Fetology

Diagnosis and Management of the Fetal Patient

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Preface to the First Edition

We wrote this book to provide a multidisciplinary approach to the full implications of a fetal sonographic or chromosomal diagnosis—from prenatal management to long-term outcome—for an affected child. We believed that what we, our colleagues, our trainees, and our patients needed was a compilation of available information to answer many of the questions that parents ask when a fetal anomaly is diagnosed.

In our experience, pregnant patients frequently receive conflicting information about the prognosis for the infant, depending on the sometimes narrow perspective of a subspecialist. The diagnosis and management of a fetus with an anomaly requires that an expertise be developed outside the traditional boundaries of the existing specialties of obstetrics, pediatrics, and surgery. These traditionally defined disciplines do not serve us well in addressing problems that exist outside our usual practice. By convention, pediatric care begins with the birth of an infant; however, we believe that pediatricians and pediatric surgeons can significantly contribute to the care of the fetus, their future patient. Similarly, obstetricians who do not generally provide medical care to the infant after delivery might enhance their antenatal care by being better informed about pediatric prognoses and outcomes. Pediatric surgeons who operate on fetuses or infants with congenital anomalies have more in common with perinatologists and neonatologists than with their other surgical colleagues. The problem-oriented multidisciplinary team approach has analogies in other specialties, such as cardiology, where the cardiologist, cardiac surgeon, and radiologist all focus on heart disease.

This book's intended audience consists of practitioners who care for fetuses or neonates with sonographically detected anomalies, and who seek prenatal and postnatal information regarding specific conditions. Included in this audience are general obstetricians, perinatologists, genetic counselors, neonatologists, pediatricians, pediatric subspecialists, and pediatric surgeons. We have also included information on some of the common chromosomal aneuploidies that may be detected when karyotyping is performed for a sonographic abnormality. Although the book is directed toward a medical audience, prospective parents were never far from our minds while we were writing. Most of the chapters were written by imagining that the prospective parents were in our offices seeking advice regarding the abnormal fetal finding. We have attempted to provide a balanced, scholarly, nondirective approach to management, which may differ significantly from what prospective parents may find on the Internet. Each chapter has a consistent format to facilitate locating specific kinds of information.

We have personally treated patients with most if not all of the conditions described within the following chapters as part of our collaborative work that began in the Fetal Diagnosis and Treatment Program at New England Medical Center and Tufts University School of Medicine in Boston in 1993. While the three of us brought to each case our individual approaches based on our different subspecialty training, we collectively recognized the need to present a coordinated and comprehensive plan to parents faced with a diagnosis of a fetal abnormality. Dr. Bianchi is a pediatrician, neonatologist, and medical geneticist who is interested in the correlation of pediatric outcome with prenatal sonographic findings; Dr. Crombleholme is a pediatric surgeon who has also trained in fetal surgical intervention. He writes extensively on the possibilities for surgical treatment of these diverse conditions and provides important information on long-term outcome. Dr. D'Alton is an obstetrician and perinatologist with expertise in antenatal sonographic diagnosis of anomalies.

Because our approach was unique, we felt that a multiauthored textbook would not specifically address the multiplicity of expertise necessary to care for the fetal patient. In establishing our Fetal Treatment Program we worked collaboratively to bring our individual training, experience, and knowledge base to each fetal patient on whom we consulted and whom we treated. We wanted this book to be more than a mere collation of facts; we wanted a cohesive approach to diagnosis, management, and in some cases, treatment of the fetal patient. We felt that in order for this book to reflect this approach it would be best for the three of us to have input into each chapter.

Finally, we must share with the reader that the most difficult aspect of writing this book was selecting a title. Although

we, as the authors, were in complete agreement regarding the body of knowledge and clinical information we wanted to convey, it did not fit simply or neatly into a single existing medical specialty. While it is the general obstetrician or perinatologist who first suspects (and diagnoses) an abnormality in the fetus, it is the pediatric medical or surgical specialist who will ultimately treat the newborn infant. In many medical settings, however, prospective parents of a fetus with an abnormality never meet with any pediatric specialists, let alone members of a fetal treatment team. After much debate, we selected the title, *Fetology: Diagnosis & Management of the Fetal Patient* to indicate that the focus of this book is on the diagnosis and the overall management of the fetal patient. No one medical specialty is devoted to the care of the fetus. By definition, therefore, *fetology* requires a multidisciplinary team approach. We wrote this book as a summary of available information for ourselves, our colleagues, our trainees, and our patients to answer many of the questions that are asked when a fetal anomaly is diagnosed.

Fetology, however, is an evolving field. Many of the subtle prenatal sonographic findings in this book have only recently been described. We therefore await future clinical research to provide further information on the long-term clinical significance of many of the fetal findings reviewed here. We hope that this reference serves to increase recognition of the unique aspects of caring for the fetal patient. We hope that by viewing conditions from both the prenatal and postnatal perspective, we will foster collaboration between the existing medical specialties, and ultimately benefit the care of fetal patients and their families.

Diana W. Bianchi, MD
Timothy M. Crombleholme, MD
Mary E. D'Alton, MD

Preface to the Second Edition

We are delighted to introduce this updated edition of our original textbook, which was intended to provide a multidisciplinary approach to the full implications of a fetal sonographic or chromosomal diagnosis—from prenatal management to long-term outcome—for an affected child.

Over the last decade since the publication of the first edition we have received considerable feedback from both patients and our colleagues regarding the strengths and areas needing improvement in the original text. Efficient access to a compilation of available information to answer many of the questions that parents ask when a fetal anomaly is diagnosed has been warmly embraced. Our colleagues have found the layout of the text to be helpful to extract the relevant pieces of information that they seek during a patient consultation. Frequently this may involve a rapid review of the sonographic features of a particular abnormality, while at other times it may require a synopsis of current surgical approaches to the repair of a complex malformation. Since 2000, the field of obstetric imaging has advanced rapidly, making many of the images in our original text dated and not reflective of contemporary imaging capabilities. This has required a complete review of all supplied images and we are grateful to our colleagues and patients for their assistance in providing the significantly improved illustrations in this latest edition. Another novel feature of this edition is the availability of succinct Key Points at the beginning of each chapter. This allows for rapid review of a particular condition when perhaps only a few moments are available for review between patient visits during a busy clinic.

As with the first edition of *Fetology*, we remain convinced that the diagnosis and management of a fetus with an anomaly requires that an expertise be developed outside the traditional boundaries of the existing specialties of obstetrics, pediatrics, and surgery. The problem-oriented multidisciplinary team approach, as illustrated by *Fetology*, has analogies in other specialties, such as cardiology, where the cardiologist, cardiac surgeon, and radiologist all focus on heart disease.

This book's intended audience remains practitioners who care for fetuses or neonates with sonographically detected anomalies, and who seek prenatal and postnatal information regarding specific conditions. Included in this audience are general obstetricians, maternal-fetal medicine subspecialists, genetic counselors, neonatologists, pediatricians, pediatric subspecialists, and pediatric surgeons. As well as including information on some of the common chromosomal aneuploidies that may be detected when karyotyping is performed for a sonographic abnormality, we have also included new chapters summarizing contemporary approaches to first and second trimester screening for aneuploidy. First trimester screening, in particular, has undergone marked changes in standards and potential over the last decade. This includes sonographic techniques, serum markers, and novel ways of combining these approaches.

Although the book is directed toward a medical audience, prospective parents remained in our thoughts while we were updating the text. Most of the chapters were written by imagining that the prospective parents were in our offices seeking advice regarding the abnormal fetal finding. We have attempted to provide a balanced, scholarly, nondirective approach to management, which may differ significantly from what prospective parents may find on the Internet. Each chapter has a consistent format to facilitate locating specific kinds of information.

Fetology began as a collaborative work at the Fetal Diagnosis and Treatment Program at New England Medical Center and Tufts University School of Medicine in Boston in 1993. By 2000, the original Boston team had dispersed to various academic medical centers throughout the United States, and today the authors represent a diverse international team of fetal medicine experts, spanning maternal-fetal medicine, neonatology, genetics and pediatric surgery. While the four of us brought to each case our individual approaches based on our different subspecialty training, we collectively recognized the need to present a coordinated and comprehensive plan to parents faced with a diagnosis of a fetal abnormality. Dr. Bianchi is a pediatrician, neonatologist, and medical geneticist who is interested in the correlation of pediatric outcome with prenatal sonographic findings; Dr. Crombleholme is a pediatric surgeon who has also trained in fetal surgical intervention. He

writes extensively on the possibilities for surgical treatment of these diverse conditions and provides important information on long-term outcome. Dr. D'Alton is an obstetrician and maternal-fetal medicine specialist with expertise in antenatal sonographic diagnosis of anomalies. Dr. Malone is also a maternal-fetal medicine specialist who has spearheaded the development of new approaches to aneuploidy screening, as well as directing an international multidisciplinary fetal therapy program.

We have remained loyal to our original premise that a multi-authored textbook would not specifically address the multiplicity of expertise necessary to care for the fetal patient. Each section of our Fetal Treatment Program has been developed collaboratively by the four of us to bring our individual training, experience, and knowledge base from each fetal patient whom we have consulted on and treated. We hope that our book remains more than a mere collation of facts, but instead is a cohesive approach to diagnosis, management, and treatment of the fetal patient. Each of the four of us therefore have had input into each chapter.

As with the first edition of *Fetology*, we hope that this reference serves to increase recognition of the unique aspects of caring for the fetal patient. We hope that by viewing conditions from both the prenatal and postnatal perspective, we will foster collaboration between the existing medical specialties, and ultimately benefit the care of fetal patients and their families.

Diana W. Bianchi, MD
Timothy M. Crombleholme, MD
Mary E. D'Alton, MD
Fergal D. Malone, MD

Acknowledgments (First Edition)

Diana W. Bianchi, MD: In addition to the faculty and fellows in maternal–fetal medicine and neonatology listed by Dr. D'Alton, I would like to acknowledge the collaboration, support, and expertise of the medical genetics faculty at Tufts University, which during the past six years has included Janet Cowan, Patricia Wheeler, Rosemarie Smith, Janey Wiggs, and Mira Irons. I am enormously grateful to the genetic counselors listed by Dr. D'Alton, who not only provided outstanding and compassionate care when a fetal anomaly was diagnosed, but alerted us to the existence of cases that would present useful teaching examples for this book. I would also like to acknowledge the perinatal genetics fellows who worked in my research laboratory during this time period, who read chapter drafts, and provided me with helpful feedback. They include Antonio Farina, JiYi Wang, Akihiko Sekizawa, Osamu Samura, Barbara Pertl, Satoshi Sohda, Kirby Johnson, Paula Farrell, Nancy Weinschenk, and Bharath Srivatsa.

I would also like to thank current or former Tufts faculty members who critically read sections of the manuscript, including Dr. Joseph Semple of Pathology, who supplied many photographs; Dr. Michael Lewis of Plastic Surgery; Dr. Michael Goldberg of Orthopedic Surgery; Drs. Gerald Marx, Ziyad Hijazi, and Jonathan Rhodes of Pediatric Cardiology; Dr. George Klauber of Urology; and Dr. N. Paul Rosman of Pediatric Neurology. In addition, I would like to thank Dr. Deborah Levine for her expertise in fetal MRI, Dr. Marjorie Treadwell for supplying additional illustrations, and Drs. Wolfgang Holzgreve and Roberto Romero for illustrations and helpful discussions. I would also like to thank my secretarial staff for their help and support in the writing and researching of the manuscript, including Lynne Aufiero, Maria McCarthy, and Glenn Christie. I would also like to thank Jane Licht, our orignal editor at Appleton & Lange, who guided me through the process of putting together a large textbook. I would like to give a special acknowledgment to Dr. Mary Ellen Avery, who not only provided moral support but helpful information on the origin of the term *neonatology,* as background for selecting the title of this book. Last but by no means least, I would like to thank Dr. Alan Guttmacher, who originally suggested the title for this book: *Fetology.* Although we as authors initially did not *bond* to this term, in the end, we decided that it was the most appropriate way to describe the body of knowledge in what is arguably a new field of medicine.

Timothy M. Crombleholme, MD: During the writing of this book, our understanding and approach to diagnosis and management of many fetal conditions has continued to evolve. Progress has only been possible through the supportive interactions of numerous professional colleagues in many disciplines who bring their unique expertise to bear on the fetus. I would like to acknowledge my research fellows and colleagues who have contributed to the development of the field of fetal surgery and fetology: at Tufts University, Sarah Garmel, Frank Robertson, Kevin Moriarty, and E. Kerry Gallivan, and at The Children's Hospital of Philadelphia, Darryl Cass, Karl Sylvester, Kenneth Liechty, Harold Lovvorn, Heung Bae Kim, Aimen Shaaban, Colette Pameijer, Danielle Walsh, Yoshihiro Kitano, Adina Knight, Ross Milner, Natalie Rintoul, Holly Hedrick, and Oluyinka Olutoye.

I wish to acknowledge the loyal support and guidance of Lori Howell, who has been instrumental in the development of fetal treatment programs, both at The University of California, San Francisco, and at The Children's Hospital of Philadelphia. The support and encouragement during the writing of this book of N. Scott Adzick and Alan Flake, my partners in fetal surgery at The Children's Hospital of Philadelphia, is gratefully acknowledged as is Michael R. Harrison, who as the father of fetal surgery was practicing fetology before it had a name. I would particularly like to thank my colleagues in other disciplines who have taught me so much and contributed to our understanding of the fetal patient, including Mark Johnson, Beverly Coleman, Stephen Horii, Jill Langer, Harvey Nisenbaum, and Mary King for their sonographic skill and enthusiastic support of fetal surgery; Anne Hubbard and Larissa Bilaniuk for their pioneering work on fetal MRI; Zhi-Yun Tien, Jack Rychik, Meryl Cohen, Marie Gleason, and Bill Mahle for their excellent echocardiographic support; and Elaine Zackai and Stefanie Kasperski for genetic evaluation and counseling at The Children's Hospital of Philadelphia.

In the operating room at the Hospital of the University of Pennsylvania and The Children's Hospital of Philadelphia, I would like to acknowledge the contributions of Ted Cheek, Bob Gaiser, Dean Kurth, David Cohen, and Jeff Galinkin, who have done so much to advance the anesthetic management of fetal surgical patients. Also, acknowledged in the operating room are Joy Kerr, Marianne Daskalakis, and Helen Lewis and, most particularly, in the postnatal care and evaluation of our fetal patients, Kelli Burns and Sue Von Nessen. Lastly, for their ability to decipher my hieroglyphic writing and secretarial support, I give special thanks to Dee Caton and Noreen Mulholland.

Mary E. D'Alton, MD: The years that I spent working with Dr. Diana Bianchi and Dr. Tim Crombleholme were some of the most rewarding years of my academic life. During this time, we worked collectively to create a seamless, multidisciplinary approach to prenatal diagnosis and therapy for our patients. Our collaboration is reflected in this manuscript. I wish to acknowledge the support of my former fellows and residents. All of these individuals in their unique way helped shape the Division of Maternal Fetal Medicine, initially at Tufts University School of Medicine, and now at Columbia University College of Physicians and Surgeons. Some former fellows stayed on as faculty, initially at Tufts, and more recently at New York Presbyterian Hospital, and others are practicing in many other areas of the world. They include Drs. Achilles M. Athanassiou, Emily R. Baker, Juan Castaner, Sabrina D. Craigo, Annette Perez Delboy, Karen Davidson, Patricia Devine, Marla Eglowstein, Sara Garmel, Martin Gillieson, Laura Goetzel, Gary Kaufman, Fergal D. Malone, Teresa Marino, Lucie Morin, Jose A. Nores, Steven Ralston, Dale P. Reisner, Rebecca Elliot Rigsby, Lynn Simpson, Julia Elizabeth Solomon, and Theresa Stewart. Other faculty members at New England Medical Center who helped create a multidisciplinary team include Drs. John Fiascone, Ivan Frantz, Michael Goldberg, Karen Harvey Wilkes, Ziyad Hijazi, George Klauber, Michael Lewis, Gerald Marx, Heber Nielsen, N. Paul Rosman, Joseph Semple, and Ralph Yarnell. I owe an enormous gratitude to the obstetric sonographers, Jean Crowley, Rachel Duguay, Peg Meyers, and Pam Sullivan, and to the genetic counselors, Beth Berlin, Mona Inati, DeeDee Lafayette, Emily Lazar, and Michele Murray, for their excellence and devotion to patient care. I extend a special thank you to a model mentor, Dr. John Hobbins, who is widely considered to be the father of obstetric ultrasound. In the program he initially established at Yale University, ultrasound assumed an integral role in patient care. This program became a model for many perinatal units throughout the United States. He irreversibly changed the way in which I considered the practice of maternal fetal medicine. In particular, I wish to acknowledge the contributions of Drs. Richard Berkowitz, Fergal D. Malone, and Lynn Simpson, who critically read many of the chapters. The loyal support and personal and professional encouragement provided by Dr. Fergal Malone on an ongoing basis is deeply acknowledged and much appreciated. My part of this manuscript could not have been completed without the superb editorial skills of Star Poole, virtuoso word processor, who served as a medical editor in the Division of Maternal Fetal Medicine at Tufts University.

Acknowledgments (Second Edition)

Diana W. Bianchi, MD: Since the publication of the first edition of *Fetology*, I have jokingly referred to it as my "third child". It weighs 7 pounds and it is never far from my mind! Alternatively, I refer to it as my "external hard drive", because it is a convenient compilation of all the facts I need or want to know when I perform a prenatal genetic consultation for a fetus with an anomaly or an abnormal karyotype. However, in the past 10 years, many sections of the book have become outdated. We seriously questioned whether we had the time or energy to perform a thorough revision for a second edition. In the end, Drs. Crombleholme, D'Alton, and I decided that we could do it only if we added a fourth author. The choice of Fergal Malone was a natural one, given his long association with Tufts and his expertise in prenatal diagnosis and fetal medicine. In contrast to the first edition, when Drs. Crombleholme, D'Alton, and I would meet for coffee in one of our offices at Tufts to review and discuss the chapters, we are now scattered across the US and Ireland. Thus, most of the writing and editing for the second edition was done via email, with occasional "marathon" meetings at the McGraw-Hill offices in Manhattan. Thanks to our editors, Alyssa Fried and Karen Davis, we received food, shelter, and administrative support during those sessions.

In addition to the people I thanked in the first edition I would like to specifically acknowledge Linda Keys, who helped me immensely with reference retrieval and typing the revised chapters. Dr. Nick Guerina transferred original color slides to digital files so that we could add color to this edition. I would also like to thank the staff at the Prenatal Diagnosis Center at Women and Infants' Hospital in Rhode Island, where I provided prenatal genetic consultations from 2000–2007. In particular, the genetic counselors Jacquelyn Halliday, Carolyn Slack and Kerry Lurix identified cases of interest for images and discussion. I would also like to thank Drs. François Luks, Steven Carr and Marshall Carpenter for referring interesting cases to me. At Tufts Medical Center I would also like to acknowledge the invaluable help of the genetic counselors Beth Berlin, Paula Delerme, Amy Sachs, Denise Lafayette, and Lauren Lichten for their help in proofreading and making editing suggestions. Similarly, Drs. Michael House, Terri Marino, Steven Ralston, and Sabrina Craigo have been enormously helpful in making the second edition even better than the first! I would also like to thank the Tufts maternal-fetal medicine fellows who have worked in my research laboratory, specifically Drs. Barbara O'Brien, Neeta Vora, Linda Kleeman, and Adam Urato, who have always stimulated me by asking great questions. Lastly, I would like to express my profound appreciation to my family, in particular my husband John, who have been understanding of the fact that the "third child" is a demanding one, and requires individual time and attention.

Timothy M. Crombleholme, MD: During the writing of this second edition, (which my children fondly refer to as "Fetology II: The Fetus Strikes Back") our understanding and approach to diagnosis and management of many fetal conditions has continued to evolve. Progress has only been possible through the supportive interactions of numerous professional colleagues in many disciplines who bring their unique expertise to bear on the fetus. I would like to acknowledge my past and present research fellows and colleagues who have contributed to the development of the field of fetal surgery and fetology: at Cincinnati Children's Hospital in the Center for Molecular Fetal Therapy, Elliott Kozin MD, Anna Katz MD, Jignesh Parvadia MD, Ahmed Marwan MD, Suzi Demiberg MD, Arturo Maldonado MD, PhD, Ursula Harkness MD, Sachin Vaikunth MD, Maria Ripberger, Fernando Vuletin-Solis MD, Lee Morris MD, Shuichi Katayama MD, Swathi Balaji PhD, Datis Alaee MS, Chuck Klanke MS, Helen Jones PhD, Louis Le MD, and Kim Lyons RN, BSN. In the Fetal Care Center of Cincinnati, Emmie Blayer, Rachel Jones, Cheryl Snell, Jenni Mason RN, Gina Sharp RN, Deborah Voet RN, Karen McGirr RN, CNM, Christine Spaeth MS, Diana Smith MS, and Erin Hillman MSW, Judith Hostiuck RNC-OB, Steven Imhoff RNC, our obstetrical nurses in The Fetal Care Center: Gina Allaire RN, Melissa Brewington RN, Judy Bryant RN, Kasey Casson RN, Kasey Duffens RN, Elizabeth Geiger RN, Deborah Kocis RN, Kelly LaFlamme RN, Lori Macke RN, Pam Mitchell RN, Monica Newman RN,

Lisa Pickett RN, Amanda Thacker RN, Autum Thompson RN, Susan Turner RN, Michelle Wesselman RN, and Lisa Wisby RN.

I wish to acknowledge the loyal support and guidance of Richard Azizkhan MD, Foong-Yen Lim MD and Kelli Young RN MS APN, and who have been instrumental in the development of the Fetal Care Center of Cincinnati. I would like to acknowledge my partners in the Fetal Care Center of Cincinnati from whom I learn from every day for their support and encouragement during the writing of this book: Sundeep G. Keswani MD, Mounira Habli MD, Jeffrey Livingston MD, William Polzin MD, Ray Bahado-Singh MD, Ronald Jaekle MD, David Lewis MD, James Van Hook MD and Kim Brady MD. I would like to acknowledge Michael R. Harrison MD, mentor and friend, who as the father of fetal surgery was practicing fetology before it had a name. I would particularly like to thank my colleagues in other disciplines who have taught me so much and contributed to our understanding of the fetal patient, including Erik Michelfelder MD, James Cnota MD, William Gottliebson MD, William Border MD, and Russell Hirsch MD in Pediatric Cardiology; Beth Kline-Fath MD, Eva Rubio MD, Maria Calvo MD, and Kyuran Choe MD in Radiology; Tariq Siddiqi MD in Maternal Fetal Medicine; James Greenberg MD, Beth Haberman MD, Paul Kingma MD, Amy Nathan MD, Tanya Cahill MD, and Kurt Schibler MD in Neonatology; Robert Hopkin MD in Genetics; Pramod Reddy MD, and Paul Noh MD in Pediatric Urology; Karin Bierbrauer MD, Francesco Mangano MD and Todd Maugans MD in Neurosurgery; Ravi Elluru MD in Pediatric ENT; Connie Bitters, Kristina Stenger, Linda Faulkner-Snyder, and Michelle King for their sonographic skill and enthusiastic support of fetal surgery; In the operating room I would like to acknowledge the contributions of Ik Lee MD, Dean Kurth MD, Anne Boat MD, Ximena Soler MD, Mohamed Mahmoud MD, Margaret Linker, and Bonnie Hugus RN, who have done so much to advance the anesthetic management of fetal surgical patients. Also, acknowledged in the operating room are Missy Ritter RN, Tracy Heidrich RN, Doug Dunbar, Britany Freeman, Todd Forte, Mary Ratliff, Latressa Rector, Curtis Johnson, Teco Gaines and most particularly, in the postnatal care and evaluation of our fetal patients, the fellows: Ala Stanford-Frey MD, Shawn Rangel MD, Sean Barnett MD, Timothy Lee MD, and Mubeen Jafri MD. Lastly, for their ability to decipher my hieroglyphic writing and secretarial support, I give special thanks to Marsha Corbett, Anne Riestenberg, Bonnie Killen and Tammie Day.

Finally, I am indebted to my co-authors Mary D'Alton MD, Diana Bianchi MD and Fergal Malone MD for the opportunity to continue a collaboration that has been the most rewarding of my professional career and continues to provide new opportunities to learn, teach and grow the field of Fetology.

Mary E. D'Alton, MD: Since coming to Columbia University Medical Center, our team has worked to create a system of seamless prenatal diagnosis and therapy for our patients described in the first edition of Fetology.

With support from New York Presbyterian Hospital and Columbia University College of Physicians and Surgeons, we have created the Center for Prenatal Pediatrics, a program focused specifically on providing multidisciplinary care to patients carrying pregnancies with fetal anomalies. Under the superb leadership of Dr. Lynn Simpson this center now sees over 500 families every year. Other physicians integral to success of the center are the other directors of the Center for Prenatal Pediatrics including Dr. Charles Kleinman, Dr. Richard Polin, Dr. Wendy Chung, Dr. Charles Stolar, and Dr. Ron Wapner. Their experience, camaraderie, and vision keep pushing us to strive for greater results. The staff of the Center act as the glue for our patients and include Ushta Davar Canteenwalla, Anne Van der Veer, Rosalie Perez, Angel Otero, and Kimberly Cordero.

It is fitting that this 2nd edition of *Fetology* will be published the same year that our Center for Prenatal Pediatrics moves to its new space. This state-of-the-art facility has been made possible by a naming gift from Carmen and John Thain and with additional funding from Sally and Mike Martell and the Klingenstein-Martell Foundation as well as ongoing support from New York Presbyterian Hospital and Columbia University College of Physicians and Surgeons.

I also wish to acknowledge the support of my current and former fellows who have played an integral role in preparing and presenting the new cases at our weekly multidisciplinary Prenatal Pediatrics conference. They include Patricia Devine, Annette Perez-Delboy, Joshua Weiss, Jane Cleary-Goldman, Tracy Shevell, George Graham, Dorothy Przydzial-Smok, Andrew Healy, Alexandra Spadola, Heather Lipkind, Young Mi Lee, Blair Wylie, Russell Miller, Danny Wai Fu Wu, Clarissa Bonanno, Karin Fuchs, Samuel Bauer, Fadi Mirza, Freddy Montero, Shai PriPaz, Jaclyn Coletta, and Joy Vink. In particular I wish to acknowledge the contributions of Dr. Richard Berkowitz, Dr. Jane Cleary-Goldman, and Dr. Karin Fuchs who critically read many of the chapters and who provided input, support, and encouragement throughout the revision process.

As I did in the first edition, I would like to extend a special thank you to Dr. John Hobbins. Dr. Hobbins not only served as a model mentor to me early in my career, but also is rightfully considered the father of obstetric ultrasound who irreversibly changed the way in which maternal fetal medicine is practiced today.

Fergal D. Malone, MD: I am indebted to my co-authors, Drs. Bianchi, D'Alton and Crombleholme, for their encouragement and support during the long process of developing and rewriting this edition. In particular, I would like to especially acknowledge Mary D'Alton for giving me my start in obstetrics, steering my career development in maternal-fetal medicine, and spurring my interest in prenatal screening and fetal therapy. Without her constant advice and mentoring, I would likely not have pursued an academic career in

maternal-fetal medicine. Despite moving to Ireland in 2005 to establish a new fetal treatment program, I remain in close contact with my colleagues in the United States. In this era of globalized medicine, I believe that continued international collaboration across continents represents the way forward for advancing the original goals of *Fetology* for all of our patients.

Finally, I would like to particularly acknowledge the never-failing support, loyalty, and inspiration of my wife, Marie. From traveling across continents in unwavering support, to being the gel that holds personal and professional lives together, I could not have achieved any of my accomplishments without her constant presence.

I

Introduction

This page intentionally left blank

Prenatal Imaging

CHAPTER 1

Key Points

- In most cases, ultrasound is the method of choice for imaging the fetus, and the majority of pregnant women in the United States undergo at least one ultrasound.
- Sonographer skill and experience play a great role in the accuracy of ultrasound.
- Ongoing quality assurance is important.
- There have been exciting advances in the field of prenatal imaging within the past few years including three-dimensional ultrasound and fetal magnetic resonance imaging, and the future holds the promise of great breakthroughs.
- It is expected that imaging modalities will continue to improve, and it is hoped that techniques utilized in the fields of noninvasive prenatal diagnosis will continue to advance.
- Accurate prenatal diagnosis of fetal abnormalities improves patient care by optimizing patient counseling and allowing for informed patient and physician decision-making.

INTRODUCTION

The development and practice of fetology has been dependent on advances in the field of prenatal imaging. Without the ability to accurately visualize the structure and well-being of the fetus within its own intrauterine environment, it would not be possible to diagnose or treat the range of abnormalities that can now be addressed by the multidisciplinary fetal health care team. Rapid advances in the technologic basis of two imaging methods—ultrasonography and magnetic resonance imaging (MRI)—have resulted in highly accurate visualization of the fetal anatomy.

PRENATAL ULTRASONOGRAPHY

Development

Ultrasonography in obstetrics was first introduced in the late 1950s and has since become the method of choice for imaging the fetus. Gray-scale imaging became available in 1973 and resulted in an enhancement of the ability to differentiate the appearance of various organs and tissue interfaces. The advent of real-time sonographic scanning during the 1970s was vital for the accurate visualization of the constantly moving fetus. The subsequent development of higher frequency transabdominal and transvaginal transducers in the late 1970s resulted in vast improvements in the resolution of fetal images and also pushed back the gestational age barrier for accurate prenatal diagnosis into the late first and early second trimesters (D'Alton, 1998).

The 1980s saw innovations in obstetric sonographic technology, including the use of pulsed and color Doppler sonography, which allowed for detailed analysis of fetal perfusion and improvements in the visualization of fetal cardiac anatomy. More recent advances include the development of power Doppler, which displays the strength of a Doppler signal rather than the direction of flow. This technique is useful in fetal imaging for low-flow states and may aid in the

definition of fetal tumors and assessing placental function (Ogle and Rodeck, 1998). Three-dimensional ultrasonography is now also available for fetal imaging and has revolutionized the field of prenatal imaging by allowing simple sonographic acquisition of a "block" of fetal tissue (Timor-Tritsch and Platt, 2002). Postacquisition computer processing allows reconstruction of any number of planes through the organ of interest as well as producing real-time surface rendering images of the fetus.

Controversies

Ultrasonographic imaging is an integral part of obstetric practice today. In the United States, it is performed in the majority of all pregnancies (Horger and Tsai, 1989; Goncalves and Romero, 1993; Martin et al., 2002). Sonography has been used routinely for accurate dating of pregnancy, confirmation of pregnancy location and number of gestations, prenatal diagnosis of congenital malformations, and assessment of fetal well-being (American College of Obstetricians and Gynecologists, 2008). With the increasing availability of ultrasound equipment, the performance of obstetric ultrasonography has grown to the point that, in some countries, one or more ultrasound examinations are recommended during all pregnancies (Royal College of Obstetricians and Gynaecologists, 1994).

Studies evaluating the performance of ultrasonography in pregnancy have yielded conflicting results. A comprehensive meta-analysis of more than 30 studies assessing the performance of routine prenatal ultrasound in screening for fetal malformations reported detection rates ranging from 13% to 82% with a mean of 27.5% (Levi, 2002). Detection rates have been shown to vary according to the nature and severity of the anomaly with higher detection rates achieved for major structural malformations than for minor malformations (Grandjean et al., 1999). The inconsistent performance of the second trimester anatomic survey may also be explained by variations in the populations screened and differences in the facilities at which the ultrasounds are performed. For example, both the Helsinki and RADIUS trials demonstrated significantly higher detection rates when screening ultrasounds were performed at tertiary care facilities than when the ultrasounds were performed at community-based facilities (Crane et al., 1994; Saari-Kemppainen et al., 1994).

Apart from the detection of congenital abnormalities, obstetric ultrasonography can be expected to be beneficial in other aspects of pregnancy management. The routine use of obstetric ultrasonography has been shown to reduce the rate of postterm pregnancies and to reduce the use of tocolytic medications, both because of an improvement in the accuracy of pregnancy dating (Saari-Kemppainen et al., 1990; LeFevre et al., 1993). In addition, the routine use of obstetric ultrasonography has been shown to significantly increase the early detection of multiple gestations, which is essential if appropriate modifications in pregnancy management are to be applied (LeFevre et al., 1993).

While the RADIUS Trial did not demonstrate any improvement in overall perinatal outcome from routine obstetric ultrasonography, this study has been criticized because of its poor performance in the detection of anomalies (Ewigman et al., 1993; Goncalves and Romero, 1993). Other studies have demonstrated a significant reduction in perinatal mortality following routine obstetric ultrasonography, mostly because of an increase in the rate of pregnancy termination for congenital anomalies (Saari-Kemppainen et al., 1990). While an initial meta-analysis of four randomized clinical trials of routine versus indicated ultrasonography also confirmed a significantly lower perinatal mortality rate in patients allocated to routine scanning (Bucher and Schmidt, 1993), another more recent review failed to confirm a perinatal mortality advantage in the general population from routine obstetric ultrasonography (Neilson, 1998).

Impact of Skill and Experience

Perhaps the most likely reason for the significant discrepancy in the sensitivities of ultrasonography for the detection of anomalies is the effect of the skill and experience of the sonographer. There is undoubtedly wide variation in the skill levels of sonographers between different centers that practice obstetric ultrasonography. In the RADIUS Trial, for example, there was a significant difference in the rates of anomaly detection between participating tertiary and nontertiary level centers (Crane et al., 1994). Nontertiary level centers detected only 13% of congenital anomalies in the RADIUS Trial and were unable to detect any craniofacial, cardiac, gastrointestinal, or skeletal malformations. Tertiary level centers performed significantly better, detecting 35% of anomalies (Goncalves and Romero, 1993). Other studies have also demonstrated that in expert hands, second trimester ultrasound can detect more than 70% of fetal malformations (Boyd et al., 1998; Van Dorsten et al., 1998).

In a retrospective study from Vienna, the impact of sonographer experience was demonstrated by a wide variation in rates of anomaly detection between different centers with different skill levels (Bernaschek et al., 1996). In that study, the overall anomaly detection rate was only 22% for obstetric ultrasonography performed in private obstetricians' offices, 40% in general hospitals, and 90% for ultrasonography performed by experts in fetal imaging.

Because of the clear association between the skill or experience of the sonographer and rates of anomaly detection, it has been suggested that obstetric ultrasonography should be performed only in tertiary level centers, where up to four times as many fetuses with anomalies may be detected (DeVore, 1994). However, it is not clear that all pregnant patients will have equal access to tertiary level centers, which may be especially problematic in rural or other underserved areas.

Accreditation and Maintenance of Standards

Given the influence of the sonographer's skill and experience on the rate of anomaly detection for obstetric

ultrasonography, it is logical to expect that basic standards and requirements for the performance of ultrasonography be delineated. However, in the United States there is no mandatory requirement for licensure or accreditation for practitioners who provide obstetric ultrasonography services. Minimum standards are described only in the form of suggested guidelines, and any form of accreditation is entirely voluntary in nature.

The American Institute of Ultrasound in Medicine has suggested minimum qualifications for all practitioners involved in obstetric ultrasonography (American Institute of Ultrasound in Medicine, 1993). One of the key components of such qualification is the completion of an approved residency program, or the performance and interpretation of at least 500 obstetric ultrasound examinations. Furthermore, the American Institute of Ultrasound in Medicine now accredits obstetric ultrasonography practices, which involves evaluation of the credentials of sonographers, quality of fetal images, type of ultrasound equipment, methods of data storage, and presence of quality control measures in place (Abuhamad et al., 2004; American Institute of Ultrasound in Medicine, 2005).

Safety

Theoretical safety risks from ultrasound energy include thermal damage or cavitation, with subsequent tissue injury. Most prenatal ultrasound examinations produce energies of 10 to 20 mW/cm^2, which is well below the arbitrarily defined safe cutoff level of 100 mW/cm^2 (American College of Obstetricians and Gynecologists, 2008). Newer prenatal imaging methods, such as those that use power Doppler, may be associated with higher energy outputs, which reinforce the need to continuously monitor power output during prenatal ultrasonography and to achieve the lowest possible energy exposure.

Randomized trials on the safety of diagnostic ultrasonography in pregnancy have demonstrated no significant differences in developmental, neurologic, or psychologic outcomes, with up to 12 years of follow-up (Stark et al., 1984). One study did demonstrate a nonsignificant increase in the frequency of dyslexia in the group exposed to ultrasound in utero, as compared with the group with no ultrasound exposure (Stark et al., 1984). A subsequent study evaluating school performance and dyslexia in groups exposed and not exposed to ultrasound in utero found no differences in any outcome measures, although there was an association between left-handedness and in utero ultrasound exposure (Salvesen et al., 1992, 1993). One study has also suggested an association between frequent ultrasound exposure in utero (five ultrasound examinations) and growth restriction, although this has not been confirmed by other investigators (Newnham et al., 1993).

Overall, it appears that routine ultrasonography in pregnancy is not associated with any adverse outcome for the fetus. Repeat ultrasound examinations should be performed only as indicated.

Current Role

The four main roles of prenatal ultrasonography in contemporary obstetric practice are

1. to confirm fetal gestational age and number;
2. to search for fetal malformation;
3. to confirm fetal well-being; and
4. to aid in the performance of invasive diagnostic and therapeutic fetal procedures.

The ability of prenatal ultrasonography to accurately confirm fetal gestational age and number of fetuses is self-evident. The RADIUS Trial demonstrated a significantly decreased chance of postterm induction of labor following accurate sonographic dating of pregnancy and a significant increase in the prenatal detection of multiple gestations (LeFevre et al., 1993).

The ability of prenatal ultrasonography to diagnose fetal malformations, both as a screening tool and for targeted examinations, has also been confirmed. In expert hands, screening ultrasonography can be expected to detect approximately 70% of all fetal malformations (Boyd et al., 1998; Van Dorsten et al., 1998). However, the detection rate for individual anomalies varies significantly. While almost all spinal, renal, and abdominal wall malformations are detected by screening prenatal ultrasonography, the detection rate for isolated cardiac defects is only approximately 50% (Boyd et al., 1998; Flood and Malone, 2008). Efforts to increase the second trimester detection rate of Down syndrome by including soft markers for aneuploidy (such as short femur, short humerus, echogenic bowel, nuchal thickening, and choroid plexus cysts) may be successful, although it is likely that any such improvement will be accompanied by an increase in the false-positive rate (Nyberg et al., 2001; Bromley et al., 2002; Filly et al., 2004). See Chapters 2 and 3 for further discussion of first and second trimester screening for Down syndrome.

Prenatal ultrasonography also plays a crucial role in the confirmation of fetal well-being, especially following the identification of a fetal abnormality or a condition associated with a high risk of adverse fetal outcome. Fetal biophysical profile and pulsed Doppler assessment of fetal arterial flow may be used for identifying fetuses with compromised reserve that may benefit from either intensive surveillance or elective premature delivery (American College of Obstetricians and Gynecologists, 2008).

The ability to perform invasive prenatal diagnostic procedures safely, as well as fetal therapy, has been significantly improved by real-time ultrasonography (American College of Obstetricians and Gynecologists, 2008). Diagnostic procedures during the first trimester, such as chorionic villus sampling and embryofetoscopy, are now commonly performed under ultrasound guidance. Amniocentesis, fetal blood sampling, vesicocentesis, thoracentesis, and fetal biopsies are also possible because of the availability of real-time ultrasonography. The ability to treat the fetus using blood transfusions, drug infusions, and shunt placement is now also possible as a result of advances in sonographic technology and availability.

Figure 1-1 3D image of a fetal face at 24 weeks' gestation.

Three-dimensional ultrasound

Three-dimensional (3D) ultrasound allows for multiplanar imaging enabling the examiner to move back and forth between different planes due to the capability of viewing the fetus in three rather than two spatial planes (Figure 1-1). Images can be reconstructed and the examiner can move the fetus into ideal desired positions that are often not possible with conventional ultrasound. In addition, 3D scanning enhances imaging capabilities by permitting surface rendering of a structure. Acquisition of data points through the entire volume of interest is required to produce 3D ultrasound pictures. Acquisition quality depends on acquisition speed. Slow speeds result in more scanned slices and are used for nonmoving organs. Fast speeds are preferable for moving structures. The "four-dimensional" (4D) real-time imaging technique requires ultrafast acquisition. 4D ultrasound displays a continuously updated and newly acquired volume in any rendering modality. This creates the impression of a moving structure (Timor-Tritsch and Platt, 2002).

Previously, it was thought that 3D ultrasound provides only aesthetic images without contributing to prenatal diagnosis. There are no accepted indications for 3D ultrasound in obstetric practice at this point. Few outcome studies have confirmed whether or not this technology changes practices or clinical outcomes (Lee, 2003; American College of Obstetricians and Gynecologists, 2008). Nonetheless, this technology is rapidly advancing and has been shown to be helpful. It appears to be useful as an adjunct to 2D ultrasound in fetal echocardiography and in the diagnosis and further evaluation of certain fetal anomalies such as cleft lip and palate and skeletal anomalies (Dyson et al., 2000; Garjian et al., 2000; Johnson et al., 2000; Sepulveda et al., 2003; Roman et al., 2004; Sklansky et al., 2004; Merz and Welter, 2005). Goncalves et al. (2006) recently conducted a study that evaluated whether or not conventional ultrasound adds important information to 3D/4D imaging (Goncalves et al., 2006). Fifty-four fetuses without abnormalities and 45 fetuses with 82 abnormalities diagnosed by 2D ultrasound were evaluated. Agreement between 3D/4D and 2D ultrasound occurred in 90.4% of cases. Six anomalies were missed by 3D/4D when compared to 2D ultrasound. There were also two discordant diagnoses. There was one abnormality suspected by 3D/4D ultrasound, which was not confirmed by 2D ultrasound. The sensitivity and specificity of 3D/4D ultrasound and 2D ultrasound was 92.2% and 76.4% and 96.1% and 72.7%, respectively. This was not found to be a statistically significant difference. The authors concluded that the findings of 3D/4D ultrasound are consistent with the findings from 2D ultrasound.

PRENATAL MAGNETIC RESONANCE IMAGING

Development

While ultrasound remains the imaging modality of choice for the fetus due to its widespread availability and reasonable cost, it has several limitations. These include small field of view, limited soft tissue acoustic contrast, poor image quality in pregnancies complicated by oligohydramnios, beam attenuation by adipose tissue, and limited visualization of certain fetal structures at later gestational ages, for example, the posterior fossa after 33 weeks of gestation due to bone calcification (Garel et al., 1998; Coakley et al., 2004). MRI is now being used in conjunction with ultrasound to provide additional information for prenatal diagnosis. The advantages of MRI include the use of multiple planes for reconstruction and a large field of view making the visualization of complicated anomalies easier.

MRI has been available for clinical use for more than 20 years, but in more recent times its role in prenatal diagnosis has increased significantly. Use of MRI was first described in pregnancy in 1983 (Smith et al., 1983). Its initial application was for maternal and placental abnormalities. The potential for MRI in prenatal diagnosis was recognized early on, with reports of imaging of fetal abnormalities (Lowe et al., 1985; McCarthy et al., 1985; Weinreb et al., 1985). A serious limitation of these early attempts at prenatal MRI was the long acquisition times of standard spin echo images. The amount of fetal movement that would occur during image acquisition degraded the images obtained. The noise associated with MRI scanning made the likelihood of a fetus sleeping motionless during the study very small. The quality of the images that were possible prompted the use of paralyzing agents administered either by intramuscular injection into the fetus or umbilical cord injection to obtain motion-free spin echo images (Daffos et al., 1988). The invasive nature of this approach dampened the initial enthusiasm for prenatal MRI.

During the early 1990s, ultrafast MRI sequences and fast scanners, such as echo planar MRI, were developed (Johnson et al., 1990; Mansfield et al., 1990). Fetal MRI became practical due to the development of single-shot rapid acquisition sequence with refocused echoes. This high quality T_2-weighted sequence has a slice acquisition time of less than 1 second and essentially "freezes" fetal motion (Kiefer et al., 1994; Semelka et al., 1996; Levine, 2001). The ultrafast

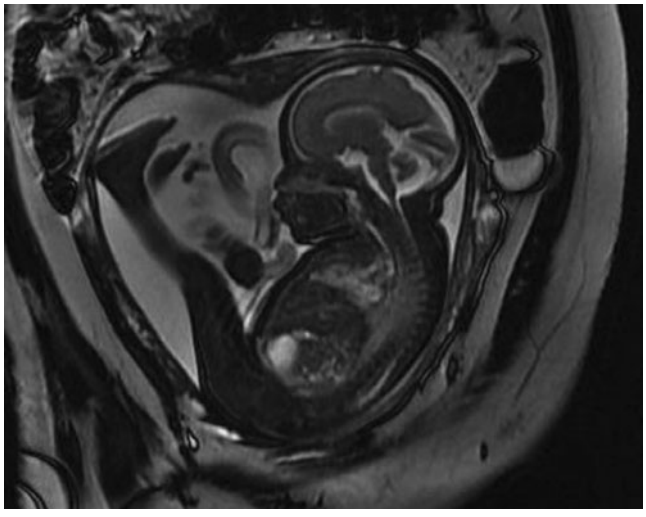

Figure 1-2 Fetal MRI demonstrating a normal fetus at 28 weeks' gestation.

scanning technique eliminates, or significantly reduces, the artifacts caused by fetal movement, making fetal sedation or paralysis unnecessary for prenatal MRI (Hubbard and Harty, 1999; Levine, 2001) (Figure 1-2).

These ultrafast sequences are now being successfully employed in imaging the human fetus (Garden et al., 1995; Levine et al., 1996; Hubbard et al., 1997a, 1997b, 1998; Yamashita et al., 1997; Quinn et al., 1998; Hubbard and Harty, 1999; Levine, 2003a). Fetal anatomy has been well visualized by MRI scanning in fetuses more than 18 weeks of gestation and is increasingly being used as an adjunct to prenatal ultrasound examination in the evaluation of structural fetal anomalies, facilitating appropriate prenatal counseling, and guiding fetal therapy (Levine et al., 1996; Quinn et al., 1998; Hubbard and Harty, 1999). The main indication for fetal MRI is further evaluation of inconclusive ultrasound findings. It is also useful for evaluation prior to fetal surgery (Levine, 2004). Definitive indications for fetal MRI have not been established and recommendations are based on case reports, small case series, and expert opinion (Coakley et al., 2004).

Safety

Provided that there is no maternal contraindication, most studies suggest that MRI is safe in pregnancy as it allows the acquisition of excellent soft tissue contrast without using ionizing radiation (Levine, 2001). To date there are no known harmful effects in the developing fetus with the use of scanners at field strengths of 1.5 T or less (Hubbard and Harty, 1999). Guidelines for patient safety were issued by the Safety Committee of the Society of Magnetic Resonance Imaging. However, several animal studies have suggested the possibility of teratogenetic effects in early pregnancy (Wolff et al., 1980; Schwartz and Crooks, 1982; Heinrichs et al., 1988; Beers, 1989; Tyndall and Sulik, 1991; Mevissen et al., 1994; Yip et al., 1994). While these studies may not be applicable to humans, they indicate that MRI should be used with caution in the first trimester. The risk of acoustic damage to the fetus is thought to be negligible (Baker et al., 1994; Gover et al., 1995). Patients can be informed that according to the Safety Committee of the Society for Magnetic Resonance Imaging, MRI is reasonable when other nonionizing forms of radiation are inadequate, or when the examination would provide information that would otherwise require exposure to ionizing radiation. While there is no evidence that MRI can harm the fetus (American College of Obstetricians and Gynecologists, 2008), it is important to note that the United States Food and Drug Administration asserts that the safety of fetal MRI "has not been established," and the majority of centers using this imaging technique in pregnancy limit its use to after the first trimester and require informed consent prior to the procedure (United States Food and Drug Administration, 1988; Levine, 2001).

MRI of the Fetal Central Nervous System

MRI had been used to characterize the developing brain as early as 1983 (Gilles et al., 1983). Ultrasound examination remains the primary method of prenatal imaging but, especially in the brain, MRI is becoming an invaluable adjunct, providing superior characterization of fetal brain maturation and morphology. In most instances, MRI is used for fetuses in which a CNS abnormality has already been demonstrated or is suspected by ultrasonography (Bilaniuk, 1999; Levine, 1997). The most common CNS abnormalities diagnosed by ultrasound examination and referred for evaluation by MRI include cysts, Dandy–Walker malformation or variant, agenesis of the corpus callosum, hydrocephalus, vein of Galen aneurysm, encephaloceles, and otherwise malformed brains.

Ventriculomegaly is a common indication for fetal MRI. T_2-weighted sequences provide excellent imaging of the size and configuration of the ventricles. Criteria for ventriculomegaly in fetal MRI is based on ultrasound data demonstrating ventricles of a width of at least 10 mm. However, the size of the ventricles tends to be slightly larger when obtained by MRI than the measurements obtained in the same fetus by ultrasound examination. Once ventriculomegaly is identified, a detailed examination of the entire fetus should be performed to detect associated anomalies (see Chapter 16). When ventricular enlargement is due to a myelomeningocele, MRI is particularly good for demonstrating the Chiari II malformation, the extent of the neural tube defect, and the level of the sac (Bilaniuk, 1999).

MRI provides excellent tissue discrimination in defining congenital CNS abnormalities such as calvarial defects, differentiating hemangioma or lymphangioma from encephalocele or meningocele, and demonstrating partial or complete agenesis of the corpus callosum. The finding of an abnormality of the corpus callosum is often not isolated and frequently indicates the presence of other cerebral abnormalities (Atlas et al., 1986; Barkovich and Norman, 1988) (see Chapter 6). Occasionally, ultrasound examination may have difficulty in differentiating partial agenesis of the corpus callosum from normal anatomy. MRI can be helpful in further delineating this anatomy.

Vein of Galen aneurysm is a vascular malformation that may be misdiagnosed as a cyst or a mass if not examined

using color Doppler on ultrasound (see Chapter 22). MRI can demonstrate not only the vascular anatomy, but also the condition of the brain, which is of concern because these lesions can be associated with encephalomalacia and macrocrania. The presence of encephalomalacia in cases of vein of Galen aneurysm indicates a poor prognosis (Bilaniuk, 1999).

In addition, MRI has changed the diagnosis and aided in the management of many cases of suspected CNS abnormalities on ultrasound (Levine et al., 2003, Sharma et al., 2003). MRI can better clarify a prenatal diagnosis and help patients make decisions such as whether or not to continue with the pregnancy. Levine et al. compared 242 ultrasound studies and 242 MRI studies of the CNS in 214 fetuses with suspected CNS abnormalities or at high risk for CNS abnormalities (Levine et al., 2003). At confirmatory ultrasound, 69 fetuses had normal CNS imaging. Approximately 80% of fetuses in the study (171/242) had postnatal follow-up. MRI imaging provided additional information in 50% (72/145) of cases and actually found a new major finding in 32% (46/145) of fetuses with abnormal ultrasound findings. In patients with previable fetuses, this information was utilized to help patients decide whether to continue or terminate the pregnancy. In patients with viable fetuses, this information was used to help determine the mode of delivery and the location of delivery (community hospital vs. tertiary care center).

MRI of the Fetal Neck

Fetal MRI may be particularly useful in evaluating fetal neck masses. Distinguishing between lymphangioma and a cervical teratoma may be difficult based on ultrasound images alone (see Chapters 32 and 110). In addition, the risk of a compromised airway at birth is high with each of these lesions. MRI can help with the assessment of the fetal airway so that proper precautions are taken at delivery. MRI of cervical fetal masses allows for more global imaging of the mass than with ultrasound because of the larger field of view. In a report by Hubbard et al. (1998), fetal MRI was able to accurately diagnose the nature of the mass and define the anatomy of the airway. In each case, as compared with ultrasound examination, fetal MRI provided better detail about the size and position of the mass and its relationship to the airway. MRI provides the best anatomic definition of the normal fetal cranial structures and their relationship to the mass (Semelka et al., 1996).

Lymphangiomas appear to be complex masses with cystic and solid components that may compress or surround the airway (Benacerraf and Frigoletto, 1987; Zadvinskis et al., 1992; Hubbard et al., 1998). Cervical teratomas arise from the anterolateral neck and tend to cross the midline (Sherer et al., 1993). These tumors can be solid and cystic with areas of calcification and hemorrhage (Rothschild et al., 1994). On more T_2-weighted fast sequences, cystic components can be evaluated. The oropharynx and trachea are filled with amniotic fluid, which is bright and can be differentiated from the tumor. Areas of acute hemorrhage can be identified by sequences that have more T_1-weighting, which helps delineate teratoma from lymphangioma (Hubbard et al., 1998). Hemorrhage and calcification can be identified on either gradient echo or echo planar images.

MRI of the Fetal Chest

The most common thoracic abnormalities identified on prenatal ultrasound examination include congenital diaphragmatic hernia (CDH), congenital cystic adenomatoid malformation (CCAM) of the lung, bronchopulmonary sequestration (BPS), and fetal hydrothorax (Morin et al., 1994; Levine et al., 2003b; Coakley et al., 2004). CDH has been recognized by herniation of the stomach to the level of the four-chamber view of the heart and a shift of the mediastinum away from the hernia (Chinn et al., 1983). Although the sonographic features of CDH are well described (see Chapter 37), the diagnosis of CDH has been missed in a significant number of fetuses that have been studied by prenatal ultrasound (Lewis et al., 1997). Even in cases in which CDH is correctly diagnosed by ultrasound examination, determination of the presence or absence of liver herniation may be difficult. Herniation of the liver has been found to be a predictor of poor postnatal outcome in CDH (Metkus et al., 1996). Ultrasound examination relies on indirect indicators of liver herniation, such as kinking of the umbilical vein as it enters the sinus venosus (Bootstaylor et al., 1995). Fetal MRI can directly identify the position and degree of herniation of the liver in CDH (Hubbard et al., 1997a). The fetal liver has high signal intensity on fast gradient echo sequences with T_1-weighting, making it easily identifiable relative to the diaphragmatic ridge and the compressed ipsilateral lung. The lung is intermediate to high in signal intensity, which allows differentiation from mediastinal structures and herniated viscera (Hubbard et al., 1997b). With T_2-weighting, the fluid filled stomach is high in signal intensity, equal to the signal intensity in amniotic fluid. The selection criteria for fetal surgery for CDH includes herniation of the liver, making accurate delineation of this anatomy all the more important (Shaaban et al., 1999).

MRIs in CCAM vary in appearance, depending on their size and number and size of cysts (see Chapter 35). The larger the size and number of cysts, the higher the signal intensity of the CCAM on sequences with T_2-weighting. MRI is able to distinguish CCAM from normal compressed lung and determine the lobe of the lung from which the tumor arises. BPS has very high signal intensity as compared with normal lung and is very homogeneous, with discrete margins (Hubbard et al., 1997). BPS in late gestation can become isoechogenic with adjacent lung and may seem to disappear on ultrasound examination (see Chapter 34). These lesions show up distinctly from adjacent normal lung on MRI (Hubbard and Harty, 1999). One disadvantage of fetal MRI in evaluating fetal chest masses has been the inability to demonstrate systemic feeding vessels to BPS. This is a distinct advantage of color flow Doppler over MRI in evaluating BPS or hybrid CCAM lesions, which also have a direct aortic blood supply. Because of its larger field of view, fetal MRI may be especially helpful in evaluating unusual chest lesions such as neurenteric

cysts, laryngotracheal or bronchial obstruction, or mediastinal masses (Hubbard et al., 1997b) (see Chapter 36).

MRI of the Fetal Abdomen and Pelvis

In most instances, ultrasound examination is excellent to evaluate anomalies of the fetal abdomen and pelvis. There are instances, however, when MRI can be helpful. In fetuses with oligohydramnios, ultrasound evaluation can be extremely difficult, whereas fetal MRI is unaffected by a lack of amniotic fluid. It is often difficult to distinguish proximal from distal small-bowel obstruction on prenatal ultrasound examination. There are different MRI signal characteristics that are helpful in these cases, distinguishing proximal from distal small bowel (Hubbard and Harty, 1999). Proximal bowel will have high to intermediate signal intensity on T_2-weighted sequences, similar to amniotic fluid, while distal bowel has intermediate to low signal intensity. Conversely, distal bowel has a high signal intensity on T_1-weighted sequences because of meconium filling the bowel lumen. Using these sequences, dilated loops of bowel may be distinguished as either proximal or distal (Hubbard and Harty, 1999). Because of the large field of view, complex anomalies such as persistent cloaca or cloacal exstrophy may be better imaged on MRI.

The imaging of the fetal urinary tract with ultrasound examination is excellent and rarely improved on by MRI. Exceptions to this include cases of obstructive uropathy complicated by oligohydramnios, polycystic kidneys, and renal tumors. This is also true of sacrococcygeal teratomas, which arise from Hensen's node at the tip of the coccyx. Sacrococcygeal teratomas are most commonly exophytic, but can also extend into the pelvis or abdomen with compression of bladder and intestines.

MRI in a Multiple Gestation

In monochorionic twin pregnancies complicated by intrauterine fetal demise (IUFD), fetal MRI can be used to diagnose multicystic encephalomalacia, a devastating neurologic disorder that may occur in up to 20% of monochorionic twins complicated by single IUFD (Coakley et al., 2004; Weiss et al., 2004) (see Chapter 118). Fetal MRI is usually performed 2 weeks following demise. A normal MRI following single IUFD in a monochorionic twin pregnancy is thought to be reassuring. In addition, fetal MRI has been used in other complicated monochorionic twins at risk for a possible neurologic ischemic episode such as cases complicated by the twin–twin transfusion syndrome and cases that have undergone invasive prenatal techniques such as selective reduction using cord ablative techniques (Coakley et al., 2004; Shevell et al., 2004). The imaging modality may also be helpful in the diagnosis of conjoined twins (Malone and D'Alton, 2000) (see Chapter 121).

Fetal MRI is not indicated as a primary imaging method in any fetal anomaly or condition. As discussed above, however, there are instances in which the information provided by fetal MRI complements that obtained by prenatal ultrasound examination. The role of MRI in prenatal diagnosis is still evolving. At present, MRI is best used selectively in cases in which prenatal sonography is unable to make a definitive diagnosis, where a larger field of view is required, or in acquiring specific information necessary for selection for fetal intervention.

First Trimester Screening for Aneuploidy

2

CHAPTER

Key Points

- Nuchal translucency measurement in the first trimester is the most powerful marker for fetal Down syndrome.
- Combination of nuchal translucency with serum markers in the first trimester detects up to 87% of cases of Down syndrome for a 5% false-positive rate.
- Septated cystic hygroma, or simple nuchal translucency of 3.0 mm or greater, are indications for chorionic villus sampling (CVS) without need to await serum marker results.
- First trimester absence of the nasal bones, reversal of flow in the ductus venosus, and tricuspid regurgitation may have a limited role as second-line screening tests for select high-risk patients by expert sonologists.
- These second-line screening tests are unlikely to have any value for routine general population screening.

INTRODUCTION

The ideal time to screen for fetal aneuploidy is now during the first trimester of pregnancy. This evolution in screening policy is due to the significant advances that have been made in serum and sonographic markers for fetal chromosomal abnormalities over the past 20 years.

FETAL NUCHAL TRANSLUCENCY

The single most powerful marker available today for differentiating Down syndrome from euploid pregnancies is the first trimester sonographic measurement of the fetal nuchal translucency space. Nuchal translucency refers to the normal subcutaneous fluid-filled space between the back of the fetal neck and the overlying skin (Figure 2-1). Figure 2-2 demonstrates an increased nuchal translucency observed in a fetus subsequently shown to have Down syndrome. By adhering to a standard ultrasonographic technique, it is possible to obtain accurate measurements of this area in the vast majority of fetuses between 10 and 14 weeks' gestation. When performing nuchal translucency sonography, it is absolutely essential to ensure optimal technique, which can be attained by focusing on the following criteria (Abuhamad, 2005):

- Fetus should be imaged in the midsagittal plane, ideally with the fetal spine down.
- The image should be adequately magnified so that only the fetal head, neck, and upper thorax fill the viewable area.

Figure 2-1 Optimizing the technique for first trimester nuchal translucency sonography: Nuchal translucency measurement in a normal fetus at 12 weeks' gestation. Components of a good sonographic screening protocol are evident, including adequate image magnification, midsagittal plane, neutral fetal neck position, and correct caliper placement.

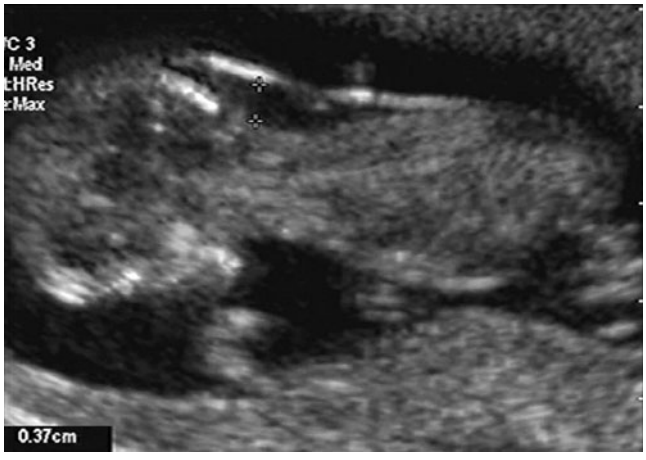

Figure 2-2 Increased nuchal translucency measurement of 3.7 mm in a fetus at 12 weeks' gestation with Down syndrome.

- Fetal neck should be neutral, with care being taken to avoid measurements in the hyperflexed or hyperextended positions.
- The skin at the fetal back should be clearly differentiated from the underlying amniotic membrane, either by visualizing separate echogenic lines or by noting that the skin line moves with the fetus.
- Measurement calipers should be placed on the inner borders of the echolucent space, and should be perpendicular to the long axis of the fetus.
- Ultrasound and transducer settings should be optimized to ensure clarity of the image and of the borders of the nuchal space in particular. This may require transvaginal sonography in certain situations.

There is a direct correlation between increasing nuchal translucency measurement and risk for Down syndrome, other aneuploidies, major structural malformations, and adverse pregnancy outcome (Malone et al., 2000, 2005b; Nicolaides et al., 2002; Wald et al., 2003b). Possible etiologies for the development of this increased fluid-filled space include cardiac failure secondary to structural malformation, abnormalities in the extracellular matrix, and abnormal or delayed development of the lymphatic system (Moscoso, 1995).

NUCHAL TRANSLUCENCY SCREENING FOR DOWN SYNDROME

Nuchal translucency sonography is the most powerful marker for general population screening for Down syndrome (Malone and D'Alton, 2003). The largest study of this form of screening was performed by the Fetal Medicine Foundation based in London (Snijders et al., 1998). This prospective study of 96,127 unselected patients at 22 centers required nuchal translucency sonography to be performed between 10 and 14 weeks' gestation by specially trained sonographers who utilized a standardized technique. The overall Down

syndrome detection rate was 77%, for a 5% false-positive rate. Another large prospective study from the United Kingdom that evaluated the role of nuchal translucency sonography in general population screening was the SURUSS Trial (Wald et al., 2003b). A total of 39,983 patients had nuchal translucency sonography obtained between 10 and 14 weeks' gestation, and the Down syndrome detection rate was 63%, for a 5% false-positive rate. The largest prospective trial of all forms of Down syndrome screening yet performed, the FASTER Trial, has also validated the important role of nuchal translucency sonography. This was a multicenter prospective study from 15 centers in the United States in which 36,306 patients from the general population had first trimester nuchal translucency sonography performed (Malone et al., 2005b). The detection rate for nuchal translucency with maternal age ranged from 70% to 64% at 11 and 13 weeks' gestation respectively, for a 5% false-positive rate. These large studies from varied centers and geographic locations confirm that nuchal translucency sonography must be a key component of first trimester screening programs for fetal Down syndrome.

COMBINED FIRST TRIMESTER SERUM AND SONOGRAPHIC SCREENING

Together with the clear role of nuchal translucency sonography, research in first trimester screening has consistently shown that pregnancies with fetal Down syndrome are associated with altered levels of certain maternal serum markers, including elevated levels of total human chorionic gonadotropin (hCG) and of the free β subunit of hCG (with a median multiple of the median [MoM] of 1.83 in affected cases) and lower levels of pregnancy-associated plasma protein A (with a median MoM of 0.38 in affected cases) (Canick and Kellner, 1999). Studies of the combination of free β subunit of hCG, pregnancy-associated plasma protein A, and maternal age uniformly demonstrate a sensitivity for Down syndrome of approximately 60% with a 5% false-positive rate.

These first trimester serum markers are largely independent of nuchal translucency, which has resulted in the development of a combined serum and sonographic screening protocol that would be more effective for screening than either component alone. The FASTER study evaluated 38,033 patients and demonstrated very high Down syndrome detection rates, and showed that performance varied significantly by gestational age. For a 5% false-positive rate, the Down syndrome detection rates using combined serum and sonographic screening were 87%, 85%, and 82% at 11, 12, and 13 weeks' gestation respectively (Malone et al., 2005b). For a 1% false-positive rate, the Down syndrome detection rates were 73%, 72%, and 67% at 11, 12, and 13 weeks' gestation respectively.

Figure 2-3 summarizes the comparative performance of the various screening options from the FASTER Trial, and demonstrates that first trimester combined screening has very similar performance to second trimester Quad marker serum screening (Malone et al., 2005b). Only when performed at 11 weeks' gestation does first trimester combined screening have a significantly better performance than second trimester Quad marker serum screening (87% vs. 81% Down syndrome detection, respectively, at a 5% false-positive rate). Additionally, the combined first trimester screening test has the lowest false-positive rate, compared with either first trimester component used alone or compared with second trimester serum screening. It is also important to realize that only the combination of first trimester nuchal translucency sonography

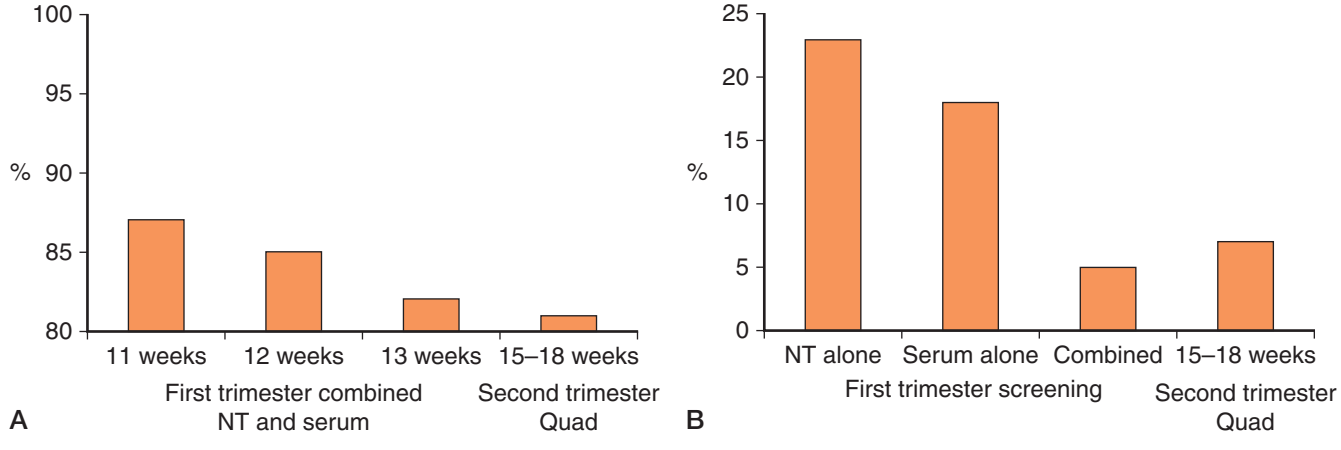

Figure 2-3 **A**. Comparison of first and second trimester screening for Down syndrome: Detection rates of combined first trimester screening at 11, 12, and 13 weeks' gestation, compared with second trimester Quad marker serum screening performed at 15 to 18 weeks' gestation (each at 5% false-positive rate). **B**. Comparison of first and second trimester screening for Down syndrome: False-positive rates of first trimester nuchal translucency alone, PAPP-A and fβhCG alone, and first trimester combined screening at 12 weeks' gestation, compared with second trimester Quad marker serum screening performed at 15 to 18 weeks' gestation (each for 85% detection rate).

with first trimester serum markers comes close to the performance of second trimester Quad marker serum screening. Nuchal translucency alone, without being combined with serum markers, has significantly inferior performance characteristics.

ENLARGED NUCHAL TRANSLUCENCY AND CYSTIC HYGROMA IN THE FIRST TRIMESTER

It is now clear that a subset of fetuses with very large nuchal translucency measurements can be effectively identified in the first trimester that have an extremely high risk of fetal aneuploidy or other adverse pregnancy outcomes. This finding has been described as septated cystic hygroma, and is present when the nuchal translucency space is enlarged extending along the entire length of the fetus, and in which septations are clearly visible (Figure 2-4) (Malone et al., 2005a). Septated cystic hygroma is seen in more than 1 in 300 first trimester pregnancies. In a recent prospective study of routine first trimester sonographic screening, septated cystic hygroma was shown to have a 50% chance of being associated with fetal aneuploidy, with most cases being Down syndrome, as well as cases of Turner syndrome and trisomy 18. Additionally, among cystic hygroma cases confirmed as being euploid, approximately 50% had a major structural fetal malformation, with most cases including cardiac malformations, as well as other malformations such as skeletal dysplasias. When compared with simple increased nuchal translucency, septated cystic hygroma cases were 5 times more likely to be aneuploid, 12 times more likely to have cardiac malformations, and 6 times more likely to result in fetal or neonatal demise.

The practical benefit of being able to counsel patients in the first trimester following the identification of septated cystic hygroma is that there is no need to delay decision-making while awaiting serum marker results or using computerized risk calculation algorithms. When faced with a 50% chance of fetal aneuploidy, it is reasonable to offer such patients the immediate option of CVS, and if fetal aneuploidy has been excluded, a detailed fetal anatomical evaluation, including fetal echocardiography, should be performed at 18 to 20 weeks' gestation.

Debate has also occurred regarding the differentiation between septated cystic hygroma and simple enlarged nuchal translucency, with some investigators believing that they are both part of a spectrum of a similar sonographic feature (Molina et al., 2006). However, the FASTER Trial, a prospective study of more than 38,000 pregnancies, has also now demonstrated that whenever a simple nuchal translucency measurement of 3.0 mm or greater is noted, CVS should be offered immediately because of a minimum risk of aneuploidy of 1 in 6 (Comstock, 2006). With such nuchal translucency measurements, there is no role for delaying decision-making while awaiting serum marker results, as such additional information does not meaningfully alter the original aneuploidy risk. This finding therefore suggests that debating the presence or absence of septations in cases of enlarged nuchal translucency is a moot point, as the risk of aneuploidy either when a nuchal translucency measurement of 3.0 mm or greater is noted, or when a septated cystic hygroma is noted, is sufficiently high to warrant immediate diagnostic testing.

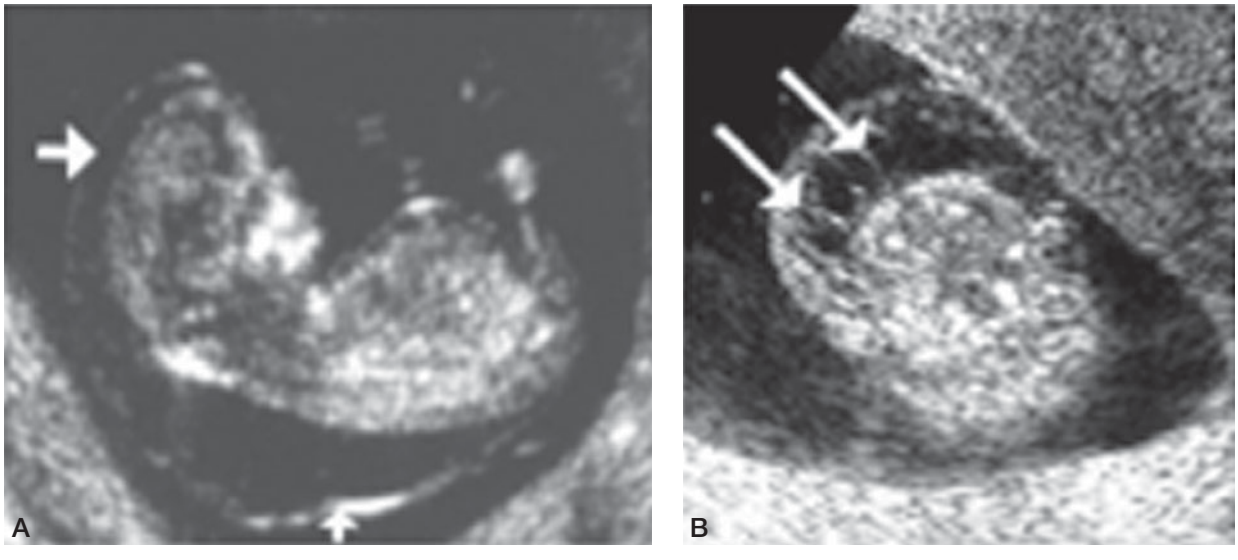

Figure 2-4 **A**. Septated cystic hygroma at 12 weeks of gestation: midsagittal sonographic view of a fetus with septated cystic hygroma, demonstrating increased nuchal translucency space extending along the entire length of the fetus. **B**. Septated cystic hygroma at 12 weeks of gestation: transverse view through the fetal neck of the same fetus demonstrating obvious septations (arrows). (*From Malone FD, Ball RH, Nyberg DA, et al. First trimester septated cystic hygroma: prevalence, natural history, and pediatric outcome.* Obstet Gynecol. *2005a;106:288-294.*)

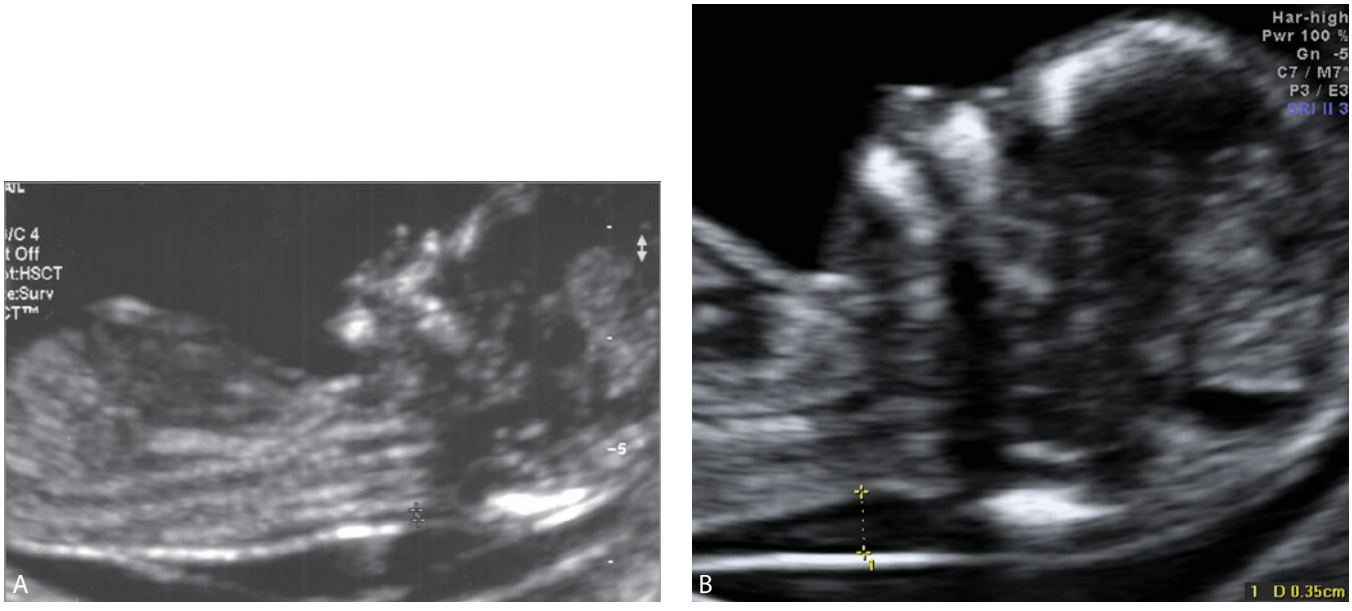

Figure 2-5 **A**. First trimester ultrasound examination of a fetus at 13 weeks' gestation, with normal nasal bones. Features of good nasal bone imaging technique are evident, including midsagittal plane, fetal profile facing upward, adequate magnification, and visualization of two parallel lines at the level of the fetal nose, one representing fetal skin (short arrow) and the deeper line representing nasal bones. **B**. First trimester ultrasound examination of a fetus at 13 weeks' gestation, with absent nasal bones and enlarged nuchal translucency thickness, in which karyotype was confirmed as trisomy 18.

NASAL BONE SONOGRAPHY IN THE FIRST TRIMESTER

There appears to be a clear association between the absence of the fetal nasal bones on first trimester ultrasound examination and Down syndrome. In a study conducted by Cicero et al. (2001), 701 fetuses with increased nuchal translucency were evaluated for the presence or absence of the nose bones during first trimester ultrasonography. The fetal nasal bones could not be visualized in 73% of Down syndrome fetuses (43 of 59) and in only 0.5% of unaffected fetuses (3 of 603). The authors also felt that the absence of the fetal nose bone was not related to nuchal translucency thickness and therefore could be combined into a single ultrasound screening modality, with a predicted sensitivity of 85% for a 1% false-positive rate. This study was subsequently expanded to a larger series of 3829 high risk, first trimester pregnancies, in which the detection rate for Down syndrome using absent nasal bones was 67%, for a 2.8% false-positive rate (Cicero et al., 2003).

Adequate imaging of the fetal nasal bones can be technically challenging in the first trimester, and careful attention to correct technique should therefore be paid to ensure consistency in technique. The nasal bones should be visualized on ultrasound along the midsagittal plane with a perfect fetal profile. The fetal spine should be down, with slight neck flexion. Two echogenic lines at the fetal nose profile should be visualized; the superficial echogenic line is the nasal skin, and the deeper echogenic line represents the nasal bones. This deeper echogenic line representing the nasal bones should be more echolucent at its distal end (Figure 2-5A). Care should be taken not to perform this evaluation with the ultrasound beam parallel to the plane of the nasal bones, because this might erroneously lead to the conclusion of absent nasal bones (Figure 2-5B).

While several other studies evaluating the role of first trimester nasal bone sonography as a screening test for fetal Down syndrome have also been published, all were limited by being derived from high-risk patient populations or lacking adequate pregnancy outcome ascertainment. The largest study of first trimester fetal nasal bone sonography published to date, and in which an unselected general patient population has been evaluated, did not confirm a useful role for this form of screening (Malone et al., 2004). In a prospective study of 6324 patients having nasal bone sonography by trained and experienced sonographers, adequate views of the fetal profile were obtained in only 76% of cases, and none of the 11 cases of fetal Down syndrome were found to have absent nasal bones. Two further studies of the role of first trimester nasal bone sonography as a screening tool in the general population have also recently been published, and have confirmed these findings that there is only a limited role of this form of screening. One study screened 7116 unselected patients from the general population including 12 cases of Down syndrome, and screened a further 510 high-risk patients including 23 cases of Down syndrome (Prefumo et al., 2006). Absent nasal bones in the first trimester was noted in only 17% of cases in the general population and in 48% of cases in the high-risk population. A further study screened 1800 consecutive patients from the

general population, and absent nasal bones was noted in only 2 of 7 (29%) of Down syndrome cases (Ramos-Corpas et al., 2006).

While it is possible that there may be a role for first trimester fetal nasal bone sonography in the hands of select experts as a second-line screening tool in high-risk patients, current data suggest that this form of sonography should not be used as a general population screening tool.

FIRST TRIMESTER DUCTUS VENOSUS SONOGRAPHY

First trimester Doppler sonographic evaluation of ductus venosus blood flow has been described as an adjunctive test for fetal aneuploidy screening. Forward triphasic pulsatile ductus venosus flow, as illustrated in Figure 2-6, is normal, while reversed flow at the time of the atrial contraction has been associated with aneuploidy and fetal cardiac malformations (Matias et al., 1998). In a series of early studies evaluating this association, between 59% and 93% of aneuploid fetuses had abnormal first trimester ductus venosus flow velocities (Malone and D'Alton, 2003). Abnormal ductus venosus flow velocities were also found in as few as 3% or as many as 21% of normal fetuses. It may therefore be possible that fetal ductus venosus flow velocity waveform analysis may be useful to modify a patient's final risk for aneuploidy following completion of the nuchal translucency measurement. This could be used to either improve the detection rate or alternatively to reduce the false-positive rate.

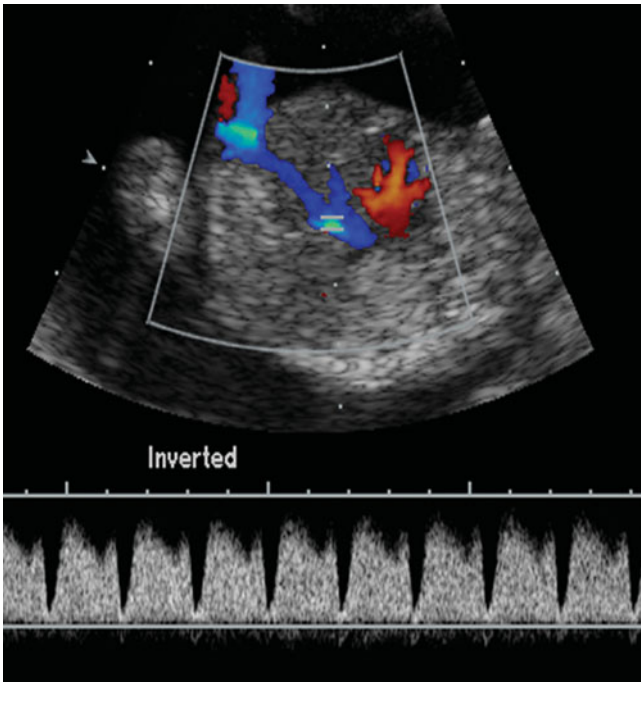

Figure 2-6 Pulsed Doppler sonography image of a normal ductus venosus waveform at 12 weeks' gestation. Of note, the ductus venosus can be identified using color flow as a small vessel with turbulent flow. The nadir of flow during the "a" wave remains forward flowing (arrow).

While it appears that there is some association between abnormal ductus venosus flow studies and aneuploidy in the first trimester, there are several pitfalls that must be considered. The ductus venosus vessel itself may be as small as 2 mm at 10 to 14 weeks, making it difficult to obtain accurate flow velocity waveforms from such a tiny vessel without contamination of the waveform from neighboring vessels. For example, if the Doppler gate is placed too proximally near the umbilical sinus, the normal continuous venous flow from the umbilical vein may obscure absence of flow during the atrial contraction in the ductus venosus. Alternatively, placement of the Doppler gate too far distally, near the insertion of the ductus venosus into the inferior vena cava may lead to the erroneous diagnosis of reversal of flow at the atrial contraction, as such reversal of flow is commonly seen in the inferior vena cava. The current consensus appears to be that first trimester ductus venosus Doppler flow studies should be performed only as a secondary screening test in the hands of experienced sonologists at referral centers, either to modify the final risk for aneuploidy or to help predict the prognosis of fetuses with normal chromosomes and an increased nuchal translucency measurement (Hecher, 2001; Nicolaides et al., 2005).

FIRST TRIMESTER TRICUSPID REGURGITATION EVALUATION

An association has been suggested between fetal aneuploidy and abnormal tricuspid regurgitation noted during first trimester sonography (Nicolaides et al., 2005). To perform this assessment, the fetus should be oriented so that the chest wall is anterior and the fetal heart should be insonated parallel to the ventricular septum. A pulsed Doppler gate of approximately 3 mm size is then placed across the tricuspid valve, with care to ensure that the angle to the direction of flow is as close to zero as possible (Figure 2-7). Significant tricuspid regurgitation is considered to be present if a regurgitant jet of at least 60 cm/s is noted extending to more than half of systole (Falcon et al., 2006).

In a series of 1557 high-risk pregnancies at 11 to 13 weeks' gestation, significant tricuspid regurgitation was noted in only 4% of chromosomally normal fetuses, but was present in 77 of 114 cases (68%) of Down syndrome and 14 of 42 cases (33%) of trisomy 18 (Falcon et al., 2006). These investigators were able to obtain adequate Doppler waveforms of the tricuspid valve in 99% of cases and there was low interobserver variability of measurements.

While these data are encouraging regarding an association between first trimester tricuspid regurgitation and chromosomal abnormalities, like ductus venosus assessment, it is unclear whether this form of screening will have any role in general population screening. Extrapolation of the results of a screening test from a high-risk population, performed in the hands of experts, to implementation in the general population

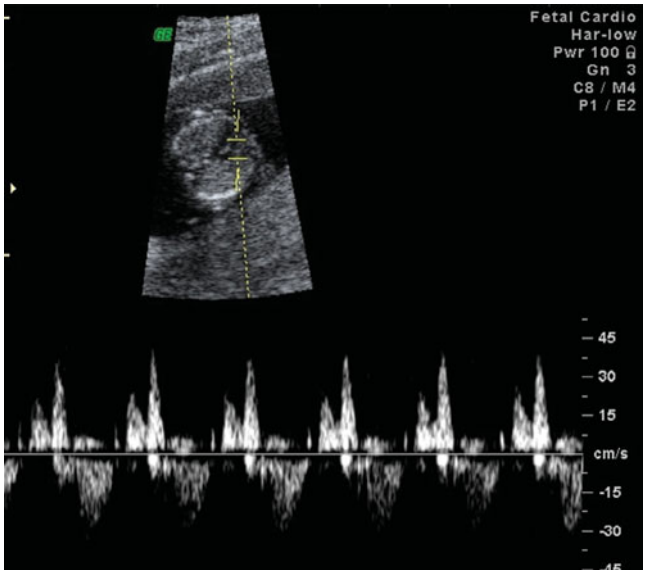

Figure 2-7 First trimester sonographic evaluation for tricuspid regurgitation in a fetus at 11 weeks' gestation. Note the pulsed Doppler gate placed across the tricuspid valve, with the angle to the direction of flow close to zero. There is no regurgitation greater than 60 cm/s.

will likely overstate the true performance of the test. It is likely that first trimester sonography for tricuspid regurgitation may have a role as a second-line test, following an initial high-risk nuchal translucency and serum screen. In this setting, it may have a role in reducing the false-positive rate of screening. In one series of 75,821 first trimester pregnancies, addition of tricuspid regurgitation as a second-line screening test following nuchal translucency and serum screening resulted in a Down syndrome detection rate of 92% for a false-positive rate of only 2.7% (Nicolaides et al., 2005).

