of PPROM occurred following an invasive procedure such as amniocentesis or fetoscopy) diagnosed between 16 and 24 weeks of gestation with an amniopatch (Quintero et al., 1999). For the amniopatch, an amniocentesis was performed with a 22-gauge needle and platelets were administered followed by cryoprecipitate. Two mililiters of indigo carmine was then instilled to aid in documentation of amniotic fluid leakage. Intravenous antibiotics were then given for one week. Three pregnancies progressed well. The amniotic fluid re-accumulated and there was no further leakage. Two patients had unexplained intrauterine fetal demise despite resealing. One patient resealed but continued to have oligohydramnios secondary to fetal bladder outlet obstruction, and one patient had a miscarriage secondary to twin-to-twin transfusion syndrome despite resealing. This study demonstrates that, although experimental, an amniopatch with platelets and cryoprecipitate might be a promising therapy for iatrogenic cases of PPROM.

Administration of a cervical plug to retard the loss of fluid from the amniotic cavity is another potential treatment of midtrimester PPROM. In one study, 15 women with PPROM (either iatrogenic or spontaneous) had a gelatin sponge placed within the uterine cavity (O'Brien et al., 2002). The research protocol included hospital admission, amnioinfusion, cerclage placement, antibiotic administration, and perioperative tocolysis. Eight pregnancies (53%) delivered after 24 weeks of gestation, 6 of whom (30%) survived until hospital discharge. There were two intrauterine fetal deaths. The mean gestational age at delivery was 31.8 weeks (range 25–36 weeks). No adverse sequelae were attributed to the gelatin sponge. However, several anatomic abnormalities were diagnosed that were likely to be secondary to decreased amniotic fluid volume. This aggressive interventional protocol may improve outcomes in patients with previable PPROM by reducing the incidence of lethal pulmonary hypoplasia. However, further study is needed, before this approach could be considered mainstream. Several issues must be addressed such as route of applications (transvaginal versus transcervical), whether combinations of plugging agents are more efficacious, which fetuses are likely to benefit, and whether or not maternal complications are associated with this intervention.

Prophylactic amnioinfusion during labor to correct abnormal fluid volumes has not been found to be beneficial unless associated with recurrent variable decelerations.

Fetal intervention by means of vesicoamniotic shunting may be considered in selected fetuses with severe

oligohydramnios secondary to bladder outlet obstruction. Benefits of shunting may include a decreased incidence of pulmonary hypoplasia. Prognosis in these cases is related to the duration of exposure of the developing fetal lung to severe oligohydramnios and to the severity of the underlying renal condition. The option of vesicoamniotic shunting in such cases is described in more detail in Chapter 82.

TREATMENT OF THE NEWBORN

The extent of newborn intervention in cases of oligohydramnios will depend on the gestational age at diagnosis, the gestational age at delivery, and the cause of the oligohydramnios. If a sonographic diagnosis of renal agenesis is certain, no resuscitation of the newborn is indicated. However, if doubt exists about the diagnosis, a neonatologist should be present at delivery to evaluate for features of Potter syndrome and pulmonary hypoplasia. Intubation and mechanical ventilation of the newborn may be considered appropriate until a more definitive diagnosis for severe oligohydramnios is made. Pulmonary air leak may develop secondary to positive pressure ventilation in the setting of pulmonary hypoplasia, which may require the placement of chest tubes.

SURGICAL TREATMENT

No surgical treatments have been described.

LONG-TERM OUTCOME

The long-term outcome will depend on the gestational age at diagnosis, the gestational age at delivery, and the underlying cause of the oligohydramnios. The longest duration of survival reported with a diagnosis of bilateral renal agenesis is 39 days. Severe oligohydramnios may result in the development of arthrogryposis (see Chapter 101). Contractures of previously normal joints may also occur in cases of severe oligohydramnios of long duration. The feet are most commonly involved, typically resulting in positional clubfoot. Compression of the fetus against the uterine wall in the setting of severe oligohydramnios can produce a spectrum of abnormalities. Potter syndrome is characterized by low-set ears, hypertelorism, receding chin, flattened nose, wrinkled skin, and joint contractures.

GENETICS AND RECURRENCE RISK

The recurrence risk of oligohydramnios will depend on the underlying cause. The cause of bilateral renal agenesis is multifactorial. The recurrence risk following delivery of an infant with bilateral renal agenesis and a negative family history is approximately 3% to 4%. In a study of 41 index patients with bilateral renal agenesis, bilateral severe renal dysgenesis, or agenesis of one kidney with dysgenesis of the other, 10 of 111 first-degree relatives were found to have clinically unsuspected renal malformations (Roodhooft et al., 1984). Parents of fetuses with oligohydramnios due to renal anomalies should therefore be evaluated by ultrasound examination for renal anomalies.

The recurrence risk for premature rupture of membranes occurring in a future pregnancy is uncertain, but may be as high as 32% (Asrat et al., 1991). Such patients should therefore be considered at high risk for this complication in all future pregnancies.

126 CHAPTER

Polyhydramnios

Key Points

- Polyhydramnios is an increase in the volume of amniotic fluid, the diagnosis of which is usually made using ultrasound.
- Causes of polyhydramnios include fetal congenital malformations, fetal neurological anomalies, fetal genetic abnormalities, and maternal issues, although the majority of cases are idiopathic.
- Sonographic assessment of polyhydramnios should include a careful survey of the fetal anatomy to rule out the presence of structural abnormalities or fetal growth restriction, and karyotyping should be considered if these are present.
- Polyhydramnios has been associated with an increased risk for preterm contractions and preterm delivery, in which case-reduction amniocentesis may be considered.
- Delivery at 39 weeks may be reasonable to relieve maternal symptoms as well as to reduce the risk of cord prolapse, should spontaneous rupture of membranes occur.
- Pregnancies complicated by polyhydramnios have a higher incidence of inefficient uterine activity leading to prolonged labor, postpartum uterine atony, and postpartum hemorrhage; cesarean delivery should be reserved for standard obstetric indications.
- Neonates should be evaluated carefully to assess for anatomical abnormalities that may have caused polyhydramnios.
- The long-term outcome for infants following a prenatal diagnosis of polyhydramnios depends on the gestational age at delivery and the presence of associated structural malformations.

CONDITION

Polyhydramnios, also known simply as hydramnios, is an increase in the volume of amniotic fluid. The diagnosis of polyhydramnios is most frequently made by ultrasound examination, but is often suspected by clinical examination revealing a fundal height greater than that expected for gestational age. Before the advent of prenatal sonography, polyhydramnios was defined as an amniotic fluid volume of more than 2 L. Sonographic diagnosis of polyhydramnios relies on the finding of a maximum vertical pocket of more than 8 cm (Figure 126-1) (Chamberlain et al., 1984). However, due to the asymmetric location of the fetus within the uterus, the use of this maximum vertical pocket (MVP) technique may lead to an overestimation of the amniotic fluid volume.

The amniotic fluid index (AFI) has been described as a more reliable means of quantifying amniotic fluid volume (Phelan et al., 1987). The AFI involves the summing of the largest vertical pockets from each of the four quadrants of the uterus. A normal amniotic fluid volume is defined as an AFI of between 8 and 18 cm, while polyhydramnios is defined as an AFI of greater than 24 cm. Normal values for the AFI throughout gestation have been described based on sonographic measurements of amniotic fluid volume in 791 uncomplicated pregnancies between 16 and 42 weeks of gestation (Moore and Cayle, 1990). These values are listed in Table 126-1. A reasonable working definition of polyhydramnios using current sonographic criteria is an AFI greater than the 95th percentile for the corresponding gestational age.

Amniotic fluid volume is the result of a balance between flow into and out of the amniotic cavity. In the first half of pregnancy, the majority of amniotic fluid is a result of active transport of sodium and chloride across the amniotic membrane and fetal skin, with water moving passively in response (Brace and Resnik, 1999). In the second half of pregnancy, the majority of amniotic fluid is a result of fetal micturition. Another major source of amniotic fluid is secretion from the

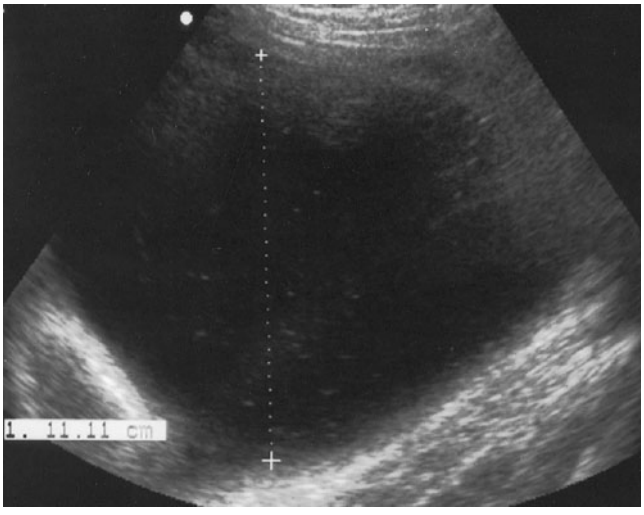

Figure 126-1 Prenatal sonographic image demonstrating a maximal vertical pocket of 11.11 cm of amniotic fluid.

fetal respiratory tract. The average amniotic fluid volume is 30 mL at 10 weeks, rising to 780 mL at 32 to 35 weeks, following which time a natural decrease in volume occurs (Brace and Resnik, 1999). The amniotic fluid volume is not stagnant, but is completely turned over at least once daily. Fetal urine first appears at 8 to 10 weeks of gestation, and reaches a production rate of 700 to 900 mL per day near term (Brace and Resnik, 1999).

Polyhydramnios can occur because of increased production of fluid by the fetus, as in the case of hydrops, or it can be due to an obstruction to fetal swallowing, as in the case of congenital gastrointestinal obstruction. Polyhydramnios is idiopathic in greater than 50% of cases (Mann et al., 2006). Maternal diabetes mellitus accounts for 15% of cases, fetal malformations for 13%, multiple gestations for 5%, and other causes for 1% (Hill and Breckle, 1987). However, the proportion of cases of polyhydramnios secondary to fetal malformation increases significantly as the severity of polyhydramnios increases. As the definition of polyhydramnios varies, so too does the reported incidence of associated fetal malformations. Two recent series have reported a 58% to 63% incidence of structural fetal malformations in pregnancies complicated by polyhydramnios (Damato et al., 1993; Many et al., 1996).

Fetal malformations associated with polyhydramnios include neural tube defects (such as anencephaly, Chapter 7), holoprosencephaly (see Chapter 14), cardiac anomalies (such as truncus arteriosus, Chapter 54), gastrointestinal atresias or stenoses (see Chapters 71–73), chest or abdominal masses such as cystic adenomatoid malformation (see Chapter 35) or diaphragmatic hernia (see Chapter 37), skeletal dysplasias, neuromuscular disorders (such as myotonic dystrophy), infections (such as parvovirus), metabolic disorders (such as Gaucher disease), chromosomal abnormalities (such as trisomy 18, Chapter 130), tumors (such as sacrococcygeal teratoma, Chapter 115), and genetic syndromes (such as Beckwith–Wiedemann syndrome).

Table 126-1

Amniotic Fluid Index Values in Normal Pregnancy

Week	No. of Patients	Amniotic Fluid Index Percentile Values				
		2.5th	5th	50th	95th	97.5th
16	32	73	79	121	185	201
17	26	77	83	127	194	211
18	17	80	87	133	202	220
19	14	83	90	137	207	225

Reproduced, with permission, from Moore TR, Cayle JE. The amniotic fluid index in normal human pregnancy. Am J Obstet Gynecol 1990;162:1168-1173.

INCIDENCE

The reported incidence of polyhydramnios varies, reflecting differences in definition. Polyhydramnios is reported in 0.1% to 3% of pregnancies when clinical methods are used to make the diagnosis (Kramer, 1966). In one series of 9,189 patients who had sonographic assessment of amniotic fluid volume by measuring the MVP, the overall incidence of polyhydramnios was 0.9% (Hill and Breckle, 1987). In this study, mild polyhydramnios was diagnosed when the MVP measured between 8 cm and 11 cm, moderate polyhydramnios was defined as an MVP of 12 cm to 15 cm, and severe polyhydramnios was diagnosed when the MVP exceeded 16 cm. Mild

polyhydramnios accounted for 79% of cases, moderate polyhydramnios 16%, and severe polyhydramnios accounted for 5% (Hill and Breckle, 1987). In another series, using an AFI cutoff of greater than 24 cm, mild polyhydramnios was diagnosed in 8% of patients (Smith et al., 1992).

SONOGRAPHIC FINDINGS

Most diagnoses of polyhydramnios are now based on sonographic findings. The two most common methods of objectively measuring the amniotic fluid volume are the maximum vertical pocket (MVP) and the amniotic fluid index (AFI). The MVP involves surveying the entire uterus and measuring the depth of the deepest pocket of amniotic fluid in centimeters. Only amniotic fluid pockets free of fetal parts and umbilical cord are measured. The most commonly used cutoff for polyhydramnios using the MVP technique is a depth greater than 8 cm. The AFI involves summing the MVPs from each of the four quadrants of the uterus. In a report of sonographic AFI measurements in 197 patients, the mean AFI rose from 7 cm at 12 weeks' gestation to 20 cm at 26 weeks' gestation, and then plateaued for the remainder of gestation at approximately 16 cm (Phelan et al., 1987). The 95th percentile value for AFI at 37 weeks is 24 cm, but decreases to 19 cm at 41 weeks, reflecting the normal decrease in amniotic fluid production at term (Moore and Cayle, 1990). It is important to measure the AFI with the patient supine, to orient the transducer in the maternal sagittal plane, to measure the sonographic planes perpendicular to the floor, to measure fluid pockets free from umbilical cord or fetal extremity, and to use the umbilicus and linea nigra as landmarks for dividing the uterus into four quadrants (Phelan et al., 1987).

There is no agreement in the obstetric literature as to which method of sonographic measurement of amniotic fluid volume is best. In one study comparing MVP with AFI, the correlation coefficient was 0.51, and the MVP was associated with a lower sensitivity (Moore, 1990). Others have found good correlation between the MVP and AFI methods, with the MVP being better (Magann et al., 1994). In another study comparing 13 different sonographic methods of amniotic fluid volume assessment with a dye dilution technique, the AFI underestimated the actual amniotic fluid volume by as much as 52% in cases of polyhydramnios (Dildy et al., 1992). When compared with the AFI, several of the other 12 methods of ultrasound prediction of amniotic fluid volume produced lower mean errors as compared with true amniotic fluid volume. However, the investigators concluded that the minimal improvement in accuracy offered by other ultrasound measurements was not sufficient to warrant replacement of the AFI (Dildy et al., 1992).

Sonographic assessment of polyhydramnios should include a careful survey of the fetal anatomy to rule out the presence of structural malformations. Because of the possibility of underlying fetal neuromuscular disorders, fetal swallowing, muscle tone, and fetal movement should be observed. In a study of 41 fetuses with a diagnosis of idiopathic polyhydramnios who were tested for the presence of a myotonic dystrophy mutation, 4 (9.7%) were shown to be affected. Three of the four fetuses had a positive family history of myotonic dystrophy (Esplin et al., 1998).

DIFFERENTIAL DIAGNOSIS

The causes of polyhydramnios are diverse, involving many maternal and fetal conditions, including those associated with immune and nonimmune hydrops fetalis (see Chapters 127 and 128). Maternal abnormalities should be considered, such as diabetes mellitus, rhesus isoimmunization, and preeclampsia resulting in the "mirror syndrome" (Ballantyne syndrome). If a multiple gestation is present, the possibility of twin–twin transfusion syndrome should be considered (see Chapter 119), especially if one fetus has severe oligohydramnios (stuck twin). Fetal infections associated with polyhydramnios include parvovirus, cytomegalovirus, toxoplasmosis, and syphilis. Polyhydramnios can also be seen with inborn errors of metabolism such as Gaucher disease, gangliosidoses, and mucopolysaccharidoses. Chromosomal abnormalities should also be considered, such as trisomy 18 (see Chapter 130), trisomy 21 (see Chapter 131), Turner syndrome (see Chapter 134), and 4p– (Wolf–Hirschhorn) syndrome.

Fetal neurologic malformations associated with polyhydramnios include anencephaly, encephalocele, meningomyelocele, holoprosencephaly, Dandy–Walker malformation, lissencephaly, and agenesis of the corpus callosum. Fetal cardiac abnormalities associated with polyhydramnios include cardiac arrhythmias, truncus arteriosus, aortic coarctation, and aortic arch interruption. Fetal thoracic abnormalities associated with polyhydramnios include congenital cystic adenomatoid malformation (CCAM), bronchopulmonary sequestration (BPS), diaphragmatic hernia, chylothorax, and tracheal atresia. Fetal gastrointestinal malformations associated with polyhydramnios include cleft lip and palate, tracheoesophageal fistula, esophageal or intestinal atresia, omphalocele, gastroschisis, and annular pancreas. Fetal skeletal abnormalities associated with polyhydramnios include achondroplasia, osteogenesis imperfecta, hypophosphatasia, campomelic dysplasia, and thanatophoric dysplasia. Fetal neuromuscular abnormalities associated with polyhydramnios include myotonic dystrophy and arthrogryposis multiplex congenita (Bianchi and Van Marter, 1994; Esplin et al., 1998). Other fetal abnormalities associated with polyhydramnios include cystic hygroma, neck masses such as cervical teratoma or goiter, sacrococcygeal teratoma, or lethal multiple pterygium syndrome.

ANTENATAL NATURAL HISTORY

The antenatal natural history of pregnancies complicated by polyhydramnios is largely determined by the underlying

cause of the polyhydramnios. In addition, different clinical forms of polyhydramnios are described. Polyhydramnios is described as being acute when there is a rapid accumulation of excessive amniotic fluid within 1 week associated with severe abdominal pain and respiratory distress, subacute when it develops over a period of 2 weeks with less severe symptoms, and chronic when there is gradual accumulation of amniotic fluid with less maternal discomfort (Desmedt et al., 1990). The most common form of polyhydramnios is a gradual progression with minimal maternal symptoms, and the vast majority of pregnancies complicated by polyhydramnios are diagnosed during the third trimester.

Adverse maternal and perinatal outcomes have been associated with polyhydramnios (Desmedt et al., 1990). The overall perinatal mortality in one series of 243 patients with polyhydramnios was 33 per 1000 births (Chamberlain et al., 1984). One of the eight perinatal deaths occurred in a structurally normal fetus, while the remaining seven perinatal deaths were related to major fetal malformations. The corrected perinatal mortality rate for normal fetuses with polyhydramnios was 4 per 1000 births. Both the overall and the corrected perinatal mortality rates in this series were significantly greater than that observed in patients with normal amniotic fluid volume (Chamberlain et al., 1984).

Polyhydramnios has been associated with a higher frequency of prematurity. The presence of an overdistended uterus appears to be significantly associated with preterm contractions and premature delivery (Queenan and Gadow, 1970). The frequency of preterm delivery in pregnancies complicated by polyhydramnios ranges from 11% to 29% (Phelan et al., 1990). The incidence of preterm delivery appears to be significantly greater for subgroups with insulin-dependent diabetes mellitus and structural fetal malformations as compared with patients with idiopathic polyhydramnios (Many et al., 1996). The incidence of preterm delivery in patients with gestational diabetes was no greater than in the general population. The higher incidence of preterm delivery in insulin-dependent diabetes is because of the higher rate of pregnancy-induced hypertension, nonreassuring fetal testing, and elective delivery (Greene et al., 1989). It would therefore appear that the underlying cause of polyhydramnios is the major determining factor in predicting the risk of preterm delivery. In patients with polyhydramnios of undetermined cause, the frequency of preterm delivery appears to be no different than in the general population (Hill and Breckle, 1987).

The clinical implications of polyhydramnios that resolve spontaneously prior to delivery are uncertain. In one series of 41 cases of resolving polyhydramnios in nondiabetic patients, there was no increase in the rate of congenital anomalies but there was significantly higher mean birth weight and glucose intolerance as compared with controls with normal amniotic fluid volume (Hill et al., 1995).

MANAGEMENT OF PREGNANCY

Following the diagnosis of polyhydramnios, a careful maternal history should be performed to evaluate for possible underlying causes, such as diabetes mellitus. If a screening test for maternal diabetes has not yet been performed, one should be performed as soon as possible. A careful sonographic survey of fetal anatomy should be performed to exclude the presence of associated structural fetal malformations. Serial sonographic examinations are recommended to follow the degree of polyhydramnios.

The need for karyotyping in a fetus with polyhydramnios and no identifiable structural abnormalities is controversial. In one series of idiopathic polyhydramnios, the incidence of aneuploidy was 3.2%, which included two cases of trisomy 21 and one case of trisomy 18 (Brady et al., 1992). In another series of 59 cases of polyhydramnios, there was one case (1.7%) of aneuploidy (Landy et al., 1987). In a series of 49 patients with an AFI of 24 cm or greater, 27 patients had unexplained polyhydramnios, and there were no chromosomal abnormalities (Carlson et al., 1990). In a further series of 131 pregnancies complicated by polyhydramnios prior to 26 weeks' gestation, all 7 cases of chromosomal abnormalities were associated with abnormal sonographic findings (Hendricks et al., 1991). Our policy is to offer amniocentesis when there are associated sonographic abnormalities, when there is intrauterine growth restriction, or when there is imperfect sonographic visualization of fetal anatomy. Although general visualization of fetal anatomy is enhanced when there is a mild increase in amniotic fluid volume, there may be great difficulty in imaging due to fetal depth in cases of extreme polyhydramnios.

If fetal sonographic imaging demonstrates the presence of polyhydramnios and abnormal posturing of the extremities, consideration should be given to prenatal DNA testing for the myotonic dystrophy mutation (Esplin et al., 1998).

Treatment of polyhydramnios should focus on the underlying cause. Intervention to reduce the amount of amniotic fluid with the goal of decreasing contractions and avoiding preterm delivery has been advocated. Such temporizing measures include the administration of indomethacin and serial reduction amniocentesis. Most of the experience with the use of serial reduction amniocentesis has been associated with treatment of the twin–twin transfusion syndrome (see Chapter 119).

Delivery should occur at a tertiary care center if there are associated structural malformations, twin–twin transfusion syndrome, or hydrops fetalis, or if a congenital neuromuscular disorder is suspected. While elective preterm delivery is not indicated in cases of severe polyhydramnios, consideration should be given to delivery at 39 weeks' gestation because of maternal discomfort and also because of the risk of umbilical cord prolapse, should rupture of membranes occur. If artificial rupture of membranes is carried out, the procedure should be performed in or near a delivery room, with the capability of performing a cesarean delivery if there is a cord prolapse or placental abruption. Amniotic fluid should be allowed to drain slowly through a needle puncture. Pregnancies complicated by polyhydramnios have a higher incidence of inefficient uterine action, prolonged labor, postpartum uterine atony, and postpartum hemorrhage. Cesarean delivery is reserved for usual obstetric indications.

FETAL INTERVENTION

Fetal therapy is possible for some causes of polyhydramnios. In cases of polyhydramnios associated with hydrops fetalis, the possibility of direct fetal intravascular transfusion may exist (see Chapter 127). Polyhydramnios and hydrops fetalis secondary to supraventricular tachyarrhythmia may be amenable to digoxin therapy (Simpson and Marx, 1994). As discussed in Chapetr 119, polyhydramnios in the setting of severe twin–twin transfusion syndrome has been successfully treated with serial reduction amniocentesis and with laser ablation of placental surface anastomotic vessels.

Several investigators have reported the successful use of indomethacin therapy for idiopathic polyhydramnios (Cabrol et al., 1987; Lange et al., 1989; Ash et al., 1990; Kirshon et al., 1990b; Mamopoulos et al., 1990; Rosen et al., 1990; Gerson et al., 1991; Malas and Hamlett, 1991). Mechanisms proposed for the therapeutic effect of indomethacin in cases of polyhydramnios include decreased fetal urine production and enhanced fluid absorption in the lungs, secondary to increased fetal breathing. Reports involving a total of 44 patients have described use of indomethacin varying from an upper dose of 2 to 3 mg per kilogram of body weight per day in the form of oral tablets or rectal suppositories, to a lower dose of 25 mg orally every 6 hours. Maternal complications of indomethacin therapy include gastrointestinal disturbance, transient cholestatic jaundice, transient renal insufficiency, and pulmonary edema (Moise, 1993b). Fetal complications include oligohydramnios and ductal constriction (Kirshon et al., 1990a; Mamopoulos et al., 1990). Neonatal complications include renal insufficiency, persistent fetal circulation, ileal perforation, and necrotizing enterocolitis (Csaba et al., 1978; Cantor et al., 1980; Mogilner et al., 1982; Vanhaesebrouck et al., 1988; Gerson et al., 1991). If indomethacin is to be used for the treatment of polyhydramnios, weekly assessment of amniotic fluid volume should be performed and the medication should be discontinued when the amniotic fluid volume reduction exceeds two-thirds of the initial volume. Fetal echocardiography should be performed within the first 24 hours after the initiation of indomethacin to evaluate for ductal constriction and should then be repeated weekly (Moise, 1993a). If mild ductal constriction is noted, the indomethacin dose should be reduced, and if tricuspid regurgitation is noted the medication should be discontinued completely.

At our center, indomethacin has not been used for the treatment of polyhydramnios because of the potential for significant fetal complications. Although indomethacin has been shown to be effective as defined by normalization of amniotic fluid volume, we have not found evidence that this resulted in any change in overall perinatal outcome. Given the risks associated with indomethacin, our approach has been to educate patients about the signs and symptoms of premature labor and to evaluate them if they are symptomatic. Amniocentesis is reserved for cases of polyhydramnios associated with significant maternal discomfort and likely impending preterm labor.

TREATMENT OF THE NEWBORN

A detailed newborn physical examination is recommended because a structural malformation may be present despite a thorough prenatal ultrasound examination. In one series of 59 cases of polyhydramnios a false-negative ultrasound survey was reported in 8 cases (Hendricks et al., 1991). Particular attention should be paid in the newborn nursery to the infant's suck-and-swallow coordination and to the passage of meconium. If bilious vomiting or abdominal distention occurs, a plain abdominal radiograph should be obtained immediately. In cases of polyhydramnios secondary to maternal diabetes, a delivery room neonatal glucose measurement should be obtained because of the possibility of profound neonatal hypoglycemia.

SURGICAL TREATMENT

No specific surgical treatment of the newborn is described for idiopathic polyhydramnios. However, surgical treatment may be necessary if associated structural malformations such as tracheoesophageal fistula or intestinal atresias are present.

LONG-TERM OUTCOME

Long-term outcome for infants following a prenatal diagnosis of polyhydramnios depends on the gestational age at delivery and on the presence of associated structural malformations. In cases of additional malformations, the long-term outcome will primarily be dictated by the nature of the abnormality rather than by the existence of polyhydramnios.

GENETICS AND RECURRENCE RISK

Recurrence of idiopathic polyhydramnios is uncommon, although case reports documenting such recurrences do exist (Sieck and Ohlsson, 1984; Weissman and Zimmer, 1987; Shimizu et al., 1988). In one series of 780 cases of polyhydramnios, there were 36 cases (4.6%) of recurrent polyhydramnios (Beischer et al., 1993). The risks associated with recurrent polyhydramnios include the risk of fetal malformation and premature delivery (Beischer et al., 1993). Polyhydramnios attributable to a specific genetic diagnosis may recur based on the pattern of inheritance of the condition.

Immune Hydrops

127
CHAPTER

Key Points

- Immune hydrops is a serious condition in which abnormal fluid collections accumulate in at least two different fetal compartments, and in which circulating antibodies against red cell antigens are detected in the mother.
- If a first-time mother is Rh negative and her fetus is Rh positive, there is a 16% risk that the fetal Rh antigen will stimulate the maternal immune system to produce anti-D antibody.
- Isoimmunization due to non-Rh(D) and non-ABO incompatibility usually occurs as a result of blood transfusions, and atypical antibodies develop in approximately 1% to 2% of recipients.
- Fetal anemia secondary to Kell isoimmunization differs from that due to Rh(D) isoimmunization because the mechanism for the anemia is most likely erythroid suppression rather than hemolysis.
- Immune and nonimmune hydrops can be differentiated by maternal indirect Coombs test to screen for antibodies associated with blood group incompatibility.
- Immune hydrops should be considered an emergency, and arrangements should be made to promptly perform percutaneous umbilical blood sampling (PUBS) and possibly fetal blood transfusion or immediate delivery depending on gestational age.
- Blood for PUBS should be group O red cells, packed to a hematocrit of approximately 80%, less than 4 days old, irradiated, anti-cytomegalovirus negative, negative for the antigen to which the mother is immunized, and Kell negative.
- It is generally not a good idea to transfuse a hydropic fetus to a final hematocrit that is greater than 25% or greater than four times the initial hematocrit, as this has been associated with fluid overload and sudden intrauterine fetal death.
- The optimal mode of delivery for the hydropic fetus is uncertain, although cesarean delivery is usually considered safer to decrease the risk of soft-tissue trauma.
- Minimal data are available regarding the long-term outcome of surviving fetuses that had immune hydrops.
- The recurrence risk for immune hydrops is significant. In general, the more severe the obstetric history of rh isoimmunization, the more likely the recurrence risk for severe disease in the future.

CONDITION

Immune hydrops fetalis is a serious fetal condition in which abnormal fluid collections accumulate in at least two different fetal compartments, and in which circulating antibodies against red cell antigens are detected in the mother. Hydrops fetalis is associated with a pathologic increase in interstitial and total fetal body water, usually appearing in fetal soft tissues and serous cavities. The cause may be either immunologic or nonimmunologic, depending on the presence or absence of maternal antibodies against fetal red cell antigens. While previously it was considered that the majority of cases of hydrops fetalis were secondary to maternal–fetal blood group incompatibilities, it is now estimated that the causes are nonimmunologic in more than 90% of cases (see Chapter 128) (Santolaya et al., 1992).

Immune hydrops is most likely a result of maternal–fetal Rhesus (Rh) blood group incompatibility, in which maternal antibodies to certain fetal blood group antigens cross the placenta, causing hemolysis of fetal blood and profound fetal anemia. This process is also referred to as Rh isoimmunization. An in-depth discussion of the pathogenesis of Rh blood group incompatibility is beyond the scope of this textbook. Briefly, the five antigens that make up the Rh system are D, C, c, E, and e. The presence of the D antigen confers Rh blood group positivity, while its absence indicates Rh negativity. Approximately 15% of Caucasians are Rh negative, while 30% of Basques are Rh negative, and 4% to 8% of blacks are Rh negative (Bowman, 1999). A total of 45% of Rh-positive individuals are homozygous, so all their offspring will be Rh positive. By contrast, 55% of Rh-positive individuals are heterozygous, so there is a 50/50 chance that their offspring will be Rh positive. If a first-time mother is Rh negative and her fetus is Rh positive, there is a 16% risk that fetal Rh antigen will stimulate the maternal immune system to produce anti-D antibody (Bowman, 1999). This first immune response generally consists of anti-D IgM antibody, which cannot cross the placenta to cause fetal hemolysis. In a subsequent pregnancy, if the fetus is again Rh positive, a more rapid immune response occurs, consisting of high titers of anti-D IgG antibody, which rapidly crosses the placenta to produce fetal hemolysis and profound fetal anemia.

The mechanism by which maternal–fetal Rh incompatibility produces immune hydrops fetalis is complex and the exact pathophysiologic process has not yet been elucidated. It is known that maternal anti-D IgG antibody attaches itself to the Rh antigen present on fetal red cells. This results in chemotaxis of phagocytes in the fetal spleen, which leads to destruction and hemolysis of fetal red cells. In response, the fetus produces more erythropoietin, which stimulates the fetal bone marrow to increase red cell production. Eventually, marrow capacity is reached, and extramedullary erythropoiesis occurs, with fetal red cell production in the fetal liver, spleen, kidney, adrenal glands, and intestine. Fetal hepatosplenomegaly is, therefore, common. Red cells produced at these sites are often immature, are nucleated, and appear in the circulation as erythroblasts. Hence, the synonym erythroblastosis fetalis for immune hydrops.

The majority of cases of Rh isoimmunization lead to mild or moderate fetal or neonatal hemolytic disease. However, approximately 20% to 25% of cases result in severe hemolytic disease, with immune hydrops developing in utero (Bowman, 1999). Hydrops develops in approximately half of these fetuses between 18 and 34 weeks of gestation, with hydrops developing in the remaining fetuses between 34 weeks and term. The pathophysiology of fetal hydrops is unclear. Several hypotheses have been suggested. One thought is that simple congestive heart failure secondary to fetal anemia leads to hydrops. Another more complicated hypothesis is that severe fetal anemia leads to extensive extramedullary erythropoiesis, with associated hepatosplenomegaly and distortion of intrahepatic architecture. This distortion results in portal and umbilical venous distortion, portal hypertension, placental edema, and placental hypoperfusion (Bowman, 1999). With deteriorating hepatic synthesis, progressive hypoalbuminemia occurs, adding to the generalized edema, anasarca, and pleural and pericardial effusions. However, a recent study calls into question whether or not hypoalbuminemia is the cause of immune hydrops (Pasman et al., 2006). Pasman et al. evaluated fetal blood samples taken at the first fetal blood transfusion in 244 Rh-D alloimmunized pregnancies. Hemoglobin concentration, albumin concentration, and severity of hydrops were assessed. Most fetuses (71%) with immune hydrops had an albumin concentration within the normal range suggesting that decreased albumin is unlikely to cause hydrops. Nonetheless, there was a negative correlation between the degree of fetal hydrops and the fetal serum albumin level suggesting that hypoalbuminemia occurs as a secondary effect in hydrops. The authors suggest that cardiac failure and lymphatic flow obstruction may be more important causative factors of hydrops.

Effective prevention programs to reduce the incidence of Rh(D) isoimmunization, using passive maternal immunization with Rh immunoglobulin, have significantly decreased the numbers of fetuses with immune hydrops. Because of the efficacy of these programs, non-Rh(D) blood group isoimmunization is becoming proportionately more frequent as a cause of immune hydrops. Immune hydrops secondary to ABO blood group incompatibility is extremely rare, as the resulting hemolytic disease is almost always mild in nature (Gilja and Shah, 1988; Bowman, 1999). Isoimmunization due to non-Rh(D) and non-ABO incompatibility usually occurs as a result of blood transfusions, with such atypical antibodies developing in 1% to 2% of recipients (Bowman, 1999). At least 60 such atypical antibodies have been identified as potentially causing hemolytic disease of the fetus or newborn, with anti-c, anti-E, and anti-Kell antibodies being the most important causes of severe disease, including hydrops (Bowman, 1990). Fetal anemia secondary to Kell isoimmunization differs from that due to Rh(D) isoimmunization, as the mechanism for anemia is most likely

erythroid suppression rather than hemolysis (Vaughan et al., 1994).

INCIDENCE

The risk of immune hydrops in a first Rh-sensitized pregnancy is approximately 8% to 10% (Bowman, 1999). The incidence of immune hydrops has decreased significantly with the widespread use of passive immunization using Rh immunoglobulin for Rh-negative mothers at 28 weeks of gestation, following suspected fetomaternal hemorrhage, and postpartum following the delivery of an Rh-positive infant. The efficacy of this prevention program has been demonstrated by a decline in the incidence of Rh hemolytic disease of the fetus or newborn, from 65 in 10,000 births in the United States in 1960 to 10.6 in 10,000 births in 1990 (Chavez et al., 1991). The relative proportion of cases of immune hydrops secondary to non-Rh(D) atypical antibodies is increasing, as the use of Rh immunoglobulin has become widespread, with Kell isoimmunization now affecting 0.1% of all pregnancies (Caine and Mueller-Heubach, 1986).

SONOGRAPHIC FINDINGS

The diagnosis of hydrops is made following the detection of abnormal or increased fluid accumulation in at least two distinct fetal body cavities. Examples include pericardial effusion, pleural effusion, ascites, subcutaneous edema, cystic hygroma, polyhydramnios, and placental thickening (Figures 127-1 to 127-3). In general, skin thickness of at least 5 mm is required to diagnose subcutaneous edema, and a placental thickness of at least 6 cm is required to diagnose placentamegaly (Romero et al., 1988). These features do not necessarily indicate hydrops; it should be noted that skin thickening of at least 5 mm may be commonly seen in macrosomic fetuses. If abnormal fluid accumulation is confined to only one

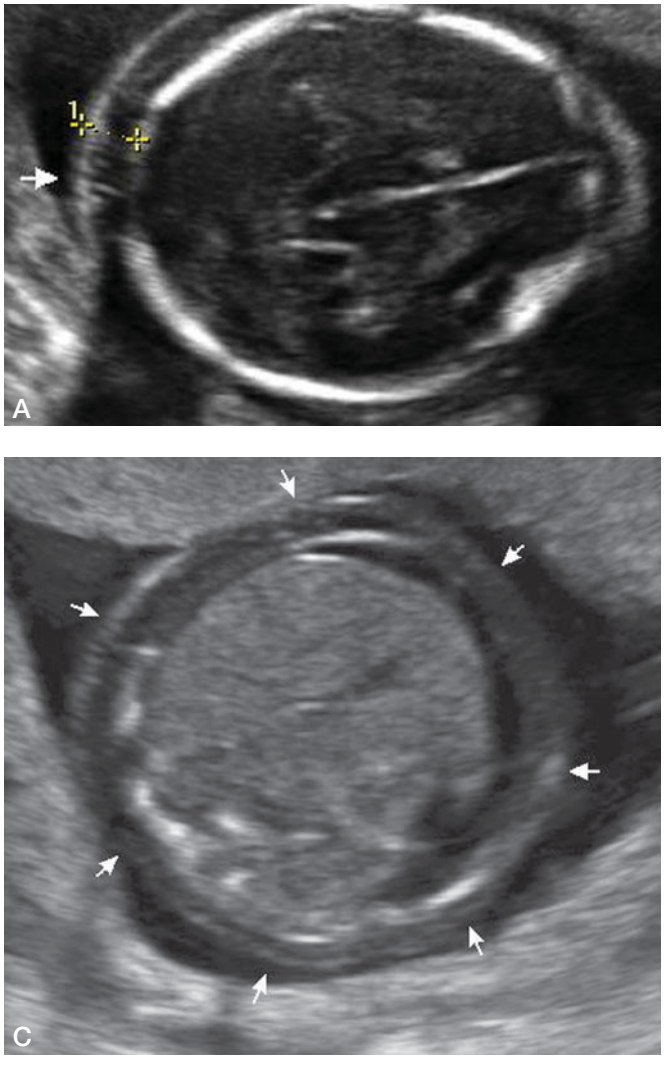

Figure 127-1 **A.** Axial image of a fetus demonstrating scalp edema due to immune hydrops. **B.** Sagittal image demonstrating edema of the scalp and face in a fetus with immune hydrops. **C.** Axial image demonstrating abdominal ascities and edema of the abdominal wall in a fetus with immune hydrops.

site, then the diagnosis of hydrops should not be used, and the case should be described simply in terms of the involved site, such as isolated ascites or isolated pleural effusion.