NUCHAL TRANSLUCENCY SCREENING IN MULTIPLE GESTATIONS

Prenatal risk assessment for Down syndrome in multiple gestation pregnancies has been quite limited before the advent of nuchal translucency-based screening. Maternal serum screening has not been widely utilized in the setting of multiple gestations because of the potential for discordancy between twins and the impact of different placentas on the various analytes. Nuchal translucency measurements are broadly similar between singleton and twin pregnancies, implying that the Down syndrome detection rates should be similar. The false-positive rate of nuchal translucency screening might be higher in monochorionic twins because some complications unique to monochorionic gestations, such as twin-to-twin transfusion syndrome, might present with increased nuchal translucency measurement (Sebire et al., 2000).

Options for first trimester screening for Down syndrome therefore include providing either a fetus-specific risk based on nuchal translucency alone, or providing an overall pregnancy risk based on combined serum and sonographic markers. In one series of 448 twin pregnancies, nuchal translucency yielded an 88% detection rate for a 7% false-positive rate (Sebire et al., 2000). In another series of 206 twin pregnancies screened using nuchal translucency and first trimester serum markers, the Down syndrome detection rate was estimated to be approximately 75% for a 5% false-positive rate (Spencer and Nicolaides, 2003). To provide a pregnancy-specific risk in twins, a likelihood ratio is calculated for each fetus' nuchal translucency measurement; these two likelihood ratios are then added together, and this is then multiplied by the biochemistry likelihood ratio to provide a final "pseudorisk" calculation (Wald et al., 2003a). Although additional research on the efficacy of this combined first trimester screening in multiple gestations is still needed, nuchal translucency measurement should at least represent an improvement over serum screening in multiple gestations. Currently, some centers use nuchal translucency sonography to assist in selecting fetuses for reduction in higher order multiple gestations.

CHAPTER 3

Second Trimester Screening for Aneuploidy

Key Points

- Quad marker serum screening is the most effective form of Down syndrome screening in the second trimester (81% detection rate at a 5% false-positive rate).
- Presence of a major structural malformation at second trimester sonographic fetal anatomy survey is an indication for genetic amniocentesis.
- A range of minor markers at second trimester sonographic fetal anatomy survey can be utilized with likelihood ratios to adjust the risk of Down syndrome.
- Absence of major or minor markers at second trimester sonographic fetal anatomy survey reduces the risk of fetal Down syndrome by 60%.
- Combinations of screening tests in both first and second trimesters, such as integrated, stepwise, and contingency screening, may be more efficient than screening in either trimester alone.

INTRODUCTION

While tremendous advances have been made in recent years regarding screening for fetal aneuploidy in the first trimester of pregnancy, the mainstay of screening for aneuploidy has been second trimester serum and sonographic screening. Despite the increasing popularity of first trimester screening, there will always be a role for second trimester aneuploidy screening given that some patients do not present for antenatal care sufficiently early in pregnancy to avail of nuchal translucency and given that a second trimester fetal anatomical survey has become an almost routine aspect of general antenatal care. Additionally, since first trimester screening requires the availability of chorionic villus sampling (CVS) to provide a first trimester diagnosis, in areas in which CVS is not available there will be a continued requirement for second trimester screening protocols leading to amniocentesis.

Options for second trimester screening include serum screening using the Quad test (alphafetoprotein, human chorionic gonadotropin, unconjugated estriol, and inhibin-A), sonographic screening using the so-called Genetic Sonogram, and combinations of serum and sonographic screening.

SECOND TRIMESTER SERUM SCREENING

Maternal serum levels of alphafetoprotein (AFP) and unconjugated estriol (uE3) are both approximately 25% lower in pregnancies complicated by Down syndrome, compared with euploid pregnancies (Wald et al., 1994; Malone et al., 2005). By contrast, levels of hCG and inhibin-A are approximately twice as high in pregnancies complicated by Down syndrome (Wald et al., 1994; Malone et al., 2005). Maternal serum levels of AFP, uE3, and hCG all tend to be decreased in pregnancies complicated by trisomy 18. The combination of AFP, uE3, and hCG, commonly known as the triple screen, can detect 69% of cases of Down syndrome, for a 5% false-positive rate (Wald et al., 2003; Malone et al., 2005). When inhibin-A is added to this test, commonly known as the Quad screen, the Down syndrome detection rate increases to 81%, for a 5% false-positive rate (Wald et al., 2003; Malone et al., 2005). Based on these results, if a second trimester serum sample is obtained for aneuploidy risk assessment, optimal performance will be obtained by measuring the four serum markers, rather than any double or triple marker combination.

Performance of serum screening tests can be maximized by accurate ascertainment of gestational age, and wherever possible, sonographic dating should be used instead of menstrual dating. It is optimal to provide serum screening between 15 and 16 weeks' gestation, thereby allowing the results to be available at the time of second trimester sonographic evaluation. Subsequently, if this sonographic evaluation reveals any markers for aneuploidy, the Down syndrome risk quoted from serum screening can be used with the ultrasound findings to determine the most precise final Down syndrome risk. Adequate time should then be available for diagnostic genetic amniocentesis if indicated by the screening results.

SECOND TRIMESTER SONOGRAPHIC SCREENING

Sonographic evaluation of the fetal anatomy at 18 weeks' gestation has become a routine aspect of antenatal care in most developed countries. When this methodical evaluation for fetal malformations is used to assess the risk for fetal aneuploidy, the term Genetic Sonogram is commonly used. Risk for fetal aneuploidy can be assessed by the detection of either major structural malformations known to be associated with aneuploidy, or by the detection of a range of minor sonographic markers that increase the chances of fetal aneuploidy (Table 3-1).

The detection of certain major structural malformations that are known to be associated with aneuploidy should prompt an immediate consideration for genetic amniocentesis. Major structural malformations that are associated with Down syndrome include cardiac malformations (AV canal defect [Figure 3-1], ventricular septal defect, tetralogy of Fallot), duodenal atresia (Figure 3-2), cystic hygroma (Figure 3-3), and hydrops fetalis (see Chapter 131). The major malformations associated with trisomy 18 include cardiac malformations (AV canal defect, ventricular septal defect, double outlet right ventricle), meningomyelocele, omphalocele, esophageal atresia, rocker bottom feet, cleft lip or palate, cystic hygroma, and hydrops fetalis (see Chapter 130). While the Genetic Sonogram can be performed at any time during the second and third trimesters, the optimal time is likely to be at 17 to 18 weeks' gestation, which is late enough to maximize fetal anatomical evaluation, yet early enough to allow for amniocentesis results to be obtained. When a major structural malformation is found, such as an AV canal defect or a double-bubble suggestive of duodenal atresia, the risk of Down syndrome in that pregnancy can be increased by approximately 20- to 30-fold (Nyberg et al., 1998). For almost all patients, such an increase in their background risk for aneuploidy will be sufficiently high to justify immediate genetic amniocentesis.

Second trimester sonography can also detect a range of minor markers for aneuploidy. The latter are not considered structural abnormalities of the fetus per se, but when noted, may be associated with an increased probability that the fetus is aneuploid. The minor markers that have been commonly linked to Down syndrome include nuchal fold thickening (Figure 3-4), nasal bone hypoplasia (Figure 3-5), mild ventriculomegaly, short femur or humerus, echogenic bowel (Figure 3-6), renal pyelectasis (Figure 3-7), echogenic intracardiac focus (Figure 3-8), clinodactyly (Figure 3-9), sandal gap toe (Figure 3-10), and widened iliac angle (Nyberg et al., 2001). The minor markers that are associated with trisomy 18 include nuchal fold thickening, mild ventriculomegaly, short femur or humerus, echogenic bowel, enlarged cisterna magna, choroid plexus cysts (Figure 3-11), micrognathia, single umbilical artery (Figure 3-12), clenched hands, and fetal growth restriction. It should be noted that almost all data supporting the role of second trimester sonography for minor markers for aneuploidy are derived from high-risk populations, such as patients of advanced maternal age or with abnormal maternal serum screening results. It is still unclear what the relative contribution of screening for such minor markers will be in lower risk patients from the general population.

The sonographic approach to establishing the presence or absence of each of the commonly utilized minor markers is summarized below:

1. *Nuchal fold.* Sonographic measurement of the nuchal fold is performed by imaging the fetal head in an axial plane passing through the posterior fossa (Figure 3-4). Calipers should be placed on the outer aspect of the occipital bone and the outer aspect of the skin. When measured between 15 and 21 weeks' gestation, a cutoff of 5 mm is commonly used to define an abnormally thickened nuchal fold. The finding of an isolated nuchal fold greater than 5 mm is associated with an 11-fold increase in background risk for Down syndrome (Benacerraf and Frigoletto, 1987; Nyberg et al., 2001).

Table 3-1

Major Structural Malformations and Minor Sonographic Markers Associated with Down Syndrome, Trisomy 18 and Trisomy 13

Feature	Down Syndrome	Trisomy 18	Trisomy 13
Major structural malformations	Cardiac defects: – AV canal defect – Ventricular septal defect – Tetralogy of Fallot Duodenal atresia Cystic hygroma Hydrops	Cardiac defects: – Double outlet right ventricle – Ventricular septal defect – AV canal defect Meningomyelocele Agenesis corpus callosum Omphalocele Diaphragmatic hernia Esophageal atresia Clubbed or rocker bottom feet Renal abnormalities Orofacial clefting Cystic hygroma Hydrops	Holoprosencephaly Orofacial clefting Cyclopia Proboscis Omphalocele Cardiac defects: – Ventricular septal defect – Hypoplastic left heart Polydactyly Clubbed or rocker bottom feet Echogenic kidneys Cystic hygroma Hydrops
Minor sonographic markers	Nuchal thickening Mild ventriculomegaly Short humerus or femur Echogenic bowel Renal pyelectasis Echogenic intracardiac focus Hypoplastic nasal bones Brachycephaly Clinodactyly Sandal gap toe Widened iliac angle Growth restriction	Nuchal thickening Mild ventriculomegaly Short humerus or femur Echogenic bowel Enlarged cisterna magna Choroid plexus cysts Micrognathia Strawberry-shaped head Clenched or overlapping fingers Single umbilical artery Growth restriction	Nuchal thickening Mild ventriculomegaly Echogenic bowel Enlarged cisterna magna Echogenic intracardiac focus Single umbilical artery Overlapping fingers Growth restriction

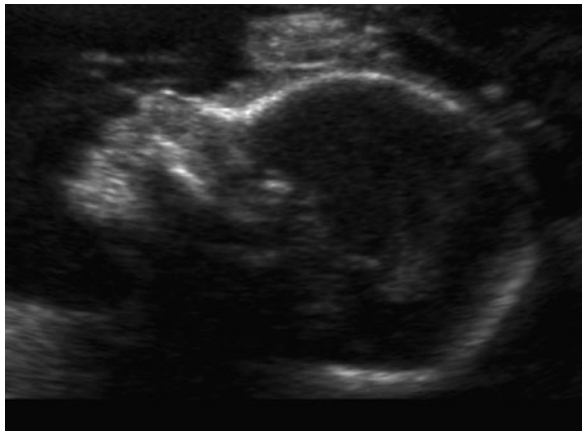

Figure 3-5 Normal fetal nasal bone evaluation at 16 weeks' gestation. A perfect midsagittal plane is demonstrated with echogenicity of the fetal nasal bones visible.

Figure 3-6 Fetal echogenic bowel at 15-week ultrasound evaluation. Transverse view through the fetal abdomen reveals bowel echogenicity as bright as fetal bone.

Figure 3-7 Sonographic evaluation of fetus at 17 weeks' gestation revealing bilateral pyelectasis with both renal pelves measuring greater than 3 mm in anteroposterior diameter.

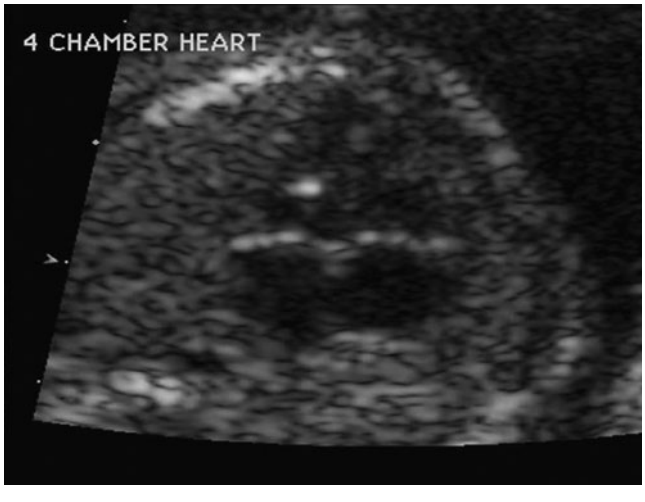

Figure 3-8 Second trimester fetal anatomic evaluation demonstrating echogenic intracardiac focus in the left ventricle of the fetal heart.

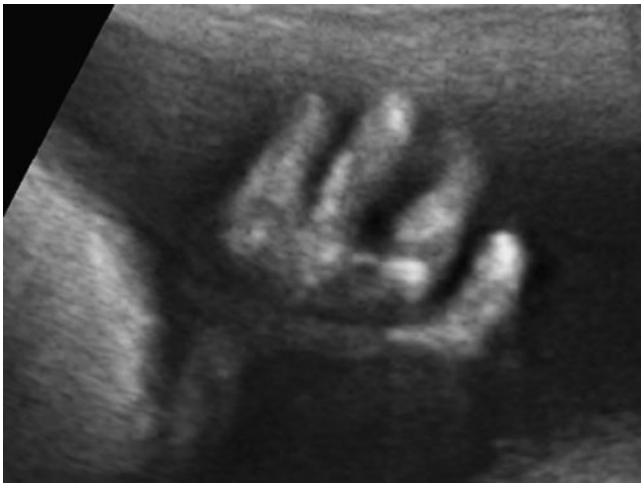

Figure 3-9 Clinodactyly in a fetus at 23 weeks' gestation with Down syndrome. The fifth digit is significantly smaller than expected with middle phalanx hypoplasia.

2. *Echogenic bowel.* Sonographic visualization of bright bowel in the fetal abdomen is considered abnormal if the echogenicity is similar to that of fetal bone (Figure 3-6) (Nyberg et al., 1990b). A common pitfall with this minor marker is to overdiagnose the finding because of inappropriately high sonographic gain settings. When present, it is associated with a 6.7-fold increase in background risk for Down syndrome.
3. *Humerus and femur length.* The expected humerus and femur lengths can be estimated after a measurement of the fetal biparietal diameter (BPD) is obtained, and can be calculated using the formula $\{-7.9404 + 0.8492 \times \text{BPD}\}$ for the humerus, or $\{-9.645 + 0.9338 \times \text{BPD}\}$ for the femur. A ratio of observed to expected humerus or femur lengths less than 0.90 is considered abnormal (Nyberg et al., 1990a, 1993). It is likely that separate norms will be needed to interpret long bone length in certain populations, such as biometry tends to be shorter amongst Asian fetuses (Shipp et al., 2001). The isolated finding of a short humerus or a short femur is associated with a fivefold and a 1.5-fold increase in background risk for Down syndrome respectively.
4. *Echogenic intracardiac focus.* Calcification of the papillary muscle in the intracardiac ventricles can be demonstrated by sonography as a discrete echogenic dot within the left or right ventricle (Figure 3-8) (Brown et al., 1994). The majority of cases are present in the left ventricle, and care should be exercised in imaging the fetal heart from multiple angles to avoid overdiagnosis due to specular reflection. Additionally, echogenic intracardiac focus may be

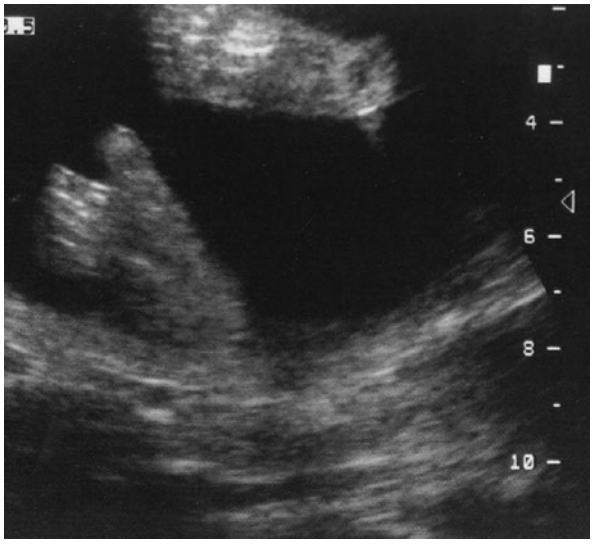

Figure 3-10 Prenatal sonographic image demonstrating the sandal gap.

Figure 3-11 Bilateral choroid plexus cysts in a fetus with trisomy 18 at 18 weeks' gestation.

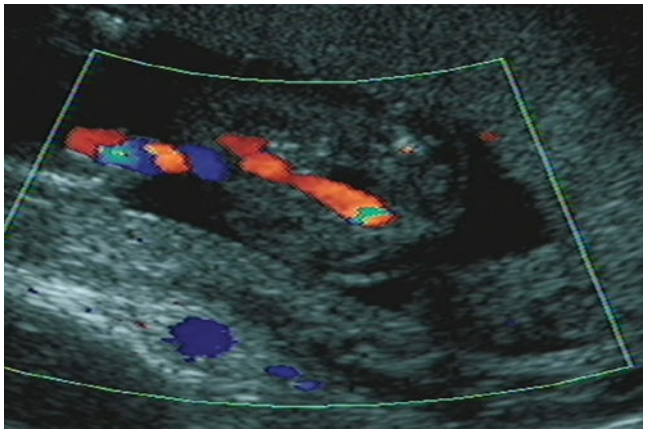

Figure 3-12 Single umbilical artery in a fetus at 23 weeks' gestation with trisomy 18. Color Doppler evaluation at the umbilical cord insertion site into the fetal abdomen, angled caudally to include the fetal bladder demonstrates only one umbilical artery at the dome of the bladder. The right umbilical artery is absent.

considered a normal variant in certain populations, being present in up to 30% of normal Asian fetuses (Shipp et al., 2000). When an echogenic intracardiac focus is detected, the background risk for Down syndrome can be increased by a factor of 1.8.

5. *Pyelectasis.* Sonographic measurement of the anteroposterior diameter of the renal pelves from 15 to 20 weeks' gestation should normally reveal a diameter of 3 mm or less (Figure 3-7) (Benacerraf et al., 1990). Bilateral pyelectasis, in which both renal pelvises measure 4 mm or greater, is associated with a 1.5-fold increase in background risk for Down syndrome.
6. *Nasal bones.* Failure to visualize the nasal bone, on a perfect sagittal fetal profile during the second trimester, or visualization of hypoplastic nasal bones, has recently been suggested as a powerful screening tool for Down syndrome (Figure 3-5) (Bromley et al., 2002; Vintzileos et al., 2003). It is likely that this second trimester approach may not be as subjective as first trimester nasal bone evaluation. Very limited data exist to date assessing the strength of this association during the second trimester. It is possible that the absence or hypoplasia of nasal bones may increase the background risk for Down syndrome by up to a factor of 8.
7. *Choroid plexus cyst.* Sonographic evaluation of the choroid plexus, using an axial view through the upper portion of the fetal head, can frequently reveal the presence of one or more discrete cysts (Figure 3-11). While debated extensively in the past, it does not appear that isolated choroid plexus cysts represent markers for Down syndrome, although they have been described as being associated with trisomy 18 (American College of Obstetricians and Gynecologists, 2001). It is possible that the detection of an isolated choroid plexus cyst might increase the background risk for trisomy 18 by a factor of 7. However, since the background risk for trisomy 18 is generally very low, it is unlikely that the finding of an isolated cyst in a low-risk patient is of any clinical significance. Additionally, it does not appear that the number, size, or evolution of choroid plexus cysts has any impact on trisomy 18 risk assessment.

USING SECOND TRIMESTER SONOGRAPHIC MARKERS FOR COUNSELING

To objectively counsel patients following the prenatal diagnosis of a minor sonographic marker, likelihood ratios can be used to create a more precise risk assessment for the patient that their fetus might be affected with Down syndrome. Table 3-2 summarizes the likelihood ratios that can be used to modify a patient's risk for Down syndrome, depending on which minor marker is detected. If no markers are present, the patient's a priori risk can be multiplied by 0.4, effectively reducing their chances of carrying a fetus with Down syndrome by 60% (Nyberg et al., 2001). The likelihood ratio values listed for each marker assume that the marker is an isolated finding. By contrast, when more than one minor marker is noted in the same fetus different likelihood ratios must be used, with the risk for Down syndrome being increased by a factor of 10 when 2 minor markers are detected and by a factor of 115 when 3 or more minor markers are found (Nyberg et al., 2001).

It should also be noted that the 95% confidence interval values for each marker's likelihood ratios are rather wide. These values should therefore be used only as a general guide for counseling patients, and care should be exercised to avoid implying too much precision in the final risk estimates. Accuracy of risk estimates however can be maximized by using the best available a priori risk value for a particular patient, such as the results of maternal serum marker screening or first trimester combined screening, rather than maternal age, when available. For example, if a 35-year-old patient has an age-related risk of Down syndrome of 1 in 250, and has had a second trimester serum Quad screen done that reveals a reduced risk of 1 in 1000, the finding of an echogenic intracardiac focus on genetic sonography should result in a final Down syndrome risk of 1 in 555 and not 1 in 140 (i.e., 1:1000 multiplied by 1.8, rather than 1:250 multiplied by 1.8).

Table 3-2

Likelihood Ratios for Down Syndrome When an Isolated Minor Sonographic Marker Is Detected. The Patient's A Priori Risk Is Multiplied by the Appropriate Positive Likelihood Ratio to Yield an Individualized Post-Test Risk for Fetal Down Syndrome

Minor Marker	Likelihood Ratio	95% Confidence Intervals
Nuchal fold >5 mm	11	6–22
Echogenic bowel	6.7	3–17
Short humerus	5.1	2–17
Short femur	1.5	0.8–3
Echogenic intracardiac focus	1.8	1–3
Pyelectasis	1.5	0.6–4
Any two minor markers	10	6.6–14
Any three or more minor markers	115	58–229
No markers	0.4	0.3–0.5

COMPARATIVE ROLE OF FIRST AND SECOND TRIMESTER SCREENING

As demonstrated in Figures 2-3A and 2-3B in the preceding chapter, second trimester serum screening for Down syndrome is similarly effective to first trimester combined screening using nuchal translucency sonography, PAPP-A and free ßhCG. Only when performed at 11 weeks' gestation does first trimester combined screening have a significantly better performance than second trimester Quad marker serum screening (87% vs. 81% Down syndrome detection, respectively, at a 5% false-positive rate). Additionally, first trimester combined screening has the lowest false-positive rate, compared with second trimester Quad marker serum screening.

COMBINED FIRST AND SECOND TRIMESTER SCREENING

Given the excellent performance characteristics of both first trimester combined screening and second trimester Quad marker serum screening, it is logical to assume that improved screening results could be obtained by performing screening tests in both trimesters in the same patient. However, with the increasing range of Down syndrome screening tests now available, confusion will likely develop when patients have more than one screening test performed.

It is not valid to perform separate Down syndrome risk assessments at different gestational ages by providing independent estimations of risk on each test. For example, if a particular population has been subjected to first trimester screening, approximately 80% of the cases of Down syndrome will have already been discovered and terminated prior to 15 weeks' gestation (Wapner et al., 2003; Malone et al., 2005; Nicolaides et al., 2005). If the remaining population is then subjected to second trimester screening with risks calculated independently, the positive predictive value of an abnormal second trimester screen will be significantly reduced. The individual risk calculation provided to such patients will be inaccurate. Additionally, since both screening tests carry their own false-positive rate, the overall population false-positive rate at the completion of all screening tests may be extremely high. In one recent study, such an independent sequential screening policy (nuchal translucency, PAPP-A, fβhCG in the first trimester, followed by triple screen performed independently in the second trimester) suggested a 98% Down syndrome detection rate, but at an unacceptably high 17% false-positive rate (Platt et al., 2004).

If screening tests are to be performed at different gestational ages in the same patient population, it is essential to ensure that earlier marker results are incorporated into the interpretation of later tests. Options that can be used to accurately combine both first and second trimester screening tests include integrated screening, stepwise sequential screening, and contingent screening.

Integrated Screening

This form of risk assessment refers to a two-step screening protocol, with results not being released until all screening steps are completed. Sonographic measurement of nuchal translucency, together with serum assay for PAPP-A, is obtained between 10 and 13 weeks' gestation, followed by a second serum assay for AFP, hCG, uE3, and inhibin-A obtained between 15 and 16 weeks' gestation. A single risk assessment is then calculated at 16 weeks' gestation. This "fully integrated" test has a Down syndrome detection rate of 95%, for a 5% false-positive rate (Wald et al., 2003; Malone et al., 2005). A variant of this approach, referred to as the "serum integrated" test, involves blood tests only, including PAPP-A in the first trimester, followed by AFP, hCG, uE3, and inhibin-A in the second trimester. This latter test, which does not require an NT ultrasound assessment, has a Down syndrome detection rate of 86%, for a 5% false-positive rate (Wald et al., 2003; Malone et al., 2005).

For some patients who are anxious to receive rapid screening results, or for those who might wish to avail of a first trimester CVS, it is possible that such integrated screening tests might not be acceptable, as a delay inevitably exists between the time of first trimester screening measurements and release of results in the second trimester. However, for patients who may not be interested in, or have access to, first trimester CVS, the efficiency of being provided with a single Down syndrome risk assessment result, which maximizes detection and minimizes false-positives, may make such integrated screening tests appear attractive.

Stepwise Screening

In contrast to integrated screening, stepwise screening refers to multiple different Down syndrome screening tests being performed, with risk estimates being provided to patients upon completion of each step. With this approach, patients undergo first trimester risk assessment using nuchal translucency, PAPP-A, and fβhCG, but immediate risk results are only provided to the highest risk patients (e.g., the highest 2.5% risk values). All other patients return at 15 weeks' gestation, at which time the Quad serum markers are obtained, and are combined with nuchal translucency and PAPP-A values to provide a final risk estimate. In the FASTER Trial, such a stepwise sequential screening program detected 95% of Down syndrome cases at a 4.9% false-positive rate (Malone et al., 2005). The benefit of this screening approach is detection and false-positive rates similar to integrated screening. A potential advantage over integrated screening is that it allows patients in the first trimester to avail of an immediate CVS, should their risk estimate justify this test, without having to wait until 16 weeks when the integrated screening results are provided. Patients could possibly get the benefit of early diagnosis associated with first trimester screening, as well as the higher detection rate for Down syndrome associated with integration of both first and second trimester screening tests (Malone, 2005).

Contingent Screening

A further refinement to stepwise sequential screening is the option of contingent screening. With this approach first trimester risk results are divided into three groups. The highest risk group of patients (e.g., risk greater than 1 in 100) is offered CVS immediately and obtains a definitive diagnosis. The lowest risk group (e.g., risk lower than 1 in 1000) is reassured in the first trimester and has no further Down syndrome screening tests performed. The intermediate risk group (e.g., risk between 1 in 100 and 1 in 1000) returns at 15 weeks' gestation, at which time the Quad serum markers are obtained and are combined with earlier markers to give a more precise final Down syndrome risk estimation.

The advantage of this approach, compared with integrated and stepwise screening, is that it may have similar detection and false-positive rates, but with only a small percentage of patients having to undergo further second trimester testing (Wright et al., 2004; Cuckle et al., 2008). In the FASTER Trial, a contingent screening protocol detected 91% of Down syndrome cases at a 4.5% false-positive rate (FPR) using cutoffs of >1 in 30 to define positive screens and 1 in 30 to 1500 to define borderline (Cuckle et al., 2008). At a fixed false-positive rate, contingent screening achieved comparable detection rates as stepwise and integrated screening, but substantially reduced the number of women needing to return for second trimester serum screening (Cuckle et al., 2008).

SECOND TRIMESTER SCREENING IN MULTIPLE GESTATIONS

As with the case for first trimester screening, prenatal risk assessment for Down syndrome in multiple gestation pregnancies is more limited than with singletons. Sonographic evaluation of each individual fetus in the second trimester for major structural malformations or minor markers will allow for the calculation of fetus-specific risks for aneuploidy. There does not appear to be any evidence that the performance of these sonographic markers is any less efficient in twin or higher order multiple gestations, other than the technical challenge in obtaining adequate imaging in such cases.

Interpretation of maternal serum screening, however, can be difficult because of the potential for discordancy between twins and the impact of different placentas on the various analytes. On average, second trimester levels of the commonly utilized biochemical markers are twice as high as in singleton pregnancies (Cuckle, 1998). In dichorionic pregnancies, if one fetus is euploid and another is aneuploid, the opposite direction in which biochemical markers from individual placentas go may be masked by the overall maternal serum levels. Maternal serum markers may be interpretable however using the "pseudorisk" approach. This involves dividing the observed multiple of the median (MoM) values found in each twin pregnancy being evaluated, by the median value found in normal singletons. Minimal data are available from twin pregnancies complicated by Down syndrome to validate this approach. The limited studies performed to date have suggested that second trimester serum screening in twins may have Down syndrome detection rates of 50% to 60% at false-positive rates of 7% to 10% (Spencer et al., 1994; Muller et al., 2001). For this reason, most prenatal diagnosis centers continue to rely on sonographic evaluation to provide aneuploidy risk assessment for multiple gestations in the second trimester.

CHAPTER 4

Prenatal Diagnostic Procedures

Key Points

- Prenatal diagnostic procedures allow prenatal detection of an ever-expanding list of fetal abnormalities by obtaining genetic, biochemical, and physiologic information about the fetus.
- The specific procedure selected depends upon the gestational age and the information needed.
- Genetic consultation should be available to help patients choose which diagnostic procedure is optimal for them.
- Earlier prenatal diagnostic methods have become increasingly more common and are likely to increase in popularity. The most studied of these is CVS. Transcervical and transabdominal techniques are equally effective.
- Early amniocentesis is not recommended now that compelling evidence regarding its disadvantages has been published.
- Advances in molecular techniques have led to a declining number of reasons for using percutaneous umbilical blood sampling. It is now rarely the procedure chosen for determining fetal karyotype.
- Percutaneous umbilical blood sampling is the most direct method of evaluating fetal anemia secondary to severe Rh_o(D) disease.
- The majority of invasive diagnostic procedures are associated with low rates of complications commensurate with provider skill and experience.

AMNIOCENTESIS

Amniocentesis was first used during the 1880s for decompression of polyhydramnios (Lambl, 1881). In 1930, placental localization was achieved after the intra-amniotic injection of contrast medium (Menees et al., 1930). Aburel (1937) described the termination of a pregnancy by the intra-amniotic injection of hypertonic saline. During the 1950s, the role of amniocentesis and measurement of bilirubin concentrations in monitoring rhesus disease was reported (Bevis, 1950; Walker, 1957).

Amniocentesis for fetal chromosome analysis was also initiated in the 1950s. (Until 1956, the number of human chromosomes was not known.) The first reported application was for fetal sex determination (Fuchs and Riis, 1956). The feasibility of culturing and karyotyping amniotic fluid cells was demonstrated by Steele and Breg in 1966. The first prenatal diagnosis of an abnormal karyotype, a balanced translocation, was reported in 1967 by Jacobson and Barter. Trisomy 21 was detected prenatally by Valenti et al., in 1968. During the same year the first diagnosis of the metabolic disorder galactosemia was reported by Nadler (1968).

Indications

Indications for amniocentesis include (1) increased risk for fetal aneuploidy, (2) increased risk for known fetal genetic or

biochemical abnormalities, (3) increased risk for fetal open neural tube defect (ONTD), (4) evaluation for fetal infection, and (5) documentation of fetal lung maturity.

In the United States, while it had been considered standard practice to offer genetic counseling and prenatal cytogenetic analysis to all women of advanced maternal age, (age 35 years or older at their expected date of delivery), these recommendations have changed. Most recent guidelines from the American College of Obstetricians and Gynecologists emphasize that all patients, regardless of age, should have the option for invasive prenatal cytogenetic analysis if they prefer (ACOG, 2007). It is no longer considered acceptable clinical practice to limit or recommend invasive testing of fetal karyotype purely on the basis of maternal age. Amniocentesis is the most common invasive test used for this indication. The risk of numerical chromosomal abnormalities (aneuploidy) increases with advancing maternal age as a result of nondisjunction, which occurs during maternal meiosis. The relationship between maternal age and the estimated risk of chromosomal abnormalities is shown in Table 4-1 (Hook, 1981; Hook et al., 1983). It is now also standard practice to offer invasive prenatal diagnosis to patients with increased risk for aneuploidy according to the results of first and/or second trimester screening for aneuploidy (see Chapters 2 and 3 for more details on the various methods of maternal screening for aneuploidy).

Similar to patients with singletons, invasive prenatal diagnosis should be considered in all patients with multiple fetuses with an increased risk for aneuploidy (Meyers et al., 1997; American Academy of Pediatrics and The American College of Obstetricians and Gynecologists, 2002; The American College of Obstetricians and Gynecologists, 2004).

Invasive prenatal diagnosis is also indicated when there is a need to obtain fetal material for cytogenetic, biochemical, or DNA studies. Increasingly, the DNA abnormalities responsible for the etiology of many disorders are being identified. A list of some of the common genetic conditions for which DNA-based prenatal diagnosis is available is given in Table 4-2, although this list is far from complete. More than 100 abnormalities of lipid, mucopolysaccharide, amino acid, and carbohydrate metabolism are also amenable to prenatal diagnosis through the biochemical analyses of cultured amniotic fluid cells. Note, however, that the substantially larger amount of tissue obtained by chorionic villus sampling (CVS) makes CVS the preferred method of diagnosing single gene biochemical disorders in which the DNA abnormality is known.

Established screening tests for fetal ONTDs include measurement of maternal serum alpha fetoprotein levels (MSAFP) during the second trimester, followed by amniocentesis in patients with elevated results (UK Collaborative Study, 1979), or sonographic screening for brain and spine malformations. The ultrasound diagnosis of fetal ONTD has been greatly enhanced by the recognition of associated abnormalities in the skull and brain. These abnormalities include cerebral ventriculomegaly, microcephaly, frontal bone scalloping (lemon sign), and obliteration of the cisterna magna with either an "absent" cerebellum or abnormal posterior curvature of the cerebellar hemispheres (banana sign) (see Chapter 19) (Nicolaides et al., 1986). Van den Hof et al. (1990) have reported on the diagnosis of ONTD in 130 fetuses among 1561 patients at high risk for fetal neural tube defects who were referred for detailed ultrasound examination. The examinations revealed associated abnormalities of the skull and brain in 129 of the 130 fetuses with ONTD. As a result of this evidence of the accuracy of ultrasound in the diagnosis of neural tube defects, the need for amniocentesis in the evaluation of an elevated MSAFP has been questioned.

Table 4-1

Relation Between Maternal Age and the Estimated Rate of Chromosomal Abnormalities*

Age	Risk of Down Syndrome	Risk of Chromosomal Abnormality

Many centers no longer offer either stand-alone MSAFP screening or amniocentesis for an elevated MSAFP level, given the significant advances in obstetric sonographic precision for this abnormality. At centers adept at diagnosing ONTD sonographically, amniocentesis can be reserved for patients with suspicious ultrasound findings or large MSAFP elevations despite a normal scan or when it is impossible to adequately visualize fetal anatomy. At such specialized centers, patients can be counseled that with a normal ultrasound examination, in which optimal views are obtained of the fetal head and spine, the risk of ONTD can be reduced by up to 95%, and therefore patients may elect not to undergo amniocentesis (American College of Obstetricians and Gynecologists, 1996). Patients who are at increased risk for neural tube defects (i.e., who have elevated MSAFP levels), who have a history of neural tube defects, or who are taking antifolate medications should be referred to centers with ultrasonographers experienced in diagnostic ultrasound. If ultrasound examination

demonstrates a normal spine, cranium, and cerebellum, the chance of an undetected spinal abnormality is low. Therefore, amniocentesis, with a procedure-related risk of 0.1% up to 1%, is probably unnecessary. Some centers have calculated a revised risk of neural tube defects on the basis of the MSAFP value and normal results on ultrasound examination at their particular center (Richards et al., 1988; Nadel et al., 1990). For example, in our reference laboratory in a Caucasian patient with an a priori risk for ONTD of 1 in 1000, an MSAFP of 2.8 multiples of the median (MoM) gives a risk of 1 in 170. When an adequate ultrasound examination is performed by competent ultrasonographers and is interpreted as a normal scan, this risk may be reduced by 95%, giving a reassigned risk of approximately 1 in 3400. In our center, amniocentesis is reserved for cases in which there is incomplete visualization of the fetus (as a result of maternal obesity or fetal position), serum levels of MSAFP greater than 3.5 MoM in the presence of normal sonographic examination, or suspicious ultrasound findings.

Premature delivery is one of the leading causes of perinatal death and long-term handicap. The association between intrauterine infection and premature labor, in the presence and absence of ruptured membranes, has stimulated research into amniocentesis for the diagnosis of subclinical intrauterine infection (Romero et al., 1989; Shim et al., 2004). Amniocentesis in the clinical management of preterm labor or preterm premature rupture of membranes (PPROM) may be utilized for cases in which there is a suspicion of intrauterine infection.

Measurement of the amniotic fluid lecithin: sphingomyelin ratio (Gluck et al., 1974) and phosphatidylglycerol (Hallman et al., 1976) level is useful for the assessment of fetal lung maturity. The need for these tests has declined because of improved neonatal care and the introduction of better methods of ultrasound assessment of gestational age and fetal surveillance. Elective preterm delivery should only be performed for a significant maternal or fetal indication. Nonetheless, amniocentesis in the third trimester is a safe procedure (Hodor et al., 2006).

Assessment of the severity of Rh disease and the need for fetal blood transfusion or early delivery had previously been based on the results of amniocentesis and the interpretation of the results of spectrophotometric estimation of amniotic fluid bilirubin (Liley, 1961). However, Doppler measurements of the middle cerebral artery peak systolic velocity have now replaced amniocentesis for this indication. MCA Dopplers can now be used to noninvasively diagnose anemia in fetuses without hydrops who are at risk for anemia secondary to conditions such as Rh_o(D) sensitization and parvovirus B19 infection (Mari et al., 2000; Cosmi et al., 2002) (Figure 4-1). This noninvasive method of detecting fetal anemia decreases the number of amniocenteses and percutaneous umbilical blood sampling (PUBS) procedures needed in these high-risk patients. The value of the middle cerebral artery peak systolic velocity is expressed as MoM. Middle cerebral artery peak systolic velocity >1.50 MoM is considered to be suggestive of anemia and is considered an indication for PUBS (Table 4-3). In the assessment of severe Rh sensitization in

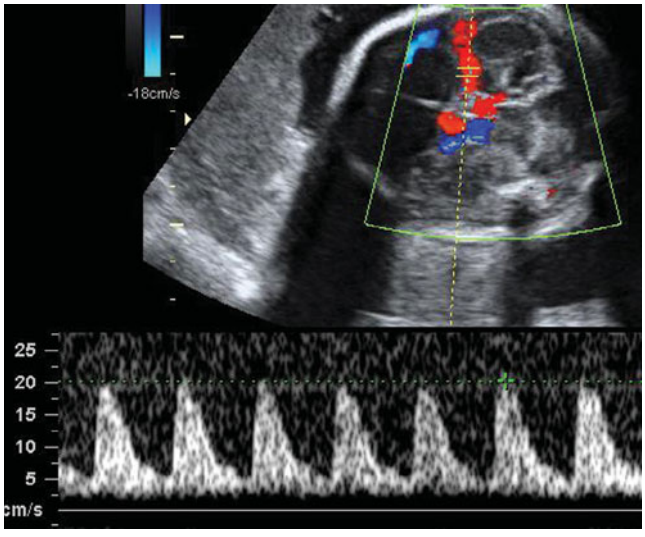

Figure 4-1 Middle cerebral artery peak systolic velocity measured in a case of fetal parvovirus exposure.

Table 4-3

Expected Middle Cerebral Artery Peak Velocity of Systolic Blood Flow by Gestational Age (cm/s)

Gestational Age	1.00 median	1.29	1.50	1.55

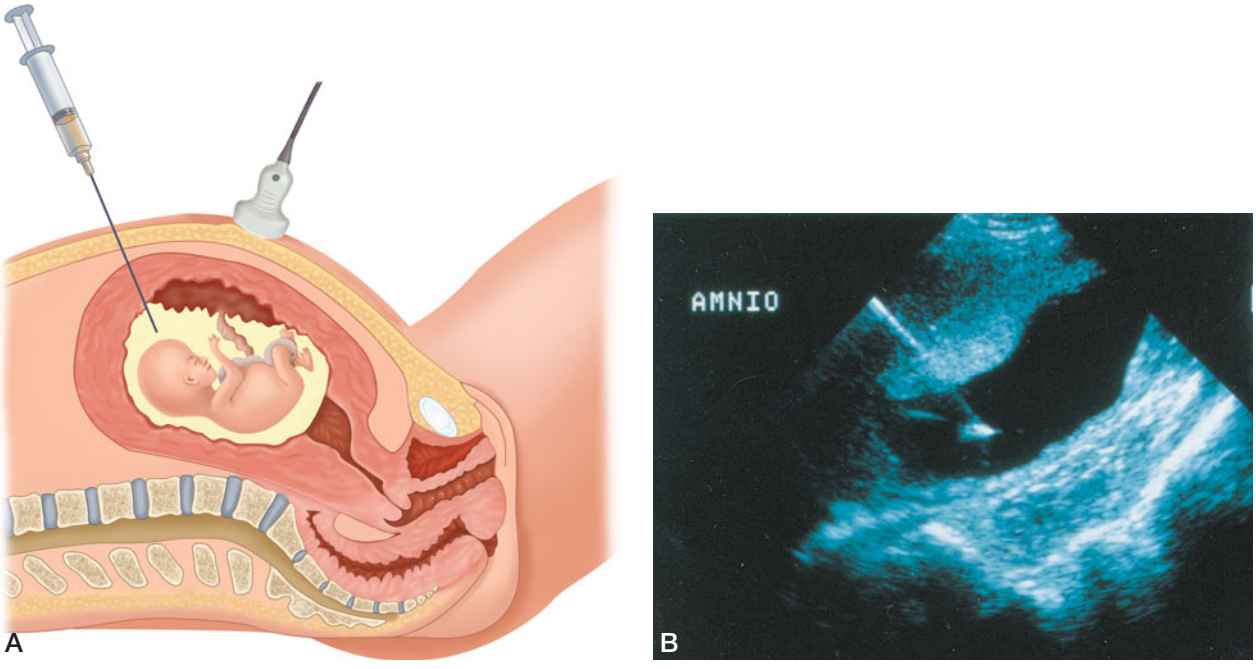

Figure 4-2 **A.** Diagrammatic representation of amniocentesis. **B.** Ultrasound image of amniocentesis.

the midtrimester, the only accurate method for predicting the severity of the disease is measurement of the hemoglobin concentration.

Technique

Early attempts at genetic amniocentesis were made transvaginally. Subsequently, the transabdominal approach has been shown to be the only acceptable approach. During the 1960s amniocentesis was performed "blindly." During the 1970s and early 1980s, ultrasonography was used to identify a placenta-free area for entry into a pocket of amniotic fluid. This position was marked on the maternal abdomen, and after a variable length of time, the operator would blindly insert the needle.

In contemporary practice, amniocentesis is always performed with continuous ultrasound guidance. An ultrasound scan is first performed to determine the number of fetuses present, to confirm gestational age and fetal viability, and to document normal anatomy. The maternal abdomen is washed with antiseptic solution; it is unnecessary for the technician to scrub and gown. Continuously guided by ultrasound, a 22-gauge needle is introduced into the amniotic cavity (Figures 4-2A and 4-2B). While the procedure may be performed either freehand or with needle guides, the vast majority of centers currently use a freehand technique (Jeanty et al., 1983; Lenke et al., 1985). The freehand technique is generally preferred because it allows easier manipulation of the needle if the position of the target is abruptly altered by a uterine contraction or fetal movement. Furthermore, this technique can be easily adapted to all ultrasound-guided diagnostic or therapeutic procedures, such as PUBS. Fetal heart rate and activity is documented immediately following the procedure.

Technique in Twins

Amniocentesis is a safe and accurate procedure for sampling twin pregnancies between 15 and 20 weeks' gestation. Amniocentesis in multiples was first described by Elias et al. in 1980 (Elias et al., 1980). Under ultrasound guidance, a spinal needle is introduced into one sac. After aspirating fluid, a blue dye (indigo carmine) is injected into that sac to serve as a marker before removing the initial needle. A second needle is then inserted into the other sac and the aspiration of clear fluid indicates that the second sac had been successfully entered (Figure 4-3). This technique is recommended when sampling either dichorionic or monochorionic twin pregnancies (but is not necessary in monoamniotic gestations). Likewise, the procedure can be used in triplets and higher order multiples. It is essential to map and document the location of each fetus and placenta at the time of amniocentesis. If discordant results are obtained and the patient desires selective termination, the appropriate fetus can then be targeted.

While use of a marker dye is extremely helpful in performing amniocentesis on patients with multiples, the instillation of some material has been associated with toxicity. For example, methylene blue has been linked to fetal hemolysis, multiple ileal obstructions, and jejunal atresia when injected into the amniotic fluid (Cowett et al., 1976; Nicolini and Monni 1990; Van der Pol et al., 1992). Indigo carmine has been evaluated and has not been shown to be associated with abnormal fetal outcomes (Cragan et al., 1993).

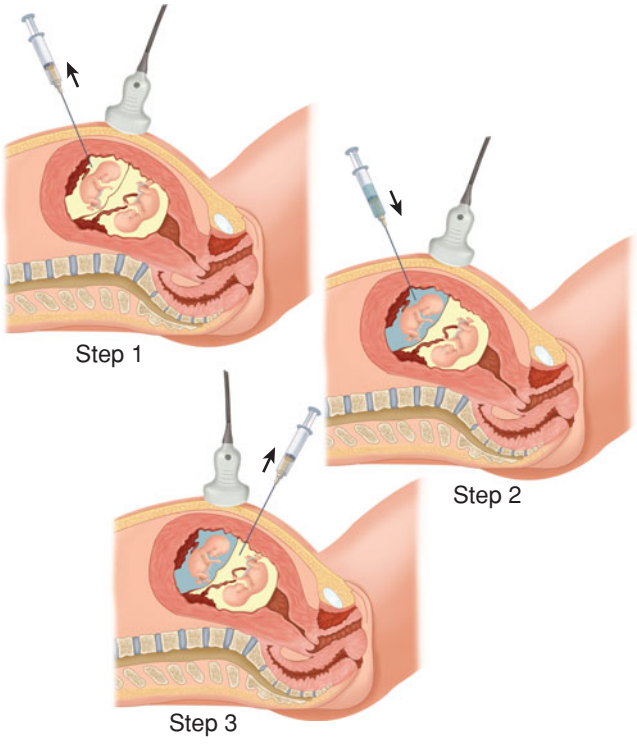

Figure 4-3 Diagrammatic representation of one method of performing amniocentesis in twins. In Step 1, the fluid is aspirated from the first amniotic sac. In Step 2, indigo carmine is injected into the first sac. In Step 3, clear fluid is aspirated from the second sac.

Alternative techniques have been described that do not use dye instillation to be sure that both sacs have been successfully sampled (Jeanty et al., 1990; Sebire et al., 1996). Sebire et al. described a technique utilizing single entry in 176 twin pregnancies (Sebire et al., 1996). After amniotic fluid is aspirated from the sac of one twin, the syringe is removed, the stylet replaced, and the needle is then advanced through the intertwin membrane into the sac of the second twin under continuous ultrasound guidance. When aspirating fluid from the second sac, the authors recommend discarding the first 1 mL in order to avoid possible contamination from amniotic fluid of the first sac. While this method is feasible, we continue to recommend the technique described earlier, using a separate needle insertion for each sac along with instillation of indigo carmine into the first in order to eliminate any chance of contaminating the samples.

Laboratory Considerations

Failure to culture amniocytes occurs in less than 1% of cases. Chromosomal mosaicism occurs in approximately 0.5% of cases. Chromosomal mosaicism is the presence of two or more cell lines with different karyotypes in a single person. This occurs as a result of postzygotic nondisjunction. The observation of multiple cell lines in a prenatal sample does not necessarily mean that the fetus has mosaicism. The most common type of mosaicism detected by amniocentesis is pseudomosaicism (Hsu and Perlis, 1984). This phenomenon should be suspected when an abnormality is evident in only one of several cultures of an amniotic fluid specimen. The abnormal cell lines arise during in vitro division; therefore, they are not present in the fetus and are not clinically important. Contamination by maternal cells can be minimized by discarding the first few drops of aspirated amniotic fluid. True fetal mosaicism, diagnosed when the same abnormality is present on more than one cover slip, is rare (0.25%) but clinically important (Hsu and Perlis, 1984). The question of whether true mosaicism is present is best resolved by karyotyping fetal lymphocytes obtained by PUBS (Gosden et al., 1988). PUBS can provide results within 48 hours. Detailed ultrasound examination is also recommended to assess fetal growth and exclude the diagnosis of structural anomalies. If both ultrasound and fetal blood sampling results are normal, the parents can be reassured that the major chromosomal abnormalities have been excluded (Gosden et al., 1988).

Complications

Serious maternal complications, such as maternal hemorrhage and sepsis, are virtually unheard of with amniocentesis in contemporary practice. Amnionitis occurs in 0.1% of cases (Turnbull and Mackenzie, 1983). The development of rhesus isoimmunization (Golbus et al., 1979; Hill et al., 1980) can be avoided by prophylactic administration of anti-D immunoglobulin to Rh_o(D)-negative women who are about to undergo amniocentesis. Amniotic fluid leak or vaginal blood loss, noted after amniocentesis by 2% to 3% of patients, is usually self-limiting, although occasionally leakage of amniotic fluid persists throughout pregnancy (NICHD Amniocentesis Registry, 1976; Simpson et al., 1981). Other common postprocedure symptoms include abdominal/pelvic cramping for 1 to 2 hours and lower abdominal discomfort for up to 48 hours after the procedure.

The safety and accuracy of midtrimester amniocentesis was documented in the mid-1970s by three collaborative studies performed in the United Kingdom, United States, and Canada (NICHD Amniocentesis Registry, 1976; Medical Research Council, 1977; Working Party on Amniocentesis, 1978). However, the only prospective, randomized, controlled trial is a study by Tabor et al. (1986), who reported on 4606 low-risk, healthy women. Patients, aged 25 to 34 years old, were randomly allocated to a group that would have amniocentesis or to one that would have ultrasound examination. The total rate of fetal loss in the patients who underwent amniocentesis was 1.7% and in the control patients 0.7% ($P < 0.01$). The conclusions of this study were initially criticized because an 18-gauge needle (which is associated with higher risks than smaller needles) was documented as having been used. Tabor et al. (1988) subsequently reported that they had been mistaken in citing the use of an 18-gauge needle and had, in fact, used a 20-gauge needle for most of the procedures. The Danish study also demonstrated that there were significant associations between pregnancy loss and puncture of the placenta, high MSAFP levels, and discolored amniotic fluid (Tabor et al., 1986).

Both the UK and Danish studies (Working Party on Amniocentesis, 1978; Tabor et al., 1986) found an increase in respiratory distress syndrome and pneumonia in neonates from the amniocentesis groups. Other studies have not found this association. The UK study showed an increased incidence of talipes and dislocation of the hip in the amniocentesis group (Working Party on Amniocentesis, 1978).

Much debate has centered on the current loss rates for amniocentesis, as anecdotal reports suggested that a 1% procedure-related loss rate appeared higher than what was seen in clinical practice. It was felt by many that the loss rate of 1% reflected clinical practice in the 1980s when ultrasound equipment and skill was significantly less advanced than contemporary practice, and when needle sizes were also different from contemporary practice. However, another randomized trial of amniocentesis will never occur due to ethical concerns. The only other option to provide contemporary data on amniocentesis safety is from large-scale prospective observational trials from the general population, and in which detailed pregnancy outcome data are available. The FASTER Trial (see Chapter 2) provided an ideal opportunity to obtain such updated safety data on amniocentesis (Malone et al., 2005). This study demonstrated a much lower procedure-related loss rate of 1 in 1600 (0.06%) (Eddleman et al., 2006). While the publication of this study has provoked much debate about the true procedure-related loss rate from amniocentesis, it is now commonly accepted that the loss rate is somewhere between the initial 1% quoted by Tabor (Tabor et al., 1986) and 0.06%, perhaps closer to 1 in 1000. The most recent ACOG statement on this topic describes the loss rate as being "less than 1 in 300–500" (ACOG, 2007).

Needle puncture of the fetus, reported in 0.1% to 3.0% of cases (NICHD Amniocentesis Registry, 1976; Karp and Hayden, 1977), has been suggested as the cause of exsanguination (Young et al., 1977), intestinal atresia (Swift et al., 1979; Therkelsen and Rehder, 1981), ileocutaneous fistula (Rickwood, 1977), gangrene of a fetal limb (Lamb, 1975), uniocular blindness (Merin and Beyth, 1980), porencephalic cysts (Youroukos et al., 1980), patellar-tendon disruption (Epley et al., 1979), skin dimples (Broome et al., 1976), and peripheral-nerve damage (Karp and Hayden, 1977). Continuous use of ultrasound to guide the needle minimizes needle puncture of the fetus. Finegan et al. (1990) have reported an increased incidence of middle ear abnormalities in children whose mothers underwent amniocentesis.

Complications in Multiple Gestation

Early studies suggested a higher fetal loss rate in twin pregnancies than in those with singletons (Pijpers et al., 1988; Anderson et al., 1991). These studies, however, did not address whether the fetal wastage following amniocentesis is attributable to the procedure or to the twin gestation itself. Patients with multiples are at increased risk for fetal loss. In a case–controlled study, Ghidini et al. (1993) reported similar loss rates between sampled twins and unsampled matched twin controls (3% vs. 2.8%). They concluded that second trimester amniocentesis in twins was not associated with excess pregnancy loss and that the likelihood of fetal wastage secondary to this procedure is probably the same as that in singletons. More recent studies, however, have contradicted this finding. In a retrospective study of 476 twins who underwent amniocentesis and 477 who did not, Yukobowich et al. (2001) found statistically different loss rates 4 weeks after the procedure, 2.7% versus 0.6%. Toth-Pal et al. (2004) compared pregnancy loss in 175 twin pregnancies that underwent amniocentesis to 300 controls. The loss rate between 18 and 24 weeks' gestation was 3.87% in the amniocentesis group versus 2.39% in the control group. Although these results were not statistically significant, the authors concluded that genetic amniocentesis slightly increases the loss rate in women carrying twins.

Early Amniocentesis

As the technique of midtrimester amniocentesis gained rapid acceptance, interest developed in the use of the same diagnostic technique at earlier gestational ages. The term "early amniocentesis" was used to describe the performance of amniocentesis at less than 14 weeks' gestation. An assumption was made that since amniocentesis was shown to be a safe and effective procedure in the second trimester of pregnancy, it would be equally safe and effective during the first trimester. However, with the completion of the CEMAT study (Canadian Early and Midtrimester Amniocentesis Trial) in 1998, it has become clear that EA from 11 weeks to 12 weeks 6 days is associated with significant disadvantages (CEMAT Group, 1998).

In the CEMAT study, 4374 patients were randomized to either EA (defined as amniocentesis from 11 weeks to 12 weeks 6 days) or midtrimester amniocentesis (defined as amniocentesis from 15 weeks to 16 weeks 6 days). It was found that EA was significantly more likely to be a technically difficult or unsuccessful procedure when compared with midtrimester amniocentesis (1.6% vs. 0.4%), and it was twice as likely that EA would require more than one needle insertion (Johnson et al., 1999). In addition, it was found that EA was significantly more likely to result in karyotype culture failure (2.4%) when compared with midtrimester amniocentesis (0.25%) (Winsor et al., 1999).

The CEMAT investigators also demonstrated significant safety concerns with the EA technique. There was a significantly higher rate of total pregnancy loss in the EA group (7.6%) versus the midtrimester group (5.9%) (CEMAT Group, 1998). Also of concern was a significantly higher rate of clubfoot in the EA group (1.3%) versus the midtrimester group (0.1%). EA was also associated with a significantly higher chance of postprocedural amniotic fluid leakage (3.5%) when compared with midtrimester amniocentesis (1.7%). The CEMAT study effectively ended the controversy on the role of EA, and suggested that this technique should generally be avoided before the 13th week of gestation. The safety of amniocentesis between 13 and 14 weeks is unknown.

Consequently, it is best to delay amniocentesis until 15 weeks' gestation.

Summary

Indications for amniocentesis have changed considerably in recent years and are likely to evolve even further. The most common indication for amniocentesis is to obtain a fetal karyotype in pregnant women with an increased risk for fetal aneuploidy. The use of amniocentesis in the investigation of elevated MSAFP is declining. The use of amniocentesis to test for fetal lung maturity has decreased because ultrasound dating of pregnancy is now obtained in many cases, and premature deliveries are performed only if there are maternal or fetal indications. For the assessment of fetal anemia in severe red-cell isoimmunized pregnancies in the second trimester, amniocentesis has been replaced by Doppler ultrasound of the middle cerebral artery. Contemporary loss rates secondary to amniocentesis are quite low, likely approaching 1 in 1000.

CHORIONIC VILLUS SAMPLING

With conventional amniocentesis, karyotype results may be received as late as the middle second trimester. This is a drawback because of the medical risks of performing pregnancy termination using dilation-and-evacuation procedures late in the pregnancy. In addition, delaying such procedures until after fetal movement is perceived may be emotionally difficult for the patient. Using chorionic villi as a source for fetal karyotyping during the 10th week of pregnancy was introduced experimentally by Hahnemann and Mohr in 1969, and the use of an endoscopic transvaginal approach (Figure 4-4) was evaluated by Hahnemann in 1974. Clinical use of chorionic villi for fetal sex determination was described in 1975 by a group from China. They performed blind transvaginal aspiration without ultrasound examination (Tietung Hospital, 1975). Once an ultrasound-guided technique for aspiration was introduced, CVS became accepted for more widespread use.

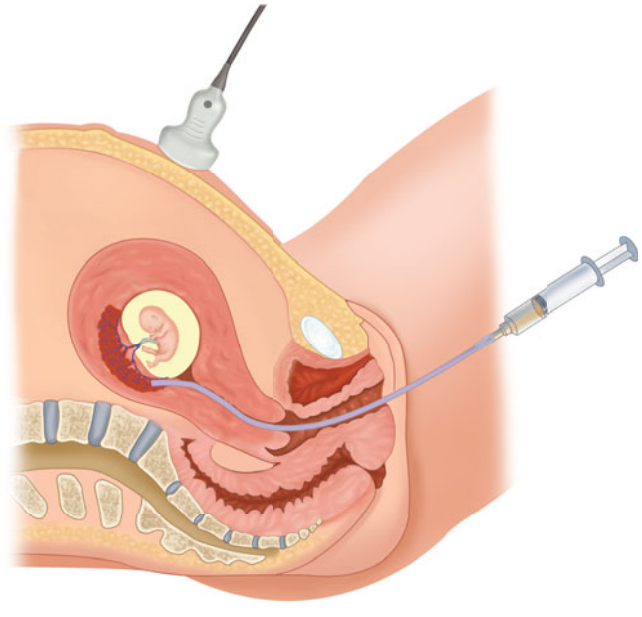

Figure 4-4 Diagrammatic representation of transcervical chorionic villus sampling.

Figure 4-5 Ultrasound image of transcervical chorionic villus sampling demonstrating the catheter in a posterior placenta.

Transcervical CVS

Ultrasound examination immediately before the procedure confirms fetal heart activity, appropriate growth, and location of the placenta (Figures 4-4 and 4-5). The position of the uterus and cervix is determined, and the anticipated catheter path is mentally mapped. If the uterus is severely anteverted, filling of the bladder frequently straightens its position. If a uterine contraction occurs it could interfere with passage of the catheter, and a decision may be made to delay the procedure until the contraction dissipates. When the uterine condition and location are favorable, the patient is placed in the lithotomy position; and the vulva, vagina, and cervix are aseptically prepared. A speculum is inserted, and the anterior lip of the cervix may be grasped with a tenaculum to aid in manipulating the uterus. The distal 3 to 5 cm of the catheter is molded into a slightly curved shape and then gently passed through the cervix until a loss of resistance is felt at the endocervix. The operator then waits until the ultrasonographer visualizes the tip of the catheter.

The catheter is inserted parallel to the placenta and passed almost to its distal end (Figures 4-4 and 4-5). The stylet is then removed and a 20-mL heparinized syringe containing nutrient medium is attached. The syringe is used to apply negative pressure. The catheter and attached syringe are then pulled back slowly, and the syringe is visually inspected for villi, which are easily seen with the naked eye as white branching structures. Once an adequate sample is obtained, the patient is discharged. The patient is instructed to inform her physician if she develops heavy bleeding, fever, or

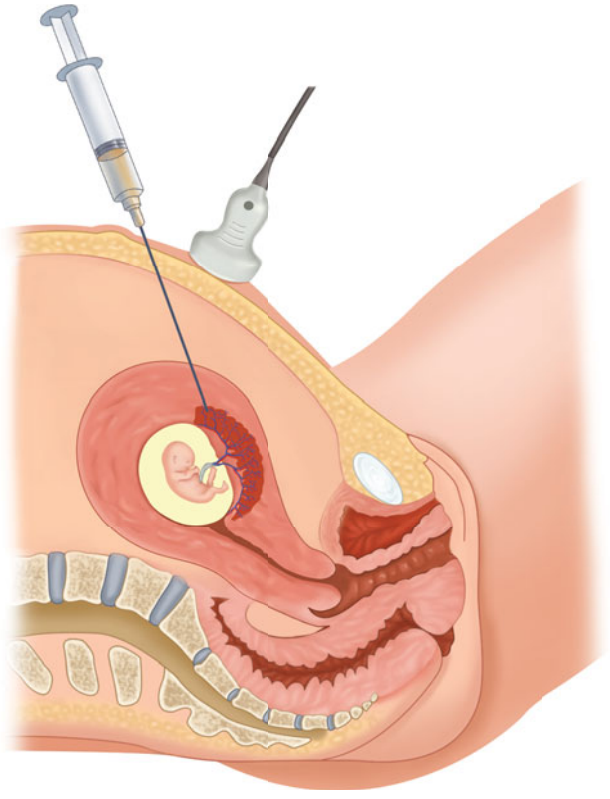

Figure 4-6 Diagrammatic representation of transabdominal chorionic villus sampling.

unusual vaginal discharge. A follow-up scan and MSAFP assay are performed at 16 weeks of gestation.

Alternative approaches to transcervical CVS include use of a reusable biopsy forceps, rather than a disposable plastic catheter. There are no comparative data available guiding which transcervical instrument is optimal.

Transabdominal CVS

Continuous ultrasound imaging is used to direct a 19- or 20-gauge spinal needle into the long axis of the placenta (Figures 4-6 and 4-7). After removal of the stylet, villi are aspirated into a 20-mL syringe containing tissue culture medium. It may be a reasonable alternative to amniocentesis or PUBS if karyotype evaluation is needed later in pregnancy when special circumstances may exist, such as severe oligohydramnios.

Multiple Gestation

CVS is considered a safe alternative to amniocentesis in multiple gestations (Brambati et al., 1991b; Pergament et al., 1992; Wapner et al., 1993). Chorionic villi for chromosome or DNA analysis can be obtained either by transcervical catheter or by transabdominal needle approaches under ultrasound guidance. The advantage of CVS over amniocentesis is the earlier availability of results and, if discordant results are obtained, selective termination can be performed early in gestation when it is associated with a lower risk of adverse outcomes. First trimester diagnosis by CVS is particularly important for women with multiple gestations who may be considering multifetal pregnancy reduction. These patients can verify that specific fetuses are euploid prior to multifetal pregnancy reduction. Similar to amniocentesis, the location of each fetus and placenta should be carefully mapped and documented at the time that CVS is performed (Appelman and Furman, 2005).

CVS in multiple gestation can be technically challenging. Both the physician and sonographer should be adequately experienced to ensure proper placement of the sampling instrument because there are no markers to confirm that each sample has been obtained from a distinct placenta. Early studies suggested that contamination from one placenta to another occurs in up to 4% of cases (Pergament et al., 1992; Wapner et al., 1994). However, more recent studies have suggested that cross-contamination between placentas is far less frequent (DeCatte et al., 2000; Brambati et al., 2001). De Catte et al. (2000) described 262 twin pregnancies that underwent CVS with 99% of the placentas being sampled adequately (DeCatte et al., 2000). In two pregnancies, the same placenta was sampled twice, and in three others there was cross-contamination between placentas. Brambati et al. (2001) described 198 sets of twins and 9 sets of triplets undergoing CVS. Sampling was successfully performed in all cases, and no evidence of incorrect sampling was reported. Methods to decrease contamination errors include collecting samples near the cord insertion site when placentas are adjacent, avoiding the dividing membrane, and using both the transabdominal and transcervical approach in certain clinical situations.

CVS appears to be an accurate diagnostic procedure in multiple gestation. The diagnostic precision of CVS and amniocentesis in twins and triplets was reviewed by van den Berg et al. (1999). Two hundred and ninety-eight women with twins underwent second trimester amniocentesis, and 163

others were sampled by CVS. Four women with triplets underwent CVS and 11 had amniocentesis. Amongst the twins, uncertain results in one or both samples requiring additional sampling was more frequent in the CVS group compared to the amniocentesis group (8/163 (5%) vs. 1/298 (0.3%)). Erroneous sampling (sampling the same placenta twice) was only seen once in the CVS group and cross-contamination was present in two of seven pregnancies that underwent CVS and DNA analysis. Uncertain results were present in eight pregnancies undergoing CVS, five of which were secondary to confined placental mosaicism. No diagnostic errors occurred in the CVS group. In the amniocentesis group, the one uncertain result was likely due to a sampling error. In the triplet group, one patient who underwent amniocentesis and one who underwent CVS needed an additional amniocentesis procedure because of abnormal results. Although CVS is associated with a higher risk of uncertain results and cross-contamination in patients with multiples, the authors concluded that clinical diagnostic uncertainties are minimal.

Laboratory Aspects

The average sample from a transcervical aspiration contains 15 to 30 mg of villous material. The villi identified in the syringe are carefully and aseptically transferred for inspection and dissection under a microscope. Visually confirming that the appropriate tissue has been aspirated is mandatory to minimize maternal decidual contamination. Clean, decidua-free villi are then transferred to petri dishes for further preparation. Villi are processed for cytogenetic analysis in two ways: Results of direct preparation are available within 3 to 4 days of the procedure; results of tissue culture are usually available within 6 to 8 days. Most laboratories wait to report both results at the same time.

It is recommended that both the direct and culture methods be used with all samples. The direct method gives rapid results on the cytotrophoblast and minimizes maternal decidual contamination. Tissue culture, which is subject to potential contamination from maternal cells, is a better means of identifying and evaluating discrepancies that may exist between the cytotrophoblast and the fetal state (Bianchi et al., 1993).

Most biochemical diagnoses that can be made from amniotic fluid or cultured amniocytes can also be made from chorionic villi (Poenaru, 1987). In many cases, the results are available more rapidly and efficiently when villi are used because enzymes are present in sufficient quantity to allow direct analysis rather than requiring the products of tissue culture.

Pregnancy Loss Following CVS

The advantage of earlier diagnosis must be weighed against any increased risk of fetal loss associated with CVS. For statistical purposes, procedure-related spontaneous loss has generally been defined as spontaneous miscarriage or diagnosed intrauterine fetal death occurring up until 28 completed weeks of gestation. Calculating such procedure-related losses is complicated by background pregnancy loss rates, since 2% to 5% of pregnancies viable at 7 to 12 weeks of gestation are either nonviable when rescanned at 8 to 20 weeks or will undergo spontaneous miscarriage before 28 weeks of gestation (Wilson et al., 1984; Gilmore and McNay, 1985; Liu et al., 1987). The background rate of spontaneous loss increases with maternal age and is therefore highest in the same age range in which women are likely to present for prenatal diagnosis (Wilson et al., 1984; Gilmore and McNay, 1985).

Data evaluating the safety of CVS come primarily from three collaborative reports (Table 4-4). In 1989, the Canadian Collaborative CVS/Amniocentesis Clinical Trial Group reported its experience with a prospective randomized trial comparing the safety of CVS to that of amniocentesis. During the study period, patients across Canada were able to undergo CVS only as part of this randomized protocol. The results from the Canadian group confirmed the safety of CVS as a first trimester diagnostic procedure. There was a 7.6% rate of fetal loss (spontaneous loss, induced abortions, and late losses) in the CVS group, and a 7.0% rate of loss in the amniocentesis group. This excess rate of loss of 0.6% for CVS over amniocentesis was not statistically significant. Surprisingly, there was a tendency toward later losses (28 weeks) in the CVS group. No significant differences were noted between the two groups in the incidence of preterm birth or low birth weight. Maternal complications were equally uncommon in each group.

The U.S. report involved a prospective, though nonrandomized, trial of 2235 women who chose either transcervical CVS or second trimester amniocentesis (Rhoads et al., 1989). An excess rate of loss of 0.8% in the CVS group over the amniocentesis group was calculated, which was not statistically significant. The rates of loss were lowest in those cases in which relatively large amounts of tissue were obtained. Repeated catheter insertions were significantly associated with pregnancy loss. Cases requiring three or more catheter insertions had a 10.8% rate of pregnancy loss, as compared with a rate of 2.9% in cases that required only one pass.

A prospective, randomized, collaborative comparison of more than 3200 pregnancies, sponsored by the European Medical Research Council, demonstrated that CVS was associated with a 4.6% greater rate of pregnancy loss than amniocentesis (95% confidence interval, 1.6% to 7.5%) (MRC Working Party, 1991). This difference reflected more spontaneous deaths before 28 weeks of gestation (2.9%), more terminations of pregnancy for chromosomal anomalies (1.0%), and more neonatal deaths (0.3%). In this study, CVS was performed by both the transcervical and transabdominal routes. The number of repeat procedures was significantly higher in the CVS group as compared with the amniocentesis group.

Exactly what factors contribute to the discrepant results between the European and North American studies remains uncertain. Variability in operator experience might account for part of this discrepancy. The U.S. trial included 7 centers and the Canadian trial 11, whereas the Medical Research

Council Trial involved 31 participating centers contributing various numbers of cases and using different sampling and cytogenetic procedures. There were, on average, 325 cases per center in the U.S. study, 106 in the Canadian study, and only 52 in the European trial. The pregnancy losses in the European series tended to occur before 20 weeks of gestation, as compared with the Canadian study, in which losses occurred significantly later. There is no apparent explanation for these findings, although some feel that the larger number of centers and operators in the European trial reflect fewer per-operator procedures and the therefore less experienced technique.

Transcervical Versus Transabdominal Approach to CVS

Brambati et al. (1991a) reported the results of a randomized trial of transabdominal versus transcervical CVS by a single operator in 1194 patients. More than 110 cases deviated from the allocated procedure, and more than 80% of the deviations occurred in the transcervical arm of the trial. Moreover, the proportion of cases in which the operator chose to deviate from the allocated procedure increased in each of the 3 years of the study (4.6%, 9.7%, and 15.5%, respectively). More chorionic tissue was obtained by the transcervical method, but the proportion of cases in which less than 10 mg was obtained was similar in both groups. Bleeding was more common following transcervical CVS, whereas cramping was more common with the transabdominal approach. No significant difference was detected in the overall rate of fetal loss (transabdominal approach, 16.5%; transcervical, 15.5%). The transabdominal technique required a significantly smaller proportion of repeat needle insertions (3.3% vs. 0.3%), although this did not seem to affect pregnancy outcome. There were also no differences in birth weight, gestational age at delivery, or congenital malformations. The authors commented that a limitation of this study was the operator's eventual preference for the transabdominal approach. They conclude that the two techniques seem equally safe and effective, and the choice to perform one particular technique may depend largely on the operator's preference.

Jackson et al. (1992) conducted a randomized comparison of transcervical and transabdominal CVS at 7 to 12 weeks of gestation. Of 3999 eligible patients, 94% in each arm of the study underwent the allocated procedure. Only one needle insertion was required in 94% of transabdominal CVS cases, and one catheter pass was required in 90% of transcervical CVS procedures. The rate of fetal loss, excluding elective terminations of pregnancy, was 3% in each group.

Smidt-Jensen et al. (1992) published their randomized comparison of routine amniocentesis, transabdominal CVS, and transcervical CVS in 3706 low-risk patients. Patients were randomly assigned to one of the three procedures. The proportion of patients for whom a cytogenetic diagnosis was successfully obtained at the first attempt was 99.7% for amniocentesis, 98.1% for transabdominal CVS, and 96.0% for transcervical CVS ($P < 0.0001$). Total rates of fetal loss were 10.9% for transcervical CVS, 6.3% for transabdominal CVS, and 6.4% for amniocentesis, a statistically significant difference. A large difference was noted between the transabdominal and transcervical CVS groups in the proportion of postprocedural losses of cytogenically normal pregnancies (3.7% for transabdominal and 7.7% for transcervical CVS). The authors concluded that although transabdominal CVS and amniocentesis carry similar risks of fetal loss, transcervical CVS is associated with an overall higher rate of fetal loss, estimated to be in excess of 4.0%.

It is reasonable to speculate that the rate of fetal loss will equilibrate in most centers once equivalent expertise is gained with either approach (Brambati et al., 1987b). Integration of both transcervical and transabdominal methods of CVS into any program offers the most practical and safe approach to first trimester diagnosis.

Other Complications with CVS

Vaginal bleeding or spotting is relatively uncommon after transabdominal CVS procedures, occurring in 1% or less of cases (Rhoads et al., 1989). Most centers report postprocedure bleeding in 7% to 10% of patients sampled by transcervical CVS (Rhoads et al., 1989). Minimal spotting is more common than bleeding and may occur in almost one-third of women sampled by the transcervical route (Rhoads et al., 1989). A subchorionic hematoma may be visualized immediately after sampling in up to 4% of patients sampled transcervically (Brambati et al., 1987b). The hematoma usually disappears before the 16th week of pregnancy and is usually not associated with an adverse outcome.

Since the initial development of transcervical CVS there has been concern that transvaginal passage of an instrument would introduce vaginal flora into the uterus, thereby increasing the risk of infection. Cultures have isolated bacteria in 30% of catheters used for CVS (Brambati and Varotto, 1985; Garden et al., 1985; McFadyen et al., 1985; Wass and Bennett, 1985; Brambati et al., 1987a). The reported incidence of post-CVS chorioamnionitis, however, is low; it occurs following both transcervical and transabdominal procedures. In the U.S. collaborative trial, infection was suspected as a possible cause of pregnancy loss in only 0.3% of cases (Rhoads et al., 1989). It has been demonstrated that, at least in some cases, infection that occurs after transabdominal CVS is a result of bowel flora introduced by inadvertent puncture by the sampling needle. Early in the development of transcervical CVS, two life-threatening pelvic infections were reported (Blakemore et al., 1985; Barela et al., 1986). A practice of using a new sterile catheter for each insertion has subsequently been universally adopted, and there have been no additional reports of serious infections resulting from the procedure.

Acute rupture of membranes within hours of the procedure can occur but is rare (Rhoads et al., 1989); in 0.3% of cases, rupture has been reported days to weeks after the procedure (Hogge et al., 1986). An acute rise in MSAFP levels after CVS has been consistently reported, implying a detectable degree of fetomaternal bleeding (Blakemore et al., 1986; Brambati et al., 1986; Shulman et al., 1990). The elevation in MSAFP levels is not related to the technique used to retrieve villi but seems to depend on the quantity of tissue aspirated (Shulman et al., 1990). Levels will return to normal ranges by 16 to 18 weeks of gestation, thus allowing serum screening to proceed according to usual prenatal protocols. All Rh-negative, nonsensitized women who are undergoing CVS should receive Rh_o(D) immune globulin after the procedure. Exacerbation of Rh immunization following CVS has been described. Existing Rh sensitization therefore represents a contraindication to the procedure (Moise and Carpenter, 1990).

Risk of Fetal Limb Abnormality Following CVS

Concern has been raised that CVS might cause severe limb deficiencies. This was first reported by Firth et al. (1991). Their series of 289 CVS pregnancies identified five infants with severe limb abnormalities. Oromandibular limb hypogenesis syndrome was present in four of the five, and the fifth had a terminal transverse limb-reduction defect. The oromandibular limb hypogenesis syndrome occurs in 1 of 175,000 livebirths (Hoyme et al., 1982); therefore, the occurrence of this abnormality in more than 1% of pregnancies in which CVS was performed strongly suggested an association. In Firth's initial report, all of the limb abnormalities followed transabdominal sampling performed: between 55 and 66 days of gestation. Burton et al. (1992) also reported transverse limb abnormalities after CVS. Apart from these two reports, most other series have found the incidence of limb-reduction defects to be not significantly different from the expected rates. Using records of the experience of the eight centers participating in the U.S. collaborative evaluation of CVS, Mahoney (1991) reported no cases of oromandibular limb hypogenesis syndrome and no increased incidence of transverse limb defects. Monni et al. (1991) reviewed their experience of CVS procedures performed before the 66th day of gestation and reported no severe limb defects in the selected population. Two mild finger abnormalities were seen in their series. Defects have also been observed when CVS is performed after 66 days. Reports of limb abnormalities after CVS procedures and population-based studies are summarized in Table 4-5 (see also, Froster-Iskenius and Baird, 1989; Froster and Baird, 1992).

A variety of mechanisms by which CVS could potentially lead to fetal malformations has been proposed. The occurrence of placental thrombosis with subsequent fetal embolization has been raised as a potential cause. Inadvertent entry into the extraembryonic coelom, resulting in amniotic bands, has also been suggested. This seems unlikely because actual bands have not been observed in any cases. The most plausible proposed mechanism is a form of vascular insult leading to underperfusion of the fetus (Brent, 1990). CVS could cause disruption of the vessels supplying the extracorporeal fetal circulation. This disruption would result in the release of vasoactive peptides, producing fetal vasospasm and hypoperfusion of the fetal peripheral circulation. Limb defects have been demonstrated in animal models after exposure to cocaine (Brent, 1990; Webster and Brown-Woodman, 1990). Theoretically, an overly vigorous technique during the CVS procedure could lead to significant placental damage, with resulting vasospasm and hypovolemia.

Using transcervical embryoscopic visualization of the first trimester embryo, Quintero et al. (1992) demonstrated the occurrence of fetal facial, head, and thoracic ecchymotic lesions following a traumatic CVS. Although these lesions consistently appeared following significant physical trauma to the placental site, the researchers were not able to produce them by the passage of a standard CVS catheter. Furthermore, these lesions were demonstrated only after the development of a subchorionic hematoma.

The most current data suggest that performance of CVS in the usual gestational age time period of 10 to 13 weeks is not associated with an increased risk of limb defects but that

performance of the procedure prior to this time may be associated with a risk of severe limb defects as high as 1% to 2% (Jenkins and Wapner, 1999). The frequency of oromandibular-limb hypogenesis syndrome seems to be more common among infants from pregnancies that underwent CVS earlier than 7 weeks of gestation (ACOG, 2007).

Accuracy of CVS Cytogenetic Results

The overall incidence of chromosomal mosaicism in CVS specimens is estimated to be approximately 1% (Vejerslev and Mikkelsen, 1989). Generalized chromosomal mosaicism originates from a mutational event in the first or second postzygotic division, and all tissues of the fetus are affected

(Kalousek and Dill, 1983). Confined placental mosaicism (CPM), defined as a dichotomy between the chromosomal constitution of placental and fetal tissues, results from nondisjunction that occurs in the trophoblast or extraembryonic mesoderm progenitor cells (Kalousek et al., 1991). In most cases of mosaicism diagnosed by CVS, the cytogenetic abnormality is confined to extraembryonic tissue (Vejerslev and Mikkelsen, 1989; Johnson et al., 1990; Breed et al., 1991).

Several studies have reported a higher incidence of adverse perinatal outcomes, including increased rates of fetal loss and intrauterine growth restriction (IUGR) in pregnancies complicated by CPM (Johnson et al., 1990; Kalousek et al., 1991; Wilkins-Haug et al., 2006). Kalousek et al. (1991) confirmed CPM in only half of placentas studied after birth. IUGR was found only in cases of CPM mosaicism confirmed in term placentas. Wapner et al. (1992) found a significantly higher rate of fetal loss (8.6%) among the 2.5% of patients with CPM, in comparison with patients with a normal karyotype (3.4%). Patients with pseudomosaicism had a rate of pregnancy loss and perinatal outcome similar to that of the normal population. It is interesting to note that the long-term health and development of children with CPM diagnosed prenatally is not thought to be adversely affected (Amor et al., 2006). Amor et al., compared 36 children with antenatally diagnosed CPM to 195 matched controls with a normal karyotype diagnosed antenatally. All children were between the ages of 4 and 11, and outcome information was obtained through maternal questionnaire. No major health problems were detected among the CPM group. There was no increase in IUGR but postnatal growth was slowed compared to controls ($p = 0.047$). Issues that still need to be investigated are the exact contribution of CPM to IUGR, the significance of the specific chromosome involved in the mosaic aneuploidy, and the significance of specific tissue sources (i.e., direct cytotrophoblast preparations or mesenchymal tissue cultures) on pregnancy outcome.

Summary

CVS is considered a viable alternative to second trimester amniocentesis for prenatal diagnosis. Its immediate and long-term safety has been demonstrated. Evaluation of transcervical and transabdominal CVS has demonstrated their comparable safety and efficiency. The techniques are complementary and offer the choice of early prenatal diagnosis to patients who have the appropriate indications for the procedure. Counseling before CVS requires a discussion of the frequency and significance of CPM and the potential need for follow-up studies, including ultrasound, amniocentesis, and PUBS (Miny et al., 1991).

PERCUTANEOUS UMBILICAL BLOOD SAMPLING

In 1983, Daffos et al. described a method of obtaining fetal blood using ultrasonographic guidance. This involved the passage of a 20-gauge spinal needle through the maternal abdomen into the umbilical cord. This technique offered considerable advantage over the fetoscopic methods previously used to obtain fetal blood. The techniques are variously described as PUBS, fetal blood sampling, cordocentesis, or funipuncture.

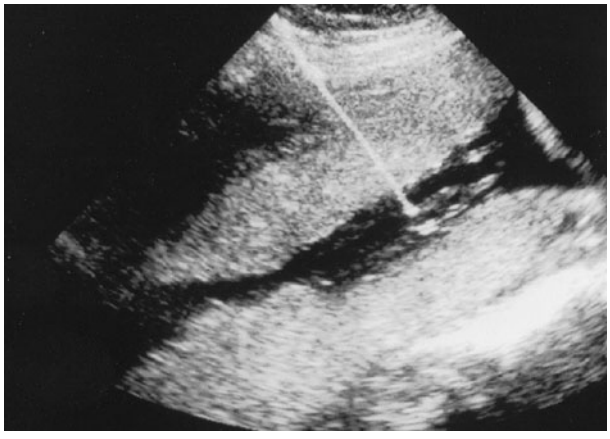

Figure 4-8 Ultrasound image of PUBS demonstrating the needle above the umbilical vein. (*From D'Alton ME. Prenatal diagnostic procedures. Part 1—Diagnosis and treatment of fetal disease.* Semin Perinatol. *1994;18:140-162.*)

Technique

The main differences in the techniques of fetal blood sampling are related to whether the operator uses a needle guide or uses a "freehand" technique. A variety of needle guides that attach to the transducer can be used. The advantage to this approach is that the needle will be directed precisely to a specific target. The disadvantage is that if the fetus moves or a contraction occurs while the needle is in the uterus, redirection of the tip may be difficult or impossible and will necessitate a repeat procedure. Because of these drawbacks, most centers performing this procedure use the freehand technique. Fetal vessels can be accessed within the cord or the fetus itself. It is easier to enter the cord at the placental insertion site because it is anchored at this location (Figure 4-8). Color Doppler imaging significantly enhances the ease of visualization of the cord insertion site (Figure 4-9) and is especially useful when oligohydramnios is present. The hepatic vein is the most accessible vessel for blood sampling within the fetal body.

Once a sample of blood has been aspirated, it is essential to verify that it is fetal in origin. The most definitive way to do this is to compare the mean corpuscular volume (MCV) of the red cells to that of a sample of maternal blood. This is easily performed on small aliquots of blood by a standard channeling instrument. It is preferable to either have this instrument in the procedure room, or alternatively have a system to allow immediate access to the instrument in an adjacent laboratory. Fetal red cells are considerably larger than those of an adult and therefore afford rapid differentiation.

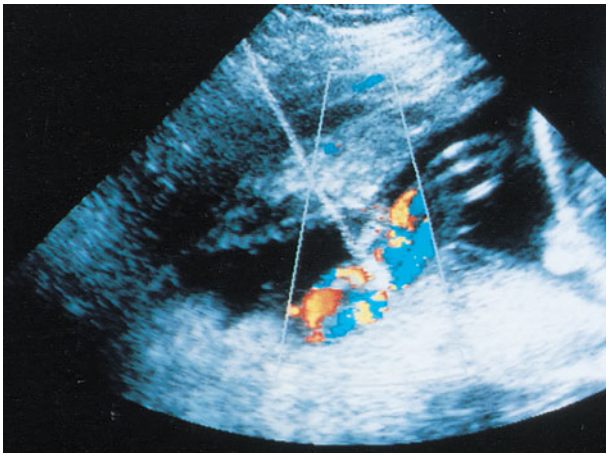

Figure 4-9 Ultrasound image of the same case shown in Figure 4-8, demonstrating the use of color Doppler to enhance visualization of the umbilical cord.

Success Rates and Safety

The rate of fetal loss after PUBS is approximately 2% higher than the background risk for that particular fetus (Daffos et al., 1985; Shulman and Elias, 1990). Because many of the fetuses studied have severe congenital malformations, the background loss rate is high in comparison with that of the generally lower risk population of women who undergo CVS amniocentesis.

The North American PUBS registry, which was maintained at Pennsylvania Hospital in Philadelphia, University of Pennsylvania, collected data from 16 centers in the United States and Canada. As of 1993, information on 7462 diagnostic procedures performed on 6023 patients was available (Ludomirsky, 1993). The most common needle used for procedures was a 22-gauge spinal needle. Fetal loss was defined as intrauterine fetal death within 14 days of the procedure. The rate of fetal loss was calculated to be 1.12% per procedure and 1.33% per patient. There were 84 pregnancies that were considered to be lost as a direct consequence of the fetal blood sampling. The major causes for fetal loss were chorioamnionitis, rupture of membranes, bleeding from the puncture site, severe bradycardia, and thrombosis. The range of losses for participating centers varied from 1% to 6.7%; this range reflects differing levels of experience of the operators. These figures are subjective, relying on the operator's impression that a pregnancy loss was directly related to the procedure itself and not to the underlying fetal condition that necessitated the procedure. Because many of these fetuses were already compromised at the time of PUBS, it is certainly possible that an in utero death following the procedure might have been entirely unrelated. Nevertheless, this assessment is subjective and could be responsible for an underestimation of the true rates of loss for PUBS. The authors concluded that the intrahepatic vein is an alternative site of sampling or transfusion when access is difficult or failure occurs at the placental cord insertion site. Nicolini et al. (1990b) described their experience with 214 fetal blood sampling procedures performed from the fetal hepatic vein and reported success rates of 91% and 90% for diagnostic and therapeutic procedures, respectively. Rates of fetal loss comparable to those for blood sampling procedures performed at the placental cord insertion site were reported. Because PUBS entails a substantially greater risk of pregnancy loss than does amniocentesis, it should be reserved for situations in which rapid diagnosis is essential or in which diagnostic information cannot be obtained by safer means (D'Alton and DeCherney, 1993).

Indications

Approximately two-thirds of the cases of diagnostic fetal blood sampling procedures reported to the PUBS registry were performed either to determine a rapid karyotype or to evaluate hematologic status in pregnancies at risk for red-cell isoimmunization (Ludomirsky, 1993). One-third of the procedures were performed to rule out fetal infection or to evaluate nonimmune hydrops, fetal acid–base status, twin-to-twin transfusion syndrome, or fetal platelet count.

Chromosome analysis

The ultrasonographic detection of fetal morphologic malformations is one of the most common indications for rapid fetal karyotyping in the United States (Table 4-6). With PUBS, fetal karyotypes are usually available from fetal white cells within 48 to 72 hours. The main advantage of PUBS is that it gives rapid results. Its disadvantage is that it entails a greater risk of pregnancy loss than does amniocentesis. We rarely use PUBS for rapid diagnosis of fetal karyotype, due to the easy availability of amniocentesis supplemented with fluorescence in situ hybridization (FISH) or polymerase chain reaction (PCR).

Table 4-6

Indications for PUBS

Most frequent
Rapid karyotyping
When ultrasound detects anatomic malformation
When mosaicism is reported from amniotic fluid or CVS specimens
Less frequent
Fetal red cell isoimmunization
Nonimmune hydrops fetalis
Fetal platelet assessment
Fetal infection
Fetal acid–base status
Diagnosis of twin–twin transfusion
Hemoglobinopathies
Coagulation factor deficiencies
Immunologic deficiencies

From D'Alton ME. Prenatal diagnostic procedures. Part 1—Diagnosis and treatment of fetal disease. Semin Perinatol. *1994;18:140–162.*

An exception is in the late second trimester, if karyotype information is needed urgently in order to make a decision regarding termination of pregnancy. Karyotyping fetal white cells may also occasionally be indicated for mosaicism detected in material obtained from amniotic fluid or chorionic villi. Although most cases of mosaicism found in chorionic villi can be effectively ruled out by amniocentesis, there have been reports of trisomy 21 mosaicism in which the chorionic villus culture revealed two cell lines. In this study, the amniotic fluid culture was entirely normal, yet true mosaicism was demonstrated in fetal blood (Ledbetter et al., 1990).

DNA analysis

Most inherited hematologic disorders can now be diagnosed by the study of fetal DNA obtained from amniocytes or chorionic villi. Therefore, the antenatal detection of most congenital coagulopathies, hemoglobinopathies, white cell disorders, and immune disorders does not usually require direct analysis of fetal blood specimens. In some of these cases, family studies are uninformative and PUBS is necessary for diagnosis. This is now the exception rather than the rule.

Fetal anemia

Assessment of fetal anemia in cases of red cell isoimmunization requires direct measurement of these parameters in fetal blood. Therefore, in severely affected cases of Rh isoimmunization, determination of the fetal hemoglobin level is the most accurate way to determine the fetal status and the optimal timing of a transfusion before.

Fetal blood sampling for determination of fetal anemia in red cell isoimmunization is a common reason for this procedure. It accounted for 23% of all cases reported to the PUBS registry (Ludomirsky, 1993). Fetal blood may also be obtained in cases of red cell isoimmunization to determine the antigen status of the fetus when the father is heterozygous for the discordant antigen. A single invasive procedure can rule out the disease, and no further diagnostic testing will be necessary. Amniocentesis initially replaced PUBS as the safest method for fetal Rh_o(D)type determination, while currently, analysis of fetal DNA in a maternal blood sample has effectively replaced all invasive tests for fetal Rh_o(D) type determination (Bennett et al., 1993; Lo et al., 1998; van der Schoot et al., 2003; Bianchi et al., 2005).

Fetal thrombocytopenia

Alloimmune thrombocytopenia is the platelet equivalent of Rh disease. In this disorder, the mother makes antibodies to antigens on the fetal platelets, and transplacental passage of these antibodies results in fetal thrombocytopenia. This disorder is associated with a marked depression of the fetal platelet count. Intracranial hemorrhage may occur in utero long before the onset of labor. Because severe thrombocytopenia and intracranial hemorrhage have been documented in this disorder as early as at 20 weeks of gestation, prolonged antenatal therapy is necessary to protect the fetus against the possibility of spontaneous bleeding. Intravenous gamma globulin at a dose of 1 g per kilogram with or without steroids is suggested to increase fetal platelet count and to decrease the risk of severe fetal hemorrhage (Bussel et al., 1988, 1996; Lynch et al., 1992).

The fetal platelet count should be obtained by PUBS prior to delivery. The risk of PUBS is higher in patients with alloimmune thrombocytopenia than in the general population. In these patients, blood sampling should be performed in a facility with access to rapid automated platelet counts at the time of the procedure, and a count should be determined before the sampling needle is withdrawn. A concentrate of washed maternal platelets should be available. If the fetal platelet count is found to be lower than 40,000 to 50,000 per cubic millimeter, a transfusion of maternal platelet concentrate can then be given.

Infectious disease diagnosis

Evaluation for fetal infection was the third most common indication for fetal blood sampling in the PUBS registry (8% of all cases). Daffos et al. (1988) reported on more than 700 pregnancies exposed to *Toxoplasma gondii* infection and demonstrated that 95% were not infected. Although PUBS has been used for *T. gondii* in the United States, screening for Toxoplasma is not routinely offered to pregnant women; therefore, PUBS is rarely performed for this diagnosis in the United States. Direct isolation of the organism from fetal blood or amniotic fluid is the most reliable evidence of fetal infection. Technical difficulties and the length of time necessary for culture of the organism often make this approach impractical. Another method is to evaluate the fetal antibody response. Production of specific IgM antibodies is gestational-age dependent and also seems to depend on the organism involved. Almost 100% of fetuses with congenital rubella infection produce specific IgM antibodies after 22 weeks of gestation (Daffos et al., 1984), whereas only 15% of those infected with *T. gondii* tested between 24 and 29 weeks produce specific IgM antibodies against the parasite (Daffos et al., 1988). Therefore, although detection of specific IgM antibodies in fetal blood is reliable evidence of fetal infection, their absence does not rule it out. Nonspecific evidence of infection includes fetal thrombocytopenia, erythroblastosis, leukocytosis, eosinophilia, elevated levels of γ-glutamyltransferase, lactic dehydrogenase, interferon (Lebon et al., 1985; Raymond et al., 1990), and total IgM antibodies.

More recently, PCR analysis has been highly reliable in detecting cytomegalovirus in amniotic fluid. Data suggest that PCR analysis of amniotic fluid is both highly sensitive and specific for the Toxoplasma organism, affording a diagnosis in a few hours (Grover et al., 1990). For this reason, amniocentesis and molecular techniques have effectively replaced PUBS for the confirmation of fetal infection.

Fetal well-being

Because cord blood pH at the time of delivery is a well-accepted indicator of neonatal status, it was hoped that fetal blood sampling for blood gases would also accurately predict

the fetal condition. Theoretically, PUBS could prove to be useful when more conventional forms of fetal assessment (nonstress testing, biophysical profile) were either equivocal or conflicting. Nicolaides et al. (1989) found significantly more hypoxemia, hypercapnia, hyperlactacidemia, and acidosis when 196 growth-restricted fetuses were compared with 208 who were appropriate in size for gestational age. However, Nicolini et al. (1990a) found that acid–base determination did not predict perinatal outcome in a group of growth-restricted fetuses. In their study, 26 growth-restricted fetuses with normal anatomy and karyotypes and absent end-diastolic flow on Doppler examination of the umbilical artery were compared with 20 similar fetuses, with end-diastolic flow evident on Doppler examination. The perinatal mortality was 65.4% in the first group and 0% in the latter. Significant differences in fetal blood values of Po_2, Pco_2, base equivalents, and nucleated red cell counts were demonstrable between the groups. However, these measurements did not discriminate between surviving fetuses and those who died perinatally. The values in fetuses who survived were similar to those in fetuses who died in the perinatal period. The authors concluded that PUBS has a limited role in monitoring fetal well-being. Appreciable fetal acidosis and hypoxia are found only when the umbilical-artery Doppler waveform and the fetal heart rate pattern are abnormal (Nicolini et al., 1990a; Pardi et al., 1993). Doppler velocimetry of the fetal vessels seems to be a much more powerful predictor than PUBS of the compromised fetus with IUGR. Furthermore, there is a high incidence of nonreassuring fetal testing necessitating emergency cesarean section when PUBS is performed in IUGR fetuses. There is a 15% incidence of fetal bradycardia reported when PUBS is performed in IUGR (Ludomirsky, 1993). Because of this, amniocentesis is the preferred technique when determination of fetal karyotype is indicated in the workup of the growth-restricted fetus.

Summary

Access to the fetal circulation has led to important contributions to the understanding of fetal physiology and disease states. PUBS has an overall rate of fetal loss of 2%. There has been a continued decline in the indications for fetal blood sampling because of advances in molecular and cytogenetic techniques, which allow for diagnosis from amniotic fluid and chorionic villi. Performance of less invasive procedures that provide the same information is encouraged. PUBS should be reserved for situations in which diagnostic information cannot be obtained by safer methods.

OTHER ADVANCES IN PRENATAL DIAGNOSIS

Preimplantation Genetic Diagnosis

In the field of reproductive endocrinology, preimplantation genetic diagnosis (PGD) is one of the most exciting recent advances (Sermon et al., 2004). It is the earliest form of antenatal diagnosis for cytogenetic and Mendelian disorders. This technique allows for genetic testing prior to embryo transfer in patients undergoing assisted reproductive technology (ART). One or two cells are biopsied from embryos at the 6 to 8 cell stage and are analyzed for chromosomal abnormalities or for single-gene disorders. Alternatively, polar bodies can be biopsied from oocytes.

PGD has been used by couples at risk for having pregnancies affected by single-gene disorders, increased risk for aneuploidy, and for couples in which one partner carries a balanced chromosomal rearrangement (Sampson et al., 2004). At the time of transfer, only embryos without the genetic abnormalities under evaluation are replaced. The main drawback to this procedure is that patients must undergo conception by in vitro fertilization (IVF) in order to have PGD even if they are not infertile. IVF has inherent risks, such as ovarian hyperstimulation and multiple gestation. In addition, the technique is expensive and not necessarily covered by insurance. At this point, PGD is reserved for patients at high risk for inherited single-gene disorders or chromosome abnormalities.

Fetal cells and nucleic acids in the maternal circulation

Noninvasive prenatal genetic diagnosis is an important area of research, as it would be preferable to invasive methods such as amniocentesis and CVS, which carry a small risk for fetal loss. Isolating fetal cells or cell-free fetal DNA from maternal plasma is currently an exciting and promising area of research that is transitioning to clinical care (Jackson, 2003). Current applications for analysis of fetal cells and of cell-free fetal DNA in maternal circulation include noninvasive detection of fetal gender and noninvasive detection of fetal Rh (D) genotype (Maron et al., 2007). Noninvasive fetal genotyping is useful for the management of Rh (D) negative women whose partners are heterozygous for the Rh (D) gene because no further diagnostic or therapeutic procedures would be necessary if the fetus was confirmed Rh (D) negative. In X-linked genetic disorders in which half of the fetuses will be female and unaffected, noninvasive determination of fetal gender could reduce the number of invasive procedures required for the diagnosis of X-linked genetic disorders by 50%. It could also guide treatment decisions regarding maternal steroids in fetuses at risk of inheriting congenital adrenal hyperplasia (Jackson, 2003). Additional clinical applications for fetal nucleic acids in maternal circulation may include screening for aneuploidy (Wataganara et al., 2003; Lo and Chiu, 2008), pre-eclampsia (Levine et al., 2004), or preterm labor (Farina et al., 2003).

CONCLUSIONS

Midtrimester amniocentesis created the field of invasive prenatal diagnosis and has become the standard by which

all other methods are judged. Earlier prenatal diagnostic methods have increasing appeal for many patients. The most studied of these methods is CVS. Transcervical and transabdominal techniques are equally effective; individual operator experience and placental location are usually the criteria used to choose between the two approaches. EA is not recommended now that compelling evidence regarding its disadvantages has been published. Advances in molecular techniques have led to a declining number of reasons for using PUBS. It is now rarely the procedure chosen for determining fetal karyotype. It is, however, the most direct method of evaluating fetal anemia secondary to severe $Rh_o(D)$ disease.

While there have been exciting advances in the field of prenatal diagnosis, the future holds the promise of more breakthroughs. It is expected that imaging modalities will continue to improve, and it is hoped that techniques utilized in the fields of noninvasive prenatal diagnosis and in PGD will continue to advance. Accurate prenatal diagnosis of fetal abnormalities improves patient care by optimizing patient counseling and allowing for informed patient and physician decision-making.

CHAPTER 5

Fetal Intervention

Key Points

- The range of interventional procedures continues to grow with refinements in criteria for treatment, technique, and instrumentation.
- Shunts work well to decompress thoracic fluid collections such as pleural effusions and cysts in congenital pulmonary airway malformation (CPAM; formerly known as congenital cystic adenomatoid malformation [CCAM]).
- Shunts work less well for treating bladder outlet obstruction; despite restoring amniotic fluid, renal outcomes are often compromised.
- Balloon valvuloplasty for aortic stenosis remains an unproven therapeutic innovation aimed at preventing progression to hypoplastic left heart syndrome.
- Fetoscopic surgery has proven safe and effective in treating twin–twin transfusion syndrome as well as other conditions such as amniotic band syndrome.
- Intrafetal radiofrequency ablation has been shown to have fewer complications and better survival than fetoscopic cord occlusion in Twin Reversed Arterial Perfusion (TRAP).
- Open fetal surgery is an option in rare cases for hydropic CPAM, sacrococcygeal teratoma (SCT), pericardial teratoma, and—depending on results of the MOMS trial—meningomyelocele (MMC).
- EXIT procedures are indicated for the management of compromised airways due to cervical teratoma, CHAOS, intrathoracic mass, and severe micrognathia.
- EXIT-to-ECMO may be beneficial in some cases of CDH or hypoplastic left heart syndrome with restrictive or intact atrial system.

Table 5-1

Fetal Malformations Treatable by Needle Aspiration and Shunting Procedures

Fetal Malformation	Fetal Presentation	Fetal/Neonatal Consequence
Posterior urethral valves	Hydronephrosis Oligohydramnios	Renal dysplasia and renal insufficiency Pulmonary hypoplasia and respiratory insufficiency
Cystic adenomatoid malformation of the lung	Mediastinal shift Hydrops	Pulmonary hypoplasia
Aqueductal stenosis	Hydrocephalus	Neurologic damage
Fetal hydrothorax	Mediastinal shift, hydrops, polyhydramnios	Pulmonary hypoplasia
Ovarian cyst	Wandering cystic abdominal mass, polyhydramnios	Ovarian torsion

Prenatal diagnosis has become increasingly sophisticated, and technologic advances have enhanced not only our diagnostic abilities, but also our understanding of the natural history of lesions detected in the prenatal period. Invasive therapies have developed as a consequence of our expanded understanding of the natural history and pathophysiology of structural anomalies (Garmel and D'Alton, 1993; Adzick and Harrison, 1994b). Despite rapid progress in prenatal diagnosis in the 1960s and 1970s, few invasive therapies were considered, much less employed (Adamsons, 1966). If a fetal malformation was made prenatally, parents had only two alternatives: pregnancy termination (if the diagnosis was made prior to 24 weeks of gestation) or continuing to term (Harrison et al., 1981b). An additional option is arranging for delivery at a tertiary care facility where appropriate pediatric specialists would be available to immediately treat the newborn with a congenital anomaly. As the natural history of many prenatally diagnosed anomalies became better understood, early delivery was recognized as an option to avoid the continuing damage caused by the anomaly in utero (Adzick and Harrison, 1994a,b). Today there are more alternatives. In this chapter we describe the treatment options available, how they were developed, and new therapies that may be available in the future.

FETAL SHUNTING PROCEDURES

A new era in invasive fetal therapy began in the early 1980s, when several independent groups introduced shunting procedures for hydrocephalus and hydronephrosis (Clewell et al., 1982; Frigoletto et al., 1982; Golbus et al., 1982). These first few cases represented an extension of invasive fetal therapy from simple intrauterine blood transfusion for a medical illness to the first attempts at in utero treatment of structural anomalies (Table 5-1).

During this period, hydronephrosis and hydrocephalus were being recognized more frequently with ultrasound examination. The prenatal natural history of these lesions was established by serial sonographic observation of untreated cases (Chervenak et al., 1984; Glick et al., 1984a,b; Clewell et al., 1985; Nakayama et al., 1986; Crombleholme et al., 1988b; Cendron et al., 1994). Fetuses with high-grade obstructive uropathy followed to term were often born with advanced hydronephrosis, type IV cystic dysplasia, and pulmonary hypoplasia that were incompatible with life (Potter, 1976; Crombleholme et al., 1988b; Cendron et al., 1994). In the case of obstructive hydrocephalus, it was known that shunting during the newborn period improved neurologic outcome, and it was reasoned that decompression in utero might avert progressive brain damage (Lawrence and Coates, 1962; Lorber, 1969; Young et al., 1973). However, the poor outcomes observed with shunting for hydrocephalus resulted in a moratorium on the use of shunts in the treatment of obstructive hydrocephalus (Clewell, 1991). In other conditions, work in appropriate animal models helped to define the pathophysiology of these lesions and establish the theoretical basis for intervention (Adzick et al., 1970; Harrison et al., 1982d, 1983; Glick et al., 1983, 1984a, 1984b).

Hydronephrosis

The first case of a fetus with obstructive uropathy treated in utero by vesicoamniotic shunting was reported by Golbus et al. in 1982. Advances soon followed in diagnosis, technique, shunt design, and patient selection (Rodeck et al., 1988; Crombleholme et al., 1988a, 1991a; Harrison and Filly, 1991; Crombleholme, 1994; Johnson et al., 1995). The enthusiasm for treating fetal obstructive uropathy has continued unabated during the past two decades. The procedure

became widely implemented before stringent selection criteria for treatment were developed and the therapeutic efficacy of the procedure was established. The widespread use of vesicoamniotic shunts also had the effects of shifting cases away from the centers studying vesicoamniotic shunts to better define their role in the management of fetal obstructive uropathy.

The lack of a prospective randomized trial makes it difficult to address the efficacy of prenatal decompression of fetal obstructive uropathy. One of the few series that attempted to address this question, was a retrospective analysis reported by Crombleholme et al. (1991a). In fetuses predicted to have either good or poor prognoses by fetal urine electrolyte and ultrasound criteria, survival was greater among those who underwent decompression in utero, as opposed to those who did not undergo decompression. In the group of fetuses predicted to have a poor prognosis by selection criteria, 10 were treated; three of these pregnancies were electively terminated, 4 neonates died from pulmonary hypoplasia or renal dysplasia, and 3 survived. All three survivors had restoration of normal amniotic fluid (AF) levels and no pulmonary complications, but two of the three subsequently developed renal failure requiring renal transplantation. Among the 14 patients with no intervention, there were no survivors (11 terminations and 3 neonatal deaths from pulmonary hypoplasia). In the entire series, uncorrected oligohydramnios was associated with a 100% neonatal mortality rate. Normal or restored AF volume was associated with a 94% survival rate (Crombleholme et al., 1991a).

Although in utero decompression seems to prevent neonatal death from pulmonary hypoplasia, the effect on renal function is less clear. The severity of renal dysplasia at birth depends on the timing and severity of obstruction before birth (Harrison et al., 1981a,b, 1982a,c, 1987, 1990; Manning et al., 1986; Crombleholme et al., 1988b, 1991a). Experimental work suggests that relief of obstruction during the most active phase of nephrogenesis (20–30 weeks of gestation) may obviate further damage and allow normal nephrogenesis to proceed (Adzick et al., 1970; Beck, 1971; Harrison et al., 1982a, 1987; Glick et al., 1984a,b; Gonzalez et al., 1985; Salinas-Madrigal et al., 1988; Peters et al., 1991). The development of postnatal renal failure in two infants who were not treated because AF volume remained normal raises the question of whether to treat fetuses with obstruction before oligohydramnios develops. Because renal development or maldevelopment is complete at birth, relief of obstruction in infancy or childhood may not prevent the progression to end-stage renal failure (Warshaw et al., 1982). Müller et al. (1993) reported on a group of fetuses with obstructive uropathy, a favorable prognostic profile, and normal AF in whom renal insufficiency developed by 1 year of age. The only feature that distinguished this group of fetuses was a urinary level of β_2-microglobulin greater than 2 mg per liter suggesting that elevated fetal urinary levels of β_2-microglobulin may identify fetuses at increased risk for ongoing renal damage from obstruction, even if AF is normal. Other investigators have not found β_2-microglobulin levels to be as useful, although levels greater than 10 mg per liter can be a predictor of poor outcome in fetuses over 20 weeks of gestation (Freedman et al., 1997). It remains an open question whether or not in utero decompression could prevent long-term renal insufficiency in these patients.

The maternal morbidity associated with vesicoamniotic shunting has been reported to be minimal, but chorioamnionitis related to the procedure has been reported (Glick et al., 1985; Crombleholme et al., 1991a). In addition, there have been reports of shunt-induced abdominal wall defects with herniation of bowel through trochar stab wounds and maternal ascites from leakage of AF through the uterine wall into the maternal peritoneal cavity (Manning et al., 1986; Robichaux et al., 1991; Ronderos-Dumit et al., 1991).

The utility of vesicoamniotic shunts is limited by the brief duration of decompression, the risk of infection, the risk of catheter obstruction or dislodgment, fetal injury during placement, and potentially inadequate decompression of the fetal urinary tract (Glick et al., 1985; Crombleholme et al., 1988a, 1991a; Estes and Harrison, 1993). These factors make vesicoamniotic shunts less effective when placed early in gestation for long-term decompression of the urinary tract and are the impetus for development of open fetal surgical and fetoscopic techniques to treat obstructive uropathy in utero (Crombleholme et al., 1988a; Estes and Harrison, 1993; Crombleholme and Lim, in press).

Fetal Hydrothorax

Thoracentesis is a diagnostic maneuver to obtain pleural fluid for differential cell count and culture and to establish whether the effusion is chylous. But even repeated thoracentesis provides inadequate decompression of the fetal chest. There have been several reports of thoracentesis for fetal hydrothorax (FHT), performed with either complete resolution or a good outcome despite reaccumulation (Petres et al., 1982; Kurjak et al., 1985; Benacerraf et al., 1989). Others have had disappointing results with repeated thoracentesis for FHT, because of rapid reaccumulation of the effusion and neonatal death from respiratory insufficiency (Longaker et al., 1989; Nicolaides and Azar, 1990). Spontaneous resolution of FHT may occur in as many as 10% of cases, and resolution following thoracentesis may or may not be related to the procedure. Thoracentesis alone cannot adequately decompress the fetal chest to allow pulmonary expansion and prevent pulmonary hypoplasia (Laberge et al., 1991).

Thoracoamniotic shunting for FHT, first reported by Rodeck et al. in 1988, provides continuous decompression of the fetal chest, allowing lung expansion. If instituted early enough, this allows compensatory lung growth and prevents neonatal death from pulmonary hypoplasia. Nicolaides and Azar (1990) reported on 48 cases of thoracoamniotic shunting, but there was no attempt to distinguish isolated primary FHT from secondary FHT. Despite intervention, mortality was high. Four of the deaths were due to termination

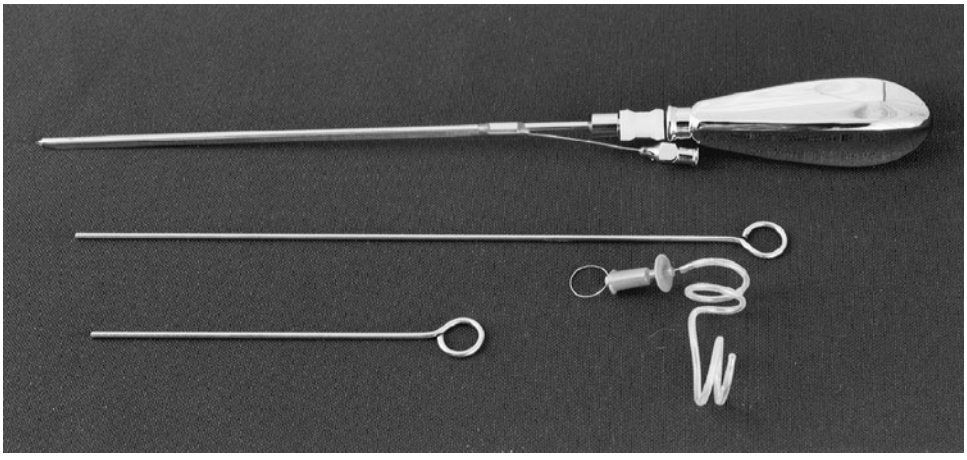

Figure 5-1 The trochar used for KCH catheter insertion, including the obturators and sheath with the KCH catheter for scale. Note the KCH catheter with the pigtail ends at 90° to each other.

of pregnancy when a chromosomal abnormality was diagnosed. In addition, there were 12 neonatal deaths despite thoracoamniotic shunt placement, but these fetuses seemed to have severe hydrops and secondary FHT. Two fetuses that died in utero also seemed to have had secondary FHT and severe hydrops. If the cases that appear to be secondary FHT are eliminated, the survival of isolated primary FHT treated with thoracoamniotic shunting is 38 of 41 (92%) cases (Nicolaides and Azar, 1990; Moran et al., 1994). A similar survival rate with thoracoamniotic shunting was found by Hagay et al. (1993) in their review of fetal pleural effusions. This is a striking improvement when compared with a survival of only 50% in untreated FHT.

The indications for thoracoamniotic shunting are not well defined. Most authors consider the presence of FHT-induced hydrops or polyhydramnios as indications for shunting (Rodeck et al., 1988; Longaker et al., 1989; Nicolaides and Azar, 1990). In addition, we recommend thoracoamniotic shunting for primary FHT with evidence of effusion under tension even in the absence of hydrops (Moran et al., 1994). Because spontaneous resolution has been observed even in severe cases of FHT, we reserve thoracoamniotic shunting for cases in which tension hydrothorax recurs after two thoracenteses.

The limited experience with thoracoamniotic shunting suggests that it is extremely effective in decompressing effusion and improving survival. The risks to mother and fetus of thoracentesis and shunt placement have been minimal and are far outweighed by the potential benefits. Few complications have been reported for either fetal thoracentesis or thoracoamniotic shunts. Procedure-related fetal death is rare, due to hemorrhage from an intercostal artery laceration or torsion of the umbilical cord (Longaker et al., 1989). Migration of the shunt under the fetal skin has also been reported, but required no intervention when the infant was born (Rodeck et al., 1988). There have been no maternal complications reported with either thoracentesis or thoracoamniotic shunting. However, it should be recognized that these procedures have the potential for significant complications, including infection, bleeding, premature rupture of membranes, preterm labor, and injury to the fetus (Moran et al., 1994).

There are currently two FDA-approved devices available for shunt placement in a broad range of applications including bladder outlet obstruction, pleural effusions, and cyst decompressions in congenital pulmonary airway malformation (CPAM). The Harrison catheter (Cook, Inc., IN) is available in a complete shunt insertion kit that includes not only the polyurethane shunt but also the trocar for insertion, the guide wire over which the double pigtail catheter is threaded and the pusher that deploys the shunt. The advantages of the Harrison catheter include the ease of insertion and the complete kit it comes with. The disadvantage of the Harrison catheter is that it is more easily dislodged.

The alternative catheter is the Rocket or KCH catheter (see Figure 5-1). The Rocket catheter requires a reusable trocar insertion device that is larger and somewhat more difficult to use compared to the Harrison catheter set. The advantage of the Rocket catheter is that it is less likely to be dislodged. The larger size of the Rocket trocar may make this less appealing for chest shunt insertion due to increased difficulty inserting the shunt and increased risk of laceration of the intercostal artery, especially in fetuses at less than 25 weeks gestation.

Miscellaneous Procedures and Other Indications for Shunts

Small ovarian cysts are common in neonates. They are typically small follicular cysts due to maternal hormonal stimulation and are rarely clinically significant. They usually regress spontaneously (Kirkinen and Jouppila, 1985). The prenatal diagnosis of an ovarian cyst should be considered in any female fetus with a cystic pelvic mass (see Chapter 67). Although they can be mistaken for mesenteric cysts, duplications, urachal cysts, or choledochal cysts, ovarian cysts are

usually simple pelvic cysts that disappear shortly after delivery. Occasionally, these cysts require surgery for complications due to size, rupture, or torsion (Kurjak et al., 1984; Kirkinen and Jouppila, 1985). Once an ovarian cyst becomes symptomatic, salvage of the ovary is unlikely.

Valenti et al. were the first to perform cyst decompression in utero, in 1975. A large (7 by 9 cm) ovarian cyst was aspirated to prevent intrapartum cyst rupture. Landrum et al. (1986) reported fetal ovarian cyst aspiration ostensibly to prevent pulmonary hypoplasia. While pulmonary hypoplasia from a pelvic mass is unlikely, aspiration to prevent in utero rupture or torsion and to preserve ovarian tissue is a more appropriate indication for treatment. Holzgreve et al. (1993) have reported their experience with 13 cases of fetal ovarian cysts. This group recommends ovarian cyst decompression if the cyst is large, rapidly increasing in size, or observed to be a "wandering mass" as cysts exhibiting these features are more likely to undergo torsion. Cyst tap revealing high levels of prostaglandin F21, progesterone, and testosterone in the fluid confirms the diagnosis. Giorlandino et al. (1990) have reported a case of ovarian cyst treated by cyst aspiration and sclerosis with tetracycline. While this treatment was successful, the use of tetracycline as a sclerosing agent in the fetus is not advised. This group has subsequently reported success in four cases of simple cyst aspiration (Giorlandino et al., 1993). Similarly, D'Addario (1990) aspirated ovarian cysts in two fetuses, but neonatal surgery was still needed. Crombleholme et al. have suggested criteria for intervention in fetal ovarian cysts with diameters of >4 cm, increasing 1 cm per week in size, or as Holzgreve suggested, noted to wander about the abdomen (Crombleholme et al., 1997). Although fetal ovarian cyst decompression seems a relatively benign procedure with the potential for ovarian preservation, the indications for fetal intervention are not uniformly accepted.

In 1987, Nicolaides et al. reported the first case of CPAM treated by shunt insertion in utero. Decompression of a large type I CCAM in a 20-week-old fetus by percutaneous placement of a thoracoamniotic shunt was subsequently reported by Clark in 1987. This procedure resulted in resolution of both mediastinal shift and hydrops and successful delivery at 37 weeks of gestation. Postnatally, the infant underwent uneventful resection of the CCAM. Recently, Wilson et al. (2006) reviewed the CHOP experience with thoracoamniotic shunts for cystic CCAMs demonstrating an average acute 70% reduction in CCAM volume with a 74% survival with thoracoamniotic shunting in the presence of hydrops, polyhydramnios or fetuses at increased risk for developing pulmonary hypoplasia. This experience is consistent with other reports of CCAMs with a dominant cyst that responded to thoracoamniotic shunt placement (Adzick, 2003, Wilson et al., 2004, 2006). There are however potential procedure-related complications including catheter dislodgment, catheter occlusion from thrombus, fetal hemorrhage, placental abruption, premature rupture of membranes or preterm delivery, and chest wall deformity (Dommergues et al., 1997; Mann et al., 2007; Merchant et al., in press). More commonly, it is the type III CCAM or microcystic lesions, which becomes enlarged, resulting in hydrops and intrauterine fetal death; in these cases, open fetal surgery and resection are indicated. However, in the rare instances in which there is a single large cyst in CCAM responsible for hydrops, thoracoamniotic shunting appears to be an appropriate treatment option (see Chapter 35).

FETAL CARDIAC PROCEDURES

Fetal Arrhythmias

Fetal arrhythmias are most often ventricular extrasystoles or tachyarrhythmias (see Chapter 41). But bradyarrhythmias account for 9% of cases reported to the Fetal Arrhythmia Registry, half of which occur in structurally normal hearts due to transplacental passage of antibody in mothers with collagen vascular disease (Kleinman and Evans, 1988) (see Chapter 42). The other half occur in structurally abnormal hearts, and bradyarrhythmia is almost uniformly fatal in that setting (Kleinman et al., 1982; Stewart et al., 1983). In structurally normal hearts in which complete heart block (CHB) develops in mothers with collagen vascular disease, hydrops will develop in 25% and is usually refractory to medical therapy (Altenburger et al., 1977; Carpenter et al., 1986; Machado et al., 1988). Based on the combined retrospective experience from the groups at Toronto Sick Kids and UCSF, fetuses with CHB may benefit from the combination of maternal steroids and β-mimetics (see Chapter 42). There is no expectation that steroids will improve the fetal heart rate but may reduce maternal Ab titer and transplacental passage and limit the ongoing injury to the fetal cardiac conduction system and the myocardium. If low-output fetal heart failure cannot be reversed by increasing heart rate with β-agonists then fetal cardiac pacing is the only alternative. Carpenter et al. (1986) reported the first fetus treated by implantation of a percutaneous transthoracic pacemaker. Unfortunately, the fetus was severely hydropic and despite successful ventricular capture and pacing the fetus died within hours. The obvious problems with the percutaneous transthoracic pacemaker are the risks of dislodgment, potential for infection (chorioamnionitis), and the temporary nature of the device in a fetus that will require pacing for the rest of gestation. These limitations prompted a group led by Michael Harrison at UCSF to attempt pacemaker placement by open fetal surgery (Harrison et al., 1993). Previous work by Crombleholme et al. (1990, 1991b) had developed the techniques for acute and chronic fetal cardiac pacing and studied the effects of CHB in fetal lambs. Based on this experimental work, Harrison et al. (1993) placed a unipolar epicardial pacemaker in a fetus at 22 weeks of gestation with CHB and hydrops. Similar to Carpenter et al.'s (1986) experience, although able to achieve ventricular capture and pacing, the heart was irreversibly damaged by 6 weeks of in utero cardiac failure and the procedure resulted in fetal death in the operation room (Harrison et al., 1993). More

recently, Crombleholme et al. performed open fetal surgery for placement of epicardial pacing lead with an implantable programmable pulse generator in VVI mode. The pacemaker was set at 65 beats per minute that doubled the combined ventricular output measured by echocardiography. The fetus expired on postoperative day 5 and autopsy was found to have extensive renal and hepatic ischemic injury that likely preceded the fetal surgery (Crombleholme et al., 2008). It is clear from these reports that a fetus with long standing CHB with severe hydrops may already have significant end organ injury that may be unsalvageable despite successful pacemaker placement. The survival of fetuses with CHB and ventricular escape rates of less than 50 beats per minute is poor (Schmidt et al., 1991). Placement of a pacemaker in the fetus with a ventricular response rate of less than 50 beats per minute before the development of hydrops may allow us to save these fetuses with an otherwise dismal prognosis.

Structural Fetal Heart Disease

Structural cardiac defects, such as pulmonic atresia with an intact ventricular septum (PAIVS) or severe aortic stenosis (AS) (see Chapters 49 and 50), may result in obstruction to blood flow, which in turn alters the development of the heart chambers as well as the pulmonic and systemic vasculature in utero (Vlahakes et al., 1981). The major morbidity from these congenital heart defects often results from the secondary alterations in heart development caused by the primary defect (i.e., hypoplasia of the right ventricle in PAIVS or hypoplastic left heart syndrome [HLHS] in AS). In theory, relief of the anatomic obstruction in utero may allow more normal cardiac development, thereby eliminating the need for corrective surgery postnatally.

AS diagnosed prenatally is frequently associated with intrauterine fetal death or neonatal death in fetuses that survive to term. Maxwell et al. (1991) reported a series of 28 fetuses diagnosed prenatally with AS either alone or associated with endocardial fibroblastosis. Only 12 mothers continued the pregnancy to term, and in 2 there was an intrauterine fetal death. None of the 10 neonates survived despite balloon valvuloplasty in 4 of them. Maxwell et al. also noted that in four fetuses the left ventricle failed to grow, resulting in hypoplastic left heart, which would make the neonate unsuitable for postnatal aortic valve reconstruction. This grim natural history for fetuses with prenatally detected AS, as well as poor outcomes with Norwood procedure in their institution, prompted Maxwell et al. (1991) to attempt the first in utero aortic balloon valvuloplasty. This procedure was performed by direct percutaneous puncture of the left ventricle under ultrasound guidance. A J-wire is passed through the stenotic valve, and the balloon catheter is passed over the wire and inflated. All three fetuses treated with this procedure survived to term; two died as neonates and one was doing well to a follow-up of 3 years of age (Maxwell et al., 1991). Two other fetuses were treated unsuccessfully by this technique by another group (Chouri et al., 1994).

More recently, the group at Boston Children's Hospital has reintroduced fetal balloon valvuloplasty in an effort to prevent progression of AS to HLHS (Mäkikallio et al., 2006). In their initial experience with 43 fetuses diagnosed with AS, they retrospectively identified a subset of patients that all progressed to HLHS postnatally. These fetuses all had AS associated with normal LV length, reversed flow in the transverse aortic arch or foramen ovale, and a monophasic mitral inflow pattern. Several centers soon followed with reports of attempts at fetal aortic valvuloplasty (see Table 5-2). Although most centers' experience is quite small, there appears to be a steep learning curve judging from the largest series reported thus far (Tworetzky and Marshall, 2004; Matsui and Gardiner, 2007). "Technical success," as defined as increased flow across the aortic valve, has been achieved in 75% of cases but only 1/3 of technically successful procedures achieve an eventual biventricular circulation postnatally (Matsui and Gardiner, 2007). This contrast between technical success and postnatal success suggests that current selection criteria do not accurately select fetuses that are likely to respond to balloon valvuloplasty.

Wright et al. (1994) have performed radiofrequency pulmonic valvotomy in a fetus with PAIVS. In the most severe forms of PAIVS, the primary valvular lesion causes secondary alteration in the intracardiac flow pattern, resulting in a hypoplastic right ventricle (Casteneda et al., 1994). In these instances, only palliative pulmonary valvotomy and systemic to pulmonary artery shunting can be performed. However, if flow can be reestablished across the pulmonic valve in utero, restoration of intracardiac blood flow may allow subsequent growth of the right ventricle and pulmonary outflow tract. The indications for fetal balloon valvuloplasty in PAIVS include a cardiovascular profile score of less than 7, decreased biventricular cardiac output, severe pulmonary stenosis and/or elevated RV pressure and/or hydrops (Matsui and Gardiner, 2007). In a 26-week-old fetus with PAIVS, no growth was observed in the right ventricle during 6 weeks of in utero observation. By direct puncture of the right ventricle, a pulmonary valvotomy was performed using a radiofrequency ablation catheter. Although only a minute hole with insignificant flow resulted, this procedure and those reported by Maxwell and Chouri et al. have established the feasibility of in utero treatment of structural heart disease. Although there have been technical successes, the outcomes have not been different from the natural history of PAIVS often due to growth failure of the pulmonic valve annulus (Matsui and Gardiner, 2007; Gardiner, 2008).

These procedures are certainly not without risk. One of Maxwell's patients died within hours of the procedure and pieces of balloon and guide wire were left within the fetal heart. All three centers have noted pericardial effusions at the conclusion of the procedure that required evacuation. In the series reported by Marshall et al. (2005), in 20 of 26 patients with technically successful procedures, 12 had at least mild regurgitation at the procedure. In a report from the same group, 45% of 83 fetuses experienced hemodynamic instability (Mizrahi-Arnaud et al., 2007) that was associated

with transventricular approach and the development of large hemopericardium. In 31 of the 37, resuscitation medications were used and—in all 37—the hemodynamic stability was restored. However, there were 5 fetal deaths (5 of 63, 8%) within 24 hours of the procedure (Mizrahi-Arnaud et al., 2007). Despite the risk of these procedures, the unfavorable outcomes for the fetuses with these structural heart defects argue in favor of continued efforts at developing safe and effective invasive fetal therapies.

FETOSCOPIC SURGERY

Diagnostic Fetoscopy

Embryoscopy was first performed via the transcervical approach early in gestation, prior to fusion of the chorion and amnion, to make a phenotypic diagnosis (Westin, 1954; Gallinat et al., 1978; Dubuisson et al., 1979; Roume et al., 1985; Dumez et al., 1988; Cullen et al., 1991; Ghirardini, 1991). Percutaneous techniques were then developed to introduce the fetoscope directly into the amniotic cavity transabdominally. Many of the initial indications for fetoscopic guidance are procedures that now are routinely performed with ultrasound guidance alone. In some instances, however, diagnostic fetoscopy can still be a useful adjunct to ultrasound, especially early in gestation. The suspicion of a significant fetal anomaly prior to 14 weeks' gestation may be difficult to definitively resolve with ultrasound alone and is too early in gestation for MRI (Deprest and Ville, 2001).

Duchenne muscular dystrophy (DMD), a progressive, degenerative muscle disease, is inherited as an X-linked recessive trait. It is one of the more common genetic diseases among all populations, affecting approximately one in 3500 liveborn male infants. DMD is caused by the deficiency of a protein component of muscle tissue called dystrophin. Dystrophin is part of the membrane cytoskeleton in normal muscle, and a deficiency leads to myofiber necrosis, presumably because of membrane instability. While 70% of cases are inherited through a carrier mother, approximately 30% of cases occur without previous family history, representing apparent de novo mutations in the dystrophin gene (Moser, 1984). Because of isolation of the dystrophin gene (Koenig et al., 1987) and its normal protein product (Hoffman et al., 1987), diagnosis of this disorder can now be made on a molecular basis. However, because of the tremendous size of the DMD gene and variation in molecular abnormalities, the underlying gene defect (usually a deletion) has been able to be identified in only 65% of affected individuals. In such a case, however, female carriers in such families can be identified with molecular testing and future male pregnancies can be tested for that specific familial gene defect.

In 1991, the first case of in utero fetal muscle biopsy for DMD diagnosis was described in a family in which the carrier status of the mother could not be determined for the reasons described above (Evans et al., 1991). Using a renal biopsy device directed into the fetal buttock under high-resolution ultrasound guidance, a satisfactory biopsy of skeletal muscle was obtained for analysis and was subsequently shown to contain normal amounts of the dystrophin protein. DMD

and other genetic conditions remain a rare but important indication for fetoscopic-guided biopsy.

Therapeutic Fetoscopy

Lower urinary tract obstruction

Fetal lower urinary tract obstruction can result in progressive oligohydramnios, pulmonary hypoplasia, and cystic renal dysplasia. Occurring mostly in males, common etiologies include posterior urethral valves, urethral atresia, and urethral hypoplasia. The presence of significant bladder dilation, bilateral hydronephrosis, and severe oligohydramnios prior to 20 weeks' gestation is almost universally associated with in utero or early neonatal death if left untreated. Experimental models of ureteral obstruction in sheep suggest that early reversal of obstruction in midgestation can prevent progression of renal damage and potentially improve postnatal survival and renal outcomes (Glick et al., 1983). This work led to the concept of in utero therapy either by open fetal surgery (Harrison et al., 1982b; Crombleholme et al., 1988a) or vesicoamniotic diverting shunts that drain urine from the bladder to the amniotic space (Harrison et al., 1981b).

However, shunt placement is a technically challenging, invasive procedure, and long-term shunt success is variable, largely due to shunt obstruction or displacement. Functional shunt failure has been reported to occur in 40% to 50% of cases after successful placement, mostly due to displacement of the shunt into the fetal abdomen or amniotic space (Hassan et al., 1997). Because of the displacement issue and the bladder dysfunction that results after catheter decompression, alternative approaches such as fetal cystoscopy have been attempted.

One approach has been based on postnatal therapy for such disorders that involves cystoscopic identification of the underlying etiology, and in cases of posterior urethral valves, destruction of the membranous obstruction. However, developing such an approach in an 18- to 20-week fetus has proven problematic. Engineering and manufacturing advances have produced successive generations of smaller fiberoptic endoscopes that have made the possibility of fetal cystoscopy a reality. Initially, using a variety of 1.7- to 2.2-mm endoscopes, Quintero et al. (1995b) were able to show that in utero diagnostic fetal cystoscopy was possible and later were able to identify proximal urethral obstructions. Several attempts at laser ablation of posterior urethral valves were technical successes, but postoperative obstetrical complications resulted in no long-term survivors from this early experience (Quintero et al., 1995a). Using a 1.2 × 2.4-mm double-lumen trocar sheath, it is possible to pass wire probes or laser fibers to assist in diagnostic evaluation and offer the possibility of laser ablation of posterior urethral valves. Design modifications and refinements to this system have recently allowed fetoscopists to more reliably visualize the source of proximal urethral obstruction and differentiate between urethral atresia and posterior urethral valves (Figure 5-2). Visualization of the posterior urethral valves may be difficult beyond 20 weeks due to increased angulation at the posterior urethra. Clifton et al. (2008) have added the placement of a transurethral stent to disrupt the valves with good renal function and bladder function at one year postnatally. It is hoped that by treating the source of the obstruction in midgestation, renal function will be preserved and the need for postnatal urologic surgery to correct secondary anatomic abnormalities may be eliminated. However, despite a compelling rationale for fetal cystoscopic treatment of posterior urethral valves and advances in fetoscopic techniques, this approach has yet to be shown to be a more effective treatment of lower urinary tract obstruction than vesicoamniotic shunting.

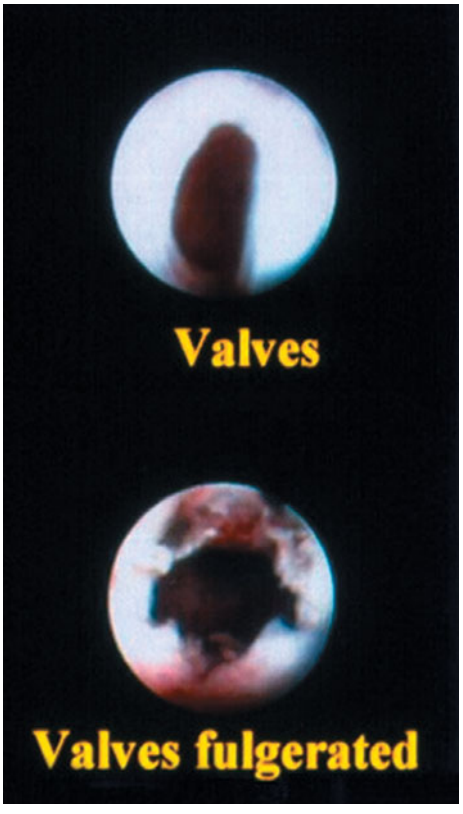

Figure 5-2 Fetal antegrade cystourethroscopy (top) prior to fulgeration of valves and immediately following (bottom).

Diaphragmatic hernia

Congenital diaphragmatic hernia (CDH) is a simple anatomic defect in the diaphragm, but in severe cases it may result in profound pulmonary hypoplasia precluding postnatal survival (Harrison et al., 1978; Harrison and deLorimier, 1981). This prenatal natural history of CDH has led to attempts to correct the diaphragmatic defect before birth, with some anecdotal success. It had been recognized in the physiology literature for decades that occlusion of the fetal trachea results in accelerated lung growth (Carmel et al., 1965; Alcorn et al., 1977). This technique was applied in animal models of CDH, demonstrating that tracheal occlusion can correct the pulmonary hypoplasia associated with CDH (DiFiore et al., 1994; Hedrick et al., 1994). This work was quickly replicated in other laboratories and was pioneered in clinical application

by Harrison and the University of California at San Francisco (UCSF) group using open fetal surgical techniques to occlude the trachea (Harrison et al., 1996). The survival using an open fetal surgical approach, however, was disappointing, and fetoscopic techniques of tracheal occlusion were developed in hopes of avoiding the problems of preterm labor and complications from tocolytic agents associated with hysterotomy (Adzick et al., 1985b; Harrison et al., 1990; Flake et al., 2000). The fetoscopic techniques used for tracheal occlusion have evolved with growing experience by the UCSF and Eurofetus group.

In their initial approach with the "fetendo" clip, Harrison et al. (1998) reported a 75% survival compared with 15% in the open fetal surgical approach to tracheal occlusion and a 38% survival with standard postnatal therapy. Not only did survival appear to be improved in this small series, but there was also a trend toward less preterm labor, less need for tocolysis, and a shorter hospital stay. The UCSF group further refined their technique, eliminating the multiple ports and the neck dissection entirely by performing an endoluminal balloon tracheal occlusion (Harrison et al., 2001). A single port is used to introduce a fetoscope into the amnion and the fetal oropharynx. The vocal cords are fetoscopically viewed for passage of a detachable balloon catheter through the vocal cords. The position in the trachea is determined sonographically before inflation and deployment of the balloon. This technique was piloted in several cases of right-sided CDH and was evaluated in a National Institutes of Health (NIH) sponsored prospective randomized clinical trial comparing fetoscopic endoluminal balloon tracheal occlusion to conventional postnatal therapy.

The NIH trial of fetoscopic tracheal occlusion was halted after randomization of only 24 subjects when it became apparent that there would be no significant difference in survival between the fetoscopic tracheal occlusion group and the conventional therapy group. The fetoscopic surgery group had a 73% (8 out of 11) survival, as predicted by preliminary data, but the conventional postnatal treatment group had a better than predicted survival of 77% (10 out of 13). The fetoscopically treated patients delivered significantly earlier compared to conventional treatment at a mean of 30.8 versus 37.0 weeks, respectively. The entry criteria for this study was LHR <1.4, which resulted in a number of patients included that would be expected to do well with conventional postnatal therapy. European centers that are a part of the Eurofetus FETO (Fetoscopic Endoluminal Tracheal Occlusion) in Leuven, Belgium, Barcelona, Spain, and London, United Kingdom have collaborated on fetoscopic tracheal occlusion for LHR <1.0 with liver herniation. This has resulted in survival of 55% that compared favorably to conventional postnatal therapy in their neonatal centers with 11% survival (Deprest et al., 2008). More recently, Deprest et al. (2008) has reported 83% survival with fetoscopic tracheal occlusion and reversal later in gestation. The reversal of tracheal occlusion is performed by either a second fetoscopic procedure for removal or by ultrasound-guided balloon puncture. The detachable balloon used in tracheal occlusion in Europe is not FDA approved. Recently, centers in the United States including UCSF and the Fetal Care Center of Cincinnati have obtained an investigational device exemptions (IDE) to perform fetoscopic tracheal occlusion in cases of severe CDH with liver herniation and a lung/head ratio (LHR) of <1.0 between 26 and 28 weeks' gestation.

Attempts at treating fetal SCT with minimally invasive fetoscopic techniques have met with mixed results. Hecher and Hackeloer (1996) reported the successful treatment of an SCT by fetoscopy using laser. The base of this SCT was unusually narrow, without distortion of the anorectal sphincter complex onto the mass. This is an important consideration, as most fetal SCTs distort the anorectal sphincter complex, and such a fetoscopic approach as described by Hecher might result in ischemic necrosis of the anorectal sphincter complex along with the SCT. In addition, the superficial vessels are the only ones accessible to the laser, while the deeper pelvic vessels, which may be more important in the development of high-output physiology, are inaccessible. These difficulties are highlighted by the UCSF experience with the use of radiofrequency ablation (RFA) (Paek et al., 2001). The goal was the coagulation of the feeding vessels to the SCT that are responsible for the high-output state. The power of the RFA in this ultrasound-guided technique could not be precisely controlled and the fetus sustained necrosis of the anus, vagina, and bladder, with injury to the sciatic nerve (Paek et al., 2001).

Myelomeningocele

In recent years, fetal surgery has moved from the treatment exclusively of life-threatening fetal anomalies such as CDH, SCT, or hydropic CPAMs to fetal anomalies that are severely debilitating, but not life threatening. Myelomeningocele (MMC) may be the most controversial of the current nonlethal indications for fetal surgery. While fetal repair of myelomeningocele is now performed using open fetal surgical techniques, it was first attempted using a fetoscopic approach by the group at Vanderbilt (Bruner, 1998; Bruner et al., 1999). The uterus was exteriorized and three fetoscopic ports were placed, one for the fetoscope and two operative ports (Bruner et al., 1999). A maternal split-thickness skin graft was placed over the myelomeningocele defect and secured using Surgicel and fibrin glue in four patients between 22 and 24 weeks' gestation. The results were disappointing: two fetal losses occurred, one from intrauterine fetal demise due to placental abruption and the other due to severe prematurity. Although the intent was palliative (i.e., providing cover and protection to the neural tube defect in utero to preserve neurologic function until a more definitive repair could be performed postnatally), none of the split-thickness skin grafts survived. The two survivors in this small series did not appear to benefit from this procedure, and the Vanderbilt group has abandoned this approach in favor of an open surgical technique until technical advances in fetoscopic instrumentation may make this a viable alternative approach (Tulipan and Bruner, 2001). More recently, Kohl and Gembruch (2008) have reported fetoscopic

closure using a gortex patch in myelomeningocele to protect the exposed spinal cord. It is not clear whether the approach offers any advantages over open techniques or the previously reported fetoscopic approach.

The MOMS (*M*anagement *o*f *M*yelomeningocele *S*tudy) trial is a National Institute of Child Health and Human Development sponsored study that began in *2003 to assess the outcomes* of prenatal and postnatal closure of myelomeningocele. This ongoing study is enrolling approximately 200 women from Fetal Surgery Units Network sites, and randomizing them either to prenatal surgery between 19 and 25 weeks of gestation or to postnatal surgery. Pediatric outcomes will be assessed at 12 months and at $2\frac{1}{2}$ years of age. When available, results of this study should provide additional information regarding the optimal timing of surgical intervention for prenatally diagnosed neural tube defects.

Amniotic band syndrome

The amniotic band syndrome (ABS) is another example of a usually nonlethal anomaly potentially treatable by fetoscopic surgery. ABS is a group of sporadic congenital anomalies (including the limbs, craniofacial regions, and trunk) ranging from constrictive bands to pseudosyndactyly to amputation, as well as multiple craniofacial, visceral, and body wall defects (Torpin, 1965; Jones et al., 1974; Higginbottom and Jones, 1979; Seeds et al., 1982; Ray et al., 1988; Lockwood et al., 1989; Seidman et al., 1989; Kulkarni and Gopal, 1990). Constrictive bands most commonly affect the extremities, but can also involve the umbilical cord and result in fetal demise (Torpin, 1965; Graf et al., 1987; Moerman et al., 1992; Kanayama et al., 1995). Recently, Crombleholme et al. (in press) successfully treated three fetuses with umbilical cord ABS, averting cord accident with survival in all three patients.

We have performed fetoscopic laser release of six cases of extremity amniotic bands, with impending limb amputation. Secondary lymphedema persisted postnatally in two fetuses, while atrophy of the hand occurred in another. One lower extremity in which the band was released before there was irreversible damage was completely normal by the time of delivery. The results of these few cases establish at least the feasibility and safety of performing fetoscopic release of amniotic bands with the potential to salvage the extremities. In cases of umbilical cord involvement, this approach also has the potential of being lifesaving.

Fetoscopic Treatment of Complications in Monochorionic Twins

Monochorionic twins discordant for anomaly

Twin gestations are at increased risk for the development of congenital anomalies. A range of congenital malformations such as anencephaly, omphalocele, hydrocephalus, and atresia/stenosis of the gastrointestinal tract are more common in twin gestations (Bajoria and Kingdom, 1997). Congenital heart defects are twice as prevalent in monozygotic twins than dizygotic twins or singleton pregnancies (Burn, 1995). In addition, it has been noted that twins discordant for anomaly deliver even earlier than the average twin delivery of 34 weeks (Malone and D'Alton, 1999). Therefore, there are increased risks for the healthy co-twin not only from intrauterine demise of the anomalous co-twin but also from the risks attendant to extremely premature delivery.

It is important to distinguish the chorionicity of a twin gestation when one of the twins has a structural or karyotypic abnormality. In a dichorionic pregnancy, it is possible to observe spontaneous intrauterine fetal demise or perform selective feticide by means of a potassium chloride injection without significant risk to the healthy co-twin (Golbus et al., 1988). This is not the case with monochorionic pregnancies in light of the vascular connections between the twins, or chorioangiopagus. In the past, because alternative interventions such as sectio parva or ultrasound-guided embolization have been unsuccessful, the usual recommendation has been to manage these pregnancies expectantly. In monochorionic gestations, however, this strategy leaves the healthy co-twin at risk for simultaneous intrauterine fetal demise or severe neurologic injury in the event of co-twin demise. Fetoscopic cord ligation or intrafetal RFA provides a viable therapeutic option under these circumstances. Crombleholme et al. (1996) reported the first use of fetoscopic cord ligation specifically to prevent neurologic injury in a surviving twin when death of a co-twin was anticipated, and several groups have since reported success with fetoscopic cord ligation or coagulation (Deprest et al., 2000; Nicolini et al., 2001; Johnson et al., 2002). A less invasive approach we currently favor is ultrasound-guided intrafetal RFA (Livingston et al., 2007) (see section on "Twin Reversed Arterial Perfusion Sequence" below).

Twin reversed arterial perfusion sequence

Twin reversed arterial perfusion (TRAP) sequence occurs only in the setting of a monochorionic pregnancy and complicates approximately 1% of monochorionic twin gestations, with an incidence of 1 in 35,000 births (James, 1977). In the TRAP sequence, the acardiac/acephalic twin receives all of its blood supply from the normal or so-called "pump" twin. The acardiac twin has a grossly anomalous circulation that is sustained in a parasitic manner by the normal co-twin ("pump" twin) through reversed perfusion of the arterial–arterial anastomoses. Because of the increased demand the abnormal circulation in TRAP sequence places on the heart of the "pump" twin, cardiac failure is the primary concern. If left untreated, the "pump" twin dies in up to 50% to 75% of cases. This is especially true when the acardiac/acephalic twin is greater than 50% of the size of the "pump" twin by estimated weight (Moore et al., 1990).

At least 33 cases of umbilical cord ligation or coagulation for TRAP sequence have now been reported (Porreco et al., 1991; McCurdy et al., 1993; Quintero et al., 1994, 1996; Hecher et al., 1995; Willcourt et al., 1995; Rodeck et al., 1998;

Deprest et al., 2000; Nicolini et al., 2001; Johnson et al., 2002) and an additional 7 cases have been treated by umbilical cord laser coagulation (Willcourt et al., 1995). Laser coagulation is not recommended after 21 weeks' gestation (Challis et al., 1999). The most common complication was the development of premature rupture of membranes, complicating up to 30% of cases (Porreco et al., 1991; McCurdy et al., 1993; Quintero et al., 1994, 1996; Hecher et al., 1995; Willcourt et al., 1995; Rodeck et al., 1998; Deprest et al., 2000; Nicolini et al., 2001; Johnson et al., 2002). Challis et al. (1999) reported a failure rate for cord coagulation of 10%, with fetal survival of 71%, and risk of preterm premature rupture of membranes of 30%.

In recent years, we have converted to the use of intrafetal RFAin TRAP sequence with 95% "pump" twin survival. This is consistent with the survival reported by UCSF (Tsao et al., 2002). The experience at Cincinnati and UCSF compare favorably with the experience of European groups who report an overall survival rate of 85% with fetoscopic bipolar electrocautery. Lee et al. (2008) reported the North American Fetal Therapy Network (NAFTNet) experience with intrafetal RFA at five centers. Not surprisingly, the centers with the most experience had the best survival and fewest complications (Lee et al., 2008).

Twin—twin transfusion syndrome

The natural history of severe twin–twin transfusion syndrome (TTTS) is well established, with mortality approaching 100% if left untreated, especially when it presents at less than 20 weeks' gestation (Weir et al., 1979; Cheung et al., 1995; Saade et al., 1997) (see Chapter 119).

The first treatment of TTTS that attempted to treat the underlying chorioangiopagus was reported by DeLia et al. (DeLia et al., 1995; Ville et al., 1995). Fetoscopic laser was used to photocoagulate vessels crossing the inter-twin membrane. In the first series of cases of TTTS, DeLia et al. (1995) reported a survival of 53% in 26 patients. While survival was not significantly better than previous reports with serial amnioreduction, the neurologic outcome was normal in 96%. Other groups from Europe have reported similar survival with fetoscopic laser photocoagulation. Ville et al. (1995) reported 53% survival with a nonselective laser technique, which was better than the survival observed with historical controls at the same center with serial amnioreduction (37%). There also appeared to be an improved neurologic outcome in fetuses treated by laser. Nonselective fetoscopic laser photocoagulation of all vessels crossing the inter-twin membrane may be problematic, as the inter-twin membrane often bears no relation to the vascular equator of the placenta. This may result in sacrifice of vessels not responsible for the TTTS, resulting in a higher death rate of the donor twin from acute placental insufficiency (Quintero et al., 1998). More recently a selective laser photocoagulation technique has been reported (Quintero et al., 1998). The selective technique does not photocoagulate every vessel crossing the inter-twin membrane; only direct, arterial–arterial and veno-venous, connections are photocoagulated, along with any unpaired artery going to a cotyledon with the corresponding vein (and vice versa) going to the opposite umbilical cord (Figure 5-3). In a nonrandomized comparison of patients treated by serial amnioreduction at one center and selective laser photocoagulation at another, the overall survival was not significantly different (61% for laser vs. 51% for serial amnioreduction) (Hecher et al., 1999). However, the survival of at least one twin with laser photocoagulation was 79%, while survival of at least one twin with serial amnioreduction was only 60% (Hecher et al., 1999). This was not a controlled trial, and patients were not randomized.

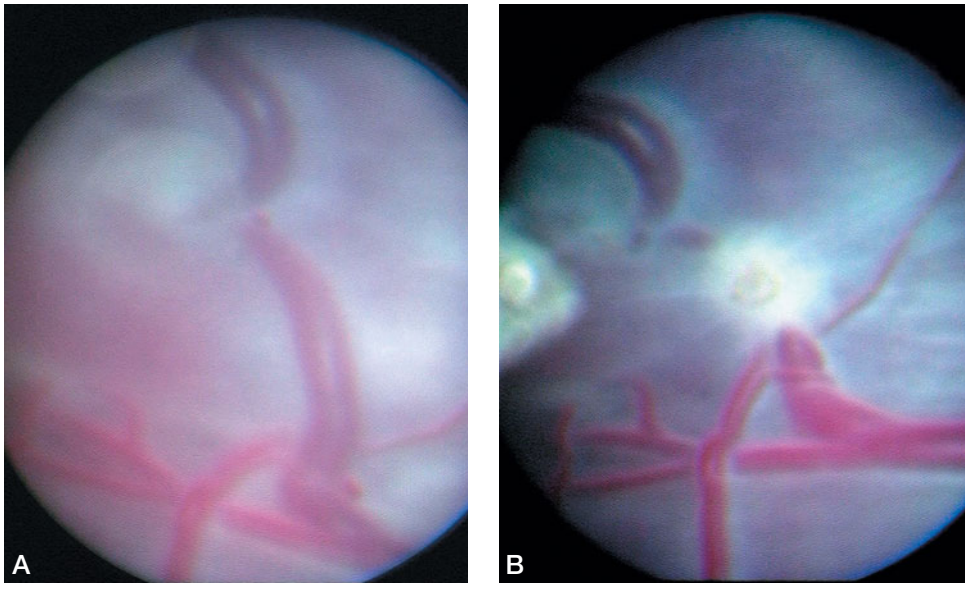

Figure 5-3 Fetoscopic view of chorioangiopagus on a monochorionic placenta before (**A**) and after (**B**) selective fetoscopic laser photocoagulation in a case of severe TTTS.

Quintero et al. (2003) retrospectively examined data from 78 patients treated by serial amnioreduction and 95 patients treated with selective laser photocoagulation with no significant difference in the distribution of patients by stage. Perinatal survival was not significantly different in the laser versus amnioreduction group (64.2% vs. 57.7%). However, there was an inverse relationship between fetal survival and stage in the amniocentesis group but not in the laser group. For stage IV disease, there was a significantly lower fetal survival in the amnioreduction group compared with the laser group (20.6% vs. 63.6%, $P = 0.001$). This information has important implications for evaluation of treatment options and the development of stage-based treatment protocols.

The Eurofoetus trial conducted by Senat et al. (2004) was the first prospective randomized trial that compared the efficacy and safety of treatment of twin-to-twin transfusion syndrome with laser therapy versus serial amnioreduction. Women presenting between 15 and 26 weeks' gestation with polyhydraminos in the recipient twin and oligohydramninos in the donor twin were allowed to participate. Fifty-two percent of patients were stage I or II, 47% were stage III, and 1% were stage IV. Enrollment was halted after a planned interim analysis revealed a significantly higher likelihood of survival of at least one twin to 28 days of age (76% vs. 56%, $P = 0.009$) and to 6 months of age (76% vs. 51%, $P = 0.002$) in the laser group compared to the amnioreduction group. More infants were alive without neurologic abnormalities detected on neuroimaging studies in the laser group as well (52% vs. 31%, $P = 0.003$). The overall survival in the laser arm was 57%. This is consistent with previous reports of nonselective fetoscopic laser (53%) (DeLia et al., 1995; Ville et al., 1995). This is significantly lower, however, than the survival reported with selective fetoscopic laser (64–68%) (Hecher et al., 2000; Fisk et al., 2004). Of particular concern is the poor survival that was observed in the amnioreduction arm. The overall survival was only 39%, which is significantly lower than previously reported (60–65%) (Elliott et al., 1991; Pinette et al., 1993; Dickinson and Evans, 2000; Mari et al., 2001). Antenatal, peripartum, and neonatal care were provided by the referring hospital and lack of standardization may explain some of these differences (Fisk et al., 2004). The decreased survival in the amnioreduction group may reflect the higher pregnancy termination rate in the amnioreduction group (16 patients vs. 0 patients in the laser group). The terminations were requested after the diagnosis of severe fetal complications; it would be instructive to know whether these women were offered cord coagulation as a means of rescuing one baby (Fisk et al., 2004). Reliable assessment of neurologic outcome is critical when assessing efficacy of treatment for TTTS. While there was a lower rate of abnormality on neurologic imaging in the laser group (7% vs. 17%), long-term neurodevelopmental assessment has revealed no difference in outcome between survivors treated by fetoscopic laser versus those treated by amnioreduction.

The NIH-sponsored TTTS trial is the only other prospective randomized trial comparing the survival with amnioreduction versus selective fetoscopic laser phtotocoagulation (Crombleholme et al., 2007). This trial differed from the Eurofetus trial in several important aspects. First, in order to qualify for the NIH Trial, the TTTS had to fail to respond to a qualifying amniocentesis. The rationale for this requirement was to eliminate subjects who were more likely to respond to amnioreduction, the so-called "single amnio paradox." Secondly, patients were only candidates if the TTTS presented earlier than 22 weeks and no stage I patients were candidates for the trial. These two requirements were quite different from the Eurofetus trial in which subjects were randomized up to 26 weeks' gestation, and 52% of those entered were stage I (Senat et al., 2004).

The study was stopped after 42 subjects were randomized because the Trial Oversight Committee detected a trend in adverse outcome affecting the recipient twin in one treatment arm. Based on this finding, the Trial Oversight Committee recommended to the Data Safety Monitoring Board that the trial be stopped early to allow biostatistical analysis of this adverse trend. The results of the NIH TTTS trial showed no statistically significant difference in overall neonatal survival to 30 days of life (60% vs. 43% p = NS) or neonatal survival of one or both twins in the same pregnancy (75% vs. 65%, p = NS) in cases of severe TTTS treated by either AR or selective fetoscopic laser photocoagulation (SFLP). Despite these overall results, there is a statistically significantly worse fetal survival observed among recipient twins in pregnancies treated by SFLP compared to those treated by AR. This apparent conundrum can be accounted for by recipient fetal losses in the SFLP arm being balanced by increased treatment failures among recipient subjects in the AR arm. These results suggest that, in these highly selected cases of severe TTTS, neither treatment is superior to the other. Once TTTS reaches this severity, the mortality among recipients will be considerable, but the losses may occur at different times depending on treatment. The impact of TTTS severity on fetal survival is further supported by the significantly worse fetal survival among recipient twins in stages III and IV compared to stage II. One of the strongest predictors of recipient demise is echocardiographic evidence of TTTS cardiomyopathy. The losses of fetal recipients treated by SFLP usually occur within 24 hours of the procedure. In contrast, the recipients treated by AR are not lost following the procedure, but there is progressive TTTS cardiomyopathy as reflected by more recipients in the AR arm meeting criteria to be declared treatment failures. Taken together these data suggest a disproportionate impact of TTTS cardiomyopathy on recipient survival in advanced stages of TTTS no matter what treatment they receive.

Recently, Rossi et al., reported a Cochrane review of TTTS with a meta-analysis including data from both the Eurofetus and NIH trials. The conclusion drawn from this analysis was that selective fetoscopic laser treatment of TTTS is preferred over amnioreduction when it is available and amnioreduction when it is not (Rossi and D'Addario, 2008). The results of this analysis are likely to be skewed toward fetoscopic laser based on the small numbers of subjects included from

Table 5-3

Comparison of Overall Survival (Number of Fetuses Treated Divided by Number of Surviving Newborns) and Percentage of Pregnancies with One or Both Twins Surviving in Reported Series Using Selective Fetoscopic Laser Photocoagulation*

	Year	Overall Fetal Survival (%)	At Least 1 Survivor (%)
Hecher	1999	61	79
Hecher	2000	68	81
Quintero	2000	61.3	83
Quintero	2003	64.2	83.2
Huber	2004	70	83
Huber	2006	71.5	83.5
Crombleholme	2007	77	91.7

** The overall survival trend has been improving indicating better outcomes as experience with this technique grows.*

the NIH trial ($n = 40$) compared to the number included from the Eurofetus trial ($n = 142$).

Amnioreduction is readily available, less costly and less invasive; laser therapy is only available at select institutions and requires specialized training. While it makes sense to use the former where treatment options give similar results, it would be prudent to move promptly to laser therapy if rigorous studies can prove laser has better short-term and long-term outcomes in the setting of advanced disease (see Table 5-3).

One potential limitation to the success of laser treatment is the presence of deep vascular AV anastomoses that cannot be identified endoscopically. In one study, vascular casts of 8 of 15 placentae (53%) demonstrated potentially significant atypical AV anastomoses such that two apparently normal cotyledons were actually communicating below the chorionic surface (Wee et al., 2005). A second type of atypical AV anastomoses was noted in 11 of the 15 placentae (73%) in which shared cotyledons arise within larger apparently normal cotyledons. One would be able to see these anastomoses as shared cotyledons on endoscopy; ablating these has the potential to destroy some surrounding normal cotyledon which, in the donor's territory, could contribute to placental insufficiency (Wee et al., 2005). It has also been recognized that in up to 20% of cases, communicating vessels on the chorionic plate are missed at the time of fetoscopic laser treatment (Lopriore et al., 2007). However, only 5% of these cases were associated with persistence of TTTS. These observations point to the necessity of a careful fetoscopic inspection of the chorionic plate to be certain that no vessel has been missed.

Open Fetal Surgery

The technical aspects of open fetal surgery were developed by Harrison and colleagues in extensive animal experiments using fetal sheep and rhesus monkeys (Harrison and Adzick, 1990). Using these experimental animal models, anesthetic, tocolytic, and surgical techniques were developed and applied clinically. Innovative techniques for opening and closing the gravid uterus were developed that minimize the risks to the mother's health and future reproductive potential (Harrison et al., 1993). This included the development of a uterine stapling device to minimize myometrial bleeding (Adzick et al., 1985a; Bond et al., 1989). The details of techniques used for specific diagnoses requiring fetal surgery are covered under the fetal intervention sections of the chapters on these topics. The approaches to entering the gravid uterus, fetal exposure, fetal and maternal monitoring, and anesthetic and tocolytic management are largely the same and are discussed below.

The maternal abdomen is exposed through a low transverse abdominal incision. The fascial incision is determined by the position of the placenta. In the case of a posterior placenta a midline fascial incision can be used, as the uterus will not need to be lifted out of the abdomen. In contrast, in an anteriorly placed placenta, the rectus muscles need to be divided in order to allow room to tilt the uterus out of the abdomen, facilitating a fundal or posterior hysterotomy. A large abdominal ring retractor (Turner-Warwick, V. Mueller, Berlin, Germany) is used to maintain exposure. Sterile intraoperative ultrasound examination is then used to map the fetal position and the placental location. The edge of the placenta is marked under ultrasound guidance using electrocautery. The position and the orientation of the hysterotomy is planned in order to stay parallel to the closest edge of the placenta and 4 to 5 cm from it.

Two different techniques have been used for performing the hysterotomy. A 2-cm incision is made through the myometrium and amnion using electrocautery. This hysterotomy incision is then extended using a specially developed absorbable Lactimer stapler (U.S. Surgical Corporation, Norwalk, CT) that is fast and hemostatic and seals the membranes to the myometrium (Adzick et al., 1985a; Bond et al., 1989). The second technique for performing a hysterotomy uses a trocar attached directly to the uterine stapling device. Two traction sutures are placed to elevate the membrane and myometrial wall from the fetus, and a specially designed trocar attachment that fits on the anvil of the uterine stapling device is inserted directly into the amniotic cavity under ultrasound guidance.

Once the hysterotomy is performed, it is necessary to infuse saline in order to avoid cord compression. A red rubber catheter attached to a Level I rapid volume infusion device is

inserted into the amniotic cavity, which delivers a continuous stream of normal saline warmed to 37°C. The appropriate fetal part is then exposed, leaving the rest of the fetus entirely within the womb. A miniaturized pulse oximeter is wrapped around the fetal palm and protected with a clear plastic adhesive, then shielded from extraneous light with sterile foil wrapping or Coban.

Once the specific defect has been repaired, the fetal part is then returned to the uterus. Full-thickness number 1 PDS stay sutures are then placed along the length of the hysterotomy. As the staples are made of polyglycolic acid and are absorbable, they are left in place to avoid bleeding from the hysterotomy edges. A watertight three-layer uterine closure is then performed, using a running O PDS. Just prior to completing the first layer, 400 to 500 mL of warm normal saline containing 500 mg of oxacillin is instilled into the amniotic cavity to restore the AF volume to a deepest vertical pocket of 3 to 5 cm. After the hysterotomy has been closed, the stay sutures are tied and the maternal laparotomy incision is closed in layers. A subcuticular maternal skin closure is used with a transparent adhesive dressing to facilitate postoperative monitoring by a tocodynamometer and ultrasound examination.

Tocolysis is administered as soon as the uterus is closed with a 6 g load of magnesium sulfate over 1 hour, which then continues at 2 g per hour, or at a higher dose, as clinically indicated by uterine irritability. As the mother emerges from deep anesthesia with isoflurane, there is a tendency for uterine tone to return and for uterine contractions to be observed. To supplement the magnesium sulfate, rectal indomethacin on a schedule of 50 mg every 4 to 6 hours is also used for the first 48 hours. When using indomethacin in this setting, it is our practice to perform daily fetal echocardiography to evaluate for ductal constriction. Patient-controlled analgesia is also an essential part of the tocolytic management. If the mother is having pain, this will be reflected in increased uterine irritability. We currently use a continuous fentanyl infusion supplemented by bupivacaine for postoperative pain control, delivered through an epidural catheter, with patient-controlled rescue doses. The systemic levels of fentanyl achieved with the use of this epidural technique are sufficient to cross the placenta and provide fetal analgesia as well.

Far and away the most difficult problem in the management of the maternal–fetal patient following fetal surgery is the control of preterm labor. The large hysterotomy necessary for these procedures uniformly results in preterm labor. This has led to the development of an aggressive tocolytic regimen that often includes combinations of indomethacin, isoflurane anesthesia, magnesium sulfate, terbutaline, calcium channel blockers, and most recently intravenous nitroglycerin as a nitric oxide donor (Adzick and Harrison, 1994b). Despite aggressive tocolytic therapy, the median interval from fetal surgery to delivery is only 8 weeks, with a range of 1 to 15 weeks (Harrison, 1993).

Although the benefits to the fetus with an otherwise lethal congenital malformation are obvious, there are no direct benefits to the mother, who must assume the risks of fetal surgery and obligatory delivery by cesarean section. Unlike any other procedure, with the possible exception of organ transplantation from a living donor, fetal surgery exposes two patients—the mother and the fetus—to the risks of anesthesia, surgery, hysterotomy, and postoperative tocolysis.

There have been no reports of maternal deaths related to open fetal surgery, but the potential for maternal morbidity is formidable. Among the 42 cases reported by Harrison, 5 patients have required perioperative blood transfusions. AF leaks were observed in five patients, two via the hysterotomy site requiring reoperation and three via the vagina. Preterm labor was uniformly observed, and the majority of the morbidity occurred as a result of aggressive treatment of preterm labor, including pulmonary edema induced by tocolytic agents (Harrison et al., 1993). In addition to these short-term complications, women undergoing fetal surgery also face long-term consequences as a result of fetal surgery. Specifically, the hysterotomy used in fetal surgery is not in the lower uterine segment and remains a weakened area in the myometrium. Accordingly, these women are at risk for rupture during active labor with subsequent pregnancies. Because of the nature of the hysterotomy used in all open fetal surgeries, it is mandatory that women undergoing open fetal surgery be delivered by cesarean section prior to onset of labor in the index pregnancy as well as in all future pregnancies.

Given the maternal risks associated with fetal surgery, careful monitoring of maternal status—including arterial blood pressure and pulse oximetry—is necessary in the postoperative period. In addition, appropriate fetal monitoring includes telemetric fetal heart monitoring, serial sonography, and surveillance of preterm labor by external tocodynamometer. Optimal monitoring of both patients can best be managed in a fetal–maternal intensive care unit that combines the capabilities and expertise of both an intensive care unit and a labor floor (Jennings et al., 1993).

The specific anatomic malformations in which open fetal surgery has already been employed are listed in Table 5-4. Detailed discussions of these specific conditions are reviewed in the chapters that follow.

Ex utero Intrapartum Treatment (EXIT procedure)

The central principle of the EXIT procedure is to maintain controlled uterine hypotonia and preserve uteroplacental circulation while performing a fetal procedure. The ex utero intrapartum technique (EXIT) procedure was initially described for reversal of tracheal occlusion in fetuses with severe CDH (Mychaliska et al., 1997). These cases required neck exploration for the removal of the tracheal clips, with maintenance of uteroplacental blood flow until the fetal airway was secured by endotracheal intubation. Experience with the EXIT technique demonstrated the ability to maintain fetal and maternal hemodynamic stability, and soon led to expanded indications for its use. Indications for EXIT procedures now include giant fetal neck masses, fetal mediastinal

Table 5-4

Fetal Malformations Treatable by Open Fetal Surgery

Fetal Malformation	Fetal Presentation	Fetal/Neonatal Consequences
Posterior urethral valves	Hydronephrosis and oligohydramnios	Renal dysplasia and renal insufficiency Pulmonary hypoplasia and respiratory insufficiency
Cystic adenomatoid malformation of the lung	Chest mass with mediastinal shift and hydrops	Pulmonary hypoplasia and respiratory insufficiency
Congenital diaphragmatic hernia	Herniated viscera in chest	Pulmonary hypoplasia and respiratory insufficiency
Twin–twin transfusion syndrome	Oligohydramnios and polyhydramnios	IUFD, heart failure, MLE
Acephalic-acardiac twin	IUFD	
Sacrococcygeal teratoma	High-output failure hydrops	IUFD, prematurity, hemorrhage
Complete heart block	Hydrops	IUFD
Fetal neck mass	Polyhydramnios	Inability to ventilate due to lack of airway

IUFD = intrauterine fetal death; MLE = multifocal leukoencephalomalacia.

or lung masses, congenital high airway obstruction syndrome (CHAOS), as well as congenital heart disease requiring immediate ECMO (see Table 5-5).

A common misconception is that an EXIT procedure is merely a cesarean section. The goals of a cesarean delivery are to (1) maximize the uterine tone to prevent postpartum hemorrhage; and (2) minimize the transplacental diffusion of inhalational anesthetic agents to avoid neonatal depression (if performed under general anesthesia). In contrast, the goals during the EXIT procedure are to (1) achieve a state of uterine hypotonia so to maintain the uteroplacental circulation using deep general anesthesia; (2) preserve uterine volume so to prevent placental abruption; (3) reach a deep plane of maternal anesthesia but maintain normal maternal blood pressure; and (4) achieve a surgical level of fetal anesthesia without cardiac depression. In addition, the EXIT procedure requires synchronized team work involving multiple disciplines, including at least one or two pediatric surgeons or a pediatric otolaryngologist, a maternal–fetal medicine specialist or obstetrician, an echocardiographer, a neonatologist, two anesthesiologists, two circulating nurses, and two scrub nurses. Unlike standard obstetric anesthetic practice in which regional anesthesia is the rule, general anesthesia is the technique of choice for patients undergoing the EXIT procedure.

As with any fetal surgical procedure, the EXIT procedure involves the treatment of two patients: the mother and her baby. For this reason, we usually have one anesthesiologist for the mother and another for the baby. There are a number of maternal and fetal anesthesia considerations that must be managed. The physiology of pregnancy contributes to a number of maternal and fetal anesthetic risks. The mother is at increased risk for aspiration pneumonitis due to pregnancy-related reduction of lower esophageal sphincter pressure, the increased pressure of the gravid uterus on the stomach, and increased gastric acid production. The cardiovascular system is also affected during pregnancy. A decrease in the preload during supine positioning can cause maternal hypotension, decreased uterine artery perfusion, and thus fetal hypoxia. It is therefore important to position the mother with a left uterine displacement to maximize venous return to the heart and preserve an adequate maternal cardiac output. In pregnancy there is an expanded blood volume, but a lower hematocrit and an increase in peripheral venous capacity. Pregnancy also affects pulmonary function, with a decrease in functional residual capacity that puts the mother at an increased risk for hypoxia. For these reasons, maternal anesthesia is induced through a rapid-sequence technique using a combination of thiopental (5 mg/kg), succinylcholine (2 mg/kg), and fentanyl (1–2 mg/kg) administered intravenously. This is followed by immediate endotracheal intubation. Paralysis is maintained using intravenous vecuronium titrated by peripheral nerve stimulation.

Support of the fetus during the EXIT procedure depends entirely on the preservation of uteroplacental gas exchange. Both uterine and umbilical artery blood flow influence fetal oxygenation. Uterine artery blood flow is affected by maternal systemic blood pressure and myometrial tone. Volatile anesthetics used during the EXIT procedure not

Laryngeal atresia
EXIT-to-Airway for micrognathia

only decrease myometrial tone but also tend to decrease both maternal blood pressure and placental blood flow. This can result in a decrease in fetal oxygenation (Luks et al., 1996). Maintenance of maternal blood pressure within 10% of baseline is therefore critical for adequate fetal oxygenation during the EXIT procedure. Maintenance of maternal blood pressure is achieved using ephedrine to counterbalance the hypotensive effects of the high concentrations of inhalational agents used in EXIT procedures. Ephedrine acts selectively on peripheral vascular resistance and sparing placental circu1ation (Gaiser and Kurth, 1999). Uteroplacental gas exchange is also dependent on umbilical artery blood flow, which is influenced by fetal cardiac output and placental vascular resistance. Preservation of fetal cardiac output is thus important in maintaining fetal oxygenation.

The cardiovascular physiology of the fetus is different from that of full-term neonates in that the cardiac output is more dependent on heart rate rather than on stroke volume. In addition, high vagal tone and low baroreceptor sensitivity cause the fetus to respond to stress with a decrease in heart rate. The fetus primarily relies on increased heart rate to increase cardiac output and blood flow redistribution in response to stress. This preserves oxygenation for the brain at the expense of the rest of the body. In addition to the peculiar characteristics of fetal physiology, inhalational anesthetics also cause a direct fetal myocardial depression, vasodilatation, and changes in arteriovenous shunting, all of which can lead to fetal hemodynamic instability (Biehl et al., 1983). These physiologic differences and responses to anesthetic agents require continuous fetal monitoring to ensure uncompromised uteroplacental gas exchange and fetal well-being.

The inhalational anesthetic regime used during the EXIT procedure passes through two different stages. Anesthesia is at first maintained with 0.5 MAC (minimal alveolar concentration) of desflurane, isoflurane, or sevoflurane in oxygen, and is then increased to 2 MAC before maternal incision. More recently, we have used total intravenous anesthesia (TIVA) to prevent transplacental passage of inhalational agent that may act as a fetal myocardial depressant. Inhalational agent is used only at time of hysterotomy to achieve the desired relaxation of uterine tone. Occasionally, a tocolytic is given to augment the uterine relaxation. A number of tocolytic agents can be used as an adjunct to inhalational agents, including indomethacin, terbutaline, or nitroglycerine. Indomethacin may also prevent prostaglandin-mediated increases in placental resistance independent of its effects on uterine tone (Holcberg et al., 2001). Maintenance of uterine volume is also important to prevent uterine contraction. This is accomplished by preventing the fetus from completely delivering and by the use of amnioinfusion with warm Ringer's lactate solution administered via a rapid infuser to prevent cord compression.