Fetal ascites is diagnosed sonographically by the visualization of an echolucent rim encompassing the entire fetal abdomen in a transverse view. Loops of bowel and the outline of the fetal liver, spleen, bladder, and diaphragm are generally more easily seen in the presence of ascites. Pericardial effusion

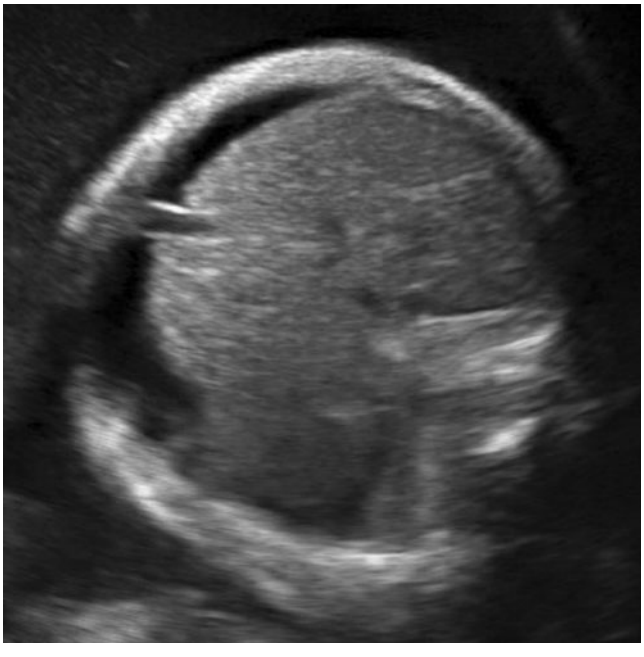

Figure 127-3 Axial image demonstrating abdominal ascites in a fetus with immune hydrops.

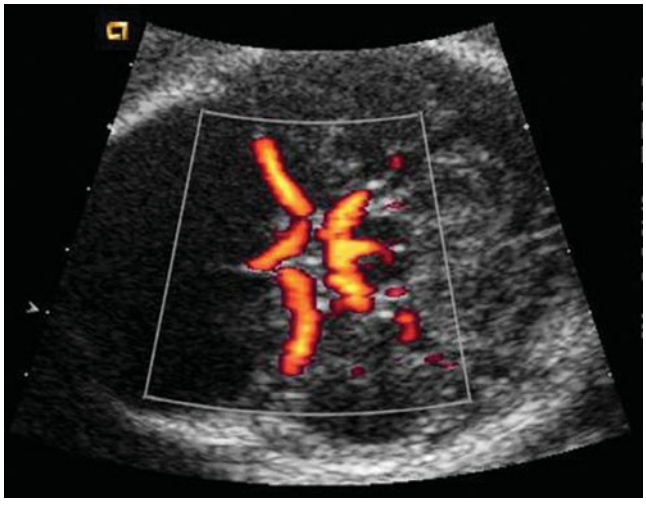

Figure 127-4 Axial section through the fetal head using power Doppler to identify the middle cerebral artery arising from the Circle of Willis.

is diagnosed by the appearance of an echolucent rim at least 1 to 3 mm thick around both cardiac ventricles.

In general, fetal hydrops is not seen sonographically until the fetal hematocrit has fallen to below one-third of its normal range. However, there is no direct relationship between actual fetal hemoglobin level and sonographic appearance or severity of hydrops. The correlation between various sonographic findings and the degree of fetal anemia has been evaluated. No correlation has been found between the degree of fetal anemia and placental thickness or umbilical vein diameter, and poor correlation has been found between fetal liver and spleen dimensions and the degree of anemia (Nicolaides et al., 1988; Roberts et al., 1989; Oepkes et al., 1993). The use of Doppler sonography to predict fetal anemia has been more successful (Mari et al., 1995). An elevated peak systolic velocity (PSV) measured in the middle cerebral artery (MCA) is associated with an increased likelihood of fetal anemia (Figures 127-4 and 127-5). Mari et al. measured hemoglobin concentration from cordocentesis and PSV of blood flow in the MCA by Doppler velocimetry in 111 fetuses at risk for anemia due to maternal red cell alloimmunization (Mari et al., 2000). Hemoglobin values were compared to 265 normal fetuses. Forty-one fetuses did not have anemia, 35 had mild anemia, 4 had moderate anemia, and 31 had severe anemia (12 of which had hydrops). The sensitivity of an increased PSV of blood flow in the MCA for the prediction of moderate or severe anemia was 100%, including all cases of hydrops. The false-positive rate of PSV in an MCA of 1.5 MoM was 12%. The authors concluded that moderate-to-severe fetal anemia can, therefore, be reliably detected noninvasively. Several studies have suggested that Doppler ultraonography can replace invasive testing (measurement of Dela OD450) in the management of Rh-alloimmunized pregnancies (Zimmerman et al., 2002; Pereira et al., 2003; Bullock et al., 2005; Oepkes et al., 2006). Such Doppler measurements may be useful for surveillance following intrauterine transfusions

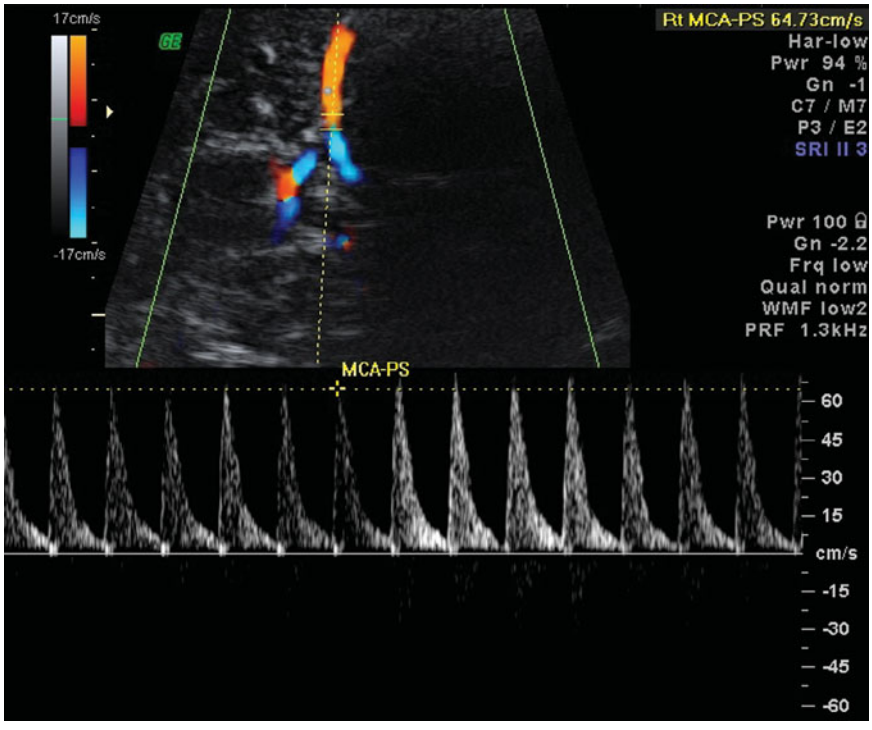

Figure 127-5 Elevated peak systolic velocity measured in the middle cerebral artery suggestive of fetal anemia in a pregnancy complicated by Rh alloimmunization.

to aid in the timing of repeat fetal blood sampling or transfusion (Mari et al., 2005). PSV in an MCA is also useful in detecting fetal anemia secondary to Kell alloimmunization (van Dongen et al., 2005).

DIFFERENTIAL DIAGNOSIS

Following the sonographic diagnosis of hydrops, the first step is to differentiate between immune and nonimmune causes. This is easily accomplished by the performance of a maternal indirect Coombs test to screen for antibodies associated with blood group incompatibility. Even if a maternal antibody that can be implicated in immune hydrops is detected, consideration should still be given in the differential diagnosis to the possibility of nonimmune hydrops. A detailed fetal sonographic survey of anatomy should be performed to exclude the presence of structural malformations that may also be associated with hydrops (see Chapter 128).

ANTENATAL NATURAL HISTORY

No data are available on the antenatal natural history of immune hydrops managed expectantly. In general, the finding of fetal hydrops in a pregnancy complicated by Rh isoimmunization or other atypical antibodies is ominous. If left untreated, the fetus will rapidly become moribund and will most likely die in utero. Therefore, the finding of fetal hydrops in such at-risk pregnancies should be considered an emergency, and arrangements should be made promptly to either perform percutaneous umbilical blood sampling (PUBS) and possibly fetal transfusion, or immediate delivery, depending on the gestational age.

PUBS is associated with high rates of fetal survival in fetuses with hydrops (78%–88.9%) (van Kamp et al., 2004; Craparo et al., 2005; Mesogitis et al., 2005). Mesogitis et al. reported on 18 patients diagnosed with fetal hydrops secondary to Rh disease (Mesogitis et al., 2005). All cases were managed with serial intravascular fetal transfusions. There were 11 mildly, and 7 severely, hydropic fetuses. Two fetuses with severe hydrops died in utero. The remaining cases delivered after 32 weeks of gestation. Hydrops reversed in utero in 90.9% of the mild cases and in 57.1% of the severe cases.

MANAGEMENT OF PREGNANCY

Following the diagnosis of immune hydrops, the patient should be immediately referred to a tertiary care center, with trained perinatologists to perform intrauterine transfusions and neonatologists to counsel parents and direct treatment of the newborn. A detailed sonographic fetal anatomy survey should be performed to quantify the severity of the hydrops and to rule out the presence of any additional structural malformations. In general, once immune hydrops has been diagnosed, the prognosis for the fetus is guarded, and arrangements to perform PUBS and possible intrauterine fetal transfusion should be expedited as rapidly as possible. It should be noted, however, that this requires the assembly of an experienced multidisciplinary team, including perinatologists, sonographers, blood bank personnel, hematology laboratory personnel, and nursing staff. The assembly of appropriate personnel can take time and is best expedited at

a tertiary care facility that has significant experience in performing fetal transfusions. If the gestational age is between 24 and 34 weeks, intramuscular betamethasone should be given to the mother to reduce the complications of prematurity in such high-risk pregnancies. If the gestational age is less than 24 weeks, the option of elective termination of the pregnancy should be discussed with the parents.

A maternal blood sample should be obtained immediately and sent to a blood bank for typing, antibody determination, and preparation of blood appropriate for fetal transfusion. The details of fetal transfusion for immune hydrops are described in the section on "Fetal Intervention." Following intrauterine transfusion, careful sonographic surveillance should be instituted, depending on the gestational age. Daily fetal testing with nonstress tests or biophysical profiles is reasonable for all potentially viable fetuses. Once there is sonographic evidence of resolution of hydrops, testing can be decreased to twice weekly. Sonographic surveillance for appropriate fetal growth should continue every 2 weeks.

Timing of delivery is variable with immune hydrops. If the fetus responds well to an initial intrauterine transfusion, repeat PUBS procedures should be scheduled at 1- to 3-week intervals, with repeat transfusions depending on changes in fetal hematocrit and the sonographic appearance of hydrops. The final PUBS is generally scheduled at 34 to 35 weeks of gestation; fetal lung maturity guides the timing of delivery. Such pregnancies should not be allowed progress beyond 37 to 38 weeks of gestation. If hydrops does not improve, or if fetal testing becomes nonreassuring despite correction of fetal anemia, premature delivery may be indicated, depending on the gestational age. It is possible that mature lecithin/sphingomyelin ratios may be obtained less frequently near term in fetuses with hydrops as compared with nonhydropic fetuses (Romero et al., 1988).

The optimal mode of delivery for the hydropic fetus is uncertain. Because of the risk of soft-tissue dystocia associated with hydrops, it is often considered safer to deliver all potentially viable fetuses with immune hydrops by cesarean. This should minimize the chances of maternal and fetal trauma. However, there are no data to support routine cesarean delivery for immune hydrops as compared with cesarean delivery based on standard obstetric indications. A trial of labor may be reasonable in cases in which the fetal anemia has been adequately corrected, and in which the hydropic features improve. In carefully selected and monitored cases, up to 80% of fetuses with immune hydrops may successfully deliver vaginally (Bowman, 1999). The optimal location of delivery should be a tertiary care center, with the immediate availability of skilled neonatologists and other appropriate pediatric subspecialists.

FETAL INTERVENTION

Immune hydrops is one of the few fetal abnormalities in which a well-established program of fetal intervention has been described. The ability to perform intrauterine fetal transfusions has revolutionized the management of Rh isoimmunization and has resulted in the survival of many fetuses that would otherwise have died from hydrops. The first step in fetal intervention for immune hydrops is to urgently schedule a PUBS procedure to document the fetal hematocrit and to perform potentially lifesaving therapy.

In all cases of immune hydrops, appropriate blood for fetal transfusion should be available at the time of a scheduled PUBS procedure. The blood should be group O red cells, packed to a hematocrit of approximately 80%, less than 4 days old, irradiated, anti-cytomegalovirus negative, negative for the antigen to which the mother is immunized, and Kell negative. If a previous PUBS has been performed, so that the fetal ABO blood group is known, and there is no maternal–fetal ABO incompatibility, red cells of the same ABO status as the fetus can be transfused (Bowman, 1999). When the initial PUBS procedure is scheduled, appropriate blood should be immediately available. This will allow for immediate transfusion as soon as the initial fetal blood sample has been obtained, without the need to replace the needle.

The appropriate target for fetal intravascular transfusion will depend on the gestational age and fetal position. In general, the preferred target is the umbilical vein, at its placental insertion site. Sterile technique is used throughout. The mother is generally premedicated with a sedative and some centers also use a prophylactic antibiotic, such as dicloxacillin. A 20-gauge spinal needle, of sufficient length to reach the target, is used to cannulate the umbilical vein under direct ultrasound guidance. The free return of blood confirms entry into the vein following removal of the needle stylet. A sample is drawn into a heparinized tuberculin syringe and sent to the hematology laboratory, which should be on standby to receive all such samples. The presence of fetal, as opposed to maternal, blood is confirmed by noting an elevated mean corpuscular volume, generally greater than 120 fL, or by alkaline denaturation. Fetal blood should also be measured for hematocrit, hemoglobin, platelet count, total bilirubin, blood type, and antibody screen. Fetal paralysis with pancuronium or vecuronium is generally not required in cases of hydrops, as fetal activity is often minimal. However, if fetal movement significant enough to dislodge needle's access to the umbilical vein occurs, pancuronium or vecuronium can be injected directly into the fetal circulation.

Since the fetal hematocrit will invariably be less than 30% in cases of immune hydrops, the fetal transfusion can be started as soon as the initial fetal sample is obtained, while awaiting results of the hematocrit from the hematology laboratory. Once the initial fetal hematocrit result is available, a calculation can be performed to estimate the volume of transfused blood needed to correct the fetal anemia. The volume of packed red cells to be transfused is derived using formulas that take into account the starting hematocrit, the hematocrit of transfused blood, the target hematocrit, and a correction factor for the volume of blood in the placental circulation. A commonly used formula for the volume of blood to be

transfused is

$$V_T = \frac{(\text{desired final hematocrit} - \text{initial fetal hematocrit})}{(\text{donor blood hematocrit})} \times (150) \times (\text{EFW}),$$

where V_T is volume of blood transfused, 150 is a placental correction factor, and EFW is estimated fetal weight in kilograms (Kaufman and Paidas, 1994).

It is generally not advised to transfuse a hydropic fetus to a final hematocrit that is either greater than 25% or greater than four times the initial hematocrit (Radunovic et al., 1992). This has been associated with fluid overload and sudden intrauterine fetal death. In cases of hydrops secondary to fetal anemia, the goal of the first intrauterine transfusion should be a hematocrit of 20% to 25%, and the transfusion should then be repeated in 48 to 72 hours to bring the final hematocrit to a level of 45% to 50%. Repeat procedures are then performed at 2- to 3-week intervals, with the last procedure being performed at 34 to 35 weeks of gestation.

Another therapeutic option for fetuses with immune hydrops is to perform a combined intravascular and intraperitoneal transfusion, with the intravascular aliquot of blood designed to provide an acute increase in fetal hematocrit and the intraperitoneal aliquot designed to provide a slower sustained increase in hematocrit. Intraperitoneal transfusion should rarely be considered an option for the hydropic fetus. If the fetus is moribund, and there is no evidence of fetal breathing, red cells placed in the intraperitoneal cavity will not be absorbed and will result in no benefit to the fetus. However, if an umbilical vessel cannot be cannulated for technical reasons, the option of intraperitoneal transfusion can be considered. If ascites is present, up to 150 mL of ascitic fluid should be drained prior to performing an intraperitoneal transfusion (Bowman, 1999). This will minimize the chance of increasing the intraperitoneal pressure to a level greater than umbilical venous pressure. To do so would result in impaired return of blood to the fetal heart and subsequent fetal death. Another alternative for fetal transfusion in cases of hydrops, if an umbilical vessel cannot be cannulated, is to perform a direct fetal cardiac transfusion. However, this should be considered a method of last resort as it is associated with a significant risk of fetal death (Westgren et al., 1988).

TREATMENT OF THE NEWBORN

Infants with hydrops should be delivered in a tertiary care center, with immediate availability of a multidisciplinary neonatal resuscitation team. Most fetuses with immune hydrops should improve with successful intrauterine transfusions, so the degree of neonatal hydrops and anemia should also be improved. However, if hydrops fails to resolve with appropriate intrauterine therapy, the neonatal team should be prepared for a complex resuscitative effort. Immediate neonatal endotracheal intubation may be needed, and such intubations can be technically difficult (Carlton et al., 1989). A high-frequency ventilator and high airway pressure settings may be needed to achieve adequate gas exchange. Paracentesis and thoracentesis, with placement of bilateral chest tubes, may also be needed to allow adequate ventilation and effective gas exchange. Placement of umbilical artery and umbilical vein lines may be needed to aid in the resuscitation (McMahan and Donovan, 1995). Use of blood products, albumin, and diuretics may be needed to effectively maintain adequate intravascular volume without significant fluid overload or soft-tissue edema. If the neonate can be stabilized in the delivery room, transport to a neonatal intensive care unit should be arranged promptly.

Approximately 50% of neonates will require "top-up" transfusions in the neonatal intensive care unit (Saade et al., 1993). Infants should therefore be followed with weekly hematocrit and reticulocyte determinations for 4 to 6 weeks. This requirement for future transfusions may reflect persistent hypoplasia of the neonatal bone marrow as well as the persistence of passively acquired IgG antibodies from the mother.

SURGICAL TREATMENT

No surgical treatments have been described.

LONG-TERM OUTCOME

Minimal data are available on the long-term follow-up of fetuses with immune hydrops. With advances in intrauterine therapy, more moribund fetuses are being rescued, and this has led to concerns regarding the long-term neurologic outcome for such infants. In one series of 38 fetuses who received intravascular transfusions for Rh isoimmunization, 35 (92%) were normal at 2 years of follow-up and 3 had cerebral palsy, which was thought to be a result of prematurity (Doyle et al., 1993).

GENETICS AND RECURRENCE RISK

The recurrence risk for immune hydrops is significant. In general, the more severe the obstetric history of Rh isoimmunization, the more likely the recurrence of severe disease in a future pregnancy. For an Rh-negative mother, if the father is homozygous for the Rh(D) allele, all of the offspring will be Rh positive and will, therefore, be at risk for severe hemolytic disease. If the father is heterozygous Rh positive, then there is a 50/50 chance that the fetus will be Rh positive. If the fetus is Rh negative, the risk of hemolytic disease is zero. Preimplantation genetic diagnosis with biopsy of the eight-cell embryo is now available in cases of a heterozygous father, to predict the Rh status of a future fetus (Van den Veyver et al., 1995). However, this approach would obviously require the performance of in vitro fertilization in future pregnancies.

Previously, another prenatal diagnosis option was to perform a chorionic villus sampling (CVS) or amniocentesis in future pregnancies with a heterozygous father, which would allow early prenatal diagnosis of fetal Rh and Kell status (Bennett et al., 1993). However, this should be avoided if possible as there is a risk of stimulating a significant antibody/antigen response in that pregnancy, especially with a CVS procedure. In Europe, such invasive testing methods using CVS or amniocentesis have been abandoned due to the easy availability of fetal Rh(D) status identification using PCR amplification of fetal DNA from a maternal blood sample. This can be performed as early as 14 weeks of gestation in a subsequent pregnancy and accurately determines whether the fetus is Rh(D) positive or negative.

Nonimmune Hydrops Fetalis

128 CHAPTER

Key Points

- Nonimmune hydrops fetalis is a serious fetal condition in which abnormal fluid accumulates in at least two different fetal compartments, and in which circulating antibodies against red-cell antigens are absent in the mother.
- Nonimmune hydrops fetalis is a heterogeneous disorder, caused by a large number of underlying pathologic processes. While the majority of cases appear to be idiopathic, the most common recognizable cause is cardiovascular pathology.
- Following the sonographic detection of hydrops, the most important step is to differentiate between immune and nonimmune causes. Once immune causes are excluded, a detailed anatomical survey is needed to rule out congenital abnormalities, which could be the cause of the hydrops.
- Nonimmune hydrops can occur secondary to fetal anatomical abnormalities (cardiac, thoracic, gastrointestinal, neurologic, genitourinary, vascular, or skeletal), placental/cord abnormalities, fetal hematologic, neoplastic or metabolic disorders, infection, fetal genetic anomalies, and maternal abnormalities.
- Maternal blood tests should include an indirect Coombs antibody screen, maternal blood type, Kleihauer–Betke stain, complete blood count with differential and erythrocyte indices, hemoglobin electrophoresis, and glucose-6-phosphate dehydrogenase deficiency screen. Additional maternal blood work should include TORCH titers, syphilis screen, and parvovirus B19 IgG and IgM titers.
- Fetal echocardiography and invasive testing for fetal karyotype should be offered.
- While the optimal mode of delivery is uncertain, cesarean section is advised for all potentially viable fetuses due to the risk for soft-tissue dystocia.
- Fetal therapy may be possible, including PUBS with transfusion, maternal administration of cardiac medications, and fetal shunt placement.
- The long-term prognosis will depend on the nature of the underlying abnormality.
- The recurrence risk will depend on the underlying etiology of the nonimmune hydrops.

CONDITION

Nonimmune hydrops fetalis (NIHF) is a serious fetal condition in which abnormal fluid accumulates in at least two different fetal compartments, and in which circulating antibodies against red cell antigens are absent in the mother. Hydrops fetalis is associated with a pathologic increase in interstitial and total fetal body water, usually appearing in fetal soft tissues and serous cavities. It may be either immunologic or nonimmunologic, depending on the presence or absence of maternal antibodies against fetal red cell antigens. While it was previously thought that the majority of cases of hydrops fetalis were secondary to maternal–fetal blood group incompatibilities, it is now estimated that over 90% of cases are nonimmunologic (Santolaya et al., 1992).

NIHF is a heterogeneous disorder, caused by a large number of underlying pathologic processes. The majority of cases appear to be idiopathic, although some investigators have stated that with thorough investigation an underlying cause can be identified in as many as 84% of cases (Holzgreve et al., 1984; Norton, 1994; Wilkins, 1999). When prenatally diagnosed cases of NIHF and cases of intrauterine fetal death are included, the success rate in discovering an underling cause for NIHF may be as low as 40% (Norton, 1994). The literature on NIHF consists almost entirely of case reports or small case series, together with reviews of these case series. A review of these reports suggests that the most common recognizable

cause of NIHF is cardiovascular pathology (accounting for 17% to 35% of cases), followed by chromosomal abnormalities (accounting for 14% to 16% of cases), and hematologic disorders (accounting for 4% to 12% of cases) (Norton, 1994). The remainder of causes of NIHF are rare conditions, many of which are difficult to diagnose prenatally. The range of possible underlying causes for NIHF is summarized in Table 128-1, listed in order of expected incidence.

Other than idiopathic cases, cardiac malformations account for the majority of cases of NIHF (Knilans, 1995). There is no particular form of cardiac abnormality that always results in hydrops, although the more severe the malformation the greater the likelihood of hydrops developing. The common mechanism of NIHF in cases of cardiac malformation or arrhythmia is the development of congestive heart failure, with increasing generalized fluid overload. The prognosis for fetuses with structural cardiac malformations and hydrops is extremely poor, with a mortality rate approaching 100% in some series (Crawford et al., 1988).

Chromosomal causes of NIHF are common; the most frequent is Turner syndrome, with its typical sonographic finding of cystic hygroma. A wide range of other genetic syndromes is also associated with NIHF, such as arthrogryposis, tuberous sclerosis, Pena–Shokeir syndrome, and Noonan syndrome (Jauniaux et al., 1990).

The underlying mechanism for the association of NIHF with hematologic abnormalities is most likely severe fetal anemia leading to high-output cardiac failure (Arcasoy and Gallagher, 1995). Fetal anemia can result from failure to manufacture normal hemoglobin (such as α-thalassemia), fetal hemorrhage (such as intracranial bleeding), hemolysis, (such as glucose-6-phosphate dehydrogenase deficiency), or failure to form erythrocytes because of marrow destruction (such as parvovirus B19 infection).

Congenital cystic adenomatoid malformation (CCAM) is the most common thoracic lesion associated with hydrops. Other thoracic causes of hydrops include bronchopulmonary sequestration, thoracic masses, and diaphragmatic hernia. The underlying mechanism for the association of hydrops with these thoracic conditions is most likely obstruction to venous return because of increased intrathoracic pressure.

Congenital infection with a wide variety of organisms is a well-recognized cause of hydrops (Barron and Pass, 1995). Causative organisms include syphilis, cytomegalovirus, parvovirus B19, toxoplasmosis, herpes simplex, rubella, and coxsackievirus. Possible mechanisms for the association of congenital infection with hydrops include fetal anemia from suppression of erythrocyte production, fetal myocarditis, or fetal hepatitis. In some cases of congenital infection, such as syphilis, the presence of hydrops is associated with a very poor prognosis. In other cases, hydrops from congenital infection may be self-limited and may resolve spontaneously. Fetal parvovirus B19 infection results in an aplastic crisis, which leads to profound anemia, and hydrops, the outcome of which may be either fetal death or spontaneous resolution without long-term morbidity (Morey et al., 1991; Levy et al., 1997).

A wide variety of structural fetal malformations has been associated with the development of NIHF. These include skeletal dysplasias, which may be associated with thoracic compression, impairment of venous return, and subsequent hydrops. The association of other structural malformations with NIHF, such as gastrointestinal, genitourinary, and neurologic abnormalities, may represent chance occurrences, as it is difficult to elucidate a plausible underlying mechanism for hydrops in many cases.

Some fetal conditions, such as Finnish nephrosis and hepatic fibrosis, result in profound hypoproteinemia or cirrhosis, which may subsequently lead to hydrops. The mechanism for the association between metabolic disorders and NIHF is unclear, but may be related to soft-tissue swelling and obstruction of venous return to the heart. Certain noncardiac fetal abnormalities may result in hydrops by causing high-output cardiac failure. Examples include sacrococcygeal teratoma, neuroblastoma, placental chorioangioma, and umbilical cord masses.

NIHF may very rarely occur in association with significant maternal medical illnesses, such as severe anemia, hypoproteinemia, or diabetes mellitus. The "mirror" syndrome, also known as Ballantyne syndrome, is the combination of fetal hydrops with generalized fluid overload and a preeclampsia-like state in the mother (Carbillon et al., 1997). In general, the maternal clinical features resolve only with delivery of the fetus and placenta.

INCIDENCE

The precise incidence of NIHF is difficult to elucidate, as many cases are not detected prior to intrauterine fetal death, and some cases may resolve spontaneously in utero. The generally reported incidence of NIHF is 1 in 1500 to 1 in 4000 deliveries (Romero et al., 1988; Wilkins, 1999).

SONOGRAPHIC FINDINGS

The diagnosis of hydrops is made following the detection of abnormal or increased fluid accumulation in at least two distinct fetal body cavities. Examples include pericardial effusion, pleural effusion, ascites, subcutaneous edema, cystic hygroma, polyhydramnios, and placental thickening (Figures 128-1 and 128-2). In general, skin thickness of at least 5 mm is required to diagnose subcutaneous edema, and a placental thickness of at least 6 cm is required to diagnose placentomegaly (Romero et al., 1988). These features do not necessarily indicate hydrops; it should be noted that skin thickening of at least 5 mm may be commonly seen in macrosomic fetuses. If abnormal fluid accumulation is confined to only one site, then the diagnosis of hydrops should not be used, and the case should be described simply in terms of the involved site, such as isolated ascites or isolated pleural effusion.

Table 128-1

Conditions Associated with Nonimmune Hydrops Fetalis

Idiopathic hydrops	Unknown cause
Cardiac malformation	Hypoplastic left ventricle; Atrioventricular canal defect; Atrial septal defect; Ventricular septal defect; Tetralogy of Fallot; Hypoplastic right ventricle; Ebstein's anomaly; Truncus arteriosus; Transposition of great vessels; Aortic stenosis or atresia; Pulmonary stenosis or atresia; Cardiomyopathy; Endocardial fibroelastosis; Premature closure of ductus arteriosus; Premature closure of foramen ovale; Rhabdomyoma; Intrapericardial teratoma
Cardiac arrhythmia	Supraventricular tachycardia; Atrial flutter; Heart block; Bradyarrhythmias; Wolff–Parkinson–White syndrome
Chromosomal abnormality	Trisomy 21; Trisomy 18; Trisomy 13; Turner syndrome; Triploidy; Tetraploidy; 18q+; 13q−; Others
Hematologic disorder	Alpha-thalassemia; Parvovirus B19 infection; Fetomaternal transfusion; In utero hemorrhage; Glucose-6-phosphate dehydrogenase deficiency; Fetal red cell enzyme deficiencies; Twin-to-twin transfusion syndrome
Thoracic abnormality	Congenital cystic adenomatoid malformation of lung; Bronchopulmonary sequestration; Diaphragmatic hernia; Chylothorax; Pulmonary lymphangiectasia; Intrathoracic mass (teratoma, leiomyosarcoma); Bronchogenic cyst
Genetic syndrome	Arthrogryposis; Multiple pterygium syndrome; Noonan syndrome; Pena–Shokeir syndrome; Cornelia de Lange syndrome; Tuberous sclerosis; Prune belly syndrome; Myotonic dystrophy; Neu–Laxova syndrome
Infectious disease	Cytomegalovirus; Parvovirus B19; Toxoplasmosis; Syphilis; Herpes simplex; Rubella; Coxsackievirus; Varicella; Respiratory syncytial virus
Skeletal dysplasia	Achondroplasia; Achondrogenesis; Osteogenesis imperfecta; Hypophosphatasia; Short rib polydactyly; Thanatophoric dwarfism; Asphyxiating thoracic dysplasia; Osteochondrodystrophy; Osteochondrodysplasia; Chondrodystrophy; Chondrodysplasia
Gastrointestinal disorder	Diaphragmatic hernia; Esophageal or intestinal atresia; Imperforate anus; Midgut volvulus; Meconium peritonitis; Duodenal diverticulum; Intestinal duplication; Malrotation
Genitourinary disorder	Congenital Finnish nephrosis; Hypoplastic kidney; Polycystic kidneys; Renal vein thrombosis; Bladder outlet obstruction; Dysplastic kidneys
Hepatic disorder	Hepatic fibrosis; Cholestasis; Polycystic liver disease; Biliary atresia; Hepatic calcification; Giant cell hepatitis; Cirrhosis with portal hypertension; Hepatic necrosis
Neoplastic disorder	Neuroblastoma; Teratoma; Congenital leukemia; Pulmonary leiomyosarcoma; Hemangioendothelioma of liver
Metabolic disorder	Gaucher disease; GM_1 gangliosidosis; Mucolipidoses; Mucopolysaccharidoses; Galactosialidosis; Carnitine deficiency; Pyruvate kinase deficiency
Neurologic disorder	Encephalocele; Fetal intracranial hemorrhage; Vein of Galen aneurysm; Porencephaly with absent corpus callosum
Vascular disorder	Arteriovenous malformation; Sacrococcygeal teratoma; Vena caval thrombosis; Hemangioendothelioma; Arterial calcification; Cerebral angioma
Placenta/cord abnormality	Chorioangioma; Chorionic vein thrombosis; Umbilical cord torsion; True knot of cord; Angiomyxoma of cord; Placental hemorrhagic endovasculitis
Maternal abnormalities	Mirror syndrome; Severe maternal anemia, diabetes mellitus or hypoproteinemia; Maternal indomethacin use

Figure 128-1 Prenatal ultrasound image of fetus at 26 weeks with nonimmune hydrops. Sagittal view demonstrates extensive ascites and pleural effusions.

NIHF may initially present with an isolated fluid accumulation in one site, such as pleural effusion with congenital cystic adenomatoid malformation, but as intrathoracic pressure increases and venous return decreases, generalized hydrops may present.

Fetal ascites is diagnosed sonographically by the visualization of an echolucent rim encompassing the entire fetal abdomen in a transverse view (see Figure 128-1). Loops of bowel and the outline of the fetal liver, spleen, bladder, and diaphragm are generally more easily seen in the presence of ascites. Pericardial effusion is diagnosed by the appearance of an echolucent rim of at least 1 to 3 mm thickness around both cardiac ventricles. Pleural effusion, which may be unilateral or bilateral, also presents as an echolucent space outlining the diaphragm.

Figure 128-2 Prenatal ultrasound image of fetus at 30 weeks with nonimmune hydrops. Transverse view through fetal chest demonstrates extensive pleural effusion with deviation of cardiac axis to left.

Other sonographic features of NIHF will depend on the cause of the hydrops. A careful fetal anatomical survey, including fetal echocardiography, should be performed in all cases to detect any associated structural fetal malformations. Measurement of the middle cerebral artery peak systolic velocity using Doppler ultrasound can help identify cases of NIHF associated with fetal anemia (Hernandez-Andrade et al., 2004).

DIFFERENTIAL DIAGNOSIS

Following the sonographic diagnosis of hydrops the first step is to differentiate between immune and nonimmune causes. This is easily accomplished by the performance of a maternal indirect Coombs test to screen for antibodies associated with blood group incompatibility.

Following the exclusion of immune causes of hydrops, each condition listed in Table 128-1 should be considered when trying to determine the cause of NIHF. This is accomplished by a review of maternal and paternal histories, detailed fetal sonographic survey, and the use of appropriate diagnostic laboratory studies.

ANTENATAL NATURAL HISTORY

The precise antenatal natural history of NIHF depends entirely on the underlying cause. The natural history of hydrops is poorly understood, so little information is available regarding prognostic factors to predict in utero progression. In general, NIHF is associated with a 75% to 90% fetal mortality rate (Romero et al., 1988). The progression of fetal signs and development reflects the underlying cause. Cases of NIHF secondary to fetal parvovirus B19 infection, for example, may result in intrauterine fetal death or may result in spontaneous resolution. By contrast, cases of NIHF associated with structural cardiac malformation almost always result in intrauterine fetal death or early neonatal death. No series are available for review describing sufficient cases of NIHF caused by each individual underlying cause, to enable accurate prediction of antenatal natural history.

MANAGEMENT OF PREGNANCY

Following the sonographic detection of hydrops, the pregnant woman should be promptly referred to a tertiary care facility, with availability of a multidisciplinary team consisting of perinatologists, neonatologists, clinical geneticists,

and other pediatric subspecialists. Careful maternal and paternal histories should be obtained, to evaluate for possible health problems, family histories, or ethnic predisposition to any of the conditions listed in Table 128-1. Maternal blood work should include an indirect Coombs antibody screen, maternal blood type, Kleihauer–Betke stain, complete blood count with differential and erythrocyte indexes, hemoglobin electrophoresis, and glucose-6-phosphate dehydrogenase deficiency screen. Additional maternal blood work should include an evaluation for infectious diseases, including TORCH (toxoplasmosis, rubella, cytomegalovirus, and herpes simplex) titers, rapid plasma reagent test, and parvovirus B19 IgG and IgM titers.

A detailed fetal sonographic anatomy survey should be performed to evaluate for possible associated structural malformations. Because of the strong association between NIHF and cardiac malformations, fetal echocardiography should also be performed, with particular attention paid to possible fetal rhythm disturbances. Fetal heart rate monitoring for 12 to 24 hours should be considered to rule out an underlying fetal arrhythmia.