The second critical stage of the anesthetic technique comes just before clamping of the cord and ending the EXIT procedure. During this stage, coordination between the surgical and anesthesia teams is crucial to prevent uterine atony and excessive maternal bleeding. The volatile anesthetic is decreased to 0.5 MAC or turned off entirely to allow uterine tone to return to normal. This is followed by administration of oxytocin 20 units in 500 mL of normal saline intravenously as a bolus followed by 10 units in a 1000-mL drip titrated to enhance uterine contraction. If required, further measures are taken to decrease the risk of uterine atony. These measures include uterine massage and administration of 0.25 mg Methergine and 250 mg carboprost (F2-alpha prostaglandin) via intramuscular or intravenous injection. After skin closure, the inhalational anesthetic is discontinued and 100% oxygen is administered. Maternal paralysis is reversed by the use of glycopyrrolate (10 mg/kg) and neostigmine (0.7 mg/kg), and the patient is extubated after spontaneous breathing is observed (Bouchard et al., 2002).

Fetal anesthesia is provided primarily through the transplacental passage of the volatile anesthetics. However, this takes about an hour to reach 70% of the maternal levels. As such, before fetal incision, a cocktail comprising 10 to 20 mg/kg fentanyl, 20 mg/kg atropine, and 0.2 mg/kg vecuronium is administered intramuscularly to supplement anesthesia and provide for postoperative analgesia.

Close maternal and fetal monitoring during the EXIT procedure are aimed at the early recognition and management of problems as they arise. Maternal monitoring includes invasive arterial blood pressure monitoring (arterial line) to recognize possible maternal hypotension that will jeopardize fetal oxygen transport, as well as continuous maternal electrocardiography, pulse oximetry, and end-tidal CO_2 monitoring.

Continuous fetal monitoring is also of paramount importance during the EXIT procedure. Fetal arterial saturation is monitored by a reflectance pulse oximeter placed on the fetal hand and wrapped with foil to decrease ambient light exposure (Dassel et al., 1992). Normal fetal arterial saturation is 60% to 70%, although values greater than 40% represent adequate fetal oxygenation. Continuous intraoperative fetal echocardiography is also used to monitor fetal cardiovascular function (Rychik et al., 2004). The use of fetal echocardiography helps to identify early problems such as decreased filling, fetal bradycardia, decreased myocardial contractility, ductal constriction, and atrioventricular valve incompetence (Figure 5-4). These are all signs of fetal distress that require prompt treatment. Fetal arterial or venous blood gases may be obtained through umbilical vessel puncture during periods of fetal distress to guide in therapy. An intravenous access is essential to allow administration of fluids, blood, or medications for inotropic support when needed.

The decision to enter the abdomen through a low transverse skin incision or through a midline fascial incision is based on the placental location, predicted site of hysterotomy, and the indication for performing the EXIT procedure. The incision of choice is usually a low transverse abdominal incision unless the anterior position of the placenta necessitates a posterior hysterotomy. In the latter case, a midline laparotomy is required. After laparotomy, the uterus is examined for adequacy of myometrial relaxation, and concentration of inhalational agents is adjusted as necessary. Before fashioning the hysterotomy, precise sonographic mapping of the placental edge is crucial to avoid placental injury and hemorrhage. A sterile intraoperative ultrasound is used to map the placental borders. This is performed while considering the position of the fetal head and neck to avoid excessive fetal manipulation after hysterotomy. The position of the hysterotomy is dictated by the placental location. A low anterior placental site precludes a low transverse hysterotomy and may necessitate a posterior approach for the hysterotomy. Special considerations are important in cases of severe polyhydramnios. Amnioreduction in these cases is necessary to avoid underestimation of the proximity of the placental edge to the hysterotomy. To adequately manipulate the fetus, it is sometimes necessary to decompress any accompanying fetal ascites or cystic mass. This can be achieved by using a 20- or 22-gauge spinal needle under U.S. guidance. In some instances, the use of amnioinfusion and fetal version before hysterotomy facilitate the exposure (Hedrick, 2003). During EXIT procedures, hysterotomy is performed using a specially designed uterine stapler (U.S. Surgical Corporation, Norwalk, CT) to decrease the incidence of bleeding (Bond et al., 1989). Following hysterotomy, maintenance of uterine volume is one of the most important steps in an EXIT procedure. This is done to decrease the likelihood of uterine contraction and placental abruption, thus maintaining continuous maternal–fetal oxygen transfer. Warm Ringer's lactate solution is infused after the hysterotomy to maintain the uterine volume and prevent cord compression. Limited exposure of the fetus during the EXIT procedure also helps in maintaining the uterine volume and fetal temperature. Only the head, neck, and shoulders are exposed while keeping the remainder of the fetus and the cord intrauterine.

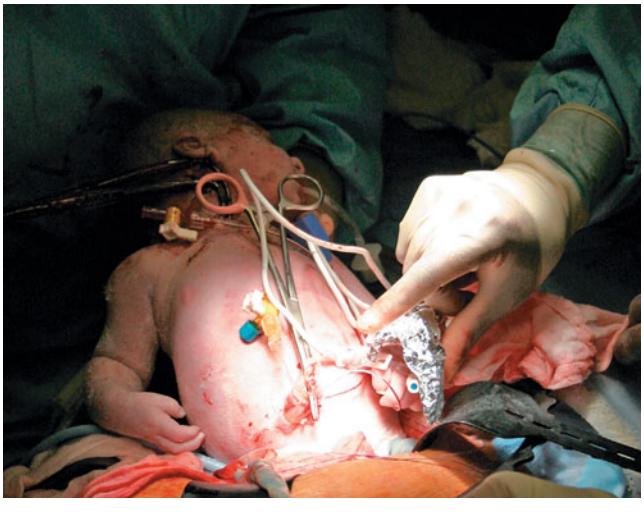

Figure 5-4 An intraoperative view during an EXIT procedure demonstrating continuous fetal monitoring using a sterile echocardiography, reflectance pulse oximetry, and IV access lines.

Figure 5-5 Bronchoscopy during an EXIT procedure to secure a fetal airway.

The most important aspect of fetal airway management during an EXIT procedure is preparedness for every contingency. In that one can never assume that the fetus will only require direct laryngoscopy and intubation, we have developed an airway algorithm. In addition to the basic instruments and setup, the following items should be available on a separate airway table managed by a second scrub nurse: direct laryngoscopy supplies with Miller 0 and 00 blades, armored endotracheal tubes (ETTs) appropriate for the size of the fetus, endotracheal tube exchangers, 2.5 and 3.0 Fr feeding tubes for surfactant administration, 2.5 or 3.0 rigid bronchoscope, a flexible bronchoscope, and a major neck tray for formal tracheostomy or mass resection.

Direct laryngoscopy and endotracheal intubation should be the first option for securing a fetal airway during EXIT procedures (Figure 5-5). In cases in which there is distortion of the normal anatomy, flexible and/or rigid bronchoscopy may be necessary to visualize and diagnose

Table 5-6

Pitfalls of the EXIT Procedure

Failure to achieve adequate uterine relaxation	Compromise uteroplacental gas exchange
Failure to treat polyhydramnios	Inaccurate mapping of placental edge—hemorrhage
Failure to plan for fetal position relative to hysterotomy	Difficult exposure for delivery of head
Failure to use uterine staples	Maternal hemorrhage
Failure to use deep inhalational anesthesia	Inadequate uterine relaxation—poor uteroplacental gas exchange
Failure to maintain adequate maternal blood pressure	Poor uterine artery perfusion or compromised uteroplacental gas exchange
Failure to recognize cord compression	Fetal bradycardia
Failure to recognize placental abruption	Fetal hemorrhage
Failure to make airway first fetal priority	May have to end EXIT acutely due to abruption, or persistent fetal bradycardia
Failure to prepare for every airway challenge	Fetal death. Must not assume that laryngoscopy will be successful. Must be prepared for bronchoscopy, tracheostomy, and/or mass resection
Failure to allow sufficient time for return of uterine tone	Uterine atony and maternal hemorrhage
Failure to use armored endotracheal tube (ETT)	Collapse of fetal endotracheal tube by tumor compression
Failure to confirm ETT tip position bronchoscopically	Malpositioned ETT. This is especially important with cervical or mediastinal tumors
Failure to maintain uterine volume	Acute loss of uterine volume may predispose to placental abruption
Failure to perform adequate intrapartum fetal monitoring	Unrecognized fetal distress or bradycardia
Failure to recognize maternal indications for terminating EXIT	Maternal hemorrhage
Failure to recognize fetal indications for terminating EXIT	Fetal bradycardia or arrest, fetal hemorrhage, or hypoxic brain injury

abnormal airway anatomy. The glottis is sometimes displaced cephalad above the level of the soft palate; in such cases, flexible bronchoscopy via the nares may be helpful. In other cases, mass effect may shift the glottis severely from its normal midline position. An ETT can be placed over the flexible bronchoscope or rigid lens and can be used to place the ETT beyond the level of obstruction. If this fails to secure an airway, then retrograde intubation becomes the next option in which a tracheotomy is performed through limited neck dissection. Using a Seldinger technique, an ETT exchanger is passed retrograde until seen in the oropharynx. The ETT is passed antegrade over the ETT exchanger and the tracheotomy repaired. In the case of large neck masses, traction by an assistant may lift the mass off the airway. This permits an armored ETT to be passed beyond the level of obstruction. If there is severe compression, release of the strap muscles may be required to permit passage of an armored ETT beyond the area of airway obstruction. Airway control is sometimes impossible even after all these techniques have been attempted. In these cases, reflection of the mass off the airway or resection of the mass to facilitate formal surgical tracheostomy may be necessary. Proper positioning of the tracheostomy is extremely important, especially in cases of giant neck masses in which the trachea is pulled out of the chest by neck hyperextension. It is not uncommon to find the carina at the level of the thoracic inlet due to the opisthotonic position of the head caused by a neck mass. Care should be taken to place the tracheostomy tube no lower than the second to third tracheal rings.

After securing the airway, it is prudent to confirm the position of the ETT or tracheostomy tube relative to the carina using flexible bronchoscopy. This is particularly important in patients with cervical or mediastinal masses. If required, surfactant can then be administered by a feeding tube passed through the ETT. The fetus is then ventilated by hand. Finally, umbilical arterial and venous access catheters can be placed and the cord clamped. Coordination between the surgical team and the anesthesiologists is of paramount importance at this moment to ensure adequate return of the uterine tone and proper hemostasis. The newborn is either taken to an adjoining operating room for further resuscitation and completion of the neck mass resection or to the neonatal intensive care unit for further resuscitation and stabilization.

The EXIT procedure is associated with an increased potential risk of maternal bleeding due to uterine hypotonia induced by high concentrations of inhalational agents. These high levels may also induce maternal hypotension. It is important to ensure the prompt return of uterine tone at the conclusion of the EXIT procedure to minimize maternal hemorrhage. Although uterine atony remains a significant risk and there is the potential need for hysterectomy, in our experience, the mean blood loss with EXIT procedures has been equivalent to that observed in cesarean sections. Early in our experience, we had to transfuse a patient in whom polyhydramnios caused us to underestimate the proximity of the placenta to the hysterotomy. In a review of the experience of clinicians at the UCSF, a slightly higher incidence of wound infection was reported with EXIT procedures than with cesarean sections. Although the EXIT procedure is specifically designed to optimize outcomes for the fetus, if it is not performed appropriately, there is also the potential for fetal complications. These are primarily related to failure to preserve uteroplacental gas exchange due to cord compression, placental abruption, or loss of myometrial relaxation (Table 5-6).

Management of Fetal Conditions Diagnosed by Sonography

This page intentionally left blank

Agenesis of the Corpus Callosum

CHAPTER 6

Key Points

- The corpus callosum is a major pathway connecting the two hemispheres of the brain. By the 17th week of gestation, the mature corpus callosum is formed.
- In agenesis of the corpus callosum (ACC), the commissural fibers do not cross the midline but rather form thick bundles of fibers called Probst bundles, which course in a posterior direction along the medial walls of the lateral ventricles. These bundles indent and separate the anterior horns of the lateral ventricles.
- ACC may be isolated, but often is associated with other malformations and genetic syndromes.
- ACC occurs in <1% of the general population and in 2% to 3% of the developmentally disabled population.
- The finding of mild ventriculomegaly during routine prenatal ultrasound examination should prompt a targeted search to confirm the presence of the corpus callosum.
- The most consistent and easy-to-identify finding is the teardrop configuration of the lateral ventricles.
- Prenatal magnetic resonance imaging (MRI) and three-dimensional ultrasound examination may be helpful in confirming the diagnosis. MRI may also be useful in identifying other subtle brain abnormalities that may not be apparent on sonogram but may have an impact on the long-term prognosis.
- The natural history of antenatally detected ACC is not known due to the fact that there have been relatively few case series reported.
- Fetal karyotype should be considered when ACC is diagnosed antenatally due to its association with chromosomal abnormalities.
- Patients prenatally diagnosed with ACC can be managed according to routine prenatal care guidelines.
- The neonate with suspected ACC should be examined carefully. MRI is the radiologic examination of choice.
- ACC in addition to other abnormalities is often associated with poor neurologic outcomes. The long-term outcome of isolated ACC has not yet been elucidated.
- The recurrence risk of ACC depends on the underlying cause.

CONDITION

The corpus callosum is a major pathway connecting the two hemispheres of the brain. The development of the corpus callosum begins during the 5th week of fetal life with the formation of the primitive lamina terminalis, which thickens to form the commissural plate. Glial cells coalesce to form a bridge-like structure that serves as a guide for the callosal fibers crossing the longitudinal cerebral fissure to their targets on the contralateral side of the brain (Rakic and Yakovlev, 1968). The mature corpus callosum is formed by the 17th week of gestation. In agenesis of the corpus callosum (ACC), the commissural fibers do not cross the midline; instead they form thick bundles of fibers, called "Probst bundles," which course in a posterior direction along the medial walls of the lateral ventricles. These bundles indent and separate the anterior horns of the lateral ventricles.

ACC may be an isolated finding; however, it is frequently associated with other malformations and genetic syndromes including chromosomal aberrations and inborn errors of metabolism (Parrish et al., 1979; Jeret et al., 1987; Dobyns, 1989). Associated central nervous system (CNS) abnormalities include Chiari malformations, anomalies of neuronal migration including lissencephaly, schizencephaly, pachygyria and polymicrogyria, encephaloceles, Dandy–Walker malformations, holoprosencephaly, and olivopontocerebellar degeneration (Barkovich and Norman, 1988). Extracranial malformations include abnormalities of the face and of the cardiovascular, genitourinary, gastrointestinal, respiratory, and musculoskeletal systems (Parrish et al., 1979; Franco et al., 1993; Kozlowski and Ouvrier, 1993).

INCIDENCE

ACC has been estimated to occur in 0.3% to 0.7% of the general population and in 2% to 3% of the developmentally disabled population (Freytag and Lindenberg, 1967; Grogono, 1968; Jeret et al., 1986). In a large series of patients diagnosed with a metabolic disease, 17% were shown to have an abnormality of the corpus callosum by computed tomography (CT), ultrasound, or autopsy examination (Bamforth et al., 1988).

In a series of 4122 perinatal or neonatal autopsy specimens, the incidence of CNS malformations was 8.8%, and of the 363 CNS malformations diagnosed, ACC accounted for 4.1% (Pinar et al., 1998).

SONOGRAPHIC FINDINGS

Usually only midsagittal and midcoronal scans of the fetal brain allow clear visualization of the corpus callosum. Such views can be obtained with standard transabdominal ultrasound examination of most fetuses in breech position or transverse lie. For fetuses in the vertex position, transvaginal sonography is the preferred technique.

On sagittal scan, the corpus callosum appears as a sonolucent band, demarcated superiorly and inferiorly by two echogenic lines. The superior line arises from the pericallosal cistern; the inferior line derives from the fornix and roof of the cavum septum pellucidum. Color Doppler sonography can demonstrate the pericallosal artery, a branch of the anterior cerebral artery that sweeps in a circular pattern over the corpus callosum. In a coronal scan, the corpus callosum appears to form the roof of the cavum septum pellucidum and frontal horns.

Classic neuroradiologic signs for the diagnosis of ACC on pneumoencephalography were described by Davidoff and Dyke (1934). Their criteria have been applied to the CT diagnosis and also can be applied to sonography (Skidmore et al., 1983). The findings include the absence of the corpus callosum and cavum septum pellucidum and a variety of indirect findings, including

1. increased separation of the frontal horns and bodies of the lateral ventricles;
2. relative dilatation of the occipital horns of the lateral ventricles;
3. concave medial border of the lateral ventricles due to protrusion of the Probst bundles;
4. general dilatation and upward displacement of the third ventricle;
5. abnormal radial orientation of the medial cerebral gyri (Comstock et al., 1985; Bertino et al., 1988; Sandri et al., 1988; Pilu et al., 1993; Maheut-Lourmiere and Paillet, 1998).

In a series of 141 cases of fetal cerebral ventriculomegaly, ACC was noted in 16 cases (11%) (Valat et al., 1998). In another series of 82 cases of mild ventriculomegaly, there were 7 cases (9%) of ACC (Vergani et al., 1998). The finding of mild ventriculomegaly during routine prenatal sonography should, therefore, prompt a targeted search to confirm the presence of the corpus callosum.

Ultrasound diagnosis of ACC is more difficult prenatally than postnatally. The earliest prenatal diagnosis has been made at 19 weeks of gestation (Pilu et al., 1993). Because the corpus callosum is not normally formed until 18 weeks, most reported cases have been diagnosed in the third trimester (Bertino et al., 1988; Bennett et al., 1996). This difficulty in prenatal diagnosis is usually due to the fact that the characteristic ventricular abnormalities can be quite subtle on the axial views of the fetal cranium that are most commonly obtained. It is preferable to use coronal and sagittal views to diagnose the characteristic ventricular abnormalities; however, these views are not as commonly used prenatally.

Routine sonography of the fetal brain is usually performed with axial scans that do not allow visualization of the corpus callosum. However, enlargement of the atria of the lateral ventricles is readily appreciated with these views. In the largest series of prenatally diagnosed ACC, 34 of 35 fetuses had atrial measurements 10 mm (Pilu et al., 1993). Once atrial enlargement has been observed, other sonographic findings

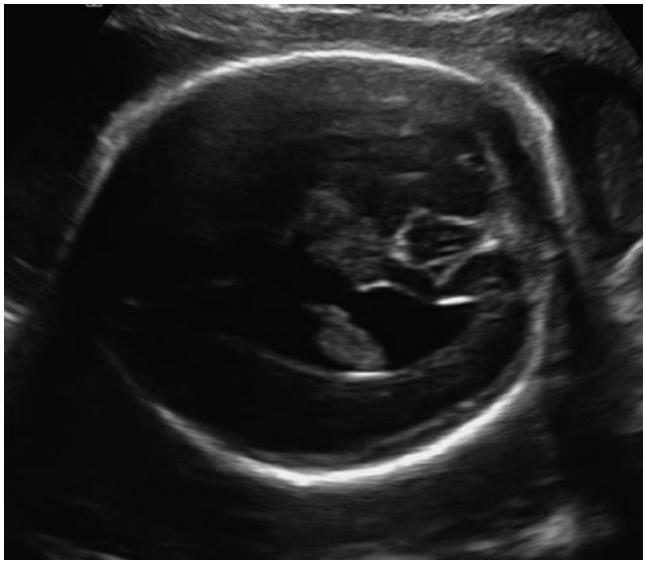

Figure 6-1 Transaxial ultrasound image demonstrating the classic teardrop configuration of the lateral ventricle.

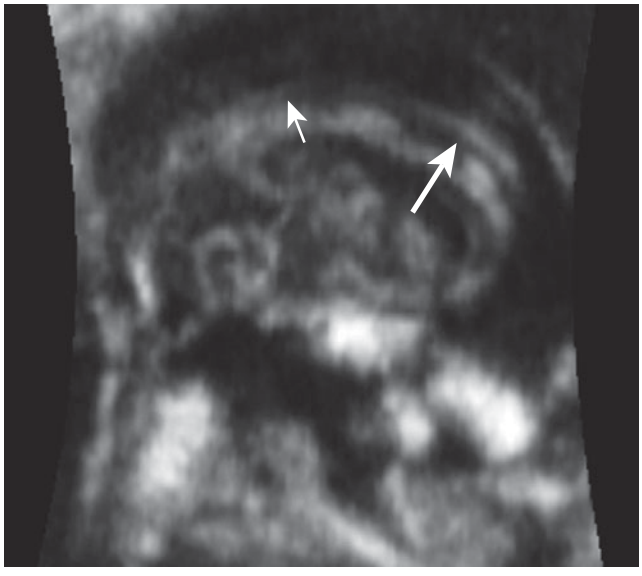

Figure 6-2 Three-dimensional ultrasound image, using VCI-C plane, of fetus at 22 weeks' gestation with partial posterior agenesis of the corpus callosum. Thick arrow demonstrates normal anterior corpus callosum fibers. Thin arrow demonstrates disappearance of this band posteriorly.

may identify possible ACC. The most consistent and easy-to-identify finding is the teardrop configuration of the lateral ventricles (Figure 6-1). In the axial plane, enlargement of the atria and occipital horns and separation of the bodies combine to generate a pattern that is readily recognizable. The teardrop configuration of the ventricles has not been documented in conditions other than ACC, and it is believed to be a specific sign for the diagnosis of callosal agenesis (Pilu et al., 1993). In order to document the callosal lesion directly, it is important to obtain midcoronal and midsagittal scans when a dilated atrium or teardrop ventricle is identified.

Prenatal diagnosis of partial ACC has been reported (Figure 6-2) (Lockwood et al., 1988; Pilu et al., 1993). The natural history of partial ACC is uncertain, and cerebral findings associated with it are probably more subtle than with the complete form. It is expected that antenatal diagnosis will not be possible in many cases. The cavum septum pellucidum is not identified in cases of complete ACC but may be visualized in cases of partial agenesis. Sonographic evaluation of the structure is potentially helpful in routine screening, alerting the sonologist to perform more coronal and sagittal scans for direct visualization of the corpus callosum. Widening of the interhemispheric fissure and upward displacement of the third ventricle can be documented in approximately half of the prenatal cases. Radial arrangement of the medial cerebral sulci has been seen only in third trimester studies. This is presumably because the surface of the hemispheres is smooth in the second trimester, with secondary sulci appearing only at the onset of the third trimester. In many cases of ACC, prenatal ultrasound examination may only cause one to suspect the diagnosis, while prenatal magnetic resonance imaging (MRI) may be needed to accurately confirm the diagnosis (Glenn et al., 2005). In one series of 14 cases of ACC, ultrasonography confirmed the diagnosis in only 4 cases, while MRI confirmed the diagnosis in 13 cases (d'Ercole et al., 1998). In another series of 20 cases of ACC, prenatal MRI made a positive diagnosis in 19 cases (Brisse et al., 1998). In a recent series of 10 cases of callosal abnormalities suspected by ultrasound examination, 8 cases were confirmed by MRI and 2 cases were found to have a normal corpus callosum (Glenn et al., 2005). MRI was also useful in identifying additional brain abnormalities that were not apparent by sonography such as abnormal sulcation. Sixty-three percent of cases (5/8) with confirmed callosal abnormalities on both ultrasound examination and MRI were found to have additional abnormalities on MRI. These occult findings were confirmed on postnatal MRI or autopsy in three of five patients. The information obtained by MRI is invaluable for patient counseling since additional brain abnormalities have been associated with worse long-term outcomes. In addition, three-dimensional ultrasound examination may also be useful to confirm the diagnosis (Kalache et al., 2006; Pilu et al., 2006).

DIFFERENTIAL DIAGNOSIS

Dilatation of the atria and occipital horns is often the most prominent sonographic finding; therefore, anything that causes hydrocephalus is also within the differential diagnosis for ACC (see Chapter 16). In ACC there is usually greater enlargement of the occipital horns, as compared with the remaining ventricular system, than is observed in other forms of hydrocephalus. When a dilated third ventricle is present, differential diagnosis includes other midline cystic spaces such as a cavum septum pellucidum, cavum vergae, interhemispheric arachnoid cyst, and medial porencephalic cyst.

ACC is associated with many recognizable genetic syndromes (see Table 6-1) (Bamforth et al., 1988; Paul et al., 2007). ACC has also been associated with abnormalities

Table 6-1

Genetic Syndromes Associated with ACC

Syndrome	Clinical Findings
With identified genes	
Andermann syndrome *(KCC3)*	ACC, progressive neuropathy, and dementia
XLAG *(ARX)*	Lissencephaly, ACC, intractable epilepsy
Mowat Wilson syndrome (*ZFHX1B*)	Hirschsprung disease, ACC
ACC with fatal lactic acidosis (*MRPS16*)	Complex I and IV deficiency, ACC, brain malformations
HSAS/MASA syndromes (*L1CAM*)	Hydrocephalus, adducted thumbs, ACC, MR
ACC seen consistently, no gene yet identified	
Acrocallosal syndrome	ACC, polydactyly, craniofacial changes, MR
Aicardi syndrome	ACC, chorioretinal lacunae, infantile spasm, MR
Chudley–McCullough syndrome	Hearing loss, hydrocephalus, ACC, colpocephaly
Donnai–Barrow syndrome	Diaphragmatic hernia, exomphalos, ACC, deafness
FG syndrome	MR, ACC, craniofacial changes, macrocephaly
Genitopatellar syndrome	Absent patellae, urogenital malformations, ACC
Temtamy syndrome	ACC, optic coloboma, craniaofacial changes, MR
Toriello–Carey syndrome	ACC, craniofacial changes, cardiac defects, MR
Vici syndrome	ACC, albinism, recurrent infections, MR
ACC seen occasionally (partial list)	
ACC with spastic paraparesis (*SPG11*)	Progressive spasticity and neuropathy, thin corpus callosum
Craniofrontonasal syndrome	Coronal craniosynostosis, facial asymmetry, bifid nose
Fryns syndrome	CDH, pulmonary hypoplasia, carniofacial changes
Marden–Walker syndrome	Blepharophimosis, micrognathia, contractures, ACC
Meckel–Gruber syndrome	Encephalocele, polydactyly, and polysystic kidneys
Microophthalmia with linear skin defects	Microopthalmia, linear skin marking, seizures
Opitz G syndrome	Pharygneal cleft, craniofacial changes, ACC, MR
Orofaciodigital syndrome	Tongue hamartoma, microretrognathia, clinodactyly
Pyruvate decarboxylase deficiency	Lactic acidosis, seizures, severe MR, and spasticity
Rubinstein–Taybi syndrome	Broad thumbs and great toes, MR, microcephaly
Septo-optic dysplasia (DeMorsier syndrome)	Hypoplasia of septum pellucidum and optic chiasm
Sotos syndrome	Physical overgrowth, MR, craniofacial changes
Warburg micro syndrome	Microcephaly, microophthalmia, microgenitalia, MR
Wolf–Hirschhorn syndrome	Microcephaly, seizures, cardiac defects, 4p-

Modified from Paul LK, Brown WS, Adolphs R, et al. Agenesis of the corpus callosum: genetic, developmental and functional aspects of connectivity. Nat Rev Neurosci. *2007;8:287-299.*

of chromosomes 8, 13, and 18 (Jeret et al., 1987). ACC also may be found in association with several inborn errors of metabolism, including nonketotic hyperglycinemia, Zellweger syndrome, adenylosuccinase deficiency, pyruvate dehydrogenase deficiency, neonatal adrenoleukodystrophy, Menkes disease, Leigh syndrome, and glutaric aciduria type II (Dobyns, 1989; Kolodny, 1989; Blum et al., 1990). Various teratogens have also been implicated as a possible cause of ACC, including alcohol, valproate, cocaine, rubella, and influenza virus (Table 6-1) (Friedman and Cohen, 1947; Cornover and Roessmann, 1990; Dominguez et al., 1991; Lindhout et al., 1992).

ANTENATAL NATURAL HISTORY

Little is known about the natural obstetric history of ACC when it occurs as an isolated finding because there have been relatively few case series reported. In one series of 37 pregnancies with prenatally diagnosed ACC, 28 resulted in elective termination of pregnancy, and in the remaining 9 cases liveborn infants were delivered (Hatem-Gantzer et al., 1998). Four of these 9 infants died in the postnatal period. It seems unlikely that the presence of isolated ACC should alter the antenatal course of pregnancy.

MANAGEMENT OF PREGNANCY

Identification of ACC demands a careful search of fetal anatomy for other intracranial and extracranial abnormalities. The association between ACC and chromosomal abnormalities has been addressed by Serur et al. (1988), who reviewed 100 cases. Identification of ACC demands a careful search of fetal anatomy for other intracranial and extracranial abnormalities. MRI is of value for confirming the diagnosis and ensuring no other intracranial malformations coexist (Brisse et al., 1998; d'Ercole et al., 1998; Glenn et al., 2005). Three-dimensional ultrasound may also be useful (Kalache et al., 2006; Pilu et al., 2006).

In the report of Serur et al., trisomy 18 was found in 29 cases, full or mosaic trisomy 8 in 21 cases, trisomy 13 in 20, and a variety of other conditions in the remaining cases. It is therefore postulated that chromosomes 8, 13, and 18 have a direct influence on the development of the corpus callosum. In Pilu et al.'s (1993) review of fetal diagnosis of ACC, three fetuses with abnormalities of chromosome 8 had ACC as the only sonographic finding. Therefore, it is our practice to offer amniocentesis for fetal karyotyping independently of the presence of other sonographically detectable abnormalities.

If an isolated ACC is detected and the chromosomes are normal, there is no indication to change the standard of obstetrical care. This diagnosis does not necessitate delivery at a tertiary care hospital. One should consult with genetics and pediatric neurology specialists. However, the presence of other associated structural abnormalities should prompt referrals to the appropriate pediatric subspecialists, and in this situation the patient should be delivered at a tertiary care hospital.

Vaginal delivery is recommended unless there is significant hydrocephalus with macrocephaly. Delivery prior to term is not recommended unless an obstetrical indication exists.

FETAL INTERVENTION

There is no fetal intervention recommended for this condition.

TREATMENT OF THE NEWBORN

Detailed examination of the newborn is required. The radiologic procedure of choice postnatally is MRI, which allows detection of subtle abnormalities not seen by the other methods, including CT and ultrasound (Davidson et al., 1985; Barkovich and Norman, 1988). Additional metabolic investigations may be necessary if inborn errors of metabolism are suspected.

SURGICAL TREATMENT

There are no surgical issues for isolated ACC; however, surgery may be indicated for additional intracranial or extracranial lesions. Some infants may require ventriculoperitoneal shunts for treatment of progressive ventricular dilatation and accelerated head growth (Lacey, 1985).

LONG-TERM OUTCOME

Children with ACC and multiple major congenital abnormalities are at high risk for neurodevelopmental retardation, especially if craniofacial defects are present. The presence of either neonatal or infantile seizures is an ominous prognostic sign; most of these children are severely retarded or exhibit delayed development (Lacey, 1985). Children with additional intracerebral abnormalities also appear to have a poor prognosis, with most infants experiencing developmental delay. A diagnosis of ACC should alert the physician to the likelihood of severe neurodevelopmental delay and subsequent seizures.

No specific risk figures are available at present to counsel parents regarding neurologic development in children with isolated ACC. Vergani et al. (1988) reported that three infants with prenatal diagnosis of ACC had normal or borderline intelligence quotients at 3-year follow-up examination. In the series by Pilu et al. (1993), a normal developmental quotient was found in 9 of 11 nonfamilial cases with a follow-up ranging between 6 months and 11 years, and borderline development was found in the remaining two. The neurologic development of surviving infants was evaluated with the Brunet–Lezine test and the Stanford–Binet Intelligence Scale. Even in the presence of normal intelligence, ACC may be associated with subtle cognitive defects (Temple et al., 1989, 1990; Jeeves, 1991). A possible relationship between ACC and psychotic disorders has also been proposed (Swayze et al., 1990).

In a survey of ACC from the United Kingdom, two thirds of 59 affected patients had epilepsy, half of the adult cases had intellectual impairment, and one-third had a psychotic disorder (Taylor and David, 1998). However, this and other series may be biased by under-ascertainment of asymptomatic cases of ACC. In another series of 10 children who had a diagnosis of ACC made prenatally, all had normal developmental outcome at 3 years of follow-up, although febrile convulsions were reported to occur more frequently than expected (Moutard et al., 1998).

Goodyear et al. (2001) compared patients with prenatally diagnosed ACC (14) to those in whom the disorder was diagnosed in postnatal period (61). The patients were evaluated for developmental milestones as well as other clinical issues. ACC was more common in males than in females, and partial ACC was more common in the postnatally diagnosed group. Complete ACC had a worse prognosis compared to partial ACC, especially when it was associated with other abnormalities, particularly those of the CNS. The only

neurodevelopmentally normal patients were in the group with an isolated finding of partial ACC. Adverse neurological outcomes included seizures, developmental delay, and mental retardation, as well as a need for special help in school.

More recently, Francesco et al. (2006) evaluated 9 children, aged 2 to 16, who had been diagnosed with ACC during the prenatal period. The diagnosis was confirmed in the post partum period. Six children had had isolated ACC, three of whom had generalized hypotonia, while three others had normal neurological development. The three with other associated findings did not have normal neurological outcomes. The authors concluded that if ACC is associated with other abnormalities a poor outcome is likely. However, if it is not, it is difficult to predict if there will be a normal neurological outcome.

With regard to partial ACC, Volpe et al. (2006) recently evaluated 19 prenatally diagnosed cases. Ten cases occurred in association with other anomalies. Nine cases were initially thought to be isolated. One of the nine cases was found to have additional brain malformations following MRI, and this case was lost to follow-up. There were 11 livebirths, 6 voluntary terminations, and 2 perinatal deaths. Thirty-two (6/19) percent of cases had normal psychomotor follow-up. All of these cases had isolated partial ACC. Two cases of isolated partial ACC had less favorable outcomes, one of which had significant developmental delay and hypotonia. Similar to the cases of isolated complete ACC, isolated partial ACC may be associated with significant adverse neurological outcomes.

GENETICS AND RECURRENCE RISK

The recurrence risk of ACC, whether it is isolated or in addition to inborn errors of metabolism or genetic syndromes, depends on the underlying cause. If ACC is associated with aneuploidy, the recurrence risk is 1% or the maternal age–related risk for aneuploidy, whichever is greater. If there is an isolated ACC with no known cause, the recurrence risk is probably on the order of 2% to 3% (Young et al., 1985). ACC is a known criterion for the diagnosis of certain syndromes, such as Aicardi, Andermann, and acrocallosal syndromes (Philip et al., 1998). While ACC is generally considered to be sporadic, familial cases have been reported (Naritomi et al., 1997).

7 CHAPTER

Anencephaly

Key Points

- Accounts for approximately one-half of all cases of neural tube defects.
- Incidence is approximately 0.3/1000 births. Maternal risk factors include Hispanic ethnicity, pregestational diabetes, obesity, and hyperthermia.
- First trimester sonographic findings include a reduced crown-rump length, and the "Mickey Mouse" sign in the coronal view. Second trimester findings include an absent upper cranial vault and no cerebral tissue above the level of the orbits.
- Differential diagnosis includes amniotic bands, ruptured encephalocele, and iniencephaly.
- Approximately a quarter of affected pregnancies are complicated by polyhydramnios.
- Consider prenatal karyotype if associated anomalies present. If anencephaly is isolated, consider postnatal karyotype.
- Condition is uniformly fatal postnatally. Only 7% of fetuses die in utero.
- Preconceptual folic acid (4 mg/day) significantly decreases recurrence if anomaly is isolated and not due to a chromosomal or single-gene disorder.

CONDITION

Anencephaly [congenital absence of a major portion of the brain, skull, and scalp (Medical Task Force on Anencephaly, 1990)] is the most severe and single most common prenatally detected neural tube defect (Goldstein and Filly, 1988). Although the cerebral hemispheres can develop in this condition, any exposed brain tissue is subsequently destroyed (see Chapter 13). This produces a hemorrhagic, fibrotic mass of neurons and glia, with no functional cortex. The brainstem and cerebellum may be spared. Despite the severe brain abnormalities, the facial bones and base of the skull are nearly normally formed. The frontal bone, however, is always absent and the brain tissue is always abnormal.

Anencephaly is sometimes divided into two subcategories. The milder form is known as meroacrania, which describes a small defect in the cranial vault covered by the area cerebrovasculosa. The more severe form is holoacrania, in which the brain is completely absent.

Van Allen et al. (1993) proposed that multisite neural-tube closure provides the best explanation for neural tube defects in humans. The closure sites are most likely controlled by separate genes expressed during embryogenesis. These authors hypothesized that the majority of neural tube defects could be explained by a failure of fusion of one of the closures or their contiguous neuropores. Anencephaly results from failure of closure site 2 for meroacranium and closures 2 and 4 for holoacranium. Folate deficiency is thought to affect the closures of sites 2 and 4. This hypothesis has been demonstrated in humans with more than one neural tube defect (Pantzar et al., 1993).

INCIDENCE

Anencephaly accounts for approximately one-half of all cases of neural tube defects (Chescheir et al., 2003). The incidence of anencephaly in livebirths and stillbirths has been estimated as 0.3 per 1000 by the Centers for Disease Control (Medical Task Force on Anencephaly, 1990). Female fetuses are more commonly affected. The ratio of affected females to males is 3:1 to 4:1 (Naidich et al., 1992). In one study, there was a 2.6 fold increased incidence of anencephaly in twins (Ben-Ami et al., 2005). There is also an increased incidence of anencephaly in Hispanic women, who are 45% more likely than white women to have an affected pregnancy (Feuchtbaum et al., 1999). Other risk factors include maternal pregestational diabetes, maternal obesity, and maternal hyperthermia (Mitchell, 2005). Unlike meningomyelocele, the risk of anencephaly is not increased in women who take valproic acid and/or carbamazepine (Mitchell, 2005). The most important environmental influence is diet. There is a well-documented protective effect of maternal periconceptual folic acid supplementation. Data from countries that have implemented mandatory folic acid fortification programs indicate a 30% to 50% reduction in the prevalence of neural tube defects postfortification (Mitchell, 2005).

In one study, Limb and Holmes (1994) documented that prenatal diagnosis and the availability of elective termination of pregnancy had significantly altered the birth status of infants with anencephaly. They noted a prevalence that varied between 1.0 and 0.4 per 1000 live and stillbirths during two different study periods (1972–1974 and 1979–1990, respectively). In the 1970s, half the infants with anencephaly were born alive at an average gestational age of 35.6 weeks. By 1988 to 1990, all affected infants were diagnosed by maternal serum α-fetoprotein screening or prenatal sonography. All parents elected to terminate, at an average gestational age of 19.6 weeks. These investigators, however, commented that their study population was potentially biased due to a higher percentage of mothers with epilepsy and diabetes delivering at their institution. More recent data, however, collected over the Internet, suggest that a larger proportion of women are opting to continue their pregnancies than would be suggested from the Limb and Holmes study (Jaquier et al., 2006).

SONOGRAPHIC FINDINGS

The first trimester sonographic appearance of anencephaly differs significantly from the second trimester (Chatzipapas et al., 1999). In the first trimester, the cerebral hemispheres are present and in direct contact with the amniotic fluid. In the coronal section of the head, the exposed cerebral lobes resemble the face of Mickey Mouse. In addition, the crown-rump length is significantly reduced in affected fetuses.

In the second trimester, the ultrasound diagnosis of anencephaly is made on the basis of the absence of the upper portion of the cranial vault (Figures 7-1 to 7-3). Above the level of the orbits, where the cerebral hemispheres are normally seen, no tissue is present or an ill-defined mass of heterogeneous density is observed. The abnormality is best demonstrated on coronal views of the fetal face (Figure 7-2). The sonographic diagnosis of this condition is very accurate and there are almost no false-positive diagnoses.

Anencephalic fetuses are usually normal in terms of body weight for gestational age (Melnick and Myrianthopoulos, 1987). Thus, intrauterine growth restriction is uncommon in isolated anencephaly. Another sonographic finding that may be present is polyhydramnios.

Goldstein and Filly (1988) reviewed the spectrum of prenatal sonographic findings in 20 fetuses with anencephaly. The sonographic diagnosis was based on the absence of brain and calvarium superior to the orbits on coronal views of the fetal head. In 45% of cases, echogenic tissue was seen superior to the orbits. This corresponded to the area cerebrovasculosa and was quite large in four fetuses. In 35% of their cases, frank polyhydramnios was seen. There were no cases of oligohydramnios. These authors stated that anencephaly can be distinguished from cranial defects associated with the amniotic band syndrome on the basis of symmetry of the

Figure 7-1 Sagittal view of fetal facial profile, demonstrating a lack of cranium above the easily visualized orbit. (Image courtesy of Prenatal Diagnosis Center, Women and Infants' Hospital).

cranial defects and the absence of limb, body wall, and spinal anomalies that generally accompany amniotic bands. In this report, prenatal diagnosis was 100% accurate after 14 weeks of gestational age. These authors missed one case initially studied at 12.5 weeks of gestation, but the defect was diagnosed on a repeat study performed at 26 weeks (Goldstein and Filly, 1988). As stated above, more recently it has become appreciated that the first trimester signs of anencephaly are different, so accuracy of detection earlier in gestation is likely to improve.

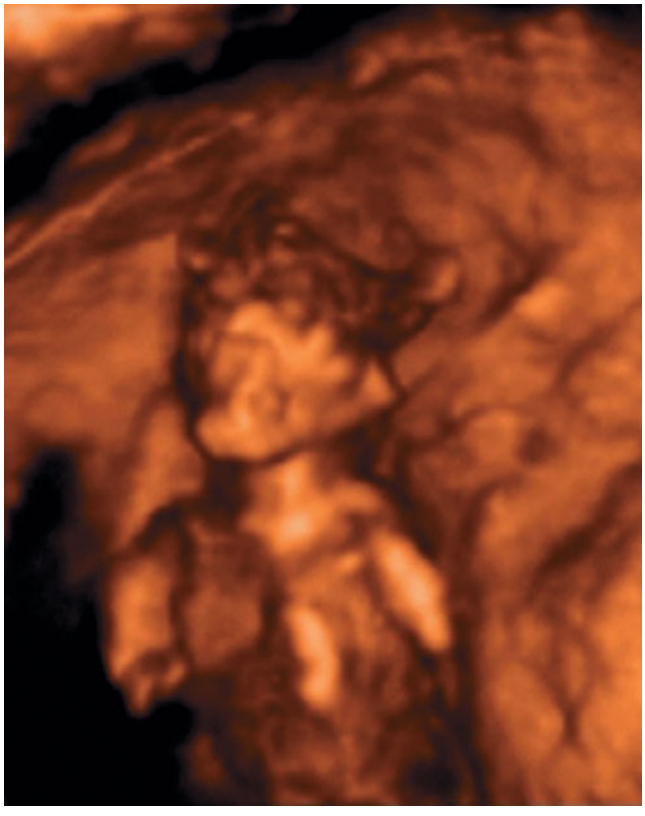

Figure 7-3 Three-dimensional ultrasound image at 12 weeks gestation of a fetus with anencephaly demonstrating lack of cranial bones above the orbits.

In postnatal studies, 13% to 33% of anencephalic infants have additional major congenital anomalies. These include congenital heart disease (4% to 15% of cases), hypoplastic lungs (5% to 34%), congenital diaphragmatic hernia (2% to 6%), malrotation of the gut (1% to 9%), renal malformations (25%) including polycystic or dysplastic kidneys (1% to 3%), hypoplasia of the adrenal glands (94%), and omphalocele (16%) (Melnick and Myrianthopoulos, 1987; Medical Task Force on Anencephaly, 1990). Additional minor anomalies that have been observed in fetuses with anencephaly include a single umbilical artery, a patent ductus arteriosus, and a patent foramen ovale, seen in 2% to 31% of cases. In one study, four-dimensional (4-D) sonography was used to study the hand and body movements of an anencephalic fetus at 19 weeks (Andonotopo et al., 2005). These were compared to a normal fetus at the same gestational age. Movement of the hand occurred in only one direction, and it was abnormal, forceful, and "jerky." In the normal fetus, movements were continuous and occurred in all directions. The anencephalic fetus showed a lack of positional changes.

DIFFERENTIAL DIAGNOSIS

The major consideration in the differential diagnosis is to distinguish anencephaly from the presence of amniotic bands. In

Table 7-1

Disorders Associated with Anencephaly

Walker–Warburg syndrome

addition, scalp-covered lesions that include demineralization of the skull can occasionally be confused with anencephaly. It is important to note that the cranial defect associated with anencephaly is always symmetric. With amniotic bands, there should be evidence of other defects, such as limb or digital amputations, asymmetric ventral wall defects, or spinal defects. Amniotic bands are often associated with oligohydramnios, which is in contrast to anencephaly, which is often associated with polyhydramnios. Other conditions in the differential diagnosis include ruptured encephalocele (see Chapter 12) and iniencephaly. The latter condition does not involve the rostral skull or the forebrain. It is very important to distinguish between anencephaly and amniotic bands because of significant differences in their respective recurrence risks. Disorders that are associated with anencephaly are listed in Table 7-1.

ANTENATAL NATURAL HISTORY

In one recent study, data were collected via a personal website from 211 women who opted to continue their pregnancies after a prenatal diagnosis of anencephaly (Jaquier et al., 2006). These data showed that only 7% of cases resulted in intrauterine fetal demise, which was lower than expected. The stillbirth rate was 20%. Polyhydramnios complicated 26% of pregnancies. Additional externally visible malformations were present in 8% of neonates. Thirty-four percent of infants were delivered prematurely and delivery by cesarean section was performed in 26% of women. The most common indications for cesarean section were breech presentation, placenta previa, twin pregnancy, and parental request. Seventy-two percent (153) of infants were liveborn. Of these, 103 died within the first 24 hours, but 6 survived for 6 to 28 days.

MANAGEMENT OF PREGNANCY

Interestingly, although maternal serum α-fetoprotein (AFP) levels are elevated in approximately 90% of cases of anencephaly (Medical Task Force on Anencephaly, 1990), as a primary screen, routine sonography detects a higher percentage of cases than second trimester maternal serum screening (Norem et al., 2005). All cases of significantly elevated maternal serum AFP levels need to be followed with a sonographic examination to confirm dating of the pregnancy and evaluate fetal anatomy. Prospective parents confirmed to be carrying a fetus with anencephaly should be referred to a tertiary care center, with ultrasound technicians and physicians who are capable of definitive diagnosis of fetuses with anomalies. If additional fetal structural anomalies are detected, a prenatal karyotype should be offered, and if declined, a postnatal karyotype is recommended. If the anencephaly is isolated, a postnatal karyotype is also encouraged, although the yield is likely to be low. In one prospective study of 46 fetuses with acrania or anencephaly, chromosome analysis was normal in 45/46 cases (Sepulveda et al., 2004). Only one fetus with anencephaly was shown to have trisomy 18.

Because pregnancy with a fetus with anencephaly carries an increased medical risk for the mother, prospective parents should be offered the opportunity to terminate, if the diagnosis is made before 24 weeks of gestation, as the prognosis for the fetus is uniformly fatal. Because polyhydramnios is often associated with this condition, premature delivery is increased (Jaquier et al., 2006). Labor and delivery are frequently associated with an unstable fetal position, and common maternal complications include dysfunctional labor (poor dilatation or dystocia) and postpartum hemorrhage (Medical Task Force on Anencephaly, 1990). There is an increased incidence of placental abruption with anencephaly (Melnick and Myrianthopoulos, 1987).

A special situation exists for twins in which one fetus has anencephaly, as there is an increased risk of premature delivery of the unaffected fetus (Leeker and Beinder, 2004) In dichorionic pregnancies, selective termination of the anencephalic fetus may prevent polyhydramnios and decrease the chance of preterm labor. The selective termination is most safely performed prior to 16 weeks of gestation.

In a review of more than 181 consecutive infants born with anencephaly, Main and Mennuti (1986) found that more than half of the cases were stillborn and virtually all others died during the neonatal period. However, more than 40% were alive at 24 hours and 5% lived to at least 7 days. These numbers were very similar in the most recent study performed by Jaquier et al. (2006). Therefore, parents should not be counseled that the infant will die immediately after birth. They should, however, be advised that the prognosis is uniformly fatal for this condition.

FETAL INTERVENTION

There is no fetal intervention for anencephaly.

TREATMENT OF THE NEWBORN

The mean gestational age at delivery for infants with anencephaly is 36.7 ± 5 weeks (Melnick and Myrianthopoulos, 1987). The mean birth weight for fetuses with anencephaly, when corrected for the absence of the brain, is within normal limits. The diagnosis of anencephaly can be confirmed on physical examination when the following criteria are met: A large portion of the skull is absent, the scalp is absent over the skull defect, and a hemorrhagic, fibrotic mass of tissue is exposed to the environment (Figure 7-4). There are no recognizable cerebral hemispheres present.

Because affected infants lack functioning cerebral cortex, they are permanently unconscious, but brainstem function is present in varying degrees. These patients are not, however, comatose. All infants have spontaneous movements of the extremities and startle myoclonus, although their tone and deep tendon reflexes are increased. Their typical behavior pattern consists of increased extensor tone and spontaneous or stimulus-induced axial myoclonus of the upper and lower extremities (Peabody et al., 1989). They respond to noxious stimuli and exhibit the primitive reflexes associated with feeding and breathing.

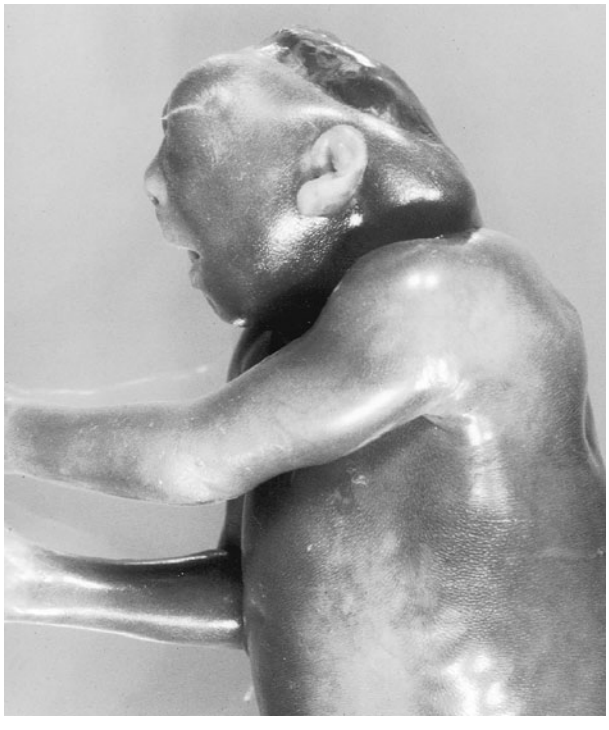

Figure 7-4 Sagittal view of a 20-week-old fetus with anencephaly. Note the total lack of cranial development above the orbits. The area cerebrovasculosa is easily seen. (*Photograph courtesy of Dr. Joseph Semple.*)

Most infants reported have died within the first few days of life, however, survival beyond 1 week of age has been reported in up to 9% of affected infants. The Medical Task Force on Anencephaly (1990) confirmed that one infant with anencephaly survived for 2 months.

SURGICAL TREATMENT

Surgical treatment is not applicable in anencephaly.

LONG-TERM OUTCOME

The major issue in long-term outcome is the potential use of anencephalic fetuses or infants as organ donors. This is a consideration because nationally 30% to 50% of children less than 2 years of age who are registered for organ transplantation die while waiting for donor organs to become available. Anencephalic infants have been considered as potential organ donors because they have a uniformly fatal prognosis. Difficulties exist, however, because of the traditional means of determining brain death for organ donors. Because anencephalic patients have no functioning cerebral cortex, the usual methods of determining brain death, such as cerebral blood flow testing and electroencephalograms (EEGs), are irrelevant to the diagnosis of anencephaly. For anencephalic patients, the diagnosis of brain death depends on documentation of disappearance of previously existing brainstem functions, such as a positive apnea test or loss of spontaneous movements.

Four different strategies have been suggested for the procurement of organs for transplantation from anencephalic patients.

The first is to place the infant on life support systems at birth and remove the organs as soon as technically possible without regard to the presence or absence of brainstem function. This strategy has been described by a group in Germany. Holzgreve et al. (1987) removed the kidneys from three infants with anencephaly and successfully transplanted them into four recipients. These authors argued that the anencephalic infants were "brain absent." Potential benefit was experienced not only by the organ recipients, but also by the parents of the anencephalic fetuses, who experienced psychologic benefits and additional moral purpose in carrying the anencephalic pregnancies to term (Holzgreve et al., 1987).

A second strategy is to place the anencephalic infant on life support systems at birth and observe the infant until all brainstem functions stop. This approach was tested by Peabody et al. (1989), who modified the medical care of 12 liveborn infants with anencephaly. For a period of 1 week, they tried to determine whether organ viability could be maintained and whether the criteria of total brain death could be met if these anencephalic infants were placed on life support for 1 week. Only 2 of the 12 infants met these criteria, and no solid organs were procured from these 12 infants. The authors concluded that most organs were suitable for

transplantation at birth and that organ function was maintained when intensive care was provided, but only one infant had conclusive evidence of brainstem death.

A third strategy is to give the infant with anencephaly only comfort care until signs of cardiorespiratory failure develop and then to place the infant on life support awaiting brain death. Peabody et al. (1989) concluded that when intensive care was delayed until brain death was imminent, most organs were damaged to the extent that they were no longer suitable for transplantation.

Most centers currently use a fourth strategy for organ donation from anencephalic infants. They provide standard comfort care until the infant dies. Then cadaver organs are removed, such as the corneas, heart valves, and kidneys.

It is important to note that most of the major organs from anencephalic infants are smaller than average for body size and have somewhat higher rates of malformation, but neither of these findings preclude their use in transplantation (Botkin, 1988).

GENETICS AND RECURRENCE RISK

A family history of spina bifida and/or anencephaly is one of the strongest risk factors for recurrence. Most cases of anencephaly are compatible with a multifactorial model, with a recurrence risk of between 2% and 5% following a single case (Medical Task Force on Anencephaly, 1990). For fetuses identified with multiple sonographic abnormalities, if a karyotype has not been performed prenatally, it should be obtained at delivery, as some cases of anencephaly are associated with chromosomal abnormalities, such as trisomies 13 and 18, and triploidy. In isolated populations, anencephaly has been described as a single-gene disorder. In Iranian Jews, who are highly inbred, anencephaly is inherited as an autosomal recessive condition (Zlotogora, 1995).

All women of reproductive age should take at least 400 mcg of folic acid daily to prevent neural tube defects. To be effective, folic acid must be consumed before conception and at least through the first 4 weeks of development. Folic acid is nontoxic even at very high doses and it is rapidly excreted in the urine. For women who have previously had a fetus or infant affected with anencephaly, the Centers for Disease Control and Prevention (CDC) recommends increasing the intake of folic acid to 4000 mcg (4mg) per day beginning at least 1 month prior to conception (Committee on Genetics, 1999). Prenatal diagnosis can be performed in a subsequent pregnancy, either by sonographic examination, or by maternal serum α-fetoprotein analysis.

The genetic basis of the interaction between folate metabolism and neural tube defects is under investigation. The conversion of homocysteine to methionine requires folate (Chescheir et al., 2003). Some—but not all—studies have shown that parents who have had a pregnancy complicated by a neural tube defect are more likely to be homozygous or a mutation in the gene for the enzyme methylenetetrahydrofolate reductase (MTHFR) than an unaffected population (Relton et al., 2003).

8 CHAPTER

Arachnoid Cyst

Key Points

- Arachnoid cysts are rare central nervous system malformations that represent 1% of neonatal intracranial masses.
- Arachnoid cysts are diagnosed prenatally as a simple, echolucent area within the fetal head and in which no communication with the ventricular system is seen.
- The main differential diagnosis for a posterior fossa arachnoid cyst is between mega cisterna magna and Dandy–Walker malformation.
- Most arachnoid cysts remain stable antenatally, but some may cause hydrocephalus by their mass effect as the pregnancy progresses.
- Management of pregnancy is generally not altered with an arachnoid cyst, unless significant hydrocephalus is present. Careful head imaging in the neonatal period is required to confirm the diagnosis and exclude associated abnormalities.
- Prognosis depends on the presence of other malformations, parenchymal hemorrhage, rate of cyst growth, and progession of ventriculomegaly.
- Pediatric management is usually either expectant, for asymptomatic cysts, or open or endoscopic fenestration or obliteration of the cyst if symptomatic.

CONDITION

Arachnoid cysts represent collections of cerebrospinal fluid enclosed within layers of pia arachnoid, that do not communicate with the intracranial ventricular system (Osborn and Preece, 2006). They are lined by arachnoidal cells and collagen. Arachnoid cysts are unilocular, round, oval, or crescentlike in shape. They initially communicate with the subarachnoid space and have the potential to grow due to this continued communication. Fluid accumulates as a result of a ball-valve mechanism (Diakoumakis et al., 1986). Choroid plexus-like tissue can be present within the cyst wall. This ectopic tissue secretes cerebrospinal fluid, resulting in progressive distention of the cyst (Diakoumakis et al., 1986). These fluid-filled masses must be distinguished on prenatal sonographic evaluation from the fourth ventricle and vallecula. The cerebellar vermis, hemispheres, and brainstem are usually normal in this condition except when the cyst compresses these structures (Altman et al., 1992).

Two types of arachnoid cysts exist: the congenital type, which is considered to be the result of maldevelopment of the leptomeninges, and the acquired type, which is the result of hemorrhage, trauma, or infection (Meizner et al., 1988). Two-thirds of prenatally detected cases are supratentorial in location, whereas one-third are located within the posterior fossa (Estroff et al., 1995). In contrast, most postnatally detected cases are located within the posterior fossa (Hogge et al., 1995). Five percent of supratentorial interhemispheric arachnoid cysts are associated with agenesis of the corpus callosum (Lena et al., 1995).

Structural features of the arachnoid cyst wall that distinguish it from the normal arachnoid membrane include

1. splitting of the arachnoid membrane at the margin of the cyst;
2. a very thick layer of collagen present in the cyst wall;
3. absence of the traversing trabecular processes within the cyst;
4. presence of hyperplastic arachnoid cells located within the cyst wall that presumably participate in collagen synthesis (Rengachary and Watanabe, 1981).

Electron micrographic studies of arachnoid cysts reveal a striking and nearly invariable association of the arachnoid cyst with the normal subarachnoid cistern. Some investigators have demonstrated that in their early stages, arachnoid cysts communicate with the subarachnoid space, revealing

the exclusively intra-arachnoid nature of the cyst (Rengachary and Watanabe, 1981). Other investigators, however, postulate that the retrocerebellar arachnoid cyst may represent a persistent diverticulum of the fourth ventricle that fails to involute, the so-called Blake pouch (Altman et al., 1992). The precise cause for the development of arachnoid cyst is unknown. The factors responsible for the formation of the normal subarachnoid cistern, however, also produce splitting of the arachnoid membrane in that location. This results in a diverticulum or enclosed cystic space. Thus, arachnoid cysts are thought to be a developmental anomaly of the subarachnoid cistern (Rengachary and Watanabe, 1981).

INCIDENCE

The incidence of arachnoid cysts is unknown. They are rare in prenatal life. Arachnoid cysts represent 1% of all space-occupying masses in childhood (Estroff et al., 1995) and are an incidental finding in 0.5% of autopsy studies (Rafferty et al., 1998). Arachnoid cysts are more common in males than in females (Kollias et al., 1993; Lena et al., 1995). The left side of the brain is more commonly affected than the right.

SONOGRAPHIC FINDINGS

Sonographic diagnosis of arachnoid cyst relies on the finding of a sonolucent mass with smooth and thin walls within the brain (Figure 8-1). This cyst does not communicate with the lateral ventricles, but may be associated with hydrocephalus

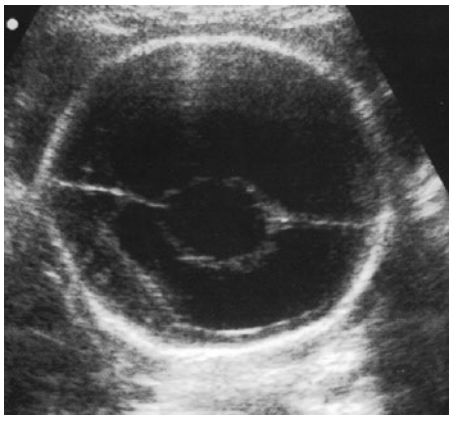

Figure 8-2 Transaxial image of a fetal head demonstrating an arachnoid cyst and associated hydrocephalus.

(Figure 8-2) due to a mass effect that obstructs the flow of cerebrospinal fluid. In this condition, the cerebellar vermis is normal in size. The cyst is usually completely echolucent, with the same signal intensity as CSF (Figure 8-2). Occasionally, hemorrhage into an arachnoid cyst may obscure its simple appearance (Osborn and Preece, 2006).

In 1986, Diakoumakis et al. described a fetal suprasellar arachnoid cyst that was detected on a routine antenatal sonographic examination at 32 weeks of gestation, and resulted in development of hydrocephalus. Postnatal cranial computed tomographic (CT) examination revealed a characteristic "head of the bunny" appearance with a midline cyst and two dilated lateral ventricles (Diakoumakis et al., 1986). In another case report, a fetus was described at 22 weeks of gestation with an isolated extraventricular supratentorial arachnoid cyst, which appeared as a rounded, fluid-filled cyst

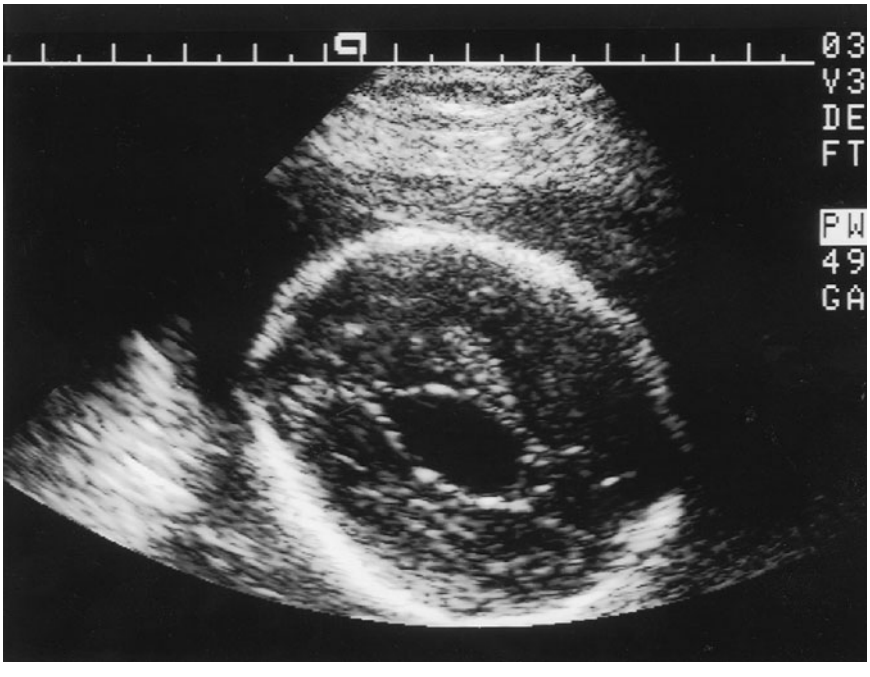

Figure 8-1 Transaxial image of fetal head demonstrating solitary arachnoid cyst.

in the right parieto-occipital lobe of the brain (Meizner et al., 1988). There was splaying of the right lateral ventricle due to a pressure effect, and the cyst enlarged progressively over the duration of pregnancy (Meizner et al., 1988).

Most cases of arachnoid cysts are detected at >20 weeks of gestation (Hogge et al., 1995; Rafferty et al., 1998). Only rarely are extracranial abnormalities detected. In one case report, a 1- by 1-cm posterior fossa cyst was detected at 18 weeks of gestation. The pregnancy was aborted because of associated chromosomal abnormalities (Hogge et al., 1995).

Estroff et al. (1995) described two cases of arachnoid cysts that, on the basis of prenatal sonographic findings, were suspected antenatally to be a Dandy–Walker malformation. These authors noted that sonographic distinction between the retrocerebellar arachnoid cysts and the Dandy–Walker cyst may be difficult. Both malformations may be associated with hydrocephalus. In arachnoid cysts, the underlying cerebellar hemispheres and vermis are normal, although they are displaced and compressed anteriorly. Typically, no extracranial abnormalities are present in arachnoid cysts (Estroff et al., 1995). At least 27 cases of fetal arachnoid cysts have been described in the literature (reviewed in Chen, 2007). Of these, 9 had prenatal MR imaging in addition to sonography. In a few cases, the diagnosis was made in the second trimester, but the majority were third trimester diagnoses. In one report, using transvaginal sonography, a posterior fossa arachnoid cyst was diagnosed at 13 weeks of gestation (Bretelle et al., 2002).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for arachnoid cysts is given in Table 8-1, and antenatal magnetic resonance imaging (MRI) may be needed for accurate evaluation (Golash et al., 2001). Mega cisterna magna can be confused with arachnoid cyst but, there is no mass effect on the cerebellar hemispheres nor hydrocephalus in the setting of mega cisterna magna (Estroff et al., 1995). Arachnoid cysts in the midline that lie wholly posterior to the cerebellum may be difficult to distinguish from the mega cisterna magna (Altman et al., 1992).

Dandy–Walker malformation can also be mistaken for an arachnoid cyst (see Chapter 11), as it is associated with a well-defined posterior fossa cyst that is separate from the ventricular system (Meizner et al., 1988). Anterior extension of an arachnoid cyst to the cerebellar hemispheres effectively rules out the Dandy–Walker malformation (Altman et al., 1992). It may be quite difficult to distinguish antenatally between Dandy–Walker malformation and posterior fossa arachnoid cysts. The determination of size, shape, and position of the fourth ventricle and cerebellar vermis is critical to accurate differentiation between arachnoid cyst and Dandy-Walker malformation (Estroff et al., 1995). The finding of associated agenesis of the corpus callosum may suggest a diagnosis of Dandy–Walker malformation. Postnatally, an invasive procedure, such as instilling radiographic contrast material into the ventricular system (cisternagram) may be necessary to distinguish among Dandy–Walker malformation and its variants (see Chapter 11), mega cisterna magna, or Blake pouch cyst (Estroff et al., 1995). La Torre et al. (1973) recommended angiographic distinction between Dandy–Walker malformation and arachnoid cysts by evaluation of the posterior inferior cerebellar artery and its vermian branch. In arachnoid cysts, all vessels are normal in size and are displaced forward and upward, while in the Dandy–Walker malformation, the posterior inferior cerebellar artery is miniature and the vermian branch of the inferior cerebellar artery and the inferior vermian vein are absent.

An additional consideration in the differential diagnosis of arachnoid cyst is a variant of normal. Knutzon et al. (1991) described a linear hyperechoic structure in the cisterna magna previously thought to be the straight sinus. This structure was identified in 92 to 95 of prenatal sonographic examinations. This structure appeared cystlike in 17 of 95 cases studied. On histopathologic correlation in aborted fetuses, this structure was shown to be formed by subarachnoid septa. It is most likely due to focal concentrations of arachnoid trabeculations in the subarachnoid space (Knutzon et al., 1991). Intrahemispheric arachnoid cysts can be confused with a dorsal cyst present in cases of alobar holoprosencephaly (see Chapter 14) (Lena et al., 1995). Porencephalic cysts are located within brain matter, communicate with the ventricular system, and do not exert a mass effect. They are often associated with prenatal or postnatal brain injury (Lena et al., 1995). Ependymal cysts occur less frequently than arachnoid cysts and tend to occupy the central white matter of the frontal or temporoparietal lobes (Rengachary and Watanabe, 1981). In ependymal cysts, the protein content of the cyst fluid is higher than that of the arachnoid cyst.

Tumor

ANTENATAL NATURAL HISTORY

Little is known about the antenatal natural history of arachnoid cysts. Some increase in size and others resolve spontaneously. Two cases have been described in the medical literature of arachnoid cysts associated with increased maternal serum α-fetoprotein levels (Kwon and Jeanty, 1991; Hogge et al., 1995). It is not known if these are etiologically related or coincidental. From the limited number of prenatal cases reported, it appears that the cyst can grow in size during antenatal life (Diakoumakis et al., 1986; Meizner et al., 1988). In addition, hydrocephalus can develop from obstruction of the foramen of Monro and displacement of the aqueduct posteriorly with blocked basal cisterns.

MANAGEMENT OF PREGNANCY

When an arachnoid cyst is detected within the fetal brain, the patient should be referred to a center capable of complete anatomic sonographic fetal diagnosis. If differential diagnosis of a posterior fossa arachnoid cyst from Dandy–Walker malformation is difficult, prenatal MRI may be necessary. Serial sonographic examination should be performed to monitor potential enlargement of the cyst and subsequent development of ventriculomegaly (Hogge et al., 1995). It is important to seek evidence of associated malformations, as arachnoid cysts may be part of a multiple malformation syndrome. For example, one rare recessively inherited condition consists of absent tibia, polydactyly, cleft palate, and the presence of retrocerebellar cysts (Holmes et al., 1995). Rare cases of arachnoid cyst have been associated with tetralogy of Fallot and neurofibromatosis type 1.

Serious consideration should be given to performing amniocentesis to obtain a fetal karyotype, particularly if other anomalies are present. In one case, a fetus with a posterior fossa arachnoid cyst was shown to have an abnormal karyotype consisting of 46,X der(X),tX:9(q22;q22). Thus, this fetus had a partial trisomy of the long arm of chromosome 9 with partial monosomy of the long arm of the X chromosome. This was due to a balanced translocation occurring in the mother between chromosomes X and 9 (Hogge et al., 1995). Other chromosome abnormalites described in association with fetal arachnoid cyst include deletion of the distal long arms of chromosome 14 (Souter et al., 2003) and chromosome 16 (Arriola et al., 2005), trisomy 18 (Pilu et al., 1997), and triploidy (Elbers and Furness, 1999).

Prospective parents of a fetus demonstrated to have an arachnoid cyst should be offered the opportunity to consult with a pediatric neurologist, neurosurgeon, and medical geneticist. The presence of an isolated arachnoid cyst is not an indication for cesarean section (Meizner et al., 1988). However, because of the potential for development of ventriculomegaly, the patient should be followed by serial sonograms to determine if the fetal head size is small enough for a vaginal delivery. An additional consideration in the determination of route of delivery is the risk of trauma and hemorrhage within the cyst (Altman et al., 1992).

FETAL INTERVENTION

There is no fetal intervention recommended for arachnoid cyst.

TREATMENT OF THE NEWBORN

Newborns who have been diagnosed with an arachnoid cyst antenatally should have an evaluation with consultants in genetics and neurology. Depending on the location of the cyst, CT or MRI scanning is indicated to confirm the presence of the cyst. A careful measurement should be made of the newborn's head circumference, and the presence of asymmetry of the calvarium should be noted. The newborn should be observed for any changes in head circumference, as the potential exists for expansion of the cyst by hemorrhage due to trauma at delivery through the rupture of bridging veins (Altman et al., 1992). Clinical characteristics at birth will depend on the size of the cyst (Kollias et al., 1993). Associated hydrocephalus is present in 30% to 100% of cases (Kollias et al., 1993). In newborns in whom an arachnoid cyst is detected postnatally, the overwhelming presenting symptom is macrocephaly (71.5% of 67 cases reported) (Pascual-Castroviejo et al., 1991). Seizures may occasionally occur in infants with arachnoid cyst. Increased intracranial pressure is rarely a presenting clinical sign.

SURGICAL TREATMENT

The operative procedures for treatment of arachnoid cysts consist of cyst excision, fenestration, or drainage into an adjacent cistern, abdominal cavity, or atrium (Richard et al., 1989). Small asymptomatic cysts do not require any intervention. Surgical excision of the cyst is indicated in the rare cases in which increased intracranial pressure is detected. Craniotomy, however, may result in severe complications. The most common treatment consists of a cystoperitoneal shunt, which results in a high rate of regression of the cyst and rarely produces recurrence or complications. These shunts may need revision due to blockage or growth of the patient (Pascual-Castroviejo et al., 1991). Most neurosurgeons prefer to treat the patient initially with expectant management, as the avoidance of a shunt is the primary goal in management (Fewel et al., 1996). More recently, an endoscopic approach to cyst obliteration has been described (Choi et al., 1999; Golash et al., 2001). Additionally, endoscopic cyst fenestration may

also be used as a less invasive alternative to open surgical management (Nakamura et al., 2001).

LONG-TERM OUTCOME

The major complications in the long-term outcome for affected patients include hydrocephalus, seizures, and neurologic abnormalities (Altman et al., 1992; Hogge et al., 1995). Estroff et al., (1995) described normal developmental outcome for a fetus diagnosed at 28 weeks of gestation with hydrocephalus and a retrocerebellar cyst following cystoperitoneal shunt decompression (Estroff et al., 1995).

In a follow-up study of 16 children with symptomatic supratentorial interhemispheric cysts ascertained postnatally, Lena et al. (1995) demonstrated that no cyst became larger but none disappeared completely. These authors had a median follow-up period of 50 months. In 16 children, the preoperative symptoms disappeared completely in 7 and partially in 4. Two of the original patient group were asymptomatic and remained completely normal. Of the 16 children, 12 were entirely neurologically normal, 1 had moderate disability, 2 had severe disability, and 1 died from unrelated pneumonia 3 months after surgery. Seizures developed in 4 of the 16 children (Lena et al., 1995). Richard et al. (1989) followed affected children into adulthood over a 48-year period. These investigators demonstrated a favorable outcome for most patients, with 62% to 93% of all individuals followed over this period having had normal physical and social development and a satisfactory quality of life. The prognosis was also noted to be related to age at operation. Independent of the surgical method used over this 48-year period, the percentage of patients with any disability as compared with all due to arachnoid cyst ranged from approximately 11% to 14%. Patients who died in this study had causes of death unrelated to the arachnoid cyst (Richard et al., 1989).

In another series of 33 cases of supratentorial arachnoid cysts managed surgically and followed to a mean of 70 months, all patients were improved symptomatically, even though most still demonstrated persistence of the cyst (Galarza et al., 2002). One of these 33 children had developmental delay and 4 had epilepsy, although all 4 of these children were seizure free on medications following surgery.

GENETICS AND RECURRENCE RISK

Most cases of arachnoid cyst appear to be sporadic (Altman et al., 1992). Rare cases of arachnoid cyst are associated with neurofibromatosis type 1 or other multiple congenital anomaly disorders due to single gene mutations (Holmes et al., 1995). For example, an unexpectedly high number of asymptomatic intracranial arachnoid cysts were found in a group of 247 patients with autosomal dominant polycystic kidney disease who underwent high-resolution CT scanning or MR imaging (Schievink et al., 1995). If a prenatal karyotype analysis is performed and an unbalanced chromosome abnormality is detected, as in the cases cited here (Hogge et al., 1995; Souter et al., 2003; Arriola et al., 2005), parental chromosome analysis is strongly suggested.

Occasional families have been described with recurrence of arachnoid cysts. For example, Handa et al. (1981) reported the presence of bilateral arachnoid cysts in the middle cranial fossa in two brothers, aged 10 months and 3 years. Other reports of siblings affected with arachnoid cysts exist in the medical literature (Wilson et al., 1988; Pomeranz et al., 1991; Tolmie et al., 1997; Hendricks et al., 1999). Arriola et al. (2005) described two families that had three affected members each. Significantly, each family had individuals with arachnoid cysts in two generations. These reports suggest the possible existence of heritable factors that predispose individuals to the formation of arachnoid cysts.

CHAPTER 9

Cerebral Calcifications

Key Points

- Cerebral calcifications are rare and are associated with fetal infections, such as CMV, rubella, toxoplasma, syphilis, and herpes, as well as with trisomies 21 and 13.
- Following the diagnosis, detailed sonographic evaluation for other markers of aneuploidy or intrauterine infection is warranted, together with maternal TORCH titers, followed by amniocentesis for the specific infectious agent as suggested by abnormal TORCH titers.
- Further pregnancy and pediatric management is dictated by the specific underlying etiology.

CONDITION

Cerebral calcifications are an unusual sonographic finding in the fetus. They are thought to occur late in gestation and result from localized neuronal-cell death. Intracranial calcifications are most commonly associated with the in utero infections due to the TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes virus) agents (Ghidini et al., 1989). This chapter covers three types of fetal cerebral calcifications: (1) focal, punctate parenchymal calcifications, (2) periventricular echogenicity, and (3) echogenic blood vessels demonstrated in the thalami and basal ganglia (Estroff et al., 1992).

INCIDENCE

Fetal intracranial calcifications are rare. Although congenital cytomegalovirus is common [affecting 30,000 to 40,000 infants each year in United States (Ross and Boppana, 2004)], most cases of congenital cytomegalovirus are not associated with cerebral calcifications. One study found fetal brain

abnormalities, including intracranial calcifications, in 10 of 39 (20%) of fetuses who were infected congenitally and had prenatal sonographic studies (Enders et al., 2001).

SONOGRAPHIC FINDINGS

Much of the information regarding the differential diagnosis and outcome for infants with intracranial calcifications derives from the postnatal pediatric radiographic literature. The use of postnatal cranial sonography as an effective means of visualizing intracranial calcifications in newborn infants with congenital infections was first described by Dykes et al. in 1982. She and her colleagues demonstrated the presence of multifocal, high-intensity echoes in infants with infection. What was unusual about this sonographic finding was that there was no acoustical shadowing from these echoes. Subsequently, Teele et al. (1988) noted the unique sonographic finding of bright, branching vessels in the thalami and basal ganglia of 12 newborn infants. This finding was strongly associated with the presence of congenital infection. In this group of 12 infants, 5 had congenital cytomegalovirus (CMV), 2 had congenital rubella, 1 had congenital syphilis, and 3 had trisomy 13 with no known evidence of infection. These findings later were extended by other investigators, including Ben-Ami et al. (1990), who studied 11 infants noted to have bright echogenic stripes in the thalami and basal ganglia. By using duplex sonography, these investigators demonstrated that the stripes derived from the lenticulostriate arteries in the basal ganglia (Figure 9-1). In their study group, 8 of 11 cases were infected in utero, and 1 additional patient had trisomy 13. In a retrospective review of 2320 neonatal cranial sonograms, 25 newborns were identified with these linear areas of echogenicity in the basal ganglia (Hughes et al., 1991). Three of the 25 newborns were shown to have abnormal chromosomes (2 had trisomy 21 and 1 had trisomy 13). An additional four patients had CMV, and eight had clinical evidence of either anoxia or other metabolic brain injury (Hughes et al., 1991).

Relatively few cases of fetal intracranial calcifications have been described in the literature on prenatal diagnosis (Ghidini et al., 1989). Fakhry and Khoury (1991) reported two cases of fetal intracranial calcifications associated with CMV. In one case, at 32 weeks of gestation, the fetus was also noted to have microcephaly (Figure 9-2). In the other case, the fetus had a completely normal sonographic examination at 17 weeks, but by 22 weeks was noted to have mild hydrocephalus and hyperechoic foci in the periventricular areas. The pattern of bilateral periventricular calcifications may be a specific finding for intrauterine CMV infection (Figure 9-3) (Tassin et al., 1991). A different fetal manifestation of congenital CMV infection has also been reported by Estroff et al. (1992). This included a hyperechoic rim in the periphery of the fetal cerebral cortex, with branching linear areas of echogenicity seen in the fetal thalami, which is likely to be the fetal equivalent of the lenticulostriate artery echogenicity

Figure 9-1 Coronal sonogram of a newborn with congenital cytomegalovirus infection, demonstrating branching, echogenic vessels in the basal ganglia. (*Reprinted, with permission, from Ben-Ami T, Yousef-zadeh D, Backus M, Reichman B, Kessler A, Hammerman-Rozenberg C. Lenticulostriate vasculopathy in infants with infections of the central nervous system: sonographic and Doppler findings.* Pediatr Radiol. *1990;20:575-579.*)

demonstrated postnatally in several studies (Teele et al., 1988; Ben-Ami et al., 1990; Hughes et al., 1991).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of fetal intracranial calcifications includes noninfectious and infectious causes. The noninfectious or structural causes include intracranial tumors (Sherer and Onyeije, 1998), the bilateral periventricular calcification of subependymal nodules seen in tuberous sclerosis (see Chapter 58), sagittal or transverse sinus thrombosis, Sturge–Weber syndrome, trisomy 13, and intracranial or intraventricular hemorrhage. Why echogenicity of the lenticulostriate arteries in the fetal thalami or basal ganglia is associated with trisomy 13 is currently not known. Case reports also exist that document the finding of fetal intracranial calcifications in rare autosomal recessive conditions such as carnitine palmitoyltransferase II deficiency (Elpeleg et al., 2001) and Aicardi–Goutières syndrome (Le Garrec et al., 2005).

The more common cause for fetal intracranial calcification is congenital infection (Degani, 2006). In many cases, the fetal intracranial calcifications are accompanied by other findings suggestive of infection, including intrauterine growth restriction, placental villitis, hepatosplenomegaly, ascites, hydrops fetalis, ventriculomegaly, or microcephaly (Ghidini et al., 1989; Enders et al., 2001). The infections likely to cause

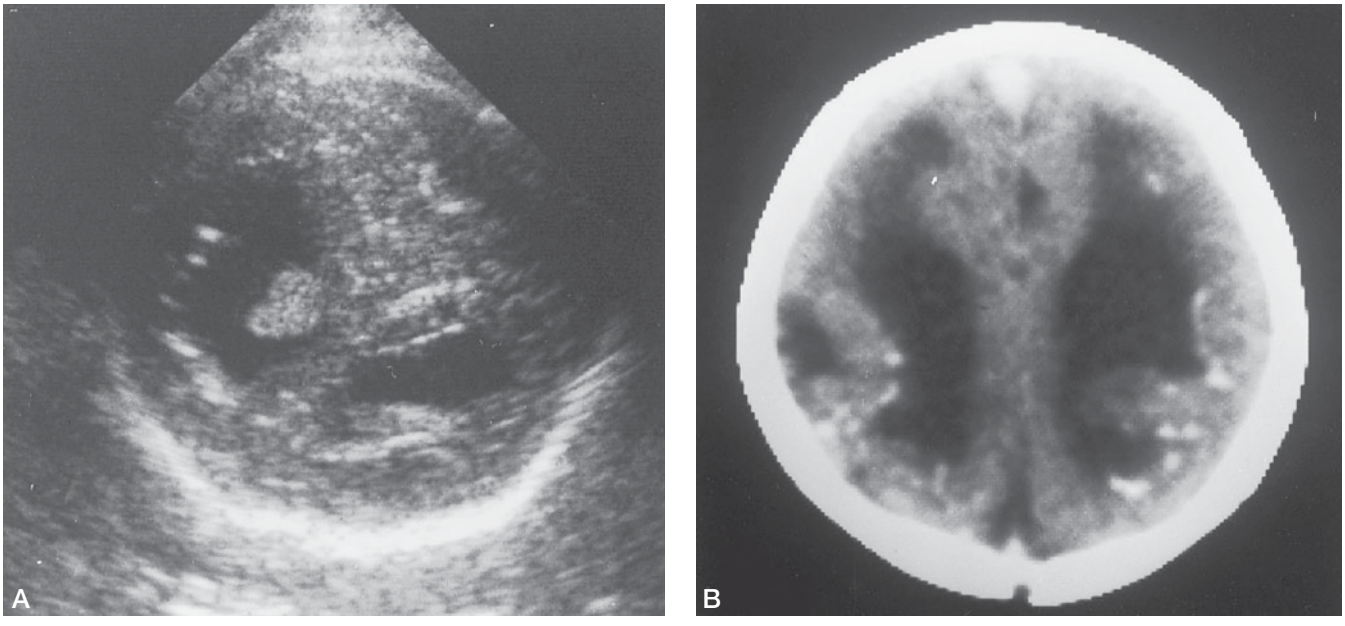

Figure 9-2 **A**. Axial scan of a fetal head at 32 weeks of gestation showing periventricular hyperechoic foci with absent acoustic shadowing. The choroid plexi are well seen in the moderately dilated ventricles. **B**. CT scan without contrast obtained after birth from the same infant, showing ventriculomegaly and periventricular and parenchymal calcifications. (*Reprinted, with permission, from Fakhry J, Khoury A. Fetal intracranial calcifications: the importance of periventricular hyperechoic foci without shadowing.* J Ultrasound Med. *1991;10:51-54.*)

intracranial calcifications include CMV (Hohlfeld et al., 1991; Estroff et al., 1992), rubella (Yamashita et al., 1991), toxoplasmosis, and herpes simplex, although CMV is overwhelmingly the most likely infectious cause (see Figures 7-1 to 7-3) (Fakhry and Khoury, 1991).

ANTENATAL NATURAL HISTORY

Toxoplasmosis, CMV, herpes simplex virus type 2, and rubella infections reach the fetal central nervous system via hematogenous dissemination. These viruses are known to have a predilection for rapidly growing subependymal or germinal matrix cells. Once the fetus is infected, these agents cause neuronal- or ganglia-cell necrosis. Necrotic cells may subsequently undergo calcification (Ghidini et al., 1989). Because of this sequence of events, cerebral calcification is rarely documented before the mid to late second trimester.

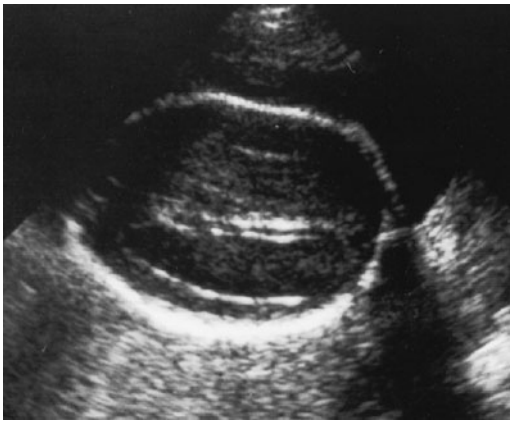

Figure 9-3 Axial scan of a fetal head in a fetus with cytomegalovirus demonstrating ventriculomegaly and bilateral periventricular calcifications. (*Reprinted, with permission, from Drose JA, Dennis MA, Thickman D. Infection in utero: US findings in 19 cases.* Radiology. *1991;178:369-374.*)

In several cases in which a neuropathologic examination was performed on infants who died with the postnatal sonographic finding of echogenic branching thalamic vessels, histopathology demonstrated thickened hypercellular walls with deposits of amorphous basophilic material, suggesting a perinatally acquired vasculitis (Teele et al., 1988). The pathophysiology behind the demonstration of echogenicity was likely due to a vascular injury resulting from a viral infection that affected the fetal central nervous system. Teele et al. concluded that postnatal sonography was helpful in detecting early noncalcific inflammation and mineralization in vasculitis due to infection. Fetuses with perinatally acquired infection are at increased risk of spontaneous abortion.

MANAGEMENT OF PREGNANCY

When fetal intracranial calcifications are documented, a careful search must be undertaken for associated structural anomalies, intrauterine growth restriction, and placental problems. The leading candidate in the differential diagnosis is CMV, so further management of pregnancy should include maternal TORCH titers. In some centers, TORCH titer testing has been replaced by testing only for CMV antibodies due to

the extremely low likelihood of finding positive results for toxoplasma, syphilis, or herpes virus (Abdel-Fattah et al., 2005). Primary CMV infection can be diagnosed if CMV-specific IgG antibodies are found in a patient previously known to be seronegative. The presence of both IgG and IgM however can be difficult to interpret, as CMV IgM can remain present following distant infection, or can be cross-reacting IgM from herpes virus infection. In such situations, CMV IgG avidity testing on maternal serum is recommended, with binding by antibodies less avidly during recent infection (Andrews, 2004). An amniocentesis is recommended for fetal karyotyping to rule out trisomies 13 and 21, and to obtain amniotic fluid for CMV analysis. Amniotic fluid can be analyzed for CMV using either viral culture, shell vial assay, PCR to quantify CMV DNA or amplification for CMV-specific RNA (Andrews, 2004). CMV culture, however, will be positive only 6 weeks after the onset of infection, and is generally only reliable after 21 weeks' gestation. In one series, two false-negative results from amniotic fluid CMV culture were reported following analysis less than 4 weeks following infection (Nicolini et al., 1994). After 18 to 20 weeks of gestation, cordocentesis can be performed to measure fetal immunoglobin M (IgM) to CMV, although this is rarely performed now due to the limited sensitivity for CMV and the improvements in amniotic fluid detection techniques. The finding of grossly abnormal liver-function tests and complete blood count has been associated with a rapidly fatal postnatal outcome (Hohlfeld et al., 1991).

One of the main challenges with identifying CMV in amniotic fluid is the lack of correlation with symptomatic congenital infection (Guerra et al., 2000). However, there does appear to be a correlation between CMV viral load and a higher likelihood of fetal infection. Serial sonograms are recommended to monitor fetal growth.

FETAL INTERVENTION

There is no known effective therapy to treat the fetus in utero (Guerina, 1994; Ross and Boppana, 2004). The results of treating newborns with ganciclovir have been encouraging, and prompt consideration may be given to fetal treatment with this antiviral agent. Because ganciclovir crosses the placenta by simple diffusion, maternal administration should be possible (Gilstrap et al., 1994). However, there are no prospective data to validate this approach.

TREATMENT OF THE NEWBORN

Because of the risk of anemia and cardiovascular complications associated with severe perinatal infection, consideration should be given to delivering potentially infected infants in a tertiary care center. After delivery, a complete physical examination is indicated, with careful attention to measurements of weight, head circumference, and length. A computed tomographic (CT) scan is useful to confirm the areas of intracranial calcification that were noted on prenatal sonography. However, if bright branching thalamic vessels were demonstrated antenatally, this finding will not be demonstrated on postnatal CT scans (Teele et al., 1988).

If amniocentesis was not performed antenatally, a neonatal urine sample should be obtained for CMV culture. Newborn TORCH titers should be drawn to pair with the maternal samples. The use of amplification techniques for CMV DNA in peripheral blood samples from the newborn may also be effective (Ross and Boppana, 2004). If the infection with CMV is confirmed, consideration should be given to treatment with ganciclovir over a 6-week course. Ophthalmologic examination may be useful to document the presence of chorioretinitis. Prior to discharge, the newborn infant should undergo hearing tests.

SURGICAL TREATMENT

There is no surgical treatment for cerebral calcifications.

LONG-TERM OUTCOME

The long-term outcome will depend on the cause of the cerebral calcifications. If the underlying diagnosis is trisomy 13, refer to Chapter 129. If the underlying diagnosis is congenital CMV infection, the prognosis is variable. The major complications include hearing loss, microcephaly, developmental delay, seizures, and visual impairment (Ben-Ami et al., 1990; Koga et al., 1990). In a review of 19 cases of prenatally acquired infection due to different agents, Drose et al. (1991) described 6 cases of CMV, 3 of which were detected prenatally by the presence of periventricular calcifications on sonography. An additional 3 were detected postnatally by CT scan or at autopsy. The outcomes for these 6 cases included 2 spontaneous losses at 23 and 24 weeks of gestation, 1 death in the neonatal period, 1 infant who survived with hydrocephalus, 1 infant who survived with hearing loss and abnormal development to 18 months of age, and 1 survivor with only hearing loss (Drose et al., 1991).

The postnatal history of intracranial calcifications in infants with treated congenital toxoplasmosis has been studied by computed tomography (Patel et al., 1996). In infants who were treated with appropriate doses of antibiotics, the majority (75%) of calcifications resolved or diminished.

GENETICS AND RECURRENCE RISK

Fetal intracranial calcifications due to an infectious cause presumably have a low risk of recurrence. Limited case reports exist of recurrence of fetal CMV, although reactivation of CMV infection in a subsequent pregnancy is much less likely to result in intrauterine infection. If echogenic branching

thalamic vessels were demonstrated due to trisomy 21 or 13, the recurrence risk is 1%, or the maternal age–related risk, whichever is greater.

10 CHAPTER Craniosynostosis

Key Points

- Condition due to premature fusion of cranial sutures (sagittal, coronal, lambdoid, or metopic).
- Incidence is 1 in 2000 livebirths. One of the most common human malformations.
- Eighty to ninety percent of cases are isolated, 10%–20% are syndromic.
- Women with fetuses suspected of having craniosynostosis should be referred for a detailed fetal anatomic survey. Sonographers should pay attention to the fetal hands, midface, heart, and central nervous system.
- Differential diagnosis includes Muenke coronal craniosynostosis, Saethre–Chotzen syndrome,

Key Points (cont.)

Apert syndrome, Crouzon syndrome, Pfeiffer syndrome, and many others.

- DNA diagnosis is available to detect mutations in the causative genes associated with craniosynostosis, including *FGFR1, FGFR2, FGFR3, TWIST, and MSX2*.
- Newborns are at risk for difficulties with breathing, feeding, and vision. Consultation with genetics and neurosurgery is indicated.
- Long-term outcome and recurrence risk depend on identification of a genetic basis through DNA analysis.

CONDITION

The term *craniosynostosis* refers to the process of premature bony fusion of the cranial sutures. The term is frequently used interchangeably with the word *craniostenosis*, which technically refers to the aberrant skull shape that results from the process of craniosynostosis (Graham, 1981). The weight of the brain doubles during the first year of life, and enlargement of the skull vault is distributed among the main cranial sutures—sagittal, coronal, lambdoid, and metopic. Premature fusion of a suture leads to reduced growth in the direction perpendicular to the fused suture (Thompson et al., 1994). Compensatory growth occurs in the remaining normal sutures. Normally, the cranial sutures are open at birth and become interdigitated by 7.5 months of age. Cranial sutures do not fuse completely until the fourth decade of life (Graham, 1981).

It is important to determine whether craniosynostosis is primary or secondary. In primary craniosynostosis, abnormal skull development is genetically determined and alteration in sutural growth is present from birth (Flores-Sarnat, 2002). In primary craniosynostosis, the head of the affected individual is frequently asymmetric. The brain grows at a normal rate but must adjust to the confined space. The brain continues to grow in areas where the sutures are open but not in areas where the sutures are closed (Lyons-Jones et al., 1980). Most children affected with primary craniosynostosis are normal neurologically and benefit from surgery. In secondary craniosynostosis, brain growth is impaired and most affected children are neurologically abnormal. In secondary craniosynostosis, a metabolic, storage, hematologic, or structural disorder results in microcephaly or otherwise abnormal brain growth (Table 10-1). In evaluating the fetus with craniosynostosis, it is important to determine whether the craniosynostosis is isolated (80–90% of cases) or syndromic (10–20% of cases). More than 150 syndromes have been described that include craniosynostosis as an associated feature (Lajeunie et al., 1995; Warren and Longaker, 2001).

Isolated craniosynostosis generally presents during the first year of life, and severe neuropsychologic sequelae are unusual (Meilstrup et al., 1995). In most studies, the sagittal suture is the most common site for isolated craniosynostosis (Figure 10-1). This is called "scaphocephaly," and it results

Table 10-1

Classification of Craniosynostosis

Primary			Secondary
Single suture	Multiple sutures		
Nonsyndromic (simple)	Nonsyndromic	Syndromic (complex)

in a narrow, elongated head. Physical examination reveals a palpable ridge along the line of the fused suture. Bilateral coronal craniosynostosis (Figure 10-2) leads to "acrobrachycephaly" and a broad, short head (Flores-Sarnat, 2002). Unilateral coronal craniosynostosis, called "plagiocephaly," results in asymmetric flattening of the forehead with loss of the supraorbital ridge. This condition is best appreciated when viewed from above the patient. In most reported studies, the least commonly involved suture is the metopic. This is called "trigonocephaly," and produces a keel-shaped forehead and orbital hypotelorism (Thompson et al., 1994). The kleeblattschädel deformity, also described as a cloverleaf skull, has a more symmetric trilobar appearance, which results from premature synostosis of the coronal and lambdoidal sutures (Meilstrup et al., 1995).

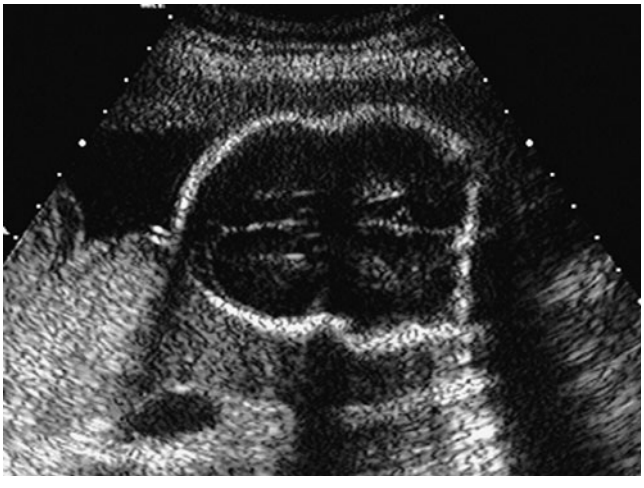

Figure 10-2 Prenatal sonographic image of a fetus at 24 weeks with bilateral coronal craniosynostosis.

INCIDENCE

Craniosynostosis is one of the most common human malformations, with an incidence of approximately 1 in 2000 livebirths (Shuper et al., 1985; Lajeunie et al., 1995; Van der Ham et al., 1995). Craniosynostosis is associated with advanced paternal age (Lajeunie et al., 1995), maternal smoking, and higher altitudes (Alderman et al., 1994, 1995). In a study of 154 patients at Johns Hopkins Hospital followed over a 2-year period, Van der Kolk and Beatty (1994) found that 78% of affected patients had only one suture involved, whereas 16% of patients had multiple sutures involved. Of these 154 patients, 94% had isolated craniosynostosis and 6% had complex or syndromic craniosynostosis. In this study, secondary synostosis occurred in four patients as a result of microcephaly or following complications of ventriculoperitoneal shunt placement (Van der Kolk and Beatty, 1994). Craniosynostosis occurs in all ethnic and racial groups.

Of the syndromic craniosynostoses, the most common are Saethre–Chotzen syndrome (Lewanda et al., 1994) and Muenke coronal craniosynostosis (Muenke et al., 1997). The next most common is Crouzon syndrome, with an incidence of 1 per 25,000 livebirths (Leo et al., 1991). Apert syndrome, with its distinctive craniofacial and digital abnormalities, occurs in 1 per 65,000 to 160,000 livebirths (Chenowith-Mitchell and Cohen, 1994; Moloney et al., 1996). Apert syndrome is associated with advanced paternal age (Moloney et al., 1996).

SONOGRAPHIC FINDINGS

Prenatal sonographic evaluation of the fetus in which craniosynostosis is suspected should include examination of

1. the symmetry of the calvarium contour (coronal views through temporal lobes and orbits);
2. the continuity of the calvarium to exclude encephalocele;
3. the size and shape of the orbits;
4. the cerebral ventricles;
5. the brain parenchyma;
6. the overall head size;
7. the remainder of fetal anatomy by detailed sonography (Meilstrup et al., 1995).

The most important consideration in the sonographic examination is the distinction between isolated and syndromic craniosynostosis. For most of the conditions associated with craniosynostosis, long-bone growth is within normal limits. It is particularly important to evaluate the fetal hands and feet, the central nervous system, and the heart.

In most published reports of prenatal diagnosis of craniosynostosis, the diagnosis was not made until the third trimester, unless a family history was present for one of the associated syndromes. In one report, 16 fetuses at risk for craniosynostosis were referred to a fetal medicine unit because of a positive family history (Delahaye et al., 2003). Serial

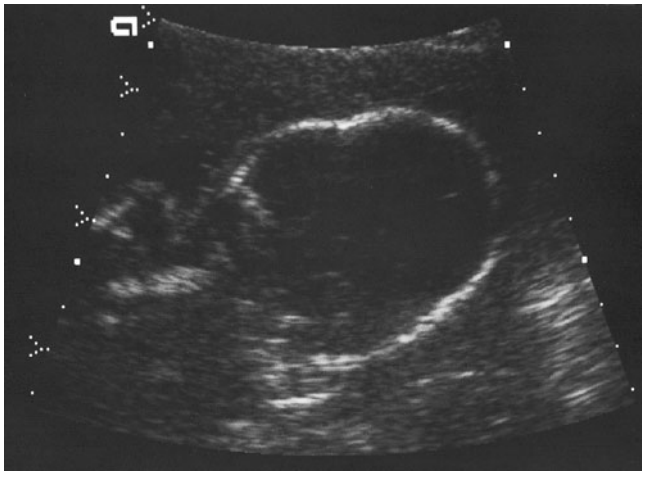

Figure 10-3 Prenatal sonographic image of a fetus at 23 weeks' gestation with Apert syndrome, demonstrating bilateral coronal suture synostosis and a tower-like shape of the skull (turricephaly).

sonographic examinations were performed at 12, 22, and 32 weeks of gestation. In all cases, postnatal diagnosis agreed with the third trimester (and, in a few cases, second trimester) diagnosis. Craniosynostosis was diagnosed when there was a loss of hypoechogenicity of the normal suture. Sutures were examined along their entire length. Dysmorphology and skull deformity preceded closure of the sutures by 4 to 16 weeks.

Fetuses at risk for Apert syndrome (Figure 10-3) should be evaluated for abnormalities of the hands (syndactyly), proptosis, congenital heart defects, agenesis of the corpus callosum, and abnormalities of the limbic structures of the brain (de León et al., 1987; Skidmore et al., 2003; Hansen et al., 2004). At least one case has been reported of Apert syndrome presenting as fetal hydrocephalus, although the presence of hydrocephalus is considered controversial (Kim et al., 1986). Some authors prefer to use the term *distortion ventriculomegaly* to indicate that the apparent abnormalities in fluid are the result of the misshapen brain (Cohen and Kreiborg, 1993b). One case of Apert syndrome presenting as nuchal-fold thickening as early as 12 weeks of gestation has been described (Chenowith-Mitchell and Cohen, 1994). This fetus did not demonstrate any additional sonographic abnormalities until after 26 weeks of gestation, when an abnormal head shape was first noted. By 29 weeks of gestation, the fetal skull was demonstrated to have prominent parietal lobes, and for the first time, lack of separate fetal finger movement was noted. This latter finding of the absence of distinct and separate movements of the fingers and toes is considered to be one of the hallmarks of Apert syndrome (Hill et al., 1987). Three-dimensional (3-D) sonographic imaging has been shown to be useful in the diagnosis of a sporadic case of Apert syndrome, specifically by demonstrating a widely open metopic suture and bilateral fusion of the coronal sutures (Esser et al., 2005).

Pfeiffer syndrome is characterized by coronal craniosynostosis, midface hypoplasia, and broad thumbs and great toes. There are three clinical subtypes: type I is the mildest presentation, type II is the most severe, and type III is intermediate. Type II is associated with a cloverleaf-shaped skull, severe ocular proptosis, midface hypoplasia, radially deviated digits, and occasional ventriculomegaly (Benacerraf et al., 2000). Several cases of the sonographic diagnosis of Pfeiffer syndrome, type II, with molecular confirmation, have been reported in the literature (Benacerraf et al., 2000; Blaumeiser et al., 2004; Gorincour et al., 2005).

DIFFERENTIAL DIAGNOSIS

Whenever craniosynostosis is considered in a fetus, an attempt should be made to rule out encephalocele (see Chapter 12) and the presence of an intracranial mass. Craniosynostosis is associated with abnormalities of chromosomes 5p, 7p, and 13q, single-gene disorders, and rare teratogens, such as aminopterin.

The most common conditions associated with syndromic craniosynostosis include Saethre–Chotzen syndrome, which includes craniosynostosis, facial asymmetry, low frontal hairline, ptosis, a deviated nasal septum, brachydactyly, and partial cutaneous syndactyly of the toes (Lewanda et al., 1994). Saethre–Chotzen syndrome is dominantly inherited, but in some families the features are so mild that they may go unrecognized.

A relatively recently identified syndrome, Muenke coronal craniosynostosis, has significant clinical overlap with Saethre–Chotzen syndrome (Vajo et al., 2000). It is also quite common. There is considerable phenotypic variability in this condition and mild cases may be missed. Affected individuals have coronal craniosynostosis, and mild abnormalities of the hands and feet, including carpal and tarsal fusion, brachydactyly, thimble-like middle phalanges, and cone-shaped epiphyses. Additional findings include sensorineural hearing loss and developmental delay (Muenke et al., 1997). This condition is also dominantly inherited.

The next most common syndrome associated with craniosynostosis is Crouzon syndrome, which includes coronal craniosynostosis, maxillary hypoplasia, shallow orbits, and ocular proptosis. This condition was first described in 1912 in an affected mother and daughter (Leo et al., 1991). Crouzon syndrome is distinguished from some of the other syndromes by the absence of abnormalities in the hands and feet. The essential features of this syndrome are limited to the skull and face, resulting in brachycephaly and orbital hypoplasia (Thompson et al., 1994).

Less common syndromes in the differential diagnosis include Jackson–Weiss, Pfeiffer (types I, II, III) and Carpenter. Jackson–Weiss syndrome was first described in an Amish kindred with more than 130 affected family members. The characteristic findings of Jackson–Weiss syndrome include craniosynostosis, maxillary retrusion, frontal prominence, hypotelorism, strabismus, and in general, anomalies of the feet but not the hands. The characteristic anomalies of the

feet include medial deviation of the big toes and partial syndactyly of the first web space (Stankovic et al., 1994). Pfeiffer syndrome has three forms. There is a relatively benign form, known as the type I, which consists of an acrocephalic skull due to bicoronal synostoses. Affected patients have broad thumbs and great toes and soft tissue syndactyly. Like many of the other syndromes associated with craniosynostosis, affected patients have hypotelorism, maxillary hypoplasia, low-set ears, and normal intelligence (Hill and Grzybeck, 1994). Two other subgroups of patients with Pfeiffer syndrome had extreme proctosis and hydrocephalus. These patients have a uniformly poor outcome and are distinguished from each other as the type II form with the cloverleaf skull deformity and the type III form without the cloverleaf skull deformity (Moore et al., 1995). The kleeblattschädel, or cloverleaf, skull deformity is also associated with thanatophoric dysplasia (see Chapter 90). Of all patients with the cloverleaf skull deformity, 20% are due to Pfeiffer syndrome and 40% are due to thanatophoric dysplasia (Hill and Grzybeck, 1994). In Carpenter syndrome, affected patients have acrocephaly, soft-tissue syndactyly, radial/tibial polydactyly, congenital heart disease, and mental retardation. In Baller–Gerold syndrome, affected patients have craniosynostosis and radial/tibial upper-limb malformations (see Chapter 106) (Boudreaux et al., 1990).

Patients with the Apert syndrome, first described in 1906, have a shortened anterior–posterior diameter of the skull with a high, full forehead, flat occiput, flat facies, shallow orbits, hypotelorism, osseous and cutaneous syndactyly, and associated anomalies (Figures 10-3 and 10-4). Ten percent of patients have cardiovascular abnormalities, and approximately 10% have genitourinary anomalies, most commonly hydronephrosis and cryptorchidism (Cohen and Kreiborg, 1993b). One of the most characteristic findings of patients affected with Apert syndrome includes the complete digital fusion of the soft tissues of the digits 2, 3, and 4, which creates a mid-digital hand mass with a single common nail (see Figures 105-1 to 105-4).

ANTENATAL NATURAL HISTORY

The cranium develops as islands of bone within a fibrous membrane called the "ectomenix." The wedge-shaped proliferation of cells at the periphery is called the "osteogenic front." When osteogenic fronts come in close proximity to each other, a suture develops. The suture allows spatial separation of cranial bones during growth. The suture includes fibrous tissue defined radiographically by lucency and by proliferating osteogenic tissue on the periphery of the bone. The cranial sutures consist of five layers including two cambial and two periosteal layers separated by a middle vascular layer. The suture allows bone growth at sutural margins secondary to distant forces separating sutures (Van der Kolk and Beatty, 1994).

Figure 10-4 Fetus from Figure 10-3 after termination, demonstrating turricephaly and a wide open metopic suture. Prenatal sonograms and post-termination photographs of this fetus' extremities are shown in Figures 105-1 to 105-4.

The antenatal natural history for fetuses affected with craniosynostosis depends on whether the condition is isolated or syndromic. In general, fetuses with isolated craniosynostosis grow and develop normally. Fetuses with syndromic craniosynostosis are also generally normal, if not sometimes large for gestational age. There is no evidence that any of these syndromes are associated with increased lethality in utero.

MANAGEMENT OF PREGNANCY

One of the most important considerations in the management of pregnancy is to obtain a detailed family history. Both parents should be examined for the presence of facial asymmetry or for partial syndactyly of the fingers or toes. These findings are consistent with the mildest expression of some of the syndromic craniosynostoses. It is also important to remember that parents affected with one of the syndromic craniosynostoses may have had extensive plastic surgical repair and will therefore have a relatively normal appearance.

We recommend referral of the pregnant patient carrying a fetus with presumed craniosynostosis to a tertiary care

center capable of targeted sonographic examination of the fetus. It is particularly important to rule out the presence of associated hand and foot abnormalities as well as the more serious cardiovascular abnormalities that can be present in some of these syndromes. If there is a positive family history of isolated craniosynostosis, no further work-up is necessary. If, however, the family history is negative, we recommend prenatal karyotyping to rule out chromosomal abnormalities associated with craniosynostosis (Fryburg and Golden, 1993). Furthermore, in the setting of a negative family history, if additional sonographic findings suggest a syndromic diagnosis, it is important that the parents meet with a medical geneticist to discuss the implications of the potential diagnoses and perform molecular diagnosis. Many of the syndromic craniosynostoses are associated with normal intelligence; however, Apert syndrome is associated with a significant chance of developmental delay.

Fetal magnetic resonance imaging (MRI) has been used to confirm cranial abnormalities in a case of Apert syndrome (Boog et al., 1999). If the diagnosis is made before 24 weeks of gestation, parents can be given the option of terminating the pregnancy. If the diagnosis is made in the third trimester, we recommend that the delivery occur in a tertiary care center because of the possibility of associated feeding and breathing difficulties in the neonate. In addition, it will be important for a medical geneticist to examine the infant after birth to confirm the presumed clinical diagnosis and perform confirmatory molecular diagnosis testing. Fetuses with skull abnormalities suggesting a head circumference larger than normal may need to be delivered by cesarean section.

FETAL INTERVENTION

In utero correction of craniosynostosis is not recommended (Warren and Longaker, 2001).

TREATMENT OF THE NEWBORN

Infants with suspected craniosynostosis should have a detailed physical examination at birth. Some of the associated physical findings in the syndromic craniosynostosis are listed in Table 10-2. Anteroposterior and lateral views of the skull should be obtained. On radiography, the prematurely fused suture is either completely absent or represented by a line of increased density. In cases of coronal synostosis, the so-called harlequin appearance of the orbit is due to elevation of the ipsilateral sphenoid wing. Physical examination of the infant should be performed in consultation with a clinical geneticist to seek specific evidence of associated abnormalities. For example, 30% of infants affected with Apert syndrome have submucous cleft palate (Mulliken and Bruneteau, 1991). Furthermore, geneticists facilitate molecular testing to provide a definitive diagnosis. This is important even in the setting of isolated unilateral coronal craniosynostosis (Mulliken et al., 2004). In one study, mutations in *FGFR2,3* or *TWIST* were found in 8 of 47 patients studied with unilateral coronal craniosynostosis. Detection of a mutation was shown to influence the type of surgical repair (Mulliken et al., 2004).

Baller–Gerold syndrome	Autosomal recessive
Gorlin–Chaudhry-Moss syndrome	Autosomal recessive
Teratogen	
Aminopterin	

For patients with suspected syndromic craniosynostosis, computed tomographic (CT) and MRI examinations are recommended to check for brain parenchymal abnormalities and for the presence of hydrocephalus.

Treatment of the affected newborn includes an assessment of four main functional areas: breathing, feeding, vision, and complications of increased intracranial pressure. In infants affected with syndromic craniosynostosis, the maxillary hypoplasia responsible for midface abnormalities reduces nasal and postnasal volume (Thompson et al., 1994). Foreshortening of the skull base, palatal arching, and choanal stenosis further compromise the upper airway. The hindbrain contents can herniate through the foramen magnum. Pediatricians should note the affected infant's respiratory rate and work of breathing, monitor oxygen saturation, and consider nasal stents or nasal prongs, or even tracheostomy to prevent airway obstruction. The role of continuous positive airway pressure (CPAP) is being investigated for affected infants. MRI of the trachea can also be considered.

The anatomic abnormalities that affect breathing also can affect feeding. Infants should be evaluated for the presence of cleft palate. Oropharyngeal coordination during sucking

and swallowing can be a major problem. A careful assessment should be made of feeding capabilities; feeding by gastrostomy tube can be considered.

One third of children with craniosynostosis have increased intracranial pressure. This is especially a problem in children who have multiple suture synostosis or syndromic synostosis (Thompson et al., 1994). Because intelligence quotient (IQ) and development can be affected, some authors recommend measurement of the intracranial pressure (Thompson et al., 1994). This helps to plan the timing of the surgical repair. Intracranial pressure can be measured by insertion of a subdural pressure transducer with pressure recordings made over a 24-hour period.

In patients with syndromic craniosynostosis who have proptosis, the globes are predisposed to infection, corneal ulceration, and recurrent prolapse of the orbital contacts. Excessive drying of the eyes may necessitate the use of artificial tears. Patients with severe proptosis are generally treated surgically.

SURGICAL TREATMENT

The primary objective of surgery is to allow adequate brain growth within the first 12 months of life. The secondary objective is to improve the patient's appearance. The optimal timing for surgical treatment of craniosynostosis is under debate. If evidence exists for symptomatic increased intracranial pressure (such as bulging fontanelles, or progressive optic atrophy), most surgeons would intervene as soon as possible (Warren and Longaker, 2001). In general, surgical repair consists of three phases: (1) suture release, cranial vault decompression, and upper orbital advancement at ages 6 to 12 months; (2) craniofacial surgery to correct midface abnormalities at ages 6 to 12 years; and (3) orthognathic surgery at ages 14 to 18 years (Warren and Longaker, 2001).

For patients who have isolated (simple) craniosynostosis, a single definitive operation performed during the first year of life produces excellent cosmetic results in 93% of affected patients (Whitaker et al., 1987; Thompson et al., 1994). For patients with scaphocephaly, a strip craniectomy is performed with a wide margin of excision. For patients with plagiocephaly and trigonocephaly, the frontal bones are removed and supraorbital ridges are adjusted via a bifrontal craniotomy (Thompson et al., 1994). Complications of surgery include bony infection, meningitis, aspiration pneumonia, and postoperative development of encephalocele (Whitaker et al., 1987).

For patients affected with syndromic craniosynostoses, a multidisciplinary assessment is recommended. The identification and control of elevated intracranial pressure is central to the planning of surgery. Most surgeons recommend an initial cranial vault expansion, followed by midface advancement to reduce maxillary hypoplasia. For patients affected with Apert syndrome, the surgery is typically staged. However, in Apert syndrome, only the coronal sutures are fused from the base upward; the sphenozygomatic, sphenotemporal, lambdoidal, and occipital mastoid sutures are all radiologically patent at birth. For individuals affected with Apert syndrome, the coronal sutures are released initially and frontal bone advancement occurs at 3 to 6 months of age (Mulliken and Bruneteau, 1991). The purpose of this initial surgery is to decompress the intracranial space, to protect proptotic globes, and to perform the initial construction of a normal-appearing supraorbital and frontal configuration. It is important for prospective parents to recognize that the syndromic craniosynostoses are more complicated than the isolated craniosynostoses. For most of the syndromes, initial decompression surgery is followed by plastic surgery in adolescence.

LONG-TERM OUTCOME

The long-term outcome depends on whether the craniosynostosis was simple or complex. In one study of 56 children with craniosynostosis, Noetzel et al. (1985) studied 27 patients with simple craniosynostosis. None of these patients had hydrocephalus on CT scan. Seventeen of 27 patients with simple craniosynostosis had average intelligence. An additional 6 had intelligence in the low average range, and 1 was developmentally delayed. This individual also had a history of perinatal depression. These authors noted that hydrocephalus occurred more frequently in complex craniosynostosis, specifically in affected patients with Pfeiffer and Crouzon syndromes. Of the 25 patients in the study who had complex or syndromic craniosynostosis, 19 had normal intelligence.

For most of the conditions associated with craniosynostosis, long-bone growth and pubertal development occur normally (Cohen and Kreiborg, 1993a). An additional complication of the complex craniosynostosis syndromes includes middle-ear infections (Kaplan et al., 1991). An unusual long-term complication of Apert syndrome is the presence of severe acne, which extends down to the forearm (Kaplan et al., 1991). This localized acne is now known to be due to a mutation in the fibroblast growth factor receptor 2 (*FGFR2*) gene (Munro and Wilkie, 1998). Patients with Apert syndrome also have excessive sweating.

GENETICS AND RECURRENCE RISK

All fetuses suspected of having craniosynostosis should have a detailed family history taken by a trained geneticist. Of 154 patients studied at John Hopkins Hospital, only 2.5% with isolated synostosis had a positive family history. In contrast, in patients affected with one of the syndromic craniosynostosis conditions, 50% had a positive family history (Van der Kolk and Beatty, 1994).

The first syndrome associated with craniosynostosis to be identified at the molecular level was a relatively rare form

of craniosynostosis known as the "Boston type." This condition is characterized by high penetrance and variable expression. Affected patients have a variety of phenotypes, including frontal orbital recession to pansynostosis to a cloverleaf skull deformity (Warman et al., 1993). Later that year Jabs et al. demonstrated that this condition was due to a substitution of histidine for a proline in the *MSX2* homeobox, which created a gain-of-function mutation. Overexpression of *MSX2* prevented osteoblast differentiation and mineralization of the extracellular matrix (Jabs et al., 1993).

The fibroblast growth factor receptor types 1, 2, and 3 genes are all involved in the molecular etiology of many of the conditions that cause craniosynostosis, specifically Apert, Crouzon, Jackson–Weiss, Pfeiffer, Muenke, and Beare–Stevenson syndromes (Li et al., 1994; Jabs et al., 1994; Gorry et al., 1995; Rutland et al., 1995; Wilkie, 2005). FGFRs are signal-transduction molecules that cross the cell membrane. All FGFRs share a similar structure in their molecular sequence, which consists of three extracellular immunoglobulin-like domains (IgI, IgII, and IgIII), a single-pass transmembrane segment, and a split tyrosine kinase domain (TK1/TK2) (Kan et al., 2002).

FGFR2 encodes a cell membrane receptor protein. Mutations in a single exon (IIIc) have been associated with three different phenotypes. The more severe phenotype associated with Apert syndrome has been mapped to exon IIIu. The mutation spectrum of Apert syndrome is suprisingly narrow. In a study of 118 unrelated patients with Apert syndrome, all had one of two specific cytosine-to-guanine transversions in the *FGFR2* gene on chromosome 10. Furthermore, in every case the mutation arose from the father (Moloney et al., 1996). The mutational spectrum of *FGFR2* is relatively narrow, with distinct mutations occurring in a limited number of exons (Kan et al., 2002). In a prospective study of 259 patients with craniosynostosis, the IgIIIa/IIIc region of the gene was shown to be a genuine mutation hotspot (Kan et al., 2002). Investigators have also shown that Pfeiffer syndrome is genetically heterogenous. It is caused by mutations in two different genes, the *FGFR1* gene, located on the short arm of chromosome 8, and *FGFR2* gene located on the long arm of chromosome 10 (Muenke et al., 1994; Schell et al., 1995). Muenke coronal craniosynostosis and a specific subtype of Crouzon syndrome with acanthosis nigricans are both caused by mutations in *FGFR3* (Vajo et al., 2000). In newly occurring cases in families, *FGFR3* mutations exclusively occur on the paternal copy of chromosome 4 and are associated with advanced paternal age (Rannan-Eliya et al., 2004).

The gene for Saethre–Chotzen syndrome has been mapped to 7p21 (Rose et al., 1994; van Herwerden et al., 1994). Saethre–Chotzen syndrome is caused by mutations in *TWIST*, a basic helix-loop-helix transcription factor (Howard et al., 1997). Drosophila embryos that lack the *TWIST* protein have a "twisted" appearance. Haploinsufficiency for this gene is the pathogenetic mechanism for this condition (Johnson et al., 1998). More than 35 mutations in *TWIST* have been described in individuals with Saethre–Chotzen syndrome (Paznekas et al., 1998). *TWIST* mutations are also the underlying basis for Baller–Gerold syndrome, which manifests as craniosynostosis and radial aplasia.

The known genes identified in the syndromic craniosynostoses are listed in Table 10-3. A summary of the

Table 10-3

Genes Involved in the Syndromic Craniosynostoses

Gene	Syndrome	Mode of Inheritance	Chromosomal Location
FGFR1	Pfeiffer (mild)	AD	8p11.2

molecular mutations discovered to date in the craniosynostosis syndromes is given in Table 10-4.

Adult individuals affected with one of the craniosynostosis syndromes should have DNA analysis to determine their specific mutation prior to contemplating pregnancy. If the underlying mutation responsible for their disorder is identified, prenatal diagnosis is available for them on fetal tissue obtained by chorionic villus sampling (CVS) or amniocentesis. The advantage of DNA testing is that the diagnosis is available earlier in gestation than by sonographic examination and it is more definitive. Adult individuals affected with one of the syndromic craniosynostoses will have a 25% or 50% risk of recurrence, depending on the specific syndrome. In theory, unaffected individuals with a prior affected child do not have an increased incidence of recurrence above the underlying background risk, although gonadal mosaicism is a small possibility. For patients with a negative family history, prenatal sonographic diagnosis in subsequent pregnancies is warranted to provide reassurance.

11 CHAPTER Dandy–Walker Malformation and Variants

Key Points

- Dandy–Walker malformation refers to the combination of hypoplasia of the cerebellar vermis, cystic dilation of the fourth ventricle communicating with the cisterna magna, and increase in size of the posterior fossa.
- Related conditions include Dandy–Walker variant (varying hypoplasia of the inferior vermis without enlargement of fourth ventricle or cisterna magna), mega cisterna magna (enlarged cisterna magna in the setting of normal vermis), and Blake's pouch cyst (extension of the fourth ventricle into the cisterna magna, represented by septae within the cisterna magna).
- Some authors feel that there is no role in differentiating Dandy–Walker malformation and variant, as both can be associated with CNS and non-CNS malformations, aneuploidy, and adverse neurological outcome.
- False-positive diagnoses of Dandy–Walker malformation are possible, especially if noted before 18 weeks, or if the abnormality is confined to the cerebellar vermis alone.
- Following diagnosis, a detailed search for other CNS and non-CNS malformations is required, including prenatal MRI, and karyotype analysis.
- Other than multidisciplinary counseling, no other alterations to standard obstetric care are indicated.

CONDITION

The Dandy–Walker malformation is a nonspecific congenital brain malformation that results from a number of diverse causes. There are two principal features of the Dandy–Walker malformation: aplasia or hypoplasia of the cerebellar vermis and posterior fossa cysts that represent cystic dilatation of the fourth ventricle (Nyberg et al., 1988).

The first case of Dandy–Walker malformation was reported in 1887 (Murray et al., 1985). In 1914, Blackfan and Dandy described a hindbrain abnormality in a patient with cystic dilatation of the fourth ventricle, hypoplasia of the cerebellar vermis, separation of the cerebellar hemispheres, and absence of the lateral and median apertures of the fourth ventricle (cited in Chang et al., 1994). The term *Dandy–Walker malformation* was first used in 1954, combining case reports

of Blackfan and Dandy, and a subsequent report of Taggart and Walker (Chen and Chu, 1994).

The Dandy–Walker malformation originates before the 6th or 7th week of embryonic development (Russ et al., 1989). The malformation may occur in single-gene disorders, in chromosomal abnormalities, in environmentally induced malformation syndromes, or in conjunction with other multifactorial anomalies (Cornford and Twining, 1992).

The full Dandy–Walker malformation consists of complete vermian agenesis, cystic dilatation of the fourth ventricle that communicates with an enlarged cisterna magna, and an enlarged posterior cranial fossa. While obstructive hydrocephalus is nearly always an associated finding postnatally, it is usually not present prenatally (Niesen, 2002). It is unclear if such hydrocephalus is due to failure of the foramina of Lushka and Magendie to open, or to some other embryological disruption.

The full Dandy–Walker malformation is sometimes distinguished from the Dandy–Walker variant and mega cisterna magna (Chen and Chu, 1994). The Dandy–Walker variant consists of variable hypoplasia of the cerebellar vermis, without enlargement of the posterior fossa. There is usually a communication between the fourth ventricle and the cisterna magna. Ventricular dilatation may or may not be present and the cerebellar hemispheres are generally within normal limits (Estroff et al., 1992; Bromley et al., 1994). In mega cisterna magna (greater than 10 mm in anteroposterior dimension), an enlarged cisterna magna is present with a normal cerebellar vermis and fourth ventricle (Estroff et al., 1992). While many authors have tried to distinguish between Dandy–Walker malformation and its variant to better delineate the expected prognosis for the affected fetus, it is unclear how useful this is in clinical practice. In one series of 50 cases of Dandy–Walker malformation and 49 cases of Dandy–Walker variant, the incidence of additional CNS and non-CNS anomalies, and the incidence of karyotypic abnormalities, were similar in both groups (Ecker et al., 2000). Some authors feel that the term Dandy–Walker variant is imprecise and should not be used, and the preferred descriptive term "cerebellar hypoplasia" be used instead (Niesen, 2002). Others consider Dandy–Walker variant to be little more than a variant of normal (Patel and Barkovich, 2002).

A further normal anatomic entity, referred to as Blake's pouch cyst, is formed from the normal dorsal expansion of the fourth ventricle into the cisterna magna, and is detected prenatally by transverse lines, or septa, within the cisterna magna behind the cerebellar vermis (Robinson and Goldstein, 2006). This finding may be associated with development of symptoms such as headache and recurrent loss of consciousness (Calabro et al., 2000).

INCIDENCE

Dandy–Walker malformation occurs in at least 1 in 5000 liveborn infants (Parisi and Dobyns, 2003). In a series of postnatally ascertained Dandy–Walker malformation, it occurred in 12% of cases of congenital hydrocephalus and 2% to 4% of cases of childhood-onset hydrocephalus (Murray et al., 1985; Chen and Chu, 1994).

SONOGRAPHIC FINDINGS

A major consideration in the diagnosis of Dandy–Walker malformation is gestational age. Although Dandy–Walker malformation has been diagnosed in the first trimester (Achiron and Achiron, 1991; Gembruch et al., 1995; Nizard et al., 2005), a false-positive diagnosis can be made at gestational ages of less than 18 weeks. Bromley et al. (1994) prospectively evaluated 897 fetuses between 13 and 21 weeks of gestation to determine the normal development of the fetal cerebellum. A total of 147 fetuses were shown to have an open vermis at the time of initial scanning, of which 56% were open at 14 weeks of gestation, 23% were open at 15 weeks of gestation, and 6% remained open at 17 weeks of gestation. After 17.5 weeks of gestation, all fetuses were noted to have a closed vermis. These authors concluded that prenatal diagnosis of cerebellar malformations, in particular subtle findings such as the Dandy–Walker variant, should not be made at less than 18 weeks' gestation because development of the cerebellar vermis may be incomplete. True Dandy–Walker malformations are usually visible earlier in gestation, because the cerebellar hemispheres are hypoplastic and laterally displaced, and in addition, a cyst can be visualized (Figure 11-1).

The sonographic features of the Dandy–Walker malformation include a central cyst communicating with the fourth ventricle, agenesis or hypoplasia of the cerebellar vermis, and splaying of the cerebellar hemispheres with anterolateral displacement against the tentorium, thereby enlarging the posterior fossa (Russ et al., 1989). In a study of 15 prenatally

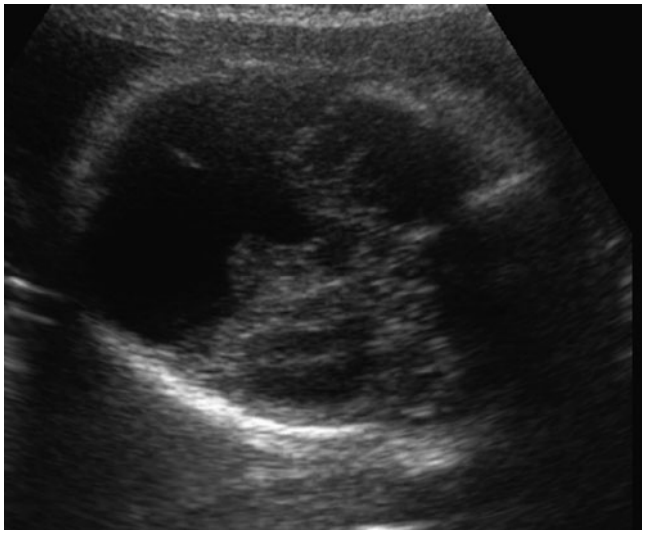

Figure 11-1 Transaxial sonogram of a fetal head demonstrating a posterior fossa cyst with cleft of the cerebellar vermis.

diagnosed cases of Dandy–Walker malformation, the anteroposterior diameter of the posterior fossa cyst was between 7 and 45 mm, with most being >10 mm (Russ et al., 1989). Macrocephaly was seen in 3 of 15 cases (20%), and there were additional brain anomalies in 68% of cases. Agenesis of the corpus callosum was seen in 7% to 17% of cases. In this study, extracranial anomalies were present in 60% of fetuses studied, including involvement of the cardiac, genitourinary, gastrointestinal, and skeletal systems. Of the 12 fetuses who had karyotyping, one-third were abnormal. Similar findings were noted by Nyberg et al. (1988), who reviewed seven proven cases of prenatally diagnosed Dandy–Walker malformation. Of the seven patients, five had hydrocephalus, four had multiple malformations, and two of these had abnormal karyotypes. These authors concluded that the presence of a Dandy–Walker malformation should prompt a careful search for concurrent abnormalities and consideration of a karyotype. In another study of 78 cases of prenatally diagnosed Dandy–Walker malformation, almost 20% had an associated karyotypic abnormality (Has et al., 2004).

Diagnostic criteria for Dandy–Walker variant are quite unclear, with some suggesting that this term should no longer be used as it does not appear to be predictive of outcome (Niesen, 2002; Patel and Barkovich, 2002). The sonographic criteria for the Dandy–Walker variant include partial or complete absence of the cerebellar vermis (Figure 11-2), with near normal-sized cerebellar hemispheres. The sonographic continuity between the fourth ventricle and the cisterna magna gives the appearance of a cleft (Estroff et al., 1992). In one study of 17 cases of Dandy–Walker variant, 4 fetuses also had ventriculomegaly and 3 had agenesis of the corpus callosum (Estroff et al., 1992). Almost half of the affected fetuses had other non-CNS abnormalities, including congenital heart disease, gastrointestinal malformations, renal malformations, and intrahepatic calcifications. Additionally, the presence of the Dandy–Walker variant was associated with a high incidence (29%) of abnormal karyotype (Estroff et al., 1992). In contrast, a recent study of 19 cases of Dandy–Walker variant, diagnosed strictly as isolated inferior vermian hypoplasia by prenatal MRI, demonstrated near normal outcome (Limperopoulos et al., 2006). This would underscore the importance of using strict prenatal diagnostic criteria, and perhaps using the term isolated inferior vermian hypoplasia for the select cases previously referred to as Dandy–Walker variant.

Figure 11-2 Transaxial sonogram demonstrating cleft of the cerebellar vermis and splaying of the cerebellar hemispheres.

The appearance of the cisterna magna has taken on increasing importance over recent years (Pretorius et al., 1992). The effacement of the cisterna magna gives the "banana sign" of the cerebellum seen in myelomeningocele (see Chapter 19 and Figure 19-2). A small cisterna magna implies an associated neural tube defect and a Chiari II malformation. In contrast, however, an enlarged cisterna magna can be associated with a Dandy–Walker cyst, cerebellar hypoplasia, and communicating hydrocephalus (Pretorius et al., 1992). Nyberg et al. (1991) studied 33 fetuses with the sonographic appearance of an enlarged cisterna magna. Of these 33 fetuses, 18 (55%) had underlying chromosomal abnormalities. Interestingly, the absence of hydrocephalus and milder enlargement correlated more strongly with the presence of an underlying chromosomal abnormality. The negative correlation between ventriculomegaly and chromosomal abnormality was also seen in another study (Chang et al., 1994). These authors tried to distinguish the prognosis based on the sonographic appearance of the fetal vermis. They reviewed sonographic findings in 65 fetuses with Dandy–Walker malformation. Of these, 37 had inferior vermian agenesis, or the milder form of the disorder, and 28 had complete vermian agenesis. Chromosomal abnormalities were seen in 23 of the 51 fetuses who were karyotyped (45%). Chromosomal abnormalities were less prevalent among fetuses with ventriculomegaly. Extracranial abnormalities were seen in 66% of fetuses with inferior vermian agenesis (Chang et al., 1994). In another series, chromosomal abnormalities were seen in 36% and 46% of cases of Dandy–Walker variant and Dandy–Walker malformation, respectively (Ecker et al., 2000).

DIFFERENTIAL DIAGNOSIS

Major considerations in the differential diagnosis include distinguishing between Dandy–Walker malformation, Dandy–Walker variant, enlarged cisterna magna, and Blake's pouch cyst, as well as the dorsal cyst seen in holoprosencephaly, and arachnoid cysts (see Chapter 8). The normal anteroposterior depth of the cisterna magna does not exceed 10 mm. The pathognomonic finding in Dandy–Walker malformation is a defect in the vermis through which the cyst communicates with fourth ventricle. The true Dandy–Walker cyst appears as a triangular midline fluid collection with symmetric splaying of the cerebellar hemispheres (see Figure 11-1) (Russ et al., 1989). Neither arachnoid cysts nor enlarged cisterna magna

is associated with vermian defects or other cerebellar or cerebral abnormalities. Retrocerebellar arachnoid cysts compress but do not communicate with the fourth ventricle. In general, arachnoid cysts are asymmetrically positioned in the posterior fossa and tend to be rounded rather than triangular. If the Dandy–Walker cyst herniates through the foramen magnum or a defect in the occiput, this may be mistaken for a primary encephalocele (Lee et al., 2005).

The dorsal cyst associated with alobar or semilobar holoprosencephaly can sometimes be confused with the Dandy–Walker malformation. However, in holoprosencephaly, the cyst is supratentorial and communicates directly with the single ventricle seen in this condition. In addition, a hallmark of the diagnosis of holoprosencephaly is the presence of fused or partially fused thalami (see Chapter 14) (Nyberg et al., 1988).

A list of the common conditions associated with Dandy–Walker malformation is given in Table 11-1. Of note are two Mendelian (single-gene) disorders that are commonly associated with Dandy–Walker malformation. In Joubert–Boltshauser syndrome, vermian agenesis is one of the criteria needed for diagnosis. Joubert–Boltshauser syndrome, an autosomal recessive disorder, consists of familial vermian agenesis, episodic hyperpnea, developmental delay, hypotonia, and abnormal eye movements (Keogan et al., 1994). In addition, Dandy–Walker malformation is seen in 53% cases of Walker–Warburg syndrome (Vohra et al., 1993). The Walker–Warburg syndrome consists of lissencephaly with cerebellar malformations, retinal malformations, and congenital muscular dystrophy. The Dandy–Walker malformation is seen in most cases of trisomy 9 or mosaic trisomy 9 (Bureau et al., 1993; McDuffie, 1994; Chen et al., 2002). Dandy–Walker malformation is now also included as one of the CNS malformations that support the diagnosis of Meckel–Gruber syndrome (Summers and Donnenfeld, 1995). For an exhaustive list of genetic disorders associated with Dandy–Walker malformation, refer to Chitayat et al. (1994).

The differential diagnosis for apparent defects of the cerebellar vermis must also include normality. False-positive diagnoses of Dandy–Walker malformation have been reported. In one series of 14 cases of prenatally diagnosed cases of Dandy–Walker malformation, subsequent autopsy confirmed this diagnosis in only 6 (43%) cases (Carroll et al., 2000).

ANTENATAL NATURAL HISTORY

The natural history for Dandy–Walker malformation in utero is not known. It appears that progressive changes usually occur slowly (Russ et al., 1989). Some degree of enlargement of the posterior fossa cyst and worsening hydrocephalus can be observed in utero, however.

Gestational age at diagnosis is important for predicting immediate pregnancy outcomes. In a study by Ulm et al. (1997), a comparison was performed of associated structural and chromosomal abnormalities in 14 fetuses with Dandy–Walker malformation diagnosed before 21 weeks and 14 fetuses diagnosed after 21 weeks. They concluded that fetuses diagnosed earlier in gestation had a worse prognosis.

It appears that the immediate prognosis for Dandy–Walker malformation is influenced by the presence of associated abnormalities. Of the nine fetuses with Dandy–Walker malformation in one report, three had multiple significant CNS and non-CNS abnormalities (Keogan et al., 1994). Fetuses with an isolated vermian hypoplasia all did well. Similarly, Cowles et al. (1993) described the presence of multiple associated CNS malformations in the Dandy–Walker malformation, including agenesis of the corpus callosum and occasional occipital encephaloceles. In their patient population, they observed extracranial malformations, including cleft lip and cleft palate, cardiac malformations, and urinary tract abnormalities. In Nyberg's study of seven prenatally diagnosed cases of Dandy–Walker malformation, there was high perinatal mortality, with five of the seven patients dying in the perinatal period (Nyberg et al., 1988).

MANAGEMENT OF PREGNANCY

When a suspected diagnosis of fetal Dandy–Walker malformation exists, the prospective parents should be referred to a center capable of a detailed anatomic survey of the fetus. There is a high incidence of associated CNS and extra-CNS malformations in this condition. Importantly, it is the presence of the additional sonographically detected anomalies that appear to adversely affect survival and prognosis for the infant and child with Dandy–Walker malformation. Summarizing many studies, the risk of associated intracranial anomalies appears to range from 25% to 70%, and the risk of additional intracranial anomalies appears to range from 20% to 60% (Chen and Chu, 1994). Between 20% and 50% of cases of Dandy–Walker malformation will have karyotypic abnormalities (Ecker et al., 2000; Has et al., 2004). Diagnosis of fetal karyotype is recommended, given the association between Dandy–Walker malformation and trisomies 9, 13, or 18, because of the confirmed association between enlarged cisterna magna and trisomy 18, and also because of the wide variety of chromosome abnormalities that have been reported with this brain malformation (Imataka et al., 2007).

There is an increased incidence of both mental retardation and perinatal mortality for fetuses and children with this condition. Therefore, the option of pregnancy termination should be made available to parents, if desired. In most cases, progressive increase in the size of the posterior fossa cyst, ventricular size, and cisterna magna dimensions occurs slowly. Rarely however, severe or rapidly increasing ventriculomegaly can necessitate aggressive obstetric intervention, possibly including elective preterm delivery (Russ et al., 1989). It is important to recognize that when Dandy–Walker malformation or variant occurs as an isolated finding, the prognosis is variable, and up to 50% of fetuses with this condition have been reported with a normal outcome. When the disorder is associated with an underlying Mendelian condition, such as one of those listed in Table 11-1, the prognosis is then distated by that specific disorder.

There are no specific indications for cesarean delivery in this condition. Similarly, delivery can occur in a community hospital; however, the prospective parents should be advised that the child will need subspecialty evaluation after birth.

FETAL INTERVENTION

There is no fetal intervention for Dandy–Walker malformation.

TREATMENT OF THE NEWBORN

The infant diagnosed prenatally with Dandy–Walker malformation or one of its variants should undergo a complete physical examination promptly at birth. The best imaging study for the posterior fossa is magnetic resonance imaging (MRI). We do not recommend obtaining a postnatal head ultrasound examination through the anterior fontanelle because of the high incidence of false-negative diagnoses. Parents should be counseled that hydrocephalus may not be present at birth, but will become apparent in 75% of survivors by 3 months of age (Estroff et al., 1992).

Both prenatal and postnatal consultation should be obtained with specialists in pediatric neurology, neurosurgery, and medical genetics. There is a high incidence of associated congenital anomalies, some of which may not be apparent on the antenatal scan. These are summarized in Table 11-2.

Interestingly, a strong association exists between the presence of large, aggressive facial hemangiomas and the Dandy–Walker malformation or similar posterior fossa abnormalities. In a postnatal study, seven of nine patients with unilateral facial hemangiomas had Dandy–Walker malformation (Reese et al., 1993). This has raised the question of a developmental-field abnormality as the cause of the Dandy–Walker malformation.

Table 11-2

Associated Abnormalities Seen in 148 Cases of Dandy–Walker Malformation

	Percent
Cranial	
Agenesis of corpus callosum	14.8
Abnormal gyral pattern	10.8
Occipital encephalocele	7.4
Aqueductal stenosis	3.3
Cardiac	
Ventriculoseptal defects	6.7
Patent ductus arteriosus	3.3
Atrial-septal defects	2.7
Pulmonary stenosis	2.0
Atrioventricular canal defect	2.0
Renal	
Obstructive uropathy	2.0
Polycystic kidneys	2.0
Abnormal uterus	2.0
Cryptorchidism	2.0
Face/hands	
Cleft lip/cleft palate	6.7
Dysmorphic face	5.4
Facial angioma	5.4
Syndactyly	2.7

SURGICAL TREATMENT

Surgical treatment in the Dandy–Walker malformation consists mainly of placement of a ventriculoperitoneal shunt for cases of symptomatic hydrocephalus (Chen and Chu, 1994). More recent surgical practice has moved away from ventriculoperitoneal shunting to a choice of either surgical fenestration of the posterior fossa cyst membrane or ventriculocystoperitoneal shunting (Kumar et al., 2001). In one series of 42 cases of Dandy–Walker malformation managed surgically, only 2 patients required revision of a ventriculocystoperitoneal shunt or a cyst fenestration procedure (Kumar et al., 2001).

LONG-TERM OUTCOME

Review of the pediatric neurosurgical literature indicates a mortality rate of between 12% and 50%. However, in general, the postnatal diagnosis of children with Dandy–Walker malformation has a better prognosis than the prenatal diagnosis of fetuses with the same condition. In a study of 65 prenatally diagnosed cases of Dandy–Walker malformation, 22 resulted in liveborn infants (Chang et al., 1994). A total of nine (41%) of these died, seven of which deaths occurred during the first month of life and the remaining two within the first year. In another study, Russ et al. (1989) reviewed the outcome for 15 cases of prenatally diagnosed Dandy–Walker malformation. Excluding the elective terminations, there was an overall mortality of 55% in this group (6 of 11 liveborn infants). However, the coexisting structural and chromosomal abnormalities contributed to 83% of the postnatal deaths. In the six liveborn infants who died, three deaths occurred within 5 days of delivery, and three between 5 and 24 months of age. Overall, therefore there appears to be a liveborn mortality rate of between 30% and 70% when detected prenatally, but only between 10% and 25% when the diagnosis is made postnatally.

With regard to longer term morbidity, in a study of 26 patients with strictly diagnosed isolated Dandy–Walker malformation confirmed by MRI, the long-term prognosis was dependent on the state of the cerebellar vermis (Klein et al., 2003). In 21 patients with a vermis that retained its two fissures and three lobes, there were no additional brain malformations and all but two were functionally normal. However, in the five cases in which the vermis was highly dysplastic, all were severely mentally retarded. In Estroff's review of patients with the Dandy–Walker variant, of 11 survivors, 1 had trisomy 21 and another was severely handicapped (Estroff et al., 1992). Nine of the remaining 11 survivors were developing normally. However, six of these nine did not have any associated extracranial abnormalities. Reviewing the long-term prognosis for eight fetuses with the Dandy–Walker variant who had an isolated anomaly, six of eight (75%) were normal. One died and one was deaf and blind (Estroff et al., 1992). The functional outcome for survivors is variable, depending on the degree of disruption of the cerebellar vermis. An IQ of less than 80 has been documented in approxiamtely 50% of cases (Russ et al., 1989). It is important to realize that disruption of the cerebellum does not lead solely to motor and coordination dysfunction in survivors. Rather, it is now clear that the residual neurological impairment also includes developmental delay, including problems with language and social skills (Niesen, 2002). Even children with isolated inferior vermian hypoplasia (which has previously been referred to simply as Dandy–Walker variant) have overall developmental, functional, and behavioral profiles below the mean (Limperopoulos et al., 2006).

Thus, an appropriate summation of the available follow-up literature seems to indicate that prognosis is significantly better for fetuses with milder anomalies and if the Dandy–Walker malformation is isolated. The presence of additional abnormalities contributes significantly to an increased risk of mortality and developmental delay. However, the data on prognosis do not support the concept that Dandy–Walker variant has a completely normal outcome. This caveat underscores the limitations of trying to differentiate between Dandy–Walker malformation and variant (Ecker et al., 2000; Pilu et al., 2000).

GENETICS AND RECURRENCE RISK

The most important consideration in determining the recurrence risk for Dandy–Walker malformation is to determine whether the finding is associated with a Mendelian disorder, such as those listed in Table 11-1, or if a chromosomal abnormality is present. If chromosome studies have not been obtained antenatally, they should be obtained during the newborn period.

For isolated Dandy–Walker malformations, familial recurrences are infrequent but do occasionally occur (Obwegeser et al., 1994; Bragg et al., 2006). Ulm et al. (1999) described a family in which the first child and subsequent dizygotic twins were all affected with isolated Dandy–Walker malformation.

In a review of the genetics of Dandy–Walker malformation, Murray et al. (1985) performed a retrospective study of 21 autopsy-proven cases of Dandy–Walker malformation, together with a literature review of an additional 92 subjects. These authors noted the increased frequency of association of Dandy–Walker malformation with congenital heart disease, cleft lip and cleft palate, and neural tube defects. Of the 113 cases studied, 7 had recognizable single-gene disorders, including two cases of Meckel–Gruber syndrome, and one case each of arthrogryposis type 2B, Walker–Warburg syndrome, Ruvalcaba syndrome, Cornelia–De Lange syndrome, and congenital rubella. Excluding the known single-gene diagnoses, of the 106 remaining cases, 22 had other associated major malformations. These authors pooled information available on 44 siblings of the 106 index patients

and 54 siblings of 26 patients with Dandy–Walker malformation associated with hydrocephalus. They documented 1 additional case in 98 siblings, thus giving a 1% risk of recurrence.

These authors concluded that the Dandy–Walker malformation is a nonspecific CNS abnormality that can occur in single-gene disorders and chromosomal abnormalities (Murray et al., 1985). It can be environmentally induced, may exist as an isolated malformation, or may exist in conjunction with other abnormalities. They suggested the following information for genetic counseling: (1) When Dandy–Walker malformation occurs as part of a Mendelian disorder, the recurrence risks are those of the specific disorder. (2) When Dandy–Walker malformation is associated with a chromosomal abnormality, the recurrence risks include those of maternal age for trisomy, and those of the family, depending on whether there is a familial risk for an unbalanced chromosomal abnormality. (3) If the Dandy–Walker malformation is associated with other multifactorial abnormalities, such as cleft lip and palate or congenital heart defects, there is an additional 5% recurrence risk for those abnormalities. (4) If the Dandy–Walker malformation was isolated, there is an empiric recurrence risk of between 1% and 5% (Murray et al., 1985).

If the presence of an unbalanced karyotype has been documented in the fetus or newborn, parental chromosomes should be studied prior to judging recurrence risks. Prenatal diagnosis is available in subsequent pregnancies through the use of targeted ultrasound examination, ideally delayed until 18 weeks' gestation so as to avoid false-positive diagnoses. However, it remains possible to diagnose the full Dandy–Walker malformation by prenatal ultrasonography as early as 12 to 14 weeks' gestation.

In general, DNA diagnosis is not available for individuals with isolated Dandy–Walker malformation. Recently, however, in a group of seven patients with Dandy–Walker malformation and de novo interstitial deletion of chromosome 3q, a critical region associated with this anomaly was identified (Grinberg et al., 2004). This region encompasses two linked zinc finger genes, *ZIC1* and *ZIC4*. Mice created with a targeted heterozygous deletion of these two genes have a phenotype that closely resembles Dandy–Walker malformation.

12 CHAPTER Encephalocele

Key Points

- Encephalocele is a rare defect of the cranial vault, which may contain meninges only, or also neural tissue.
- Most cases in Caucasian populations are occipital in location, while Southeast Asian populations are more commonly frontal.
- Causes include maternal diabetes, rubella, hypervitaminosis-A, isolated neural tube defect, amniotic-band syndrome, aneuploidy such as trisomies 13 and 18, and genetic syndromes such as Meckel–Gruber.
- Differential diagnosis includes cystic hygroma, cervical teratoma or hemangioma, or epidermal scalp cysts, while false-positive diagnoses have been made by mistaking clumps of fetal hair in the third trimester.
- Natural history and prognosis depends on the presence of associated malformations and presence of neural tissue within the meningeal sac.
- Pregnancy management includes prenatal MRI to confirm absence of neural tissue within the sac, and possible elective cesarean delivery if prognosis appears favorable.

CONDITION

Encephalocele refers to the herniation of cranial contents through a defect in the skull. This term includes both encephaloceles, which contain meninges and brain, as well as meningoceles, which consist of meninges and cerebrospinal fluid. Empty meningoceles are not as common as encephaloceles. Encephaloceles are subdivided according to their location: occipital and frontal. This distinction is important, as each of the conditions has a different prognosis based on their location. In occipital encephaloceles, the defect lies between the lambda and foramen magnum (Simpson et al., 1984). These encephaloceles are considered part of the spectrum of

neural tube defects. Sincipital or frontal encephaloceles are situated between the bregma and anterior margin of the ethmoid bone. The majority of these encephaloceles extend into the root of the nose, and they are not considered a form of neural tube defect, but rather are likely secondary to an environmental exposure. Occipital encephaloceles are considerably more common than frontal encephaloceles in populations of European descent, whereas frontal encephaloceles are much more common in populations from Southeast Asia.

The cause of encephalocele is unknown, but occipital encephaloceles are thought to be caused by failure of closure of the rostral neural pore. The majority of encephaloceles occur in the midline; however, they may also result from disruption of fetal-skull formation, such as in the amnion rupture sequence (Chervenak et al., 1984). Encephaloceles occur between 25 and 50 days of gestation for anterior defects and up to 60 days for posterior defects (Brown and Sheridan-Pereira, 1992).

INCIDENCE

In a recent review from New Zealand, encephaloceles were seen in one in 13,000 births (Monteith et al., 2005). In an earlier U.S. study extending more than 17 years, Wiswell et al. (1990) documented 112 cases of encephalocele in 763,364 livebirths, or 0.15 per 1000 livebirths. Of these infants with encephaloceles, 40% had associated congenital anomalies. Encephalocele is more often associated with extra-CNS malformations than anencephaly or spina bifida (Kalien et al., 1998). In an Australian study, the incidence of encephalocele was shown to be 0.08 per 1000 total births (David and Proudman, 1989). In Australians of European descent, the occipital location for the encephalocele is more common, whereas in patients of Southeast Asian extraction, the frontal location is more common (Richards, 1992). The United Kingdom, with its generally higher rate of all neural tube defects, has a higher incidence of encephalocele—between 0.3 and 0.6 per 1000 livebirths (Fleming et al., 1991).

Encephaloceles are associated with maternal rubella, diabetes, genetic syndromes (such as Meckel–Gruber), and amniotic bands. They have been produced experimentally with X-irradiation and hypervitaminosis A. In the Western world, 75% of encephaloceles are located in the occipital region (Chervenak et al., 1984). The frontoethmoidal encephalocele is more prevalent in Malaysia, Thailand, Indonesia, Burma, and parts of Russia. In Burma, a high prevalence of encephalocele has been noted among rural and peasant rice farmers (David and Proudman, 1989). There is no relationship between encephalocele and parental age.

SONOGRAPHIC FINDINGS

The sonographic appearance of encephalocele is diverse, depending on its contents. Encephaloceles can appear as a purely cystic mass, a solid mass with a gyral pattern continuous with the cranium, or a combined cystic and solid mass (Graham et al., 1982; Winter et al., 1993). A calvarial defect is usually identified. In most European studies, the encephalocele is present in the occipital region 75% of the time, in the frontal/sincipital region 15% of the time, and at the vertex 5% of the time. An encephalocele that is observed in an asymmetric or atypical location may be related to the amniotic-band syndrome or limb–body wall complex (Graham et al., 1982; Winter et al., 1993). Encephaloceles have been noted to have a unique "cyst within a cyst" (Figures 12-1A and 12-1B) or "target sign" appearance when the encephalocele is viewed from the en face position (Goldstein et al., 1991; Adetiloye et al., 1993).

To diagnose an encephalocele sonographically, the following considerations should be taken into account:

- The mass should be seen attached to the fetal head or move with the fetal head.
- A bony defect should be revealed.
- Intracranial anatomic abnormalities should be detected, such as hydrocephalus.
- The spine should be examined to exclude associated spina bifida.
- The fetal kidneys should be examined, because of a high incidence of association with renal cystic disease (Meckel–Gruber syndrome).

In 7% to 15% of cases, neural tube defects are shown to be present in association with the encephalocele (Fleming et al., 1991). In addition, microcephaly is seen in 20% of cases. Other associated central nervous system (CNS) anomalies that may occur with encephalocele include agenesis of the corpus callosum, orofacial clefting, craniosynostosis, Dandy–Walker malformation, Arnold–Chiari malformation, hemifacial microsomia, Klippel–Feil anomaly, iniencephaly, and myelomeningocele (Cohen and Lemire, 1982).

In one study, Budorick et al. (1995) reviewed 26 cases of prenatally diagnosed encephalocele. Seventy-one percent of these cases were in the occipital location. Sixty-five percent of cases had associated major congenital anomalies. CNS features that were observed and helped with the diagnosis of encephalocele included visible skull defect (seen in 96% of cases), ventriculomegaly (23%), microcephaly (50%), beaked tectal plate (38%), and flattened occiput (38%).

In another study, Goldstein et al. (1991) reviewed the prenatal sonograms of encephaloceles in 15 fetuses. Of these, 13 were in the occipital location, 1 in the ethmoidal, and 1 frontoparietal. These authors could not accurately distinguish prenatally between meningocele and meningoencephalocele. They also noted an inward depression of the frontal bones (the lemon sign) in 33% of fetuses with encephalocele. Of the nine cases in which prenatal chromosome studies were performed, four (44%) were abnormal, including trisomy 13, trisomy 18, mosaic trisomy 20, and an unbalanced chromosome translocation. The outcome for the remaining 11 patients included 5 terminations of pregnancy, 2 stillbirths, and 4 neonatal deaths. Similarly, Wininger and Donnenfeld (1994) reviewed 15 cases of prenatally diagnosed encephalocele.

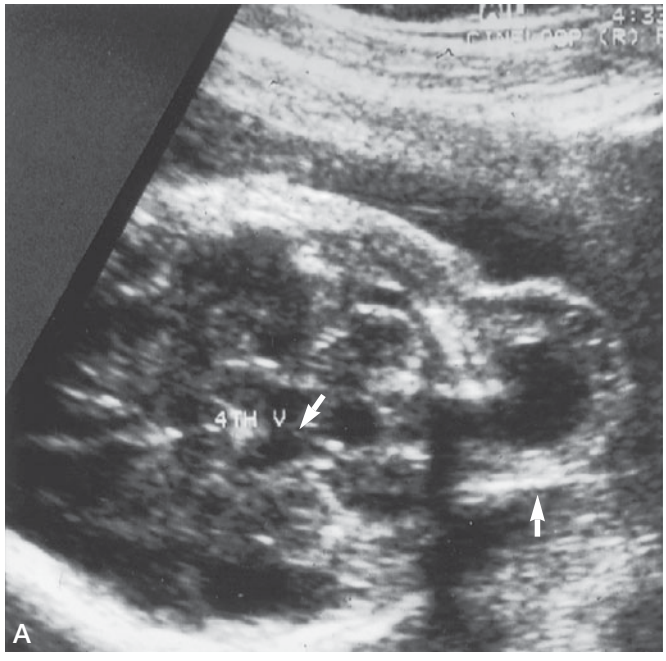

Figure 12-1 **A.** Transaxial sonogram demonstrating an occipital encephalocele with the appearance of a cyst within a cyst. The arrow indicates the location of the encephalocele. 4th v = the fourth ventricle. **B.** Sagittal half-Fourier single-shot turbo spin-echo sequence (HASTE) magnetic resonance image of the fetus with a posterior encephalocele shown in part (A). A small amount of brain tissue is seen within the sac. The remainder of the fetal brain appears normal except for the posterior aspect of the occipital lobe. (*Image courtesy of Dr. Deborah Levine.*)

These authors also demonstrated a high incidence of associated major anomalies (60% of cases). The mean gestational age at detection of these cases was 12 to 14 weeks. These authors identified three multifactorial disorders, two cases of chromosomal abnormalities, and two autosomal recessive syndromes.

DIFFERENTIAL DIAGNOSIS

Important considerations in the sonographic differential diagnosis of encephalocele include location of the extracranial mass (midline or lateral), contents of the mass (cystic or solid), and whether or not the anomaly is associated with an underlying cranial bony defect (Sherer et al., 1993). Encephaloceles are typically midline cystic structures that overlie or project through a defect in the calvarium. The diagnosis is helped by the identification of herniated brain tissue and associated hydrocephalus.

A major consideration in the differential diagnosis is cystic hygroma (Table 12-1). An occipital meningocele that contains only cerebrospinal fluid can be confused with a cystic hygroma. With cystic hygromas, however, the margins of the mass blend into the skin line, and a bony defect in the cranial vault should not be visible. Cystic hygromas frequently contain septations and there may be fewer CNS anomalies associated with cystic hygromas (see Chapters 31 and 32). In

Table 12-1

Differential Diagnosis Between Cystic Hygroma and Encephalocele

Sonographic Finding	Cystic Hygroma	Encephalocele
Bone defect in skull	Never	Always
Septae	Present and bilateral; often extend to neck	If present, only in midline; continuous with fetal brain
Contents of sac	Fluid only	Variable
Associated microcephaly	Rare	Common
Location	Posterolateral aspect of neck	Occipital, 70%; frontal, parietal, or nasofrontal, 30%

addition, other findings of hydrops, such as pleural effusions and ascites, are often found with cystic hygroma (Pearce et al., 1985; Goldstein et al., 1991). Encephaloceles can also be confused with cervical teratomas, which are solid or heterogeneous but have no demonstrable brain tissue. Hemangioma is an additional soft tissue mass that can be confused with encephalocele; they are heterogeneously echogenic, with no identifiable skull defects. They form an obtuse angle with the adjacent skull, as opposed to encephaloceles, which typically form an acute angle with the adjacent skull (Bronshtein et al., 1992; Winter et al., 1993). Sherer et al. (1993) described the case of a 27-week-old fetus with a right retroauricular mass thought to overlay a bony defect of the skull. This was initially diagnosed as an encephalocele, but it was later shown to be a subcutaneous hemangioma. Other considerations in the differential diagnosis include scalp edema (Winter et al., 1993), a clump of fetal hair (Noriega et al., 2001), epidermal scalp cyst (Shahabi and Busine, 1998), and branchial cleft cysts.

Once the encephalocele has been verified, a careful search must be made for associated anomalies. Encephaloceles are frequently associated with other anomalies, and the demonstration of such findings may help to make a syndromic diagnosis. A significant cause of encephaloceles is amniotic band or amniotic rupture (see Chapter 100). Encephaloceles due to amniotic bands tend to have irregular surfaces, and asymmetric placement.

A listing of the major syndromes of which encephalocele is a component is given in Table 12-2. The most common of these is Meckel–Gruber syndrome, an autosomal recessive condition that is characterized by the presence of an occipital encephalocele, polydactyly, polycystic kidneys, and multiple associated anomalies (Figures 12-2A and 12-2B). Meckel–Gruber syndrome should be suspected in fetuses with encephalocele and oligohydramnios, with four of five patients with oligohydramnios and encephalocele having this syndrome (Budorick et al., 1995). Encephalocele is found in association with several different chromosome abnormalities.

ANTENATAL NATURAL HISTORY

The presence of encephalocele is associated with an increased incidence of death in utero. An encephalocele is the predominant neural axis anomaly found in fetuses spontaneously aborted at less than 20 weeks' gestational age (Goldstein et al., 1991). The concept of antenatal evolution of encephalocele has also been documented. A report by Bronshtein and Zimmer (1991) documented by sonography the formation of a cephalocele in two stages. Initially, an occipital meningocele was detected by transvaginal scan at 13 weeks of gestation. By 19 weeks, brain tissue was visualized, and the diagnosis was changed to a meningoencephalocele, illustrating that the primary process was the formation of the meningocele, but that once an opening became present, brain tissue protruded into it at a later stage.

In the Budorick et al. (1995) study of 26 cases of prenatally diagnosed encephalocele, if more than 50% of the intracranial contents were exteriorized, postnatal survival was unlikely. In another study of 15 prenatally diagnosed cases, the long-term outcome was uniformly poor with only 3 of 14 fetuses with adequate follow-up being born alive (21%) (Goldstein et al., 1991). In a further review of 15 prenatally diagnosed encephaloceles, pregnancy outcome was also poor, with one fetus miscarrying at 23 weeks, and six terminations of pregnancy (Wininger and Donnenfeld, 1994). Of the eight liveborn infants, only five survived beyond the neonatal period, and all of the three for whom follow-up information was available had developmental delay.

Predictors of more favorable outcome in cases of prenatally diagnosed encephalocele include normal karyotype

Table 12-2

Syndromes in Which Encephalocele is a Major Component

Condition	Pattern of Inheritance	Associated Findings
Chemke syndrome	Autosomal recessive	Hydrocephalus, cerebellar dysgenesis, retinal dysplasia, corneal opacities, cataracts
Cryptophthalmos syndrome (Fraser)	Autosomal recessive	Skin of forehead covers one or both eyes; total/partial syndactyly of fingers or toes
Dyssegmental dwarfism	Autosomal recessive	Short tubular bones, bowing of extremities, vertebral anomalies, small thorax, cleft palate, micrognathia
Frontonasal dysplasia	Sporadic	Ocular hypertelorism, median cleft lip
Knobloch syndrome	Autosomal recessive	Retinal detachment, myopia, normal intelligence
Meckel–Gruber syndrome	Autosomal recessive	Polydactyly, polycystic kidneys, oligohydramnios, other CNS abnormalities
Amniotic band (rupture)	Sporadic	Limb amputations, facial clefts, thoracoabdominal wall defects, skull malformations
Roberts syndrome	Autosomal recessive	Short or absent limbs, facial cleft, hypertelorism, heart and kidney defects

and lack of associated CNS or other malformations. In such cases of isolated encephalocele prognosis may be favorable. In a series of 13 cases of isolated encephalocele, 6 cases in which neural tissue was present in the sac were terminated (Bannister et al., 2000). In the remaining seven cases with minimal or no neural tissue within the sac, one resulted in a stillbirth and the other six were liveborn with relatively normal outcome.

MANAGEMENT OF PREGNANCY

Fetuses in which encephalocele is suspected should be referred to a center capable of thorough anatomic study. Detailed sonography should be performed to verify the presence of the encephalocele and to search for associated anomalies. Because of the increased incidence of chromosomal abnormalities, a prenatal karyotype should be offered. Most encephaloceles are covered by skin, so typically there is no increase in the maternal serum α-fetoprotein level if second trimester biochemical screening is performed.

Once the encephalocele is diagnosed, further obstetrical management is dictated by the size of the defect, the gestational age at diagnosis, and the presence or absence of associated anomalies. A thorough discussion should be held with the prospective parents that describes the expected prognosis for the infant. Prognosis depends on

1. the presence and amount of brain in the herniated sac;
2. the presence or absence of hydrocephalus;
3. the presence or absence of microcephaly;
4. the presence or absence of other anomalies that suggest a syndromic diagnosis (Fleming et al., 1991).

Magnetic resonance imaging may help to better delineate fetal CNS anatomy (Figure 12-1B). Encephaloceles in the sincipital or frontal location have a better prognosis. This is probably because the defects are in general smaller, resulting in less herniation of neural tissue. Also, it appears that the loss of some areas of frontal cortex may produce fewer neurologic defects (Chervenak et al., 1984). Termination of pregnancy should be discussed with the parents. If parents want to continue the pregnancy, the opportunity to meet with a neurosurgeon, neonatologist, and medical geneticist should be provided.

The route of delivery is determined by fetal sonographic findings. If a large amount of neural tissue is observed in the sac, or if associated anomalies are present, minimizing maternal risk should be the primary consideration, and cesarean section probably has little role. Cesarean section may be considered when

Corresponding autopsy photograph of the same fetus with an intact encephalocele. The fetus also has micrognathia. (*Photograph courtesy of Dr. Joseph Semple.*)

1. the encephalocele is large enough to cause cephalopelvic disproportion;
2. other obstetric considerations are present, such as a previous uterine surgery;
3. a coincidental viable twin is present;
4. the parents are aware of the risk of significant developmental defects in the infant but, after accepting these risks, still want full pediatric intervention (Chervenak et al., 1984; Chatterjee et al., 1985).

In situations in which parents wish full pediatric intervention, we recommend that the baby be delivered at a tertiary care center to facilitate coordination of services for the newborn.

FETAL INTERVENTION

There is no fetal intervention indicated for encephalocele.

TREATMENT OF THE NEWBORN

Treatment of the newborn with encephalocele depends to a large extent on the size and location of the lesion and whether or not associated anomalies are present. For large occipital encephaloceles, the long-term outcome is uniformly poor. Even if parents have decided not to terminate the pregnancy, they may decide that no aggressive intervention should be taken. Alternatively, certain parents may desire that everything be done for their newborn. Infants with encephalocele typically have an intact skin cover, and are usually microcephalic. A complete physical examination is indicated to rule out an associated syndrome (see Table 12-2). Consultation with a medical genetics specialist should be obtained, and with a pediatric neurosurgeon if the parents are considering surgery. In general, surgical treatment is performed as soon as possible, although few data exist that correlate timing of surgery with ultimate developmental outcome.

SURGICAL TREATMENT

The surgical challenges in cases of encephalocele include closing the anatomical defect in the cranial vault and achieving as near normal functional outcome as possible with minimal psychomotor defects (Habal, 1993). Surgical repair of encephalocele consists of opening and exploring the sac, excising malformed brain tissue, and closing the basal dural defect. Surgical repair is generally timed for 0 to 4 months of age (Date et al., 1993). Bony grafting is usually required in such situations to close the cranial defect (Bozinov et al., 2005). In cases of giant occipital encephaloceles with microcephaly secondary to massive brain herniation, the use of a fine mesh has been described to provide a rigid extracranial compartment for the encephalocele. Daily digital compression is performed and the mesh is gradually imbricated into the calvarium (Gallo, 1992).

Surgical considerations for frontal/sincipital encephaloceles are different because of the associated craniofacial deformities, and typically require multidisciplinary approach, including neurosurgery, ophthalmology, ENT, and plastic surgery (Barsani and Cecchi, 2006). In general, surgical treatment for frontal/sincipital encephaloceles include removal of the encephalocele, closure of the dura intracranially, followed by transcranial bone grafting, and correction of orbital hypertelorism or dystopia (David and Proudman, 1989). Hockley et al. (1990) described the following indications for urgent surgery: absence of skin cover, hemorrhage, airway obstruction, or impairment of vision. For most cases of frontal encephalocele, surgery is elective, with indications including protection of the brain; facilitation of nursing; prevention of infection; improvement of the airway, speech, and vision; or treatment of associated anomalies, such as hydrocephalus and hypertelorism.

LONG-TERM OUTCOME

The most important consideration in the long-term follow-up of a patient with encephalocele appears to be whether or not brain tissue is present in the extracranial sac. There is no question that the prognosis is much better for a fetus with a meningocele as opposed to a meningoencephalocele. In one report of 24 patients with surgically repaired encephalocele, follow-up information was available on 22 patients who survived (Date et al., 1993). In this study, one patient died from pneumonia at 8 months of age and another at 4 years. Of the 22 surviving patients, 14 had meningoceles. All of these surviving children were normal. Of the eight survivors with meningoencephalocele only two were normal, four were ambulatory and had mild to moderate retardation, and two were bedridden with marked retardation. These authors concluded that the presence of gross brain tissue in the sac was the most important prognostic factor (Date et al., 1993).

Similar results were seen by Simpson et al. (1984), who studied the outcome for 74 patients with encephaloceles. Of these infants, 17 had meningoceles; all did well, even if associated hydrocephalus developed. Of the 57 infants with meningoencephalocele, almost all did poorly despite surgical expansion of the cranial cavity or decompression of enlarged ventricles.

Docherty et al. (1991) described the outcome for 52 patients with occipital encephaloceles between 1971 and 1990. This study was limited, in that no information was given regarding whether the lesion was a meningocele or a meningoencephalocele. Hydrocephalus developed in 57% of patients, and over half of these required shunting. Twenty-three percent of patients died within the first year. Of the 23 survivors, 14 were normal and 9 were significantly handicapped, but this study was limited in that the underlying pathology of the lesion was not described. Based on the available literature, it seems reasonable to conclude that outcome for fetuses with meningocele is reasonably good, whereas outcome for fetuses with demonstrable brain tissue in the mass is uniformly poor. A more recent review of 31 cases of prenatally diagnosed encephalocele supported this view, with good long-term outcome for six of the seven cases of meningocele (Bannister et al., 2000).

GENETICS AND RECURRENCE RISK

An important consideration in the genetics of encephalocele is to determine whether the lesion is isolated. Rare families have been described in the literature with autosomal dominantly

inherited occipital encephalocele (Bassuk et al., 2004; Zhao et al., 2007). In one family there was clear documentation of 21 affected out of 113 members over five generations (Zhao et al., 2007). All affected individuals had normal or nearly normal neurologic function. Many nonisolated encephaloceles are associated with specific syndromes; in general, many of these are inherited as autosomal recessive conditions (see Table 12-2). It is therefore extremely important to determine whether the encephalocele has associated anomalies, making it consistent with a syndromic diagnosis, such as Meckel–Gruber syndrome.

An attempt should be made to study chromosomes either prenatally or postnatally. Previously reported chromosomal abnormalities that have been demonstrated in fetuses with encephaloceles include trisomies 13 and 18 and mosaic trisomy 20, as well as unbalanced translocations and inversions (Goldstein et al., 1991).

Although isolated encephalocele is not generally considered to have an increased risk of recurrence, parents can be offered early prenatal sonography in a subsequent pregnancy. Encephaloceles have been diagnosed as early as 12 weeks of gestation by transvaginal sonography (Cullen et al., 1990; Fleming et al., 1991). In a patient with a previous pregnancy affected by Meckel–Gruber syndrome, it is possible to diagnose encephalocele as early as 12 to 13 weeks in a subsequent pregnancy, thereby confirming the recurrence of the condition (Tanriverdi et al., 2002).

13 CHAPTER

Exencephaly/Acrania

Key Points

- Rare fetal anomaly that is incompatible with survival.
- Bones of the cranial vault are absent but facial structures and skull base are preserved. Residual brain tissue is present and floats free in amniotic fluid.
- Likely to be the first trimester precursor to anencephaly. Now called fetal acrania–anencephaly sequence.
- Incidence is 3 per 10,000 second trimester pregnancies.
- Sonographic findings in the first trimester include: absent calcification of the cranial bones, lateral widening of the cerebral hemispheres (the "Mickey Mouse" sign), and echogenic amniotic fluid. Second trimester findings include free-floating disorganized brain tissue with preservation of the face.
- Often associated with omphalocele, amniotic band syndrome, limb–body wall complex, and pentalogy of Cantrell.
- Differential diagnosis includes acalvaria, massive meningoencephalocele, amniotic bands, limb–body wall complex, hypophosphatasia, and osteogenesis imperfecta type II.
- Condition is uniformly fatal postnatally.
- Recurrence risk depends on underlying etiology. If syndromic may have 25% to 50% recurrence risk. Otherwise, recurrence risk is 2% to 5%.
- Preconceptual folic acid (4 mg/day) is recommended for subsequent pregnancies.