Invasive testing for fetal karyotype should also be offered. This can be performed by means of amniocentesis, with the use of fluorescence in situ hybridization or polymerase chain reaction (PCR), to facilitate a rapid diagnosis of the common aneuploidies. While previously the preferred invasive diagnostic procedure at late gestational age was a fetal percutaneous umbilical blood sample (PUBS), this is now rarely necessary. The previously cited advantage of a PUBS was that it allowed rapid determination of fetal karyotype, in addition to providing details of fetal hematocrit, platelet count, liver-function tests, hemoglobin electrophoresis, and fetal IgM specific to the various infectious causes of NIHF. In addition, it also allowed the opportunity to transfuse the fetus with packed red cells immediately if profound fetal anemia is diagnosed. However, given the precision of middle cerebral artery Doppler evaluation in predicting the anemic fetus, and the easy availability of either FISH or PCR for rapid chromosome evaluation, the need for PUBS continues to decrease. Amniotic fluid (obtained either at the same time as a PUBS or by amniocentesis) may be sent for α-fetoprotein level (increased in Finnish nephrosis and sacrococcygeal teratoma), and polymerase chain reaction (PCR) testing for infectious agents. Metabolic testing can also be performed on amniotic fluid when a specific disorder is suspected.

Following the laboratory and sonographic evaluation, a diagnosis of idiopathic NIHF, or NIHF secondary to a specific condition, will be made. If a specific underlying cause has been discovered, patient counseling will be dictated by the particular abnormality. In general, the presence of hydrops together with a structural malformation, such as cardiac abnormality, is associated with a very poor prognosis. Counseling should therefore also include the possibility of elective pregnancy termination, depending on the gestational age at presentation. Patients should be counseled by a multidisciplinary team that includes a perinatologist, neonatologist, geneticist, and appropriate additional pediatric subspecialists. Options for fetal intervention to treat the underlying problem and hydrops are available and are discussed in the following section.

If expectant management of the fetus with NIHF is chosen, careful sonographic surveillance should be performed, including biophysical profiles on a frequent basis. The precise timing of fetal surveillance testing is uncertain and depends on the gestational age at presentation. If the fetus is considered viable, it may be reasonable to admit the mother and perform daily fetal testing with nonstress tests or biophysical profiles. If the hydrops appears to be resolving it would be reasonable to decrease the frequency of testing, provided that fetal testing has been reassuring to date. Repeat sonographic fetal anatomy surveys should be performed every 2 weeks to confirm appropriate fetal growth and to improve the chances of detecting an underlying structural fetal malformation.

Timing of delivery is also uncertain with NIHF. Depending on the gestational age, premature delivery may be indicated if fetal testing becomes nonreassuring. Otherwise, the most common practice is to continue expectant management until 37 weeks of gestation, or until fetal lung maturity has been confirmed by amniocentesis. It is possible that mature lecithin:sphingomyelin ratios may be less frequently obtained near term in the fetus with hydrops, as compared with nonhydropic fetuses (Romero et al., 1988). Expectant management may also be complicated by preeclampsia in up to 50% of cases, and this may necessitate immediate preterm delivery. In addition, NIHF is frequently associated with polyhydramnios, which may precipitate preterm labor due to uterine overdistention. Periodic reduction amniocenteses may be required to relieve maternal discomfort from severe polyhydramnios.

The optimal mode of delivery for the hydropic fetus is uncertain, as the overall prognosis is poor regardless of the form of delivery. Because of the risk of soft-tissue dystocia associated with hydrops, it is generally advisable to deliver all potentially viable fetuses with NIHF by cesarean. This should minimize the chances of maternal and fetal trauma. In cases in which the fetus is not expected to survive, the option of therapeutic thoracentesis or paracentesis to optimize a vaginal delivery is also reasonable. However, patients should be made aware of the extremely small likelihood of neonatal survival. The optimal location of delivery should be a tertiary care center, with the immediate availability of skilled neonatologists and other appropriate pediatric subspecialists.

FETAL INTERVENTION

The option of fetal therapy in select cases of NIHF is possible. The underlying pathology that is most amenable to prenatal therapy is fetal anemia. When a diagnostic PUBS is undertaken for any fetus with NIHF, immediate transfusion of packed red cells, if profound fetal anemia is diagnosed, should be performed. Arrangements prior to performance of a PUBS

in such cases should include preparation of group O, irradiated, packed red blood cells that are anticytomegalovirus negative, $Rh_o(D)$ negative, Kell negative, and cross-matched compatible with maternal serum. The unit of red cells should be tightly packed with a hematocrit of at least 80%, and a blood transfusion setup should be primed as the diagnostic PUBS is performed. This will ensure that prompt intravascular fetal transfusion can be performed as soon as significant fetal anemia is diagnosed, and prior to withdrawal of the needle from the umbilical vein. Once a fetal hematocrit of less than 30% is detected, fetal intravascular transfusion should begin. Fetal paralysis with pancuronium or vecuronium is generally not required in cases of hydrops, as fetal activity is often minimal.

The volume of packed red cells to be transfused is derived using formulas that take into account the starting hematocrit, hematocrit of transfused blood, target hematocrit, and a correction factor for the volume of blood in the placental circulation. A commonly used formula for volume of blood to be transfused is

$$V_T = \frac{(\text{desired final hematocrit} - \text{initial fetal hematocrit})}{(\text{donor blood hematocrit})} \times (150) \times (\text{EFW})$$

where V_T is volume of blood transfused, 150 is a placental correction factor, and EFW is the estimated fetal weight in kilograms (Kaufman and Paidas, 1994). It is generally not advisable to transfuse a hydropic fetus to a final hematocrit that is either greater than 25% or greater than four times the initial hematocrit (Radunovic et al., 1992). This has been associated with fluid overload and sudden intrauterine fetal death. In cases of NIHF secondary to fetal anemia, the goal of the first intrauterine transfusion should be a hematocrit of 20% to 25%, and the transfusion should then be repeated in 48 to 72 hours to bring the final hematocrit to a level of 40% to 45%. For many fetuses with NIHF and anemia secondary to parvovirus B19 infection, this transfusion may be all that is needed to maintain a normal fetal hematocrit, as the initial insult to the fetal marrow is generally self-limiting. Another therapeutic option for fetuses with NIHF and anemia is to perform a combined intravascular and intraperitoneal transfusion, with the intravascular aliquot of blood designed to provide an acute increase in fetal hematocrit and the intraperitoneal aliquot designed to provide a slower sustained increase in hematocrit. To date there are no adequate series comparing these different approaches for the treatment of NIHF secondary to fetal anemia.

Other forms of fetal intervention for NIHF include medical therapy for the mother to correct fetal arrhythmias (see Chapters 42 and 54). Digoxin administration to pregnant women has been successful in the treatment of fetal arrhythmias, with resolution of hydrops in some cases (Knilans, 1995).

Surgical treatment for the fetus with NIHF is also possible. Fetal thoracentesis may be performed under sonographic guidance with resolution of pleural effusions (Jones, 1995). If repeat thoracenteses are needed, consideration should be given to placement of a thoracoamniotic shunt. Such procedures are likely to be beneficial only for cases of NIHF in which pleural effusions are secondary to intrinsic thoracic malformations. Other surgical procedures that can be considered for fetuses with NIHF and underlying structural malformations include open fetal surgical resection of thoracic masses or sacrococcygeal teratoma (Bullard and Harrison, 1995). However, few data are available confirming whether such invasive approaches have a significant impact on fetal or neonatal outcome.

TREATMENT OF THE NEWBORN

Infants with hydrops should be delivered in a tertiary care center with immediate availability of a multidisciplinary neonatal resuscitation team. Immediate neonatal endotracheal intubation will almost certainly be needed, and such intubations can be technically difficult (Carlton et al., 1989). A high-frequency ventilator and high airway-pressure settings may be needed to achieve adequate gas exchange. Paracentesis and thoracentesis, with placement of bilateral chest tubes, may also be needed to allow adequate ventilation and effective gas exchange. Placement of umbilical artery and umbilical vein lines may be needed to aid in the resuscitation (McMahan and Donovan, 1995). Use of blood products, albumin, and diuretics may be needed to effectively maintain adequate intravascular volume without significant fluid overload or soft-tissue edema.

If the neonate can be stabilized in the delivery room, transport to a neonatal intensive care unit should be arranged promptly. This should be followed by a thorough physical examination, with the aid of appropriate radiologic investigations and echocardiography, to confirm absence of significant structural malformation. If additional structural malformations are detected, specific therapy should be tailored to the individual abnormalities. Appropriate pediatric subspecialist consultation, including a clinical geneticist, should also be arranged.

SURGICAL TREATMENT

Possible surgical treatments for fetal hydrops include fetal thoracoamniotic shunt placement for cases of NIHF associated with thoracic masses or persistent pleural effusions. Open fetal surgical resection of thoracic masses, such as congenital cystic adenomatoid malformation (see Chapter 35) and bronchopulmonary sequestration (see Chapter 34), are also possible (Bullard and Harrison, 1995). Open surgical resection of fetal sacrococcygeal teratoma with associated hydrops is also possible, although there are so few cases that it is currently difficult to evaluate the role of such invasive procedures (see Chapter 115).

LONG-TERM OUTCOME

The prognosis for infants with hydrops depends entirely on the nature of any underlying abnormalities. The perinatal mortality rate ranges from 40% to 90%, depending on the cause, but may approach 100% in cases of NIHF associated with structural cardiac malformations (Romero et al., 1988; Wilkins, 1999; Jones, 1995). No long-term studies are available for counseling parents on the likely survival or morbidity if a successful neonatal resuscitation is achieved.

GENETICS AND RECURRENCE RISK

A postmortem examination is indicated in all cases of NIHF that result in fetal or neonatal death. This will maximize the number of cases in which a definite underlying cause is identified and will facilitate appropriate genetic counseling and prediction of recurrence risk (Steiner, 1995). Recurrence of idiopathic NIHF is rare, although case series of recurrences have been documented (Wilkins, 1999). In one case series, one mother had three consecutive pregnancies complicated by recurrent idiopathic NIHF and another had two consecutive pregnancies complicated by recurrent idiopathic NIHF (Onwude et al., 1992). Patients should therefore be made aware that, while idiopathic NIHF is extremely rare, recurrences can and do occur.

Management of Fetal Chromosome Abnormalities

This page intentionally left blank

Trisomy 13

129 CHAPTER

Key Points

- Third most common liveborn autosomal aneuploidy. Incidence is approximately 1 in 5000 livebirths.
- Sonographic findings include holoprosencephaly, abnormal midface, congenital heart defects, polydactyly, and echogenic kidneys. First trimester findings include increased nuchal translucency measurement, fetal tachycardia, and early onset growth restriction.
- Differential diagnosis includes pseudotrisomy 13, Meckel–Gruber syndrome, Bardet–Biedl syndrome, and Smith–Lemli–Opitz syndrome.
- Associated with increased lethality in utero, and increased incidence of preeclampsia.
- 80% of patients have full trisomy 13; 20% have mosaicism or a translocation. If a translocation is demonstrated, parental chromosomes should be studied.
- Prognosis is uniformly poor. Median survival time is 7 to 10 days. Five to 10% of patients survive up to one year of age.

CONDITION

Trisomy 13 presents as constellation of congenital anomalies that result from the presence of an extra chromosome 13, either whole or translocated onto another chromosome. It is not known how the presence of the extra chromosome disrupts so many different systems during organogenesis.

Although the clinical findings of the condition were previously known, the association of the extra chromosome with the clinical syndrome was not described until 1960 (Patau et al., 1960). Synonyms for trisomy 13 include trisomy D or Patau syndrome.

INCIDENCE

Trisomy 13 is the third most common liveborn autosomal aneuploidy. The incidence of trisomy 13 has been variously reported as 1 in 2206 to 1 in 7602 livebirths (Taylor, 1968). Most authors give the approximate incidence figure of 1 in 5000 livebirths (Wladimiroff et al., 1989). The incidence of trisomy 13 is equal among all races. It is thought that there are equal numbers of conceptuses of both genders. However, a slight excess of females exists at birth presumably due to a survival advantage (Jacobs et al., 1987).

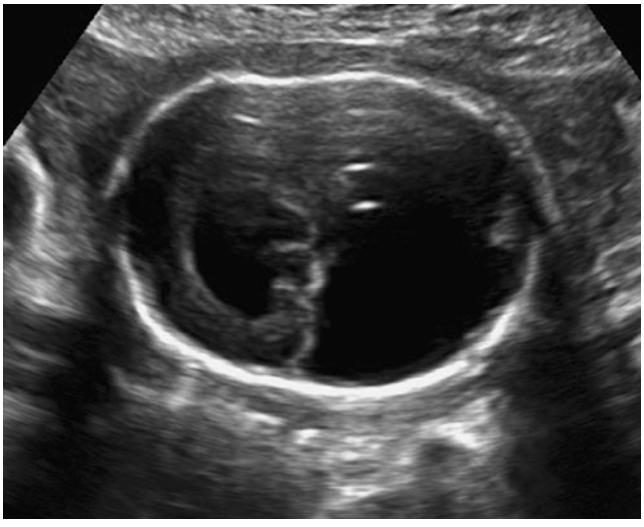

Figure 129-1 Transaxial view of fetal head indicating alobar holoprosencephaly in a fetus at 23 weeks with trisomy 13.

SONOGRAPHIC FINDINGS

Fetuses with trisomy 13 are more active in utero than comparable fetuses with trisomy 18. In addition, fetuses with trisomy 13 have a higher frequency of major congenital anomalies than fetuses with trisomy 21. The most common major abnormality seen in trisomy 13 is holoprosencephaly, which can be seen as early as 12 weeks of gestation (Figure 129-1). Other important findings associated with trisomy 13 include an abnormal midface with hypotelorism, cleft lip or palate, and even cyclopia (see Chapter 14) (Figure 129-2). Many studies have shown that there is a greatly increased incidence of congenital heart disease in fetuses affected with trisomy 13

Figure 129-2 Sonographic profile of a fetus with trisomy 13 demonstrating severely abnormal midface with proboscis and absent orbit.

(Wladimiroff et al., 1995). The most common cardiac defects include ventricular septal defect (VSD), hypoplastic left ventricle, or double outlet right ventricle. Other common sonographic findings include ulnar/fibular polydactyly and echogenic or polycystic kidneys. In one study, all fetuses with trisomy 13 had one or more sonographic abnormalities or abnormal measurements present (Seoud et al., 1994).

Benacerraf et al. (1988, 1992, 1994) developed a sonographic scoring index to identify fetuses with aneuploidy. She and her co-authors gave 2 points for nuchal thickening of greater than 6 mm, 2 points for demonstration of a major structural defect, and 1 point each for a short femur, short humerus, and the presence of renal pyelectasis. This scoring system identified 2 of 2 fetuses with trisomy 13. In another report, Benacerraf et al. (1986) demonstrated that 6 of 6 affected fetuses with trisomy 13 had holoprosencephaly and a severely malformed face.

In the largest study of sonographic abnormalities in 33 consecutive fetuses with trisomy 13, Lehman et al. (1995) demonstrated that 91% of affected fetuses had one or more sonographically detectable abnormalities. In this study, 18 of the 33 fetuses described were at less than 20 weeks of gestation, and 15 of the affected fetuses were at greater than 20 weeks of gestation. The mean gestational age for the fetuses in the study was 20.7 weeks. Thirty of the 33 fetuses had structural abnormalities, as documented in Table 129-1. Only 3 of the fetuses had no sonographically detectable abnormalities. The most common abnormalities observed were holoprosencephaly, other central nervous system abnormalities, facial abnormalities, and cardiac defects (Table 129-1).

An increased nuchal translucency measurement for gestational age is also associated with trisomy 13 (Pandya et al., 1994). In the Pandya study, 80% of fetuses with trisomy 13, 18, or 21 had a nuchal translucency of at least 3 mm. Omphalocele is also somewhat frequent in fetuses with trisomy 13. In the presence of an omphalocele, the risk of trisomy of 13 or 18 is increased by 340-fold (Snijders et al., 1995).

First trimester sonographic findings in fetuses with trisomy 13 include increased nuchal translucency measurement, early onset fetal growth restriction, fetal tachycardia (2/3 of cases), holoprosencephaly, megacystis and omphalocele (Snijders et al., 1999; Nicolaides, 2004). Nonspecific sonographic markers seen in trisomy 13 include mild dilatation of the lateral cerebral ventricles, echogenic bowel, and echogenic intracardiac foci (EIF). The combination of EIF and a hypoplastic left heart is characteristic of trisomy 13 (Nyberg and Souter, 2001).

In summary, fetuses with holoprosencephaly, cardiac abnormalities, evidence of facial clefting or midface anomalies, and possibly polydactyly should strongly suggest a diagnosis of trisomy 13 (Twining and Zuccollo, 1993).

DIFFERENTIAL DIAGNOSIS

Since holoprosencephaly is one of the most commonly found malformations in trisomy 13, isolated holoprosencephaly

Table 129-1

Prenatal Ultrasound Findings in 33 Fetuses with Trisomy 13 Syndrome*

should be considered within the differential diagnosis (see Chapter 14). Trisomy 13 is a diagnosis that can be made definitively only by karyotyping. Prior to obtaining karyotype results, however, the following diagnoses should also be considered: pseudotrisomy 13 (Cohen–Gorlin syndrome), Smith–Lemli–Opitz syndrome, Meckel–Gruber syndrome, Bardet–Biedl syndrome, and Pallister–Hall syndrome.

Pseudotrisomy 13 syndrome has been described to encompass the triad of normal chromosomes, holoprosencephaly, and ulnar-fibular polydactyly (Seller et al., 1993). The phenotype has been expanded to include hypoplastic radii (Boles et al., 1992). The inheritance of this condition is autosomal recessive and carries a 25% risk of recurrence. Neither holoprosencephaly nor polydactyly is an obligatory manifestation of pseudotrisomy 13. Each of these anomalies is found only in 60% of affected siblings. The diagnostic criteria for this condition are a normal karyotype with either holoprosencephaly and ulnar-fibular polydactyly, or holoprosencephaly plus other major malformations without polydactyly, or ulnar-fibular polydactyly with other brain defects, such as microcephaly, hydrocephaly, or agenesis of the corpus callosum, with the presence of other malformations (Lurie and Wulfsberg, 1993). Other specific organ findings can distinguish trisomy 13 from pseudotrisomy 13 in the absence of karyotyping. For example, patients with trisomy 13 have a very characteristic type of renal cystic dysplasia, whereas patients with pseudotrisomy 13 have hypoplastic kidneys but no evidence of cysts. Patients with trisomy 13 have hydronephrosis and patients with pseudotrisomy 13 have horseshoe kidneys. Scalp defects (Figure 129-3) and a pathognomonic type of pancreatic fibrosis are present in patients with trisomy 13; neither of these findings is present in pseudotrisomy 13.

Another important consideration in the differential diagnosis is Meckel–Gruber syndrome. This condition was described in 1822 by Meckel and redefined by Gruber in 1934, who called the condition "dysencephalia splanchnocystica." In this condition, 100% of affected patients have polycystic kidneys, 80% have encephalocele, 70% have polydactyly, and 30% have cleft lip and palate. This condition is also inherited as an autosomal recessive (Miller, 1983). In a study of 38 affected siblings, the cystic renal dysplasia was invariably present. The other findings associated with the condition, however, were less common. For example, occipital meningocele was present in only 63% of siblings and polydactyly was present in only 55% of siblings (Miller, 1983). Meckel–Gruber syndrome is associated with increased levels of α-fetoprotein in the amniotic fluid.

Figure 129-3 Scalp defects in an infant with trisomy 13.

ANTENATAL NATURAL HISTORY

Trisomy 13 is associated with increased lethality in utero. For every trisomy 13 patient born alive, approximately 50 are lost prenatally as a spontaneous abortion (Jacobs et al., 1987). In one study, Jacobs et al. (1987) described a series of 2922 spontaneous abortuses who were karyotyped. Of these, 62 had trisomy 13. Forty-six had 47 chromosomes, consistent with a full trisomy. Sixteen had translocation trisomy 13. A similar proportion of translocation cases to full trisomy cases were seen in this study as is seen in liveborn infants. Therefore, full trisomy 13 and translocation trisomy 13 are similar with respect to their effect on intrauterine mortality. In this spontaneous abortion study, trisomy 13 was shown to be the fourth most common trisomy (after trisomies 16, 21, and 22).

With regard to antenatal natural history, the mean gestational age of the fetuses with full trisomy 13 that spontaneously miscarried was 79.8 days and translocation trisomy 13, 82.6 days. These ages are significantly less than the fetuses with normal chromosomes that were miscarried. Only 5 of the trisomy 13 conceptuses in the study were older than 100 days of gestational age. This data suggests that specific stages in development exist in which trisomy 13 conceptuses are likely to die, but if they survive, they may survive until term.

MANAGEMENT OF PREGNANCY

Fetuses with sonographic evidence of either holoprosencephaly or congenital heart disease in addition to other structural abnormalities or intrauterine growth restriction should have karyotyping performed (Figure 129-4). Once the diagnosis of trisomy 13 has been made, the prospective parents should have the opportunity to speak with a medical geneticist regarding the implications of this diagnosis. The overall prognosis for extra uterine survival for an infant with trisomy 13 is extremely poor. In addition, there are complications for the mother when a diagnosis of trisomy 13 has been made. In particular, trisomy 13 is associated with increased risk of the mother developing preeclampsia. This was first noted by Boyd et al. (1987) who described five nulliparous women who had a fetus with trisomy 13; severe preeclampsia developed in all of the mothers. The medical records of these women were compared with four women whose first babies had

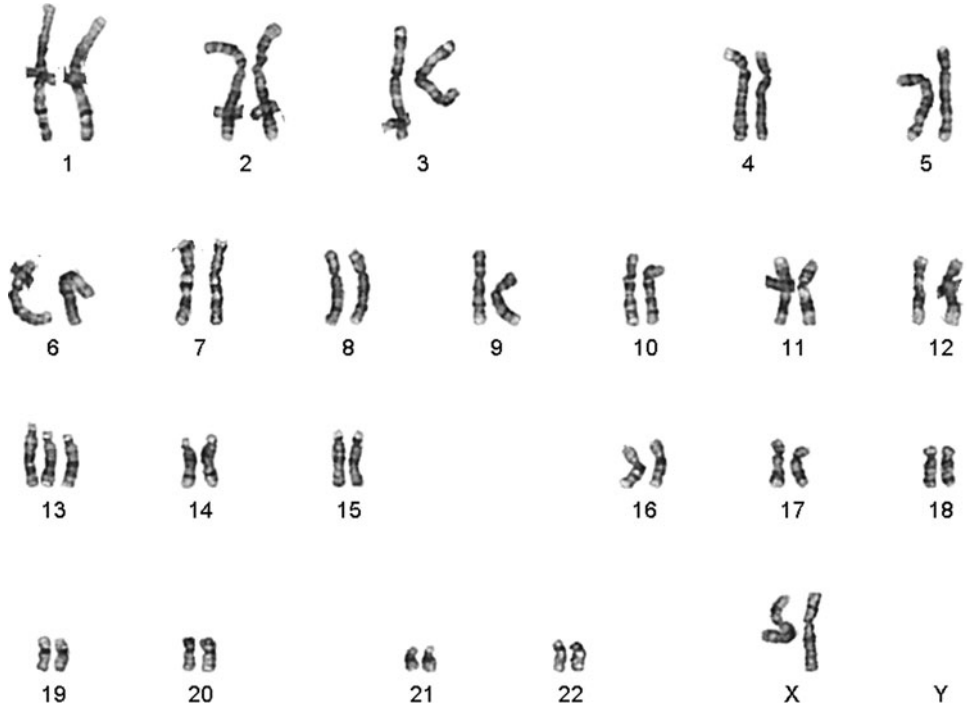

Figure 129-4 The karyotype in a female fetus with trisomy 13. (*Courtesy of Dr. Janet Cowan.*)

trisomy 18 and seven women whose first babies had trisomy 21; preeclampsia did not develop in any of these women. A similar finding was not seen in control patients. The association between trisomy 13 and preeclampsia was later extended in a study of 25 women who gave birth to an infant with trisomy 13. These investigators showed that the incidence of preeclampsia is significantly higher when the fetus has trisomy 13 as compared with pregnancies in which the fetus has trisomy 18 or a normal karyotype (Tuohy and James, 1992). Interestingly, pregnant women carrying a trisomy 13 fetus have excess circulating soluble fmslike tyrosine kinase-1 and decreased circulating placental growth factor (Bdolah et al., 2006). The gene for soluble fms-like tyrosine kinase-1 maps to chromosome 13q12, so it is hypothesized that the extra copy of this gene affects maternalcirculating angiogenic proteins, which may account for the increased incidence of preeclampsia in trisomy 13 pregnancies.

The current second trimester maternal quadruple serum screen (α-fetoprotein, human chorionic gonadotropin, unconjugated estriol, inhibin-A) does not detect fetuses with trisomy 13. A newer serum analyte, pregnancy-associated plasma protein A (PAPP-A) may be more useful in the first trimester detection of fetuses with trisomy 13. The median maternal serum PAPP-A levels are significantly lower in pregnancies that have a trisomy 13 fetus than in normal pregnancies. A level of less than 0.4 multiples of the median (MoM) detects 89% of fetuses with trisomy 13 at a calculated false-positive rate of 5% (Brizot et al., 1994). Maternal cell free fetal DNA levels are increased in archived second trimester serum samples of women carrying fetuses with trisomy 13 (Wataganara et al., 2003).

If the diagnosis of trisomy 13 is made before 24 weeks of gestation, the parents should be offered the opportunity to terminate the pregnancy. If a definite diagnosis of trisomy 13 is made after 24 weeks of gestation there is no need to deliver at a tertiary care center, provided that the community obstetrician and pediatrician are comfortable with providing supportive care for the affected infant. The experience of a couple's decision to continue an affected pregnancy and deliver their son has been published (Locock, 2005).

FETAL INTERVENTION

There are no fetal interventions for trisomy 13.

TREATMENT OF THE NEWBORN

Most infants with trisomy 13 deliver between 38 and 40 weeks of gestation, with an average birth weight of 2.48 kg (Warkany et al., 1966). The most common physical findings in liveborn infants with trisomy 13 include scalp defects, which are often confused with lacerations made by fetal scalp electrodes; microcephaly with a sloping forehead; microphthalmia; cleft lip and palate; congenital heart disease in 80% to 100% of patients; omphalocele; genital abnormalities, including cryptorchidism in all males, with micropenis in some males, and bicornuate uterus with ovarian abnormalities in most females; cystic kidneys; polydactyly, which is the most frequent external malformation of trisomy 13; and capillary

hemangiomata (Hodes et al., 1978). Laboratory findings include abnormalities in the complete blood count, manifested by an increased frequency of nuclear projections in polymorphonuclear leukocytes and persistence of fetal hemoglobin. Infants, who are delivered with a suspected diagnosis of trisomy 13, but without an antenatal confirmatory chromosome analysis, should have karyotyping performed. Peripheral blood leukocytes should give a definitive answer within 48 hours. If an affected infant has a life threatening anatomic obstruction requiring surgery, fluorescence in situ hybridization (FISH) can be performed using a chromosome 13-specific probe. This study will give a tentative diagnosis of trisomy 13 within a few hours of obtaining the blood sample.

Because the few infants who survive with trisomy 13 are severely retarded, usually only comfort measures are indicated. Early involvement of a medical genetics team is recommended to provide family support, to provide continuity of care if the infant is discharged to home, and to counsel about risk recurrence. Most infants with trisomy 13 die during the perinatal period.

Autopsy findings in 12 cases of trisomy 13 were described by Moerman et al. (1988). Of the 12 cases, 6 were liveborn, 1 was stillborn, 4 were terminated electively, and 1 died in utero. The longest survival postnatally was 6 days of age. Severe craniofacial, ocular, and cerebral malformations were noted in 10 of 12 patients (Figure 129-5). Eight of the 12 had holoprosencephaly. In all cases in which the eyes were examined, retinal dysplasia was present. The main cardiovascular anomalies were ventricular septal defect and abnormalities of the arterial valves. Four of 12 patients had complex cardiac disease, including tetralogy of Fallot or double outlet right ventricle. Interestingly, 11 of 12 patients had malformations of the gastrointestinal tract, specifically malrotation and unfixed mesentery. A pathognomonic microscopic pancreatic dysplasia was also present. Renal cystic disease was demonstrated in most patients. Renal cysts became more prominent in number and diameter as gestational age increased. Congenital malformations of the Müllerian duct system were present in 5 of 8 affected females. The ovaries were invariably small and demonstrated ovarian dysgenesis (Moerman et al., 1988).

Figure 129-5 Infant with trisomy 13, showing severe midface abnormalities, including cleft lip and palate. The infant also has postaxial polydactyly of the left hand.

SURGICAL TREATMENT

Surgical treatment is indicated only as a temporizing measure to allow a potentially affected infant with trisomy 13 to survive long enough to make a definitive diagnosis. Surgical treatment does not improve or change the overall prognosis.

LONG-TERM OUTCOME

Rasmussen et al. (2003) used two population-based strategies to determine mortality in trisomy 13. The median survival time was 7 to 10 days. Five to 10% of patients survived to at least one year of age. Race and gender seemed to affect survival in that females and blacks had higher median ages at death. All infants who survive the perinatal period are severely retarded. Postnatal survival is inversely correlated with the severity of cardiac and brain anomalies.

Common medical problems for affected infants with trisomy 13 who survive beyond 1 month of age include feeding difficulties, gastroesophageal reflux, poor postnatal growth, apnea, seizures, hypertension, severe developmental delay, and scoliosis. Early puberty (at 8 ½ years) was described in a female with full trisomy 13 who survived until the age of 12 years, 2 months (Iliopoulos et al., 2006). A support organization exists for parents of long-term survivors with trisomies 13 and 18. The organization is known as S.O.F.T. (Support Organization for Trisomies 13 and 18). This organization recommends routine child care and anticipatory guidance, thorough cardiac evaluation, antibiotics prior to dental procedures if a cardiac abnormality is present, hearing evaluation, evaluation by an infant preschool intervention team, screening for scoliosis, and ongoing social support for families.

GENETICS AND RECURRENCE RISK

Eighty percent of affected individuals with trisomy 13 have the full trisomy due to meiotic or mitotic nondisjunction (47, XX, +13 or 47, XY +13). Twenty percent of patients have mosaicism or a translocation. The proportion of cases of translocation trisomy 13 (20% to 25%) is much higher than that seen in trisomy 21 (4%) (Jacobs et al., 1987). The mean maternal age is increased for the full trisomies but not for translocations, although the rate of increased risk with advanced maternal age does not increase as sharply as for trisomies 18 and 21 (Schreinemachers et al., 1982).

Hassold et al. (1987) used chromosome heteromorphisms and restriction fragment length polymorphisms

(RFLPs) to determine parental origin of the extra chromosome in 33 cases of trisomy 13. In 68% of cases, maternal meiosis I was the source of the error. This study demonstrated that pairing failure is not the primary cause of trisomy 13, as crossing over between the two nondisjoined chromosomes was detected in almost all of the cases studied. In the cases of mosaic trisomy 13, these authors demonstrated that conception began as a trisomic zygote. Subsequently, the paternal copy of chromosome 13 was lost in some cells with remaining maternal disomy due to a maternal meiosis type I error.

When the affected fetus or infant has been shown to have the full trisomy 13, the recurrence risk is 1% or the risk according to maternal age, whichever is higher. For the affected infant with a translocation, parental chromosomes should be studied. If the parents are both shown to be normal, there is less than a 1% risk of recurrence. If one parent has a balanced translocation involving chromosome 13, there is a 20% risk of a spontaneous abortion and a 5% risk of a liveborn infant with trisomy 13 in subsequent pregnancies. However, if one of the parents is demonstrated to have a robertsonian translocation (a translocation between two acrocentric chromosomes that results in the loss of ribosomal material in the short arm and fusion between the two centromeres) between both copies of chromosome 13, no normal offspring are possible, and gamete donation should be considered. For parents who have had a fetus or infant with trisomy 13, prenatal diagnosis in subsequent pregnancies can be achieved by obtaining a karyotype on chorionic villus material or on amniocytes obtained at midtrimester amniocentesis.

130 CHAPTER Trisomy 18

Key Points

- Second most common autosomal trisomy in liveborn infants.
- Eighty to 85% of cases result from full trisomy, 10% are mosaics, and 5% are due to translocation.
- Incidence is about 1 in 3000 livebirths. Females are more likely to be born alive and survive longer.
- Most affected fetuses have more than one sonographic abnormality. Most common sonographic abnormalities include IUGR, cardiac structural anomalies, choroid plexus cysts, central nervous system anomalies, and overlapping fingers/clenched hands.
- Associated with low maternal serum screening levels of pregnancy-associated plasma protein A, estriol, α-fetoprotein, and β human chorionic gonadotropin.
- Median postnatal survival for males is 1 to 2 months, and for females it is 9 to 10 months. The presence of a heart defect (surprisingly) does not affect postnatal survival time. About 5% to 10% of infants survive until their first birthday.
- All long-term survivors are profoundly retarded. Despite this, there are increasing reports in the literature of aggressive postnatal treatment, including mechanical ventilation, cardiovascular drugs, parenteral nutrition, and surgical repair of congenital anomalies.
- Reports exist of adults with mosaic trisomy 18 who have normal intelligence.

CONDITION

Trisomy 18 is a chromosomal abnormality that results from the presence of an extra copy of chromosome 18. It is the second most common autosomal trisomy in liveborn infants. The clinical features associated with the abnormality were first described by Edwards in 1960. The condition is also known as Edwards syndrome or trisomy E. Of patients with trisomy 18, 80% to 85% have a full extra copy of chromosome 18 in all of their cells, 10% have mosaicism, with a normal cell line in some of their cells, and 5% have the long arm of chromosome 18 translocated onto another chromosome (Hill, 1996).

INCIDENCE

The incidence of trisomy 18 varies from approximately 1 in 3000 to 1 in 7000 livebirths. The specific incidence of trisomy 18 in Leicestershire, England, was studied during the years 1980 through 1985. At that time the incidence was noted to be 1 in 3086 livebirths (Young et al., 1986). A less frequent incidence of 1 in 6806 livebirths was noted during a 10-year period in Denmark (Goldstein and Nielsen, 1988). The incidence of trisomy 18 mosaicism is approximately 1 in 70,000 livebirths (Bass et al., 1982). Interestingly, the sex ratio of fetuses and livebirths with trisomy 18 differs. Sex ratios are defined as the number of males divided by the number of females. In prenatal normal controls, the ratio is 1.07. The sex ratio for fetal cases of trisomy 18 is 0.90 and for livebirths it is 0.63. Therefore, a clear-cut differential natural selection against males with trisomy 18 exists after 16 weeks of gestation (Huether et al., 1996). Females with trisomy 18 are more likely to be born alive and survive longer than males (Rasmussen et al., 2003; Lin et al., 2006; Niedrist et al., 2006).

SONOGRAPHIC FINDINGS

Nyberg et al. (1993) reviewed prenatal sonographic findings in 47 consecutive fetuses with trisomy 18. They documented that the type and frequency of sonographic abnormalities varies with gestational age (Table 130-1). Excluding choroid

Table 130-1

Frequency of Abnormalities Among 47 Fetuses with Trisomy 18 Examined with Prenatal Sonography by Menstrual Age at Detection

	Time of Sonographic Examination*		
Sonographic Abnormality	**14–24 Weeks ($n = 29$)**	**24–40 Weeks ($n = 18$)**	**Total Ultrasound Findings ($n = 47$)**
Cystic hygroma or nuchal thickening	9 (31%)†	0 (0%)	9 (19%)
Omphalocele	5 (17%)	5 (28%)	10 (21%)
Large cisterna magna	1 (3%)	8 (44%)	9 (19%)
Cardiac defects	4 (14%)	14 (78%)	18 (38%)
Clenched hands	5 (17%)	4 (22%)	9 (19%)
Clubfeet or rocker-bottom feet	6 (21%)	4 (22%)	10 (21%)
Single umbilical artery	3 (10%)	3 (17%)	6 (13%)
Meningomyelocele	4 (14%)	4 (22%)	8 (17%)
Renal anomaly	5 (17%)	2 (11%)	7 (15%)
Intrauterine growth restriction	8 (28%)	16 (89%)†	24 (51%)

** Numbers in parentheses are percentages.*
† Statistically significant difference ($P < 0.05$) between frequency of detection before 24 weeks versus after 24 weeks.

plexus cysts, one or more sonographic abnormalities were found in 39 of 47 (83%) of fetuses with trisomy 18, including 21 of 29 fetuses examined between 14 and 24 weeks of gestation and 100% of fetuses examined at greater than 24 weeks of gestation. Intrauterine growth restriction (IUGR) was the most common abnormality. It was observed in 51% of all fetuses with trisomy 18 and in 89% of fetuses after 24 weeks of gestation. The most common abnormalities seen before 24 weeks of gestation included cystic hygroma, nuchal thickening, and meningomyelocele. After 24 weeks of gestation, IUGR, cardiac defects, and enlarged cisterna magna were more commonly detected. In this study, choroid plexus cysts were seen in 25% of fetuses with trisomy 18 (Nyberg et al., 1993).

A variety of sonographic abnormalities are seen in fetuses with trisomy 18 (Table 130-2). IUGR occurs as early as the first trimester (Lynch and Berkowitz, 1989). The long bones of the extremities are significantly shortened in trisomy 18 (Droste et al., 1990). This affects the lower extremities more than the upper extremities and this begins before the 18th week of gestation. In addition, Droste et al. (1990) documented a poor correlation between fetal foot length and gestational age by menstrual dating. The results of this study imply a significant effect of this chromosomal abnormality on fetal bone growth. Two sonographic markers, the biparietal diameter (BPD) to femur length (FL) ratio and nuchal translucency measurement were found to be sensitive indicators for the prenatal detection of trisomy 18. A BPD:FL ratio of greater than 1.5 SD above the mean identified three of four fetuses with trisomy 18, whereas nuchal thickening identified two of four fetuses with trisomy 18 (Ginsberg et al., 1990). Combining these sonographic markers gave a positive predictive value of 1 in 47 for the detection of trisomy 18.