CONDITION

Exencephaly is a rare fetal anomaly that is incompatible with extrauterine life. In exencephaly, the bones of the cranial vault are absent (acrania), but the facial structures and the base of the skull are preserved (Casellas et al., 1993). The terms exencephaly and acrania are used interchangeably in this chapter. Exencephaly is a precursor to anencephaly (the so-called fetal acrania-anencephaly sequence); it differs from anencephaly in that residual brain tissue is present and floating free in the amniotic fluid.

Exencephaly is frequently noted in animal teratogen studies. Human exencephaly appears to be confined to early gestation. Only rare reports exist of a third trimester diagnosis of an exencephalic fetus (Wilkins-Haug and Freedman, 1991). Anencephaly, however, is more common in humans than in animals. The greater prevalence of anencephaly in humans is attributed to a longer gestational period, which presents the opportunity for destruction of the free-floating brain matter.

Exencephaly is due to the failure of the anterior neuropore to close during the 4th week of embryonic development. The underlying defect is due to a failure in mesenchymal migration (Stagiannis et al., 1995). In pathologic studies, the exencephalic brain is noted to be covered by a highly vascular epithelial layer. In exencephaly, two relatively equivalent cerebral hemispheric remnants are present within a reddish mass of disorganized tissues, remnants of deep cerebral neural elements, blood vessels, fibrous tissues, and fluid-filled spaces (Hendricks et al., 1988). The remaining brain has been termed the "anencephalic area cerebrovasculosa." In exencephalic brain tissue, the gyri and sulci are shallow, flattened, and disorganized. All surfaces of the brain are highly vascular. The remaining central nervous system tissue is dysplastic, with little or no neuronal differentiation, and very little normal cortex (Hendricks et al., 1988).

INCIDENCE

Papp et al. (1986) reviewed cases of neural tube defect detected by maternal serum α-fetoprotein (AFP) screening. In 36,075 screened pregnancies, 10 cases of exencephaly were detected. This equals an incidence of 3 cases per 10,000 screened pregnancies. The same population had 14 cases of anencephaly per 10,000 screened pregnancies. In this report from Hungary, the mean age of the mothers of fetuses with exencephaly was 22 years. Of the 10 affected pregnancies detected, 9 were singletons and 1 was a twin gestation. In eight of the nine cases described, the maternal serum AFP levels were greater than 2.5 multiples of the median.

In experimental animals, there is an increased incidence of exencephaly in fetuses of female mice injected with clomiphene citrate prior to ovulation (Dziadek, 1993). In addition, hyperglycemia in mice induces exencephaly (Sadler, 1980). The phenomenon in mice is similar to the inhibition of neural tube closure seen in infants of mothers with diabetes.

SONOGRAPHIC FINDINGS

Exencephaly/acrania can be detected early and late in gestation. In the normal fetus, echogenic areas can be seen that correspond to calcification of the cranial bones at approximately 11 weeks. If calcification is absent at this point in gestation, exencephaly should be considered. Another finding can be lateral widening of the cerebral hemispheres with clear delineation of the interhemispheric fissure, the "Mickey Mouse" sign. Later in gestation, the most common finding in exencephalic fetuses is the presence of a large quantity of disorganized brain tissue that is not covered by the bones of the skull, with concomitant preservation of facial structures and bones at the base of the skull (Figure 13-1).

The first prenatal sonographic diagnosis of exencephaly was made at 39 weeks and described by Cox et al. in 1985. Subsequently, the gestational age at diagnosis has decreased considerably. Multiple case reports have contributed to the information available regarding sonographic diagnosis. In one report, in a routine sonographic examination performed at 29 weeks of gestation, the flat bones of the skull were noted to be absent with only a small part of the occipital bone present (meroacrania). Disorganized brain tissue was noted to be floating free in the amniotic cavity. In addition, no evidence of cerebral ventricles was seen, and the gyri were noted be extremely disorganized (Casellas et al., 1993).

Exencephaly is often associated with other major malformations, most commonly omphalocele, amniotic band syndrome, limb–body wall complex, and pentalogy of Cantrell.

First trimester diagnosis of exencephaly is possible (Nishi and Nakano, 1994; Bognoni et al., 1999). In a case diagnosed at 9 weeks, the following sonographic features were observed: the cranial pole was smaller than the chest, the cranial pole bulged dorsally, and the surface of the cranium was irregular (Becker et al., 2000). In another report at 10 weeks, a vaginal sonogram demonstrated absence of the calvarium, choroid, and echolucent areas normally seen in the brain at that point in gestation (Kennedy et al., 1990). In the affected fetus, the brain appeared echodense, with a pulsatile prominence in the area of the forebrain. Because of the concern regarding lack of cranial calcification, repeat sonography was performed at 14 weeks of gestation. At this later time, the cranium was noted to be absent above the occipital bones, a widened cervical spine was present, and fragments of neural tissue were seen attached but floating in the amniotic fluid in the process of degeneration (Kennedy et al., 1990).

More recently, Cafici and Sepulveda (2003) described an indirect sonographic sign of acrania/exencephaly, echogenic amniotic fluid. It is hypothesized that after 10 weeks

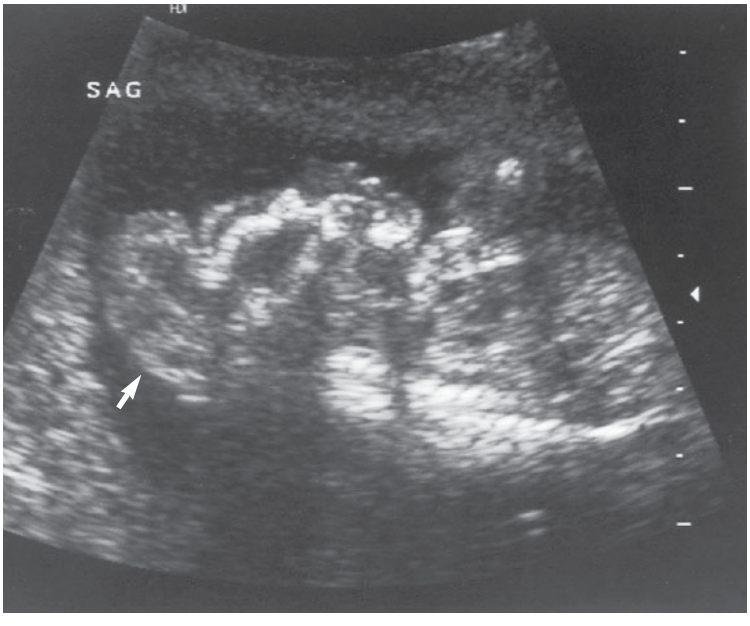

Figure 13-1 Sagittal view of a fetus demonstrating a large quantity of disorganized brain tissue not covered by skull bones (*arrow*).

of gestation, the exposed fetal brain rubs against the uterine wall. This mechanical trauma results in the exfoliation of blood and neural tissue into the amniotic fluid, which can be identified as echogenic free-floating particles.

Three-dimensional (3-D) scanning in the diagnosis of acrania–anencephaly sequence has also been described (Liu et al., 2005).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for exencephaly includes acrania, acalvaria, massive meningoencephalocele, amniotic bands or amniotic rupture, limb–body wall complex, and skeletal dysplasias. It is important to distinguish exencephaly from massive meningoencephalocele because the latter condition is not lethal. In massive meningoencephalocele, the cranial vault is always detected, and part of the brain is intracranial (Abu Musa et al., 1990). In meningoencephalocele, the exposed brain tissue appears more normal than in exencephaly, in which marked dysplasia and disorganized development of rudimentary brain tissue exists.

Acrania is a lethal malformation characterized by partial or complete absence of the calvarium and disorganized brain anatomy. It overlaps clinically with exencephaly. Acalvaria is a rare congenital anomaly in which the flat bones of the cranial vault, dura mater, and associated muscles are absent, but the skull base, facial bones, and intrancranial contents are present (Bianca et al., 2005). Acalvaria is potentially compatible with life.

In the amniotic band syndrome, rupture of the amnion leads to subsequent entanglement of fetal parts by fibrous mesodermic bands. This condition is suggested by the presence of asymmetric lesions in the brain, with associated defects of the spine, abdominal wall, and limbs (Hendricks et al., 1988; Abu Musa et al., 1990; Casellas et al., 1993; Cincore et al., 2003; Chen et al., 2004). In limb–body wall complex, exencephaly or encephalocele are associated with facial clefts, limb defects, and scoliosis. This condition is diagnosed by disruption of the body wall in association with multiple severe abnormalities (Pumberger et al., 2001; Luehr et al., 2002). Pentalogy of Cantrell (see Chapter 61) consists of a supraumbilical wall defect, defect of the lower sternum, deficiency of the anterior diaphragm, defect of the diaphragmatic pericardium, and the presence of intracardiac defects. In several reports, approximately 10% of patients with pentalogy of Cantrell have associated central nervous system malformations, including exencephaly (Hori et al., 1984; Denath et al., 1994; Bognoni et al., 1999). A final consideration in the differential diagnosis is the presence of a skeletal dysplasia. This can be suggested by lack of mineralization of skull bones, such as is seen in hypophosphatasia (see Chapter 98) and osteogenesis imperfecta type II (see Chapter 91). In the skeletal dysplasias, however, the intracranial anatomy is normal. Typical of the skeletal dysplasias are the abnormalities of the long bones, which include shortening or bowing.

ANTENATAL NATURAL HISTORY

Exencephaly is considered to be a precursor to anencephaly. In animals with short gestational periods, exencephaly is frequently observed. However, if the gestation is prolonged artificially, the exposed cerebral structures experience destruction, resulting in anencephaly (Casellas et al., 1993). Wood and Smith (1984) developed an experimental model for anencephaly by administering vitamin A to pregnant rats. The fetuses were noted to have exencephaly that spontaneously disintegrated and eventually became anencephaly. It is thought that the chemical and physical trauma to which the cerebral tissue (unprotected by its sheltering bone cover) is exposed determines its eventual destruction. In humans, destruction of exposed developing brain structures may be complete by 8 to 10 weeks of gestation (Abu Musa et al., 1990).

It has now been demonstrated in humans that a similar progression from exencephaly to anencephaly exists. Wilkins-Haug and Freedman (1991) described a case in which progression to anencephaly was demonstrated by multiple sonograms in a continuing pregnancy. In their case, a 16-week-old fetus was diagnosed with exencephaly. In the cranial area, a well-circumscribed tissue mass was demonstrated without sonographic evidence of cranial calcification. At 18 weeks of gestation, these findings were unchanged, and the parents elected to continue the pregnancy. Repeat sonography was performed at 24 weeks of gestation, when polyhydramnios was demonstrated, and the brain tissue appearance had changed significantly. The disorganized tissue mass was no longer well circumscribed, but was convoluted and floating free in the amniotic fluid cephalad to the frontal bones. At 29 weeks of gestation, the volume of the free-floating brain tissue had significantly decreased. Only a thin layer of tissue remained above the frontal bones. A female infant was delivered by spontaneous vaginal delivery at 30 weeks of gestation with Apgar scores of 1 and 0. The physical appearance of this infant was consistent with classic anencephaly. Physical examination of the cranial area revealed a minimal amount of erythematous, spongy tissue, without cranial or skin covering. This case demonstrates the destruction and disorganization of the developing brain that eventually results in the development of the anencephalic area cerebrovasculosa. A similar phenomenon has been described in another case report, in which selective feticide was performed in a twin pregnancy at 18 weeks of gestation. One twin was normal and the other affected with exencephaly (Papp et al., 1986). This case was followed by repeated sonograms for the healthy twin, and the exposed cerebral mass in the affected twin also regressed over time.

MANAGEMENT OF PREGNANCY

In a study of 3600 pregnant women in Taiwan who received first trimester serum and nuchal translucency screening for

Down syndrome, results were reviewed to determine if these tests could also diagnose acrania. Seven cases of exencephaly/acrania occurred, and all were detetected by nuchal translucency screening (Cheng et al., 2003) Five of the seven affected pregnancies underwent screening with free beta hCG and PAPP-A levels, and there were no differences between the affected and control pregnancies. However, fetuses with exencephaly are accurately detected with second trimester maternal serum screening (Driscoll and Professional Practice and Guidelines Committee of the American College of Medical Genetics, 2004). Maternal serum AFP, maternal serum human chorionic gonadotropin (hCG), and urinary β-core hCG levels are all elevated in this condition (Hayashi et al., 1994). Fetuses in which exencephaly is suspected should be referred to a center capable of detailed sonographic screening to confirm the diagnosis. Pregnancies in which amniocenteses have been performed also reveal extremely high levels of amniotic-fluid AFP (Papp et al., 1986). In addition, large numbers of actively phagocytic macrophages can be demonstrated in the amniotic fluid of fetuses with exencephaly (Papp et al., 1986). It is thought that the degeneration of the exposed neural tissue is potentiated by the macrophages, although it is not known whether these macrophages are fetal or maternal in origin.

Typically, exencephaly is not associated with chromosomal abnormalities, although one case reported deletion of the long arm of chromosome 13 (Lam et al., 1998). However, because of the severity of the defect, a chromosome analysis should be performed to permit accurate genetic counseling. Exencephaly is not compatible with postnatal life. Therefore, the parents should be given the option of termination of pregnancy if this condition is diagnosed before 24 weeks of gestation. Cesarean delivery should be considered for maternal indications.

FETAL INTERVENTION

There is no fetal intervention for exencephaly.

TREATMENT OF THE NEWBORN

Exencephaly is a lethal condition. There is no indication for resuscitation of the newborn.

SURGICAL TREATMENT

There is no surgical treatment for exencephaly.

LONG-TERM OUTCOME

Exencephaly is uniformly fatal.

GENETICS AND RECURRENCE RISK

Exencephaly may be one part of a multiple congenital anomaly syndrome that is inherited as a single-gene disorder. For example, exencephaly is part of the Roberts syndrome, which is inherited as an autosomal recessive condition and consists of limb-reduction anomalies, unilateral anophthalmia, and premature centromeric splitting on karyotype (Verloes et al., 1989). Exencephaly has also been reported to be associated with an autosomal dominant brachydactyly pedigree (Stagiannis et al., 1995). Exencephaly can also be an extreme manifestation of the Adams–Oliver syndrome, which is inherited as an autosomal dominant gene. This condition consists of congenital scalp defects and distal limb anomalies. Every attempt should be made to determine whether the exencephaly is isolated or part of a multiple malformation syndrome. If the fetus is terminated, an autopsy should be performed and chromosome analysis should be performed at the time of termination.

Exencephaly has been described in a product of a consanguineous (brother/sister) mating in which both parents had Waardenburg syndrome. This mating raised the question of homozygosity for a mutation in the *PAX3* gene. The *PAX3* gene is analogous to the mouse splotch gene. In splotch homozygotes, exencephaly develops in half of litters. This human mating possibly demonstrates the role of *PAX3* in neurulation, neural crest cell migration, and development of limb muscles in the human as well as the mouse (Aymé and Philip, 1995).

The recurrence risk for exencephaly depends on its underlying etiology. Cases that are associated with amnion rupture do not have an increased risk of recurrence. If a single-gene disorder is present, the recurrence risk will depend on whether it is autosomal recessive, autosomal dominant, or X-linked. Exencephaly is considered to be within the spectrum of neural tube defects, which have an increased risk of recurrence on the order to 2% to 5%. Preconceptual folic acid and sonographic examination are recommended in subsequent pregnancies.

14 CHAPTER

Holoprosencephaly

Key Points

- A complex brain malformation characterized by the forebrain failing to cleave into two hemispheres, a process that is usually completed by 5 weeks.
- Four subtypes exist, listed in order of decreasing severity: alobar, semilobar, lobar, and middle hemispheric variant.
- Incidence is approximately 1 in 8000 second trimester pregnancies.
- Approximately 40% of cases have a chromosome abnormality. Of these 75% are due to trisomy 13.
- Maternal diabetes increases the risk of holoprosencephaly by 200-fold.
- Management of pregnancy should include fetal karyotype, DNA mutation testing, and consideration of fetal MRI. A detailed family history should be obtained.
- Mutations in eight different genes are associated with holoprosencephaly (*SHH*, *PTCH*, *SIX3*, *SL12*, *ZIC2*, *TGIF*, *TDGF1*, and *FAST1*).
- If chromosome abnormalities and craniofacial anomalies are absent, long-term survival is possible.

CONDITION

The term *holoprosencephaly* describes a spectrum of cerebral and facial malformations that result from absent or incomplete division of the embryonic forebrain, the prosencephalon. The abnormality occurs during the 3rd week of gestation (Müller and O'Rahilly, 1989). Two separate sets of terms are used to describe the facial and brain anomalies. DeMyer (1964) proposed a subclassification of holoprosencephaly based on the extent of sagittal division of the cerebral cortex, thalamus, and hypothalamus. In the most severe form, alobar holoprosencephaly, midline structures are absent and there is no division of the hemispheres. A single common ventricle is present and the thalami are fused. In semilobar holoprosencephaly, incomplete division of the forebrain results in partial separation of the hemispheres. In lobar holoprosencephaly, there is normal cortical division and two thalami, but abnormalities exist in the corpus callosum, septum pellucidum, or olfactory tract or bulbs. More recently, a fourth subtype of holoprosencephaly was described, known as the middle interhemispheric variant (MIH) (Simon et al., 2002; Pulitzer et al., 2004). In MIH, the posterior frontal and parietal lobes fail to separate, but the poles of the frontal and occipital lobes are well separated.

The facial abnormalities accompanying holoprosencephaly range from subtle to grotesque (Figure 14-1). In general, the more severe facial malformations are associated with alobar holoprosencephaly, but exceptions do occur (Table 14-1). The most severe facial malformation is cyclopia, a single or fused double eye and absent nasal structures (Figures 14-1A and 14-1B). A proboscis, a cylindrical protuberance, may also be present (Figure 14-1C). In ethmocephaly, the eyes are separate but closely placed (hypotelorism); a proboscis is present (Figure 14-1D). Ethmocephaly is the rarest of the facial malformations seen in holoprosencephaly. In cebocephaly, ocular hypotelorism is present along with a nasal structure that has a single nostril (Figure 14-1E). In the milder forms of holoprosencephaly, ocular hypotelorism, flat nose, and a median cleft lip occur (Figure 14-1F). *Arrhinencephaly* refers to the absence of the olfactory tracts and bulbs. Subtle, often missed forms of holoprosencephaly include mild hypotelorism, eye abnormalities (iris or retinal colobomas), mild midface hypoplasia, bifid uvula, and single central maxillary incisor tooth (Figure 14-1G).

INCIDENCE

The true incidence of holoprosencephaly is unknown, as presumably there is a high incidence of death in early embryonic life. In a study of 36,380 spontaneous abortions, Matsunaga and Shiota (1977) noted 150 embryos with holoprosencephaly. This equals a prevalence of 40 per 10,000. Using data from a population-based birth defects registry from California, Croen et al. (1996) identified 121 cases among a cohort of 1,035,386 livebirths and fetal deaths. This equaled a prevalence of 1.2 per 10,000 births. Of all cases, 41% (50 of 121) had a chromosomal abnormality, most commonly, trisomy 13. Among cases with normal chromosomes, increased risks are observed among Hispanic and Pakistani women

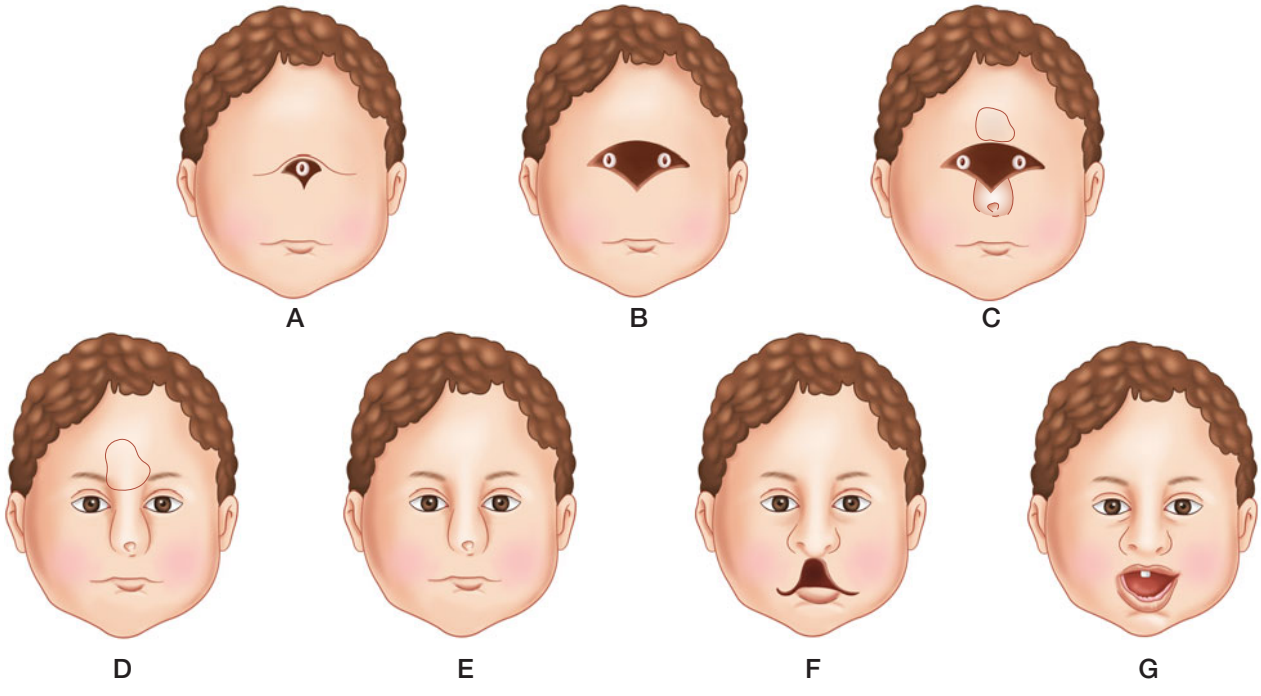

Figure 14-1 The spectrum of facial malformations that can accompany holoprosencephaly. **A** and **B** demonstrate cyclopia. **C** shows cyclopia with a proboscis. **D** shows ethmocephaly with a proboscis. **E** demonstrates cebocephaly with a single nostril. **F** shows mild holoprosencephaly with a midline cleft lip. **G** is the mildest form of holoprosencephaly with a single central incisor (see text for details).

Table 14-1

Post Delivery Assessment of a Fetus/Infant with Alobar Holoprosencephaly

Brain	Face	Clinical Findings
Alobar HP	Cyclopia	Median single or fused eyes; may have no eye; proboscis present or absent
Alobar HP	Ethmocephaly	Rarest facial type; severe ocular hypotelorism with proboscis
Generally alobar HP	Cebocephaly	Ocular hypotelorism and blind-ended, single nostril nose
Generally alobar HP	Median cleft lip	Ocular hypotelorism, flat nose, median cleft lip
Semilobar or lobar HP	Mild dysmorphism	Spectrum of milder abnormalities, including ocular hypotelorism, flattened midface and nose, unilateral or bilateral cleft lip, iris coloboma, single central incisor. Could also appear normal.

(Ong et al., 2007). There is an excess of female conceptuses in alobar (3:1), as opposed to lobar (1:1) holoprosencephaly (Cohen, 1989a). Prevalence is also increased in twins (Suslak et al., 1987). A more recent U.K. population-based survey included all cases in which the pregnancy was terminated after prenatal diagnosis (Bullen et al., 2001). The total prevalence (including terminations) was 1.2 cases per 10,000 registered births. The birth prevalence (affected livebirths and stillbirths at >24 weeks) was 0.49 cases per 10,000 births. Prenatal detection was 86% of cases with a program of routine second-trimester anatomic survey.

Maternal diabetes is the only confirmed human teratogen associated with holoprosencephaly; the incidence of holoprosencephaly among diabetics is increased 200-fold as compared with controls (Barr et al., 1983; Cohen and Shiota, 2002). Other postulated teratogens include ethanol (Jellinger et al., 1981; Ronen and Andrews, 1991; Cohen and Shiota, 2002), salicylate (Benawra et al., 1980), cytomegalovirus (Byrne et al., 1987), retinoic acid, and products of the cholesterol biosynthesis pathway (Cohen and Shiota, 2002).

SONOGRAPHIC FINDINGS

In most fetuses, a midline echo is normally generated by the reflection of sound waves from acoustic interfaces at the interhemispheric fissure. This echo is absent in alobar holoprosencephaly (Figure 14-2) (Pilu et al., 1987). In addition,

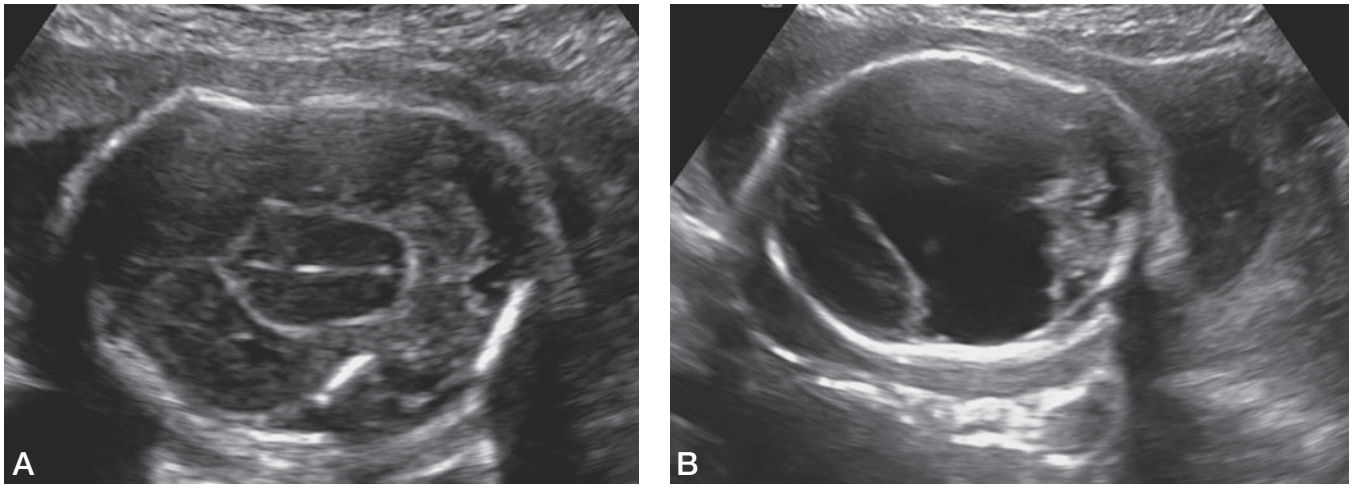

Figure 14-2 Prenatal sonographic image at 23 weeks from fetus with alobar holoprosencephaly. **A.** Axial view with fused thalami. **B.** Single communicating ventricle.

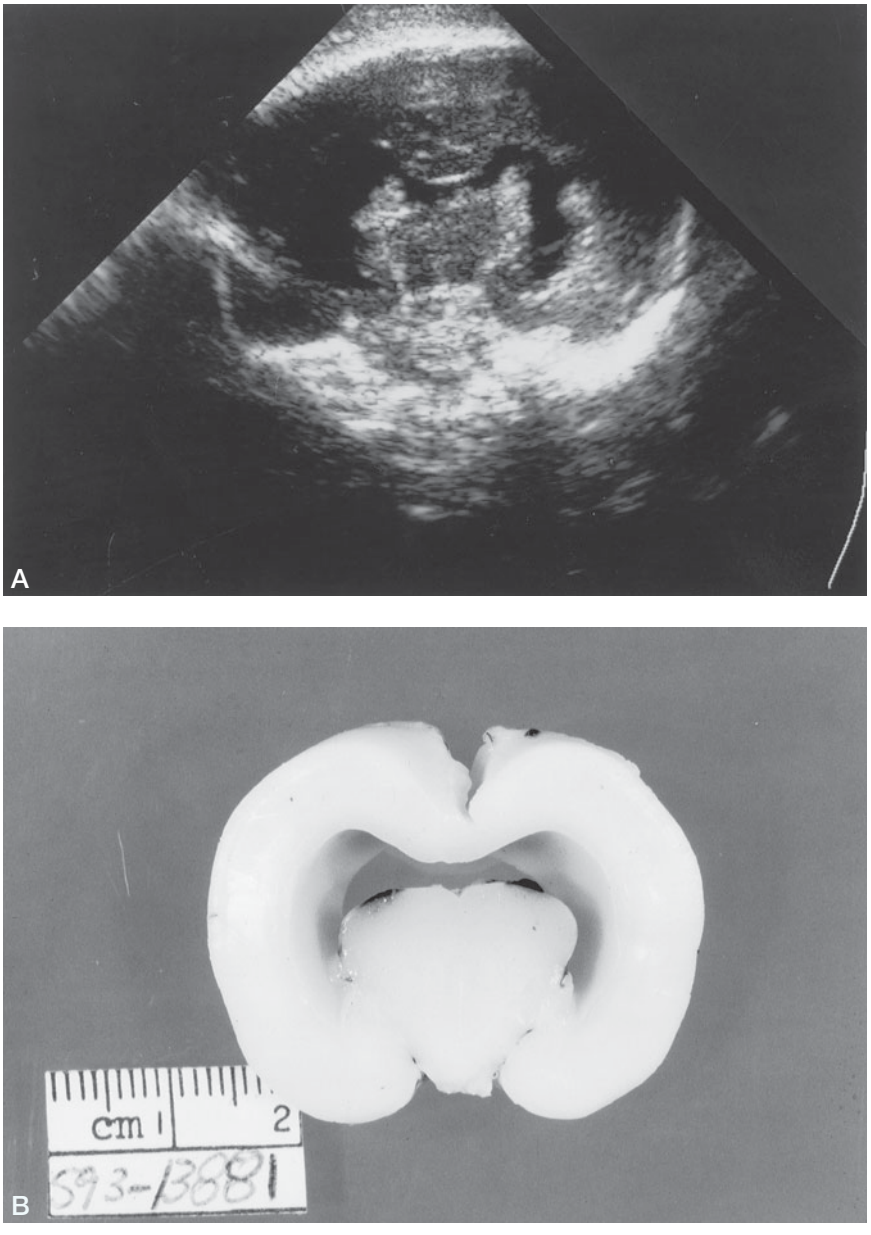

Figure 14-3 **A.** Coronal sonographic image demonstrating thalamic fusion. **B.** Corresponding pathologic specimen from a fetal brain, demonstrating a single ventricle and thalamic fusion. (*Photograph courtesy of Dr. Joseph Semple.*)

in the standard transverse view of the fetal head obtained during measurement of the biparietal diameter (BPD), ventriculomegaly may be noted. The extent of thalamic fusion is best evaluated on a coronal scan (Figure 14-3). When a large cystic abnormality of the fetal head is detected, evaluation of the midline structures of the fetal face is recommended. Greene et al. (1987) have described the use of two sonographic criteria for the diagnosis of holoprosencephaly: intracranial abnormalities and structural abnormalities of the face. In any case of suspected holoprosencephaly, the bony orbits should be visualized. Normal standards exist for the distance between orbits; this is important in the diagnosis of ocular hypotelorism (Mayden et al., 1982). Facial views will also demonstrate the presence of a proboscis. First trimester holoprosencephaly has been diagnosed by two and three-dimensional transvaginal sonography (Bronshtein and Wiener, 1991; Hamada et al., 1992; Stagiannis et al., 1995; Tongsong et al., 1999; Lai et al., 2000; Chen et al., 2005). The first trimester cross-sectional view of the fetal brain demonstrating both choroid plexuses (the so-called "butterfly sign") has been advocated as a screen for holoproscencephaly (Sepulveda et al., 2004).

Several studies have shown that extracranial abnormalities occur in approximately 50% of cases (Berry et al., 1990; McGahan et al., 1990). The most common anomalies are meningomyelocele, renal dysplasia, cardiac defects, and polydactyly.

DIFFERENTIAL DIAGNOSIS

The main considerations in the differential diagnosis of holoprosencephaly include hydrocephalus, midline cerebral defects, such as septo-optic dysplasia, hydranencephaly,

and porencephalic cysts. Holoprosencephaly may be distinguished from fetal hydrocephalus by demonstration of the absence of the midline echo and fusion of the thalami. Hydrocephalus due to aqueductal stenosis or an Arnold–Chiari malformation displays an intact falx cerebri, distinct and separate ventricles, and splayed thalami (Nyberg et al., 1987). In hydranencephaly, a thinned cerebral cortex may be noted. Finally, although both hydranencephaly and porencephalic cyst can demonstrate an absent or deviated falx, the thalami should be distinct with these diagnoses (Nyberg et al., 1987). Holoprosencephaly can occur as an isolated finding or in combination with other anomalies in a single-gene disorder, such as Smith–Lemli–Opitz syndrome (Peebles, 1998).

ANTENATAL NATURAL HISTORY

Holoprosencephaly is highly lethal during fetal life. It has been estimated that only 3% of holoprosencephalic conceptuses are liveborn (Cohen, 1989b). In a retrospective study, 40% of cases were associated with vaginal bleeding and were considered threatened miscarriages (Berry et al., 1990). The perinatal mortality rate is on the order of 89% (McGahan et al., 1990). It is important to recognize, however, there is a correlation between the severity of the condition and the outcome.

MANAGEMENT OF PREGNANCY

Holoprosencephaly is a profound fetal brain anomaly that cannot be altered or treated. Considerations for management of pregnancy include elective termination if the diagnosis is made earlier than 24 weeks, determining the cause of the holoprosencephaly, and planning the route of delivery. Because approximately 30% to 50% of fetuses with holoprosencephaly have chromosomal abnormalities, prenatal karyotype is strongly recommended. A chromosomal abnormality is more likely to be present if extrafacial abnormalities are detected on sonography (Berry et al., 1990; Bullen et al., 2001). Trisomy 13 accounts for ~75% of the chromosome abnormalities. A wide variety of other chromosomal abnormalities have also been described (Aronson et al., 1987; Gillerot et al., 1987; Münke, 1988, 1989; Urioste et al., 1988; Helmuth et al., 1989; Estabrooks et al., 1990; Isada et al., 1990; Lurie et al., 1990; Hamada et al., 1991; Hatziioannou et al., 1991; Kuchle et al., 1991; Petit et al., 1991; Van Allen et al., 1993).

If the karyotype is normal, we recommend sending amniocytes for commercial DNA mutation testing of the genes *SHH*, *TGIF*, *SIX3*, and *ZIC2* (see section "Genetics and Recurrence Risk").

Since familial recurrences of holoprosencephaly have been reported, a family history should be obtained to elicit information on family members with mental retardation, microcephaly, cleft lip and/or cleft palate, eye abnormalities, flattening of the midface, or the presence of a single central incisor (Figure 14-4) (Berry et al., 1984; Hattori et al., 1987). The mother should be asked whether she has a history of diabetes mellitus or was exposed to ethanol or salicylates. TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex) titers should be considered. Although sonography should adequately identify the presence of holoprosencephaly, fetal magnetic resonance imaging (MRI) has been reported as an alternative to improve antenatal definition of the central nervous system (CNS) anatomy (Horvath and Seeds, 1989; Toma et al., 1990; Pulitzer et al., 2004; Wong et al., 2005).

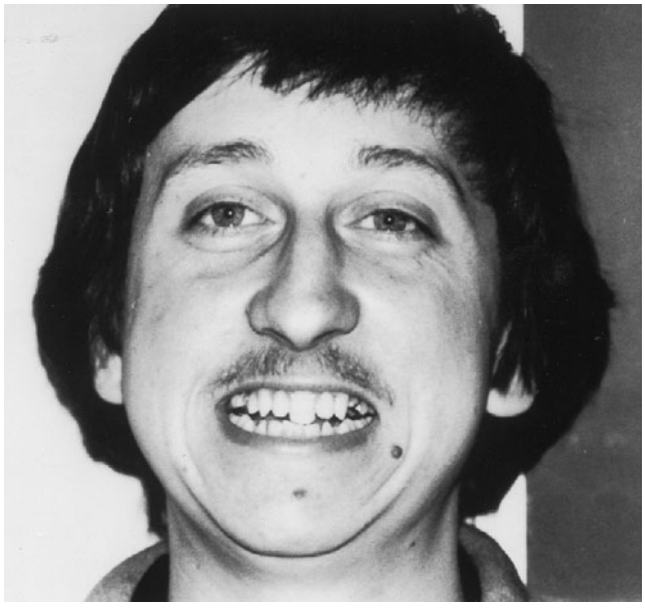

Figure 14-4 Adult with mild phenotypic features of holoprosencephaly, including a central incisor tooth and hypotelorism. These features may not be noticed in apparently normal individuals, yet they place the parent at high risk for offspring with more severe forms of holoprosencephaly. (*From Johnson VP. Holoprosencephaly: a developmental field defect.* Am J Med Genet. *1989;34:258-264.*)

Cesarean delivery may be considered for mild cases of holoprosencephaly. Occasionally, macrocephaly due to ventriculomegaly may prevent vaginal delivery. In nonviable cases of alobar holoprosencephaly, cephalocentesis may facilitate a nonoperative delivery. In a large study of 104 long-term surviviors with holoprosencephaly, the mean gestational age at birth was 38 weeks (Stashinko et al., 2004).

FETAL INTERVENTION

There is no fetal intervention for this condition.

TREATMENT OF THE NEWBORN

Infants with cyclopia, ethmocephaly, and cebocephaly do not survive the perinatal period. Given the expectations for severe

mental retardation in infants who survive with alobar holoprosencephaly, aggressive resuscitation, including mechanical ventilation, is contraindicated. In the delivery room, the infant should be warmed and dried. A thorough physical examination is recommended to document the presence of associated anomalies. If a karyotype was not obtained prenatally, it should be obtained at birth. Some infants will breathe and maintain their own temperature. Potential problems for the newborn include seizures, apnea, and feeding difficulties. If the parents are willing to take the infant home, they can be taught to feed the infant by gavage. Postnatal high-resolution MRI of the neonatal head may be helpful to further define anatomy and prognosis.

A common misperception is that children with holoprosencephaly do not survive past infancy (Hahn and Plawner, 2004). When chromosome abnormalities or severe craniofacial anomalies are present, this is true. However, infants with mild-to-moderate forms of holoprosencephaly will survive into childhood and adolescence.

LONG-TERM OUTCOME

There are increasing reports of long-term survivors with holoprosencephaly (Barr and Cohen, 1999; Hahn and Plawner, 2004; Stashinko et al., 2004) (Figure 14-5). Problems include mental retardation, seizures, feeding difficulties, endocrinopathies, such as diabetes insipidus, and abnormalities of tone and movement. Children with alobar holoprosencephaly are unable to walk, reach objects, or speak (Hahn and Plawner, 2004). In a study of 104 survivors with holoprosencephaly, only 4 of 30 individuals with semilobar holoprosencephaly had normal hand or arm function and only 2 could speak in sentences. In contrast, about half of the lobar holoprosencephaly patients could walk independently, use their upper extremities normally, and speak in sentences (Hahn and Plawner, 2004).

GENETICS AND RECURRENCE RISK

The various etiologies of holoprosencephaly are listed in Table 14-2. Holoprosencephaly due to sporadic, nonchromosomal, nonsyndromic reasons carries an empiric recurrence risk of 6% (Roach et al., 1975). In a 20-year review of cases from Western Scotland, Whiteford and Tolmie (1996) suggested that holoprosencephaly does not necessarily breed true, and that affected families had a 12% recurrence risk for serious neurologic disability. If a chromosomal abnormality is detected, the recurrence risk may be approximately 1% (in the case of trisomy 13 or 18) or higher (if a balanced translocation was found in a parent). In women with diabetes mellitus, the recurrence risk is 1% (Barr et al., 1983). A careful search must be made for relatives with the subtle findings of holoprosencephaly. The autosomal dominant form is notable for variation in the phenotype (see Figures 14-4 and 14-5 [Right]). Penetrance of the gene is on the order of 30% (Collins et al., 1993). In addition, DeMyer et al. (1963) described an autosomal recessive pattern of inheritance for holoprosencephaly.

Figure 14-5 Postnatal photographs of surviving infants with milder forms of holoprosencephaly. (*Left*) Infant with severe hypotelorism, upslanting palpebral fissures, severe midface and nasal hypoplasia, and median cleft lip and palate. (*Right*) More mildly affected infant with midface hypoplasia, and a median cleft lip and palate that have been repaired. She is the daughter of the man shown in Figure 14-4. (*From Johnson VP. Holoprosencephaly: a developmental field defect.* Am J Med Genet. *1989;34:258-264.*)

Table 14-2

Etiologies of Holoprosencephaly

Categories	Factors
Genetic factors	Familial holoprosencephaly
Chromosomal abnormalities	Trisomy 13 Trisomy 18 Duplications, deletions, and rearrangements of multiple chromosomes
Monogenic syndromes	Pseudotrisomy 13 Pallister–Hall syndrome Meckel syndrome Velocardiofacial syndrome Smith–Lemli–Opitz syndrome
HPE gene mutations	*SHH* *PTCH* *TGIF* *TDGF1* *ZIC2* *SIX3* *GLI2* *FAST1*
Environmental exposures	Antiepileptic drugs Retinoic acid Alcohol Smoking Statin drugs Pregestational diabetes Cytomegalovirus infection Maternal hypocholesterolemia

Much progress has occurred in the molecular understanding of the development of holoprosencephaly (Münke et al., 1989). At least eight different human genes have been identified that are involved in the development of holoprosencephaly (Table 14-2) (Hahn and Plawner, 2004). Two of these genes (*SHH* and *PTCH*) are part of the sonic hedgehog signaling pathway, which regulates mental development in the forebrain and spinal cord (Hahn and Plawner, 2004). The human sonic hedgehog gene (*SHH*) has been shown to be the same as the holoprosencephaly 3 (*HPE 3*) gene located on chromosome 7q36 (Belloni et al., 1996; Roessler et al., 1996). In humans, loss of one *SHH* allele is sufficient to cause holoprosencephaly (Roessler et al., 1996, 1997). Results of a complete DNA analysis of the *SHH* gene in 344 unrelated cases of holoprosencephaly has identified 23 different mutations (Nanni et al., 1999). These include nonsense and missense mutations, deletions, and an insertion. No genotype–phenotype correlation is apparent based upon this mutational analysis. In autosomal dominant holoprosencephaly, mutations in *SHH* are the most commonly indentified genetic defect (Nanni et al., 1999). Furthermore, Smith–Lemli–Opitz syndrome, a recessively inherited disorder of cholesterol biosynthesis, is associated with holoprosencephaly. Low cholesterol levels lead to abnormal or incomplete modification of the *SHH* protein.

Genes that are involved in the nodal signaling pathway (important in neural patterning) are also involved in the pathogenesis of holoprosencephaly. These include transcriptional corepressor TG-interacting factor (*TGIF*), *TDGF1*, which encodes a membrane-associated protein, and *FAST1*. Other genes involved in the etiology of holoprosencephaly do not play a role in the above pathways. These include *SIX3*, the *HPE2* locus on human chromosome 2p21. This homeobox gene contains information that is essential for the development of the anterior neural plate and eye in humans (Wallis et al., 1999). *ZIC2*, a human homologue of the Drosophila odd-paired gene, maps to chromosome 13q32. Heterozygous mutations in *ZIC2* are the underlying cause of holoprosencephaly in approximately 3% to 4% of cases (Brown et al., 1998, 2001). Interestingly, patients with *ZIC2* mutations tend to have relatively normal faces (Brown et al., 2001). *GL12* mutations are associated with a distinctive phenotype that consists of abnormal anterior pituitary formation and panhypopituitarism, midface hypoplasia, with or without overt abnormalites of forebrain cleavage (Roessler et al., 2003). Table 14-3 summarizes our recommendations for postdelivery assessment of a fetus or infant with holoprosencephaly. Given the rapid progress in human genetic and developmental research, we recommend obtaining a skin biopsy or placental material to establish a fibroblast cell line for future DNA studies. Finally, in all cases of holoprosencephaly, it is essential to hold a follow-up meeting with the parents after delivery or termination to review all pathologic studies and to

Table 14-3

Postdelivery Assessment of a Fetus/Infant with Holoprosencephaly

Rule out chromosomal abnormality with high-resolution banding
Obtain a detailed family history
Examine the proband's family to rule out subtle abnormalities
Obtain an autopsy
Bank DNA for future genetic studies
Hold follow-up meeting to summarize results of above studies

summarize the understanding of the cause, genetics, and recurrence risk.

15 CHAPTER

Hydranencephaly

Key Points

- Hydranencephaly is a rare condition in which the cerebral hemispheres are virtually absent.
- The typical case is that of an isolated finding without additional abnormalities.
- The diagnosis should be expected when a large cystic mass fills the cranial cavity and there is no recognizable cerebral cortex.
- The antenatal natural history is not well known but appears to represent an evolving intrauterine process secondary to a vascular insult.
- Correct diagnosis is important for the management of these cases. Vaginal delivery is optimal.
- The long-term outcomes associated with complete hydranencephaly are extremely poor.
- In most cases, there is no recurrence risk since hydranencephaly is most often associated with a destructive process rather than with a primary malformation.

CONDITION

Hydranencephaly describes a condition in which the cerebral hemispheres are virtually absent. The hemispheres are replaced by membranous sacs containing cerebrospinal fluid. The meninges and skull are intact. The cerebellum and brainstem are typically normal. The falx is usually present but may be partially or completely absent. Hydranencephaly is considered the most severe form of a spectrum of disorders that includes porencephalic cyst and schizencephaly. It is differentiated from extreme hydrocephalus by the lack of any identifiable cerebral cortex in hydranencephaly.

The most commonly accepted mechanism for the development of hydranencephaly is bilateral internal carotid artery occlusion resulting in cerebral infarction. Myers (1969) described the surgical ligation of the common carotid arteries and jugular veins of a rhesus monkey fetus at 84 to 86 days of gestation. On subsequent postmortem examination the fetal cranium was fully developed; however, the cerebral hemispheres were absent and replaced by thin membranous sacs filled with cerebrospinal fluid, while the brainstem and cerebellum were normal (Myers, 1969). Prenatal infections including toxoplasmosis (Altshuler, 1973; Plantaz et al., 1987), cytomegalovirus (Kubo et al., 1994), rubella (Deshmukh et al., 1993), and herpes simplex infections (Christie et al., 1986; Hutto et al., 1987) have also been associated with hydranencephaly. Hemorrhagic states such as familial factor XIII deficiency have also been reported (Takada et al., 1989).

The typical case of hydranencephaly is that of an isolated finding with no additional abnormalities. A variety of syndromes has been reported in association with hydranencephaly, including trisomy 13 (Dixon, 1988), agnathia malformation complex (Persutte et al., 1990), hypoplastic thumbs (Norman and Donnai, 1992), lethal multiple pterygium syndrome (Mbakop et al., 1986), and both renal aplastic dysplasia and polyvalvular developmental heart defect (Bendon et al., 1987). Four cases of hydranencephaly associated with severely dysplastic kidneys have also been reported (Gschwendtner et al., 1997). Hydranencephaly may occur in a surviving co-twin following single intrauterine fetal demise in a monochorionic pregnancy (Hahn et al., 2003). In addition, although this condition is usually sporadic, affected siblings (Hamby et al., 1950; Najafzadeh et al., 1982) and a set of affected twins have been reported (Regec and Bernstine, 1979). Hydranencephaly has also been reported in association with a primary congenital rhabdoid tumor of the brain (Velasco et al., 1993).

INCIDENCE

The reported incidence of hydranencephaly is between 1 in 4000 and 1 in 10,000 births (Romero et al., 1988). Hemihydranencephaly is an extremely rare condition and has been reported on six occasions (Muir, 1959; Warkany, 1971; Moser and Seljeskog, 1981; Suzuki et al., 1985; Ohtsuka, 1986; van Doornik and Hennekam, 1992).

SONOGRAPHIC FINDINGS

Hydranencephaly can be diagnosed in the first trimester and should be suspected when a large cystic mass fills the cranial cavity without recognizable cerebral cortex (Lin et al., 1992; Lam and Tang, 2000) (Figure 15-1). The lack of cerebral cortex differentiates the condition from severe hydrocephalus. The midbrain, basal ganglia, and posterior fossa are usually normal, and there is often a characteristic protrusion of the brainstem into the cystic mass (Romero et al., 1988). The falx is usually present but may be partially or completely absent. Macrocephaly may be present and is attributed to continuing production of cerebrospinal fluid by the choroid plexus (Raybaud, 1983; Greene et al., 1985). Polyhydramnios can be a common associated finding (Fleischer and Brown, 1977).

The sonographic appearance of hydranencephaly may sometimes be difficult, because visualization of a completely anechoic cystic mass is dependent on the timing of sonography in relation to the vascular insult. The diagnosis of hydranencephaly may not be clear when the infarction and hemorrhage are evolving. Recent hemorrhage appears echogenic, and as clot lyses it assumes the characteristic anechoic appearance of hydranencephaly (Greene et al., 1985; Edmondson et al., 1992). Serial sonography may therefore be

Figure 15-1 Prenatal sonographic image demonstrating the absence of cerebral cortex and presence of a large fluid-filled mass.

necessary to confirm the diagnosis, as hydranencephaly is an evolving process (Lam and Tang, 2000). Magnetic resonance imaging can be used to confirm the diagnosis (Byers et al., 2005).

DIFFERENTIAL DIAGNOSIS

The most common differential diagnoses that should be considered include extreme hydrocephalus, porencephaly, and lobar holoprosencephaly. When hydrocephalus is extreme the cerebral cortex may be very thin and closely applied to the cranium, thereby making it difficult to differentiate from cases of hydranencephaly with preserved falx. The presence of even minimal cerebral cortex indicates extreme hydrocephalus rather than hydranencephaly. In addition, hydranencephaly usually demonstrates a pronounced bulging of the brainstem into the cystic cavity, while in extreme hydrocephalus the presence of residual cortical matter prevents this characteristic appearance (Romero et al., 1988). Magnetic resonance imaging (MRI) has been reported as a complementary technique for the definitive intrauterine diagnosis of hydranencephaly (Vila-Coro and Dominguez, 1989; Byers et al., 2005).

Porencephaly may be differentiated from hydranencephaly by the asymmetric appearance of porencephalic cysts, although complete differentiation of the two conditions can be difficult because they may represent a continuum (Sanders et al., 1996). Features that help differentiate lobar holoprosencephaly from hydranencephaly include absence of the falx and midline structures, absence of the third ventricle, fusion of the thalami, and preservation of some cortical tissue in holoprosencephaly. Furthermore, facial anomalies and additional central nervous system anomalies are usually present with alobar holoprosencephaly. A list of the conditions that have been associated with hydranencephaly is given in Table 15-1.

ANTENATAL NATURAL HISTORY

Little is known about the antenatal natural history of hydranencephaly. In one reported case, the initial sonographic evaluation was normal at 18 weeks' gestation. Follow-up ultrasound examination at 25 weeks revealed sonographic evidence of hydranencephaly (Sanders, 1996). Other case reports document the intrauterine diagnosis of massive intracranial hemorrhage at 27 and 30 weeks of gestation, with subsequent development of hydranencephaly over a period of weeks (Greene et al., 1985; Edmondson et al., 1992). These findings confirm the theory that hydranencephaly represents an evolving intrauterine process that may be secondary to a profound vascular insult.

Table 15-1

Reported Associations with Hydranencephaly

Infections
Cytomegalovirus (Kubo et al., 1994)
Herpes simplex (Christie et al., 1986; Hutto et al., 1987)
Rubella (Deshmukh et al., 1993)
Toxoplasmosis (Altshuler, 1973; Plantaz et al., 1987)
Chromosomal abnormalities
Trisomy 13 (Dixon, 1988)
Neoplasms
Congenital rhabdoid tumor of the brain (Velasco et al., 1993)
Bleeding disorders
Factor XIII deficiency (Takada et al., 1989)
Syndromes associated with hydranencephaly
Agnathia malformation complex (Persutte et al., 1990)
Hypoplastic thumbs (Norman and Donnai, 1992)
Renal dysplasia (Bendon et al., 1987; Gschwendtner et al., 1997)
Polyvalvular heart defect (Bendon et al., 1987)
Lethal multiple pterygium syndrome (Mbakop et al., 1986)

MANAGEMENT OF PREGNANCY

An accurate prenatal diagnosis is necessary for appropriate management decisions. It is particularly important to make the distinction between hydranencephaly and extreme hydrocephalus. Patients should be counseled about the poor prognosis associated with this congenital anomaly, and termination should be offered. MRI is suggested (Vila-Coro and Dominguez, 1989). Serology and/or cultures for toxoplasmosis, cytomegalovirus, rubella, and herpes should also be performed. If there is any sonographic suspicion of other abnormalities, fetal karyotyping should be considered.

Serial ultrasound examinations are recommended to evaluate for the development of macrocephaly. Vaginal delivery is the preferred route of delivery due to the poor prognosis associated with hydranencephaly. Because macrocephaly is commonly associated with the disorder, cephalocentesis may be necessary to facilitate successful vaginal delivery (Greene et al., 1985). Cephalocentesis is performed by inserting an 18- or 20-gauge spinal needle into the fetal head under ultrasound guidance and aspirating cerebrospinal fluid. The fluid

removed is usually dark brown (Greene et al., 1985). If the fluid obtained is not dark brown, it should prompt analysis for protein concentration because in hydranencephaly a highly proteinaceous fluid is suggestive of an intracranial neoplasm (Velasco et al., 1993).

If there is any doubt about the diagnosis, delivery should be performed in a tertiary care setting where qualified subspecialists are available for resuscitation and syndrome diagnosis. If there is no doubt regarding the diagnosis, there is no advantage to delivery in a tertiary care setting. Fetal monitoring is not indicated. If fetal monitoring is performed and the results are not reassuring, cesarean delivery is not recommended.

FETAL INTERVENTION

No fetal interventions have been described following the prenatal diagnosis of hydranencephaly.

TREATMENT OF THE NEWBORN

The neonate with hydranencephaly usually presents with macrocephaly and frequent seizures, although the diagnosis may be delayed for several months because of relatively appropriate early behavior. In one series of 22 patients, the average age at diagnosis was 12 weeks, with a range of 1 day to 10.5 months (Herman et al., 1988). Common presenting symptoms include increasing head size, psychomotor retardation, and increasing spasticity. Most patients have ophthalmic abnormalities involving optic-nerve abnormalities, strabismus, and inferior displacement of the globe (the "setting sun" sign). Transillumination of the skull was the traditional method of postnatal diagnosis of hydranencephaly. However, transillumination of the skull may also be seen with extreme hydrocephalus. Computed tomographic (CT) scanning is helpful in distinguishing hydranencephaly from extreme hydrocephalus and may demonstrate maximal preservation of the frontal cortex and a normal cerebral vascular architecture in hydrocephalus (Herman et al., 1988). MRI is the most definitive imaging technique for the diagnosis of hydranencephaly (Hanigan and Aldrich, 1988).

Electrophysiologic studies, specifically electroencephalography (EEG) and visual evoked responses may also be helpful in distinguishing extreme hydrocephalus from hydranencephaly (Iinuma et al., 1989). The EEG in hydranencephaly is typically flat, and visual evoked potentials show no response. By contrast, in neonates with extreme hydrocephalus there is some EEG activity and normal visual evoked potentials (Herman et al., 1988; Iinuma et al., 1989). Auditory evoked potentials in hydranencephaly show an absent middle latency response, while somatic evoked potentials show an absent cortical response (Hanigan and Aldrich, 1988). If prenatal testing was not performed for cytomegalovirus, toxoplasmosis, rubella, and herpes infections, then appropriate serologic and microbiologic studies should be done during the newborn period.

SURGICAL TREATMENT

Unlike extreme hydrocephalus, shunting procedures are not indicated in hydranencephaly. Sutton et al. (1980) followed neonates with hydranencephaly with serial CT, EEG, and developmental evaluations for 4 to 23 months. No improvement was demonstrated in these five infants by radiologic or neurologic criteria despite aggressive surgical treatment and shunt placement. In contrast, five infants with extreme hydrocephalus treated during the same period improved dramatically after shunt placement (Sutton et al., 1980). In cases of unilateral hydranencephaly, shunting to prevent increasing compromise of the uninvolved side is indicated and has demonstrated favorable results (van Doornik and Hennekam, 1992). No other surgical interventions are recommended for hydranencephaly.

LONG-TERM OUTCOME

The outcome for children with complete hydranencephaly is universally poor. There is no specific treatment, and active medical intervention is not indicated. Almost half of infants with hydranencephaly die within 1 month, and fewer than 15% survive 1 year (Dixon, 1988). Nonetheless, it is important to counsel patients that prolonged survival can occur. In a series of 22 patients, 3 patients were alive at ages 9, 12, and 17 years, but all 3 required constant custodial care (Herman et al., 1988). Survival up to 19 and 20 years has been reported (McAbee et al., 2000; Covington et al., 2003).

In contrast, the prognosis for unilateral hydranencephaly is more favorable (Greco et al., 2001). In one study of the six patients with this disorder, four patients demonstrated mild developmental delay (van Doornik and Hennekam, 1992). No data were provided for one patient. Another patient had multiple congenital defects combined with hemihydranencephaly and severe retardation (van Doornik and Hennekam, 1992).

GENETICS AND RECURRENCE RISK

Hydranencephaly is usually the result of a destructive process in a previously normally formed brain rather than a primary malformation. There has been a reported association with trisomy 13 (Dixon, 1988). Therefore, for most cases there will be no recurrence risk. Familial cases are extremely rare,

and such families should be offered prenatal diagnosis with ultrasound examination in a subsequent pregnancy.

16 CHAPTER Hydrocephalus

Key Points

- Hydrocephalus is usually due to obstruction of CSF flow, either within (noncommunicating hydrocephalus) or outside (communicating hydrocephalus) the ventricles.
- Ventriculomegaly simply refers to enlargement of intracranial ventricles. It can be associated with hydrocephalus or abnormal brain development.
- Ventriculomegaly is commonly defined as a measurement of 10 mm or greater in the posterior horns of the lateral ventricles noted on an axial brain scan, irrespective of gestational age.
- Approximately 40% of cases of ventriculomegaly have associated CNS or extra-CNS abnormalities, and 12% have an abnormal karyotype.
- Underlying causes include aqueductal stenosis, meningomyelocele, intrauterine infection (CMV, toxoplasmosis, syphilis), agenesis of corpus callosum, X-linked hydrocephalus syndromes, intracranial hemorrhage, Dandy–Walker malformation, and intracranial tumors.
- *L1CAM* gene mutations account for up to 25% of male cases of isolated congenital hydrocephalus.
- Recurrence risk, in the absence of a positive family history, or a known *L1CAM* mutation, is approximately 4%.

CONDITION

Hydrocephalus is a pathologic increase in intracranial cerebrospinal fluid (CSF) volume, whether intraparenchymal or extraparenchymal, independent of hydrostatic or barometric pressure (Raimondi, 1994). CSF is formed within the ventricular system—50% from the choroid plexus and 50% from the cerebral capillaries. The circulation of CSF is unidirectional (Vintzileos et al., 1983). It flows from the lateral ventricles through the foramen of Monro into the third ventricle. It then flows from the third ventricle to the aqueduct of Sylvius through the fourth ventricle into the spinal subarachnoid space (foramen of Magendie) or to the basal cisterns (foramen of Luschka) over the cerebral hemispheres. CSF is reabsorbed by arachnoid villi in venous sinuses. The flow of CSF is partially derived by arterial pulsations of the choroid plexus (Vintzileos et al., 1983).

Hydrocephalus may result from either fluid production that exceeds absorption or primary atrophy of the cerebral parenchyma. Most cases are due to mechanical obstruction to the flow of CSF at some level (DeLange, 1977). The site of obstruction may be inside the ventricular system (noncommunicating or internal hydrocephalus) or outside the ventricles (communicating or external hydrocephalus). Aqueductal stenosis comprises one-third of the cases of hydrocephalus in postnatal series; it is less common in prenatal studies. The aqueduct of Sylvius is the narrowest portion of the spaces through which the CSF flows, and aqueductal stenosis can be diagnosed following the finding of dilation of both lateral, and the third, ventricles (Raimondi, 1994; Davis, 2003).

Ventriculomegaly is a descriptive term of a pathologic process that has many causes. It may occur due to obstruction of CSF flow, or as a consequence of maldevelopment of the ventricle in anomalies such as agenesis of the corpus callosum (colpocephaly) or as an *ex vacuo* (destructive) phenomenon secondary to cerebral atrophy (Cardoza et al., 1988a). Ventriculomegaly is an indicator of underlying central nervous system (CNS) anomalies. It may also be the first sign of associated extra-CNS anomalies. The main causes of ventriculomegaly are aqueductal stenosis, Chiari II malformation (associated with meningomyelocele), Dandy–Walker malformation, agenesis of the corpus callosum, and fetal aneuploidy (D'Addario et al., 2007).

The hereditary nature of hydrocephalus was first appreciated by Bickers and Adams in 1949. It is now known that mutations in *L1CAM*, which result in a collection of X-linked conditions known as the L1 spectrum disorders, account for the majority of inherited cases of hydrocephalus (Zhang et al., 2006).

INCIDENCE

The incidence of isolated fetal ventriculomegaly is 0.5 to 1.5 per 1000 pregnancies. (Wilson et al., 1989; Wiswell et al., 1990; Davis, 2003). In a retrospective analysis of all liveborn and stillborn infants in U.S. Army hospitals between 1971 and 1987, 370 of 763,364 pregnancies had hydrocephalus (Wiswell et al., 1990). This equaled an incidence of 0.5 per 1000 total births, or 1 per 2063 total births. Of the infants with hydrocephalus, 37% had additional anomalies unrelated to the primary defect. No significant racial differences were seen, but an increased incidence of affected males was noted (64% male, 36% were female). A predominance of males is consistently observed in all studies of hydrocephalus due to the inherited X-linked forms of the abnormality.

SONOGRAPHIC FINDINGS

Hydrocephalus is generally easily diagnosed prenatally due to the striking sonographic appearance of enlarged ventricles (Figure 16-1). It is important to note that the fetal biparietal diameter may not necessarily be increased when the ventricles are dilated. The lateral ventricles can be visualized as early as 12 weeks of gestation. Early in the second trimester, the choroid plexus is very echogenic and large relative to the volume of the cerebral hemispheres, normally filling the entire lateral ventricle posterior to the foramen of Monro. This tends to obscure the lateral ventricular wall to which it is closely applied (Fadel, 1989). This, together with the hypoechoic brain mantle, may falsely be interpreted as dilated ventricles filled with CSF. In second trimester fetuses with hydrocephalus, the first recognizable abnormality is generally the relative shrinkage of the normally prominent choroid plexus. Additionally, the choroid plexus appears to hang away from the ventricular walls, an appearance that is referred to as "dangling choroid."

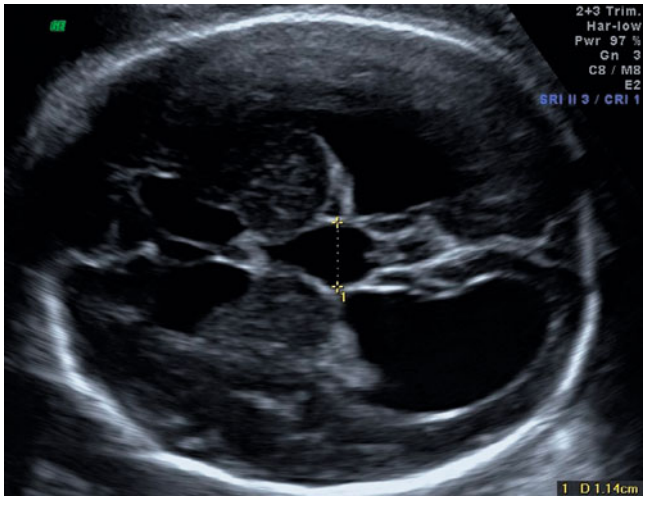

Figure 16-1 Axial sonographic image of a fetal head with communicating hydrocephalus. Third ventricle and lateral ventricles are markedly enlarged.

Several different methods have been proposed to quantitatively evaluate increased CSF. These methods include measurement of the ratio of the lateral ventricular width (LVW) to the hemispheric width (HW), (the LVW:HW ratio), or measurement of the ventricular atria. However, the LVW:HW ratio is not sensitive in early pregnancy. The first measurement of lateral ventricular dilation is the displacement of the medial wall of the lateral ventricle toward the midline, which will not change the LVW:HW ratio (Fadel, 1989). Furthermore, the echogenic outer lines originally thought to represent the lateral walls of the lateral ventricle in an axial scan of the fetal head have been shown by Hertzberg et al. (1987) to originate from deep cerebral veins. These reflections from small venous structures and deep fetal white matter may be displaced in the presence of hydrocephalus. The position of the fetal choroid plexus relative to the ventricular walls is dependent on gravity, and so the choroid angle (the angle between the long axis of the choroid plexus and the linear midline echo on a transverse axial sonogram through the body of the lateral ventricle), may be a useful indicator of ventricular size (Cardoza et al., 1988a). In normal-sized ventricles, this angle varies from 6 to 22 degrees, while in fetuses with ventriculomegaly the angle ranges from 29 to 90 degrees (Cardoza et al., 1988a). The choroid angle appears to increase with the severity of hydrocephalus.

The most common method for assessing ventricular size today is the atrial diameter measured on an axial sonogram through the fetal brain. In a study of 100 healthy fetuses between 14 and 38 weeks of gestation, the normal atrial diameter remained relatively constant throughout gestation despite growth of the surrounding brain (Cardoza et al., 1988b). These measurements were compared with 38 fetuses in whom ventriculomegaly had already been diagnosed. The mean diameter of the normal atrium was 7.6 $\pm$ 0.6 mm, and it was suggested that atrial diameters >10 mm, (greater than 4 SD above the mean), indicated the presence of ventriculomegaly. This measurement is quick to perform, is reproducible, and does not vary by gestational age (Cardoza et al., 1988b).

While an atrial diameter of >10 mm is considered abnormal, the term borderline ventriculomegaly is often used to refer to an atrial measurement of between 10 and 12 mm. Borderline ventriculomegaly is associated with an increased risk of CNS and non-CNS abnormalities, and suggests the need for a more detailed fetal anatomic examination. Several studies have substantiated this recommendation. Mahony et al. (1988) performed a prospective study of 20 fetuses with

apparently isolated borderline ventriculomegaly (defined as a 3- to 8-mm separation existing between the choroid plexus in the atrium of the lateral cerebral ventricle and the adjacent ventricular wall on an axial scan). Of the 20 fetuses identified, 8 had a normal outcome (40%). The remaining 12 fetuses had additional sonographic abnormalities. Of these 12, 4 had an uncertain prognosis and 8 died. In another study of 55 fetuses with borderline ventriculomegaly, 13 had isolated ventriculomegaly and 42 had associated abnormalities (Goldstein et al., 1990). Of 15 living children who could be identified, 9 (60%) were normal at 6 to 30 months of postnatal age, 3 (20%) were abnormal, and 3 (20%) were lost to follow-up. These authors concluded that borderline ventriculomegaly, when isolated, was associated with a better prognosis than more substantial ventriculomegaly. A literature review in 1993 found 109 cases of mild ventriculomegaly, 92 of which were isolated, and 11 of these had an abnormal karyotype (12%) (Achiron et al., 1993). In another retrospective study of 44 fetuses with borderline ventriculomegaly (10–12 mm), 17 fetuses (39%) had other sonographic abnormalities, 6 of which were in the CNS (Bromley et al., 1991). Of 36 liveborn neonates in this study, 26 were developmentally and clinically normal at 3 to 18 months of postnatal age, while 10 of the 36 were developmentally impaired, including 5 cases from apparently isolated borderline ventriculomegaly.

Unilateral hydrocephalus is extremely uncommon. This condition carries a better prognosis than bilateral hydrocephalus. Of eight reported prenatal cases, five were due to congenital absence or stenosis of the foramen of Monro, one was due to transient obstruction of CSF flow by an intracranial hematoma, one was due to holoprosencephaly, and one was due to unknown causes (Patten et al., 1991). It appears that unilateral hydrocephalus is not associated with the presence of extracranial anomalies, and such patients generally have required postnatal placement of a ventriculoperitoneal shunt (Patten et al., 1991; Anderson et al., 1993; Chari et al., 1993).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for hydrocephalus and ventriculomegaly includes aqueductal stenosis, meningomyelocele (Chiari II malformation), Dandy–Walker malformation, agenesis of the corpus callosum, aneuploidy, intrauterine infection (cytomegalovirus, toxoplasmosis, or syphilis), intracranial hemorrhage, CNS tumor, hydranencephaly, porencephaly, and holoprosencephaly. Meningomyelocele can be the underlying reason for hydrocephalus due to herniation of the cerebellum through the foramen magnum resulting in the Chiari II malformation. The fetal spine should therefore be carefully examined in multiple planes in all such cases (see Chapter 19).

In hydranencephaly, only remnants of the cortex remain, with fluid-filled sacs that are lined by leptomeninges replacing the rest of the brain (see Chapter 15). In porencephaly, the parenchyma of the brain contains one or more fluid-filled cavities (see Chapter 21). The Dandy–Walker malformation includes ventricular dilation (see Chapter 11). Demonstration of the absence of falx cerebri and fusion of the thalami can distinguish holoprosencephaly from other causes of hydrocephalus (see Chapter 14). Consideration should also be given to the possibility of underlying single-gene disorder.

One of the major concerns with the antenatal sonographic finding of hydrocephalus is the fact that ventriculomegaly is frequently associated with additional anomalies within and outside of the fetal brain. Associated intracranial anomalies (such as agenesis of the corpus callosum or the Dandy–Walker malformation) are present in at least one-third of cases. Extracranial abnormalities have been demonstrated in two-thirds of cases (Fadel, 1989). In another series of 61 cases of hydrocephalus, 51 fetuses (84%) had associated abnormalities, 34 of which were extracranial and 27 had multiple malformations (Nyberg et al., 1987). In this series, false-negative diagnoses were common, and included esophageal atresia, spinal abnormalities, lung hypoplasia, and cardiac defects. Of 61 fetuses, 41 ultimately died from associated conditions such as asphyxiating thoracic dystrophy (Jeune syndrome), Apert syndrome, in which hydrocephalus is considered a major associated malformation (Hyon et al., 1986), and the Walker–Warburg syndrome. This latter recessively inherited condition includes hydrocephalus, multiple CNS malformations, microophthalmia, severe mental retardation, congenital myopathy, and a limited life span (Crowe et al., 1986). Finally, inborn errors of metabolism, such as fumarase deficiency, can cause polyhydramnios and hydrocephalus in utero (Remes et al., 1992). In this condition, enlargement of the cerebral ventricles is due to cerebral atrophy, while the associated polyhydramnios is due to intrauterine hypotonia, causing poor swallowing.

ANTENATAL NATURAL HISTORY

In a review of 24 cases of fetal hydrocephalus, four fetuses underwent transabdominal or transvaginal cephalocentesis prenatally and intracranial pressures were measured. The results suggested that the fetal brain is subjected to extremely high intracranial pressures, resulting from a mixture of hydrocephalic pressure and intermittent uterine constriction (Oi et al., 1990). In another study of patients with fetal CNS defects who had cephalocentesis performed at the time of termination of pregnancy, intracranial CSF pressures and volumes were quite variable, with no correlation between the type of lesion and intracranial pressure observed (Simpson et al., 1988). It therefore does not appear that there is any value in measuring fetal intracranial pressure for predicting outcome.

Following the diagnosis of borderline ventriculomegaly, a significant number of fetuses will demonstrate spontaneous resolution of the ventricular enlargement and will have a normal outcome. In a study of 63 fetuses with

apparently isolated ventriculomegaly of 10 to 15 mm, 26 (41%) showed normalization of lateral ventricles, 27 (43%) remained stable, and only 10 (16%) demonstrated progressive enlargement (Parilla et al., 2006).

MANAGEMENT OF PREGNANCY

The finding of prenatal ventriculomegaly mandates referral to a center capable of targeted sonographic examination of the fetus due to the high incidence of associated CNS and extra-CNS anomalies. Prospective parents should be counseled regarding the diversity of conditions that can be associated with hydrocephalus (Pober et al., 1986). They should be counseled that ventriculomegaly is progressive in 2.5% to 4.5% of cases, and that the incidence of associated abnormalities varies from 54% to 84% (Rosseau et al., 1992). Serial sonograms should therefore be performed to determine whether the hydrocephalus is stable, progressive, or resolving.

The major factor that influences prognosis is the presence of associated abnormalities (Pober et al., 1986). Given the difficulty in excluding other CNS abnormalities, it would be reasonable to consider performance of a fetal magnetic resonance image (MRI) in cases of significant ventriculomegaly. In general, decisions about management options depend on the gestational age at the time of diagnosis and the presence and nature of associated abnormalities. Pregnancy termination may also be considered. Further recommended diagnostic studies include chromosome analysis, DNA analysis for *L1CAM* mutations, and an infectious work-up to rule out cytomegalovirus and toxoplasmosis. The most commonly associated chromosome abnormalities include trisomies 9, 13, and 18, as well as triploidy (Schrander-Stumpel and Fryns, 1998).

Mode of delivery should be individualized in all cases. In general, a cesarean delivery after demonstrating pulmonary maturity is recommended if the fetal head size is significantly enlarged (Figures 16-2 and 16-3). However, if ventriculomegaly is isolated, without significant head enlargement, vaginal delivery is also reasonable. If severe abnormalities incompatible with extrauterine life are present, such as thanatophoric dysplasia, cephalocentesis (removal of CSF from the ventricular system) to reduce head size to permit vaginal delivery can be considered.

FETAL INTERVENTION

In utero treatment, using shunts or repeated cephalocenteses, has been previously attempted for hydrocephalus to try to prevent progressive damage to the fetal brain caused by the chronically increased CSF pressure (Birnholz and Frigoletto, 1981; Clewell et al., 1982). Specific criteria for intrauterine therapy were established by the International Fetal Medicine and Surgery Society (IFMSS), including ventriculomegaly,

Figure 16-2 Axial 3D image showing marked bilateral ventriculomegaly.

and gestational age of less than 30 weeks. A registry was formed in 1982 under the auspices of the IFMSS (Manning et al., 1986; Drugan et al., 1989). This group analyzed the results of 39 antenatal procedures performed in the United States and 5 in Italy between 1982 and 1985. Of the 44 cases, 36 (82%) fetuses survived and 8 (19%) died in utero or during the perinatal period. Four of these deaths were related to the in utero procedure. Twenty-two of 36 survivors were left with varying neurologic and physical handicaps, with 48% being severely handicapped (Manning et al., 1986). Because of the high rate of procedure-related death and lack of significant improvement in outcome, such in utero treatment has been abandoned.

Hudgins et al. (1988) retrospectively reviewed the outcomes of 47 fetuses evaluated during a 4-year period in the fetal treatment program at the University of California at San Francisco. Twenty-five of these 47 fetuses with ventriculomegaly had severe associated abnormalities and were either electively terminated or died during the perinatal period. Of the remaining 22, 19 had stable ventriculomegaly, 2 had progressive ventriculomegaly, and 1 resolved in utero. Of the 19 postnatal long-term survivors, 13 (68%) were normal and 6 (32%) had moderate-to-severe developmental delay. Associated abnormalities were detected in 74% of fetuses, and there was a 20% false-negative rate of detection of associated abnormalities. These authors concluded that they were unable

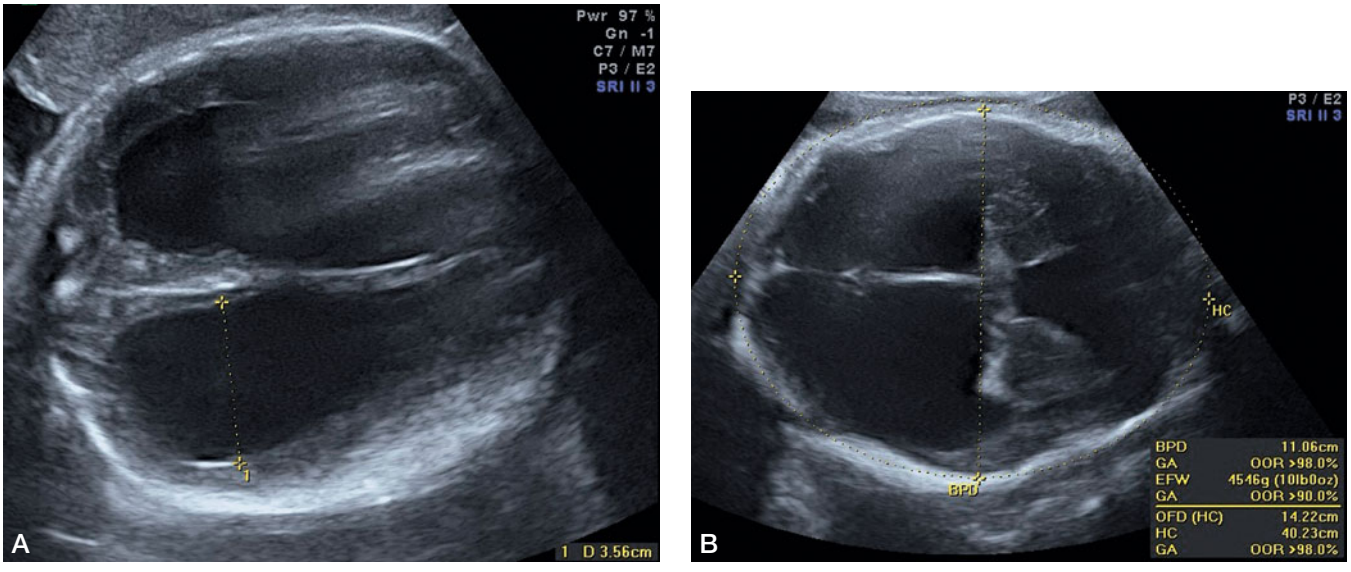

Figure 16-3 **A.** Aqueductal stenosis leading to marked hydrocephalus and **B.** macrocephaly at 36 weeks' of gestation.

to define a group of patients that would benefit from in utero shunting. In their series, only a 14% incidence of isolated, progressive ventriculomegaly was noted. While such fetuses with isolated, progressive ventriculomegaly are the most likely to benefit from in utero treatment, these fetuses represent such a small minority of the total population of fetuses with ventriculomegaly that in utero treatment is currently not recommended. Indeed, since 1985, a moratorium on fetal shunts for hydrocephalus had been agreed upon by members of the IFMSS (Davis, 2003). However, experimental approaches to more invasive fetal surgery for select cases of hydrocephalus are being investigated, such as hysterotomy and placement of a tunneled shunt from the fetal lateral ventricles to the skin at the fetal back (Davis, 2003).

Fetal intervention for hydrocephalus occurring secondary to meningomyelocele is discussed in Chapter 19.

TREATMENT OF THE NEWBORN

Infants who are delivered following a prenatal diagnosis of ventriculomegaly need a detailed physical examination (Figure 16-4). Consultation with a medical geneticist and a neurosurgeon is recommended. Postnatal diagnostic imaging of the CNS may include computed tomographic (CT) scan and magnetic resonance imaging (MRI). If a chromosome analysis was not performed prenatally, it should be performed during the newborn period. The major goals of treatment of the newborn are to determine an underlying cause for the hydrocephalus and to stabilize the infant for the placement of a ventriculoperitoneal shunt. Provided the newborn with significant hydrocephalus is not diagnosed with other abnormalities incompatible with life, the goal will usually be to arrange shunting in the first 4 days of life (Futagi et al., 2002).

If the infant has been found to have multiple associated abnormalities incompatible with survival, a detailed autopsy is recommended if death occurs during the neonatal period.

SURGICAL TREATMENT

The major treatment of hydrocephalus is the placement of a ventriculoperitoneal shunt. The shunt has a proximal portion, typically placed in the frontal horn of the lateral ventricle, together with a one-way valve that is placed extracranially. This then connects to the distal portion of the shunt, which is usually tunneled subcutaneously to the peritoneal cavity, although other rarer sites include the right atrium or the subclavian vein. High pressure between the intracranial portion and the intraperitoneal portion of the device results in flow out of the ventricular system.

Figure 16-4 Postnatal photograph of a newborn infant diagnosed prenatally with hydrocephalus. Note enlarged head and prominent venous pattern on scalp.

Mortality related to this surgery is minimal. The major morbidities are associated with malfunction or blockage of the shunt and shunt infection. Unfortunately, such complications are extremely common, with 25% to 50% of all shunts requiring revision within the first 2 years of life (Liptak and McDonald, 1985).

LONG-TERM OUTCOME

The most important factor in the long-term outcome is the presence of associated abnormalities. In one study, Rosseau et al. (1992) reviewed follow-up data on 40 patients identified prenatally with hydrocephalus in a community-acquired series. Of these 40 patients, 3 were electively terminated and 37 delivered. Of the 37, 26 (70%) underwent the placement of a ventriculoperitoneal shunt. Ten of these 26 (38%) had satisfactory cognitive ability. Of the 11 patients who were not treated, reasons for nontreatment included misdiagnosis, resolution of hydrocephalus, or parental refusal. Multiple studies seem to indicate that approximately 40% to 50% of survivors have a normal IQ. The IQs are not proportional to brain expansion after the placement of the shunt. Degree of ventricular dilatation does not appear to be associated with long-term outcome (Hirsch, 1994). Similarly, the site of obstruction does not affect long-term intelligence.

In a study of 27 fetuses with isolated, borderline ventriculomegaly, 25 had a normal neurological outcome, 1 had petit mal seizures, and one was electively terminated (Lipitz et al., 1998). Approximately 10% of survivors have a seizure disorder (Hirsch, 1994). In a study of intelligence outcome in 44 children with shunted hydrocephalus, the site of obstruction, the number of shunt revisions, the number of postsurgical complications such as infection or hematoma, or the presence of seizures did not correlate with abnormalities in neuropsychologic functioning. Verbal intelligence was shown to be affected by the presence of motor deficits and the need for antiepileptic therapy. Nonverbal intelligence was affected by the presence of a brain malformation or the age at the time of shunt placement. In this study, if a shunt was placed later in life it indicated that the aqueductal stenosis developed slowly (Riva et al., 1994).

Futagi et al. (2002) reviewed 38 children who had surgical management of prenatally diagnosed hydrocephalus. Neurodevelopmental outcome was normal at a mean age of 7.4 years in only three patients, while one had borderline intelligence, seven had intellectual impairment, and 27 had significant motor impairment.

GENETICS AND RECURRENCE RISK

The major considerations in the genetics of hydrocephalus are related to the underlying cause. In a review of the causes of hydrocephalus in liveborn infants, Burton (1979) demonstrated that only 1.4% of siblings of 205 affected patients also had hydrocephalus. Specific subgroups were identified to be at high risk, including males with aqueductal stenosis. Classic X-linked recessive hydrocephalus, known as Bickers–Adams disease, or hereditary stenosis of the aqueduct of Sylvius (HSAS), has been mapped to chromosome Xq28 by linkage analysis (Willems et al., 1990). X-linked hydrocephalus is the most common of the inheritance patterns. In a fetus identified with hydrocephalus, a complete family history is essential. It is important to note that males affected with X-linked HSAS may be normocephalic and nondysmorphic, but they will have mental retardation (Kelley et al., 1988). Families with autosomal recessively inherited hydrocephalus have been described, but in general, consanguinity is also present (Zlotogora et al., 1994). Rare families with apparently dominantly inherited hydrocephalus have also been reported in the literature (Ferlini et al., 1995; Verhagen et al., 1998).

X-linked hydrocephalus comprises approximately 5% of all cases of hydrocephalus (Schrander-Stumpel and Fryns, 1998). These conditions are collectively known as L1 disease, and include HSAS (hydrocephalus due to aqueductal stenosis, mental retardation, clasped thumbs, and spastic paraparesis), MASA (mental retardation, aphasia, shuffling gate, and adducted thumbs), X-linked agenesis of the corpus callosum, and spastic paraparesis type 1 (SPG1) (Weller and Gärtner, 2001). MASA syndrome and SPG1 present with milder symptoms and have a longer life expectancy than HSAS. These four conditions are all caused by heterogeneous mutations in the gene encoding the neural cell adhesion molecule L1. L1 is involved in intracellular recognition and neuronal migration in the CNS (Jouet et al., 1995). A wide variation is observed in patients belonging to the same family, as well as in patients from different families.

L1 is a member of the immunoglobulin superfamily. Jouet et al. (1995) reviewed the 23 mutations described by that time in the L1 gene. Three mutations had been identified that affect different fibronectin domains and are critical for L1 function in brain development. More recently, over 140 different pathogenic mutations have been described in L1 (Finckh and Gal, 2000; Weller and Gärtner, 2001). Thus, heterogeneous mutations in the L1 gene form a clinical spectrum of disorders that can be recognized both prenatally and postnatally (Takechi et al., 1996). In one study, *L1CAM* mutations were identified in 22% (15/67) of cases of suspected L1 disease without a family history (Finckh and Gal, 2000). Therefore DNA testing is recommended for all affected male fetuses independent of family history. Families who have a history that suggests the presence of an X-linked disorder should have DNA collected to try to prospectively identify L1 gene mutations.

A family history should alert the health care provider to the potential presence of an X-linked disorder in the family. For families with no other family history and negative *L1CAM* mutation testing, the recurrence rate of hydrocephalus is 4%. This figure was ascertained from a prospective study performed of 251 pregnancies with couples with at least one

previous child with hydrocephalus (Váradi et al., 1988). Of 261 pregnancies, 15 had fetal CNS malformations including 12 cases of hydrocephalus and 3 cases of isolated neural tube defects.

Families in whom no genetic etiology can be identified should be offered detailed prenatal sonographic evaluation in a subsequent pregnancy due to the recurrence risk of 4%.

17 CHAPTER

Intracranial Hemorrhage

Key Points

- Fetal intracranial hemorrhage is generally diagnosed in the late second trimester as an asymmetric echogenic mass within the ventricles, mostly associated with some degree of ventriculomegaly.
- Causes to be considered include drug use (warfarin, cocaine), alloimmune thrombocytopenia, coagulation disorders, or trauma.
- Grading of severity uses a similar scale to that for neonatal intraventricular hemorrhage (IVH), with prognosis being quite poor for most cases of Grades III or IV IVH.
- The only specific treatment relates to situations in which the underlying cause is alloimmune thrombocytopenia, where aggressive therapy with IVIG and steroids in subsequent pregnancies may minimize recurrence.