A variety of cranial abnormalities are seen in trisomy 18. There is an unusually shaped head with a wide occipitoparietal and narrow frontal diameter. This has been called the "strawberry sign" by Nicolaides et al. (1992). Nicolaides and colleagues hypothesized that the narrowed frontal cranium is due to hypoplasia of the face and underdevelopment of the frontal lobes. The presence of choroid plexus cysts has elicited much debate over the association between this finding and trisomy 18. Choroid plexus cysts are present in 50% of fetuses with trisomy 18, but these are never an isolated finding

Table 130-2

Sonographic Malformations Associated with Trisomy 18

- Craniofacial
  - "Strawberry" calvarium
  - Low-set, abnormally shaped ears
  - Micrognathia
  - Thickened nuchal fold or translucency
- Central nervous system
  - Choroid plexus cysts
  - Meningomyelocele
  - Enlarged cisterna magna
  - Cerebellar hypoplasia
  - Absence of the corpus callosum
  - Microcephaly
- Cardiovascular system
  - Atrial septal defect
  - Membranous ventricular septal defect
  - Double outlet right ventricle
  - Atrioventricular canal defect
  - Coarctation of the aorta
  - Dextroposition of the heart
  - Calcification of the chordae tendineae
  - Two-vessel umbilical cord
  - Pulsatile flow in umbilical vein
  - Abnormal blood flow during atrial contraction
- Gastrointestinal system
  - Omphalocele
  - Diaphragmatic hernia
  - Esophageal atresia with tracheoesophageal fistula
- Urogenital system
  - Horseshoe kidneys
  - Cystic renal dysplasia
  - Hydronephrosis
  - Unilateral renal agenesis
- Skeletal system
  - Overlapping fingers
  - Limb-reduction abnormalities
  - Clubfeet
  - Rocker-bottom feet
- Amniotic fluid volume
  - Polyhydramnios
- Intrauterine growth restriction
  - Small placenta
- Behavioral abnormalities

Source: Hill LM. The sonographic detection of trisomies 13, 18 and 21. Clin Obstet Gynecol. *1996;39:831-850.*

(Seoud et al., 1994; Snijders et al., 1994; Hill, 1996; DeVore, 2000; Yeo et al., 2003). Another cranial sonographic finding associated with trisomy 18 is the presence of an enlarged cisterna magna due to cerebellar hypoplasia. Thurmond et al. (1989) described five fetuses with enlarged cisterna magna, which prompted a search for additional fetal anomalies. These five fetuses had a predicted biparietal diameter less than the measured biparietal diameter, and all turned out to have trisomy 18 (Thurmond et al., 1989).

Although echogenic bowel is more characteristic of fetuses with trisomy 21, it has also been described in fetuses with trisomy 18 (Hamada et al., 1996). Hamada et al., described a normal-appearing fetus during the second trimester, but echogenic bowel developed during the third trimester. They hypothesized that the mechanisms for the echogenic bowel included decreased fetal swallowing, hypoperistalsis, and a hypercellular meconium. They also noted that this fetus was growth-restricted, which potentially caused redistribution of regional blood flow, further causing ischemia of the mesentery and the impairment of bowel motility. These abnormalities resulted in thickened echogenic meconium.

Cardiovascular abnormalities are present in 73% to 90% of fetuses with trisomy 18. Most commonly, these include large ventricular septal defects (VSD), atrial septal defects (ASD), tetralogy of Fallot, and left heart disease (Moyano et al., 2005). Diagnosis of heart malformations can be made reliably in the first trimester. One study suggested that male fetuses with trisomy 18 have more complex congenital heart disease than female fetuses (Chen, 2006). This may be the underlying basis for the increased mortality seen in affected males.

Wladimiroff et al. (1989) described the antenatal sonographic markers in 16 fetuses with trisomy 18. All fetuses had a cardiac abnormality. The majority of these were due to VSDs, double outlet right ventricle, or complete atrioventricular septal defect. The extracardiac structural pathology consisted of abnormal hands and feet, symmetrical IUGR, and polyhydramnios. It is thought that the increased nuchal translucency (see Chapter 2) seen in 90% of affected fetuses with trisomy 18 may be due to the cardiac abnormalities. The increased fluid collection at the back of the neck may be an early sign of congestive heart failure.

A variety of limb abnormalities are also a characteristic of trisomy 18, including the typical overlapping flexed fingers, positional abnormalities of the wrist or fingers, and rocker-bottom feet. Overlapping of the fingers occurs sometime between 12 and 14 weeks (Quintero et al., 1999). The prenatal detection of preaxial upper limb reduction facilitated the diagnosis of trisomy 18 in three cases (Sepulveda et al., 1995). In a report of 7 cases of fetal radial ray reduction malformations, three fetuses had trisomy 18 (Brons et al., 1990).

Figure 130-1 Prenatal sonographic profile of a fetus with trisomy 18. Note the micrognathia and the suggestion of a prominent occiput.

A single umbilical artery (see Chapter 109) is seen in 38% to 50% of fetuses with trisomy 18 (Baty et al., 1994a). Yeo et al. (2003) showed that a short ear length (<10% for gestational age) was present in 96% of fetuses with trisomy 18.

Several investigators have described findings that in combination tend to predict a high risk of trisomy 18. These include the combination of polyhydramnios, abnormal hand posturing, and other major structural abnormalities (Carlson et al., 1992), and abnormalities of the fetal face and extremities (Figures 130-1 and 130-2) (Benacerraf et al., 1986, 1988). Benacerraf and colleagues (1994) developed a scoring system to identify fetuses with trisomy 18 based on the presence of certain sonographic findings. Her group specifically looked for the presence of nuchal translucency, long-bone shortening, choroid plexus cysts, echogenic bowel, and other major anatomic defects. They prospectively evaluated 60 fetuses with various autosomal trisomies between 14 and 21 weeks of gestation and 106 normal fetuses at the same gestational age. A sonographic score of 2 or more enabled the prospective identification of trisomy 18 in 11 of 13 affected fetuses. DeVore (2000) identified six sonographic markers (choroid plexus cysts, central nervous system malformations, abnormal nuchal skin fold, ventricular septal defect, outflow tract abnormalities, and right to left chamber disproportion of the heart) that collectively identify 93% of fetuses with trisomy 18 at a false-positive rate of 8.9%. Snijders et al. (1994) calculated a risk of trisomy 18 relative to maternal age and the number of additional sonographic abnormalities present.

Figure 130-2 Prenatal sonographic image of same fetus shown in Figure 130-1. Note the flexed fingers, which were fixed in position, indicating the presence of camptodactyly.

First trimester sonographic findings observed in fetuses with trisomy 18 include increased nuchal translucency thickness and pulsatile blood flow in the umbilical vein (Sherod et al., 1997; Brown et al., 1999).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of trisomy 18 includes Pena–Shokeir I syndrome, pseudotrisomy 18, and arthrogryposis multiplex congenita (see Chapter 101).

Pena–Shokeir I syndrome is an autosomal recessive syndrome whose hallmark features include IUGR, low-set malformed ears, a depressed tip of the nose, small mouth, micrognathia, multiple flexion contractures, camptodactyly, rocker-bottom feet, pulmonary hypoplasia, and cryptorchidism (Muller and deJong, 1986). This condition is highly lethal—30% of affected fetuses are stillborn. The prenatal sonographic findings described for this condition include polyhydramnios, scalp edema, retrognathia, feeble limb movements, flattened nasal bridge, deformed ears, flexion deformities of the extremities, small thorax, and absent fetal respiratory movements. The distinguishing features between trisomy 18 and Pena–Shokeir I syndrome are scalp edema and lung hypoplasia. Prenatal sonographic diagnosis of Pena–Shokeir I syndrome is possible only in cases of a known family history for this condition.

Pseudotrisomy 18 is a diagnosis of exclusion after a karyotype has revealed normal chromosomes. This is an autosomal recessive lethal condition that presents with micrognathia, flexion contractures of the fingers, low-set malformed ears, and IUGR (Le Marec et al., 1981). To distinguish between pseudotrisomy 18 and trisomy 18, a normal karyotype is necessary. There are an equal number of affected females and males with pseudotrisomy 18. This differs from the excess of females seen with trisomy 18. Also, cardiac abnormalities are not characteristic of pseudotrisomy 18. Pseudotrisomy 18 is associated with consanguinity. A history of advanced maternal age is more typical for cases of trisomy 18.

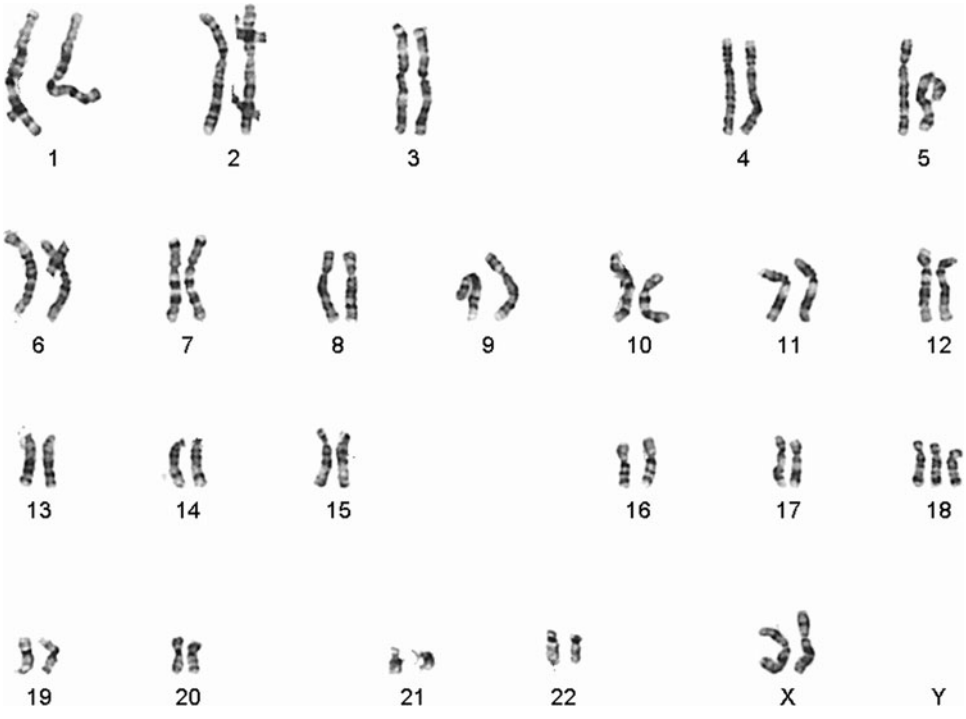

Figure 130-3 Karyotype demonstrating full trisomy 18 in a female. (*Courtesy of Dr. Janet Cowan.*)

The multiple flexion contractures seen in fetuses in which trisomy 18 is suspected may also be characteristic of arthrogryposis multiplex congenita (see Chapter 101). Fetuses affected with arthrogryposis may have camptodactyly, small thorax, and micrognathia.

ANTENATAL NATURAL HISTORY

Trisomy 18 is highly lethal in utero, although fetal demise does not occur at any specific gestation (Won et al., 2005; Yamanaka et al., 2006). In a survey of the rates of spontaneous death of fetuses with chromosomal abnormalities detected at second-trimester amniocentesis in which the mother did not elect to terminate the pregnancy, Hook et al. (1989) determined an excess risk of 63.8% (range, 49.3% to 79.8%) of in utero death of fetuses with trisomy 18. There is significant loss of male fetuses with trisomy 18 during the second half of pregnancy (Huether et al., 1996).

Hyett et al. (1995) studied the cardiac defects in fetuses with trisomy 18 that were identified by increased nuchal translucency measurement and were terminated between 11 and 14 weeks of gestation. There was an unusually high frequency of perimembranous ventricular septal defects and polyvalvular abnormalities, which were consistent with the developmental arrest of the cardiovascular system occurring between 6 and 8 weeks of gestation. These investigators studied 50 apparently normal fetuses and 19 fetuses with trisomy 18. All 19 had cardiac defects. A ventricular septal defect was demonstrated in 16 of 19 (84%) fetuses, and valvular abnormalities were also seen in 84% of fetuses. Fourteen of 16 fetuses with abnormalities had more than one valve affected. In addition, 10 of 18 fetuses studied had a hypoplastic aortic isthmus or pulmonary trunk and 6 of 18 fetuses had persistence of the left superior vena cava. It was hypothesized that hemodynamic changes due to valvular abnormalities and hypoplasia of the great vessels may be the mechanism for the increased nuchal translucency seen in trisomic fetuses (Hyett et al., 1995).

Although 80% to 85% of fetuses with trisomy 18 have a full trisomy when their amniocytes or lymphocytes are studied (Figure 130-3), when the placenta is studied it has been documented that 5% of the fetuses have a mosaic placenta with a normal diploid cell line. The use of cytogenetic analysis has demonstrated that this diploid cell line is confined to the cytotrophoblast in viable pregnancies with trisomy 18. This suggests that a normal diploid component of the trophoblast may facilitate the prolonged intrauterine survival in cases of trisomy 18 (Harrison et al., 1993). This postzygotic loss of the trisomic chromosome in a progenitor cell of a trophectoderm facilitates intrauterine survival of a trisomy 18 conceptus. It is placental function, therefore, that determines intrauterine survival (Kalousek et al., 1989).

MANAGEMENT OF PREGNANCY

Clinical suspicion of trisomy 18 can develop because of increased nuchal translucency measurement (Moyano et al., 2005), IUGR in the third trimester, or an abnormal

serum integrated screen. Multiple abnormalities of serum screening have been associated with trisomy 18, including low pregnancy-associated plasma protein A (PAPP-A) and α-fetoprotein (AFP) levels, low unconjugated estriol values, and a low β human chorionic gonadotropin (β-hCG) level. In one study, the maternal serum free β-hCG level was 0.37 multiples of the median (MoM) and the AFP level was 0.71 MoM in trisomy 18 (Spencer et al., 1993). These results were validated by Leporrier et al. (1996), who documented a low mean hCG and a mean unconjugated estriol 3 (UE3) of 0.4 MoM. With these abnormal values, the detection rate for trisomy 18 is 48% for a 0.8% false-positive rate and 79% for a 3% false-positive rate. Therefore, serum screening is more sensitive and specific for the detection of trisomy 18 than for trisomy 21. More recently, using integrated screening with the results of the first and second trimester markers, the combination of low PAPP-A, low AFP, low estriol, and low hCG detected 90% of trisomy 18 fetuses at a false-positive rate of 0.1% (Palomaki et al., 2003).

Fetuses in which trisomy 18 is suspected either on the basis of abnormal serum screen or by IUGR and evidence of fetal distress should be referred to a center capable of performing detailed anatomic scanning of the fetus. Furthermore, a karyotype should be performed, even when the abnormalities are detected during the third trimester. This is important, because it is well documented that fetuses with trisomy 18 have an excess of postterm deliveries and fetal distress prompting emergency cesarean section. In two separate studies performed in two different countries, the incidence of cesarean delivery for fetuses with trisomy 18 was on the order of 50% (David and Glew, 1980; Schneider et al., 1981). Therefore, a definitive diagnosis of a fetus with trisomy 18 may help the obstetrician and prospective parents to avoid unnecessary fetal monitoring and emergency cesarean delivery. Furthermore, antenatal knowledge that the infant has trisomy 18 will help to appropriately plan newborn resuscitation and further management.

FETAL INTERVENTION

There are no fetal interventions for trisomy 18.

TREATMENT OF THE NEWBORN

If the karyotype has not been performed antenatally, it should be performed at birth. A complete physical examination is indicated. Typically it will demonstrate the presence of intrauterine growth restriction, a prominent occiput, and a short sternum. No single physical finding is pathognomonic for trisomy 18. The major clinical features include hypertonia, anteroposterior elongation of the skull, partial syndactyly of the toes, hypoplastic toenails, narrow chest, micrognathia, short sternum, congenital heart disease, and renal anomalies (Taylor, 1968). The presence of low-arch dermal ridges, which can be seen only with a magnifying lens, is a helpful diagnostic finding, as it is generally seen in most of the fingers of affected patients with trisomy 18. Because of the delay in obtaining chromosome analysis, Marion et al. (1988) developed a bedside score for the clinical diagnosis of trisomy 18 during the immediate neonatal period. Points are given for features reported in a majority of infants with trisomy 18. The maximal attainable score is 160. In this report, in 11 patients with trisomy 18, the average score was 94.3 (range, 70 to 113). In 11 patients without trisomy 18, the average score was 41.4 (Marion et al., 1988).

Infants in whom trisomy 18 is suspected should undergo echocardiography because of the 90% incidence of congenital heart disease in affected patients. In one study of 15 autopsied cases of trisomy 18, all infants were shown to have congenital polyvalvular heart disease. Membranous VSDs were present in 87% of infants, patent ductus arteriosus (PDA) in 73%, and a high takeoff of the right coronary ostium in 80% (Matsouka et al., 1983). The most severe changes were present in the tricuspid and mitral valves with derangement of the spongiosa and fibrosa and defective elastic fibers. The heart valves are dysplastic in trisomy 18 and are noted to be thickened, gelatinous, and nodular. Other findings include long chordae tendineae and hypoplastic or absent papillary muscles (Van Praagh et al., 1989) (see Figure 130-3). Musewe et al. (1990) reviewed the role that cardiac anomalies play in the early death seen in cases of trisomy 18. They noted that most VSDs and PDAs were large and valvular dysplasia of one or more valves was seen in 68% of cases. However, the valvular dysplasia was not associated with evidence of significant regurgitation or stenosis on Doppler studies. Interestingly, several large-scale studies on long-term outcome in trisomy 18 have shown that the presence of a heart defect does not affect survival (Rasmussen et al., 2003; Niedrist et al., 2006).

There is a high incidence of 11 pairs of ribs in cases of trisomy 18 (Ho, 1989). Because of the severity of the clinical consequences of trisomy 18 and the poor prognosis, we recommend that chromosome analysis be performed as soon as possible after birth if it was not performed antenatally. If a surgical emergency is present, consideration should be given to performing fluorescence in situ hybridization (FISH) using chromosome 18–specific probes. This will provide rapid confirmation of the clinically suspected diagnosis, and in this setting, emergency surgery should be avoided if possible (Bos et al., 1992). Major surgery is likely to inflict suffering in an infant whose life expectancy is otherwise poor.

SURGICAL TREATMENT

As discussed above, surgical treatment to prolong life should be discussed with the family. In the relatively rare long-term survivors, surgical treatment may ultimately be indicated to improve their quality of life.

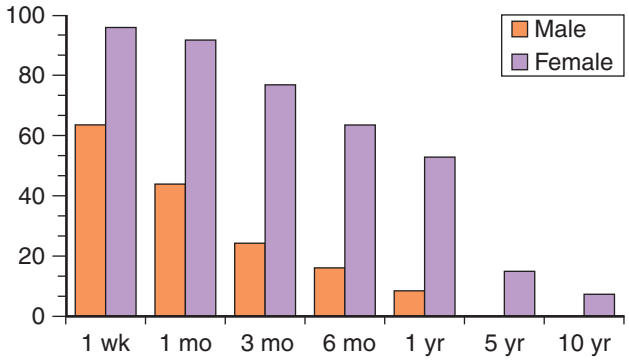

Figure 130-4 The longer-term survival of female versus male infants with trisomy 18 is clearly demonstrated in this graph. Data are based on 70 cases.

LONG-TERM OUTCOME

In an extensive survey of 98 families with an index case of trisomy 18, Baty et al., (1994a) documented an average length of survival of 1.4 months for males with trisomy 18 and 9.6 months for females with trisomy 18 (Figure 130-4). Many obstetricians and pediatricians mistakenly think that trisomy 18 is lethal during the newborn period. Although 55% to 65% of newborns with trisomy 18 die during the first week of life, 5% to 10% of infants are alive at 1 year of age (Root and Carey, 1994; Rasmussen et al., 2003).

In Baty et al.'s (1994a) study of the long-term medical outcome for infants with trisomy 18, the average neonatal hospital stay was 19.6 days, with an average number of 10.1 days on a ventilator. Eighty percent of their trisomy 18 cases went home from the hospital. Of these, 5% went home on oxygen, 12% went home on a cardiac monitor, and 44% were bottle- or breastfed. Nineteen percent of patients eventually required placement of a gastrostomy tube, but the average age of insertion of this tube was 8.4 months. Of long-term survivors, 17% had a known hearing loss, and of these patients, 41% eventually obtained a hearing aid. The major medical problems for long-term survivors with trisomy 18 include scoliosis, gastroesophageal reflux, hearing loss, and Wilms' tumor (Carey, 1992).

Baty et al. (1994a) generated growth curves for long-term survivors with trisomy 18. These demonstrate that the weight and height curves for patients with trisomy 18 are consistently below the normal curve, except for an overlap at birth (Figure 130-5). Long-term survivors were given immunizations in the first 6 months of life and there were no adverse complications directly attributable to the immunization.

In a related study, Baty et al. (1994b) collected developmental data on 50 individuals with trisomy 18. The developmental quotient (DQ), developmental age divided by the chronologic age, was on average 0.18. The developmental ages were studied in seven skill areas, and these differed significantly among the areas. Daily living skills and receptive language had the highest values, whereas motor and communication skill had the lowest values. During the first year of life, affected individuals with trisomy 18 achieved the following skills: following, cooing, rolling, social smile, reaching, and recognition of close adults. During the next 2 years, these individuals were able to sit unsupported, object permanence developed, and they were able to imitate actions and to recognize words. By the age of 4 to 6, affected individuals began to crawl and to follow simple commands, began helping with hygiene, and were capable of both independent playing and the use of signs. These investigators concluded that patients with trisomy 18 achieved some psychomotor maturation and continued to learn, although very slowly (Baty et al., 1994b).

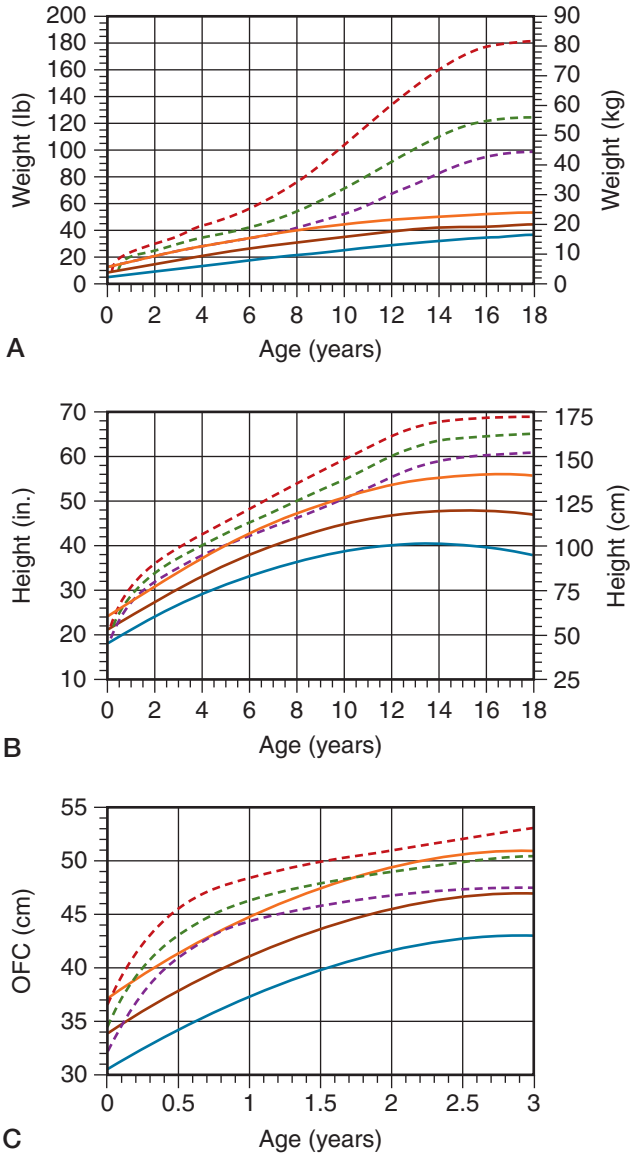

Figure 130-5 Growth curves for infants and children with trisomy 18.

Recently, studies have begun to appear in the literature that document a more aggressive approach to the treatment of infants and children with trisomy 18 (Goc et al., 2006; Kosho et al., 2006). These studies, originating in newborn intensive care units, document the use of mechanical ventilation,

cardiovascular drugs, parenteral nutrition, and surgical treatment of congenital anomalies. Graham et al. (2004) reported on cardiac surgical results in 24 infants with trisomy 18. The overwhelming majority of infants survived the surgery and were discharged alive. Although there may be slightly increased 1-year survival rates with aggressive treatment, it is important to realize that all long-term survivors with trisomy 18 are profoundly retarded.

The most common causes of death in individuals with trisomy 18 are apnea, cardiopulmonary arrest, congenital heart disease, and pneumonia (Baty et al., 1994a; Embleton et al., 1996). Many long-term survivors develop secondary protective lesions, such as pulmonary artery stenosis in the presence of a large VSD (Kelly et al., 2002).

GENETICS AND RECURRENCE RISK

Trisomy 18 is due to the presence of an extra chromosome 18, which is demonstrated on karyotyping. The recurrence risk for full trisomy 18 is commonly quoted as 1% or the age-related maternal risk, whichever is higher. The data from Baty et al. (1994a) on recurrence risk for trisomies 13 and 18 was 0.55%, based on one affected sibling from 181 subsequent pregnancies.

The origin of the extra chromosome in trisomy 18 is almost always maternal. Using molecular analysis and DNA polymorphisms, the origin of the extra chromosome was studied in 23 individuals with trisomy 18. Twenty of 23 were informative. In 19 of 20 the extra chromosome was maternal in origin (Kupke and Müller, 1989). Using DNA repeat sequences and a polymerase chain reaction-based assay, Nöthen et al. (1993) traced the parental origin in 30 cases of trisomy 18. The extra chromosome was maternal in 26 of 30 (86.7%) of cases and paternal in the remainder. When the nondisjunction resulting in trisomy 18 is due to a meiotic error, Eggermann et al. (1996) demonstrated that there was an increased number of meiosis II errors. This is somewhat different from trisomy 13 and 21, in which errors in the first meiotic division predominate.

To date, the specific region of chromosome 18 that is needed to produce the full phenotype of trisomy 18 has not been identified using molecular techniques (Boghosian-Sell et al., 1994). Duplication of part of the long arm of chromosome 18 may be associated with the mental retardation seen in trisomy 18.

There is an increasing appreciation of trisomy 18 mosaicism in women who have normal intelligence but a history of amenorrhea or miscarriages (Satge et al., 1996; Uehara et al., 1996). Kohn and Shohat (1987) described a 30-year-old woman with minor dysmorphic features and normal intelligence who had karyotyping because of a history of three miscarriages. Trisomy 18 was present in 18% of her lymphocytes and 2% of her skin fibroblasts. Several patients have been diagnosed because they gave birth to a child with trisomy 18 or have had infertility workups (Bettio et al., 2003).

Prenatal diagnosis in subsequent pregnancies is by karyotyping. Prospective parents can be offered chromosome analysis on chorionic villus cells or amniocytes, which will give a definitive diagnosis in a subsequent pregnancy.

Trisomy 21 (Down Syndrome)

131 CHAPTER

Key Points

- Ninety percent of individuals with Down syndrome have three full copies of chromosome 21. Three to 4% have an unbalanced translocation, and 1% have mosaicism.
- Prevalence in the United States is 13.65 per 10,000 livebirths.
- Fetuses with Down syndrome are more likely to die in utero than normal fetuses.
- Karyotype analysis is diagnostic.
- Once trisomy 21 is diagnosed, prospective parents should be offered an echocardiogram and a detailed sonographic evaluation of fetal anatomy (if not performed previously). Fifty percent of fetuses have cardiac anomalies.
- If no structural heart disease or gastrointestinal obstruction is present, delivery can occur in the community. If structural anomalies in the heart or other organs are present, delivery should occur in a tertiary center.
- Newborns often have feeding difficulties due to hypotonia.
- There is an increased risk of hematologic disorders and hypothyroidism.
- Affected children have mild to moderate mental retardation (IQ 40–70).
- The precise number and function of genes of 21q is not fully known.
- Recurrence risk for full trisomy 21 is 1%, or the maternal age-associated risk (whichever is greater).

CONDITION

Trisomy 21 is an abnormality due to the presence of an extra copy of chromosome 21 (Figure 131-1). Individuals with the clinical characteristics of what we now know as Down syndrome were first described by Dr. John Langdon Down in 1866. Dr. Down was a physician at the Earlswood asylum in Surrey, England. His erroneous ideas about a racial cause for Down syndrome, along with a superficial similarity in facial appearance to persons of mongoloid origin, led to the term mongolism (Cooley and Graham, 1991). Interestingly, Dr. Down eventually had a grandson who was also named John Langdon Down, and he had Down syndrome (Patterson and Costa, 2005).

The association between the clinical entity Down syndrome and an extra copy of chromosome 21 was noted simultaneously in 1959 by Drs. Jerome Lejeune in France and Patricia Jacobs in Scotland. Ninety-five percent of individuals with Down syndrome have three copies of chromosome 21, which results from meiotic nondisjunction of the pair of number 21 chromosomes in the formation of an egg or sperm prior to fertilization (Sherman et al., 2005). Ninety-four percent of the time, the extra copy of the chromosome 21 is maternal in origin (Antonarakis, 1991). Approximately 3% to 4% of cases of Down syndrome are due to an unbalanced translocation involving chromosome 21. Fifty percent of the translocation cases occur spontaneously (de novo) and 50% are inherited from a parent with a balanced translocation. One percent of cases of Down syndrome are due to mosaicism, beginning as a trisomic conceptus with selective loss of one copy of chromosome 21 ("disomic rescue") or as mitotic nondisjunction occurring after fertilization in a specific cell line or lines.

A full extra copy of chromosome 21 is not needed to cause the symptoms of Down syndrome. The phenotype of Down syndrome is thought to be due to triplication of the genes expressed in a relatively small region of chromosome 21, band 21q22. However, recent gene expression studies using cell-free fetal RNA in amniotic fluid of second trimester affected fetuses suggests that the fetal phenotype is due to differential regulation of many genes that are not on chromosome 21 (Slonim et al., 2009). Furthermore, second trimester

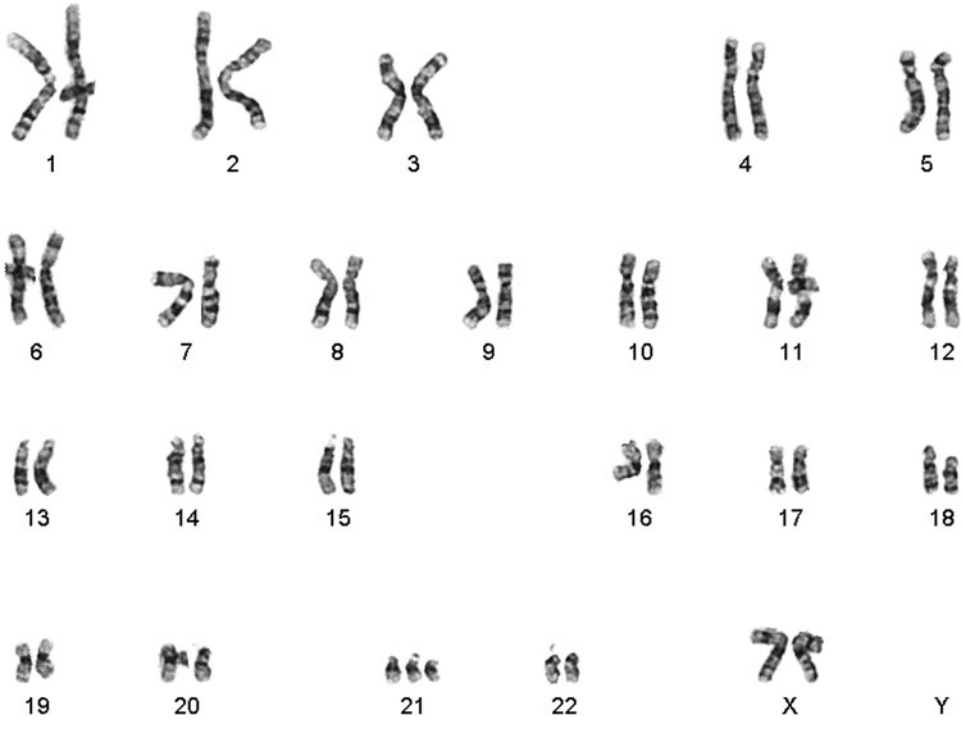

Figure 131-1 Karyotype from a female individual with Down syndrome, indicating the presence of three copies of chromosome 21. (*Courtesy of Dr. Janet Cowan.*)

fetuses with Down syndrome experience significant oxidative stress.

Currently, there is much interest in the noninvasive detection of Down syndrome, by first and second trimester serum screening and nuchal translucency measurement (Nicolaides et al., 1992a) (see Chapters 2 and 3). The analysis of cell-free fetal nucleic acids in maternal blood may eventually have a role in the noninvasive prenatal diagnosis of Down syndrome (Maron and Bianchi, 2007; Lo, 2009).

INCIDENCE

The incidence of trisomy 21 is 1 in 920 livebirths (Krivchenia et al., 1993). The frequency of Down syndrome increases with advanced maternal age. The incidence of Down syndrome is somewhat similar in all ethnic and racial groups, although population-based data from the United States National Birth Defects Prevention Network suggest that there is a higher incidence in Hispanics and a lower incidence in blacks compared to non-Hispanic white women (Canfield et al., 2006).

Cuckle et al. (1991) estimated the "natural birth prevalence" of Down syndrome, which they defined as the birth prevalence that would be expected in the absence of prenatal diagnosis or induced abortion. In their study, performed in England and Wales from 1974 to 1987, the natural birth prevalence of Down syndrome increased from 12.2 in 10,000 to 13.2 in 10,000—an average of 12.6 in 10,000 births. Fourteen percent of cases of Down syndrome were avoided by prenatal diagnosis and termination of affected pregnancies. The actual birth prevalence, which reflected the utilization of prenatal diagnosis, was 10.8 in 10,000 births in this population (Cuckle et al., 1991). In a more recent U.S. population-based study, the prevalence of Down syndrome was 13.65 per 10,000 livebirths (Canfield et al., 2006).

SONOGRAPHIC FINDINGS

The major sonographic findings seen in fetuses with trisomy 21 are listed in Table 131-1. Many of these findings are discussed in individual chapters and in Chapters 2 and 3. The frequency of major internal congenital malformations is less than with trisomies 13 or 18 (Hill, 1996). In general, in cases of trisomy 21, sonographic defects tend to be more subtle than in cases of Trisomies 13 or 18, such as flattening of the facial profile (Figure 131-2). These "soft" markers include nuchal edema, hydronephrosis, clinodactyly, sandal gap (wide space between first and second toes), macroglossia (Nicolaides et al., 1992b), as well as absent or shortened nasal bone (Sonek and Nicolaides, 2002) and increased frontomaxillary facial angle (Sonek et al., 2007).

DIFFERENTIAL DIAGNOSIS

Relatively long differential diagnoses exist for each individual sonographic finding that has been reported to be associated with Down syndrome. A karyotype that demonstrates the presence of an extra chromosome 21 is diagnostic and highly accurate. Once the chromosomes have been studied, there is no longer a need for a differential diagnosis. Postnatally,

Table 131-1

Sonographically Detectable Malformations Associated with Trisomy 21

Craniofacial
Absent or hypoplastic nasal bone
Increased frontomaxillary facial angle
Thickened nuchal fold
Increased nuchal translucency measurement
Cystic hygroma
Protuberant tongue
Central nervous system
Choroid plexus cysts
Mild ventriculomegaly
Cardiovascular system
Ventricular septal defect
Atrial septal defect
Endocardial cushion defect
Calcification of the chordae tendinae
Gastrointestinal system
Duodenal atresia
Echogenic bowel
Imperforate anus
Urogenital system
Pyelectasis
Skeletal system
Brachycephaly with flat occiput
Shortened long bones
Clinodactyly
Syndactyly
Short, thick fingers
Gap between 1st and 2nd toes
Elongated ischial bones
Nonimmune hydrops
Amniotic fluid volume
Polyhydramnios
Intrauterine growth restriction

however, findings such as muscular hypotonia in the newborn may suggest a diagnosis of congenital muscular dystrophy. Furthermore, abnormalities in the facial profile may suggest a diagnosis of Zellweger syndrome.

ANTENATAL NATURAL HISTORY

The incidence of Down syndrome in clinically recognized pregnancies is reported to be as high as 1 in 225 (Hecht and Hecht, 1987). The difference between the incidence of Down syndrome in conceptuses and livebirths indicates the strong selection pressure against this chromosomal abnormality.

Fetuses with Down syndrome have a higher rate of spontaneous abortion or stillbirth than normal fetuses (Figure 131-3). This has been studied extensively by Hook et al. (1989, 1995). This group reported the results of an ongoing survey of rates of spontaneous death of fetuses with trisomy 21 that were detected at second trimester amniocentesis in which the mother did not elect termination of pregnancy. The loss rates were ~50% for fetuses ascertained at 15 to 17 weeks, 43% at 18 weeks, 31% at 19 weeks, 25% at 20 weeks, and 21% to 25% at 21 to 28 weeks (Hook et al., 1995). This was adjusted for the likelihood that spontaneous fetal death would occur in a fetus with a normal karyotype in a population of women with advanced maternal age.

Figure 131-2 Three-dimensional sonographic image of a 20-week fetus with trisomy 21 showing the flattening of the face. The characteristic small ears and overfolded helices seen in Down syndrome are also especially well seen.

MANAGEMENT OF PREGNANCY

In our practice, we routinely offer a genetic amniocentesis or CVS to all pregnant women carrying a fetus with a major or multiple minor sonographic abnormalities that are associated with trisomy 21. If an isolated minor sonographic finding is present, the subsequent course of action is less clear (see Chapter 3).

Once the chromosomal analysis reveals trisomy 21, the prospective parents should be given the opportunity to meet with a medical geneticist to fully discuss the expected medical outcome for a child with Down syndrome prior to making

Figure 131-3 Nineteen-week-old fetus with trisomy 21. Note the relative nasal hypoplasia, small mouth, prominent tongue, and cystic hygroma. (*Courtesy of Dr. Joseph Semple.*)

a decision regarding continuation of pregnancy. Also, it is often helpful to have the prospective parents speak to parents who are raising a child with Down syndrome. Options for pregnancy termination should also be presented.

Once the fetus is diagnosed with trisomy 21, the pregnant patient should be referred to a center capable of diagnosing cardiac and other anatomic defects. Unless the fetus is known antenatally to have a severe congenital heart malformation or a malformation that will require immediate surgical repair, such as duodenal atresia, there is no reason to deliver the infant with trisomy 21 at a tertiary care center. We also recommend prenatal consultation with a pediatric cardiologist if a cardiac abnormality is present.

FETAL INTERVENTION

At present, there are no fetal interventions for trisomy 21.

TREATMENT OF THE NEWBORN

The newborn with Down syndrome should receive a complete physical examination (Figures 131-4 and 131-5). If a chromosome analysis has not been obtained prenatally, it should be obtained at birth. A chromosome analysis based on peripheral blood lymphocytes in the newborn should take a maximum of 48 hours. Fluorescence in situ hybridization (FISH) using chromosome-21-specific probes should enable a diagnosis to be made within a few hours. Prior to the availability of FISH, several diagnostic bedside tests based on the presence of certain physical examination findings were described

Figure 131-4 An infant with Down syndrome. Note the round face with midface hypoplasia and the epicanthal folds.

Figure 131-5 The "sandal gap" in a premature newborn with Down syndrome.

(Jackson et al., 1976; Preus, 1977; Rex and Preus, 1982). The newborn with Down syndrome is almost always hypotonic. Many of these infants have feeding difficulties, which result in their eventual transfer to a tertiary care center. Twelve percent of infants with Down syndrome have gastrointestinal abnormalities, including duodenal atresia, celiac disease, Hirschsprung disease, annular pancreas, and imperforate anus (Cooley and Graham, 1991).

An infant with Down syndrome may have breathing difficulties due to the presence of pulmonary hypoplasia. In one study, six of seven patients had hypoplastic lungs (Cooney and Thurlbeck, 1982). The presence of pulmonary hypoplasia is independent of the presence or absence of congenital heart disease. Structural abnormalities that have been described in cases of Down syndrome include a decreased number of alveoli in relation to pulmonary acini. There is a smaller alveolar surface area, which results in reduced capillary surface area. This can cause aggravation of pulmonary hypertension, which is a significant problem in children with Down syndrome.

The 50% incidence of congenital heart disease in cases of Down syndrome mandates that a chest X-ray examination, electrocardiography, and echocardiography be performed during the first month of life. Cardiac symptoms may be masked by the presence of physiologic pulmonary hypertension. In 40% to 60% of the cases of congenital heart disease, the underlying problem is an atrioventricular canal defect (see Chapter 45). The rest of the cardiac anomalies in Down syndrome are due to ventricular septal defect, tetralogy of Fallot, or atrial septal defect (Carey, 1992).

With regard to routine blood tests during the newborn period, a complete blood count should be performed to rule out hyperviscosity syndrome and a transient myeloproliferative disorder, which has a 10-fold to 30-fold greater incidence in individuals with Down syndrome, as compared with the general population. Other common hematologic abnormalities observed among neonates with Down syndrome include neurophilia, thrombocytopenia, and polycythemia (Henry et al., 2007). Transient megakaryoblastic leukemia is found in 10% of newborns with Down syndrome. In most cases the leukemic cells disappear spontaneously within a few months. However, in 20% of these individuals, irreversible acute megakaryoblastic leukemia develops within 4 years (Hitzler and Zipursky, 2005). The leukemic cells carry specific mutations of the hematopoietic transcription factor *GATA1*, which surprisingly maps to the X chromosome and not to 21. *GATA1* mutations have been detected in erythroblasts studied antenatally. Thus, the mutational event occurs in utero. The type of leukemia seen in Down syndrome shows increased sensitivity to chemotherapy (Hitzler and Zipursky, 2005).

There is an increased incidence of congenital hypothyroidism in Down syndrome infants. Therefore, a special effort must be made to check the results of the newborn screening for hypothyroidism. All infants with Down syndrome should be referred to early intervention services in the family's home community. The cardinal physical findings in the newborn with Down syndrome are listed in Table 131-2. Recommendations for the routine health care management of children with Down syndrome have been published (Committee on Genetics, 1994; American Academy of Pediatrics, 2001). Universal screening for celiac disease, starting at age 2 years, is recommended.

SURGICAL TREATMENT

Surgical treatment depends on the presence of structural abnormalities that are amenable to surgical repair, such as duodenal atresia or the presence of an atrioventricular cardiac defect. For specific treatment of each condition, please refer to the appropriate chapter (Chapters 72 and 45, respectively).

Table 131-2

Cardinal Physical Findings in the Newborn with Down Syndrome

Finding	Frequency (percent of cases)
Flat facial profile	90
Absent Moro reflex	85
Muscle hypotonia	80
Oblique palpebral fissures	80
Excess skin at back of neck	80
Joint hyperflexibility	80
Dysplastic pelvis on X-ray examination	70
Dysplastic ear	60
Dysplastic middle pharynx of 5th finger (on X-ray examination)	60
Simian crease	45

Table 131-3

Life Expectancy for Individuals with Down Syndrome

Age	Chance of Survival with Congenital Heart Disease (%)	Chance of Survival Without Congenital Heart Disease (%)
1 year	76.3	90.7
5 years	61.8	87.2
10 years	57.1	84.9
20 years	53.1	81.9
30 years	49.9	79.2

Source: Baird PA, Sadovnick AD. Life expectancy in Down syndrome. J Pediatr *1987;110:849-854.*

LONG-TERM OUTCOME

Eighty percent of individuals with Down syndrome survive to age 30 or beyond (Cooley and Graham, 1991). The life expectancy for individuals with Down syndrome differs based on the presence or absence of congenital heart disease. This is summarized in Table 131-3. The median age at death has increased to 49 years of age (Yang et al., 2002). Although there is an increased risk of leukemia early in life, there is a lower risk of all other solid tumors, such as breast and colon.

All individuals with Down syndrome have delayed growth, and many have problems with obesity. They are generally followed as outpatients with specific growth charts designed for individuals with Down syndrome (Cronk et al., 1988). All individuals with Down syndrome have mental retardation. Their IQs are in the mild to moderate mentally retarded range (IQ = 40–70). Children with Down syndrome walk, talk, and toilet train, but all of these milestones occur later than average as compared with individuals who do not have Down syndrome. Individuals with Down syndrome are better at visual tasks as compared with tasks that require auditory processing. There is an increased incidence of behavioral and psychiatric problems such as attention deficit/hyperactivity disorder and depression (Roberts et al., 2007).

Individuals with Down syndrome are at risk for hearing loss. This is partly due to the development of serous otitis media, which causes a conductive hearing loss. This finding has a 50% to 70% prevalence in individuals with Down syndrome. Patients with Down syndrome should be referred for audiology and tympanometry before 8 months of age (Carey, 1992), as hearing problems affect language development (Roberts et al., 2007). There is also an increased risk of ocular abnormalities. Patients with Down syndrome are at risk for cataracts, strabismus, nystagmus, and myopia. An annual thyroid screen is also recommended, because of the increased prevalence of hypothyroidism that continues throughout life (Carey, 1992), although the recommendation has been challenged (Van Vliet, 2005).

A controversial area is the screening for atlanto-axial instability, which is caused by a ligamentous laxity in the C1-C2 area. The diagnosis is generally made radiographically if the atlanto-dens interval is 5 mm. The concern is that this instability will lead to dislocation and will develop into an upper spinal cord injury. Atlanto-axial instability reportedly affects 10% to 30% of patients with Down syndrome (Carey, 1992). The Special Olympics organization has made screening for atlanto-axial instability a requirement prior to participation in active sports. However, much controversy exists as to whether neck radiography is an effective screening tool for this abnormality. In most patients who have atlanto-axial instability, neurologic symptoms will develop well in advance of any problems that lead to dislocation.

Fertility is very rare for a male with Down syndrome (Pradhan et al., 2006). However, pregnancy is possible for a

female, for whom the recurrence risk is 50%. Contraceptive measures should be discussed for a sexually active adolescent female with Down syndrome.

With regard to neurologic abnormalities, 5% to 10% of patients with Down syndrome will develop myoclonic seizures. Ultimately, the brains of nearly all adults with Down syndrome who are older than 35 years of age will have senile plaques and neurofibrillary tangles consistent with Alzheimer disease (Antonarakis and Epstein, 2006). Down syndrome is unique in that it confers a 100% risk of developing early onset Alzheimer disease. The mean onset of dementia in patients with Down syndrome is 51.3 years (range, 46–57 years).

GENETICS AND RECURRENCE RISK

Despite the completion of the Human Genome Project, the precise genetic composition of the long arm of chromosome 21 (21q) is not fully known. The total number of protein-coding genes is estimated to be between 271 and 364 (Antonarakis and Epstein, 2006). Recent studies of the transcriptional activity of 21q suggest that there are nonprotein coding RNA molecules present.

The recurrence risk for Down syndrome depends on whether an extra whole chromosome 21 is present or whether a translocation is noted on the karyotype. For the more common situation of a full or "free" trisomy 21, the recurrence risk is 1% or the maternal age–associated risk, whichever is greater (Eunpu et al., 1986). In one study, the recurrence risk in second-degree relatives (uncles and aunts of individuals with trisomy 21) was not increased (Eunpu et al., 1986). Cytogenetic studies, using chromosome heteromorphisms, show that 70% to 80% of cases of trisomy 21 are maternal in origin (Juberg and Mowrey, 1983). However, molecular studies show that the incidence is 94% maternal in origin (Antonarakis, 1991).

If a translocation is documented in the fetal or infant karyotype, parental blood studies must be obtained. The risk of recurrence is 16% if the mother is a carrier of the translocation and 5% if the father is a carrier of the translocation (Cooley and Graham, 1991).

In a subsequent pregnancy, parents who have had either a stillbirth, a spontaneous abortion, or a pregnancy or liveborn infant affected with Down syndrome should be offered prenatal genetic diagnosis for a subsequent pregnancy.

132 CHAPTER Triploidy

Key Points

- Occurs in 1% to 2% of clinically recognized conceptions but only 1/10,000 livebirths. Not associated with advanced maternal age.
- Most cases are 69, XXY (60%) or 69, XXX (37%); only 3% of cases are 69, XYY.
- In the type I phenotype the fetus is relatively well grown with a large cystic placenta.
- In the type II phenotype the fetus is markedly growth restricted with a disproportionately large head and a small, noncystic placenta.
- One third of cases survive beyond 15 weeks and are associated with abnormal maternal serum screen results.
- The longest postnatal survival for an affected infant was 10½ months.

CONDITION

Triploidy is defined as the presence of three complete sets of the normal haploid genome found in gametes. Triploidy occurs in one of three ways: (1) failure of division in meiosis I or II in the spermatocyte, resulting in an extra set of paternal chromosomes (diandry); (2) failure of division in meiosis I or II in the oocyte, resulting in an extra set of maternal chromosomes (digyny); or (3) double fertilization of a normal haploid ovum (dispermy). Using special chromosome-staining techniques, it has been shown that the extra set of chromosomes is paternal in origin in three quarters of cases (Jacobs et al., 1982). Most of the paternally derived cases are due to dispermy (Kajii and Niikawa, 1977). The distribution of karyotypes seen in triploid conceptuses is 69, XXY (60%), 69, XXX (37%), and 69, XYY (3%) (Jacobs et al., 1982). The infrequent occurrence of XYY suggests that either diandry must be uncommon or that XYY carries a disadvantage for survival.

Triploid fetuses can present with a broad spectrum of phenotypic features that can range from near normalcy to multisystem involvement. McFadden and Kalousek (1991) have described two distinct fetal and placental phenotypes that appear to correlate with the parent of origin in the extra set of chromosomes. In the type I phenotype, the fetus is relatively well grown and has a proportionate head size or microcephaly. The placenta is large, with cystic changes. At the microscopic level there is trophoblastic hyperplasia, scalloping of the villus surface, and focal hydropic change (Sergi et al., 2000). These cases are generally associated with diandry (Figure 132-1A). The type II phenotype predominates in the cases diagnosed after the first trimester; it consists of a markedly growth-restricted fetus

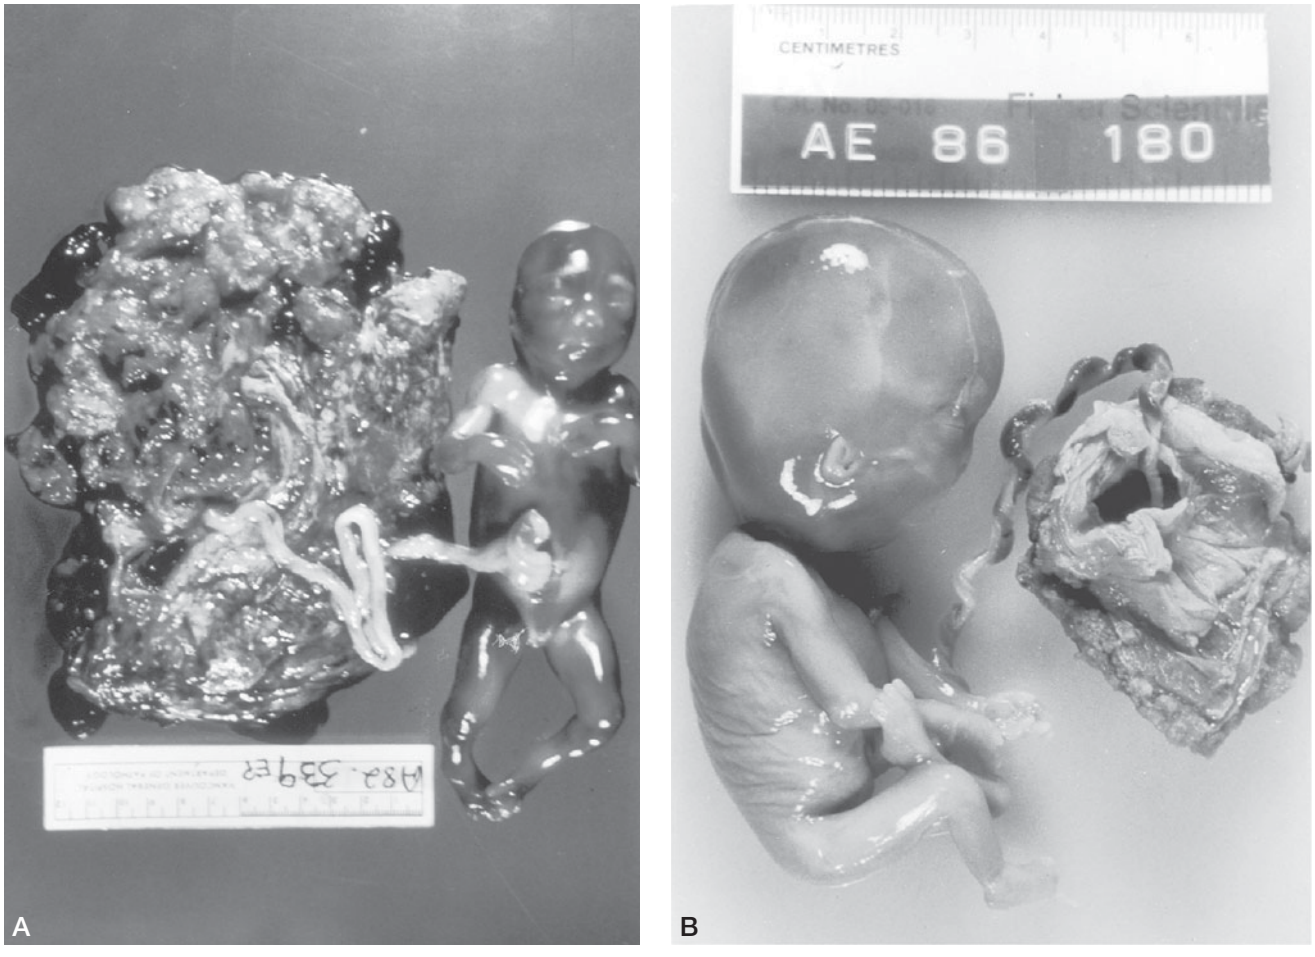

Figure 132-1 **A.** Relatively well-grown fetus with large cystic placenta seen in type I triploidy. **B.** Markedly growth-restricted fetus with a disproportionately large head and a small, noncystic placenta seen in type II triploidy. (*Reprinted from McFadden DE, Kalousek DK. Two different phenotypes of fetuses with chromosomal triploidy: correlation with parental origin of the extra haploid set.* Am J Med Genet. *1991;38:535-538. Copyright 1991 John Wiley & Sons. Reprinted, by permission, of John Wiley & Sons, Inc.*)

with a disproportionately large head and a small, noncystic placenta (Figure 132-1B). In their series, McFadden and Kalousek were able to demonstrate that one case of type II triploidy originated from an error in maternal gametogenesis.

INCIDENCE

Human triploidy is a relatively common condition, occurring in 1% to 2% of all clinically recognized conceptions (Jacobs et al., 1978). Triploidy accounts for approximately 20% of spontaneous abortions due to chromosomal abnormalities (Niebuhr, 1974; Wertelecki et al., 1976). After Turner syndrome (45, X), triploidy and trisomy 16 are the most common chromosomal abnormalities diagnosed in first trimester products of conception (Lindor et al., 1992). The early pregnancy wastage is high—for each triploid infant born alive, it is estimated that 1200 are miscarried (Doshi et al., 1983).

Although triploid conceptions are very common, the incidence is only 1 per 10,000 livebirths (Jacobs et al., 1982). There is no evidence for an increased risk due to advanced maternal age (Rochon and Vekemans, 1990). In experimental animals, triploidy has been induced by colchicine administration, hypoxia, and heat shock (Niebuhr, 1974). There is a questionable association between triploidy and delayed fertilization, due to prolonged menstrual cycles or discontinuation from oral contraceptives (Niebuhr, 1974). Uchida and Freeman (1985) have described an association between preconceptual diagnostic abdominal X-ray exposure and subsequent triploid conceptuses.

SONOGRAPHIC FINDINGS

No single anomaly on sonographic examination is pathognomonic of triploidy (Pircon et al., 1989a). The diagnosis of triploidy should be suspected in any pregnancy with cystic placental changes and fetal anomalies. Similarly, severe intrauterine growth restriction and a markedly increased head:body size ratio should elicit consideration of triploidy (Figure 132-2).

Figure 132-2 Prenatal sonographic image demonstrating increased head to body size ratio.

Intrauterine growth restriction in triploidy has been reported as early as the first trimester (Benacerraf, 1988), but the classic presentation is in the second trimester. Crane et al. (1985) have described growth curves for triploid fetuses studied on several occasions during gestation. The characteristic finding is an abnormally increased head:abdominal circumference ratio that gives the appearance of relative macrocephaly. Oligohydramnios has been reported in as many as 60% of cases (Mittal et al., 1998). Hydrocephalus is common and can be seen in the first trimester (Crane et al., 1985; Benacerraf, 1988). Facial anomalies include micrognathia, microphthalmia (Wertelecki et al., 1976), a bulbous nose, and a small mouth (Bendon et al., 1988). A relatively specific finding is syndactyly of the third and fourth digits (Figure 132-3) (Bendon et al., 1988). Approximately 25% of triploid fetuses have a neural tube defect (Gosden et al., 1976) and 10% to 18% have associated omphalocele or gastroschisis (Blackburn et al., 1982). Male triploid fetuses may have genital abnormalities. Ambiguous genitalia may also be due to the presence of a mosaic karyotype, with two cell lines that contain different sex chromosomes. Both polyhydramnios and oligohydramnios have been described. Other fetal findings that may be apparent sonographically include cardiac anomalies (ventricular septal defect and atrial septal defect), pulmonary hypoplasia, and renal cystic changes. It should also be noted that the absence of anomalies does not preclude a diagnosis of triploidy.

Figure 132-3 Syndactyly of the third and fourth digits seen in an infant with triploidy.

Placental abnormalities are typical of type I (diandric) triploidy (Mittal et al., 1998). Characteristic findings include placental enlargement, hydropic changes (Wertelecki et al., 1976), a generalized hyperechoic appearance, and the presence of multiple small or a single large cyst (see Figure 132-1) (Rubenstein et al., 1986). Abnormal placental Doppler studies are also common (Jauniaux, 1999).

In cases in which triploidy is suspected, sonographic examination of the maternal ovaries may reveal the presence of associated theca lutein cysts (Meizner et al., 1991).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes severe intrauterine growth restriction due to uteroplacental insufficiency, infection, or other genetic syndromes, or other aneuploidies such as trisomy 18. The possibility of a complete mole, with its risk for malignant change, must also be excluded.

ANTENATAL NATURAL HISTORY

The majority of triploid conceptions are lost during the first trimester, but one-third survive beyond 15 weeks of gestation (Warburton et al., 1994). Approximately 1 in 200 ongoing pregnancies at 15 weeks involve a triploid fetus, although some of these fetuses are already dead (Hassold et al., 1980; Jacobs et al., 1982). Between 16 and 19 weeks of gestation, triploidy is found in 8.1% of all spontaneous abortions. In one study, 43% of the chromosomally abnormal fetuses lost between 16 and 19 weeks were shown to be triploid (Warburton et al., 1994).

Development of hydatidiform changes in the placenta ("partial mole") is primarily associated with the presence of two paternal sets of chromosomes (diandry or dispermy). These moles rarely undergo malignant change, as opposed to diploid moles that are not associated with the formation of a fetus.

Abnormalities in maternal serum testing are present in triploid pregnancies that survive to the second trimester. Increased maternal serum α-fetoprotein (AFP) levels have been demonstrated in several reports (O'Brien et al., 1988; Freeman et al., 1989; Pircon et al., 1989b). In most cases, amniotic fluid AFP levels have been normal unless an associated neural tube defect is present (Freeman et al., 1989). It is important to consider triploidy in the differential diagnosis of elevated maternal serum AFP levels, as in several reported cases, the sonographic examination was within normal limits (Pircon

et al., 1989a). Low levels of human chorionic gonadotropin (hCG) and estriols are also associated with triploidy (Fejgin et al., 1992). It has been questioned whether this finding is due to an extra set of maternal chromosomes impairing placental function (Schmidt et al., 1994). As first trimester prenatal diagnosis has become more common it has also become appreciated that triploidy is associated with very low levels of pregnancy-associated plasma protein A (PAPP-A) (De Graaf et al., 1999; Campbell et al., 1999).

MANAGEMENT OF PREGNANCY

Prenatal diagnosis of triploidy is important, as this condition carries serious medical risks for the mother. These risks include vaginal bleeding and severe pre-eclampsia (Jauniaux, 1999). Prenatal recognition also prevents unnecessary cesarean delivery (Graham et al., 1989). The abnormally large cystic placenta can cause severe postpartum hemorrhage and may be retained after birth (Niebuhr, 1974).

We recommend that prenatal karyotyping be performed for the following clinical situations: (1) severe intrauterine growth restriction with or without fetal anomalies documented on second trimester sonographic examination; (2) hydatidiform placental changes noted on sonography; (3) abnormally increased maternal serum AFP levels (greater than 3.5 MoM); and (4) severe pre-eclampsia with fetal anomalies or hydatidiform placental changes. A full metaphase karyotype will make a definitive diagnosis and also rule out the presence of mosaicism. If a rapid diagnosis is necessary, fluorescence in situ hybridization (FISH) analysis using chromosome probes has been used on uncultured amniocytes to diagnose triploidy (Christensen et al., 1992; Gersen et al., 1995).

Once the diagnosis of triploidy has been made, the poor prognosis and maternal risks should be discussed with the parents, and termination of pregnancy should be offered if the gestational age is less than 24 weeks. Early induction of labor is recommended if the diagnosis is made after 24 weeks because of the maternal medical risks associated with continuing the pregnancy. Cesarean section is not indicated except to facilitate delivery for maternal health. Delivery in a tertiary care center is not necessary. The advantages of delivering in a tertiary care center are that: (1) if the infant survives postnatally, neonatal transfer will not occur; (2) when the infant dies, perinatal pathologists are available for autopsy; (3) many tertiary care centers offer coordinated services for bereavement and genetic counseling; and (4) appropriate subspecialty referral is available for the mother if she has medical complications.

FETAL INTERVENTION

There are no fetal interventions for triploidy.

TREATMENT OF THE NEWBORN

Given the relative infrequency of this condition in the liveborn population and the subtlety of the associated dysmorphic features, the diagnosis of triploidy in the newborn is sometimes unsuspected. The severe growth restriction usually prompts an investigation of the chromosomes, but results are usually not available for 3 to 7 days. The phenotypic features of infants presenting with complete triploidy are summarized in Table 132-1. The typical infant who survives postnatally has the "type II" phenotype of McFadden and Kalousek, with growth restriction, relative macrocephaly, dysplastic calvarium, ocular colobomas, cleft palate, micrognathia, hypotonicity, and genital abnormalities (if male) (Graham et al., 1989). Gosden et al. (1976) have also described an unusual appearance of the thighs due to muscular hyperplasia. They termed this physical finding "wine bottle thighs."

Hematologic abnormalities in triploid infants have also been reported. Typical findings include macrocytosis, anisocytosis, polychromasia, an increase in platelet size, and abnormalities of the granulocytes (Strobel and Brandt, 1985).

Doshi et al. (1983) have documented pathologic findings in 43 complete and 11 mosaic triploid fetuses or infants delivered after 22 weeks of gestation. In addition to the anomalies already mentioned, they reported ovarian, adrenal, and pulmonary hypoplasia as well as testicular Leydig cell hyperplasia. True hermaphroditism has also been reported (Petit et al., 1992).

Importantly, the diagnosis of complete triploidy is considered lethal. There have been no survivors beyond the age of 10.5 months (Sherard et al., 1986). Newborn resuscitation and mechanical ventilation are not indicated. Warmth, nutrition, and comfort measures are recommended. Faix et al. (1984) have eloquently described the ethical dilemmas in a case of triploidy in which the parents insisted on employment of the full range of life-support technology. Even with their aggressive support, the infant survived for only 4 months and had marked impairment of his growth and development.

SURGICAL TREATMENT

The lethal nature of complete triploidy precludes intervention in surgically correctable anomalies such as abdominal wall defects. A more aggressive approach to surgically correctable lesions may be considered in cases of diploid/triploid mosaicism.

LONG-TERM OUTCOME

The longest reported survival of an infant with triploidy is 10.5 months (Sherard et al., 1986). This male infant was small for gestational age, with a complete cleft lip and palate, digital abnormalities, and a large ventricular septal defect (Figure 132-4). His medical problems included congestive

Table 132-1

Phenotypic Features of Infants with Complete Triploidy

General
Intrauterine growth restriction
Head
Relative macrocephaly
Malformed, low-set ears
Microophthalmia
Ocular coloboma
Micrognathia
Chest
Pulmonary hypoplasia
Cardiac
Ventricular and atrial septal defects
Abdomen

heart failure (treated with digitalis and diuretics), seizures (treated with phenobarbital), and upper respiratory infections. He died from respiratory complications.

Genotyping studies demonstrated that the extra set of chromosomes was maternal in origin. In three of the longest-surviving infants with triploidy, the extra genome was also maternal (Fryns et al., 1977; Galan et al., 1991) although at least one other case was paternally derived (Niemann-Seyde et al., 1993). In the future, we may understand the importance

Long survival in a 69, XXY triploid male.* Am J Med Genet *1986;25:307-312. Copyright © 1986 John Wiley & Sons. Reprinted, by permission, of John Wiley & Sons, Inc.*)

of the parent of origin differences in the extra chromosome set. Imprinting of certain genes may play a role.

Infants who are shown to have diploid/triploid mosaicism on their karyotype will, in general, have a milder phenotype that may permit prolonged survival to adulthood (Tantravahi et al., 1986). The majority of the patients reported have had developmental delay. Other features described in these diploid/triploid individuals include hemihypertrophy, syndactyly, ambiguous genitalia, and mild craniofacial abnormalities (Dewald et al., 1975).

GENETICS AND RECURRENCE RISK

The issue of whether triploidy is a random event or whether it affects future reproductive performance is currently unresolved. Three studies have suggested a slightly increased risk for other chromosomal abnormalities in future pregnancies (Boué et al., 1973; Stene et al., 1984; Uchida and Freeman,

1985). We recommend prenatal cytogenetic diagnosis in subsequent pregnancies. Genetic counseling is indicated so that the family can understand the cause of the triploidy and the risk of recurrence.

133 CHAPTER Other Autosomal Aneuploidies

Key Points

- Trisomies 8, 9, 14, 16, and 20, if present in mosaic form, are compatible with postnatal survival.
- Mosaic trisomies are generally associated with nondisjunction due to advanced maternal age.
- Trisomy 16 occurs in at least 1.5% of all clinically recognized pregnancies and 31% of all spontaneous losses due to chromosome abnormalities.
- Trisomy 20 accounts for 2% of trisomic miscarriages and is a common cause of true mosaicism in amniotic fluid cultures.
- For mosaic trisomies 8, 9, and 14, a detailed sonographic survey of fetal anatomy and consultation with a medical geneticist are indicated.
- Women carrying fetuses with mosaic trisomy 16 are at risk for developing pre-eclampsia.
- Phenotype does not correlate with percent of mosaic cells except for trisomy 20. The presence of more than 60% of cells with trisomy 20 is associated with a poor prognosis.
- All continuing pregnancies should have involvement of the medical genetics team.
- Survivors with trisomy 16 have excellent postnatal catch-up growth and the majority have a good developmental outcome. Mosaic trisomies 8, 9, and 14 have variable outcomes. Mosaic trisomy 20 has a normal outcome if there are less than 60% abnormal cells.

CONDITION

In this chapter, information will be discussed regarding trisomies 8, 9, 14, 16, and 20. These are the trisomies that, if present in a mosaic form, are compatible with fetal survival at least until the end of the first trimester. They present with sonographic abnormalities or abnormalities of maternal serum screening analytes. All of these conditions are detected by cytogenetic analysis. Mosaic trisomies account for around 5% of the trisomies detected in human spontaneous abortions. In general, they are associated with advanced maternal age (James and Jacobs, 1996). For most of the trisomies, the general mechanism is nondisjunction in maternal meiosis I. This is then followed by a second mitotic error in chromosome division. The second division corrects the trisomy, but about a third of the time results in leaving behind two maternal copies of the particular chromosome. This is known as uniparental disomy (UPD). UPD can then cause an abnormal phenotype through homozygosity for recessive genes or if there are areas of imprinted genes on that particular chromosome (Reish et al., 1998). In contrast, current evidence seems to indicate that trisomy 8 has a different underlying mechanism. It appears to be due to postzygotic nondisjunction with a gain of a chromosome in some tissues.

Trisomies 8, 9, 14, 16 and 20 are generally lethal when present as a full trisomy. In this chapter only the mosaic trisomies will be discussed, as those are what is encountered clinically. For most of the mosaic trisomies, there is no relationship between the percent mosaicism and the clinical outcome, with the exception of trisomy 20.

Interestingly, all of the mosaic trisomies may present with postnatal skin pigmentation defects, such as hypomelanosis of Ito. The precise connection between mosaicism and the skin pigmentation defects is unknown. Also, a number of the mosaic trisomies can demonstrate subtle body asymmetries.

INCIDENCE

It is difficult to get accurate livebirth incidences for the mosaic trisomies. Most of the data that have been reported are from the prenatal diagnosis or the pathology literature. For example, full trisomy 16 is the most common trisomy that is found in spontaneous abortions. Trisomy 16 occurs in at least 1.5% of all clinically recognized pregnancies (Wolstenholme, 1995). This condition comprises 31% of all autosomal trisomies in products of conception. Similarly, trisomy 20 is one of the most common forms of autosomal mosaicism diagnosed at amniocentesis (Hsu et al., 1987). Mosaic trisomy 20 accounts for 2% of all trisomic miscarriages (Hsu et al., 1987; Robinson et al., 2005). Mosaicism for trisomy 8 has been detected in approximately 1 in 3870 amniocenteses (van Haelst et al., 2001). Trisomies 9 and 14 account for 2.7% and 3.7%, respectively, of chromosomally abnormal miscarriages (Fujimoto, 1992; Chitayat et al., 1995).

SONOGRAPHIC FINDINGS

Trisomy 8

The sonographic findings for trisomy 8 include nuchal fold thickening, hemivertebrae, ventriculomegaly (Southgate et al., 1998), reversed end-diastolic ductus venosus blood flow (Campbell et al., 2001), pyelectasis, hydronephrosis, ureteral reflux, and cardiac abnormalities (Miller et al., 2001).

Trisomy 9

Stipoljev et al. (2003) reviewed the sonographic findings in 12 nonmosaic and 13 mosaic fetuses with trisomy 9. The sonographic abnormalities seen in full trisomy 9 included intrauterine growth restriction, microcephaly, increased nuchal translucency measurement, cystic hygroma, micrognathia, hydrops, decrease in the long bone measurements for age, congenital heart defects, skeletal abnormalities, and Dandy–Walker malformation. Dandy–Walker malformation (see Chapter 11) is seen in 12% to 15% of fetuses with trisomy 9. For the mosaic fetuses, the characteristic abnormalities are Dandy–Walker malformation, intrauterine growth restriction, micrognathia, and hydronephrosis. Other abnormalities associated with trisomy 9 include hepatic calcifications, diaphragmatic hernia, and male genital abnormalities.

Trisomy 14

There have been no comprehensive reports of prenatal sonographic findings in trisomy 14. However, from the postnatal literature, what might be expected would be intrauterine growth restriction, micrognathia, congenital heart disease (especially tetralogy of Fallot), polyhydramnios, and micropenis.

Trisomy 16

Characteristic pathologic findings associated with trisomy 16 include intrauterine growth restriction, congenital heart disease (atrial septal defect, ventricular septal defect, and tetralogy of Fallot), single umbilical artery, and renal anomalies. Astner et al. (1998) reported on sonographically associated anomalies associated with confined placental mosaicism for trisomy 16. They noted the presence of a thickened and enlarged cystic placenta. The cysts that were present in the second trimester but disappeared in the third trimester had an unusual appearance in that they were multiple and round without a hyper-reflective border. They speculated that this might be a sonographic marker for trisomy 16.

Trisomy 20

For the majority of cases of mosaic trisomy 20, the sonographic findings have been normal. James et al. (2002) reported on 14 cases of trisomy 20 mosaicism. Of these, three had an increased nuchal translucency measurement on a first trimester scan. The remaining 11 cases had a detailed second trimester anatomy scan that was normal. What might be expected from the postnatal literature would also be the possibility of a heart or renal malformation.

DIFFERENTIAL DIAGNOSIS

The diagnosis of each of these conditions is based on highly accurate cytogenetic analysis.

ANTENATAL NATURAL HISTORY

For all of these conditions, full trisomy is generally lethal in utero. Whether or not the fetus survives depends on a number of factors. These include whether or not the trisomy is confined to the placenta, whether or not there is a rescue disomy, and whether or not UPD of the remaining disomic chromosomes exists. Because trisomies 16 and 20 are more common than trisomies 8, 9, and 14, relatively more information is available.

Trisomy 16

In cases of mosaic trisomy 16, placental mosaicism is always present. In spontaneous abortions with trisomy 16, the extra copy of 16 is always maternal in origin (Hsu et al., 1998). The mosaic trisomy 16 cases that derive from full trisomy and undergo disomic rescue have approximately a 30% to 40% chance of maternal UPD for chromosome 16. If UPD for 16 is present, there is an increased incidence of both intrauterine growth restriction and congenital anomalies (Yong et al., 2002). Most cases of trisomy 16 spontaneously abort between 8 and 15 weeks of gestation (Wolstenholme, 1995;

Benn, 1998). Trisomy 16 detected at amniocentesis is more likely to be associated with anomalies as compared with trisomy 16 detected at CVS, which is more likely to be due to confined placental mosaicism. It has been shown by many investigators that adverse fetal outcomes are more common when the trisomy is detected in the amniotic fluid (Yong et al., 2003; Langlois et al., 2006; Neiswanger et al., 2006).

Trisomy 20

Trisomy 20 is more frequently detected in specific fetal tissues, such as kidney, rectum, and esophagus. Trisomy 20 cells have not been detected in fetal blood. Interestingly, there is a clear association between the percent trisomy and outcome in mosaic trisomy 20. Several investigators have shown that a percent mosaicism above 60% is associated with an abnormal outcome (Hsu et al., 1987; Robinson et al., 2005).

MANAGEMENT OF PREGNANCY

In general, the cytogenetic detection of a mosaic aneuploidy mandates that a detailed sonographic assessment of fetal anatomy should be performed in a tertiary center. As stated earlier, clinical phenotype does not correlate with the percentage of mosaicism for most autosomal trisomies; the only exception to this is trisomy 20. For the mosaic trisomies 8, 9, and 14, there are no specific recommendations, other than to perform a detailed sonographic assessment of fetal anatomy and to meet with a clinical geneticist for the prognosis for an infant with these conditions. For a woman carrying a fetus with mosaic trisomy 16, the pregnancy is at significant risk for developing pre-eclampsia (Yong et al., 2006). In one study, 25 cases of prenatally diagnosed mosaic trisomy 16 were reviewed and 6 of the pregnant women (24%) developed pre-eclampsia compared with 3 of 44 (7%) of controls. No clinical variables were predictive of which women carrying fetuses with mosaic trisomy 16 would develop pre-eclampsia. Therefore, the recommendation is that all women carrying fetuses with mosaic trisomy 16 who continue their pregnancies should be monitored for this complication. Percutaneous umbilical blood sampling (PUBS) is not recommended to determine the prognosis for trisomy 16, as it is not helpful. Also, it is not currently recommended to test fetal material for the presence of maternal UPD for chromosome 16 (Yong et al., 2002). Furthermore, it should be noted that pregnancies affected by mosaic trisomy 16 generally have extremely high hCG values with a median multiple of the median (MOM) of 8.62. These pregnancies also have high α-fetoprotein levels and low unconjugated estriol levels (Benn, 1998).