CONDITION

Fetal intracranial hemorrhage refers to bleeding that occurs antenatally from a blood vessel into the ventricles, subdural space, or parenchyma of the brain. Whereas neonatal hemorrhage is a relatively common occurrence, affecting 40% to 60% of infants delivered before 32 weeks of gestation, fetal intracranial hemorrhage is quite rare. Factors that may place the fetus at risk for intracranial hemorrhage include alterations in maternal blood pressure, a maternal seizure disorder, placental abruption, specific medication or substance exposure (such as warfarin or cocaine), severe abdominal trauma, hereditary coagulation disorders (Komlósi et al., 2005) or alloimmune platelet disorders (Kuhn et al., 1992; Sherer et al., 1998; Lynch et al., 2002). Coagulation disorders associated with fetal intracranial hemorrhage incude factor V Leiden (Komlósi et al., 2005), Factor X mutations (Herrmann et al., 2005), prothrombin G20210A mutation, protein C or S deficiency, antithrombin III deficiency, and antiphospholipid antibody syndrome (Lynch et al., 2002).

Three types of intracranial hemorrhages can occur: intraventricular (or periventricular), intraparenchymal, and subdural. Intraventricular or periventricular hemorrhages are the most common, emanating from small vessels within the subependymal germinal matrix before 33 weeks of gestation (McGahan et al., 1984). The pathogenesis of intraventricular hemorrhage (IVH) is related to fragility of the capillary bed of germinal matrix, a disproportionate amount of total cerebral blood flow to the periventricular area, and the lack of autoregulation of cerebral blood flow in the fetus or premature infant. IVH is the most common form of intracranial hemorrhage seen in the neonate and is categorized in severity on a four-point scale, with the most severe fourth grade including parenchymal involvement (Lynch et al., 2002).

Intraparenchymal hemorrhages may be identified as distinct echogenic areas within the cerebral tissue, with or without displacement of the underlying ventricular or outer surfaces of the brain. As these hemorrhages evolve, they become hypoechoic and flattened as the hematoma liquefies. Residual changes may include development of a

porencephalic cyst (see Chapter 21) or ventricular enlargement. Clots in the ventricular system are seen as bright echogenic areas that are similar to choroid plexus.

Subdural hematoma generally presents as fetal macrocephaly, with separation of the skull from the cerebral cortex. Hyperechoic and hypoechoic areas are identified, filling the space between the brain gyri and the skull. The presence of cerebral edema may cause acoustic enhancement of brain gyri. Catanzarite et al. (1995) have reported on the diagnosis of fetal subdural hemorrhage. They recommended imaging the fetal head in the axial or coronal plane at one level of the sylvian fissure. Normally the separation between the cortex and the inner table of the skull is less than 4 mm. Subdural bleeding can be seen as a collection of echodense material outlining the cortex and separating the sylvian fissure from the inner table of the skull. An additional report on fetal subdural hematoma came from Rottmensch et al. (1991), who identified enhanced echogenicity of the sulci as an indication of brain edema. These authors stated that brain function cannot be predicted sonographically except in the most severe cases.

In a retrospective study of pregnant women in whom a diagnosis of fetal intracranial hemorrhage was made, Achiron et al. (1993) identified five fetuses between 26 and 36 weeks of gestation at the time of diagnosis. Hyperechoic lesions were shown in the brain parenchyma and lateral ventricles in three of five fetuses. Transvaginal sonography permitted the enhanced visualization of ventriculomegaly in one fetus and periventricular leukomalacia in the second fetus. Of the five fetuses studied, two growth-restricted fetuses died after birth, and of the three survivors, two had normal long-term development. One infant developed hydrocephalus, suffered from neurodevelopmental retardation and eventually died at age 7 months (Achiron et al., 1993). In another series, Vergani et al. (1996) described their experience with six cases diagnosed at the University of Milan and 35 cases identified from the English literature. Of the 41 cases of fetal intracranial hemorrhage reviewed, 20 had isolated IVH, 13 had parenchymal hemorrhage, and eight had subdural or subarachnoid hemorrhage. These investigators devised a prognostic scoring system for IVH. A favorable outcome was seen in 50% (6 of 12) fetuses observed with Grade II IVH, but none of the fetuses with the equivalent of a Grade III IVH (blood filling the ventricles) had a favorable outcome.

INCIDENCE

In one study performed at a single institution, the University of Milan, six cases of antenatal intracranial hemorrhage were detected in 6651 fetuses studied. This suggests an incidence of almost one per 1000 fetuses (Vergani et al., 1996). An unusually high incidence of fetal subdural intracranial hemorrhage has been documented in Pacific Islanders who emigrate to New Zealand (Becroft and Gunn, 1989). The cause for this high incidence is unknown, but it suspected to be due to traditional forms of abdominal massage used to change fetal position in utero.

In one study, Sims et al. (1985) reviewed the clinical features and neuropathology of intracranial hemorrhage in 433 consecutive stillbirth autopsies. The authors identified 25 cases of periventricular or intraventricular hemorrhage or gliosis. Of the 25 cases, 10 had IVH alone, 5 had IVH plus an additional intraparenchymal hemorrhage, 5 had parenchymal hemorrhage only, and 5 had gliosis, indicating a remote neurologic injury. Other studies have shown that IVH is present in 6% of stillbirths at autopsy (Minkoff et al., 1985).

Immune thrombocytopenic purpura is the most common autoimmune disorder affecting pregnant women, with an incidence of 1 in 1000 to 1 in 10,000 pregnancies. Fewer than 1% of these women will have babies in whom an intracranial hemorrhage develops. In contrast, severe fetal thrombocytopenia commonly occurs with alloimmune thrombocytopenia, which develops as a result of maternal sensitization to fetal platelet antigens. This occurs in 1 in 2000 to 1 in 5000 pregnancies. Of these cases, approximately 10% to 30% are at risk for intracranial hemorrhage (Johnson et al., 1997; Bussel et al., 1988). This makes alloimmune thrombocytopenia the most common cause of severe thrombocytopenia in fetuses, and the most frequent cause of intracranial hemorrhage in term neonates (Bussel et al., 2005; Berkowitz et al., 2007).

SONOGRAPHIC FINDINGS

Sonographic diagnosis of fetal intracranial hemorrhage was first reported in 1982 in a woman with recurrent episodes of pancreatitis and a fetal death at 29 weeks of gestation (Kim and Elyaderani, 1982). Subsequently, the majority of reported antenatally detected cases of intracranial hemorrhage have occurred during the late second and third trimesters (Catanzarite et al., 1995; Elchalal et al., 2005).

Intracranial hemorrhage is identified as an echogenic area within the ventricles or brain parenchyma. Blood clots are usually echogenic (Figures 17-1 and 17-2) and evolve to characteristic echolucent cystic areas. The sonographic criteria for an intracranial hemorrhage include the presence of an echogenic mass, unilateral or bilateral ventriculomegaly with the presence of intraventricular echogenic foci, germinal matrix, echogenicity, or the presence of periventricular hypoechoic lesions (cysts). In approximately 50% of cases of IVH, sonographic findings will be bilateral (Elchalal et al., 2005).

The commonly used IVH classification system in neonatal imaging has been applied to prenatal sonographic findings, with some modifications (Elchalal et al., 2005). Grade I IVH refers to hemorrhage limited to the subependymal matrix; Grade II refers to no more than 50% filling of the ventricles and lateral ventricular enlargement of no more than 15 mm; Grade III involves more than 50% ventricular filling together with significant ventriculomegaly; Grade IV

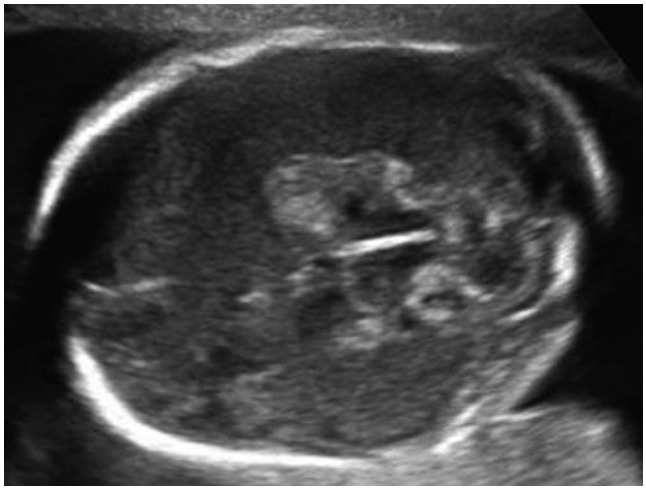

Figure 17-1 Axial sonographic image showing large echogenic area consistent with intracranial hemorrhage.

refers to intraventricular bleeding that also involves the periventricular parenchyma.

DIFFERENTIAL DIAGNOSIS

The major considerations in the differential diagnosis include identifying other potential causes of intraparenchymal or intraventricular masses, as well as identifying potential causes for hemorrhage. It is important to rule out the presence of a prominent choroid plexus. This may present as a densely echogenic mass within the ventricles, mimicking blood clot. The choroid plexus can occupy a large proportion of ventricular space, but this is a normal finding with an expected normal prognosis (Kim and Elyaderani, 1982). Other causes of an echogenic midbrain mass include intracranial neoplasm or infection. A case of malignant glioblastoma multiforme presenting with the appearance of significant intracranial hemorrhage in a 32-week fetus has been reported (Sell et al., 2006).

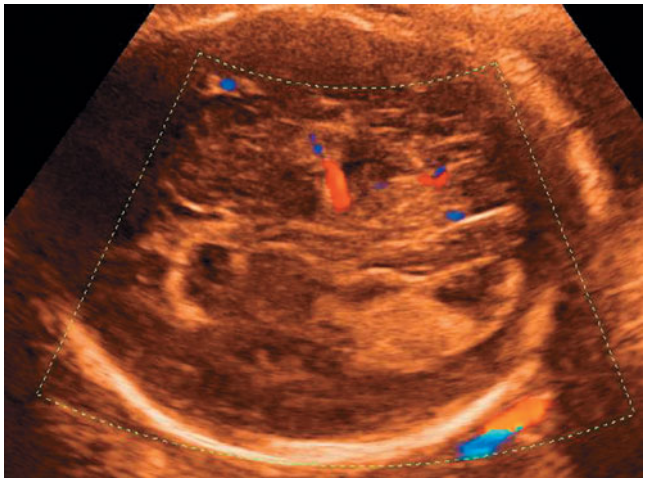

Figure 17-2 Axial sonographic image showing echogenic debris within lateral ventricles consistent with intraventricular hemorrhage.

Considerations in the differential diagnosis of the cause of hemorrhage include coagulation disorders, such as factor V Leiden (Komlósi et al., 2005), Factor X gene mutations (Herrmann et al., 2005), prothrombin G20210A mutation, protein C or S deficiency, antithrombin III deficiency, and antiphospholipid antibody syndrome (Lynch et al., 2002). Fetal thrombocytopenia due to maternal immune thrombocytopenia or maternal platelet antigen incompatibility should also be considered, with the latter being a much more likely cause of significant fetal thrombocytopenia and hemorrhage (Bussel et al., 2005; Berkowitz et al., 2007). Maternal TORCH infection and maternal medication or substance use are also causes of fetal intracranial hemorrhage.

ANTENATAL NATURAL HISTORY

Two main factors are implicated in the pathogenesis of neonatal intracranial hemorrhage, and the same factors are relevant for fetal intracranial hemorrhage: sudden changes in cerebral blood pressure, which cause subependymal hemorrhage in the fragile premature capillary bed of germinal matrix, and perinatal asphyxia, with its attendant hypoxia that tends to induce fluctuations in cerebral blood pressure, resulting in intracranial hemorrhage (Volpe, 1981). The pathogenesis of spontaneous intrauterine subdural hematoma remains less clear. It has been postulated that subdural hematoma may be due to the presence of intermittent aqueductal obstruction, which results in intermittent decompression. This can result in tearing of bridging veins and the development of subdural hematoma (Atluru and Kumar, 1987).

The natural history of intracranial hemorrhage can evolve from bleeding to clot formation to obstruction of spinal fluid drainage, which results in hydrocephalus, or the clot can destroy brain parenchyma and develop into a porencephalic cyst (see Chapter 21).

Porencephaly is defined as a fluid-filled cavity present within the cerebral hemispheres, which may or may not communicate with the spaces that contain cerebrospinal fluid (Eller and Kuller, 1995). A porencephalic cyst results from destruction of cerebral tissues secondary to trauma, infection, or hemorrhage (see Chapter 21). Type 1 porencephaly is a condition that is acquired during the third trimester, due to a destructive process. The area of destroyed cerebral parenchyma is replaced with cerebrospinal fluid. The germinal matrix is especially vulnerable to hypoxia and ischemia between 24 and 32 weeks of gestation due to the sparse supportive stroma, delicate vasculature, and increased metabolic activity of this area (Eller and Kuller, 1995).

Another complication in the evolution of fetal intracranial hemorrhage is hydranencephaly. Hydranencephaly is a congenital abnormality of the central nervous system marked

by absence of cerebral tissue, which can evolve following a subacute intraparenchymal hemorrhage (see Chapter 15). Edmondson et al. (1992) described a circumscribed hyperechoic mass that progressively became more sonolucent with increased fluid accumulation and resulted in loss of identifiable cerebral cortex over the left parietal and occipital lobes. Macrocephaly developed. The infant eventually died on day 4 of life. At autopsy, an organizing hematoma and extensive resorption of the underlying cortex were seen, leaving a fluid-filled cavity with a meningeal covering.

In a series of 33 cases of prenatally diagnosed intracranial hemorrhage, 16 were managed expectantly and 2 of these 16 (12%) resulted in spontaneous intrauterine demise (Elchalal et al., 2005).

MANAGEMENT OF PREGNANCY

The major consideration in the management of pregnancy is to determine the cause of the intracranial hemorrhage. The pregnant patient should be questioned regarding her medical history or the possibility of drug exposure. Maternal conditions associated with fetal intracranial hemorrhage include pancreatitis, preeclampsia, seizures, immune and alloimmune thrombocytopenia, and other disorders of coagulation. These include factor V Leiden, prothrombin G20210A mutation, protein C or S deficiency, antithrombin III deficiency, and antiphospholipid antibody syndrome (Lynch et al., 2002). Fetal conditions that have been reported to be associated with intracranial hemorrhage include factors V and X deficiency (Catanzarite et al., 1995). Alterations in maternal blood pressure, such as hypotension or hypertension associated with placental abruption or preeclampsia, can result in fetal intracranial hemorrhage.

An extensive history regarding the possibility of drug exposure should be obtained. For example, maternal exposure to warfarin has been associated with fetal subdural hemorrhage and evolution to hydrocephalus (Robinson et al., 1980; Ville et al., 1993). The pregnant patient who requires anticoagulation should be changed to heparin during pregnancy. In the normal second trimester fetus, vitamin K_2 is 20% of adult levels and vitamin K_1 is undetectable. Even in subtherapeutic doses, warfarin further reduces the bioavailability of vitamin K to the fetus (Ville et al., 1993). Also, maternal cholestasis and ingestion of cholestyramine can lead to vitamin K deficiency (Sadler et al., 1995). Furthermore, ingestion of aspirin has also been shown to result in fetal hemorrhage (Karlowicz and White, 1993). Salicylate competes with vitamin K at prosthetic group sites on enzymes that synthesize coagulant proteins. Cocaine has also been postulated to be important as a cause of fetal intrauterine hemorrhage because cocaine use leads to destructive lesions of the fetal brain, particularly cerebral infarction (Volpe, 1992). In another study, however, although maternal cocaine exposure was shown to lead to placental abruption, investigators did not find an association between prenatal cocaine use and fetal or neonatal intracranial hemorrhage (Dusick et al., 1993). Fetal trauma, such as in the traditional Polynesian maternal massage, can result in fetal subdural hemorrhage (Gunn et al., 1988).

The presence of a maternal seizure disorder can predispose to fetal intracranial hemorrhage. Neonates exposed to anticonvulsants in utero can have coagulation defects. Fetal anoxia that occurs during a maternal seizure may lead to redistribution of blood flow to the brain and to arterial hypertension (Minkoff et al., 1985). These authors recommended that the fetus of a patient with a seizure disorder who has seizures during pregnancy should be evaluated after the seizure for the presence of intracranial hemorrhage.

The fetus identified antenatally with an intracranial hemorrhage may have abnormal fetal heart rate patterns (Catanzarite et al., 1995), a nonreactive nonstress test, fetal tachycardia, or a positive oxytocin challenge test related to fetal anemia. No relationship, however, has been demonstrated between the umbilical and cerebral artery pulsatility index and severe intracranial hemorrhage (Scherjon et al., 1993).

Repeated sonography is indicated to monitor the evolution of the bleeding, to monitor for the development of hydrocephalus, porencephaly or hydranencephaly. Serial middle cerebral artery Doppler evaluation to check for significant fetal anemia is also recommended. Depending on the cause of the hemorrhage, the fetus may require transfusion with red cells, platelets, and intravenous γ-globulin (in the case of alloimmune thrombocytopenia). Some investigators have suggested daily nonstress tests and contraction stress tests, daily biophysical profiles, and weekly sonography until there is evidence of fetal lung maturity (Pretorius et al., 1986)

Aggressive antenatal management may be indicated for fetuses with alloimmune thrombocytopenia (AIT). Murphy and Bussel (2006) have suggested a regimen of intravenous γ-globulin (IVIG) with or without prednisolone from 20 weeks' gestation onward for patients with AIT at risk for fetal intracranial hemorrhage. Response to therapy can be guided by percutaneous cordocentesis and direct fetal platelet quantification (see Chapter 4). Patients can be categorized as high risk, in which a previous pregnancy has been complicated by fetal intracranial hemorrhage, or standard risk, in which AIT has been diagnosed but without an index case of intracranial hemorrhage. High-risk patients will likely do better with a more aggressive approach of IVIG combined with prednisolone from the second trimester onward, and with further treatment guided by fetal blood sampling. Such further treatment may also include serial fetal platelet transfusions in nonresponding cases. Standard-risk patients may be able to avoid fetal blood sampling, with its inherent morbidity, and may be managed with IVIG alone (Murphy and Bussel, 2006; Berkowitz et al., 2007). The rationale behind the efficacy of maternal IVIG administration is that it may either reduce maternal antibody production or transport across the placenta, or may delay the destruction of antibody-coated platelets in the fetal reticuloendothelial system.

The serologic diagnosis of AIT can be made by satisfying three requirements: demonstration of a platelet antigen incompatibility between the parents, demonstration of a

platelet antibody in maternal serum that binds paternal but not maternal platelets, and identification of an antibody as specific for platelet antigen incompatibility. When a prior sibling has had an antenatal intracranial hemorrhage due to AIT, the clinical manifestations are the same or worse in subsequent fetuses who carry the same antigen (Bussel et al., 1997; Murphy and Bussel, 2006). To prevent antenatal intracranial hemorrhage, treatment must be initiated as early as possible in the subsequent pregnancy.

Following the diagnosis of fetal intracranial hemorrhage it may also be useful to perform fetal MRI examination of the cranial anatomy. In certain cases, in which prenatal ultrasound examination has suggested a Grade II or Grade III IVH, fetal MRI may reveal additional information useful for predicting neurological prognosis (Elchalal et al., 2005).

We recommend that the fetus with an intracranial hemorrhage be delivered at a tertiary care center capable of resuscitation of the newborn infant. Cesarean delivery should be considered for fetuses known to have AIT (Burrows et al., 1988).

Aggressive management may or may not be indicated in the case of fetal subdural hematoma. In one report, a fetus with subdural hematoma was detected in utero at 32 weeks of gestation by the presence of multiple blood clots in the subdural space with secondary compression of brain tissue. Cordocentesis detected anemia in the fetus, who was treated aggressively with transfusion of packed red cells and platelets. Following transfusion, the nonstress test and biophysical profile improved, but delivery was delayed to reduce anticipated complications of prematurity. Nine days later, a second episode of intracerebral bleeding occurred, prompting delivery by emergency cesarean section. Despite the aggressive treatment, the infant died at 6 hours of age (Rottmensch et al., 1991).

FETAL INTERVENTION

No specific intervention is indicated for the fetus other than transfusion of intravenous γ-globulin and/or platelets in cases of AIT.

TREATMENT OF THE NEWBORN

Specific attention should be paid to evidence of increased intracranial pressure, by measurement of the head circumference and palpation of the sutures and fontanelles. The infant should also be specifically examined for the presence of petechiae or ecchymoses as evidence of coagulopathy. A blood count is indicated to determine whether the infant is anemic. Depending on the cause of the hemorrhage, postnatal transfusion with intravenous γ-globulin, packed red blood cells, or platelets lacking an incompatible antigen or steroid therapy in the case of AIT, may be indicated. A diagnostic work-up for AIT and viral sepsis should also be performed.

Postnatally, cranial anatomy should be assessed by computed tomography (CT) scan or magnetic resonance imaging (MRI). Specific consideration should be given to monitoring for the presence of posthemorrhagic hydrocephalus. Hydrocephalus develops as a consequence of acute obstruction to cerebrospinal fluid flow by a blood clot. If posthemorrhagic hydrocephalus is present, consultation with a neurosurgeon is appropriate.

SURGICAL TREATMENT

If posthemorrhagic hydrocephalus is present, the infant may need the placement of a ventriculoperitoneal shunt to drain cerebrospinal fluid.

LONG-TERM OUTCOME

In their review of 41 antenatally detected cases of intracranial hemorrhage, Vergani et al. (1996) documented that a poor outcome was present in 68% of fetuses. The outcome was directly related to the location and extent of the hemorrhage. A poor outcome was present in seven of eight (88%) fetuses with subdural or subarachnoid hemorrhage. Similarly, a poor outcome was present for 12 of 13 (92%) fetuses with parenchymal hemorrhage. A more favorable prognosis was present for fetuses with IVH, in which 9 of 20 cases (45%) had a poor outcome, but these were all observed in Grade II and III hemorrhages. Therefore, the presence of a Grade I IVH observed antenatally is generally associated with a favorable prognosis. In a series of 33 prenatally diagnosed cases of intracranial hemorrhage of 16 fetuses managed expectantly, a total of 8 neonates had moderate to severe neurological deficit at a mean age of 3 years (Elchalal et al., 2005).

All fetuses with intracranial hemorrhage are at an increased risk for the postnatal development of seizures and cerebral palsy (Scher et al., 1991). Similarly, the potential exists for the prenatal or postnatal development of hydrocephalus and neurodevelopmental delay.

The clinical course for fetuses diagnosed with AIT is more variable. The outcome ranges from benign resolution within 2 to 3 weeks after birth to an occasional fatal hemorrhage (Kuhn et al., 1992).

GENETICS AND RECURRENCE RISK

The genetic causes of intracranial hemorrhage include platelet incompatibility disorders and the hereditary coagulopathies.

Every attempt should be made to diagnose the underlying basis of the hemorrhage, as a number of the coagulopathies that involve protein or factor deficiencies are inherited in an autosomal dominant manner and are expected to have a 50% risk of recurrence. The exceptions are Factor X mutations, which are inherited as autosomal recessive conditions.

Ninety-eight percent of the population of fetuses with AIT are phospholipase A_1 (PLA1)-positive. The transmission of the gene for this platelet antigen is autosomal dominant (Morales and Stroup, 1985). Two percent of the population lacks this platelet antigen. The affected infant is generally diagnosed only after an initial hemorrhagic episode. The chance of recurrence depends on whether the father of the baby is homozygous, meaning that both of his chromosomes carry the gene for the platelet antigen. If the father is a homozygote, there is a 100% chance of having a subsequently affected child. However, if the father is heterozygous there is only a 50% chance that a subsequent child will inherit the chromosome carrying the gene for PLA1 (Kuhn et al., 1992). A review of the medical literature shows an overall 75% chance of having a subsequently affected child, but it is important to remember that the risk is either 50% or 100% for an individual couple.

For many of the inherited coagulopathies or platelet disorders, prenatal diagnosis is available on a DNA basis from chorionic villi or amniotic fluid cells, or by obtaining fetal blood at cordocentesis. Because of the relatively high recurrence risk for these conditions, careful sonographic monitoring in a subsequent pregnancy is indicated to monitor for the potential for fetal intracranial hemorrhage.

Macrocephaly

18

CHAPTER

Key Points

- Macrocephaly is defined as a head circumference greater than three standard deviations (SDs) above the mean for age and sex.
- This disorder is rare, and the exact incidence is unknown.
- The antenatal natural history has not been elucidated.
- During the antepartum period, other causes of macrocephaly should be excluded such as hydrocephalus or intracranial space-occupying lesion.
- The diagnosis of macrocephaly should not alter prenatal care with regard to timing of delivery or mode of delivery.
- Long-term outcome regarding macrocephaly is sparse. The majority of cases appear to do well; however, it appears to be associated with an increased risk for autism. Unilateral macrocephaly seems to be associated with poor outcomes.
- The inheritance pattern of benign macrocephaly is autosomal dominant with incomplete penetrance with a male to female preponderance of 4:1. Differential diagnosis should include consideration of overgrowth syndromes, which may be due to single-gene disorders.

CONDITION

Macrocephaly is defined as a head circumference greater than 3 SD above the mean for age and sex. The terms *macroencephaly* and *megaloencephaly* have been used interchangeably with *macrocephaly*, which indicates an increased brain volume in the absence of hydrocephalus (Gooskens et al., 1988). It may be associated with subdural hematoma, other space-occupying lesions, an unduly thickened skull, or a large brain (Lorber and Priestley, 1981). Normal brains of adults usually weigh less than 1500 g. Weights above this are considered abnormal and macrocephalic. At birth the normal brain weighs approximately 370 g. Almost all cases of macrocephaly represent normal variants with a normal large brain (Lorber and Priestley, 1981).

The most common variety of this condition is benign familial macrocephaly, accounting for at least 50% of cases. It is usually associated with an autosomal dominant pattern of inheritance (DeMeyer, 1972). There is a male to female preponderance of 4:1 (Lorber and Priestley, 1981). Isolated sporadic macrocephaly without evidence of a familial disorder is less common (DeMeyer, 1972; Pettit et al., 1980). Macrocephaly may also be associated with generalized disorders of overgrowth, such as cerebral gigantism (Sotos syndrome),

Figure 18-1 Nine-year-old boy who exhibits macrocephaly as part of an overgrowth syndrome. His head circumference is 4 SD above the mean. (*Photograph courtesy of Dr. Patricia Wheeler.*)

Beckwith–Wiedemann syndrome, Weaver syndrome, and achondroplasia (Ott and Robinson, 1969; Dodge et al., 1983) (see Chapter 124) (Figure 18-1).

Several neurocutaneous disorders are associated with macrocephaly. It is seen most consistently with multiple hemangiomatosis syndrome (Riley and Smith, 1960) and Bannayan–Riley–Ruvalcaba syndrome (Gorlin et al., 1992). Hypotonia associated with gross motor and developmental delay is also common (DiLiberti, 1992). In one series of 14 children with hypotonia and macrocephaly, 13 demonstrated evidence of lipid storage myopathy on muscle biopsy (DiLiberti, 1992). All 13 children had clinical examinations consistent with either benign familial macrocephaly or the Bannayan–Riley–Ruvalcaba syndrome. Although macrocephaly is generally a benign condition, in several series it has been associated with intellectual impairment. A syndrome of X-linked mental retardation associated with macrocephaly, coarse facies, hypertelorism, and macro-orchidism has been reported (Atkin et al., 1985). The affected males were moderately intellectually impaired, and there was some expression in heterozygotes. In another report, three sisters with moderate to severe intellectual impairment together with macrocephaly and distinctive facies were described, and it was suggested that this was either a dominant condition or the heterozygous expression of an X-linked entity (Fryns et al., 1988). In a subsequent report, a family with X-linked mental retardation was described in which the affected members had macrocephaly with heterozygous expression (Turner et al., 1994).

Unilateral macrocephaly is an unusual variant of macrocephaly, in which there is enlargement of only one cerebral hemisphere. It is due to abnormal neuronal cell migration in utero. It is usually associated with severe seizures during the neonatal period. The term *macrocephaly* is rather simplistic in such cases, as the anomaly is more typical of a hamartomatous malformation than a simple hypertrophy (Bignami et al., 1968; Townsend et al., 1975). Unilateral macrocephaly seems to be equally distributed between the right and left sides (King et al., 1985; Robain et al., 1988).

INCIDENCE

Macrocephaly is an unusual prenatal finding with an unknown incidence.

SONOGRAPHIC FINDINGS

Macrocephaly should be suspected in the presence of abnormally large head measurements (greater than 3 SD above the mean for gestational age), without evidence of hydrocephalus or intracranial masses. Sonography should confirm the absence of other fetal anomalies, particularly hydrocephalus, by the identification of a normal fetal lateral ventricle:hemisphere ratio. Magnetic resonance imaging (MRI) can be used as an adjunct to determine if the macrocephaly is isolated or complicated by other brain malformations (Parazzini et al., 2005).

Benign familial macrocephaly has rarely been diagnosed in utero. In one case report, the abnormally large head circumference was first noted at 32 weeks' gestation, at which time the biparietal diameter was consistent with a gestational age of 39 weeks (DeRosa et al., 1989). As the pregnancy progressed, the head size increased proportionately with other fetal biometric parameters.

Sonographic findings in unilateral macrocephaly include enlargement of one cerebral hemisphere, a shift of the midline structures, and mild ipsilateral ventriculomegaly (Sandri et al., 1991; Ramirez et al., 1994).

DIFFERENTIAL DIAGNOSIS

A family history and physical examination of the parents, including measurement of their head circumferences, may be helpful when the diagnosis of macrocephaly is considered

(DeRosa et al., 1989). Hydrocephalus, intracranial hemorrhage, and other intracranial masses (such as an intracranial tumor or vein of Galen aneurysm) should all be considered in the differential diagnosis. Syndromes associated with macrocephaly include Beckwith–Wiedemann syndrome, Gorlin syndrome (basal-cell-nevus syndrome), FG syndrome, Weaver syndrome, Sotos syndrome, and Bannayan–Riley–Ruvalcaba syndrome. Porencephaly, intracranial tumors, and other conditions associated with a shift of the midline echo should also be considered in the differential diagnosis of unilateral macrocephaly.

ANTENATAL NATURAL HISTORY

Little information is available for counseling the patient on the natural history of prenatally diagnosed macrocephaly. Counseling will depend on the etiology of the macrocephaly.

MANAGEMENT OF PREGNANCY

If the diagnosis of macrocephaly is suspected prenatally, a detailed sonographic examination is indicated to rule out other conditions associated with an enlarged fetal head, such as hydrocephalus or intracranial space-occupying lesions (Table 18-1). If no other abnormalities are identified, and no additional risk factors are present, there does not seem to be an indication for amniocentesis. A family history should be obtained, and a physical examination of the parents, including measurement of their head circumferences, should be performed to search for possible genetic syndromes associated with macrocephaly (DeRosa et al., 1989). Serial sonography is recommended to confirm the diagnosis and exclude other conditions that may become apparent later in gestation, such as short-limb skeletal dysplasias or hydrocephalus.

In one of the few case reports of prenatally diagnosed macrocephaly, a normal spontaneous vaginal delivery occurred in a patient with a maternal height of 4 ft 11 in and a weight of 211 lb (DeRosa et al., 1989). With regard to management of delivery, there does not seem to be a significant risk of macrosomia associated with the diagnosis of macrocephaly. In a series of 109 cases of macrocephaly, the mean birth weight in 95 full-term infants was normal (3462 g) (Lorber and Priestley, 1981). Only 13 children had birth weights above the 90th percentile (Lorber and Priestley, 1981). Head circumference at birth in 51 infants ranged from 32 to 40.5 cm, with a mean of 36.2 cm, as compared with a normal mean of 34.6 cm (Lorber and Priestley, 1981). A diagnosis of macrocephaly should not change the timing of delivery, and there is no indication for routine cesarean delivery unless other standard obstetric indications exist. It is not necessary for delivery to occur in a tertiary care setting.

Table 18-1

Conditions Associated with Macrocephaly

Benign familial macrocephaly
Sporadic macrocephaly
Neurofibromatosis
Cerebral gigantism (Sotos syndrome)
Achondroplasia
Osteogenesis imperfecta
Beckwith–Wiedemann syndrome
Neurocutaneous syndromes
Bannayan–Riley–Ruvalcaba syndrome
Weaver syndrome
Unilateral macrocephaly

FETAL INTERVENTION

No fetal intervention has been described for macrocephaly.

TREATMENT OF THE NEWBORN

Most cases of isolated macrocephaly do not give rise to difficulty in the delivery room. The clinical presentation varies from no apparent neurologic deficit in the majority of cases to severe seizures and mental retardation. It is interesting to note that idiopathic macrocephaly has been linked to an increased risk for autism (Bolton et al., 2001; Dementieva et al., 2005).

A thorough physical examination should be performed to search for phenotypic features of any of the genetic syndromes associated with macrocephaly. Measurement of the head circumference in children is a standard and essential part of the newborn clinical examination. Composite charts for head circumference from birth to 18 years are available, and a single head circumference measurement outside the range of normal should lead to further evaluation of the child (Nellhaus, 1968).

Other causes of macrocephaly, such as hydrocephalus, subdural hematoma, intracranial tumor, or other space-occupying lesions, must be ruled out as soon as possible.

Macrocephaly should be considered a diagnosis of exclusion following thorough clinical examination and imaging of the head. Cranial ultrasound examination is usually the first line for imaging of the neonatal head. Postnatal computed tomographic (CT) scanning or MRI is the more usual examination in older infants and children since the anterior fontanelle may not provide an adequate ultrasound scanning window. In some cases of autosomal dominant macrocephaly, histochemical examination of skeletal muscle biopsies for lipid storage myopathy may be useful in resolving clinical ambiguities (DiLiberti, 1992).

The clinical presentation of unilateral megaloencephaly is characterized by severe seizures in early infancy. Cranial asymmetry may be overlooked in the newborn if the skull is not examined carefully. CT imaging in such cases demonstrates enlargement of the hemisphere and displacement of the ventricles and the falx. MRI may be helpful in the radiologic evaluation of unilateral macrocephaly (Kalifa et al., 1987).

SURGICAL TREATMENT

No surgical treatment is required for benign, isolated macrocephaly.

LONG-TERM OUTCOME

The long-term prognosis for macrocephaly is not well known and depends on the etiology of the disorder. In a follow-up study of 109 children with macrocephaly, the rate of head growth was noted to be above normal in 80% of children during the first 4 months of life, and in a further 12% at 1 to 2 years of age (Lorber and Priestley, 1981). The majority of these children were neurologically normal. Ninety-six children were judged to be of normal intelligence, and of the remaining 13 children, 6 were judged to be in the normal-to-below average range. Seven children had significant intellectual impairment; 6 of these 7 children had normal CT examinations. Persistent muscular hypotonia was noted in 5 children, and 2 had seizures (Lorber and Priestley, 1981).

Nonetheless, it is interesting to note that macrocephaly appears to be associated with an increased risk for autism, and that macrocephaly is one of the most consistent physical findings in people with autism. In a case–control study of a cohort of boys born with macrocephaly, infantile macrocephaly was associated with an increased risk for autism (odds ratio 5.44, 95% CI 1.11–52.15; $p = 0.03$) (Bolton et al., 2001). Abnormal acceleration of head growth may be one of the reasons why these individuals are at risk for autism (Dementieva et al., 2005).

The prognosis for unilateral macrocephaly seems to be universally poor. In the reviews of this condition 8 of 16 children had died by 6 months of life and 7 more had died before 5 years of age (King et al., 1985; Robain et al., 1988). The remaining infant was 11 months of age at the time of reporting. In another series, all five children with unilateral macrocephaly were still alive at ages up to 9 years (Kalifa et al., 1987). The reason for better survival in this series may be improvements in anticonvulsant therapy.

GENETICS AND RECURRENCE RISK

The inheritance pattern of benign macrocephaly is autosomal dominant with incomplete penetrance (Asch and Myers, 1976; Lorber and Priestley, 1981; Cole and Hughes, 1991).

The high male:female ratio is puzzling for a condition with a well-defined autosomal dominant mode of inheritance. It is possible that boys are more likely to be referred for evaluation of hypotonia or weakness than girls (DiLiberti, 1992), but this is an unlikely explanation for the entire sex-ratio discordance. The recurrence risk for other causes of macrocephaly depends on the underlying syndrome diagnosed. Several of the conditions associated with generalized overgrowth, such as Sotos syndrome and Bannayan–Riley–Ruvalcaba syndrome, are due to known mutations in specific genes (*NSD1* and *PTEN*, respectively).

19 CHAPTER Myelomeningocele

Key Points

- Open spinal cord defect that protrudes dorsally, is not covered by skin, and is associated with spinal-nerve paralysis.
- Current prevalence in the United States is still 0.5 to 1 case per 1000 pregnancies.
- Maternal risk factors include obesity, anticonvulsant medication, short interpregnancy interval, and genetic polymorphisms in various enzymes in the homocysteine methylation pathway.
- Sonographic findings include a small biparietal diameter, scalloping of the frontal bones, a compressed cerebellum, lateral ventriculomegaly, Chiari II abnormalities, splaying of dorsal vertebrae, and a dorsal sac.
- Karyotype should be performed, even in isolated neural tube defects.
- A prospective clinical trial comparing outcomes for open fetal surgery compared to standard postnatal surgery is in progress.
- Long-term outcome depends on the level of the spinal defect and the presence of associated anomalies.
- Morbidity has been significantly improved by interventricular shunting for hydrocephalus and clean intermittent bladder catheterization to reduce renal complications.
- Most neural tube defects are isolated and have a multifactorial inheritance pattern.

CONDITION

Myelomeningocele is an open spinal cord defect that protrudes dorsally, is not covered by skin, and is usually associated with spinal nerve paralysis. Technically, *spina bifida* refers to a cleft or opening in the vertebral body; this term is also used to collectively describe a group of disorders that involve the spinal cord. Lumbosacral lipomas are subcutaneous masses of fat in the lumbosacral region (Shurtleff and Lemire, 1995). Myelomeningoceles are malformations that result from

failure of the neural tube to fuse during early embryogenesis, between 25 and 28 days postovulation, when the anterior and posterior neuropores close. Skin-covered defects, such as lipomyelomeningocele, result from abnormalities in secondary neurulation and retrogressive differentiation that occurs between 28 and 56 days postovulation (Shurtleff and Lemire, 1995).

The first medical report of a myelomeningocele was made by a Dutch physician, Nicholas Tulp, who practiced between 1593 and 1674. He described a series of six cases of patients with spina bifida (Tulp, 1716).

"Open" neural tube defects are myelomeningoceles that are not covered by skin. Leakage of α-fetoprotein (AFP) from the cerebrospinal fluid (CSF) into the amniotic fluid results in an increased transport of AFP into the maternal circulation. Screening by maternal serum AFP analysis has resulted in an increased ability to detect these lesions prenatally.

Herniation of the spinal cord probably reduces intraspinal pressure. This allows the hindbrain to become downwardly displaced, resulting in the hindbrain herniation that is part of the Chiari type II malformation, which is seen almost exclusively in patients affected with myelodysplasia. It is characterized by caudal movement of the cerebellar vermis, brainstem, and fourth ventricle. The Chiari type II malformation is responsible for many of the early deaths in patients affected with myelodysplasia. Chiari, a professor of pathology in Prague, wrote two papers in 1891 and 1896 that described four types of pathologic changes occurring in 40 affected patients (Rauzzino and Oakes, 1995). These changes concerned the abnormal position of the cerebellum in relation to the foramen magnum. Arnold, in contrast, published a single case report in 1894 that described a single patient with myelodysplasia and other congenital anomalies (Rauzzino and Oakes, 1995).

INCIDENCE

The incidence and livebirth prevalence of myelomeningocele are correlated strongly with ethnic and geographic factors. The highest frequencies of neural tube defects are found in Great Britain, Ireland, Pakistan, Northern India, Egypt, and Arab countries. The lowest incidences are found in Finland, Japan, and Israel. Even in the United States, a geographic distribution of these defects occurs, with the frequency being the highest in the East and the South, and the lowest in the West (Harmon et al., 1995). There is an increased incidence of neural tube defects in Hispanics, especially if the mother was born in Mexico (Shaw et al., 1994).

The livebirth prevalence of infants with myelomeningocele has changed dramatically since the advent of widespread maternal serum screening for AFP. Before 1980, the livebirth prevalence of infants with neural tube defects was between 1.5 and 4.5 per 1000 livebirths. After 1980, this decreased to 0.74 to 2.5 per 1000 livebirths (Shurtleff and Lemire, 1995). In the United States, the current prevalence of neural tube defects is 0.5 to 1 per 1000 pregnancies (Shaer et al., 2007). The lowest incidence of neural tube defects is in African blacks, who have a livebirth prevalence of 1 per 10,000 (Shurtleff and Lemire, 1995). Because the screening tests detect anencephaly (see Chapter 7) as well as myelomeningocele, and many parents decide to terminate pregnancies affected with the uniformly fatal anencephaly, the incidence of myelomeningocele has increased as a percentage of all cases of neural tube defects (Rieder, 1994).

In a review of factors associated with neural tube defects in the NIH-sponsored Collaborative Perinatal Project that reviewed the pregnancies of 53,000 pregnant women, Myrianthopoulos and Melnick (1987) demonstrated that maternal diabetes mellitus, heart disease, lung disease, and use of diuretics, antihistamines, or sulfonamides were all associated with an increased risk of neural tube defects. In addition, women who had a short interval between the end of the previous pregnancy and the current pregnancy had an increased incidence of neural tube defects.

More recently, it has been shown that maternal use of the anticonvulsants valproic acid and carbamazepine, or the folic acid inhibitor aminopterin, is also associated with neural tube defects. Similarly, a maternal history of prepregnancy obesity or type II diabetes increases the chance of conceiving a child with neural tube defect (Shaw et al., 2000; Watkins et al., 2003). Neural tube defects are also associated with low socioeconomic status, a positive family history, and twinning. In general, females are affected more often than males (Källén et al., 1994).

Maternal polymorphisms or mutations in various enzymes in the homocysteine remethylation pathway confer an increased risk for fetal neural tube defects. The enzyme 5,10-methylenetetrahydrofolate reductase (MTHFR) is important in the production of the circulating form of folic acid. Specific polymorphisms in the gene for MTHFR, such as maternal homozygosity for the 677T allele, or compound heterozygosity for the C677T/A1298C alleles, carry an increased risk (Peadar et al., 2004). Maternal variation in the gene for another enzyme, methionine synthase (MTRR) also carries an increased risk for affected fetuses when present in combination with an MTHFR polymorphism or low B12 levels (van der Linden et al., 2006).

The etiology of myelomeningocele is thought to be multifactorial in most cases; however, women who preconceptually take at least 400 μg of folate a day for 3 months have 70% to 80% reduction in risk of their fetuses having open neural tube defect (Centers for Disease Control and Prevention, 1992). The Center for Disease Control and Prevention estimated that the rates of open neural tube defects, both anencephaly and myelomeningocele, have fallen by 26% in the United States, compared to before 1998 when mandatory folate fortification of cereal grain products began (Matthews et al., 2002; Centers for Disease Control and Prevention, 2004).

SONOGRAPHIC FINDINGS

Prior to the mid-1980s, sonographic diagnosis of myelomeningocele relied on the meticulous scanning of the fetal vertebrae for abnormalities. Using this method, neural tube defects were missed. More recently, the prenatal sonographic diagnosis of myelomeningocele has been enhanced by the recognition of specific brain abnormalities that generally precede detection of the spinal lesion (Blumenfeld et al., 1993) (Table 19-1).

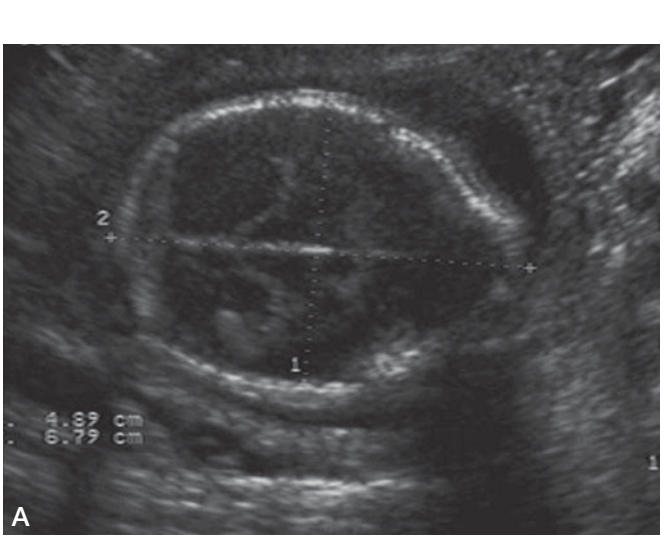
Intracranial Findings

The central nervous system (CNS) abnormalities described in neural tube defects include cerebral ventriculomegaly, microcephaly, abnormalities of the frontal bone, and obliteration of the cisterna magna with an apparently absent cerebellum or an abnormal concavity of the cerebellar hemispheres. These latter abnormalities have been referred to as the "fruit" findings, which include the lemon and the banana signs. The lemon sign (Figure 19-1) describes a concave or flattened frontal contour of the fetal calvarium rather than a normal convex frontal contour. The banana sign (Figure 19-2) describes the posterior convexity of the cerebellum within the posterior cranial fossa (Nicolaides et al., 1986). The lemon sign has been described in 1% of apparently normal fetuses, whereas the banana sign is not found in normal fetuses. The abnormal CNS sonographic findings are a consequence of the Arnold–Chiari malformation. In a prospective analysis, Campbell et al. (1987), who studied 436 fetuses at high risk for spina bifida, identified 26 fetuses with an open neural tube defect. Of the 26, 17 (62%) had a small biparietal diameter for gestational age, 9 (35%) had an abnormally small head circumference, and 100% had a positive lemon sign. In addition, 25 of 26 fetuses (96%) had a cerebellar abnormality. Of these, nine had an absent cerebellum, and 16 had a positive banana sign. Only one fetus in the study with an open neural tube defect had a normal cerebellum. These findings were further defined by Van den Hof et al. (1990), who demonstrated that

Table 19-1

Sonographic Abnormalities in Myelomeningocele

Intracranial Findings
Small biparietal diameter
Small head circumference
Lemon sign—scalloping of frontal bones
Banana sign—compressed cerebellum
Lateral ventriculomegaly
Chiari II abnormalities
Beaking of tectum
Hindbrain herniation—cerebellar vermis through foramen magnum
Elongation and kinking of medulla
Obliteration of cisterna magna
Spinal Findings
Splaying of dorsal vertebral elements
Meningocele sac
Myelomeningocele sac
Presence of placode on surface of sac
Neural elements bridging across the sac



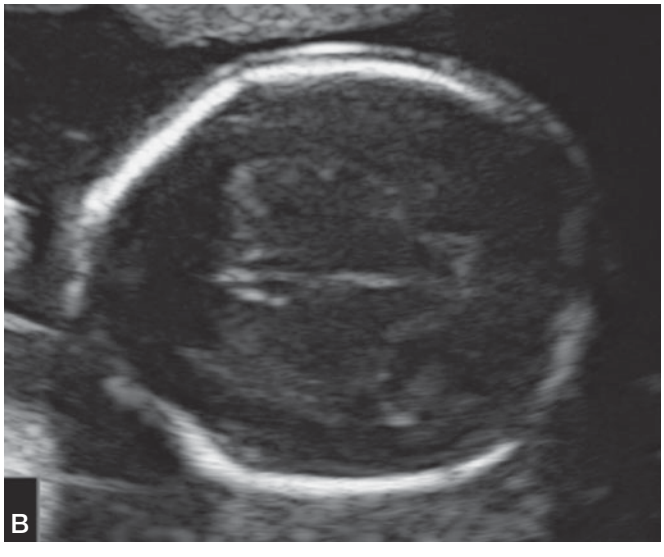


Figure 19-1 **A**. Transverse view of a fetal head demonstrating the "lemon sign" in a fetus with myelomeningocele. **B**. Similar sonographic presentation of an apparent lemon sign. This fetus, however, has craniosynostosis.

Figure 19-2 Suboccipital bregmatic view of a fetal head demonstrating the "banana sign," which derives from anterior curving of the cerebellar hemispheres with simultaneous obliteration of the cisterna magna.

the CNS abnormalities seen in myelomeningocele evolve with gestation. These authors studied 130 fetuses with open spina bifida and demonstrated a relationship between gestational age and the presence of the lemon and banana signs. A lemon sign was present in 98% of fetuses with open spina bifida at ≤24 weeks of gestation, although this finding was seen in only 13% of fetuses at >24 weeks. Cerebellar abnormalities were seen in 95% of fetuses at any stage of gestation, although the banana sign was more typical at <24 weeks, and apparent cerebellar absence was typical of fetuses at >24 weeks. Because the lemon sign is due to decreased intracranial pressure because of caudal herniation of the hindbrain contents, lack of the lemon sign may be due to skull maturation. Alternatively, the cerebroventriculomegaly that is very common in open spina bifida may compensate for the loss of the brain mass. This may displace the skull bones.

More recently, Ball et al. (1993) demonstrated that the lemon sign is not specific for myelomeningocele (Figure 19-1B). In this report of 23 cases of a positive lemon sign, 12 were associated with an open spina bifida, and 6 were seen in cases of encephalocele (see Chapter 12). An additional 5 fetuses did not have a neural tube defect, although they had a variety of other abnormalities, including thanatophoric dysplasia, cystic hygroma, and agenesis of the corpus callosum. An additional CNS finding associated with myelomeningocele was effacement of the cisterna magna, which was seen in 19 of 20 fetuses studied with myelomeningocele (Goldstein et al., 1989). In a review of 234 fetuses with open spina bifida diagnosed at <24 weeks of gestation, Watson et al. (1991) demonstrated that all but two fetuses had at least one of the cranial abnormalities described for affected fetuses. They also questioned whether there was a higher positive predictive value for open spina bifida when more than one sign was observed antenatally. These authors also cautioned that evaluation of motor function in the fetus was not predictive of future neuromuscular status.

A common accompanying intracranial finding in myelomeningocele (MMC) is lateral ventriculomegaly, in which the atrial measurements of the posterior horns exceed 1 cm. In the second trimester, the biparietal diameter and head circumference may be below the 5% for gestational age (Shaer et al., 2007). When MMC is diagnosed between 16 and 24 weeks, microcephaly has been observed in up to 69% of fetuses (Campbell et al., 1987; Thiagarajah et al., 1990). As pregnancy progresses, both biparietal diameter and head circumference tend to normalize in late second trimester. Hydrocephalus, present in 75% of cases, tends to progress slowly during the third trimester (Shaer et al., 2007).

Spinal Findings

As stated in Chapter 88, evaluation of the fetal spine depends on the visualization of the three ossification centers within the fetal vertebra. The centers of the neural arches should be parallel or converging. In the longitudinal plane, the spine should appear like a "railroad track," with gradual widening toward the fetal head and tapering toward the sacrum. However, the distal part of the spine may not be ossified in healthy fetuses at <22 weeks of gestation (Budorick et al., 1995). Spina bifida can be demonstrated in both the coronal and transverse planes. In the coronal plane, widening of the ossification centers in the neural arch interrupts the normal parallel configuration of the vertebral arches (Figure 19-3A). In the transverse plane, ossification centers in the neural arch either diverge or take on a U-shaped configuration (Figure 19-4). The presence of scoliosis or kyphosis is associated with neural tube defects (Figure 19-3B).

Kollias et al. (1992) assessed the sonographic accuracy of the estimation of spinal level involved in the MMC. Of 28 cases studied, sonographic and pathologic levels were in agreement in 18 (64%) and within one spinal level in 22 (79%).

Other sonographic findings that may suggest a MMC include a cystic meningeal sac, which may have a shimmering effect with fetal motion (Figure 19-5) (Budorick et al., 1995). The sonographer should also examine the fetus's lower extremities for the possibility of clubfeet.

With the presence of skin covering the neural tube defect, the lesion is considered to be a closed neural tube defect, such as lipomyelomeningocele, which has a different etiology. Closed neural tube defects are not usually associated with Arnold–Chiari II malformations and they have a much more favorable prognosis (Tortori-Donati et al., 2000; Ramin et al., 2002).

Magnetic Resonance Imaging

The adjunctive use of magnetic resonance imaging (MRI) of the fetus has provided additional and complementary information to ultrasound examination alone (Figure 19-6). The results of at least two studies suggest that fetal MRI is superior to ultrasound examination for prenatal diagnosis of the intracranial abnormalities associated with MMC (Dinh et al., 1990; Levine et al., 1999). In a comparison of sonography and MRI, both were equally accurate in assignment of MMC level

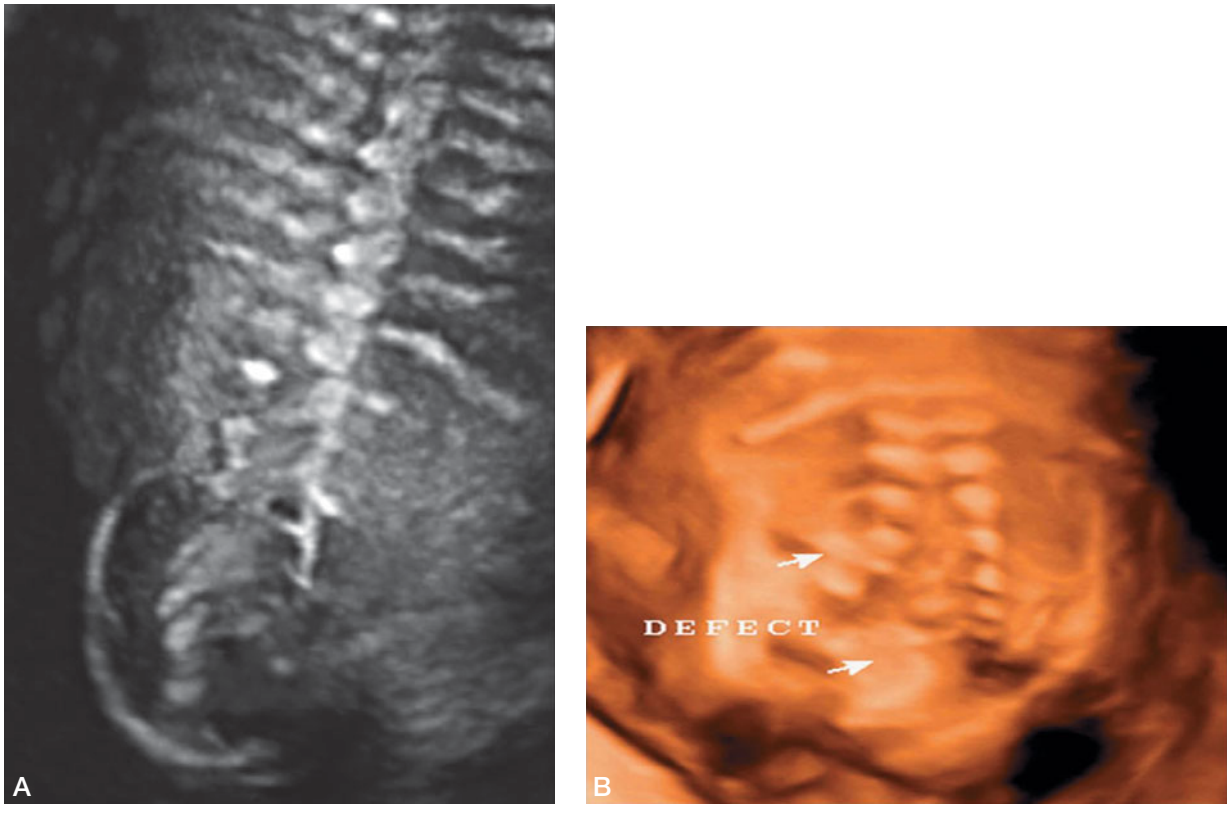

Figure 19-3 **A.** Ultrasound image in coronal plane demonstrating widened ossification centers of the neural arches which interrupt the normal parallel configuration. **B.** Three-dimensional reconstruction demonstrating scoliosis at the level of dysraphic defect.

(Aaronson et al., 2003). MRI may be a particularly helpful adjunct to ultrasound examination when there is a large maternal body habitus, oligohydramnios, low position of fetal head, or posterior position of fetal spine present (Glenn and Barkovich, 2006).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for MMC includes isolated hemivertebrae (see Chapter 88). The lemon sign, as stated earlier, has also been seen in encephalocele (see Chapter 12), thanatophoric dysplasia (see Chapter 90), cystic hygroma (see Chapter 31), and craniosynostosis (see Chapter 10 and Figure 19-1B). The demonstration of a mass near the fetal sacrum should also suggest a possible diagnosis of sacrococcygeal teratoma (see Chapter 115). Sacrococcygeal teratomas are large cystic or solid masses arising from the coccyx. These masses may be associated with fetal hydrops or polyhydramnios. If the fetal sacral bones cannot be visualized, considerations in the differential diagnosis also include the caudal regression syndrome and sirenomelia (see Chapter 87).

ANTENATAL NATURAL HISTORY

With the presence of an open neural tube defect there is increased in utero lethality. For example, at 8 weeks of gestation, one fourth of all conceptuses with neural tube defects will be liveborn, one-fourth will be stillborn, and one half will spontaneously abort (Main and Mennuti, 1986).

Embryology

The formation of the neural tube begins at approximately day 19 with formation of the primitive streak. Epiblasts transform to ectoderm along the dorsal midline of the embryo. This gives rise to the neural plate, which then enfolds to form the neural groove. In the middle of the 4th week, neural folds on each side of the neural groove begin to fuse, thus forming the neural tube (Rieder, 1994). Current evidence suggests that there are two parallel processes that occur. At the level of the fifth somite, where the brain and spinal cord meet, the normal folds join in a zipperlike fashion that proceeds cranially and candally (Shaer et al., 2007). A second closure site appears in the forebrain; fusion also occurs at that site in two directions, and meets the zipper process proceeding from the hindbrain. In parallel, the zipper process moves to close the most rostral part of the forebrain. Lack of signaling between the neural tissue and overlying ectoderm and mesoderm may result in the bony defect that overlie the unfused sections of the neural tube (O'Rahily and Muller, 2002).

Open Neural Tube Defects

More than 80% of children with a neural tube defect can be detected by maternal serum AFP screening before birth (Brock and Sutcliffe, 1972). Although the determination of amniotic fluid acetylcholinesterase can be helpful, ultrasound examination is the method of choice for the diagnosis of neural tube defects. Direct visualization of the fetal spine can usually be accomplished by 16 weeks' gestation. Since the 1980s, the sonographic diagnosis of MMC has been enhanced by the introduction of high-resolution imaging tools and by recognition of specific brain abnormalities (Blumenfeld et al., 1993). First described by Arnold and Chiari at the end of the 19th century (Arnold, 1894; Chiari, 1895), the *Arnold–Chiari II malformation* is defined as the maldevelopment of a small posterior fossa and the herniation of the cerebellar vermis and brainstem (including the fourth ventricle) through an enlarged foramen magnum. Additionally, agenesis of the corpus callosum, enlargement of the massa intermedia, cortical heterotopia, and polymicrogyria can be seen. The origin of the Arnold–Chiari II malformation remains in dispute. The predominant hypothesis maintains that an imbalance of hydrodynamic forces occurs secondary to loss of CSF from the lesion (Padget, 1968; McLone and Knepper, 1989; Paek et al., 2000; Bouchard et al., 2003). An alternative theory interprets the hindbrain herniation as the consequence of a traction injury caused by cranial growth imbalance (Penfield and Coburn, 1938; Lichtenstein, 1942; Hoffman et al., 1975; McLone and Knepper, 1989). Overgrowth of the cerebellum and brainstem, along with a posterior fossa that is smaller than normal, leads to downward dislodgment of these structures, resulting in Arnold–Chiari II malformation (Barry et al., 1957). Despite the controversies about the origin of MMC-associated hindbrain herniation, these lesions are identifiable in the embryo from as early as 8 weeks of gestation and are established in the fetus by the 12th week.

Pathologic studies of human embryos and fetuses with MMC in earlier stages of gestation reveal an open neural tube but undamaged neural tissue with almost normal cytoarchitecture (Patten, 1953). This suggests that neural degeneration occurs at some point later in gestation (the "two-hit" hypothesis) (Ehlers et al., 1992; Hutchins et al., 1996). The first "hit" is the failure of neurulation early in gestation. The second "hit" is the spinal cord injury resulting from prolonged

exposure of the neural tissue to the intrauterine environment. In theory, this secondary event can be prevented if an adequate prenatal covering of the exposed neural tube can be provided. To have the best outcome, this repair must be fashioned before the onset of irreversible neural damage. There are several observations in human embryos, fetuses, and infants to support this premise (Neumann et al., 1994; Meuli et al., 1997).

In a pathologic examination of spinal cords of stillborn human fetuses with MMC (19–25 weeks of gestation), varying degrees of neural tissue loss at the site of the lesion were observed, but the dorsal and ventral horns were normal proximal to the defect (Hutchins et al., 1996). This group was among the first to suggest the two-hit hypothesis because they attributed these alterations to injuries occurring subsequent to the failure of primary neural tube formation. A study of 10 additional fetuses had similar findings (Meuli et al., 1997). Additional support exists for the two-hit hypothesis from in vitro studies. Drewek et al. (1997) reported that damage to open neural tissue appears to be progressive and results from exposure to toxic substances in the amniotic fluid during the third trimester.

Korenromp et al. (1986) observed that fetuses with MMC exhibited leg movement at 16 to 17 weeks. These investigators suggested that the affected fetuses did have good function at that point in gestation. No follow-up could be reported in this series because pregnancies were interrupted. Furthermore, Sival et al. (1997) compared the leg movements of 13 fetuses with MMC prenatally and postnatally. Only one of the 13 had abnormal leg movements before birth, but 11 demonstrated abnormal leg movements postnatally. Two possible explanations for this phenomenon exist. The prenatal leg movements could be secondary to spinal cord reflex rather than of cerebral origin, thus permitting motion without electrical impulses conducted through the damaged spinal cord tissue. In addition, leg movements early in pregnancy could result from cerebral function conducted through an exposed spinal cord that is not yet damaged. However, even extremely experienced sonographers find it difficult to distinguish between spontaneous and reflex-based fetal leg movements (Filly, 1994).

Most newborns with MMC show severe neurologic impairment of the lower extremities at birth, a finding suggesting that the neurologic injury may occur later in gestation or even at the time of delivery. It is remarkable that patients with lipomeningomyelocele (in which the neural tissue is covered and protected by skin) often have almost normal lower leg function and continence, despite a neurulation abnormality that is nearly identical to that present in newborns with open neural tube defects. These studies support direct injury to the protruding spinal cord as the primary cause of damage and loss of function (Hutchins et al., 1996; Meuli et al., 1997). As the pregnancy progresses, the volume of the amniotic fluid decreases, and this may result in more frequent contact of the exposed neural tissue with the uterine wall. Chick models of oligohydramnios, in which pressure necrosis of prominent areas of the body developed, support this hypothesis (Thévenet and Sengel, 1986).

Closed Neural Tube Defects

Clinically, closed neural tube defects should be differentiated from open neural tube defects because the embryogenesis appears to differ in most cases. In open defects, there is an essential failure during the primary neurulation, whereas closed neural tube defects appear to result from another form of disturbance during neural tube formation (McComb, 1996). With few exceptions, the structural malformations of closed neural tube defects are limited to the spinal cord and are not associated with the Arnold–Chiari II malformation or hydrocephalus. In contrast to open defects, newborns with a closed neural tube defect have no exposed neural tissue and do not leak CSF. Additionally, the prognosis of an infant affected by a closed defect is significantly better than one with an open neural tube defect. Generally, children born with closed defects have an intellectual function that is of the same distribution as the normal population, do not require CSF-diverting shunts, and have considerably fewer problems with lower extremity sensorimotor function and with bladder and bowel function (McComb, 1997). Because the clinical manifestations of closed defects can be undetected for days or even years, the origin of this group of neural tube defects is unidentified; no link to genetic, environmental, or dietary factors have been found. The major forms of closed neural tube defect are briefly described in the sections below.

Meningoceles are commonly located in the lumbosacral region in the vertebral arches. These lesions are often covered with skin, and the bony abnormality rarely involves more than two to three vertebrae. The meningocele sac consists of both arachnoid and dural meninges with CSF. Most meningoceles also contain neural elements. Meningoceles are an infrequent and heterogeneous group of cystic lesions. The accurate prevalence of meningocele is subject to debate, because meningoceles are often grouped with MMCs. Furthermore, their pathogenesis remains unknown. The neurologic outcome of affected newborns is normal, but surgical correction and resection of the herniated meninges are indicated (McComb and Chen, 1996).

Lipomatous malformations include all the closed neural-tube defects with excessive lipomatous tissue present within or attached to the spinal cord or filum terminale. These lesions are called lipomyelomeningocele, lipomyelocele, leptomyelolipoma, lumbosacral lipoma, or lipoma of the filum terminale. The origin of lipomatous closed neural tube defects is controversial. Two different theories have been advanced: (1) lipomas arise from cells originating from the somatic mesoderm and (2) lipomatous closed neural tube defects are a true malformation resulting from defective neurulation (Catala, 1997). Most affected infants have a good prognosis with nearly normal leg and urologic function.

Anencephaly and MMC are important contributors to fetal and infant mortality. All newborns affected by

anencephaly are stillborn or die shortly after birth, whereas children born with MMC usually survive. However, the risk of death with neural tube defects varies significantly worldwide, depending not only on the severity of the defect but also on such aspects as availability, use, and acceptance of medical and surgical intervention. For example, in some regions of northern China, nearly 100% (Moore et al., 1997); in the Netherlands, 35% (den Ouden et al., 1996); and in the United States, 10% (Shurtleff et al., 1994) of children affected by neural tube defects die.

MANAGEMENT OF PREGNANCY

MMC may be suspected either by abnormalities in maternal serum AFP screening or an abnormal sonographic examination. Once the MMC is suspected, the patient should be referred to a center capable of thorough anatomic diagnosis of the fetus. Confirmation of the MMC can be made by noting the presence of the cranial abnormalities discussed in the "Sonographic Findings" section. In addition, associated anomalies should be sought. Once the neural tube defect has been definitively identified, the parent should be offered the opportunity to obtain amniotic fluid for fetal karyotype analysis.

In a study of 77 fetuses retrospectively identified with isolated neural tube defects (Harmon et al., 1995), karyotype information was available in 43. The risk for chromosomal abnormalities based on the maternal age of this population was 0.3%. In the study group, however, 7 chromosomal abnormalities were discovered, an incidence of 16.3%. The difference between the expected occurrence of chromosomal abnormalities based on maternal age and the observed incidence of chromosomal abnormalities was highly significant. In the study, two cases of trisomy 18, three cases of triploidy, one case of a balanced Robertsonian translocation, and one Xq inversion were demonstrated. Subsequent studies have confirmed that between 2% and 16% of isolated neural tube defects occur in association with a chromosome abnormality or single-gene defect (Shaer et al., 2007). The most commonly associated aneuploidy in MMC is trisomy 18. We recommend obtaining a fetal karyotype because knowledge of the fetal cytogenetic status affects prognosis, management of the pregnancy, intervention, as well as recurrence risks.

Once the diagnosis of neural tube defect is confirmed, the parents should be offered the opportunity to discuss the long-term prognosis for a child with MMC with pediatric subspecialists. This is best performed in the context of a multidisciplinary team. We recommend that parents meet with a neonatologist, geneticist, pediatric neurologist, pediatric neurosurgeon, pediatric urologist, pediatric orthopedic surgeon, and if available, the physician coordinating the MMC clinic.

Long-term prognosis is related to the location of the MMC. In general, the lower the defect is on the fetus, the better the prognosis. If the diagnosis is made at <24 weeks of gestation, the parents should be offered the opportunity to terminate the pregnancy. Data from the statewide California AFP Screening Program suggest that families will act on information regarding neural tube defects. At <24 weeks of gestation, 80% of pregnant women will terminate the pregnancy when the defect is nonfatal, and 93% will terminate the pregnancy when the defect is fatal, such as anencephaly (Budorick et al., 1995).

If the diagnosis is made at >24 weeks of gestation, or if the parents elect to continue the pregnancy, the risks and benefits of elective cesarean section delivery prior to labor should be discussed. In 1991, Luthy et al. (1991) described their results of performing elective cesarean section without labor on fetuses with neural tube defects. They documented a lower risk of severe paralysis and on average, a motor function that was 3.3 spinal segments better than that expected on the basis of the anatomic level of the lesion when the affected children were 2 years of age. These authors suggested that unsplinted neural tissue and its blood supply were potentially traumatized by intrauterine pressures generated during labor. The study was subsequently criticized because it was not randomized. With additional observations, the most recent recommendations for delivery are the following (Shurtleff and Lemire, 1995): elective cesarean section is indicated when the fetus demonstrates movement of the knees and ankles and a MMC sac is observed protruding dorsally beyond the plane of the infant's back; cesarean section is contraindicated for fetuses with a known chromosomal abnormality, other congenital anomalies that significantly interfere with survival, or the absence of fetal knee or ankle movement; cesarean section has not been shown to be beneficial in primiparous women with a fetus already engaged in the breech position, fetuses with gibbous deformities, and fetuses with hypoplastic spinal cords.

FETAL INTERVENTION

The severity of complications observed in children with MMC prompted interest in the potential of in utero MMC repair to prevent these complications. The rationale for repair in utero is that the open neural tube defect allows exposure of the spinal cord to secondary injury from exposure to amniotic fluid, direct trauma or hydrostatic pressure (Adzick and Walsh, 2003). As described under "Antenatal Natural History," this has been referred to as the "two-hit hypothesis" (Hutchins et al., 1996).

Meuli-Simmen et al. (1995) used the latissimus dorsi muscle flap for fetal MMC repair in seven sheep fetuses with an artificially created lumbar MMC. Three fetuses survived the pregnancy. At term, the sheep survivors had healed cutaneous wounds and normal hind-limb function. These authors concluded that the latissimus dorsi flap is suitable for fetal surgery and provides efficient coverage of the lesion.

As a result of experimental work in animals, it is known that the neurologic deficits associated with open spina bifida

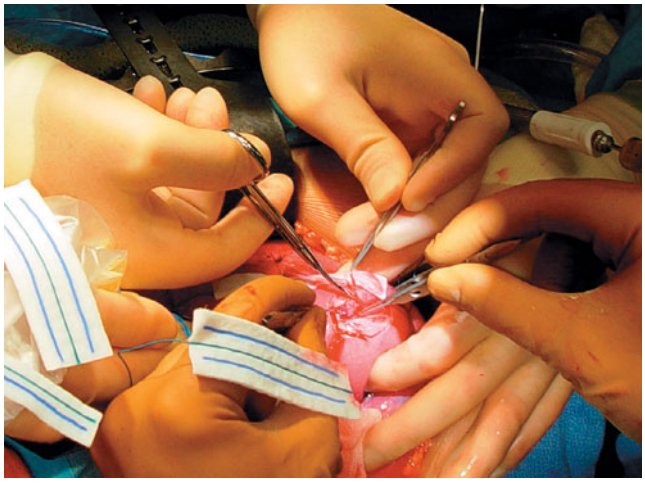

Figure 19-7 Intraoperative view of fetal surgical procedure performed at the Center for Fetal Diagnosis and Treatment at the Children's Hospital of Philadelphia prior to the start of the MOMS trial. The cystic component of the myelomeningocele is just being excised. The next steps in the procedure include closure of the dura to "neurulate" the plaquode and then mobilization of adjacent fascia to cover the repaired myelomeningocele. Lastly, extensive skin flaps are raised circumferentially to allow a skin closure of the top of the fascial closure.

are due partly to chronic mechanical injury and chemical trauma induced by exposure to amniotic fluid. These exposures progressively damage the unprotected fetal neural tissue during gestation. In fetal sheep, in utero repair of neural tube defects restored neurologic function by the time of birth (Meuli et al., 1997).

Fetal surgery to repair MMC is performed by maternal laparotomy and hysterotomy (Figure 19-7). The cystic membrane of the lesion is excised, the dura is closed over the placode and fascial layers are developed and closed over the defect. Lastly, skin flaps are developed laterally to complete closure of the defect (Adzick et al., 1998). Amniotic fluid is replaced with warmed lactated Ringer's solution. After repair, tocolysis was maintained with magnesium sulphate infusion, indomethacin rectal suppositories, and subcutaneous terbutaline.

The first attempt to repair by providing skin coverage for MMC was reported by Bruner et al. in 1997, using a maternal split thin skin graft endoscopically applied (Bruner et al., 1997). One patient died shortly after the surgery and the second patient showed no sign of improvement postnatally. Subsequently, the same group reported four patients who underwent open fetal surgical repair between 28 and 32 weeks' gestation with reversal of hindbrain herniation at birth (Tulipan and Bruner, 1998).

Similarly, the group at Children's Hospital of Philadelphia (CHOP) reported reversal of hindbrain herniation (Adzick et al., 1998). This was subsequently confirmed in a series of 10 patients undergoing MMC closure at 22 to 25 weeks' gestation (Sutton et al., 1999), in which 9 of 10 survived with reversal of hindbrain herniation. Four of the 9 later required ventriculoperitoneal shunting (Adzick and Walsh, 2003). Bruner et al. (1997) showed that 62% of 29 patients had reversal of hindbrain herniation when operated on between 24 and 30 weeks' gestation. Ventriculoperitoneal shunting was required in 17 of 29 (59%), but still compared favorably with historical controls in which 90% required ventriculoperitoneal shunting (Rintoul et al., 2002).

Prior to the start of the Management of Meningomyelocele (MOMS) trial, experience with open fetal surgical repair had been performed at CHOP, Vanderbilt, University of North Carolina, and the University of California at San Francisco, with a combined experience of approximately 160 patients. Findings suggested improved outcomes compared to historical controls. Sutton et al. reported that hindbrain herniation was uniformly reversed in the CHOP experience and only 43% required ventriculoperitoneal compared to an 84% rate observed in 297 historical controls (Sutton et al., 1999; Rintoul et al., 2002). Of note in this series of 50 patients were 3 deaths from preterm delivery at 25 weeks. The average gestational age at delivery was 34 4/7 weeks (Rintoul et al., 2002). While this study suggested a reduced need for ventriculoperitoneal shunting, it should be pointed out that the controls were historical and neurosurgical indications for shunting had become more conservative during this period. In addition, some infants undergoing fetal surgery for MMC merely experienced delayed time for ventriculoperitoneal shunting.

Danzer et al. (2007) have reported that open fetal surgery for MMC alters the fetal head growth. Repaired MMC fetuses have disproportionately small head circumference measurements while the lateral ventricles progressively enlarge (Van den Hof et al., 1990; Babcock et al., 1994; Bannister et al., 1998). In a series of 50 fetuses undergoing open fetal surgery to repair MMC, Danzer et al. (2007) found a significant increase in cortical index (head circumference/lateral ventricular diameter). Early neurodevelopmental evaluations at 2 years of age in the cohort of 51 MMC patients treated by open fetal surgery at CHOP reveal that 67% had cognitive language and personal-social skills in the normal range, 20% had mild delays, and 13% had significant delays (Johnson et al., 2006).

The lower extremity neuromotor evaluation following open fetal surgery for MMC suggests that 58% of patients had a better than predicted lower extremity function compared to infants with postnatally repaired MMC (Danzer et al., 2006; Carr, 2007). In this relatively early follow-up series (39 $\pm$ 15 months) of open fetal surgically repaired MMC, 21 children (52.5%) walked independently, 8 (20%) walked with braces, 7 (15.5%) ambulated with a walker, and 4 (10%) used a wheelchair. This was in contrast to less favorable outcomes in postnatally repaired MMCs in which only 1 child (6%) walked independently, 5 (29%) walked with braces, 10 (58.8%) ambulated with a walker, and 1 (6%) used a wheelchair (follow-up at 41.9 $\pm$ 16.6 months). This early assessment of lower extremity function may be misleading, as many children who had previously been able to ambulate with or without braces or walkers revert to a wheelchair at puberty due to increased weight and size that make ambulation very difficult.

Carr (2007) reported his experience with urodynamic evaluation of 22 patients who underwent fetal surgical repair of MMC at CHOP. In 13 of 22 patients he evaluated voiding spontaneously with 3 of 22 (13.6%) achieving volitional voiding. This compares favorably with expected 2% to 3% volitional voiding in postnatal MMC repair (Carr, 2006). The remainder of the 22 patients had either vesicoureteral reflex (10%), urinary tract infections (33%), or required vesicostomy (5%), or clean intermittent catheterization.

In order to address many of the questions raised by early outcomes of open fetal surgery in MMC, the NIH funded the MOMS trial. This prospective randomized trial will compare outcomes with open fetal surgery performed at 18 to 25 6/7 weeks' gestation with postnatal surgery. As of 2008, the recruitment to the trial has been slow, with only one half of the anticipated 200 patients enrolled. The primary outcome variables for this trial are the need for a ventriculoperitoneal shunt at 1 year of age and fetal or infant mortality. Additional information regarding the MOMS trial can be obtained at the website www.spinabifidamoms.com.

TREATMENT OF THE NEWBORN

The newborn infant with MMC should be handled in as sterile a manner as possible. The spinal lesion should be immediately covered with a nonadherent dressing moistened with warm physiologic Ringer's lactate or normal saline. A firm, protective ring of sterile dressings should be placed around the sac, and the sac itself should be covered with a nonadhesive dressing (Hahn, 1995; Shurtleff and Lemire, 1995). If the infant needs to be intubated, this should be performed in the prone or in the lateral recumbent position if possible. At all times, normothermia must be maintained.

An initial physical examination should be performed by the neonatologist and the pediatric neurologist or neurosurgeon to assess the functional level and the extent of the neurologic deficit (Figure 19-8). The sensory level can be determined by stimulating dermatomes with pinpricks.

Figure 19-8 Appearance of a large thoracolumbar MMC at birth.

The spinal column should be examined for evidence of early scoliosis or kyphosis. Consideration should be given to performing a cranial computed tomographic (CT) and/or MRI scan so that the neurosurgeon can plan the postnatal surgical approach. The parents should be informed that if hydrocephalus is not present antenatally, it may develop after repair of the neural tube defect. Generally, if a shunt is necessary, it is placed before subsequent urologic or orthopedic repair.

The Arnold–Chiari type II malformation is present in 95% of patients with MMC. In 6% of affected patients, central ventilatory dysfunction may be present, as demonstrated by central apnea, stridor, respiratory distress, or aspiration. Bulbar involvement may result in vocal cord paralysis or dysphagia. Unfortunately, approximately half of all newborns with MMC have pneumographic abnormalities or abnormal responses to increasing CO_2 content in inspired air (Petersen et al., 1995). Therefore, standard tests of respiratory function are not useful to predict which infants will become symptomatic because of an Arnold–Chiari malformation.

SURGICAL TREATMENT

The earliest recorded surgical treatment of a child with spina bifida was performed in 1910 (Hahn, 1995). With the development of antibiotics, there was increased interest in treating this condition. It is currently recommended that surgical closure should occur within the first 24 to 72 hours of life to decrease morbidity and mortality as long as the sac is intact.

Exposure of neural tissue to trauma during birth potentially causes a shocklike state to the neural placode. The goals of operative repair include preserving all viable neural tissue, reconstituting a normal anatomic environment, and minimizing the chance of infection or preventing ascending infection of the neural axis (Hahn, 1995). During repair, the neurosurgeon must

1. identify the neural placode, intermediate epithelial layer, and the pia, arachnoid, and dura;
2. preserve neural tissues;
3. reconstitute a normal neural environment with reconstitution of the pia—arachnoidal, dural, fascial, and skin layers;
4. complete skin closure;
5. prevent leakage of CSF (Pang, 1995).

The operative mortality for MMC repair is near 0%. Currently, there is expected to be a 95% or higher survival rate for the first 2 years of life (Hahn, 1995).

Hydrocephalus develops in 80% of cases of MMC. This is often not apparent until the neural tube defect is repaired. It is not uncommon to require a shunt placement within a few days after neural tube defect repair.

Rintoul et al. (2002) performed a retrospective review of 297 patients born with MMC and described the natural history of ventricular shunting in MMC patients in relation to radiologic and functional criteria. Most closures (92%) and shunt placements (62%) were performed in the first week of life. The timing of shunt placement and the number of

shunt revisions were independent of the level of lesion. The incidence of shunting by functional level was 81%, which is consistent within the generally accepted range of 80% to 85% for an unselected spina bifida population (McLone, 1983; Caldarelli et al., 1996). The rate of ventricular shunting is significantly correlated to the anatomic level of the lesion (Rintoul et al., 2002). One hundred percent of the patients with thoracic-level lesions required postnatal shunting, compared with 88% of those with lumbar-level lesions and 68% of those with sacral-level lesions.

LONG-TERM OUTCOME

For those infants affected by MMC, the significant lifelong disabilities accompanying this malformation include paraplegia, hydrocephalus (Rintoul et al., 2002), pulmonary dysfunction (Sherman et al., 1997), sexual dysfunction, skeletal deformations and spinal deformities (Iborra et al., 1999), incontinence, and cognitive impairment (Tsai et al., 2002), with approximately 15% of them requiring some form of custodial care (McLone et al., 1985; McLone, 1998).

The long-term considerations for the infant and child with MMC include neuromuscular and urologic function, as well as prevention of orthopedic abnormalities. To stand erect, motor function is needed to at least the third lumbar level. To walk, the child must exhibit motor function from the fourth to the fifth lumbar level. To function sexually as an adult, a male must have motor function to at least the second to fourth sacral level.

The degree of handicap and survival rate depends on the level of spinal segments, the severity of the lesion, the treatment program, and the associated anomalies (Budorick et al., 1995). The lower the spinal level, the better the prognosis. Prediction of long-term IQ is impossible. Approximately one-fourth of patients have an IQ below 50, one-fourth of patients have an IQ above 100, and 50% of patients have a learning disability (Budorick et al., 1995).

Infants with MMC almost always have evidence of Chiari II malformation on MRI (Ruge et al., 1992). Despite aggressive postnatal intervention, nearly 14% of neonates with spina bifida do not survive past 5 years of age, with the mortality rising to 35% in those with symptoms of brainstem dysfunction secondary to the Chiari II malformation (Rauzzino and Oakes, 1995; Worley et al., 1996). Clinical symptoms include swallowing difficulty, apnea, and stridor. Strabismus, a nonlethal Chiari II complication, is found in as many as 61% of patients with MMC (Biglan, 1995). Furthermore, the hindbrain deformity leads to ventriculomegaly in most cases because of impaired circulation of CSF. Complications of ventriculomegaly probably lead to the impaired cognitive development seen in children with MMC (McLone and Naidich, 1989).

In recent years, there has been an increased appreciation of the long-term consequences of renal failure in adulthood (Zawin and Lebowitz, 1992). Therefore, urologic management is more aggressive and directed toward maintaining normal renal function (Stone, 1995). After the neural tube defect has been closed and a shunt has been placed, urodynamic studies are recommended. If the patient has high pressures due to bladder–sphincter dyssynergia, a voiding cystourethrogram (VCUG) can be performed to rule out vesicoureteric reflux. For many cases, anticholinergics or smooth muscle relaxants are recommended to alter the overreactivity of the abnormal detrusor. This treatment is meant to increase the capacity of the bladder. Prophylactic antibiotics are used to prevent urinary tract infection. Children are taught how to perform clean, intermittent bladder catheterization. This technique safely and effectively empties the bladder, preventing both upper tract deterioration and overflow incontinence (Zawin and Lebowitz, 1992). If frequent urinary tract infection is a problem, a vesicostomy can be performed, creating a fistula between the bladder and the abdominal wall. Eighty percent of children with neural tube defects achieve continence by intermittent catheterization and the use of anticholinergic medications.

Another potentially preventable complication of spina bifida is disease-associated latex sensitization (Cremer et al., 1998; Zsolt et al., 1999). Up to 43% of children with spina bifida are affected (Zsolt et al., 1999). However, it remains unclear whether this association is only a consequence of repeated exposure to latex-containing products (e.g., gloves or catheter material) (Chen et al., 1997) or is the result of a potential genetic contribution and alteration of the human leukocyte antigen phenotype (Rihs et al., 1998).

The presence of myelodysplasia can lead to musculoskeletal deformities. The goals of the orthopedic surgeon are to maintain mobile and pain-free joints, as well as to prevent decubitus ulcers in insensate limbs (Karol, 1995). The spine is at risk for the subsequent development of kyphosis and scoliosis. Significant spine deformities that require surgery develop in 10% of children with lesions at the thoracic level. Scoliosis is the most commonly encountered spinal deformity, which is treated by spinal fusion. Although patients with MMC can dislocate their hips, they are rarely surgically reduced. Contractures at the hip are surgically released to allow children to fit orthoses. External tibia rotation is commonly seen at the ankles. Sixty percent of children with MMC have clubfeet (see Chapter 107). This is treated differently for the child with MMC as compared with otherwise normal children. Neurologic clubfeet are more rigid than idiopathic clubfeet. The application of skin casts with stretching—the usual treatment for idiopathic clubfoot—can lead to skin breakdown for the child with MMC. Surgical treatment is generally recommended, but this should be delayed until the child is developmentally ready to stand.

Hunt (1990) and Hunt and Poulton (1995) described the long-term follow-up of 117 babies (50 boys, 67 girls) born between 1963 and 1971. All of these infants had surgical repair within the first 48 hours after birth. Of this cohort, 25 infants died within the first year of life, 15 died between ages 1 and 5 years, 8 died between ages 5 and 16 years, and 8 died between 16 and 25 years (Figure 19-9). The reports cover 69 survivors in 1990 and 61 survivors in 1995. Remarkably, 16 of the 56 deaths were from renal failure. In general,

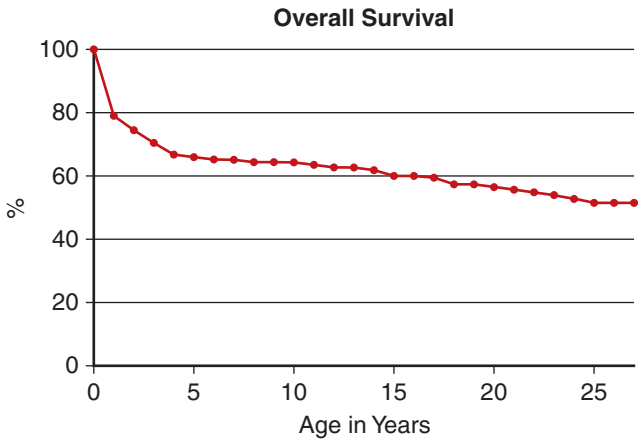

Figure 19-9 Overall survival for a cohort of 117 babies born with myelomeningocele between 1963 and 1971.

survival was lowest and disability greatest when the sensory level affected was above T11 (Figure 19-10). The survival was highest and disability the lowest when the sensory level was below L3 (Figure 19-11). Most severely affected cases had a poor renal prognosis due to neuropathic obstruction of bladder outflow. Of the survivors in 1990, 50% could walk for 50 yards or more and 50% were wheelchair-bound. Forty-seven of the 69 survivors had an IQ of >80, 12 had an IQ of between 60 and 79, and 10 had an IQ of <60. Approximately half of the young adults remained continent or managed their own incontinence. The other half needed help from other adults, and 43% of survivors used some sort of adult diaper or padding.