Similarly, there is insufficient evidence to warrant testing for UPD in mosaic trisomy 20 (Robinson et al., 2005). Because mosaic trisomy 20 has only rarely been shown to be present in fetal blood, PUBS is also not recommended for mosaic trisomy 20. For cases of mosaic trisomy 20, the results of the fetal anatomic survey will dictate further management. One study showed that if the fetal anatomy appears normal on prenatal ultrasound examination, the prospective parents should be counseled that the risk of a fetal abnormality is less than 10% (James et al., 2002). Several other studies have examined the correlation between the percent mosaicism in the amniocentesis and CVS sample and outcome. If the mosaicism is less than 40%, there is a 4% chance of an abnormal outcome (Robinson et al., 2005); however, even in cases with high levels of mosaicism in the amniotic fluid culture, half of the cases will have a normal outcome.

FETAL INTERVENTION

No fetal interventions are indicated for the mosaic aneuploidies.

TREATMENT OF THE NEWBORN

Newborns with the mosaic trisomies should be delivered in a tertiary center capable of pediatric subspecialty care or transferred to an institution with these services. A complete physical examination is indicated, as well as consultation with a medical geneticist. An echocardiogram and an abdominal sonogram should be considered to evaluate for the presence of cardiac and renal anomalies.

Trisomy 8

Newborns with trisomy 8 have several characteristic anomalies, including deep plantar and palmar creases, a prominent forehead, large dysplastic ears, agenesis of the corpus callosum, and skeletal abnormalities, including camptodactyly and clinodactyly.

Trisomy 9

Infants with trisomy 9 have intrauterine growth restriction, a dysmorphic face with retromicrognathia and small palpebral fissures, microcephaly, dislocated hips, knees and elbows, and abnormal genitalia (Chitayat et al., 1995). The typical trisomy 9 facial phenotype includes a bulbous nose, microophthalmia, and dislocated limbs (Arnold et al., 1995) (Figures 133-1 and 133-2).

Trisomy 14

The major clinical findings in trisomy 14 include a normal birth weight, but with postnatal failure to thrive, a dysmorphic face that consists of a broad nose, micrognathia, hypertelorism, small palpebral fissures, a prominent forehead, and a large mouth. Affected infants sometimes have a cleft or a high arched palate, congenital heart disease, micropenis, cryptorchidism, body asymmetry, and abnormal skin pigmentation (Fujimoto et al., 1992).

Figure 133-1 Term infant with mosaic trisomy 18 showing growth restriction, dislocated hips, and clenched hands. These infants are sometimes initially suspected of having trisomy 18.

Trisomy 16

Yong et al. (2003) reviewed 162 cases with a prenatal diagnosis of trisomy 16. Two-thirds of the cases resulted in a live-birth at an average gestational age of 35.7 weeks. Among the infants that were liveborn, 45% had at least one congenital anomaly. The most common malformations were ventricular septal defects, atrioseptal defects, and hypospadias. One of the biggest characteristics of mosaic trisomy 16 is severe intrauterine growth restriction. In this study, the average birth weight was approximately 2 standard deviations below the population mean. Other malformations that were present in eight or more of the cases in the study included two-vessel cord, clinodactyly, and pulmonary hypoplasia (Yong et al., 2003).

Figure 133-2 Same infant shown in Figure 133-1, showing dysmorphic face with microphthalmia, micrognathia, and low-set ears.

Trisomy 20

Most cases of trisomy 20 have been associated with a normal phenotype (Reish et al., 1998).

SURGICAL TREATMENT

There is no surgical treatment that is typical for the mosaic autosomal trisomies. Surgical treatment will depend on whether or not a congenital anomaly is present. The most likely organ systems to require surgical treatment are the cardiac and genitourinary systems.

LONG-TERM OUTCOME

Long-term survival is possible for each of the mosaic trisomies described in this chapter.

Trisomy 8

The long-term outcome for trisomy 8 is very variable. The outcome ranges from mental retardation and failure to thrive to normal development and function. Rauen et al. (2003) described a 23-year-old woman with mosaic trisomy 8 who had cleft palate, mixed bilateral hearing loss, short stature, developmental delay, and dysmorphic features. However, she became pregnant and had a relatively uncomplicated pregnancy. Her daughter had a normal karyotype.

Trisomy 9

In general, long-term survivors with mosaic trisomy 9 have mental impairment that can range from mild to severe. The oldest reported survivor with mosaic trisomy 9 is 9 years old (Saneto et al., 1998).

Trisomy 14

Individuals with trisomy 14 have postnatal failure to thrive and show growth restriction before the completion of their first year of life. For long-term survivors, congenital heart disease is the major issue (Fujimoto et al., 1992). The oldest known surviving woman with mosaic trisomy 14 is 29 years old and has an IQ of 60.

Trisomy 16

Langlois et al. (2006) performed a study of the long-term outcome for children with mosaic trisomy 16. They were able to ascertain 36 cases in which the child was older than 1 year of age. Of the 36, 19 were diagnosed by CVS and 17 cases were diagnosed by amniocentesis. Almost all affected infants were severely growth restricted at birth, but 80% to 90% of the children showed significant catch-up growth. Of the children in which mosaicism was diagnosed at CVS, none had global developmental delay and one had a delay in speech development. The prognosis was worse for those detected at amniocentesis in which 4 of 17 had global developmental delay. None of these children had maternal UPD for chromosome 16. These investigators concluded that the majority of infants and children with mosaic trisomy 16 have a good outcome. Mosaicism at amniocentesis is associated with a greater risk for developmental delay especially if accompanied by the presence of major congenital anomalies on a level II sonogram. Most infants with this condition are not dysmorphic (Figure 133-3).

Figure 133-3 Infant with mosaic trisomy 16 demonstrating a normal facial appearance.

Trisomy 20

The long-term outcome for mosaic trisomy 20 is, in general, good. Robinson et al. (2005) described the outcome for 206 affected pregnancies that ended in a livebirth. Of the 206, only 9 had an abnormal outcome. These included three cases of multiple congenital anomalies, three cases of intrauterine growth restriction, one case of intrauterine growth restriction with hypotonia and micrognathia, one case of cleft lip, and one case of Williams syndrome (which was—in all likelihood—unrelated to the mosaic trisomy 20). Similarly, in a follow-up study performed in New Zealand, James et al. (2002) identified 14 children with mosaic trisomy 20. The longest follow-up period was 10 years. Twelve of the affected children were physically and developmentally normal and 2 cases had only minor abnormalities.

GENETICS AND RECURRENCE RISK

In general, the mosaic autosomal aneuploidies derive from maternal meiosis I errors as the result of advanced maternal age. The exception to this is trisomy 8, in which 50% of the cases are due to maternal meiosis I and 50% are due to a postzygotic mitotic gain of chromosome 8 (James and Jacobs, 1996). In general, the recurrence risk for these conditions is related to maternal age. The exception is when one of the parents has a balanced translocation that involves the affected chromosomes. Parents of fetuses with trisomy 9 have an increased incidence of structural variations in chromosome 9, such as a large heterochromatic region of the long arm of chromosome 9 and/or pericentric heterochromatic inversions of chromosome 9 (Arnold et al., 1995).

If the fetal karyotype shows the presence of a full free-standing extra chromosome, parental chromosome studies are not indicated. However, if the fetus shows the presence of a translocation, parental studies are then indicated.

45, X (Turner Syndrome)

134 CHAPTER

Key Points

- Most common chromosomal abnormality that occurs in females. Only 1% of conceptuses with Turner syndrome survive to term.
- Incidence is 1 in 2500 female livebirths. No association with advanced maternal age.
- Approximately 50% of cases have full 45, X, 30% to 40% have mosaicism, and 10% to 20% have a structural abnormality of one X chromosome. Severity of clinical phenotype cannot be predicted from the karyotype.
- Characteristic sonographic abnormalities include very large cystic hygroma, hydrops fetalis, short femur, coarctation of the aorta, hypoplastic left heart, and renal anomalies.
- In the presence of lymphatic or cardiac malformations, delivery should occur at a tertiary center.
- Major considerations for long-term follow-up include: growth hormone treatment for short stature, estrogen treatment for feminization and bone health, monitoring for cardiovascular complications such as aortic dilatation and rupture, severe hypertension, and propensity toward autoimmune disease.
- Intelligence is normal, but there may be mild learning difficulties related to visual-spatial issues.
- Phenotype may differ depending upon whether the maternal or paternal X is retained. In ~75% of women the maternal X remains.

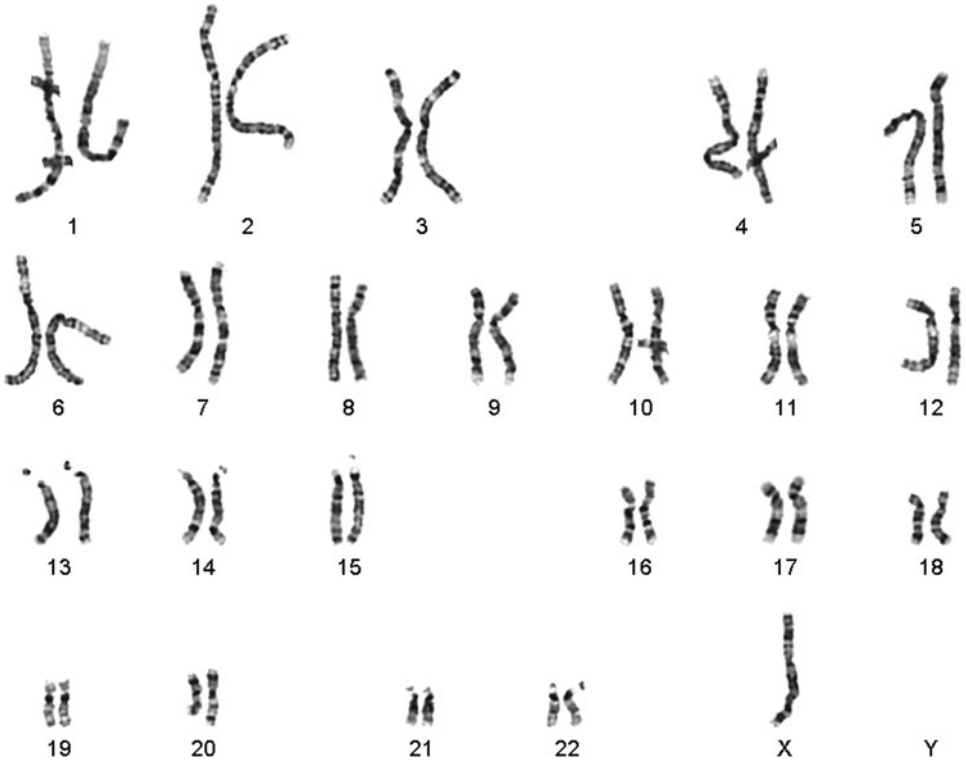

Figure 134-1 Chromosome analysis demonstrating 45, X, which is found in about 50% of cases of Turner syndrome. (*Courtesy of Dr. Janet Cowan.*)

CONDITION

Turner syndrome is named for Henry Turner, who in 1938 recognized the combination of sexual infantilism, webbed neck, and cubitus valgus to be a distinct entity. However, the underlying chromosomal abnormality in the condition was not recognized until 1959 (Ford et al., 1959). Turner syndrome exclusively affects females, and affected patients are generally missing all or part of the X chromosome in all or part of their cells. Postnatally, Turner syndrome is clinically suspected because of short stature, gonadal dysgenesis, or lymphedema. There are no pathognomonic clinical features (Hall and Gilchrist, 1990).

Turner syndrome is the most common chromosomal abnormality that occurs in females. It affects an estimated 3% of all females conceived, but only 1% of these survive to complete a full-term gestation. There are between 50,000 and 75,000 girls and women with Turner syndrome in the United States (Saenger, 1996).

INCIDENCE

The prevalence of Turner syndrome in Denmark is 392 in 100,000 cases ascertained at chorionic villus sampling (CVS), 176 in 100,000 amniocentesis cases, and 32 in 100,000 live female births (Højberg-Gravholt et al., 1996). The incidence of Turner syndrome of 1 in 2500 female livebirths is the most commonly quoted figure (Hall et al., 1982). Turner syndrome does not increase in incidence with advanced maternal age (Koeberl et al., 1995).

Turner syndrome is highly lethal in embryonic and fetal life. Although 1% to 2% of all conceptuses have 45, X, 98% to 99% of affected fetuses miscarry. When spontaneous abortuses are karyotyped, approximately 10% of them are shown to have Turner syndrome (Hall et al., 1982).

Of patients diagnosed with Turner syndrome, approximately 50% have 45, X (monosomy X) (Figure 134-1). An additional 30 to 40% of patients have mosaicism with a normal cell line. However, it is postulated that the incidence of mosaicism is in reality much higher, and that cases that survive to a full-term delivery have placental mosaicism. Of the remaining cases of Turner syndrome, 10% to 20% have a structural rearrangement of the X chromosome, most commonly, isochromosome X (duplication of one arm of the X chromosome with loss of the other arm). Any combination of physical features can be seen with any X chromosomal abnormality. The severity of the clinical phenotype cannot be predicted from the karyotype (Hall et al., 1982).

SONOGRAPHIC FINDINGS

Sonography is the most useful tool to detect cases at risk for Turner syndrome. The prenatal sonographic findings

Figure 134-2 Septated cystic hygroma in the posterior nuchal region, as demonstrated by a fetal sonographic image. This fetus was shown to have 45, X.

that are characteristically found in Turner syndrome include increased nuchal translucency measurement (Kagan et al., 2006), cystic hygroma, renal malformations, and left-sided cardiac anomalies (Papp et al., 2006).

Bronshtein et al. (2003) described a "classic" cluster of abnormalities visualized by transvaginal sonography in 13 fetuses with Turner syndrome studied at 14 to 16 weeks. These included very large cystic hygroma, severe subcutaneous edema, hydrops fetalis, short femur, and narrow aortic arch. Cystic hygromas are the fetal expression of anomalous lymphatic development (see Chapter 31). The most common anatomic site for cystic hygromas is the nuchal region (Figure 134-2). Cystic hygroma is an ominous prenatal finding. In one study, 93% of continuing pregnancies with cystic hygroma resulted in fetal or neonatal death (Cohen et al., 1989). However, several cases have documented resolution of the cystic hygroma in Turner syndrome. For example, Brookhyser et al. (1993) described the spontaneous resolution of a nuchal cystic hygroma and pleural effusion during the third trimester in a fetus with Turner syndrome. There was a good outcome for this case. Similarly, Chodirker et al. (1988) also described resolution of a cystic hygroma, but demonstrated the postnatal appearance of a webbed neck (pterygium colli) and a rotated ear. Other manifestations of lymphatic malformations include transient bilateral pleural effusion, which has been demonstrated as early as the first trimester using transvaginal imaging (Shimizu et al., 1997).

The sonographic diagnosis of cystic hygroma is made by the demonstration of a thin-walled multiseptated asymmetrical fluid-filled mass attached to the lateral aspect of the fetal head or neck (see Figure 134-2). The mass is in a constant location with respect to the fetal occiput and is independent of fetal motion (Garden et al., 1986; Donnenfeld and Mennuti, 1988).

A somewhat rarer presentation of the fetal lymphatic malformations seen in Turner syndrome is isolated fetal ascites. Wax et al. (1992) presented a case of massive fetal ascites and polyhydramnios detected at 32 weeks of gestation resulting from congenital intestinal lymphangiectasia. The diagnosis was later shown to be Turner syndrome.

Other manifestations of Turner syndrome include cardiovascular anomalies. In 2003, Surerus et al. reported on 53 fetuses with 45, X; 47 of them were ascertained by the presence of an increased nuchal translucency measurement. Cardiac malformations were detected in 33/53 fetuses (62.2%). Nuchal translucency measurement was greater in the fetuses with congenital heart disease than in those without. Coarctation of the aorta was observed in 24/53 fetuses (45.3%). Hypoplastic left heart syndrome was the next most common finding (seen in 7/53, or 13.2% of cases). These authors concluded that structural heart disease is more common in prenatal than postnatal life, and that the type of lesions observed was different. For example, postnatally, bicuspid aortic valve is the most common abnormality in Turner syndrome (Gøtzsche et al., 1994).

Approximately 30% to 60% of patients with Turner syndrome have a structural or positional renal anomaly (Hall et al., 1982; Hall and Gilchrist, 1990). Horseshoe kidney is especially common, seen in 20% of patients with Turner syndrome. Other typical malformations include duplication of the collecting system (20% of cases) and malrotation (seen in 50% of kidneys). Renal anomalies seen in Turner syndrome rarely result in renal malfunction but may predispose to postnatal urinary tract infections.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis varies according to the age at presentation of symptoms. Prenatally, the lymphatic malformations predominate. The differential diagnosis for cystic hygroma includes cystic teratoma, meningocele, encephalocele, and neural tube defect (Bluth et al., 1984). Cystic hygroma

can be differentiated from neural tube defects by the demonstration of bilateral echo-free spaces divided by septae. In addition, with a cystic hygroma there is an intact cranial vault and an intact spinal canal. Ascites and an edematous placenta can be seen in association with cystic hygroma, but is generally not seen in association with neural tube defects or cystic teratoma.

At birth, peripheral lymphedema has the differential diagnosis of Milroy disease, and other single-gene disorders associated with lymphedema, such as lymphedema with recurrent cholestasis or lymphedema with intestinal lymphangiectasia.

Turner syndrome can be detected later in life because of short stature or amenorrhea. The differential diagnosis of short stature includes familial short stature, Noonan syndrome, dyschondrosteosis (Leri–Weill syndrome), growth hormone deficiency, and hypothyroidism (Hall et al., 1982).

Noonan syndrome can be distinguished from Turner syndrome on the basis of a normal chromosome analysis.

ANTENATAL NATURAL HISTORY

Turner syndrome results from haploinsufficiency for specific genes located on the X chromosome. It is highly lethal in utero (Committee on Genetics, American Academy of Pediatrics, 1995) (Figure 134-3). It is estimated that as many as 80% of liveborn infants with Turner syndrome have an additional normal cell line that permits postnatal survival (Amiel et al., 1996). In one study of four fetuses with Turner syndrome, three were phenotypically normal and one had malformations. All three that were phenotypically normal had the presence of an additional normal cell line. In the one fetus with malformations, no normal cell line could be demonstrated in any of the tissues examined (Amiel et al., 1996). In a study of 16 first trimester fetuses with a variety of chromosomal abnormalities, a monoclonal antibody was used to study the distribution syndrome of lymphatic vessels (von Kaisenberg et al., 1999). In the 3 fetuses with Turner syndrome, the vessels were hypoplastic in the upper dermis.

It is thought that the lymphatic malformations originate from hypoalbuminemia. In a study by Shepard and Fantel (1986), fetuses with Turner syndrome had lower albumin levels in their plasma as compared with control fetuses. These investigators postulated that early edema resulting from hypoalbuminemia may interfere with the normal development of the lymphatics. In fact, most of the congenital anomalies seen in Turner syndrome can be explained on the basis of lymphedema at critical points in development (Hall and Gilchrist, 1990). Some investigators hypothesize that the lymphedema is the result of failure to open embryonic lymph channels. Pterygium colli (webbed neck) results from an in utero persistence of embryonic lymph sacs.

A correlation between neck webbing and the presence of coarctation of the aorta has been noted by Clark (1984), who postulated that large lymph channels adjacent to the aortic outflow tract misdirect blood flow to the aorta, thus producing an abnormal blood flow through the ductus arteriosus. In a study of 12 fetuses terminated between 16 and 26 weeks of gestation because of a prenatal finding of cystic hygroma or hydrops, 8 demonstrated a consistent constellation of cardiac defects. These included a small ascending aorta, relatively large pulmonary arteries that were 1.5 to 3 times the size of the aorta, a large patent ductus arteriosus, and a juxtaductal coarctation of the aorta (Lacro et al., 1988). The high incidence of left-sided flow defects among the fetuses in this study supports the hypothesis that there is a pathogenetic relationship between lymphatic obstruction and the subsequent development of congenital heart disease. In this study, lymphatic distention was demonstrated on histologic sections obtained through the base of the heart and the pulmonary hila. These data support the concept that hydrostatic pressure occurring within the jugular lymphatic sac can also distend the cardiac lymphatics (Lacro et al., 1988).

Figure 134-3 Postmortem photograph of a fetus with Turner syndrome. Note the large septated cystic hygroma, body wall edema, and presence of pedal edema. (*Courtesy of Dr. Joseph Semple.*)

MANAGEMENT OF PREGNANCY

In general, Turner syndrome is suspected because of the presence of an abnormal sonogram or an abnormal serum screening result. Some cases of Turner syndrome are also unexpectedly detected at amniocentesis for advanced maternal age. A unique pattern of serum screening markers is present in both hydropic and nonhydropic cases of Turner syndrome. Typically, there is a slightly reduced α-fetoprotein level, markedly reduced estriol, and increased human chorionic gonadotropin (hCG) levels in hydropic cases of Turner syndrome (Saller et al., 1992; Ruiz et al., 1999). Free β-hCG is thought to be the most effective serum marker for Turner syndrome (Laundon et al., 1996). In Laundon et al.'s study of 17 cases of Turner syndrome, the median level for the multiple of the median for free β-hCG was 4.04.

In the setting of either an abnormal sonogram or an abnormal serum screen, prospective parents should meet with a genetic counselor to discuss the indications for an invasive diagnostic procedure. Turner syndrome is definitively diagnosed by prenatal karyotype. Once the chromosome analysis confirms the finding of Turner syndrome, prospective parents should meet with a medical geneticist to discuss the long-term implications of the findings, which will differ according to the karyotype. In general, parents should know that a diagnosis of Turner syndrome implies short stature, some congenital anomalies, infertility without assisted reproductive technology, and some learning difficulties. However, girls with Turner syndrome have normal intelligence.

If mosaicism is present, the implications of the specific karyotype should be discussed. For example, Koeberl et al. (1995) described their experience with 12 patients diagnosed with amniocentesis for advanced maternal age or maternal serum screen and a documented fetal karyotype of 45, X/46, XX. They compared the long-term outcome for the prenatally diagnosed group with a group of 41 postnatally diagnosed girls with mosaic Turner syndrome. The patients that were diagnosed prenatally had less severe findings than the postnatal patients. These girls all had normal linear growth. Only 4 of the 12 had structural anomalies, which included atrial septal defect, ptosis, labial fusion, dysplastic kidneys, and hydrometrocolpos. None of the prenatally diagnosed group had physical findings that would have warranted karyotyping for a clinical suspicion of Turner syndrome at birth. This contrasted with the postnatally diagnosed group, who presented with a variety of congenital anomalies and short stature. These investigators suggested that most individuals with 45, X/46, XX would normally escape detection during the newborn period.

A study of 76 cases of 45, X/46, XY mosaicism was published by Chang et al. (1990). Of these patients, 95% had normal male genitalia. Four patients had significant genital anomalies, which included three cases of hypospadias and one female with clitoromegaly. The degree of amniotic fluid mosaicism did not predict the degree of genital or gonadal abnormality. It is commonly stated that patients with 45, X/46, XY are at risk for gonadoblastoma. In 11 patients who underwent gonadal biopsy, 3 had abnormal gonadal histology.

There is no indication for a cesarean section based on the diagnosis of Turner syndrome alone. The decision about whether to deliver in a tertiary care center is made on the basis of the significance of the lymphatic malformations and the presence of cardiac disease. If the fetus has hydrops fetalis, delivery should occur at a tertiary care center. Similarly, if there is concern that the cystic hygroma may interfere in any way with airway management in the newborn infant, delivery should occur at a tertiary care center. For a patient with a known fetal diagnosis of Turner syndrome, but no sonographic abnormalities, delivery can safely occur in a community medical center. However, plans should be made for postnatal consultation with a pediatric cardiologist and a medical geneticist.

FETAL INTERVENTION

There are no fetal interventions for Turner syndrome.

TREATMENT OF THE NEWBORN

The average birth weight of newborns with Turner syndrome is 2.8 kg (around 500 g below average) and the average length is 48 cm (2.8 cm below average) (Hall and Gilchrist, 1990). Untreated infants with Turner syndrome tend to remain small, generally at the 3rd to 10th percentile for age. At birth, a complete physical examination is indicated and congenital hip dysplasia should be ruled out. We recommend consultation with a pediatric cardiologist at birth and echocardiography to rule out left-sided cardiac defects. The published percentage of individuals with Turner syndrome who have cardiovascular malformations is between 17 and 47% (Gøtzsche et al., 1994). The specific abnormalities that are greatly increased in this population of patients include aortic coarctation and bicuspid aortic valve. In a large retrospective review, Sybert (1998) demonstrated that 136 of 244 patients with Turner syndrome (56%) had cardiovascular abnormalities. Of these, 71% were structural and 29% were functional. The functional abnormalities included hypertension, mitral valve prolapse, and conduction defects. Sybert confirmed that coarctation of the aorta and bicuspid aortic valve comprised greater than 50% of the structural abnormalities.

Eighty percent of babies with Turner syndrome are born with lymphedema. The pedal lymphedema is treated symptomatically. The cystic hygroma generally recedes, leaving folds of skin in the neck and a low hairline on the back of the neck. The protruberant ears with upturned lobules are a residual manifestation of the lymphatic abnormalities that were present in utero (Figure 134-4).

During the newborn period, an abdominal ultrasound examination is also indicated to look for the presence of

Figure 134-4 Photograph of a young girl with Turner syndrome, demonstrating the postnatal appearance of the neck webbing. (*Courtesy of Dr. Patricia Wheeler.*)

renal malformations. In a postnatal study of 141 patients with Turner syndrome, Lippe et al. (1988) demonstrated renal abnormalities in 47 (33%) of patients. Ten of these patients had a horseshoe kidney, 1 had a double collecting system, 4 had complete absence of one kidney, 3 had crossed ectopia, 3 had ureteropelvic obstruction, 2 had ureterovesical obstruction, and 1 had a pelvic kidney. The 7% incidence of horseshoe kidney in patients with Turner syndrome can be compared to a prevalence of 1 in 600 normal individuals (Lippe et al., 1988).

Additional problems that can exist during the newborn period for patients with Turner syndrome include feeding difficulties due to the presence of a high arched palate and inefficient sucking and swallowing. Also, patients with Turner syndrome are subject to recurrent otitis media due to anatomic alterations at the base of the skull that change the angle of the eustachian tube.

Routine pediatric management recommendations for females with Turner syndrome have been published (Committee on Genetics, American Academy of Pediatrics, 1995; Frias and Davenport, 2003; Bondy, 2007).

SURGICAL TREATMENT

Thomson et al. (1990) described the surgical treatment for the simple neck webbing found in Turner syndrome. In four cases, they excised the excess neck skin and closed the defect to flatten the web against the side of the neck. In patients with Turner syndrome, they found that a defined band of fibrous tissue ran from the acromion to the mastoid process and was present in all cases studied. The underlying muscle and superficial layer of deep cervical fascia were noted to be normal and separate from the web. The skin anterior to the web was normal but the skin posterior to the web was freely mobile. When they biopsied the fibrous bands, they were demonstrated to consist of fibrous tissue and no other abnormalities (Thomson et al., 1990). These investigators achieved excellent cosmetic results. They recommended the lateral approach to elevate the hairline.

LONG-TERM OUTCOME

The major considerations regarding long-term follow-up include treatment of short stature, cardiovascular abnormalities, including complications due to vascular malformations and hypertension, specific issues related to cognitive development, the propensity toward autoimmune disease, and issues surrounding fertility.

With regard to short stature, familial height plays a role in the ultimate height of patients affected with Turner syndrome (Hall et al., 1982). In other words, taller parents have taller daughters. For most patients with Turner syndrome, the bone age is within normal limits until ages 12 to 14 but without the influence of pubertal hormones there is no adolescent growth spurt. In a large survey taken in United States, untreated patients with Turner syndrome achieved an adult height of 143.0 cm (4 ft 8 in.). With growth hormone, patients achieved a mean height of 151.9 cm (4 ft 11.5 in.), a net gain of 8.1 cm (Saenger, 1993). Growth hormone treatment should be initiated when the child's height drops below the fifth percentile of the normal female growth curve. This generally occurs between ages 2 and 5 years (Saenger, 1996). Most endocrinologists recommend treatment with growth hormone until the bone age is greater than 15 years and the growth slows to less than 2 cm per year. In addition, estrogen therapy is recommended beginning at around age 14 to induce the secondary sexual characteristics and to promote bone health. Only natural estrogens are recommended for these patients, as synthetic estrogens are incompletely metabolized. Approximately 20% to 25% of patients with Turner syndrome have spontaneous pubertal development and 2% to 5% have spontaneous onset of menstrual periods (Saenger, 1996).

Patients with Turner syndrome are predisposed to vascular malformations, which include intestinal telengiectasias and hemangiomas, and they have an increased incidence of ulcerative colitis and Crohn disease. The incidence of

hypertension in adults with Turner syndrome is 30% (Hall et al., 1982). Individuals with Turner syndrome need to be monitored for hypertension on a lifelong basis (Sybert, 1998). Magnetic resonance angiography in addition to ultrasonography is currently recommended for periodic follow-up of the cardiovascular system (Bondy, 2007). The majority of patients with aortic dilation have associated risk factors, such as bicuspid aortic valve or coarctation or systemic hypertension (Lin et al., 1998).

With regard to specific learning difficulties in patients with Turner syndrome, Bender et al. (1984) studied an unselected group of 16 patients with Turner syndrome. They noted a slight delay in walking and average development of language skills, but a striking deficit in perceptual organization and fine motor skills. Patients with Turner syndrome have a type of space–form blindness. They have difficulties identifying position in space, mentally rotating geometric shapes, and orienting to left–right directions. This visual-spatial impairment may be due to bilateral small volumes of the hippocampus and caudate, lenticular, and thalamic nuclei as well as parieto-occipital brain matter, as measured by MRI (Murphy et al., 1993). Importantly, intelligence is normal in Turner syndrome, unless a specific X chromosome abnormality is present.

Other complications in patients with Turner syndrome include otitis media, progressive sensorineural hearing loss in more than 60% of patients (Morimoto et al., 2006), conductive middle ear disease (Sculerati et al., 1996), strabismus and other eye findings, such as ptosis, hypertelorism, and red–green color deficiency (Chrousos et al., 1984). Scoliosis is present in 10% of cases (Saenger, 1996) and specific dermatologic abnormalities such as pigmented nevi and increased keloid formation are also characteristic. In addition, there is an increased incidence of autoimmune thyroid disease (Gruñeiro de Papendieck et al., 1987). Adult women with Turner syndrome have a high incidence of undiagnosed lipid, thyroid, and bone mineral density abnormalities (Garden et al., 1996). Women with Turner syndrome have a high incidence of coronary artery disease (Aligeti and Horn, 2007).

Fertility issues are significant for adult patients with Turner syndrome (Sutton et al., 2005). Several studies have performed pelvic sonography in childhood (Massarano et al., 1989; Mazzanti et al., 1997). During childhood, the ovaries can be classified as streak or nonstreak. Nonstreak ovaries retain a range of function. Patients with mosaicism have the highest percentage of detectable ovaries, as compared with patients with full monosomy 45, X (Mazzanti et al., 1997). Patients with Turner syndrome are infertile due to the streak ovaries, which result in an inability to ovulate. With the addition of hormonal replacement during early adolescence, patients can achieve secondary sexual characteristics and establish menses. Spontaneous pregnancy is rare, but possible. Reported cases of spontaneous pregnancy in Turner syndrome patients are associated with an increased incidence of miscarriage, perinatal fetal death, and malformations (Tarani et al., 1998).

Over the past decade, fertility has become possible using assisted reproductive technology and oocyte donation. In one study of 29 patients with Turner syndrome, Khastgir et al. (1997) documented 28 clinical pregnancies, including two sets of triplets. These investigators achieved a pregnancy rate of 41.2% per treatment cycle and a 17.1% implantation rate per embryo transferred. The recipient's age, specific karyotype or uterine anomaly had no influence on the treatment outcome. However, as more women with Turner syndrome undergo pregnancy, previously unknown complications have emerged (Practice Committee of the American Society for Reproductive Medicine, 2006). These include aortic rupture and dissection, significant hypertension, and risk of death. Women with Turner syndrome who are interested in oocyte donation need careful cardiac evaluation prior to comtemplating pregnancy.

GENETICS AND RECURRENCE RISK

In general, Turner syndrome is considered to be a sporadic condition. It is not associated with advanced maternal age. Genes that are important in the phenotype of Turner syndrome include the short-stature-homeobox (*SHOX*) gene, which maps to Xp22.2, and *USP9X*, which maps to Xp11.4, and is a candidate for gonadal dysgenesis. *D1APH2*, located at Xq, is required for normal ovarian function (Baena et al., 2004).

In several studies, the role of genetic imprinting has been investigated. On average, about 75% of Turner syndrome patients retain their maternal X chromosome (Sagi et al., 2007; Jacobs et al., 1997). There is a highly significant correlation between the child's height and the maternal height percentile when the X chromosome is inherited from the mother but not from the father. Similarly, there is also a strong correlation between the presence of cardiovascular abnormalities, neck webbing, and renal malformations with retention of the maternal X chromosome. In addition, the retention of the paternal X chromosome results in better social adjustment and superior verbal and higher-order executive function skills (Skuse et al., 1997). These data indicate that there is a genetic locus for social cognition, which is imprinted, and not expressed from the maternally derived X chromosome.

Patients who have Turner syndrome and have mosaicism for a small portion of the Y chromosome face a risk of gonadoblastoma. Cytogenetic analysis can fail to detect rare cells bearing a normal or structurally abnormal Y chromosome. Binder et al. (1995) screened 53 individuals with Turner syndrome for the presence of the sex-determining region Y (*SRY*) sequence. Of the 53 individuals, none were positive for Y specific loci after the first round of polymerase chain reaction (PCR) but 2 were positive *SRY* after the second round of PCR. This indicates that the distal short arm of the Y chromosome is occasionally present. More recent studies of girls who

were 45, X by conventional karyotype showed that up to 35% had evidence of hidden Y chromosome mosaicism by PCR (Bianco et al., 2006). These data suggest that PCR should be considered in girls with Turner syndrome to determine who is at risk for gonadoblastoma.

Patients with Turner syndrome who conceive spontaneously have a 30% chance of having a fetus with chromosomal abnormalities or congenital anomalies (Saenger, 1996). Any woman with Turner syndrome who conceives spontaneously should be offered amniocentesis. Women who conceive using oocyte donation will only need amniocentesis if their donor is over age 35.

Patients who have had a previous fetus or infant with Turner syndrome may be offered chromosome analysis in a subsequent pregnancy for reassurance.

47, XXY (Klinefelter Syndrome)

135 CHAPTER

Key Points

- Results from meiotic nondisjunction that occurs in the sperm (44% of cases) or egg (56% of cases).
- About 10% of all cases are diagnosed prenatally and 26% of cases are diagnosed postnatally. The majority of cases are never diagnosed, which suggests that symptoms are mild.
- Incidence of 47, XXY is 1 in 500 to 1 in 800 male births. Incidence of 48, XXXY is 1 in 20,000.
- No sonographic findings are characteristic. Nuchal translucency measurement may be increased.
- The most significant factors regarding the decision whether or not to terminate the affected pregnancy are the presence of sonographic abnormalities and the medical specialty of the person providing the genetic counseling.
- Affected males are tall, but phenotypically normal, with an increased risk for developmental delays in speech, neuromotor, and learning disabilites.
- Testosterone treatment is recommended, beginning at puberty.
- 50% to 80% of affected males develop gynecomastia, but it is usually mild.
- Fertility is now possible with assisted reproductive technology.
- Motor impairment and speech and language problems are more common if the extra X chromosome is paternally derived.

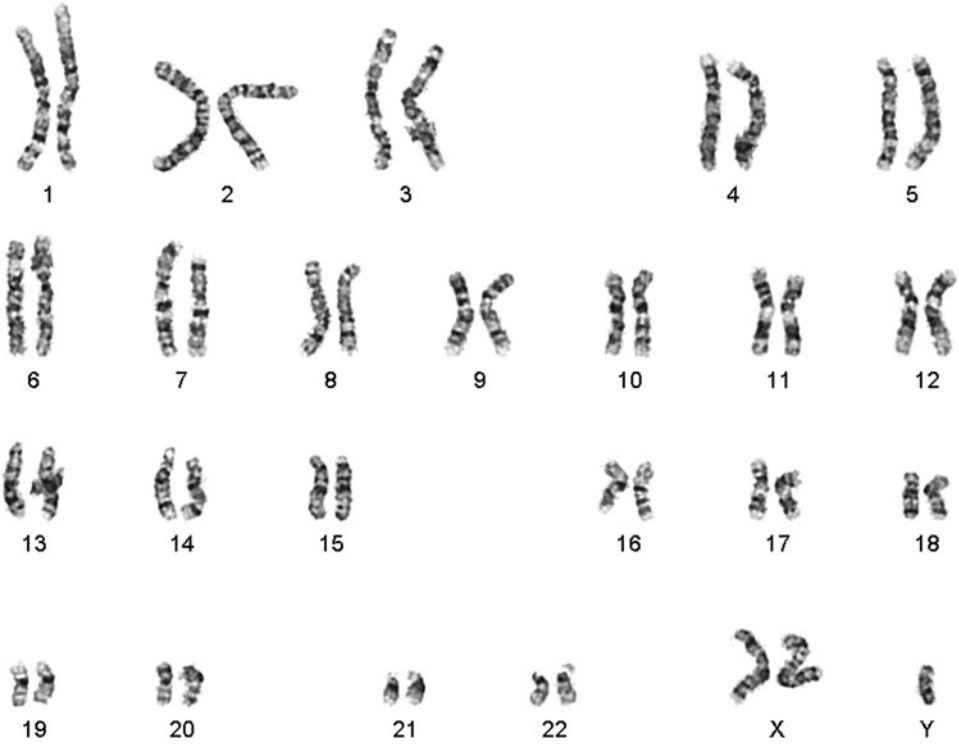

Figure 135-1 Karyotype obtained from a patient with Klinefelter syndrome, demonstrating presence of two X and one Y chromosomes. (*Courtesy of Dr. Janet Cowan.*)

CONDITION

Klinefelter syndrome (47, XXY karyotype) is the spectrum of phenotypic features resulting from a sex chromosome complement that includes two or more X chromosomes and one Y chromosome (Figure 135-1). It results from meiotic nondisjunction occurring during gametogenesis of the egg or sperm with subsequent fertilization of an XX ovum by a Y bearing sperm, or fertilization of an X ovum by a sperm bearing both the X and Y chromosomes (Mandoki et al., 1991). There are no known predisposing factors except advanced maternal age in some, but not all, cases. The condition was first described in nine men with gynecomastia, infertility with normal Leydig cells, a normal to low 17-ketosteroid level, and a high follicle stimulating hormone level in the urine (Klinefelter et al., 1942; Schwartz and Root, 1991). It was not until 1956 that the chromosomal basis of this abnormality was appreciated by noting the presence of the Barr body on buccal smears obtained from affected patients, which represented the inactive extra X chromosome (Arens et al., 1988). The specific chromosomal abnormality reponsible for the disorder was not known until 1959.

The phenotype in Klinefelter syndrome is extremely variable and may be subtle. Most cases are never diagnosed. In general, affected males are identified by age-related clinical concerns (Table 135-1). Infant patients are identified by either prenatal cytogenetic testing for advanced maternal age or by the presence of mild genital abnormalities (Schwartz

Table 135-1

Clinical Features of Klinefelter Syndrome Across the Lifespan

Age	Features
Fetus	Usually none
Infant	Usually none; occasionally, small penis; hypotonia
Toddler	Delay in expressive speech development
Child	Accelerated linear growth velocity (long legs); learning disabilities
Adolescent	Sparse facial, axillary, pubic hair Gynecomastia (50% to 80%) Small testicular volume (<5 mL) Long legs, narrow shoulders, wide hips
Adult	Infertility (azoospermia) Leg ulcers

and Root, 1991). During school-age years, affected patients may be identified by the occurrence of learning disabilities and behavioral problems, whereas in adolescence, the clinical diagnosis is usually suspected from gynecomastia, a taller than average stature, and a possible delay in pubertal development. However, a large number of patients with Klinefelter syndrome are identified as adults when they present during a workup for infertility (Schwartz and Root, 1991).

INCIDENCE

A study of 34,910 newborns performed over 13 years in Arhus, Denmark, put the incidence of Klinefelter syndrome at 1 in 576 newborn male infants (Nielsen and Wohlert, 1991). 47, XXY is generally described as occurring in 1 in 500 to 1 in 800 live male births (Mandoki et al., 1991). About 7% of cases are mosaic (46, XY/47, XXY) (Bojesen et al., 2003). Other variants of Klinefelter syndrome include the karyotypes 48, XXXY, which occurs in 1 in 20,000 live male births, and the karyotype 49, XXXY, which occurs in 1 in 85,000 live male births (Kleczkowska et al., 1988). For a review of the more severe clinical manifestations of 48, XXY, the reader is referred to a study by Linden et al. (1995). In the variant Klinefelter karyotypes, it has been shown that a single parent contributes all of the extra chromosomes present.

The incidence of 47, XXY is increased in twins. In one large study of fetal karyotypes obtained at amniocentesis performed primarily for advanced maternal age, 2 cases of 47, XXY were seen in 1821 singleton fetuses. Three cases of 47, XXY were seen in 21 pairs of twins, giving an incidence of 7.1% in the twin population (Flannery et al., 1984).

Two large, population based studies using national cytogenetic registries have shown that most boys and men with Klinefelter syndrome are not clinically recognized. In the United Kingdom, Abramsky and Chapple (1997) demonstrated that 10% of 47, XXY cases are diagnosed prenatally and 26% are diagnosed in adolescence or adulthood. In Denmark, where all karyotype results are recorded in a central registry, a marked discrepancy between the prevalence of prenatally ascertained cases (153/100,000 male fetuses) and postnatally ascertained cases (40/100,000 males) was shown (Bojesen et al., 2003). Thus, only about a fourth of cases are diagnosed postnatally, which suggests that symptoms are mild.

SONOGRAPHIC FINDINGS

No sonographic findings are characteristic for a fetus with Klinefelter syndrome. In a review of 35 cases of fetal omphalocele, one fetus had a 47, XXY karyotype, but this is probably unrelated (Gilbert and Nicolaides, 1987). Another study has suggested that the median nuchal translucency measurement is increased in cases of sex chromosome abnormalities (Spencer et al., 2000). In general, the fetal phenotype is extremely mild and difficult to distinguish from normal.

ANTENATAL NATURAL HISTORY

In cases of 47, XXY, the phenotype is not distinctly recognizable, even in fetuses studied at autopsy. In one fetus terminated at 20 weeks of gestation, the clinical features of Klinefelter syndrome noted in the fetus included an arm span less than its height, a minor ear abnormality, fifth-finger clinodactyly, and undescended testes (which is not unusual for a fetus at this point in gestation). Significantly, the testicular histology was normal (Flannery et al., 1984). Amniotic fluid testosterone levels do not differ between 46, XY and 47, XXY fetuses (Ratcliffe, 1999).

Using older data, there is a suggestion that there is a slightly increased risk of miscarriage in fetuses with Klinefelter syndrome (Simpson et al., 2003). The risk was derived by comparing the incidence of 47, XXY at amniocentesis and at birth in newborn studies. However, a more recent Danish dataset did not find any cases of spontaneous abortions or stillbirths among prenatally diagnosed cases that were not electively terminated (Bojesen et al., 2003).

MANAGEMENT OF PREGNANCY

Fetuses with Klinefelter syndrome are most commonly identified during amniocentesis performed for advanced maternal age, where it is the third most common chromosomal abnormality diagnosed, after trisomies 21 and 18 (Robinson et al., 1992; Linden and Bender, 2002). It is unlikely that an affected fetus will be identified on the basis of an abnormal sonographic finding. Occasionally, Klinefelter syndrome is associated with abnormalities in maternal serum screening. Reported maternal serum abnormalities include elevated levels of α-fetoprotein (Fejgin et al., 1990) and human chorionic gonadatropin (hCG) (Ben-Neriah et al., 1991; Barnes-Kedar et al., 1993).

The main concern regarding management of pregnancy is the parental decision whether to continue or terminate the pregnancy. One of the difficulties in this area has been the ascertainment bias that exists in the medical literature, overreporting of the more extreme phenotypic aspects of Klinefelter syndrome, and underreporting of patients who have few or no symptoms related to the condition. Ongoing studies regarding developmental outcome for children who have been prenatally diagnosed with 47, XXY suggests a milder phenotype and considerable variability in physical and psychologic development (Robinson et al., 1992; Linden and Bender, 2002). Approximately 30 to 55% of well-informed couples opt to continue their pregnancy after an antenatal diagnosis of 47, XXY (Holmes-Siedle et al., 1987; Lancet editorial, 1988; Robinson et al., 1992; Meschede et al., 1998; Marteau et al., 2002). The most significant factors that influence the decision to terminate the pregnancy include the presence of sonographic abnormalities (Christian et al., 2000; Hamamy and Dahoun, 2004) and the medical specialty of the person providing the genetic counseling following the

karyotype results. In general, the pregnancy is more likely to be continued if the counseling is provided by a geneticist instead of an obstetrician (Hall et al., 2001; Marteau et al., 2002). Robinson et al. (1992) suggest that the following information be given to prospective parents during prenatal counseling for a fetal diagnosis of 47, XXY:

1. Their son will likely be tall but phenotypically normal.
2. Puberty is usually entered normally, but testosterone supplementation therapy may be desirable after midadolescence.
3. Their son will be infertile without the use of assisted reproductive technology.
4. Their son will be at risk for gynecomastia, but this will most likely be mild.
5. Their son will belong to a group of children who are at risk for developmental problems and delays in speech, neuromotor, and learning abilities.
6. Due to some of the language issues, boys with 47, XXY may be shy and insecure.

However, these investigators write that a stable, nurturing, and stimulating environment will considerably enhance developmental outcome (Robinson et al., 1992).

In cases of 46, XY/47, XXY mosaicism, the prognosis is better than for the nonmosiac karyotype, with fewer developmental abnormalities and potential spontaneous fertility (Robinson et al., 1992).

If the decision is made to continue the pregnancy, there is no need for a particular route of delivery. Arrangements should be made to have the parents discuss the prenatal finding of 47, XXY with a medical geneticist.

FETAL INTERVENTION

There are no fetal interventions for 47, XXY.

TREATMENT OF THE NEWBORN

Most newborn male infants with 47, XXY not ascertained by prenatal chromosome analysis will be missed during the neonatal period. In general, findings are normal on physical examination, although the incidence of minor congenital abnormalities may be increased as compared with siblings (Mandoki et al., 1991). Newborns with Klinefelter syndrome may have minor abnormalities of the genitalia, including cryptorchidism and hypospadias (Kleczkowska et al., 1988). A minority of infants with 47, XXY has a small penis, but penile growth occurs with local systemic testosterone treatment (Ratcliffe, 1999). The mean birth weight and height for affected newborns falls well within the range of normal, although the head circumference may be and remain slightly on the small side (Ratcliffe, 1999). A complete physical examination is necessary to ascertain the presence of additional congenital anomalies, but otherwise there is no indication for specific treatment during the newborn period. Exogenous testosterone therapy should not begin until around 11 to 12 years of age (Winter, 1991).

SURGICAL TREATMENT

Gynecomastia may be treated surgically in adolescence or adulthood. The other symptoms of Klinefelter syndrome do not require surgical treatment.

LONG-TERM OUTCOME

There have been several recent, comprehensive review articles that summarize primary care issues for children and adults with Klinefelter syndrome (Visootsak et al., 2001; Simpson et al., 2003; Lanfranco et al., 2004). Adult individuals with 47, XXY have a moderate increase in stature due to excessive growth of the lower extremities, resulting in a height that is greater than or equal to the arm span (Schwartz and Root, 1991). The mean adult height for men with 47, XXY is at the 75th percentile (Lancet editorial, 1988).

Most males enter puberty normally. Basal serum gonadotropins and response to gonadotropin-releasing hormone are normal until 12 years of age, when they rapidly elevate to reach uniformly hypergonadotropic values by age 14 (Winter, 1991). With the onset of puberty, there is an initial increase in testicular volume, but during this time the seminiferous tubules undergo irregular progressive hyalinization and fibrosis, which restricts further growth beyond 2.5 cm (Rutgers, 1991; Schwartz and Root, 1991; Winter, 1991). Patients with nonmosaic Klinefelter syndrome are almost always infertile without the use of assisted reproductive technology. In a large review of 544 Belgian 47, XXY males diagnosed between 1966 and 1987, the majority (397) of affected patients were adults who were diagnosed only by an infertility workup performed for azoospermia (Kleczkowska et al., 1988). There is no increase in homosexual preference in males with 47, XXY (Ratcliffe, 1999). Successful pregnancies in the partners of affected men have been achieved by testicular fine needle aspiration, intracytoplasmic sperm injection, and preimplatation genetic diagnosis (Reubinoff et al., 1998) (see Genetics and Recurrence Risk, below).

Adult men with Klinefelter syndrome demonstrate persistently low circulating testosterone and dihydrotestosterone levels, together with normal or elevated estradiol levels (Hsueh et al., 1978; Winter, 1991). The increased ratio of estradiol to testosterone may play a role in the development of gynecomastia, a condition that affects 50% to 80% of XXY males (Winter, 1991). Gynecomastia most often regresses spontaneously, and cosmetic surgery is rarely needed (Lancet editorial, 1988).

Prospective parents facing a fetal diagnosis of 47, XXY are frequently most concerned regarding the implications for developmental outcome. Individuals with 47, XXY have, in general, average to above average intelligence. In one study, 18.7% of affected individuals had an IQ of less than 90, but the

scores were lowered by verbal deficits (Mandoki et al., 1991). It is now appreciated that 47, XXY males have difficulties with language production more than language comprehension (Graham et al., 1988). They may have delayed speech development, poor short-term auditory memory, and difficulties with reading and spelling (Graham et al., 1988; Lancet editorial, 1988; Ratcliffe, 1999). It is recommended that special attention be paid to language development in affected males and that early referral to a speech therapist be considered. The neurocognitive problems seen are not unique to 47, XXY individuals and management is the same as that for individuals with language problems and normal chromosomes. Less than 4% of 47, XXY males are considered mildly to moderately retarded (Kleczkowska et al., 1988). The overwhelming majority of the adult patients reported in the long-term Belgian study was employed and had a normal work life, and 43% were married (Kleczkowska et al., 1988). In a 20-year follow-up of 47, XXY males, considerable improvement in mental health, working capacity, social adjustment, and activity level was noted between the ages of 27 and 37 years (Nielsen and Pelsen, 1987).

Testosterone therapy is currently recommended, beginning in adolescence. It improves concentration, mood, social interaction, and libido, and prevents osteoporosis, autoimmune disease, and the development of gynecomastia and a eunuchoid body habitus (Winter, 1991; Lanfranco et al., 2004). It does not, however, affect fertility.

The incidence of breast cancer is increased in affected individuals (Evans and Crichlow, 1987; Rutgers, 1991; Bojesen et al., 2006). In one study of 93 males with breast cancer, 7 had 47, XXY, as ascertained by FISH analysis of surgically removed lymph nodes. This represents a 50-fold increased risk above the normal male population (Hultborn et al., 1997). 47, XXY males also have an increased risk for the development of extragonadal germ cell tumors, including mediastinal teratocarcinoma, choriocarcinoma, and cerebral germinoma (Arens et al., 1988; Rutgers, 1991; Hasle et al., 1992; Swerdlow et al., 2005). It is hypothesized that these midline tumors develop in 47, XXY males because of an alteration in testicular gonadal ridge differentiation, which subsequently leads to abnormal migration of primordial germ cells from the yolk sac. Instead of advancing toward the gonads, these germ cells migrate caudally along the midline, and may undergo malignant transformation when they settle in a nonphysiologic location (Arens et al., 1988; Rutgers, 1991).

GENETICS AND RECURRENCE RISK

Klinefelter syndrome is due to nondisjunction occurring during meiosis. Counseling about recurrence risk should incorporate consideration of maternal age, although 50% of cases are paternal in origin. Females known to be carriers of the fragile X mutation have an increased tendency toward nondisjunction of the affected X chromosome. The incidence of the simultaneous occurrence of XXY and fragile X is 1 in 153 males with the XXY karyotype (Kleczkowska et al., 1988).

The parental origin of the extra X chromosome was assessed using 26 DNA probes that detected X chromosome restriction-site polymorphisms in a total of 111 47, XXY individuals (Harvey et al., 1991). In 61 XXY males ascertained by large-scale newborn cytogenetic surveys, 27 (44%) were paternal and 34 (56%) were maternal in origin. In 41 XXY males who presented with clinical features of Klinefelter syndrome, 171 (41%) were maternal and 22 (54%) were paternal in origin. Of a group of 9 cases ascertained by amniocentesis for advanced maternal age, 4 (44%) were maternal, 4 (44%) were paternal, and 1 was unknown in origin (Harvey et al., 1991). Thirty-nine of the maternally derived cases were studied to determine the source of the nondisjunctional error. In 78% of cases it occurred during meiosis I and in 22% of cases it occurred during meiosis II. In another study, the origin of the X chromosome in 41 paternally derived cases of 47, XXY was studied using six different polymorphic genetic loci. Most cases of paternal origin were shown to result from meioses in which the X and Y chromosomes failed to recombine (Hassold and Sherman, 1993).

Until recently, it was thought that there was no phenotypic difference in cases in which the extra X chromosome was maternally versus paternally derived. In 2006, Stemkens et al. studied 54 men with Klinefelter syndrome, and showed that motor impairment and speech and language problems were significantly more common in the men with an extra paternal X chromosome. Similarly, a number of anthropometric parameters related to body size were larger in the paternal X group. This was not surprising, as animal data has shown that paternally expressed genes enhance growth. This study suggested that there is an imprinting effect of the X chromosome on educational performance and body size.

It is possible for men with Klinefelter syndrome to biologically father children using surgical sperm recovery, coordination with egg retrieval, and use of intracytoplasmic sperm injection (ICSI) (Lanfranco et al., 2004). The outcome data on liveborn infants conceived in this way indicates that the overwhelming majority is healthy and has a normal karyotype. The use of preimplantation genetic diagnosis on biopsied blastocysts should be considered, due to data suggeting that embryos derived from men with Klinefelter syndrome have an increased rate (9/23) of both sex chromosome and autosomal aneuploidy (Kahraman et al., 2003). For couples with a previously affected child but in which the father does not have Klinefelter syndrome, prenatal cytogenetic diagnosis by amniocentesis or CVS can be offered in subsequent pregnancies.

47, XXX (Triple X Syndrome, Trisomy X)

136 CHAPTER

Key Points

- Incidence is 1 in 1000 females.
- Most cases are undiagnosed.
- Associated with advanced maternal age (70% are due to a meiosis I error).
- There are no characteristic fetal sonographic findings in this condition, except for occasional genitourinary anomalies.
- IQ of affected women is in the normal range, but 10 to 15 points lower than siblings.
- Mild learning disabilities are primarily verbal.
- Adult women with 47, XXX are tall and fertile.

CONDITION

The chromosome constitution 47, XXX was first described by Jacobs et al. (1959) in a woman of average intelligence with secondary amenorrhea. Since that time, several hundred cases have been reported in the medical literature. The phenotype of infants who are prenatally diagnosed with 47, XXX is significantly different from infants who are diagnosed by newborn screening or clinical symptomatology (Robinson et al., 1992; Linden and Bender, 2002). In general, the prenatally diagnosed infants have a more normal developmental profile. This may be due to factors unrelated to the chromosomes, such as socioeconomic status and level of parental education.

The sex chromosome aneuploidies are the most common group of abnormalities found in prenatal karyotypes, with an incidence of 1 in 250 amniocenteses (Robinson et al., 1992). Despite their frequency, sex chromosome aneuploidy is rarely discussed in preprocedural genetic counseling. Thus, the finding of a fetal sex chromosome abnormality is usually not expected by the pregnant patient (Krone et al., 1975). This diagnosis prompts anxiety and ambivalence because, although the karyotype is abnormal, the phenotype of the affected child can be quite variable. Trisomy X can be associated with a normal outcome. In fact, most cases of 47, XXX are undiagnosed (Ratcliffe, 1999).

INCIDENCE

The incidence of 47, XXX is approximately 1 in 1000 at midtrimester amniocentesis (Hook and Hamerton, 1977) and 0.7 in 1000 livebirths (Tennes et al., 1975). These differences reflect different study populations and are not thought to reflect an increased perinatal mortality for 47, XXX fetuses. Using X-linked restriction fragment length polymorphisms, May et al. (1990) determined the parental origin of the extra X chromosome in 28 individuals with 47, XXX. Maternal nondisjunction was demonstrated in 26 of 28 cases. Seventy percent of these cases were due to an error in meiosis I. Thus, the etiology of trisomy X more closely resembles the autosomal trisomies. In this regard, trisomy X differs from the other sex chromosome aneuploidies, in that there is a maternal age effect. Mitotic errors do not play a significant role in 47, XXX (May et al., 1990).

SONOGRAPHIC FINDINGS

In general, there is no characteristic phenotype associated with trisomy X. The overwhelming majority of fetuses with trisomy X will have normal results on sonographic examination. The diagnosis is typically made at amniocentesis for advanced maternal age. In one study, the fetal nuchal

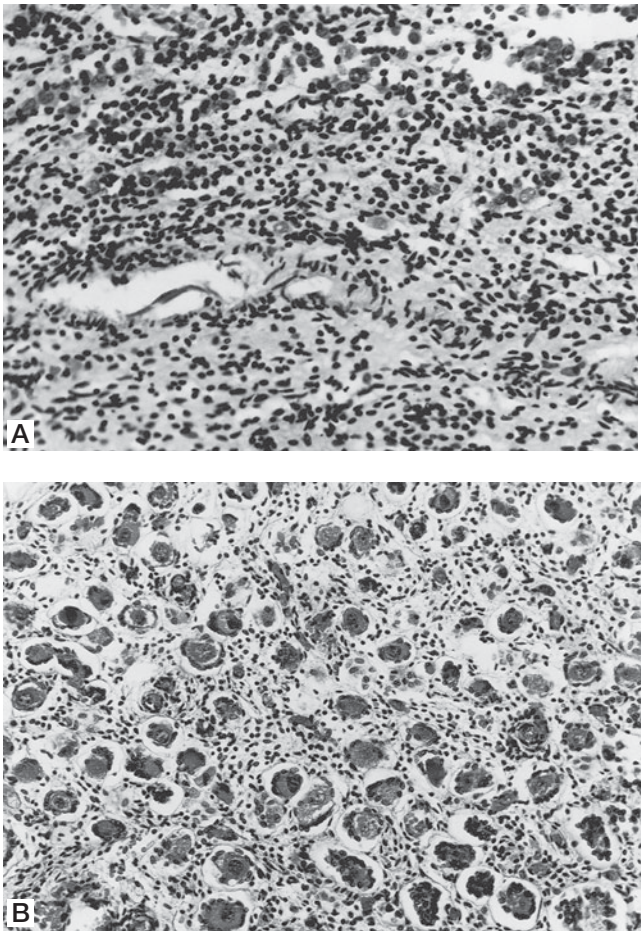

Figure 136-1 **A.** Postmortem photomicrograph of the cortex of the ovary from a fetus who spontaneously died in utero with 47, XXX. Note the relative absence of primordial follicles and germ cells. **B.** Comparison view of an ovary from a stillborn female fetus at 26 weeks of gestation, demonstrating numerous primordial follicles. (*Reprinted from Spear GS, Porto M. 47, XXX chromosome constitution, ovarian dysgenesis, and genitourinary malformation.* Am J Med Genet. *1988;29:511-515. Copyright 1988 by Wiley-Liss, Inc. Reprinted, by permission, of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.*)

translucency measurement was above the 95th percentile in 40% of the cases with 47, XXX, 47, XYY, or 48, XXXY (Sebire et al., 1998). In rare cases, structural abnormalities of the genitourinary tract have been described. These include bilateral renal agenesis and developmental arrest of the mesonephric and paramesonephric systems (Hogge et al., 1989); ovarian dysgenesis (Figure 136-1), urinary tract malformation, meconium peritonitis, and nonimmune fetal ascites (Spear and Porto, 1988); exstrophy of the cloaca with unilateral renal agenesis (Lin et al., 1993); and unilateral renal agenesis, hydrometrocolpos, ovarian dysgenesis, laryngeal atresia, pulmonary hypoplasia, and craniofacial anomalies (Hood et al., 1990). Because of the apparent clustering of cases with abnormalities in the genitourinary system, it has been suggested that the developing urogenital field may be affected by the presence of an extra X chromosome (Lin et al., 1993).

DIFFERENTIAL DIAGNOSIS

When the karyotype is 47, XXX, the main consideration in the differential diagnosis is whether the abnormality is present in all cells or in a fraction of the cells (mosaicism). A 46, XX/47, XXX mosaic karyotype will result in a significantly reduced likelihood of clinical symptoms (Salbenblatt et al., 1989; Robinson et al., 1992).

ANTENATAL NATURAL HISTORY

The antenatal natural history does not differ from fetuses with a normal karyotype. If a level II sonogram was not performed at the time of the original amniocentesis, it should be offered. The parents should be counseled regarding the expectation that the remainder of the pregnancy will not be different from pregnancy with a chromosomally normal fetus.

MANAGEMENT OF PREGNANCY

The main dilemma in management is the parental decision whether to continue the pregnancy (see "Long-Term Outcome"). Robinson et al. (1989, 1992) have reported their clinical experience with 530 phone consultations for a prenatal diagnosis of sex chromosome aneuploidy. In these series, 162 of the 530 consultations were reported for a diagnosis of trisomy X. Although their sample was admittedly biased, in that their patient population consisted of women who elected to undergo prenatal cytogenetic diagnosis, 85% of whom were college graduates and in an upper socioeconomic class, certain trends emerged. In general, the affected patients were developing in a manner that was comparable to their normal siblings. They also had better peer relations than the previously reported group of children with sex chromosome abnormalities (Robinson et al., 1979). In the prenatally diagnosed group of children with sex chromosome abnormalities, only 2 of 20 had intellectual quotients (IQ) as low as 90. The remainder of the children were in the normal range, greater than 110. Robinson et al. (1992) hypothesized that the improved developmental outcome was related to the supportive home environment provided by parents who knew the diagnosis and decided to continue the pregnancy. For the couples faced with a diagnosis of trisomy X in their fetus, 65% continued the pregnancy after phone consultation with Robinson's group.

Several recent studies have indicated an overall decreased trend in termination for fetal sex chromosome abnormalities. All three studies, performed in Canada, Switzerland, and Hungary, showed significantly lower rates of termination for 47, XXX compared to 45, X and 47, XXY fetuses (Christian et al., 2000; Hamamy and Dahoun, 2004; Mezei et al., 2004). In general, the decision to terminate in this condition was strongly influenced by the presence of a fetal anomaly on sonographic examination.

FETAL INTERVENTION

There are no fetal interventions for 47, XXX karyotype.

TREATMENT OF THE NEWBORN

In a study of 43 infants with trisomy X, the mean birth weight at term was 2.97 kg. There was no recognizable phenotype at birth. These infants were identified by prospective cytogenetic screening of all newborns in Denver. Their karyotype would not have been suspected from their physical examinations. Congenital heart disease was diagnosed in two infants and congenital hip dislocation in one. There was an increased frequency of epicanthal folds and clinodactyly (Robinson et al., 1979). The presence of minor anomalies such as these is possibly increased in 47, XXX females as compared with controls (Chudley et al., 1990).

SURGICAL TREATMENT

There are no surgical treatments indicated for XXX alone.

LONG-TERM OUTCOME

The most important statement regarding the long-term prognosis for a fetus with 47, XXX is that the phenotype is very variable (Tennes et al., 1975; Puck et al., 1983; Linden et al., 1988). The developmental outcome has ranged from mild mental retardation to college graduation (Linden et al., 1988). The general health of these children is excellent. Although their birth lengths are in the normal range, they become progressively taller as compared with their peers. The mean adult height of 47, XXX women is 167.9 + 7.7 cm, as compared with that in a white British control population—162.2 + 6 cm (Ogata and Matsuo, 1993). The mean head circumference remains at 10% for age (Ratcliffe, 1999). In infancy, a slight delay in neuromotor development has been noted. Salbenblatt et al. (1989) described a delay in the age of independent walking. In a prospective study of 11 girls identified at birth and followed over 22 years, Linden et al. (1988) noted that only two walked before the age of 12 months. About 50% of 47, XXX females have delays in speech and language that requires speech therapy during the preschool years (Ratcliffe, 1999). These delays are due to a specific deficit in auditory perception and in the ability to process linguistic information (Pennington et al., 1980; Bender et al., 1983, Bender et al., 1989).

The difficulties with verbal expression are described as the most severe of those described for the sex chromosome abnormalities (Linden et al., 1988). In a long-term follow-up study of 17 affected females (ages 7–18) 11 had school difficulties (Linden and Bender, 2002). Most of the 11 females received grades of Bs or Cs but none failed or repeated a grade. The mean IQ in this group was 103. Fifteen of 17 girls were involved in sports. None required psychological counseling services. In 47, XXX, sexual development is normal, with an average age of menarche of 12 years 8 months. In one fetus studied with 47, XXX, the ovary was histologically normal (Autio-Harmainen et al., 1980). Fertility and reproductive outcome is surprisingly good, with a low incidence of aneuploidy among offspring (Dewhurst, 1978). One case has been reported of an individual with trisomy X, premature ovarian failure, and the presence of antithyroid and antinuclear antibodies (Michalak et al., 1983). Females with trisomy X have thicker tooth enamel than females with disomy X. This indicates that the extra X chromosome escapes inactivation to promote amelogenesis (Alvesalo et al., 1987).

GENETICS AND RECURRENCE RISK

Since the majority of cases are due to a maternal meiosis I error, the risk of recurrence is most strongly related to maternal age. Amniocentesis or chorionic villus sampling should be offered in a subsequent pregnancy. Theoretically, half the offspring of an individual with 47, XXX should be normal and half 47, XXX or 47, XXY. This has not been shown empirically. Scattered case reports exist of 47, XXX mothers who have had children with sex chromosome and autosomal aneuploidies (Singer et al., 1972; Zizka et al., 1975), but most offspring are cytogenetically normal.

137 CHAPTER 47, XYY

Key Points

- Incidence is 1 in 1000 males.
- Most cases are undiagnosed.
- Not associated with advanced parental age.
- There are no characteristic fetal sonographic findings.
- IQ of affected males is in the normal range, but 10-15 points lower than siblings.
- Mild learning disabilities involve verbal but not mathematical skills.
- Adult males are tall, thin, and fertile.
- Pregnant partners of adult males with 47, XYY should be offered testing for the fetal karyotype due to the increased incidence of sex chromosome abnormalities in sperm.

CONDITION

The cytogenetic finding 47, XYY refers to the presence of an extra Y chromosome in the fetal cells. The extra Y chromosome is always paternal in origin and results from nondisjunction in the second meiotic division (84% of cases) or a postfertilization mitotic error (16%) (Robinson and Jacobs, 1999). XYY is one of the diagnoses included in the group of

disorders known as sex chromosome abnormalities. Anomalies involving the sex chromosomes are the most common abnormal findings in prenatal cytogenetic diagnosis, accounting for 25% of abnormal amniocentesis results, yet their existence is rarely discussed in preprocedural genetic counseling. Thus, while prospective parents are reasonably prepared for a prenatal diagnosis of autosomal trisomy, the diagnosis of XYY usually comes as a surprise.

Much of the confusion regarding prognosis for males with XYY stems from studies performed in the 1960s that were highly biased by ascertainment of patients in maximum security hospitals or prisons (Price and Whatmore, 1967). Fortunately, prospective longitudinal studies of newborns identified at birth do not support an increased incidence of aggression or criminality (Ratcliffe et al., 1990). As with all of the sex chromosome abnormalities, the developmental phenotype is variable and subject to many other influences, such as parental IQ, socioeconomic status, and family stability.

INCIDENCE

The incidence of 47, XYY is 1.45 in 1000 livebirths (Autio-Harmainen et al., 1980) and 1 in 1000 amniocenteses for advanced maternal age (Robinson et al., 1992a). The incidence is not increased among offspring of parents with advanced age. As opposed to the other sex chromosome abnormalities, the XYY karyotype does not carry an increased chance of in utero mortality (Ferguson-Smith and Yates, 1984). As many as 85% of cases are believed to be undiagnosed (Ratcliffe, 1999).

SONOGRAPHIC FINDINGS

There are no characteristic sonographic findings because the fetal phenotype in this condition is generally normal (Autio-Harmainen et al., 1980). In one study, the fetal nuchal translucency measurement was above the 95th percentile in 40% of the fetuses with 47, XXX, 47, XYY, or 47, XXY (Sebire et al., 1998). More recently, Maymon et al. (2002) reported on two fetuses with 47, XYY that had brain anomalies detected on prenatal sonographic examination. One had complete agenesis of the corpus callosum and one had a Dandy–Walker malformation. Both were terminated, so long-term developmental outcome is unknown.

DIFFERENTIAL DIAGNOSIS

47, XYY is a definitive diagnosis obtained by prenatal karyotype (Figure 137-1). Occasionally, cases of 46, XY/47, XYY mosaicism are detected, resulting from mitotic nondisjunction after fertilization. These patients are expected to have milder manifestations of the developmental abnormalities seen in this condition.

ANTENATAL NATURAL HISTORY

The antenatal natural history for these fetuses does not differ from normal fetuses. A few patients with 47, XYY have been identified through abnormally increased maternal serum

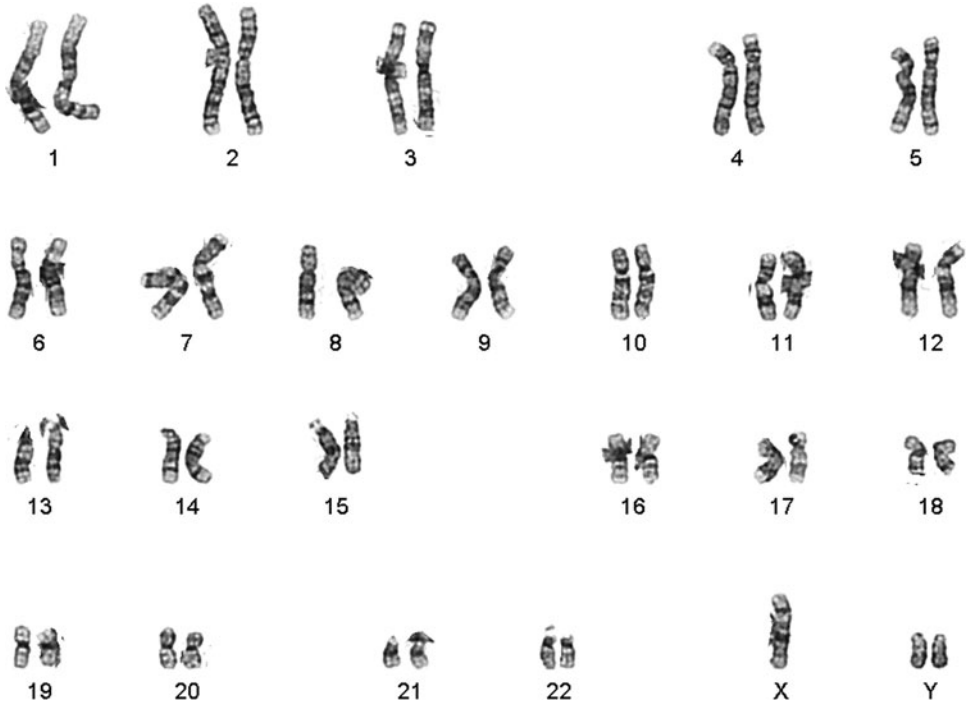

Figure 137-1 Karyotype obtained from a patient with 47, XYY demonstrating the presence of two identical Y chromosomes.

α-fetoprotein levels (Robinson et al., 1992a). It is unclear whether a true relationship exists between abnormalities in serum analytes and this particular chromosomal abnormality.

MANAGEMENT OF PREGNANCY

The subsequent management of the pregnancy should include subspecialty referral to a clinical geneticist for parental education and counseling. No additional maternal testing is necessary other than that indicated by standard obstetric practice. There is no need for delivery at a tertiary care center.

The major issue to be discussed with the expectant couple is whether or not to continue the pregnancy. Several recent studies have indicated an overall decreased trend over time in termination for fetal sex chromosome abnormalities. All three studies, performed in Canada, Switzerland, and Hungary, showed significantly lower rates of termination for 47, XYY compared to 45, X and 47, XXY fetuses (Christian et al., 2000; Hamamy and Dahoun, 2004; Mezei et al., 2004). In general, the presence of a fetal anomaly on sonographic examination correlated with a decision to terminate.

FETAL INTERVENTION

There are no fetal interventions indicated for a 47, XXY karyotype.

TREATMENT OF THE NEWBORN

The birth weights, head circumferences, and lengths of males with XYY are no different from control infants (Robinson et al., 1979; Ratcliffe et al., 1990). Although the phenotype is normal for this condition, an increased incidence of minor anomalies has been reported. In a study of 43 XYY infants identified by screening of all Denver newborns, one had congenital dislocation of the hip. Eight of the infants had one or more minor anomalies, including clinodactyly, inguinal hernia, abnormally formed ears, pectus carinatum, large or asymmetric head, strabismus, epicanthal folds, micrognathia, simian crease, and heart murmur (Robinson et al., 1979).

SURGICAL TREATMENT

There are no surgical treatments indicated solely for XYY.

LONG-TERM OUTCOME

XYY males tend to be tall and thin, with an average height of greater than the 75th percentile for age. This is due to an increased growth velocity from age 2 onwards as compared with normal individuals (Ratcliffe et al., 1992; Ratcliffe, 1999) and affects size rather than body proportions (Varrela and Alvesalo, 1985). XYY adult males achieve heights that are, on average, 13 cm taller than their fathers (Ratcliffe et al., 1990). The onset of puberty, defined as an increase in testicular volume to 4 ml or the appearance of pubic hair, occurs, on average, 6 months later than in controls (Ratcliffe et al., 1990; Robinson et al., 1992a; Ratcliffe, 1999). Testosterone production, pubertal development, and heterosexual interest have all been normal. The histology of the fetal testes in one case of 47, XYY was normal (Autio-Harmainen et al., 1980). The germ-cell depletion characteristic of other chromosome abnormality syndromes is apparently rarely affected by the presence of the extra Y chromosome (Coerdt et al., 1985). XYY males have normal spermatogenesis and have fathered normal infants. In one study, human sperm chromosomes were analyzed from a 47, XYY male and all of them contained only one sex chromosome. The frequencies of numerical, structural, and total abnormalities did not differ significantly from normal controls, suggesting that one Y chromosome is eliminated from the germ cells of males with XYY (Benet and Martin, 1988). Despite these encouraging findings, another study reported an increased incidence of miscarriage, stillbirth, perinatal death, and chromosomally abnormal offspring in pregnancies conceived with 47, XYY men (Grass et al., 1984). More recent analyses using 3-color probes and fluorescent in situ hybridization techniques suggest that there is an increased incidence of sperm carrying two sex chromosomes (Shi and Martin, 2000).

Interestingly, the presence of the extra Y chromosome affects dimensions of the palate and mandible. Palatal height and mandibular width are smaller in 47, XYY men as compared with their chromosomally normal first-degree male relatives (Laine and Alvesalo, 1993). In addition, there appears to be a regulatory influence of the Y chromosome on amelogenesis that results in thicker dental enamel and larger size in the permanent teeth of 47, XYY males (Alvesalo et al., 1985).

Early development in XYY infants is essentially within normal limits. Gross motor milestones are generally first noted to be slightly delayed, with an average age of walking at 14 to 16 months. Characteristic findings include hypotonia, motor planning dysfunction, primitive reflex retention, and difficulties with bilateral coordination and visual–perceptual–motor integration. This decreased muscle tone and joint proprioception diminishes joint stability, which particularly affects the shoulder and pelvic girdles and results in an awkward and inefficient gait (Salbenblatt et al., 1987). In addition, about 10% of affected individuals have an intention tremor (Ratcliffe, 1999).

In general, males with 47, XYY are not mentally retarded, but their IQs are 10 to 15 points lower than their chromosomally normal siblings (Robinson et al., 1992a). Intelligence level has a major effect on the development of psychosocial problems (Fryns, 1998). Specific risks exist for mild language impairment, affecting both receptive and

expressive function (Bender et al., 1983), and presenting initially as speech delay. In neurodevelopmental studies, Walzer et al. (1990) have shown that XYY males have difficulty understanding complex sentence structures, deficits in auditory memory, problems with word finding and narrative formulation, and persistent distractibility. Recommended educational intervention for 47, XYY males is no different than that for chromosomally normal children with reading and spelling difficulties.

In Ratcliffe's (1999) Scottish study of 19 affected males, followed from birth until early adulthood, 42% had speech delay and 54% had reading difficulties (compared to 18% of controls). However, a significant percentage of these young men went to college and had a wide range of employment. None had difficulty with mathematics.

With regard to concern over the association between aggressive behavior and XYY karyotype, prospective studies of thirty-nine 47, XYY probands have not revealed marked psychiatric disturbances. However, an increased frequency of distractibility, hyperactivity, and temper tantrums have been reported (Robinson et al., 1990; Ratcliffe, 1999). The importance of a supportive family environment has been noted by Robinson et al. (1992b), who have described significant developmental differences between 47, XYY males ascertained by prenatal diagnosis versus those discovered by newborn screening. All the children in this study who were diagnosed prenatally belonged to well educated and economically stable families. These children had fewer language deficits and learning problems, a mean IQ of 123 (range 109–147), and were getting As and Bs in school (Robinson et al., 1992b).

GENETICS AND RECURRENCE RISK

Although few data exist regarding the specific recurrence risk for XYY, the risk for nondisjunction involving any of the other chromosomes may be as high as 1%. Prenatal cytogenetic studies should be offered in subsequent pregnancies. Pregnant partners of 47, XYY men should also be offered prenatal karyotyping, due to the increased incidence of sex chromosome abnormalities seen in sperm studies (Shi and Martin, 2000).

138 CHAPTER Tetrasomy 12p (Pallister–Killian Syndrome)

Key Points

- Characterized by tissue-specific presence of an abnormal extra chromosome, which consists of two copies of the short arm of chromosome 12.
- Abnormal (marker) chromosome is more likely to be found in amniocytes or fibroblasts than blood.
- Associated with advanced maternal age.
- Sonographic findings: polyhydramnios, diaphragmatic hernia, rhizomelic short limbs.
- Main consideration in differential diagnosis is Fryns syndrome.
- Very poor long-term prognosis. All survivors are mentally retarded.
- Sporadic inheritance.

CONDITION

Tetrasomy 12p is a multiple congenital anomaly syndrome characterized by the tissue-specific presence of a marker chromosome in fibroblasts, but not lymphocytes, of affected patients. The clinical symptoms associated with this condition were first recognized in 1977, when Pallister described two adults, aged 19 and 37, who had profound retardation, severe hypotonia, coarse facial features, and pigmentary abnormalities. Both of these patients had an extra chromosome that was identified as a probable isochromosome of the short arm of chromosome 12 (Pallister, 1977). Independently, Teschler-Nicola and Killian (1981) reported a 3-year-old with severe mental retardation, dysmorphic facies, and sparse, dystrophic hair. Buyse and Korf (1983) were the first to suggest that these two seemingly disparate clinical presentations actually represented different manifestations of the same syndrome. The discrepancy between the two was explained by the fact that the isochromosome 12p was demonstrable in fibroblasts but not lymphocytes from affected patients. The interesting and unique aspect of this syndrome is that mosaicism exists for the chromosomal abnormality, and diagnosis usually depends on performing a chromosome analysis on amniocytes or fibroblasts from a skin biopsy.

From the prenatal perspective, tetrasomy 12p is usually diagnosed in one of two ways: either it is a karyotype abnormality found at amniocentesis performed for advanced maternal age (32% of cases) or it is detected when karyotyping is performed because fetal anomalies have been detected on sonography (52% of cases) (Wilson et al., 1994; Doray et al., 2002). Advanced maternal age is known to be a risk factor for the development of the isochromosome 12p. In a review of 30 case reports of Pallister–Killian syndrome, Wenger et al. (1988) found that the average age of the mothers of affected patients was 30 years. It is currently thought that there is an initial nondisjunctional event that results in trisomy 12. This is then followed by a centromeric misdivision at meiosis I or II (Struthers et al., 1999). The abnormal extra isochromosome is progressively lost in vivo during embryogenesis and in vitro during tissue culture. This hypothesis has been proven in several cases using molecular markers (Cormier-Daire et al., 1998; de Ravel et al., 2004).

The diagnosis of tetrasomy 12p is made by karyotype (Figure 138-1). The extra chromosome in this syndrome was originally thought to be derived from the long arm of chromosome 21 based on similarities in the cytogenetic banding patterns between the short arm of chromosome 12 and the long arm of chromosome 21 (Zhang et al., 1989). Identification of the marker chromosome as 12p was initially based on the twice-normal expression of the lactate dehydrogenase-B (LDH-B) isoenzyme gene, which maps to chromosome 12. Normal levels of superoxide dismutase 1 (SOD-1), which maps to chromosome 21, ruled out an increased dosage effect from extra copies of chromosome 21 (Gilgenkrantz et al., 1985). Fluorescence in situ hybridization (FISH) studies using DNA markers specific to the short arm of chromosome 12

Figure 138-1 Karyotype obtained from amniocytes in an affected fetus with Pallister–Killian syndrome. Note the presence of an extra chromosome next to the normal chromosome 12 pair. (*Courtesy of Dr. Janet Cowan.*)

have now definitively identified the marker chromosome as the short arm of chromosome 12 (Tejuda et al., 1992; Larramendy et al., 1993; Ohashi et al., 1993; Butler and Dev, 1995). The ability to detect the isochromosome 12p is affected by the tissue type studied, the patient's age (fetal versus infant versus adult) and the in vitro age of the cells (Priest et al., 1992). Peripheral blood lymphocytes are continually dividing, and it has been hypothesized that they lose the extra chromosome with their frequent divisions. In contrast, fibroblasts obtained from a skin biopsy normally cycle less frequently. In addition, a time-dependent in vitro selection occurs against cells that contain the isochromosome. In one study, the percentage of cells containing the isochromosome went from 100% to 20% after only five passages in tissue culture (Speleman et al., 1991). Detection of the isochromosome 12p may be difficult in peripheral blood lymphocytes, although the marker has been seen in bone marrow aspirates obtained from newborns (Ward et al., 1988). Several authors have suggested the use of FISH analysis to detect the presence of the extra chromosome 12 short arm interphase nuclei as opposed to metaphase chromosomes (Reeser and Wenger, 1992; Larramendy et al., 1993).

INCIDENCE

The incidence of Pallister–Killian syndrome or tetrasomy 12p is unknown. Tetrasomy 12p is the most frequent autosomal tetrasomy in humans (Bresson et al., 1991). The disorder is being increasingly recognized in clinical medicine.

SONOGRAPHIC FINDINGS

The sonographic findings for fetuses with tetrasomy 12p are summarized in Table 138-1. The most consistent prenatal findings include polyhydramnios, short femurs, and diaphragmatic hernia (Figure 138-2) (Priest et al., 1992; Wilson et al., 1994). Wilson et al. reviewed 15 cases of tetrasomy 12p diagnosed prenatally. In six of the cases that were ascertained by amniocentesis performed for advanced maternal age, only one had fetal anomalies detected between 16 and 18 weeks of gestation. In the cases that were ascertained by the presence of fetal structural anomalies, the gestational

Figure 138-2 Prenatal sonographic image from a fetus with tetrasomy 12p demonstrating a shortened lower extremity.

age was more advanced, between 16 and 32 weeks (Wilson et al., 1994). The extensive range of sonographic findings described varies from normal to a large diaphragmatic hernia with shift of the heart to right side of the chest (see Chapter 37). Additional sonographic findings reported include congenital heart disease (Wilson et al., 1994) and increased cisterna magna, suggesting agenesis of the vermis or cerebellar hypoplasia (Gilgenkrantz et al., 1985; McLean et al., 1992). An additional clinical finding in fetuses with Pallister–Killian syndrome is hypertelorism. Many fetuses with tetrasomy 12p also have nuchal edema or other hydropic changes (Figure 138-3). In 2002, Doray et al. summarized the existing literature on 63 prenatally diagnosed cases of Pallister–Killian syndrome (Doray et al., 2002). Sonographic abnormalities were described in 31 cases. The three most commonly found abnormalities were: polyhydramnios (26/31, 84%), diaphragmatic hernia (5/31, 16%), and rhizomelic micromelia (3/31, 10%). Other anomalies detected at a frequency of less than 10% included: hydrops fetalis, cystic hygroma, increased nuchal translucency measurement (see Langford et al., 2000), fetal overgrowth, ventriculomegaly, dilated cavum pellucidum, absent stomach visualization, and presence of a sacral appendix. Importantly, intrauterine growth restriction has never been described in this syndrome.

Figure 138-3 Prenatal sonographic image from the same fetus shown in Figure 138-2 demonstrating the fetal face in profile. Note the presence of frontal bossing and subcutaneous edema.

DIFFERENTIAL DIAGNOSIS

When isochromosome 12p is detected on an amniocentesis, it is diagnostic for Pallister–Killian syndrome. In the setting of an unknown marker chromosome with the presence of fetal anomalies, the possible diagnosis of tetrasomy 12p must be considered. It can be confirmed with the FISH technique using chromosome-specific probes for the short arm of chromosome 12 (Mowery-Rushton et al., 1997). In the setting of a fetus with sonographic anomalies suggestive of Pallister–Killian syndrome, the main consideration in the differential diagnosis is Fryns syndrome. However, Fryns syndrome is generally associated with growth restriction and Pallister–Killian syndrome is associated with normal, or even excessive growth for gestational age. Furthermore, Paladini et al. (2000) have described specific sonographic findings of the fetal face that aid in the diagnosis of Pallister–Killian syndrome. These include flat facial profile, small nose, and thin lips.

Fryns syndrome is a lethal condition inherited in an autosomal recessive pattern. Characteristic clinical findings during the newborn period include a coarse face, cleft palate, diaphragmatic hernia, distal digital hypoplasia, and neonatal death due to pulmonary hypoplasia. Chromosomes are normal in this syndrome. There is considerable clinical overlap between Fryns and Pallister–Killian syndromes. The diagnosis of Pallister–Killian syndrome is generally made in an older infant who has developmental delay and progressive coarsening of the facial features. Once the typical clinical findings of Pallister–Killian have been observed, karyotype studies generally include a skin biopsy for fibroblast culture. Babies who die during the neonatal period are more likely to have a diagnosis of Fryns syndrome, especially if a peripheral blood karyotype has been obtained and it is normal (Rodriguez et al., 1994). It has been suggested that newborn infants with clinical findings consistent with either Fryns or Pallister–Killian syndrome should have karyotypes performed on multiple tissue types to allow a correct diagnosis to be made (McPherson et al., 1993). This is important because Fryns and Pallister–Killian syndromes have different prognoses and different recurrence risks. Fryns syndrome is an autosomal recessive and Pallister–Killian syndrome (tetrasomy 12p) is considered to be a sporadic event.

ANTENATAL NATURAL HISTORY

In the review of Doray et al. (2002), 28/59 (47%) cases were terminated at an average age of 21 weeks. An additional 24

(41%) were liveborn, at an average gestational age of 30 weeks, but subsequently died. In three cases (5%) there was an intrauterine fetal death. Only four children survived past the neonatal period.

MANAGEMENT OF PREGNANCY

If polyhydramnios, short femur, and diaphragmatic hernia have been documented by prenatal sonographic examination, the diagnosis of Pallister–Killian syndrome should be considered. In this setting, an amniocentesis is more likely to be diagnostic of the chromosomal abnormality than cordocentesis, because the chromosomal abnormality is present in the majority of amniocytes but not in fetal lymphocytes (Donnenfeld et al., 1993; Wilson et al., 1994). However, at least one case has been detected at cordocentesis (Chiesa et al., 1998). If an unknown marker chromosome is detected on amniocentesis, consideration should be given to performing FISH studies using chromosome 12p-specific probes. This is best performed in a referral cytogenetics laboratory with experience in FISH analysis.

The abnormal marker chromosome can also be recognized in samples obtained by chorionic villus biopsy. The marker has been documented in 93% of cells derived from the direct preparation (Sharland et al., 1991) and 100% of cells derived from a cultured preparation (Bernert et al., 1992). In one case, however, karyotype results from chorionic villus sampling were normal, but the infant had clinical findings of Pallister–Killian syndrome. Fibroblast cultures obtained from a skin biopsy at 1 year of age demonstrated isochromosome 12p mosaicism (Horn et al., 1995).

Once a diagnosis of tetrasomy 12p has been made, the poor prognosis for a child with this condition should be discussed with the family. If the diagnosis is made at less than 24 weeks of gestation, termination of pregnancy can be offered. Cesarean section should not be performed for fetal distress. However, if the parents desire that everything be performed for the infant, delivery in a tertiary care hospital may be necessary because of the high frequency of associated pulmonary hypoplasia due to diaphragmatic hernia, which necessitates resuscitation by a neonatologist and treatment by a pediatric surgeon.

FETAL INTERVENTION

There are no fetal interventions for tetrasomy 12p.

TREATMENT OF THE NEWBORN

Because of the poor prognosis associated with this finding, resuscitation of the newborn infant with tetrasomy 12p should consist of basic supportive but not heroic measures. Recognition of the clinical features of Pallister–Killian syndrome during the newborn period is important because a normal peripheral blood karyotype does not exclude the diagnosis. To make the diagnosis in a newborn infant who did not have an amniocentesis performed prenatally, a fibroblast culture must be established from a skin biopsy (Bergoffen et al., 1993).

Newborns with tetrasomy 12p generally have a normal birth weight or they are large for gestational age. The average birth weight at term for affected infants is 3.6 kg (Reynolds et al., 1987). The typical physical findings in a newborn with Pallister–Killian syndrome include dysmorphic facies consisting of a high forehead with frontal bossing, sparse hair with bitemporal alopecia, hypertelorism, wide and flat nasal bridge, long philtrum, large mouth, short, webbed neck, supernumerary nipples, congenital heart disease, diaphragmatic hernia, proximal shortness of the upper and lower limbs, hypotonia, and imperforate anus (Reynolds et al., 1987; Schinzel, 1991). In time, skin pigmentary abnormalities (hypopigmentation and hyperpigmentation) may develop. These are best diagnosed by skin examination under a Woods lamp.

SURGICAL TREATMENT

Surgical treatment for infants with tetrasomy 12p is generally not indicated. Because of the overall poor prognosis, repair of a diaphragmatic hernia in a patient with known tetrasomy 12p is not advisable. Surgical treatment for these infants generally consists of supportive care, such as gastrostomy tube placement to permit feeding in cases in which survival beyond the immediate neonatal period is anticipated. A diverting colostomy in infants with imperforate anus may be necessary to permit normal bowel function.

LONG-TERM OUTCOME

The physical appearance of affected infants and children with tetrasomy 12p changes over time. The face becomes increasingly coarse and dysmorphic. Thick lips and a protruding tongue develop. The frontotemporal balding disappears, and hair growth becomes normal after a few years. Most affected children and adults have a generalized pigmentary dysplasia that may be evident only by Woods lamp examination. Some older patients with tetrasomy 12p are misdiagnosed as having hypomelanosis of Ito.

Most patients with tetrasomy 12p are profoundly retarded, and are completely bedridden, with flexion contractures. Almost all affected children and adults never speak or become continent and completely lack self-help skills (Schinzel, 1991). However, a few reports exist of affected individuals with a milder phenotype (Genevieve et al., 2003). The oldest reported patient is 45 years of age; thus, the chromosomal abnormality is in some cases compatible with prolonged survival.

GENETICS AND RECURRENCE RISK

Tetrasomy 12p is considered to be a sporadic condition with no increased risk of recurrence (Reynolds et al., 1987; Wenger et al., 1988; Bergoffen et al., 1993). There is also no history of recurrent miscarriage in affected families.

The isochromosome 12p is generally seen in 0% to 2% of lymphocytes in a peripheral blood karyotype but 50% to 100% of fibroblasts. Importantly, the proportion of tetrasomic cells present does not correlate with the severity of malformations, postnatal survival, or the extent of mental retardation.

For purposes of genetic counseling, the diagnosis of tetrasomy 12p can be made retrospectively on perinatal autopsy specimens in fetuses with hydrops, rhizomelic limb shortening, hypertelorism, diaphragmatic hernia, and congenital heart disease using FISH on fetal and placental tissues. This approach can be successful for diagnosis on formalin-fixed tissues (Wilson et al., 1994). Mothers who have given birth to an infant or fetus with tetrasomy 12p should be counseled that there is no increased recurrence risk. Amniocentesis is potentially indicated in a subsequent pregnancy, however, for reassurance.

22q11.2 Deletion (DiGeorge Syndrome)

139 CHAPTER

Key Points

- Most common microdeletion syndrome reported in humans.
- 22q11.2 deletion is associated with DiGeorge syndrome, velocardiofacial syndrome (VCFS), Opitz G/BBB syndrome, and Cayler cardiofacial syndrome (also known as asymmetric crying facies syndrome).
- Incidence is 1 in 6000 livebirths.
- Deletion is associated with specific types of congenital heart disease, including tetralogy of Fallot, truncus arteriosus, absent pulmonary valve, and aortic arch abnormalities.
- Other associated sonographic findings include growth restriction, nuchal translucency, thymic hypoplasia, and renal anomalies. The presence of polyhydramnios is predictive of postnatal feeding difficulties.
- Once the deletion is found, both parents should also undergo cytogenetic analysis.
- Delivery should occur in a tertiary center.
- Affected neonates are at risk for seizure disorders due to hypocalcemia.
- Postnatal problems include speech defects due to palatal abnormalities, repeated infections due to immunodeficiency, developmental delay, feeding issues, and serious behavioral and psychiatric problems.
- 22q11.2 deletion is inherited as an autosomal dominant trait.
- The major causative gene is *TBX1*, a member of the T-box protein family of genes.

CONDITION

22q11.2 deletion is the most common microdeletion syndrome that has been reported in humans. It is also the most common syndrome associated with cleft palate and the most common syndrome associated with conotruncal anomalies (Shprintzen et al., 2005). Microdeletion syndromes are genetic disorders caused by the loss of a small chromosome segment contains multiple genes, but that is too small to be detected via the 400-band standard metaphase karyotype. 22q11.2 deletion is commonly thought of as being equivalent with DiGeorge syndrome.

DiGeorge syndrome was first described in 1965 by Dr. Angelo DiGeorge as a developmental field defect that affected structures derived from the 3rd and 4th pharyngeal arches. It is now known that 22q11.2 deletion is actually associated with a variety of different syndromes that appear to be phenotypic variants of the same disorder. 22q11.2 deletion encompasses DiGeorge syndrome, velocardiofacial syndrome (VCFS), conotruncal anomaly face syndrome, Opitz G/BBB syndrome, and Cayler cardiofacial syndrome, which is also known as asymmetric crying facies syndrome. Ninety percent of patients with DiGeorge syndrome who have an apparently normal karyotype actually have a microdeletion of chromosome 22q11.2 (Figure 139-1). This was not appreciated until the development of molecular cytogenetic techniques such as fluorescence in situ hybridization (FISH).

The clinical findings of 22q11.2 deletion are highly variable, both between families and within families (Yamagishi and Srivastava, 2003). Approximately 75% of patients with 22q11.2 deletion have congenital heart disease, most commonly abnormalities involving the outflow tracts and the aortic arch. Patients with this deletion have a characteristic facial appearance, immunodeficiency due to thymic hypoplasia, velopharyngeal dysfunction either with or without cleft palate, hypocalcemia due to hypoparathyroidism,

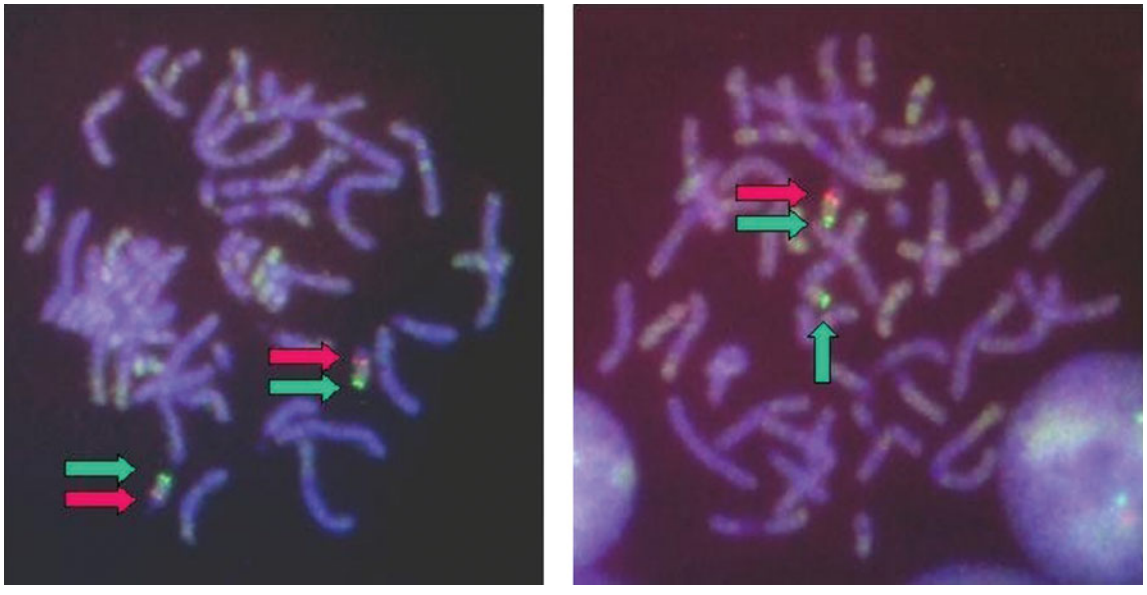

Figure 139-1 Chromosome analysis demonstrating the presence of the 22q11.2 deletion by FISH. On the left is a normal control. On the right is an affected individual. The green probes, as indicated by green arrows, map to the end of chromosome 22. The red probes, as indicated by the red arrows, map to the 22q11.2 region. The image on the right shows the presence of only one red probe, which indicates a deletion of this region on one copy of 22. This finding is diagnostic of DiGeorge syndrome. (*Photograph courtesy of Dr. Janet Cowan.*)

developmental and behavioral problems, and psychiatric disorders in adulthood (Yamagishi and Srivastava, 2003).

INCIDENCE

The minimum incidence of 22q11.2 deletion is 1 in 6395 livebirths, as described in the Flemish region of Belgium (DeVriendt et al., 1998a). In 2003, Botto et al. performed a population-based study, using matched records from the metropolitan Atlanta congenital defects program, the Sibley Heart Center, and the Division of Medical Genetics at Emory University School of Medicine. This group found 43 children with cytogenetic laboratory confirmed 22q11.2 deletion in a total population of 255,849 births. This gave an overall prevalence of 1 in 5950 births, with a slight racial difference observed. The prevalence was 1 in 6000 among white, black, and Asian individuals, and 1 in 3800 among Hispanics. The reason for the discrepancy was not known. The importance of the cytogenetic deletion was illustrated by the fact that 22q11.2 deletion was shown to contribute to 1 in 68 cases of congenital heart defects, 1 in 2 cases of interrupted aortic arch type B, 1 in 5 cases of truncus arteriosus, and 1 in 8 cases of tetralogy of Fallot.

SONOGRAPHIC FINDINGS

A deletion of 22q11.2 should be considered in fetuses with specific types of isolated congenital heart disease, such as tetralogy of Fallot, truncus arteriosus (Figure 139-2), aortic arch anomalies, absent pulmonary valve, or ventricular septal defect with pulmonary atresia or aortic arch anomalies (Goldmuntz, 2005). Deletion 22q11.2 should also be considered in any fetus with congenital heart disease and some other feature that has been described in fetuses with this condition, such as polyhydramnios (DeVriendt et al., 1998b), vertebral anomalies, holoprosencephaly, spina bifida, or renal anomalies (Stewart et al., 1999).

In one study, all fetuses with sonographically detected cardiac anomalies, an unremarkable family history and a normal metaphase karyotype were studied specifically for

Figure 139-2 Sonogram demonstrating the presence of truncus arteriosus. A single cardiac outflow tract is seen straddling both ventricles. This finding prompted FISH testing for the 22q11.2 deletion, which was positive.

the incidence of the 22q11.2 deletion over a 3-year period (Manji et al., 2001). A total of 46 cases were studied by FISH. Five out of the 46 cases (10.8%) had the deletion. The fetal sonographic abnormalities found included tetralogy of Fallot, atrial ventricular canal defect, VSD with truncus arteriosus, and VSD and ASD. Parental chromosome studies showed that one case was maternally inherited, three represented de novo mutations, and in one case the parents declined cytogenetic testing. In another study, 261 consecutive fetuses with a conotruncal cardiac malformation and a normal karyotype were studied for the presence of the 22q11.2 microdeletion (Table 139-1) (Boudjemline et al., 2001). A microdeletion was found in 54 of 261 fetuses (20.7%). Recently, multiple studies have appeared that have taken specific fetal cardiac anomalies and analyzed the relative percentage of microdeletions present. For example, Galindo et al. (2006) studied 14 cases of the rare malformation of absent pulmonary valve; 3 of these had microdeletion 22q11.2. Similarly, in a study of 71 cases of antenatally presenting right aortic arch, 7 cases (10%) had the microdeletion (Berg et al., 2006). However, all of these seven cases had associated extracardiac anomalies. In a large study of 92 fetuses with tetralogy of Fallot that had cytogenetic studies performed, 15 had evidence of 22q11.2 microdeletion (16.3%) (Poon et al., 2007).

Table 139-1

Frequency of 22q11.2 Deletion in Congenital Heart Disease

Type of Heart Defect	Antenatal Data (%)*	Postnatal Data (%)†
Interrupted aortic arch	45	50
Truncus arteriosus	31	35
Tetralogy of Fallot	14	16
Absent pulmonary valve	38	
Isolated aortic arch anomaly		24
Ventricular septal defect (isolated)		10
With aortic arch anomaly		40
With pulmonary atresia	21.5	
Double outlet right ventricle		<5
Transposition of great arteries	4	<1

* *Data from Boudjemline Y, Fermont L, Le Bidois J, Lyonnet S, Sidi D, Bonnet D. Prevalence of 22q11 deletion in fetuses with conotruncal cardiac defects: a 6-year prospective study.* J Pediatr. *2001;138:520-524.*
† *Data from Goldmuntz E. DiGeorge syndrome: new insights.* Clin Perinatol. *2005;32:963-978.*

Other sonographic findings that are associated with the 22q11.2 microdeletion include increased nuchal translucency measurement (Lazanakis et al., 1998) and polyhydramnios (DeVriendt et al., 1998b). In the latter study, 52 fetuses that had cytogenetic analysis were retrospectively reviewed to determine whether polyhydramnios was present. This finding was seen in 8 of 52 (16%) fetuses. The severity and time of onset of the polyhydramnios was variable, but interestingly, it was predictive of postnatal feeding difficulties. Another sonographic finding associated with the microdeletion is an absent or hypoplastic thymus (Chaoui et al., 2002). The thymus can only be visualized after 15 or 16 weeks of gestation, so this is not an appropriate first trimester test. Chaoui et al. (2002) studied 149 fetuses with congenital heart disease. Of these, 76 had evidence of conotruncal abnormalities and 10 of the 76 (13.1%) had the 22q11.2 microdeletion. Thymic hypoplasia was suspected in 11 cases and of these 9 had the cytogenetic deletion. The absent or hypoplastic thymus provided an additional clinical finding to suggest the presence of a microdeletion. The thymic hypoplasia sign has a sensitivity of 90%, a specificity of 98.5%, a positive predictive value of 81.8%, and a negative predictive value of 99.2%. Only one fetus with the deletion had a normal thymus.

Sonographically detectable renal anomalies are also associated with the microdeletion. Two studies in postnatal patients suggested that renal abnormalities were part of this condition. In Europe, a large-scale study of 558 patients with 22q11.2 deletions had medical records reviewed to determine if renal imaging studies were performed. In 136, renal studies were performed and abnormalities were detected in 49 patients (36%) (Ryan et al., 1997). In a smaller study, 13 patients with a known cytogenetic deletion had renal sonography performed. Five of these 13 cases (a very similar 38.4%) had evidence of a renal anomaly. Specific anomalies seen in this population included bilateral duplex kidneys, unilateral renal agenesis, unilateral multicystic dysplastic kidneys, and bilateral extremely small kidneys (Stewart et al., 1999). Similarly, these findings have been observed in fetuses affected with the 22q11.2 deletion. Goodship et al. (1997) described three fetuses with renal anomalies as the main presenting symptom of the deletion. The findings in affected fetuses included absent kidneys, multicystic kidneys, obstructive abnormalities, and vesicoureteric reflux.

Another finding in affected fetuses is growth restriction. In an unbiased study of 27 consecutive growth-restricted fetuses with normal karyotypes, 3 of the 27 (11%) had the microdeletion (Chen et al., 2006).

DIFFERENTIAL DIAGNOSIS

In postnatal studies, it is of interest that the diagnosis of 22q11.2 deletion is made later in those individuals who do not have a heart defect. Overwhelmingly, the presence of the

heart defect triggers the diagnosis in a fetus or infant. Once speech begins, it is the presence of either nasal speech or the delay of speech development that usually prompts evaluation and testing. The diagnosis of 22q11.2 deletion is made by cytogenetic diagnosis (Figure 139-1). However, once this cytogenetic abnormality has been detected, it encompasses several different clinical conditions.

DiGeorge syndrome is characterized by a distinctive face, hypoplasia or aplasia of the thymus and parathyroid glands, and conotruncal cardiac defects. The essential triad consists of hypocalcemia, immunodeficiency, and congenital heart disease. VCFS is usually diagnosed in an older child with either cleft palate or velopharyngeal incompetence. Patients with VCFS also have a distinctive face that is long and narrow with a prominent nose, and long and tapering fingers. Conotruncal facial anomaly syndrome consists of a specific type of dysmorphism originally described in Japanese children in association with conotruncal cardiac anomalies. All three conditions are thought to be phenotypic variants of the same disorder. Cayler cardiofacial syndrome is characterized by an asymmetric appearance of the child while crying, along with the presence of cardiac anomalies. Lastly, Opitz G/BBB syndrome, the autosomal dominant form, has been shown to be associated with the 22q11.2 deletion. Affected patients manifest hypertelorism (see Chapter 25), laryngotracheal esophageal clefts, cleft palate, swallowing difficulties, genitourinary defects, and developmental delay.

ANTENATAL NATURAL HISTORY

The antenatal natural history of fetuses affected with a 22q11.2 deletion has not been studied prospectively nor systematically. Occasional case reports exist that document in utero demise secondary to the presence of complex congenital heart disease (Machlitt et al., 2002).

MANAGEMENT OF PREGNANCY

Current indications for prenatal testing for the 22q11.2 deletion include having had a previous child with the deletion or clinically diagnosed DiGeorge or VCFS, an affected parent with a 22q11.2 deletion, or the in utero detection of a conotruncal cardiac defect (Figure 139-2) (Driscoll, 2001). Approximately 6% to 10% of cases of the deletion are familial, and the deletion is transmitted as an autosomal dominant trait. Therefore, in pregnancies at risk for inheritance of the deletion, an amniocentesis or chorionic villus sampling should be performed. If the fetus is diagnosed as having the deletion, a fetal echocardiogram and consultation with a pediatric cardiologist should be offered (Goldmuntz, 2005). In addition, consultation with a medical geneticist is recommended. Furthermore, because of the high incidence of associated renal abnormalities, particular attention should be paid to the presence of renal malformations on a level II sonogram. As stated earlier, the presence of polyhydramnios is associated with postnatal feeding difficulties.

Fetuses diagnosed with the 22q11.2 deletion should be delivered in a tertiary center, because of the risk of developing hypocalcemic seizures as well as the availability of pediatric cardiology.

FETAL INTERVENTION

There has been no fetal invention reported for this condition.

TREATMENT OF THE NEWBORN

There are three major considerations for the treatment of a newborn with the 22q11.2 deletion. Cardiac disease, if present, must be treated. A neonatal cardiac consultation should be obtained to get better anatomic delineation of the cardiac anomalies present. Other major problems that occur in the newborn period include seizures due to hypocalcemia, and feeding difficulties due to the presence of either palatal abnormalities or dysmotility (Emanuel et al., 2001). Postnatal studies that should be performed include obtaining a renal sonogram, echocardiogram, electrocardiogram, ionized calcium level, and baseline immune profile. Consultations should be arranged with cardiology, ear nose and throat, audiology, and potentially immunology. In infants with repeated infectious illnesses secondary to immunodeficiency, a novel treatment is thymic transplant. This has been performed in at least one case of confirmed 22q11.2 deletion (Markert et al., 2004).

Patients with this deletion have a high percentage of palatal abnormalities, including submucosal cleft palate, isolated cleft palate, bifid uvula, cleft lip with cleft palate, and velopharyngeal incompetence. This latter finding is never diagnosed until speech develops.

SURGICAL TREATMENT

Surgical treatment is performed for the presence of specific cardiac abnormalities or palatal abnormalities.

LONG-TERM OUTCOME

22q11.2 deletion is a complex disorder that affects many organ systems. Affected individuals have a high incidence of associated congenital heart disease and may require medical treatment for congestive heart failure. Affected individuals have a variety of other problems associated with respiratory

abnormalities, such as stridor secondary to vascular ring. In addition, they have a variety of ear, nose, and throat abnormalities, including chronic otitis media, hearing loss, growth failure secondary to feeding problems, immunodeficiency, developmental delay, and later in life, serious behavioral and psychiatric problems. Early intervention is recommended. In 1 to 2% of individuals studied with schizophrenia, the 22q11.2 deletion is present (Shprintzen et al., 2005).

GENETICS AND RECURRENCE RISK

The 22q11.2 deletion is inherited as an autosomal dominant trait. Most of these cytogenetic deletions are de novo. It is now known that this particular part of the human genome is relatively unstable. 22q11.2 deletions and duplications arise simultaneously from proximal interchromosomal exchange during meiosis (Saitta et al., 2004). The 22q11.2 location is characterized by a large number of low copy repeat sequences. Unequal crossing over occurs between these low copy repeat sequences, and this results in a 3 Mb deletion in one 22 chromosome homolog and a reciprocal, similarly sized duplication in the other homolog. There are approximately 30 genes that have been mapped to the 3 Mb deletion of 22q11.2 (Yagi et al., 2003). In one study, 235 unrelated patients with rigorously clinically diagnosed 22q11.2 syndrome underwent cytogenetic analysis. Of these, 225 or the 235 (96%) had the characteristic deletion. This group then sequenced the gene *TBX1* in the 10 patients who had the clinical diagnosis but no evidence of the cytogenetic deletion. Three mutations in the *TBX1* gene were identified in two unrelated patients and three patients from one family. These mutations were three newly described point mutations. Yagi et al. (2003) therefore concluded that the *TBX1* mutation is a major determinant of clinical findings in nondeletion 22q11.2 syndrome. *TBX1* has been identified as the candidate gene responsible for the abnormal face, cardiac defects, thymic hypoplasia, velopharyngeal insufficiency, cleft palate, and hypocalcemia seen in this syndrome, but *TBX1* mutation alone is not associated with mental retardation. Therefore, the full DiGeorge syndrome phenotype results from a contiguous gene deletion, meaning that more that one gene is deleted and different genes are responsible for different components of the syndrome. *TBX1* is part of the T-box protein family of genes. The T-box proteins have a range of roles in early vertebrate development, including development of the heart and limbs. Mutations in *TBX3* are the underlying basis for ulnar mammary syndrome and mutations in *TBX5* are the cause of Holt–Oram syndrome.

Another interesting candidate gene, *COMT*, is also located within 22q11.2. *COMT* degrades synaptic dopamine in the brain. Two polymorphisms in the *COMT* gene have been described in patients with nondeletion "velocardialfacial" symptoms. The polymorphisms are *COMT* 158^{Met} and *COMT* 158^{Val}. The most severe form of mental illness in adults seems to be associated with *COMT* 158^{Met} (Shprintzen et al., 2005).

When a fetus is diagnosed with 22q11.2 deletion, parental cytogenetic testing should always be performed. As stated earlier, in 6% to 10% of cases one of the parents will be shown to be affected. However, even if both parents are negative by FISH studies, parents should be advised that germline mosaicism has been reported for this condition (Kasprzak et al., 1998; Sandrin-Garcia et al., 2002). Therefore, the recurrence risk is never zero after having had an affected fetus with this condition. This is why one of the indications for prenatal testing for 22q11.2 is having had a previously affected child.