With regard to disability, 12% of patients walked normally and had a normal IQ. Fifty percent of patients could walk 50 yards and had normal intelligence. Twenty-five percent of patients had severe disability and could not walk or stand and had mental retardation. Twelve percent of patients had severe disability, blindness, and mental retardation, and needed help with transfers, dressing, and incontinence.

With regard to general health, one-third of patients had precocious puberty, one-third were overweight, and visual defects were common among these patients, including blindness in two of them. The presence of a history of ventriculitis, septicemia, or intracranial hemorrhage was associated with mental retardation, epilepsy, and blindness.

Sixteen of the 69 adult survivors were employed. Their occupations included light assembly work, clerical jobs, garage mechanic, gardener, and hairdresser. These authors concluded that most of the surviving young adults were badly handicapped. Thirty percent had mental retardation, as defined by an IQ of <80.

These authors stated that the sensory level to pinprick at birth was especially useful in the determination of long-term disability. When the sensory level was above T11, there was 50% survival to adult life. If the patient survived, there was a 50% chance of a normal IQ. Most of these patients had severe disability, with no prospect of walking or continence and only a 10% chance of being able to live independently. When the sensory level was between T11 and L3, there was a 55% chance of survival to adulthood. If the patient survived, there was a 70% chance of a normal IQ. Of this group of patients, 40% could walk, 15% were continent, and 45% were able to live independently. For the patients with a sensory level below L3, there was a 70% chance of survival to adulthood, and for the survivors there was an 80% chance of a normal IQ. Of these patients, 90% could walk and 45% were continent. Eighty-five percent of this group were able to live independently (Hunt, 1990; Hunt and Poulton, 1995).

In addition to the emotional impact on the family, the financial burden for family and community is enormous. In

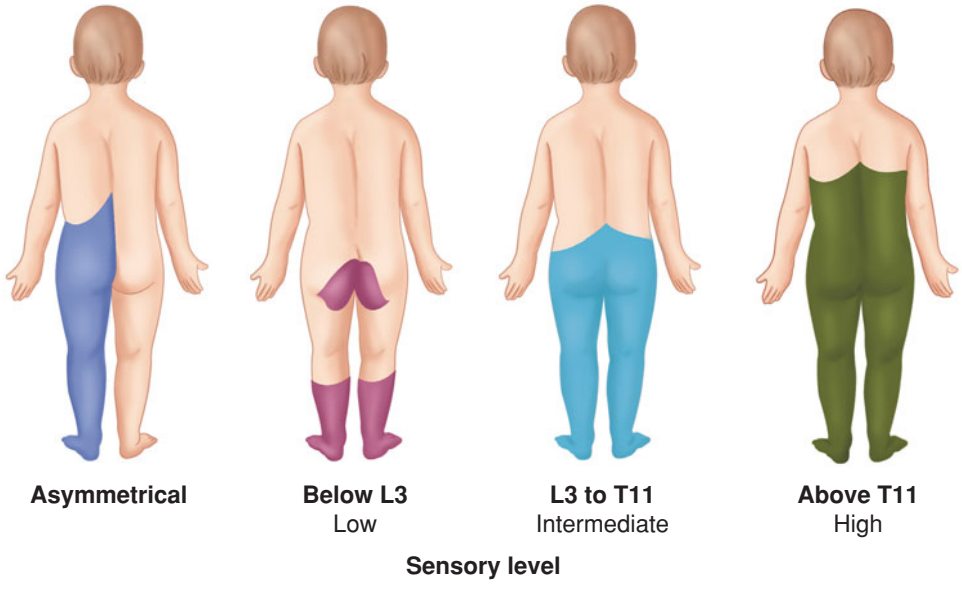

Figure 19-10 Illustration of sensory areas affected by the different anatomic locations of the neural tube defect. The hatch marks and coloration used in this figure relate to the data in Figure 19-11.

the United States, the cost of care for infants with spina bifida in 1988 was almost 500 million dollars per year or $294,000 for each infant (Waitzman et al., 1996).

GENETICS AND RECURRENCE RISK

The vast majority of neural tube defects are isolated and multifactorial in origin (Main and Mennuti, 1986). In a landmark study, Holmes et al. (1976) classified 106 stillborn and liveborn infants with neural tube defects. They identified six different causes for the anomalies. This study consisted of a retrospective analysis of 79 autopsy cases and a prospective analysis of 27 liveborn infants. Of the 27 liveborn infants, 23 had an isolated neural tube defect, and of these 15 had anencephaly. Of the 79 retrospective cases, 67 were consistent with multifactorial inheritance. Five of the cases were consistent with a single-gene disorder, and all were thought to be due to Meckel–Gruber syndrome, an autosomal recessive condition. One case was clinically diagnosed as trisomy 13, although the definitive chromosome analysis was unavailable. One of the 79 was an infant of a mother with diabetics. Three cases were due to amniotic bands, and two cases were due to cloacal exstrophy. These authors suggested that the cause of neural tube defects was highly variable and that genetic counseling could not support a uniform 5% recurrence risk for all patients.

Main and Mennuti (1986) have suggested a recurrence risk of 1.5% to 3%, although with two affected siblings the recurrence risk increases to 5.7% in the United States and 12% in the United Kingdom (Main and Mennuti, 1986). For sisters of the mother who gives birth to an affected child with a neural tube defect, there is an increased risk. The presence of spina bifida occulta of a single vertebra in a parent does not increase the risk for a neural tube defect in the offspring.

Women who have already given birth to an affected infant with a neural tube defect should take 4 mg of folic acid daily at least 3 months prior to the next pregnancy (Wald et al., 1991). Several studies to date have demonstrated the preventive effect of folic acid supplementation prior to conception. These studies have been summarized by Rieder (1994). In one study, 11 cases of neural tube defects were observed in 1188 pregnancies supplemented with folic acid, or a prevalence of 0.9 per 100 livebirths. The patients not taking supplements had 54 cases of neural tube defects in 1286 livebirths, for a prevalence of 4 cases per 100. The mechanism by which folic acid mediates neural tube closure is unknown, although the preventive effect has been shown even in low-risk women (Milunsky, 1996). It is currently recommended that all women of childbearing age take at least 0.4 mg of folic acid every day (Wald et al., 1991; Baty et al., 1996).

Prenatal diagnosis of neural tube defects in a subsequent pregnancy can be performed by maternal serum AFP screening, amniotic fluid AFP screening, and prenatal sonographic examination.

20 CHAPTER Microcephaly

Key Points

- Microcephaly is characterized by a smaller than normal head circumference. A head circumference measurement of 3 SD below the mean gives a clinically meaningful definition because it has been associated with mental retardation.
- Microcephaly has been associated with a number of genetic, infectious, and environmental exposures.
- Detailed ultrasound examination to exclude other anomalies is necessary.
- A careful history is needed when this diagnosis is suspected. Likewise, the head circumferences of the parents should be measured.
- Little information is known about the antenatal natural history of microcephaly, especially during the first and second trimesters.
- The diagnosis of microcephaly should not alter obstetric management.
- Newborns with microcephaly require an extensive work-up to determine the etiology of the condition.
- The long-term prognosis and recurrence risk for microcephaly is related to its underlying cause.

CONDITION

Microcephaly is characterized by a smaller-than-normal head circumference (Figures 20-1 and 20-2). The clinical significance of microcephaly is its association with a small brain—microencephaly. A difference of opinion exists as to whether the lower limit of a normal head circumference should be defined as 2 or 3 SD below the mean (Avery et al., 1972). When a head circumference of 2 SD below the mean is used to define microcephaly, the association with mental retardation is inconsistent. Using such a definition, 2.5% of the general population would be considered microcephalic, and therefore a large number of infants with normal intellectual function would be included (Martin, 1970; Sells, 1977). A head circumference measurement of 3 SD below the mean gives a more clinically meaningful definition of microcephaly, as the correlation of this measurement with mental retardation is stronger (Davies and Kirman, 1962; Warkany et al., 1981).

The most affected part of the brain in microcephaly is the forebrain, and there is frequently associated macrogyria, pachygyria, and basal ganglia atrophy (Davies and Kirman, 1962).

Microcephaly is caused by diverse genetic and environmental factors that disturb brain growth in prenatal and early postnatal life (Warkany et al., 1981). The proportion of cases of microcephaly due to genetic causes has been estimated at 20% to 33% (Van den Bosch, 1959; Cowie, 1987). However, much of the data on which such estimates are based relate to patients born before recent advances in syndrome diagnosis and genetics.

The classification of microcephaly has generally reflected a distinction between genetic and acquired causes (Table 20-1). The term *primary*, or *true*, *microcephaly* has been used when the condition is isolated and is due to an arrest of brain development. The term *secondary microcephaly* has been applied to acquired insults to the brain. Microcephaly may also be classified based on the presence or absence of associated malformations.

Determination of the precise cause of microcephaly is difficult. The diagnosis of isolated developmental microcephaly is usually one of exclusion, with other causes of microcephaly having been ruled out (Hunter, 1993).

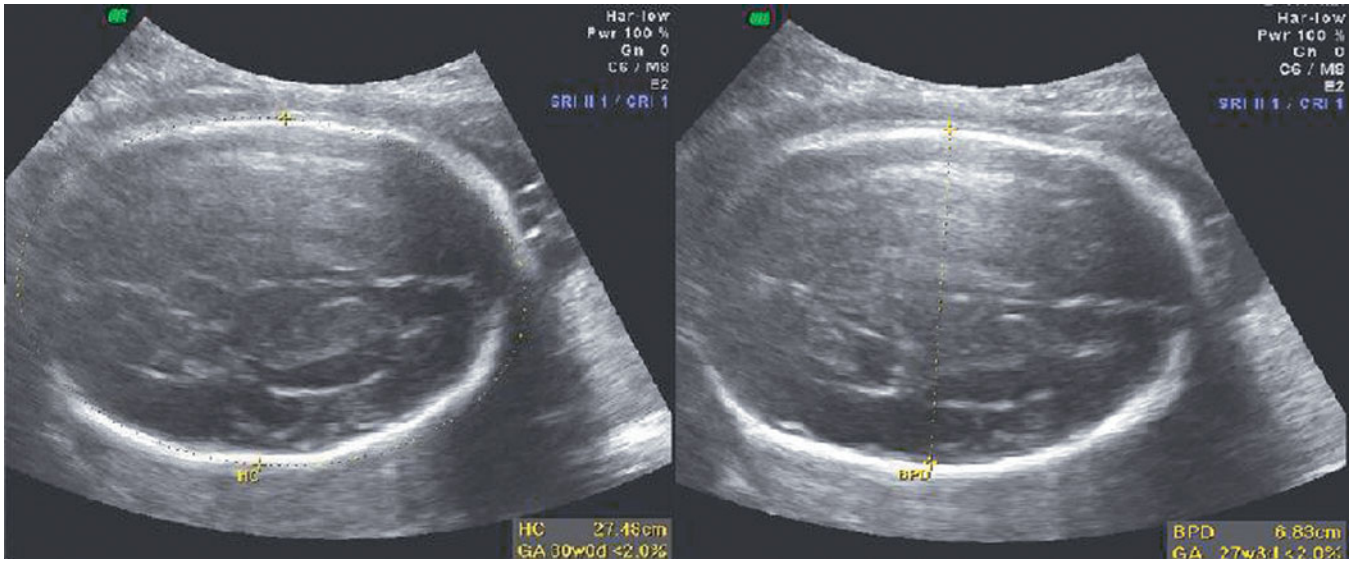

Figure 20-1 Axial image of fetal head showing biparietal diameter and head circumference measuring at less than the 2nd percentile for expected gestational age.

INCIDENCE

The overall incidence of microcephaly was 1.6 in 1000 livebirths in the U.S. Collaborative Perinatal Project, in which infants were observed throughout the first year of life. The incidence in whites was found to be 1.3 in 1000 livebirths and in blacks, 1.9 in 1000 livebirths (Myrianthopoulos and Chung, 1974). Estimates of the frequency of developmental microcephaly vary, depending on the population studied, ranging from 1 in 25,000 to 1 in 250,000 (Book et al., 1953; Van Den Bosch, 1959). The frequency of microcephaly from all causes in the Netherlands was estimated to be 1 in 93,000 (Van den Bosch, 1959). The variation in quoted incidence rates probably reflects different levels of ascertainment in different populations, as many studies do not include stillbirths or spontaneous losses.

Figure 20-2 Newborn infant with severe microcephaly. The infant's length and weight were at 95%, but the head circumference was below 5%. The etiology for this infant's microcephaly, which was detected prenatally, is unknown (*Courtesy of John Foster.*)

SONOGRAPHIC FINDINGS

The diagnosis of microcephaly should be considered when the fetal head circumference is 3 SD below the mean for gestational age. A detailed fetal sonographic evaluation for associated anomalies should be performed in all cases of suspected microcephaly.

The use of head circumference rather than biparietal diameter (BPD) is more appropriate in the diagnosis of microcephaly. The BPD can be inaccurate if the fetus is breech and in conditions that cause intrauterine molding, such as oligohydramnios and multiple gestation. By contrast, the fetal head circumference should not be affected by molding. One series found that a BPD smaller than 3 SD below the mean was associated with a normal outcome in 44% of cases (Chervenak et al., 1984). This high incidence of falsely abnormal results was probably due to the inclusion of fetuses with simple intrauterine molding. In a later series of 24 fetuses with BPD values of more than 3 SD below the mean, only 4 proved to be microcephalic after birth, and 3 of these 4 fetuses had additional major malformations (Chervenak et al., 1987).

Table 20-1

Classification of Microcephaly by Etiology

Microcephaly with Associated Malformations		Microcephaly Without Associated Malformations
Genetic		Genetic
Chromosomal abnormalities		Primary microcephaly
Trisomy 21		Alpers syndrome
Trisomy 13		Paine syndrome
Trisomy 18		Inborn errors of metabolism
Trisomy 22		Disorders of folic acid metabolism
4p–		Hyperlysinemia
5p–		Methylmalonic acidemia
18p–		Phenylketonuria
18q–		
Single gene defects	Mode of inheritance	
Angelman syndrome	Deletion 15q	
Bloom syndrome	Autosomal recessive	
Borjeson–Forssman–Lehmann syndrome	Sex-linked recessive	
Cockayne syndrome	Autosomal recessive	
Coffin–Siris syndrome	Autosomal recessive	
DeLange syndrome	Autosomal dominant	
DeSanctis–Cacchione syndrome	Autosomal recessive	
Dubowitz syndrome	Autosomal recessive	
Fanconi pancytopenia	Autosomal recessive	
Focal dermal hypoplasia	X-linked dominant	
Incontinentia pigmenti	X-linked dominant	
Johanson–Blizzard syndrome	Autosomal recessive	
Langer–Giedion syndrome	Deletion 8q	
Lissencephaly syndrome	Autosomal recessive	
Meckel–Gruber syndrome	Autosomal recessive	
Menkes syndrome	Sex-linked recessive	
Roberts syndrome	Autosomal recessive	
Rubinstein–Taybi syndrome	Autosomal dominant/new mutation	
Seckel bird–headed dwarfism	Autosomal recessive	
Smith–Lemli–Opitz syndrome	Autosomal recessive	
Williams syndrome	Elastin mutation	
Environmental		Environmental
Prenatal exposure to infections		Prenatal exposure to radiation
Rubella syndrome		Fetal malnutrition
Cytomegalovirus disease		Perinatal trauma or hypoxia
Herpes virus		Postnatal infections
Toxoplasmosis		
Varicella zoster		
Prenatal exposure to drugs or chemicals		
Fetal alcohol syndrome		
Fetal hydantoin syndrome		
Vitamin A or vitamin A analog		
Aminopterin syndrome		
Cocaine exposure		
Methylmercury exposure		
Solvent exposure: toluene, gasoline		
Carbon monoxide poisoning		
Irradiation		
Maternal phenylketonuria		

Adapted from Ross JJ, Frias JL. Microcephaly. In: Vipken PJ, Bruyn AW, eds. Handbook of Clinical Neurology. Vol 30. *Amsterdam: Elsevier; 1977:507-524.*

Microcephaly may also be diagnosed based on an abnormal ratio of head circumference to femur length or of head circumference to abdominal circumference. Normograms for these ratios have been published (Romero et al., 1988). A diagnosis of microcephaly should be made with caution when using such normograms, because some causes of microcephaly may be associated with intrauterine growth restriction or abnormal long bone growth.

When microcephaly is present, the most affected part of the fetal brain is the forebrain. This has prompted investigators to evaluate the role of frontal-lobe measurements in the diagnosis of microcephaly. Ultrasonographic measurements of the frontal lobe and thalamic-frontal-lobe distance were below 2 SD in three cases of microcephaly diagnosed in utero and confirmed after birth (Goldstein et al., 1988). In two of the three cases, other conventional diagnostic measurements (BPD, occipitofrontal diameter, and head circumference) were also reduced. In one case in which the conventional parameters were equivocal, the authors found that additional measurements of the frontal lobe were diagnostic of microcephaly. Neonatal evaluation confirmed the diagnosis.

In a report on the prospective prenatal diagnosis of microcephaly in 21 pregnancies occurring in 15 families with a previously affected child with microcephaly, serial measurements of the fetal head, abdomen, and femur were made by ultrasound examination at intervals of approximately 4 weeks (Tolmie et al., 1987). Four fetuses with microcephaly were detected in the third trimester. One affected fetus was missed because no scans were performed after 24 weeks of gestation. The main reason for late diagnosis of affected fetuses was that the head growth did not slow appreciably until the third trimester (Tolmie et al., 1987). A diagnosis of microcephaly cannot be excluded by ultrasonography performed during the second trimester of pregnancy and a repeat third trimester ultrasound examination may result in better diagnosis and patient counseling (Malinger et al., 2002).

In addition, in cases of microcephaly, Doppler ultrasonography has been used during the second trimester to diagnose abnormal intracranial vascular anatomy (Pilu et al., 1998). It has been postulated that microcephaly in these cases was due to a reduced blood supply to the cerebral hemispheres.

DIFFERENTIAL DIAGNOSIS

If the microcephaly is isolated, the most likely consideration in the differential diagnosis is familial microcephaly. A detailed family history is imperative whenever a diagnosis of microcephaly is considered. The history should include a careful search for consanguinity and measurement of the head size of the parents and siblings. A maternal history of alcohol or other substance abuse, irradiation, use of medications (including phenytoin and isotretinoin), maternal disease, fever, and rash should be obtained.

If the microcephaly is seen in association with other anomalies, there is an extensive differential diagnosis that is beyond the scope of this chapter. McKusick's Online Catalog of Mendelian Inheritance in Man (OMIM), lists almost 500 entries for microcephaly (Abuelo, 2007).

ANTENATAL NATURAL HISTORY

Little information is available on the intrauterine natural history of microcephaly. In one series evaluating the presence of microcephaly prenatally, one affected fetus was missed following an ultrasound examination that was normal at 24 weeks (Tolmie et al., 1987). Microcephaly becomes more obvious in utero as gestation progresses. Because the prenatal diagnosis of microcephaly is rarely made before the third trimester of pregnancy, little is known about what occurs during the first and second trimesters.

MANAGEMENT OF PREGNANCY

A detailed sonographic examination is indicated to identify both intracranial and extracranial abnormalities associated with microcephaly. Karyotyping should be offered. A detailed background history should be obtained and should exclude consanguinity, prenatal infections (such as a febrile illness or a rash), prenatal exposure to drugs or chemicals (especially alcohol), and maternal phenylketonuria (PKU). If there is a history suggestive of maternal infection, maternal serology and polymerase chain reaction (PCR) studies of the amniotic fluid are indicated. Measurement of the head sizes of the parents and siblings may be helpful in determining whether this is a familial trait.

It is important to counsel parents about the difficulties encountered in the antenatal diagnosis of microcephaly (Schwarzler et al., 2003). It is often useful to counsel parents that definitive diagnosis in the newborn period may also be very difficult. Antenatal referral of the pregnant patient to a medical geneticist is recommended.

If there are other associated abnormalities, delivery should occur in a tertiary care center. Timing and mode of delivery should not be influenced by the presence of isolated microcephaly. If there are no other associated abnormalities it is reasonable to deliver the patient at a community hospital with appropriate postnatal subspecialty referral to medical genetics and pediatric neurology specialists.

FETAL INTERVENTION

No fetal intervention has been described following the prenatal diagnosis of microcephaly.

TREATMENT OF THE NEWBORN

Newborns with isolated microcephaly do not usually show evidence of neurologic deficits or seizures (Penrose, 1972; Volpe, 1987). This is in contrast to microcephaly due to other causes, such as chromosomal abnormalities or infection.

Neuroradiologic investigations may be useful in ruling out an underlying cause for microcephaly, such as hypoxic ischemic damage or neurologic injury due to the in utero death of a twin (Hughes and Miskin, 1986; Sherer et al., 1993). Postnatal imaging of the brain through the use of computed tomographic or magnetic resonance imaging is reasonable in most cases (Persutte et al., 1990). Serologic studies, such as TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes virus) titers, may be useful in ruling out antenatal infection.

Newborns with microcephaly should have a careful ophthalmologic examination, because the association of microcephaly and eye abnormalities is common. In one series, eye abnormalities were found in 23 of 40 cases with "true" microcephaly (Alzial et al., 1980). In a further series of 131 cases of microcephaly, eye abnormalities were present in 36% (Brandon et al., 1959). Eye abnormalities have been described in autosomal dominant microcephaly, autosomal recessive microcephaly, sex-linked microcephaly, and microcephaly secondary to maternal infection (Webster and Smith, 1977; Tenconi et al., 1983; Siber, 1984).

The postnatal onset of microcephaly potentially suggests an inborn error of metabolism, such as PKU, hyperlysinuria, or methylmalonic acidemia.

SURGICAL TREATMENT

No surgical intervention has been described for microcephaly.

LONG-TERM OUTCOME

The prognosis for microcephaly is related to its underlying cause. Microcephaly, when associated with other malformations or congenital infections, has a very poor prognosis, with minimal data available on long-term follow-up. Intellectual impairment in children with a head circumference 3 SD below the mean was more common in children with additional disorders (Dolk, 1991). Fifteen of 16 children with microcephaly and other disorders had mental retardation. Of 25 microcephalic children with no other disorders, only 25% had mental retardation (Dolk, 1991).

The predictive value of head size at 1 year of age for intelligence at 4 years of age was not strong in one series, with an IQ below 80 occurring in less than 50% of those with head circumference at least 2.5 SD below the mean (Nelson and Deutschberger, 1970). In another series of children who consistently had microcephaly (3 SD below the mean) on repeated measurements in infancy, 21 of 41 (51%) term infants had an IQ below 70 at 7 years of age (Dolk, 1991). Head circumference 2 SD below the mean was associated with an IQ below 70 in 11% of cases (Dolk, 1991).

GENETICS AND RECURRENCE RISK

The recurrence risk for microcephaly depends on the underlying cause. Both autosomal dominant and autosomal recessive patterns of inheritance for isolated microcephaly have been described. If the microcephaly is due to an aneuploidy, such as trisomy 18, the recurrence risk is approximately 1% in addition to the maternal age–related risk. If the microcephaly is due to a deletion or rearrangement in the chromosomes, parental karyotyping should be performed to rule out a balanced translocation, which would increase the recurrence risk. If microcephaly is secondary to drug exposure or infection, the recurrence risk is expected to be minimal in a subsequent pregnancy.

Empiric recurrence risks have been calculated for idiopathic severe microcephaly. Estimates of the recurrence risk for microcephaly with mental retardation in siblings are shown in Table 20-2. In one case series that reviewed the outcomes for 51 siblings of 21 patients identified with microcephaly and mental retardation, no cases of recurrence were noted in siblings (Bundey and Carter, 1974). The reason for this low recurrence risk is not known but may be that patients with isolated microcephaly were excluded from the study (Tolmie et al., 1987). In another series of 11 index cases with microcephaly and spasticity, three recurrences

Table 20-2

Recurrence Risks for Microcephaly with Mental Retardation

Reference	Recurrence Risk in Siblings (%)
Brandon et al. (1959)	6
Bundey and Carter (1974)	0
Bundey and Griffiths (1977)	13
Opitz et al. (1978)	20
Bartley and Hall (1978)	11
Herbst and Baird (1982)	5.9
Tolmie et al. (1987)	19

were found among 23 siblings (Bundey and Griffiths, 1977). In a population-based study from British Columbia that attempted total ascertainment, a 6% recurrence risk for microcephaly with mental retardation was noted (Herbst and Baird, 1982). It was not clear from this study whether microcephaly was defined as a head circumference of less than 2 or less than 3 SD below the mean. In a further series, a recurrence risk of 19% was reported from 29 cases of microcephaly in a referral genetic service for the west of Scotland (Tolmie et al., 1987).

A possible explanation for the higher risk of recurrence found in selected population studies (Bundey and Carter, 1974; Bartley and Hall, 1978; Tolmie et al., 1987) in comparison to other studies (Herbst and Baird, 1982) may be ascertainment bias. Nevertheless, these studies provide a useful source of information for prenatal diagnosis and counseling of parents with a diagnosis of fetal microcephaly.

Relatively recently, it has become appreciated that there is a new condition known as autosomal recessive primary microcephaly (MCPH) (Woods et al., 2005; Abuelo, 2007). This condition is characterized by congenital microcephaly, nonprogressive mild-to-moderate mental retardation, and an otherwise normal appearance. The brain is architecturally normal, but there is a significant reduction in the size of the cerebral cortex. At least four genes have been identified that are mutated in this disorder (Woods et al., 2005).

21 CHAPTER Porencephaly

Key Points

- There are two main forms of porencephaly: (1) developmental porencephaly and (2) congenital encephaloclastic porencephaly. The first type represents primary failure of neuronal development and migration. The second type is more common and results from cortical destruction due to an external insult in an otherwise normal brain.
- Porencephaly can be diagnosed prenatally using sonography when fluid-filled spaces are noted in the fetal brain. MRI is a useful adjunct.
- A complete family history should be obtained to look for stroke, thrombosis, thromboembolism, and recurrent porencephaly.
- Work-up should include ruling out maternal cocaine and warfarin use, infection, hereditary thrombophilias, and increased bleeding.
- Long-term prognosis depends on the size and location of the lesions, and whether there is a hereditary thrombophilia or vasculopathy.
- The neonate should be evaluated after birth by a pediatric neurologist. Follow-up brain imaging is recommended.
- In most cases, an underlying cause for porencephaly is not identified. Most familial cases are due to underlying autosomal dominant mutations.

CONDITION

Porencephaly is a term that describes a fluid-filled cavity in open communication with the lateral ventricle (van der Knaap et al., 2006). The term *porencephaly* is often used interchangeably with *porencephalic cyst, schizencephaly, cystic brain degeneration*, and *congenital brain clefts.* Porencephaly was first described in 1859 as a cavity or cleft of the cerebral cortex (Heschl, 1859). These lesions may or may not communicate with the ventricular and subarachnoid systems. Two major subgroups are described: developmental porencephaly, which includes schizencephaly and congenital midline porencephaly and congenital encephaloclastic porencephaly (Hall, 2006).

Developmental porencephaly represents a primary failure of neuronal development and migration. Synonyms include *true porencephaly, schizencephaly*, and *congenital porencephaly.* Congenital midline porencephaly is a more recently described malformation, consisting of the triad of a midline parietal scalp anomaly (such as alopecia or cephalocele), hydrocephalus, and a midline intracranial cyst (Yokota and Matsukado, 1979; Vintzileos et al., 1987). While this malformation most likely represents a form of porencephaly, some authors consider it a variant of holoprosencephaly (Vintzileos et al., 1987).

In contrast, congenital encephaloclastic (disruptive) porencephaly results from cortical destruction due to an external insult in an otherwise normally developed brain. Synonyms include *pseudoporencephaly, false porencephaly*, and *cystic brain degeneration.* This destruction results in an intracerebral cystic cavity containing cerebrospinal fluid, and such a cyst may be single or multiple (Figure 21-1) (Hall, 2006). Congenital encephaloclastic porencephaly may have many different causes; of these, hemorrhagic infarction due to fetal venous congestion or occlusion is considered to be the most common (Dekaban, 1965; Cantu and LeMay, 1967; Nixon et al., 1974).

The known risk factors for acquired porencephaly are conditions that cause thrombophilia (such as Factor V Leiden and protein C deficiency), increased bleeding (perinatal alloimmune thrombocytopenia, von Willebrand disease), vasculopathy following in utero exposure to cocaine (Dominguez et al., 1991), infection with Coxsackie virus or cytomegalovirus (Tominaga et al., 1996; Chalhub et al., 1977),

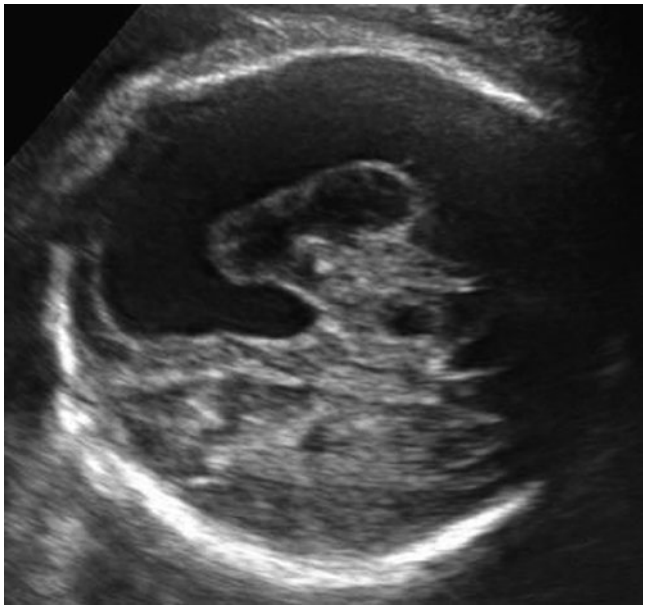

Figure 21-1 Axial image demonstrating a large porencephalic cyst with adjacent echogenic area suggestive of prior hemorrhage.

and trauma, resulting from ventricular puncture (Lorber and Grainger, 1963), amniocentesis (Eller and Kuller, 1994), or chorionic villus sampling (Sharma and Phadke, 1991) (Table 21-1). Familial porencephaly, consistent with both autosomal dominant and recessive patterns of inheritance, has also been reported (Berg et al., 1983; Sensi et al., 1990; Haverkamp et al., 1995). Mutations in the *COL4A1* gene are increasingly being recognized as an important cause of blood vessel rupture in the fetus (van der Knaap et al., 2006).

Table 21-1

Risk Factors for Encephaloclastic (Acquired) Porencephaly

Hereditary thrombophilias Factor V Leiden, protein C deficiency
Increased bleeding tendencies Maternal warfarin use, perinatal alloimmune thrombocytopenia, von Willebrand disease
Vasculopathy Maternal cocaine use, congenital infection
Trauma Amniocentesis, CVS
Familial *COL4A1* mutation

INCIDENCE

Porencephaly is an extremely rare condition with an unknown incidence.

SONOGRAPHIC FINDINGS

Porencephaly has been successfully diagnosed prenatally using both sonography and magnetic resonance imaging (Lithuania et al., 1989; Komarniski et al., 1990; Meizner and Elchalal, 1996; Levine et al., 1997; Pilu et al., 1997). The sonographic appearance is that of a fluid-filled space in the normal brain parenchyma. The cyst is more commonly unilateral but may be bilateral (Figures 21-1 and 21-2). When cysts are multiple they are frequently symmetric in appearance (Klingensmith and Cioffi-Ragan, 1986). Loss of cerebral tissue is often easily visible on coronal scans. Color Doppler sonography may be helpful in delineating a particular vascular abnormality associated with the cystic lesion (Suchet, 1994). Communication with the lateral ventricles or subarachnoid space is often visible. The ipsilateral ventricle is usually enlarged to compensate for the smaller brain mass. The diagnosis of porencephaly should be considered whenever marked asymmetric ventriculomegaly is found (Chervenak et al., 1983; Toma et al., 1990).

Figure 21-2 Postnatal CT scan taken in an infant noted antenatally to have an intracranial hemorrhage. The scan shows the evolution of the hemorrhage into a massive porencephalic cyst.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes other cystic brain lesions such as arachnoid cyst (see Chapter 8) and, more rarely, cystic tumors (Sauerbrei and Cooperberg, 1983). In one case of asymmetric hydrocephalus, the diagnosis of porencephaly was suspected but could not be confirmed with an ultrasound examination. Magnetic resonance imaging correctly identified the porencephalic cavity communicating with the lateral ventricle (Toma et al., 1990). If severe hydrocephalus is also present it must be distinguished from hydranencephaly. Hydranencephaly is considered to be an extreme form of encephaloclastic porencephaly.

ANTENATAL NATURAL HISTORY

In keeping with the vascular cause of many cases of porencephaly, in utero deterioration of porencephalic cystic masses has been documented (Klingensmith and Cioffi-Ragan, 1986). In this case, significant deterioration of cystic areas was noted between ultrasound examinations performed at 31 and at 36 weeks of gestation. In addition, the cystic deterioration corresponded to the distribution of the middle cerebral arteries (Klingensmith and Cioffi-Ragan, 1986). Other than this case report, little information is available to guide counseling of the patient with fetal porencephaly.

MANAGEMENT OF PREGNANCY

The pregnant woman should be asked if she has used either cocaine or warfarin. Serologic testing for cytomegalovirus, coxsackie virus, and toxoplasma should be considered. A complete family history should be obtained, with particular attention paid to occurrence of stroke, thromboembolism, and venous thromboses. If an autosomal dominant pattern of any of these conditions is established, the pregnant woman should be referred to a medical geneticist who can facilitate molecular testing for the hereditary thrombophilias and the hereditary vasculopathies. Because there are no reported associations with chromosomal disorders, amniocentesis for karyotyping is not indicated.

The prospective parents should be counseled that the prognosis depends on the location and size of the lesion. However, in almost all cases of true porencephaly, the neonatal outcome will be poor, with severe intellectual and neurologic sequelae (Romero et al., 1988). Neurologic sequelae can include spastic tetraplegia, blindness, and severe speech impediment. Fetal magnetic resonance imaging may be helpful in differentiating fetal intracranial cystic lesions (Levine et al., 1997). Consultation with a pediatric neurologist and a neonatalogist is recommended to discuss neonatal management. If diagnosed before 24 weeks of gestation, termination of pregnancy should be offered. Delivery at a tertiary care center is recommended. In cases of developmental porencephaly, vaginal delivery should be allowed in almost all cases because of the invariably poor neonatal outcome. In encephaloclastic porencephaly, particularly due to a known *COL4A1* mutation, cesarean section delivery should be offered to minimize birth trauma (Gould et al., 2005).

FETAL INTERVENTION

No fetal intervention has been described for this condition, and none is likely, as porencephaly appears as a result of the absence of cerebral tissue. Furthermore, if there is a vasculopathy present, intervention would in all likelihood cause additional damage.

TREATMENT OF THE NEWBORN

The infant should be evaluated promptly after birth by a pediatric neurologist. Imaging of the neonatal brain, using sonography and magnetic resonance imaging should be performed to aid in defining the extent of neurologic deficit. The initial signs and symptoms of porencephaly depend on the location of the defect and include seizures, varying degrees of developmental delay, visual and sensory deficits, and hydrocephalus. Porencephaly should be considered in any child with unexplained hemiparesis. The degree of impairment is variable, with some patients initially showing only mild to borderline impairment, while other infants are profoundly impaired (Nixon et al., 1974; Tardieu et al., 1981). No specific treatment is indicated, although appropriate medical therapy to control seizures is often needed.

SURGICAL TREATMENT

In some cases of porencephaly with associated hydrocephalus, there may be a role for surgical intervention to prevent further hydrocephalus-associated injury. This may be especially helpful in cases of a unilateral intracerebral cyst, resulting in a midline shift toward the contralateral side. Progression of impairment may therefore occur, unless a shunt is placed to collapse the cyst (Hall, 2006). In one series of nine children with progressive porencephaly, improvement was demonstrated following surgical placement of a ventriculoperitoneal shunt (Tardieu et al., 1981). The authors suggested shunts for any patient with progressive clinical signs of neurologic deterioration. They recommended shunts in patients less than 2 years of age in whom a large cyst is demonstrated, with hydrocephalus, macrocephaly, and developmental delay (Tardieu et al., 1981).

LONG-TERM OUTCOME

The long-term outcome for infants with porencephaly depends on the extent of the cystic destruction of cerebral tissue. Minimal data are available for accurate counseling. In most cases there is severe cerebral destruction, and the long-term outcome for such infants is extremely poor. A severe variety of postnatal encephaloclastic porencephaly has been described in 15 neonates with a birth weight of 600 to 1270 g and a gestational age at delivery of 24 to 32 weeks (Cross et al., 1992). Cerebral ultrasound examinations were characterized by irregular cystic lesions involving the periphery of the brain. Fourteen of the 15 infants died in the first 6 weeks of life, and 8 had clinical evidence of neurologic abnormality resulting in seizures. The only survivor had severe neurologic deficit at 12 months of age (Cross et al., 1992).

GENETICS AND RECURRENCE RISK

In many cases the underlying cause for porencephaly will not be identified. Prevention of porencephaly may be possible in cases of monochorionic twins with impending death of one fetus. In such cases, consideration of elective preterm delivery, or fetoscopic cord ligation of the abnormal twin, may prevent porencephaly, which may be caused by profound hypotension at the time of death of the twin (see Chapter 118).

Recently, there has been increasing appreciation of families that have an autosomal dominant form of porencephaly (van der Knaap et al., 2005; Breedveld et al., 2006). In the past, the dominant nature of the condition has been obscured because of individuals who appeared to lack expression of the phenotype. More recent studies, using MRI, demonstrate subtle CNS anomalies but no porencephaly, in individuals who are obligate carriers of dominant mutations. In parallel, in 2005, Gould et al. studied a mutant mouse that develops porencephaly. They showed that the perinatal cerebral hemorrhage was due to vascular defects resulting from a dominant mutation in the procollagen type IVa 1 gene (*CO14a1*). They subsequently went on to show in two human families with autosomal dominant porencephaly that there were mutations in the *COL4A1* gene. These findings have been validated in other studies (Breedveld et al., 2006; van der Knaap et al., 2006) and suggest that consideration of molecular testing is important if there is a positive family history.

Additional evidence to suggest the importance of autosomal dominant gene mutations that predispose to porencephaly comes from a German case–control study in which 76 porencephalic and 76 healthy infants were investigated for Factor V Leiden G1691A mutation, factor II G20210A variant, methylenetetrahydrofolate reductase (MTHFR) C677T variant, lipoprotein (a), proteins S and C, and antithrombin (Debus et al., 2004). Only the Factor V Leiden mutation, or a combination of two or three different risk factors was statistically significantly associated with porencephaly.

Families in which a *COL4A1* or Factor V Leiden (G1691A) mutation has been documented should be counseled that they potentially have a 50% incidence of recurrence. *COL4A1* mutations are associated with an increased incidence of strokes in the early adult years.

22 CHAPTER Vein of Galen Aneurysm

Key Points

- The vein of Galen is a single, midline structure formed by the convergence of the two internal cerebral veins and the basal veins of Rosenthal posterior to the splenium of the corpus callosum; the vein courses posteriorly to empty into the straight sinus.
- Vein of Galen malformation, an extremely rare anomaly, is a complex arteriovenous malformation affecting the vein of Galen and the cerebral arteries.
- The size of the aneurysm determines its clinical presentation. A large aneurysm can result in as much as 50% to 60% of the cardiac output shunting through the lesion that may cause high-output congestive heart failure. This can present in utero as hydrops or as cardiac failure in early neonatal life.
- Cerebral parenchymal injury including cerebral infarction, periventricular leukomalacia, and hemorrhagic infarction can also be associated with this anomaly.
- Vein of Galen aneurysm may be suspected on antenatal ultrasound examination when a cystic or tubular mass is noted in the midline of the brain just above and behind the thalamus. Turbulent venous or arterial flow may be demonstrated using color Doppler within the draining vessel.
- Generalized cardiomegaly or right ventricular enlargement is commonly noted but should not be attributed to high-output cardiac failure until targeted fetal echocardiography has been performed.
- The differential diagnosis includes other midline cystic structures within the brain such as an arachnoid cyst or an interhemispheric cyst associated with agenesis of the corpus callosum.
- Because of the differences in the fetal and neonatal circulations, cardiac failure does not often occur until after birth.
- Serial antenatal ultrasound examinations should be performed to determine a change in size of the aneurysm and to monitor for hydrocephalus or congestive heart failure.
- Joint management with a pediatric cardiologist and pediatric neurosurgeon is suggested.
- The approach to therapy for a patient with a vein of Galen aneurysm will depend on the age of the patient, the clinical symptoms, and the angiographic architecture of the malformation.

LONG-TERM OUTCOME OF PRENATALLY DIAGNOSED VEIN OF GALEN ANEURYSM IS STILL NOT A WELL-KNOWN CONDITION

Vein of Galen aneurysm is also referred to as a varix of the vein of Galen or vein of Galen malformation. This anomaly is a complex arteriovenous malformation affecting the vein of Galen and the cerebral arteries. The vein of Galen is a single, midline structure formed by the convergence of the two internal cerebral veins and the basal veins of Rosenthal posterior to the splenium of the corpus callosum; the vein courses posteriorly to empty into the straight sinus. During embryologic development, cerebral arteries and veins cross in close proximity to each other; fistulous connections may exist because only a few cell layers separate these vessels (Padget, 1956). These fistulas persist because of an arteriovenous pressure gradient. The size and number of arteriovenous fistulous connections determine the eventual size of a vein of Galen aneurysm.

Aneurysm of the vein of Galen was first described in 1937 by Jaeger et al. (1937). The first precise anatomical definitions of these vascular malformations were described in 1960 (Litvak et al., 1960). Malformations of the vein of Galen most probably arise early in embryogenesis in the 20- to 40-mm fetus, when arteries and veins are still simple endothelial tubes (Padget, 1956). Following an anatomic analysis of 23 cases of vein of Galen aneurysm, it was concluded that the venous sac most probably represents persistence of the embryonic median prosencephalic vein of Markowski, not the vein of Galen per se (Raybaud et al., 1989). Even though there is plausible evidence that the aneurysmal sac is the persistent embryonic median prosencephalic vein of Markowski rather than the true vein of Galen, this author concluded that it was reasonable to retain the generally accepted nomenclature of *vein of Galen aneurysm*, but to restrict its use to cases in which the arteriovenous fistulas are within the wall of the venous sac. Vein of Galen aneurysms may be defined as direct arteriovenous fistulas situated between choroidal and/or quadrigeminal arteries and an overlying single median venous sac.

The size of the aneurysm of the vein of Galen determines its clinical presentation. When the aneurysm is large, as much as 50% to 60% of the cardiac output may be shunted through the lesion (Cumming, 1980). This arteriovenous shunt may result in high-output congestive heart failure, and these patients tend to present with hydrops in utero, or with cardiac failure in early neonatal life.

Other cases of vein of Galen aneurysm are not associated with cardiac failure and may not present until the first year of life. Hydrocephalus may also occur in association with a large vein of Galen aneurysm, although the cause is uncertain. Possible mechanisms for the development of hydrocephalus include compression of the sylvian aqueduct by the aneurysmal mass and defective cerebrospinal fluid resorption resulting from intracranial venous hypertension (Gold et al., 1964; Diebler et al., 1981).

Cerebral damage including cerebral infarction, periventricular leukomalacia, and hemorrhagic infarction may also occur in association with aneurysm of the vein of Galen (Norman and Becker, 1974). Suggested mechanisms by which such cerebral parenchymal injury may occur include

1. a steal-induced ischemic phenomenon from overlying abnormal vessels;
2. cerebral ischemia due to compromised perfusion from congestive heart failure;
3. hemorrhagic infarction from thrombosis of the dilated vein of Galen;
4. atrophy resulting from compression of adjacent structures by the aneurysm;
5. alteration of flow occurring as a result of surgical therapy (Gold et al., 1964; Norman and Becker, 1974).

Vein of Galen aneurysms have been classified into four subtypes according to the severity of the lesion and the age of the patient at the onset of symptoms (Amacher and Shillito, 1973). Four groups have been described:

1. Neonates with severe heart failure and cranial bruit.
2. Children with mild heart failure and cranial bruit.
3. Children younger than 1 year of age with cranial bruit and hydrocephalus.
4. Patients with headaches and syncope.

Thrombosed vein of Galen aneurysm may also represent a fifth subtype (Beltramello et al., 1991). Congestive heart failure does not seem to be a feature of thrombosed vein of Galen aneurysm, as it is possible that occlusion of the aneurysm by the thrombosis may protect patients from this complication. In all cases of vein of Galen aneurysm thrombosis described to date, the initial presenting symptoms were attributed to hydrocephalus (Beltramello et al., 1991). Twenty-one cases of vein of Galen aneurysm thrombosis have been reported in the literature (Beltramello et al., 1991). Of these, 12 cases were diagnosed in patients younger than 1 year of age, 4 in patients between 1 and 14 years of age, and 5 in adults. Neuroradiology findings in vein of Galen aneurysm thrombosis include intracranial calcifications in the region of the vein of Galen in 50% of cases and a midline spherical mass, shown by computed tomographic (CT) scanning, that does not fill angiographically (Beltramello et al., 1991).

INCIDENCE

The true incidence of vein of Galen aneurysm is unknown, but it is an extremely rare abnormality. One of the largest reported series has described 43 cases that had been referred for endovascular treatment, together with a review of 335 additional cases previously reported in the literature (Zerah et al., 1992). More recently, there have been more than 30 cases of prenatal aneurysm of the vein of Galen diagnosed through the use of ultrasound and pulsed Doppler examination

(Suma et al., 1991; Rodesch et al., 1994; Pilu et al., 1997; Has et al., 2003; Paternoster et al., 2003). The largest single prenatal experience described 18 cases of vein of Galen aneurysm diagnosed in the third trimester (Rodesch et al., 1994).

SONOGRAPHIC FINDINGS

The typical prenatal sonographic finding is that of a cystic or tubular mass in the midline of the brain just above and behind the thalamus (Figure 22-1). A draining vessel may be seen extending posteriorly in the direction of the straight sinus. Around this central cystic mass, heterogeneous cystic areas may be present that represent dilated blood vessels (Figure 22-2) (Comstock and Kirk, 1991). Turbulent venous or arterial flow may be demonstrated using color Doppler examination within the draining vessel (Figure 22-1) (Jeanty et al., 1990; Sepulveda et al., 1995). Occasionally, turbulent flow may be seen within the cystic mass even without the aid of Doppler sonography (Comstock and Kirk, 1991).

Magnetic resonance imaging (MRI) appears to be an important adjunctive tool in patients suspected to have vein of Galen aneurysm prenatally. MRI can be used to confirm the diagnosis and to demonstrate the anatomical structure of the anomaly (Kurihara et al., 2001) (Figure 22-3). Both MRI and 3D ultrasound may be useful because they allow a better understanding of the spatial orientation and the course of the vessels and they may help guide the postnatal management (Heling et al., 2000; Lee et al., 2000; Has et al., 2003)

Appearance of the cerebral ventricles is variable. Hydrocephalus may be seen prenatally and seems to be unrelated to the size of the aneurysmal dilatation (Comstock and Kirk, 1991). The antenatal appearance of the heart is also variable, but generalized cardiomegaly or right ventricular enlargement is commonly noted (Comstock and Kirk, 1991). Enlargement of the heart should not be ascribed simply to presumed high-output cardiac failure until targeted fetal echocardiography is performed. Coarctation of the aorta and transposition of the great vessels occur with increased frequency in infants with vein of Galen aneurysm (Figure 22-3) and may also be responsible for cardiomegaly (Warkany, 1971; Watson et al., 1976). Massive hydrops has been reported as early as 31 weeks of gestation (Hirsch et al., 1983; Reiter et al.,

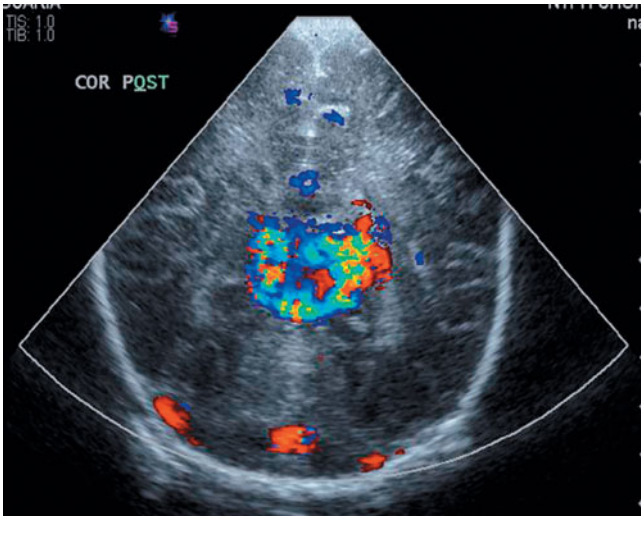

Figure 22-1 Prenatal sonographic image demonstrating midline cystic lesion suggestive of vein of Galen aneurysm in a 36-week fetus. Color Doppler demonstrates turbulent vascular flow.

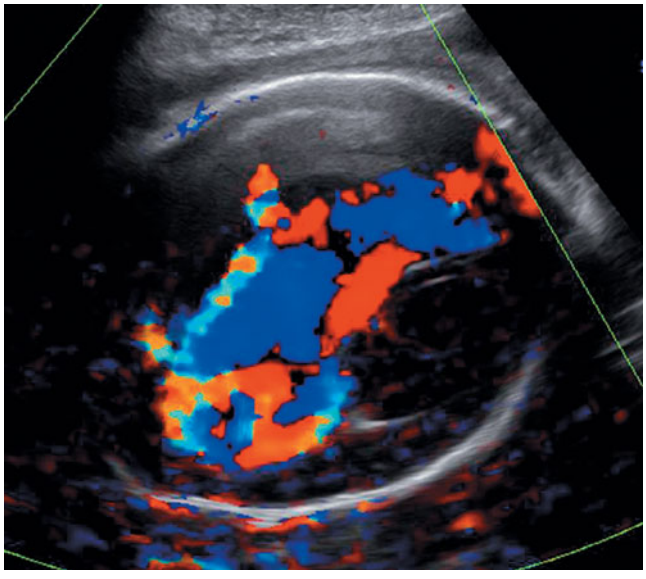

Figure 22-2 Doppler color flow studies demonstrating the presence of prominent convoluted vessels in a 33-week fetus with a large vein of Galen aneurysm.

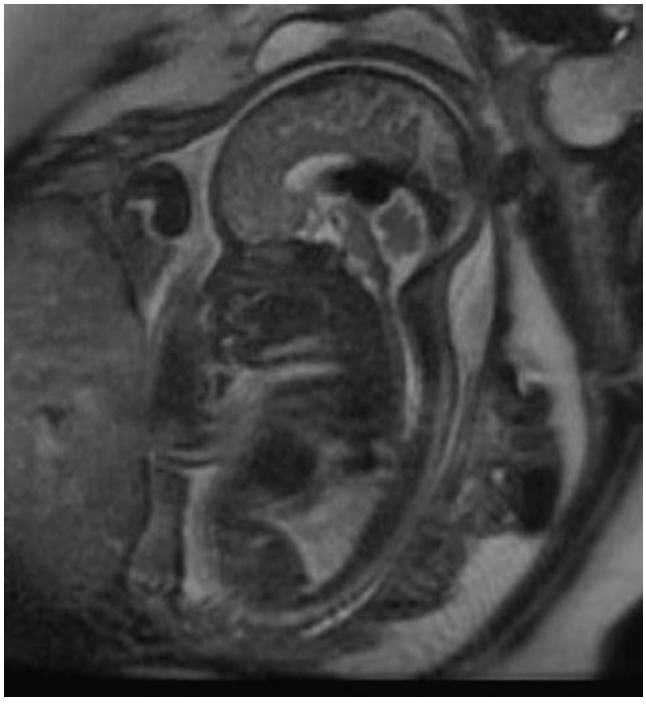

Figure 22-3 Magnetic resonance imaging of the same 36-week fetus demonstrates vein of Galen aneurysm in a sagittal plane.

1986). In addition, there have been autopsy reports of prenatal brain ischemia, periventricular leukomalacia, and cortical brain atrophy associated with vein of Galen aneurysm (Hirsch et al., 1983; Reiter et al., 1986; Baenziger et al., 1993).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of vein of Galen aneurysm includes other midline cystic masses within the brain, such as an arachnoid cyst or an interhemispheric cyst associated with agenesis of the corpus callosum. The major helpful diagnostic features of aneurysm of vein of Galen include the typical location of the cyst superior and posterior to the thalami and high-velocity blood flow within the cyst on Doppler examination (Figures 22-1 and 22-2). Neither an arachnoid cyst nor an interhemispheric cyst should demonstrate blood flow. A normal intracranial cystic structure, the quadrageminal cistern, may also mimic vein of Galen aneurysm in initial appearance, although in the case of a cistern, blood flow will not be demonstrable. The visualization of cardiomegaly or signs of congestive cardiac failure in utero add confirmatory evidence of an aneurysm of the vein of Galen. Prenatal MRI has been reported as a useful additional imaging tool in at least two cases in which vein of Galen aneurysm was suspected at prenatal ultrasonography (Yamashita et al., 1992; Martínez-Lage et al., 1993).

ANTENATAL NATURAL HISTORY

Because relatively few cases of prenatally diagnosed vein of Galen aneurysm have been reported in the literature, little is known about its antenatal natural history. The earliest prenatal diagnosis was made at 25 weeks of gestation, which was followed by an intrauterine fetal death at 28 weeks of gestation (Ballester et al., 1994). Most cases are not diagnosed until the third trimester, which limits the available knowledge on antenatal natural history (Suma et al., 1991; Rodesch et al., 1994).

The arteriovenous shunt develops in utero, but because of differences in the hemodynamics of the fetal and neonatal circulations, severe cardiac failure does not appear in most cases until after birth (Ciricillo et al., 1990). Fetal systemic vascular resistance is lower in the fetus because of the low placental resistance, and at birth, this resistance increases markedly as the placental circulation is removed. Following birth, low resistance remains within the cerebral arteriovenous fistula, which results in an abrupt increase in flow through the aneurysm and increased venous return to the right side of the heart. Pulmonary hypertension develops because of the resulting increase in pulmonary blood flow. Subsequently, right-to-left shunting at the atrial and ductal levels causes arterial hypoxemia. The increased diastolic flow to the aneurysm reduces coronary blood flow, which mainly occurs during diastole. Increased ventricular pressures also reduce subendocardial perfusion, which causes further myocardial ischemia and exacerbates cardiac failure. In the largest series of prenatally diagnosed vein of Galen aneurysms, there were no intrauterine fetal deaths, and the first clinical symptoms occurred in the newborn period in 94% of cases (Rodesch et al., 1994).

Although blood flow through a vascular malformation should be small in the fetus because of generally low systemic vascular resistance, there have also been reports of high-output cardiac failure occurring in utero with vein of Galen aneurysms (Hirsch et al., 1983; Reiter et al., 1986). These fetuses were hydropic as early as 31 weeks of gestation. At autopsy their brains exhibited periventricular leukomalacia and areas of diffuse microinfarction in both the gray and white matter. These autopsy findings were similar to the pathologic changes described in seven neonates with vein of Galen aneurysm (Norman and Becker, 1974). These observations demonstrate that in some cases irreversible brain ischemia may occur even before birth (Hirsch et al., 1983; Reiter et al., 1986).

MANAGEMENT OF PREGNANCY

Prenatal evaluation should include targeted sonography to exclude additional malformations, such as cerebral parenchyma destruction, as well as fetal echocardiography. Serial obstetric ultrasonography should be performed every 2 weeks to determine change in size of the aneurysm and to monitor for development of hydrocephalus or congestive cardiac failure. Karyotyping is not indicated. If there is any doubt about the diagnosis, prenatal MRI may help in making a definitive diagnosis of vein of Galen aneurysm (Martinez-Lage et al., 1993). In the unlikely event that the diagnosis is made before 24 weeks of gestation, termination should be offered because of the high perinatal mortality rate. However, most cases will present during the third trimester, thereby limiting options for parents (Suma et al., 1991; Rodesch et al., 1994). Subspecialty consultation with a pediatric cardiologist and a pediatric neurosurgeon is suggested because both the timing of neonatal surgical management and the prognosis will depend on the degree of cardiovascular involvement and the presence of parenchymal brain damage (Amacher and Shillito, 1973; Mickle et al., 1994).

Delivery should take place at a center where immediate neonatal consultation is available from subspecialists in pediatric neuroradiology, neurosurgery, and cardiology. No data are available regarding the optimal mode of delivery for fetuses with aneurysm of the vein of Galen (Doren et al., 1995). Elective delivery near term following confirmation of fetal lung maturity is reasonable. In one series, elective cesarean delivery was performed in many of the prenatally diagnosed cases (Suma et al., 1991). In another series of 18 cases of prenatally diagnosed vein of Galen aneurysm, there were 12 vaginal deliveries, five cesarean deliveries, and one induced abortion (Rodesch et al., 1994). If hydrocephalus and macrocephaly

are present, cesarean delivery is preferable. In the absence of associated hydrocephalus and macrocephaly, vaginal delivery with continuous intrapartum fetal heart rate monitoring is reasonable. Decreased intrapartum short- and long-term fetal heart rate variability in association with normal umbilical cord blood gas values was reported in one case in which an aneurysm of the vein of Galen was diagnosed in the neonatal period (Koh and Grundy, 1988).

FETAL INTERVENTION

There are no case reports of fetal intervention for vein of Galen aneurysm. Theoretically, if serial sonography demonstrates deteriorating cardiovascular status, early delivery might be an option to allow appropriate postnatal cardiovascular stabilization and neurosurgical treatment of the aneurysm.

TREATMENT OF THE NEWBORN

The clinical presentation of vein of Galen aneurysm depends on the age at which symptoms appear and on the amount of cardiovascular compromise that has been sustained (Amacher and Shillito, 1973; Diebler et al., 1981). The most severe presentation is in early neonatal life and consists of congestive heart failure and seizures. The possibility of an intracerebral arteriovenous fistula should be considered in any infant presenting with unexplained cardiac failure. In such cases, auscultation of the neonatal head for a cranial bruit may suggest the diagnosis, which can then be confirmed by cerebral ultrasound examination (O'Donnabhain and Duff, 1989). Death in the infant with vein of Galen aneurysm is usually caused by intractable cardiac failure associated with myocardial ischemia (McLeod et al., 1982), acute circulatory overload following ligation of a feeding vessel (Yasargil et al., 1976), or thrombosis of the aneurysm (Six et al., 1980).

The approach to therapy for the patient with a vein of Galen aneurysm depends on the age of the patient, the clinical symptoms, and the angiographic architecture of the malformation. Most patients diagnosed in utero will present with cardiac manifestations in early neonatal life (Suma et al., 1991; Rodesch et al., 1994). When vein of Galen aneurysm is suspected, confirmatory cerebral ultrasonography should be performed. Transcranial color Doppler ultrasound examination allows a rapid bedside diagnosis (Stockberger et al., 1993). Subsequent MRI with cerebral angiography will allow precise documentation of the abnormal vascular anatomy.

Pediatric cardiology consultation together with echocardiographic evaluation is important for assessing and treating associated congestive cardiac failure. In one series of prenatally diagnosed vein of Galen aneurysms, 12 of 16 newborns with cardiac symptoms were initially managed effectively with digitalization and diuretic therapy (Rodesch et al., 1994). Four of these infants died shortly after birth from acute heart failure or multiorgan failure with extensive brain damage. However, the majority of patients who are symptomatic at birth will require more aggressive intervention with either surgery or interventional radiology. Infants who are asymptomatic at birth should be treated expectantly, with follow-up radiologic imaging at 6 months of age. If the malformation persists, treatment is usually administered between 6 and 9 months of age.

SURGICAL TREATMENT

The first attempt at a direct neurosurgical approach for treatment of an infant with vein of Galen aneurysm was reported in 1947 (Osherwitz and Davidoff, 1947). Subsequently, another patient was successfully treated by clipping the posterior cerebral arteries feeding the malformation (Boldry and Miller, 1949). Open surgical intervention via craniotomy was the primary method of treatment of vein of Galen aneurysms until the early 1980s, although results were disappointing (Hoffman et al., 1982; Johnston et al., 1987). Subsequently, interventional neuroradiologic techniques have become the method of choice for treatment of these lesions. Initial imaging studies with CT scanning or MRI are suggested for patient selection before neurosurgical or radiologic intervention (Mickle and Quisling, 1994). Patients with severe multicystic encephalomalacia or other significant neurologic injury should not be considered candidates for aggressive therapy.

Most authors now agree that the main goal of therapy in the neonate with vein of Galen aneurysm and congestive heart failure is not complete occlusion of the aneurysm but improvement in cardiac function (Matjasko et al., 1988; Ciricillo et al., 1990; Horowitz et al., 1994).

Transvenous and transarterial embolization techniques have been increasingly described in the literature (Mickle and Quisling, 1986; Ciricillo et al., 1990; Lasjaunias et al., 1991). In the infant with congestive heart failure the initial procedure of choice appears to be endovascular, with a venous approach, either transfemoral or transtorcular (Horowitz et al., 1994; Mickle et al., 1994). The immediate goal is to increase resistance in the aneurysm to right ventricular output. The advantages of a transvenous approach over a transarterial approach include shorter anesthesia time and minimal contrast administration (Horowitz et al., 1994). The transvenous approach can be repeated as many times as needed and may be supplemented by transarterial embolizations. Endovascular coils are commonly used for venous embolizations (Horowitz et al., 1994). Another advantage of repeated embolizations with the transvenous approach is a graded thrombosis of the aneurysm, which may serve to minimize the risk of hemorrhage and neurologic injury (Horowitz et al., 1994).

Color and pulsed Doppler ultrasound examinations are useful in the evaluation of the success of interventional radiologic techniques. Pulsed Doppler analysis in the proximal descending aorta demonstrating diastolic retrograde velocity exceeding 20% to 25% of the systolic antegrade velocity

suggests that the aneurysm is still very large and that further interventional treatment is required (Ciricillo et al., 1990).

Survival statistics following interventional neuroradiologic techniques for the treatment of vein of Galen aneurysm appear to be substantially better than with open surgical procedures. In a review of experience with vein of Galen aneurysm at the University of California at San Francisco, five infants underwent craniotomy and clipping of feeding vessels between 1978 and 1983, and all died in the perioperative period (Ciricillo et al., 1990). Since 1983, at least eight neonates have been treated with interventional neuroradiologic embolization techniques; six survived (Ciricillo et al., 1990). In a more recent series of 11 cases, there was no infant mortality following therapy with embolization techniques (Friedman et al., 1993). Approximately 50% of neonates suffering from severe progressive cardiac failure can be expected to survive following such embolization techniques (Mickle and Quisling, 1994).

LONG-TERM OUTCOME

Little information is available on the long-term follow-up of prenatally diagnosed cases of vein of Galen aneurysm. In one series of 18 patients diagnosed prenatally, 13 infants survived the immediate neonatal period and 12 underwent embolization of the aneurysm (Rodesch et al., 1994). Total occlusion of the aneurysm was obtained in eight cases. Sixty-seven percent of the surviving newborns were neurologically normal when assessed with Denver Development Tests (Rodesch et al., 1994).

In another series of 22 patients with vein of Galen aneurysm treated with embolization techniques, there was a 50% mortality rate and a 37% incidence of severe mental retardation in survivors of procedures performed soon after the introduction of the technique (Friedman et al., 1993). For procedures performed after modification of the original technique, there was no mortality, and 6 of the 11 patients were functionally normal at 30 months of follow-up. Two patients had severe neurologic deficiency, and some developmental delay was observed in one other patient. The improvement in outcome results was attributed to earlier diagnosis, improvement in the microcatheters used for embolization, avoidance of overly aggressive neurosurgical procedures, and general improvements in neonatal care (Friedman et al., 1993). In addition, when vein of Galen aneurysm first presents in the older child, results of therapy are more favorable, with mortality rates as low as 20% (Hoffman et al., 1982).

Infants who require shunting for hydrocephalus with vein of Galen aneurysm appear to have a less favorable neurologic outcome (Zerah et al., 1992). For these infants, a significant difference in the clinical outcome was noted between the groups with shunting and those with no shunting (Zerah et al., 1992). Of the patients without shunts, 67% were free of any neurologic deficit or mental retardation, and fewer than 5% had significant mental retardation. In contrast, only 33% of the patients with a shunt had a favorable outcome, and significant mental retardation developed in more than 15% (Zerah et al., 1992). The authors' conclusion was that treatment of hydrocephalus in vein of Galen aneurysm can be achieved through obliteration of the malformation and that shunting should not be the preferred treatment for hydrocephalus in this condition.

The prognosis for patients with thrombosed vein of Galen aneurysm seems to be more favorable. The impact of treatment on outcome for thrombosed vein of Galen aneurysms is controversial. Some authors believe a clotted vein of Galen aneurysm may constitute a risk to the motor and mental development of the patient, whereas others feel that the thrombosed vein may shrink or fibrose without intervention and therefore may not be clinically significant (Six et al., 1980). In one case report of thrombosed vein of Galen aneurysm, spontaneous resolution of hydrocephalus occurred, and shunting was unnecessary (Six et al., 1980). In two other cases radiologic evidence of progressive shrinking of the clotted aneurysm to a residual inert calcification was demonstrated, without the need for therapeutic intervention (Beltramello et al., 1991).

GENETICS AND RECURRENCE RISK

There have been no reported cases of recurrent vein of Galen aneurysm. The inheritance pattern appears to be sporadic.

Cleft Lip and Cleft Palate

23 CHAPTER

Key Points

- Overall incidence is 1 in 700 births. Marked ethnic and racial variation occurs in cleft lip with or without cleft palate.
- Seventy percent of cases are nonsyndromic, 30% are syndromic based on the presence of other anomalies and/or developmental delay.
- 2D sonographic detection rate of orofacial clefts is on the order of 65% to 73% of cases. 3D sonography allows better visualization of defects in the palate and MRI allows assessment of secondary palate.
- If a suspected orofacial cleft is diagnosed, referral should be made to a level II facility. Prenatal karyotype should be considered. There is a high rate of associated anomalies, particularly of the heart and central nervous system.
- Fetal treatment has been performed on animals.
- Long-term issues include midface hypoplasia, facial appearance, dental abnormalities, speech disorders, and hearing problems.
- More than 400 single-gene disorders are associated with cleft lip and palate. A family history should be obtained, and parents should be examined for subtle findings such as bifid uvula and missing teeth.
- At birth a thorough physical examination should be performed and a medical geneticist should be consulted. Many infants are treated by a multidisciplinary team that includes emphasis on feeding and adequate nutrition.

CONDITION

Cleft lip and palate are relatively common facial malformations that occur early in gestation. Although they are distinct anomalies, they frequently occur together (Seeds and Cefalo, 1983). In all cases of orofacial clefting, 60% to 75% involve cleft lip, with or without cleft palate, and 25% to 40% are isolated cleft palate (Figure 23-1). Most cases (80%) are unilateral, occurring twice as commonly on the left side as on the right (Gorlin et al., 1971; Seeds and Cefalo, 1983; Bronshtein et al., 1991). Isolated cleft palate is more frequently associated with other anomalies (Jones, 1988a).

Orofacial clefts derive from abnormalities in the migration and proliferation of facial mesenchyme, a neural crest cell derivative. Coalescence of facial mesenchyme results in the formation of the primary palate, which creates the initial separation between oral and nasal cavities, eventually creating part of the upper lip and anterior maxilla (Ross and Johnston, 1972). Cleft lip with or without cleft palate results from failure of the nasal and maxillary facial processes to fuse. Fusion of these processes may be affected by the amount of

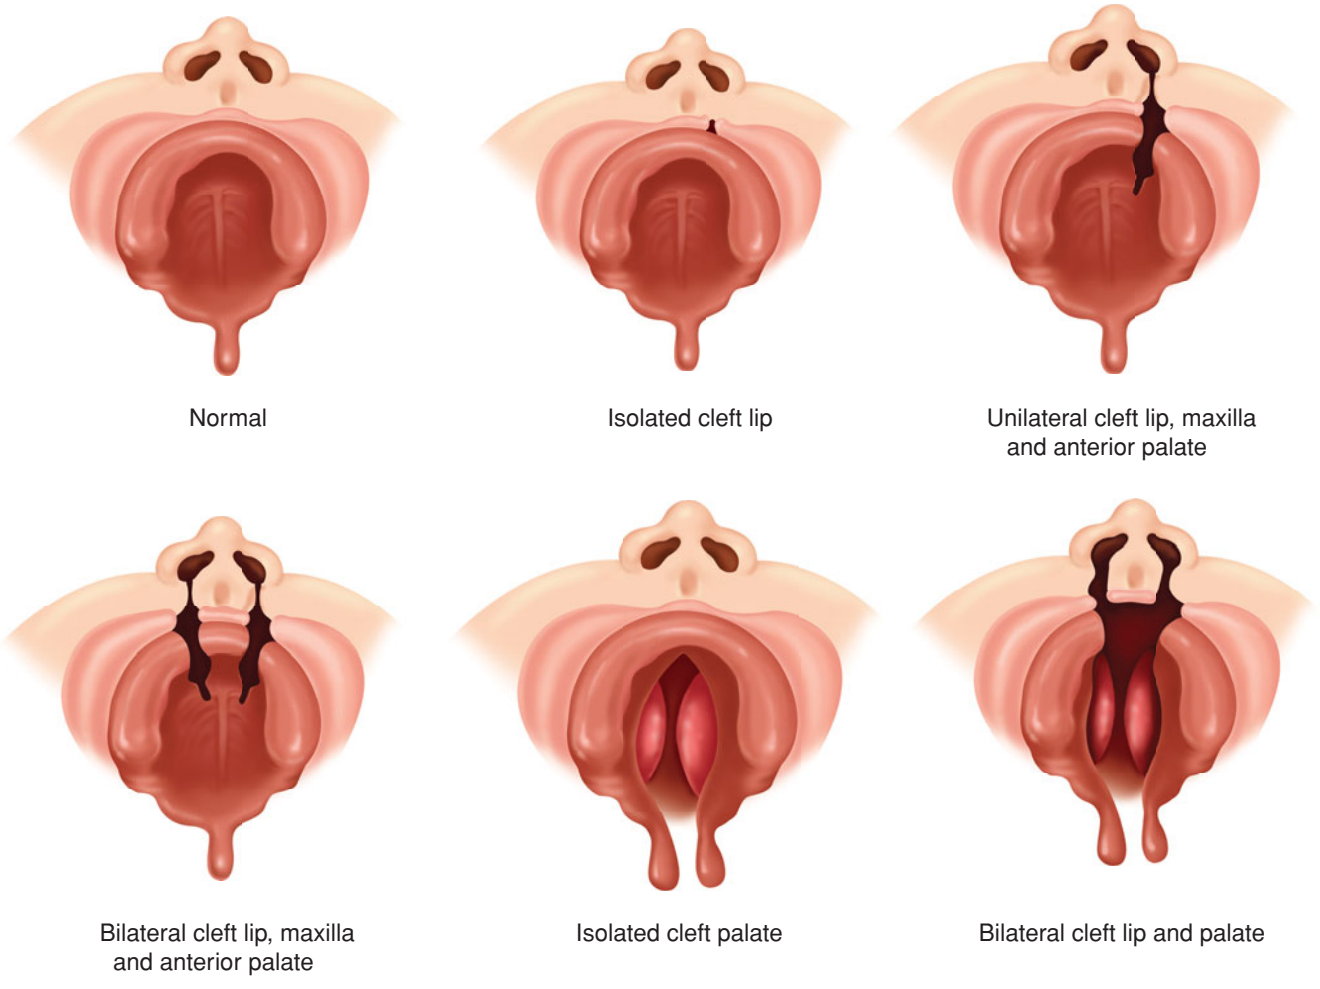

Figure 23-1 Schematic representation of the different types of malformations found in cases of orofacial clefting. The perspective is from the inside of the mouth looking upward toward the nose.

mesenchyme present, its rate of migration, and the distance over which this migration occurs (Lynch and Kimberling, 1981).

Fifty percent of cleft lip patients also have cleft palate, which is a secondary effect resulting from a defect in facial prominence fusion that precedes palate formation. Isolated cleft palate has a different pathophysiology than either cleft lip or cleft lip associated with cleft palate. It results from interference in any of the following processes that occur during normal closure of the palate:

1. The palatal shelves move from bilateral vertical positions lateral to each side of the tongue to horizontal positions overlying the tongue.
2. The tongue exerts resistance to the movement of the palatal shelves.
3. The tongue moves downward to below the palatal shelves.
4. The horizontal palatal shelves become flattened and extend their leading edges toward the midline.
5. The shelves meet in the midline and fuse. Their respective epithelia then dissolve at the point of contact (Lynch and Kimberling, 1981).

From the description above, it is apparent that the tongue plays a role in the etiology of cleft palate. Any factor that interferes with downward displacement of the tongue, tongue movement, or tongue pressure may interfere with palatal fusion.

INCIDENCE

The worldwide incidence of cleft lip with or without cleft palate is 1 in 700 births (Murray, 2002). Marked variation occurs in different racial and ethnic groups. Black infants have a lower incidence (1 in 2273 births), whereas the incidence among Japanese and Native Americans is higher (1 in 584 and 1 in 276, respectively) (Tretsven, 1963; Lynch and Kimberling, 1981). Isolated cleft palate occurs more rarely and does not vary in different ethnic backgrounds. Cleft lip and palate occur twice as often in males as in females (Bronshtein et al., 1991). In some studies, orofacial clefting has been shown to occur more commonly in fetuses whose mothers are of advanced age (Womersley and Stone, 1987; Shaw et al., 1991);

in a large population-based registry, however, no association between maternal age and cleft disorders was seen (Baird et al., 1994). Maternal smoking and alcohol use during pregnancy are thought to increase the incidence of clefts through gene-environment interactions (Eppley et al., 2005). Periconceptual multivitamin use, specifically folate supplementation, decreases the incidence of cleft palate (Werler et al., 1999, Eppley et al., 2005).

SONOGRAPHIC FINDINGS

Although fusion of the midline structures of the fetal face is complete by 7 weeks of gestation, the mandible and maxilla are not clearly visualized sonographically until week 10 (Cockell and Lees, 2000). Cleft lip and palate cannot be reliably diagnosed until 13 to 14 weeks by transabdominal sonography. The fetal palate is best observed in the axial plane and the fetal lips in the coronal views. Seeds and Cefalo (1983) were the first investigators to advocate a combination of frontal and coronal scanning of the midface (Figure 23-2). In 1984, Benacerraf et al. recommended routinely examining the face as part of a complete antenatal sonographic examination. They described a coronal view through fetal facial structures that encompassed both orbits, the maxilla, and the anterior portion of the mandible in one vertical plane. Sherer et al. (1991) described an oblique coronal facial view that was achieved by aiming the transducer beneath the fetal chin using the nares as a landmark. They sought echogenic evidence of an intact fissure created by the closed lips. The two advantages of this approach are that rarely was this view unobtainable due to position of the fetus and that the appearance of the philtrum was clearly defined. Using a combination of transverse, coronal, and profile views, Turner and Twining (1993) were able to define fetal facial structures in 95% to 97% of fetuses at 16 to 20 weeks of gestation.

Figure 23-2 Coronal facial view of fetus at 23 weeks with a midline cleft lip. Arrow indicates the site of the cleft.

Bronshtein et al. (1994) described the use of transvaginal sonography to detect facial clefts in the early second trimester. In 14,988 examinations performed, 11 cases of orofacial clefts were detected. Of these, 10 were cases of cleft lip and palate and 1 was isolated cleft lip. All diagnoses were confirmed after termination of the pregnancy or at birth.

Despite these studies, sonographic diagnosis of facial clefts remains challenging. The overall detection rate is currently on the order of 65% (Cash et al., 2001) to 73% (Robinson et al., 2001). In general, cleft lip is easier to demonstrate than cleft palate. Bronshtein et al. (1991) advocated the use of the sagittal paramedian view to detect pseudoprognathism, a protrusion of the mandible relative to the maxilla. In bilateral cleft lip and palate, a paranasal echogenic mass may be present due to premaxillary protrusion of the prolabial structure that exists in this condition (Nyberg et al., 1992, 1993). Sherer et al. (1993) have advocated for the use of color Doppler imaging to demonstrate abnormal amniotic fluid flow across the fetal pharyngeal bone defect, although this technique has not gained widespread acceptance and is of uncertain value.

Because of the challenges associated with the 2D sonographic diagnosis of orofacial clefts, several authors advocate for a 3D approach (Figures 23-3A and 23-3B). One study examined the use of 3D sonographic visualization of fetal tooth buds as a means of improving antenatal characterization of fetal facial clefts (Ulm et al., 1999). In all 17 fetuses studied, it was possible to classify the clefts as either cleft lip alone or unilateral or bilateral cleft lip and palate. Lee et al. (2000) described a standardized 3D protocol that included multiplanar imaging of the upper lips and sequential axial views to evaluate the alveolar ridge contour and anterior tooth socket alignment.

More recently, 3D ultrasound has been used to evaluate the anatomy of the fetal palate from within the fetal head. Using this technique, a 3D volume of the fetal head is obtained and then a cut volume of tissue is removed from the back of the head. By rotating the remaining volume containing the anterior part of the face and head, the fetal palate can then be inspected from behind the face, revealing the interior of the mouth (Platt et al., 2006). Alveolar ridge disruption, or premaxillary protrusion (by multiplanar imaging or surface rendering) suggests the presence of bilateral cleft lip and palate. Additional advantages of 3D sonography include the fact that it allows assessment of the secondary (posterior) palate, it saves time, and that it is easier for prospective parents to visualize the defect (Rotten and Levaillant, 2004).

Fetal MRI is being increasingly used to evaluate structures that are difficult to identify by sonography alone. With MRI, the fetal nose and lips are best seen with coronal images. The secondary palate is best seen when amniotic fluid fills the mouth and outlines the tongue and palate (Smith et al., 2004). A major advantage of MRI appears to be that it allows a more accurate assessment of the secondary palate, which cannot be seen by 2D sonography (Ghi et al., 2003; Kazan-Tannus et al., 2005).

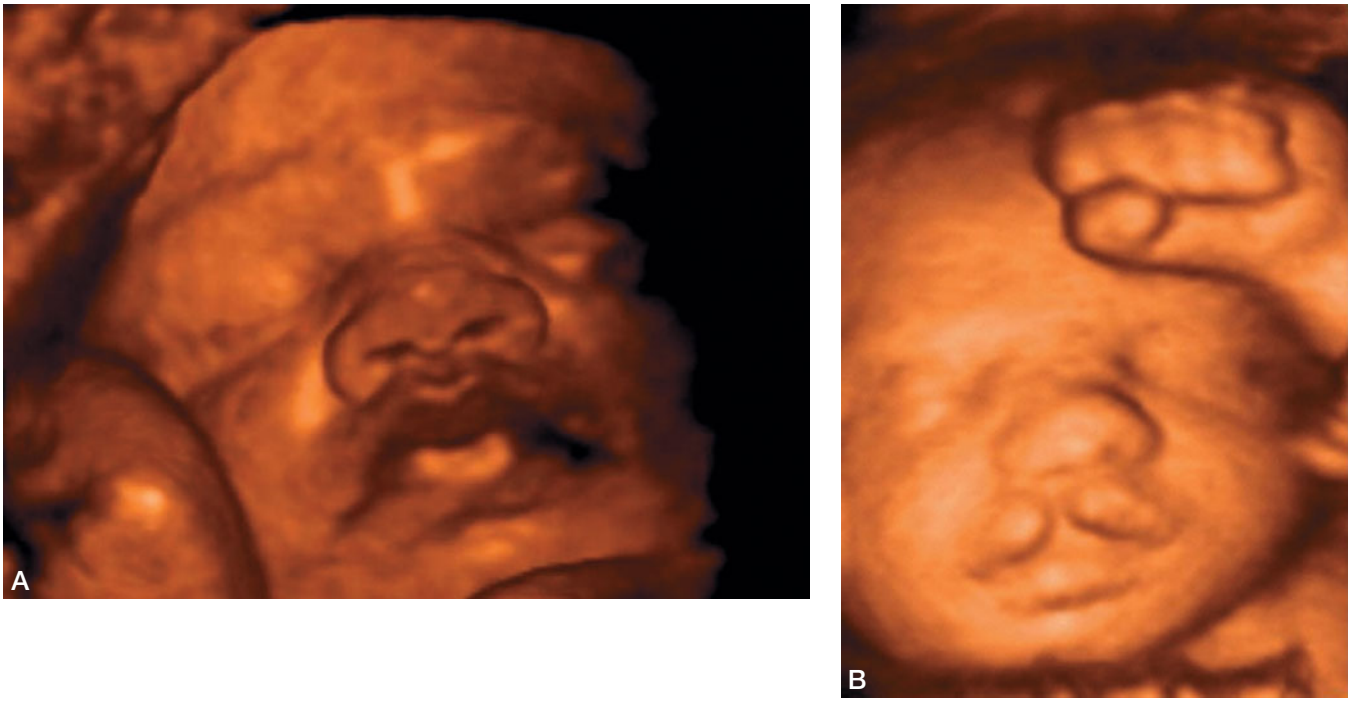

Figure 23-3 **A**. Three-dimensional ultrasound image of normal fetal face and lips. **B**. Three-dimensional ultrasound image of a fetus with a right unilateral cleft lip.

DIFFERENTIAL DIAGNOSIS

The most important consideration in the differential diagnosis of cleft lip is to distinguish between the normal vertical midline appearance of the philtrum and a pathologic median cleft lip. Although most cleft lips are left-sided and unilateral, a median cleft lip can be associated with syndromes such as orofacialdigital, type I, or frontonasal dysplasia. Consideration should also be given to detection of premaxillary agenesis, which is almost always associated with alobar holoprosencephaly (see Chapter 14).

When a paranasal echogenic mass is detected in cases of bilateral cleft lip and palate, the differential diagnosis includes hemangioma, anterior meningocele, teratoma, and enlarged tongue and proboscis (Nyberg et al., 1992). Of these conditions, only premaxillary protrusion associated with cleft lip and palate contains bone within the mass, resulting from anterior migration of maxillary and alveolar bones (Nyberg et al., 1992).

Once a cleft is identified, a diligent search should be made to detect associated anomalies. The finding of additional anomalies will significantly affect the differential diagnosis. More than 400 syndromes are associated with facial clefts (Shprintzen et al., 1985; Lidral and Murray, 2004). Common syndromes include Goldenhar (facioauriculovertebral dysplasia), Treacher–Collins (mandibulofacial dysostosis), Pierre–Robin, Stickler, DiGeorge, and Shprintzen (velocardiofacial) (Table 23-1). Additional anomalies seen in cases of Pierre–Robin sequence include micrognathia and polyhydramnios (Hsieh et al., 1999). Neurologic and myopathic conditions such as Stickler syndrome, can be associated with cleft palate. Syndromes that involve relatively broad faces, such as Crouzon and Waardenburg, are associated with an increased incidence of facial clefts.

ANTENATAL NATURAL HISTORY

Cleft lip and palate are seen more frequently in first trimester abortuses than in newborns. In one study of 3216 pregnancy losses, Kraus et al. (1963) demonstrated that 11.5% of fetuses spontaneously aborted at 8 weeks of gestation, 1.8% of abortuses at 6 to 19 weeks of gestation, and 0.16% of liveborn infants had orofacial clefts. Thus, fetuses with cleft lip and palate are at increased risk for intrauterine demise. The risk for fetal loss is related to the presence of associated anomalies, which were found in 61.7% of cases studied (Kraus et al., 1963).

In general, the antenatal detection of a facial cleft is more likely to be associated with other malformations than is the detection of a cleft at birth. In one study, Saltzman et al. (1986) described 12 cases of orofacial clefts diagnosed prenatally. Other malformations were detected in 10 (83%) of these fetuses. The chromosomes of 7 of these fetuses were studied prenatally or postnatally; 4 were abnormal due to trisomy 13 or 18. In a slightly larger study, Turner and Twining

Table 23-1

Common Syndromes Associated with Facial Clefts

Syndrome	Associated Findings
Goldenhar (facioauriculovertebral dysplasia)	Asymmetric facial hypoplasia, microtia, preauricular skin tags, hemivertebrae, cardiac defects
Pierre–Robin sequence	Micrognathia, U-shaped cleft of soft palate
Shprintzen (velocardiofacial syndrome)	Cardiac defects, hypotonia, growth restriction, chromosome 22q microdeletion; autosomal dominant
Stickler (hereditary arthro-ophthalmopathy)	Flat facies, micrognathia, hypotonia, myopia, scoliosis; autosomal dominant
Treacher–Collins (mandibulofacial dysostosis)	Malar and mandibular hypoplasia, downslanting palpebral fissures, ear malformations, absent lower eyelashes; autosomal dominant
Trisomy 13	Polydactyly, congenital heart disease, central nervous system abnormalities
Trisomy 18	Intrauterine growth restriction, congenital heart disease
Van der Woude (lip pit–cleft lip syndrome)	Lower lip pits, missing teeth; autosomal dominant

(1993) demonstrated additional anomalies in 88% of fetuses with facial clefts. Notable in this study were the large number of fetuses (9) with clefts and skeletal dysplasia. Benacerraf and Mulliken (1993) described a group of 32 fetuses at 16 to 40 weeks of gestation and over a 3.5-year period ascertained that 17 (53%) had associated anomalies. Five cases of trisomy 13 and 1 case of trisomy 18 were reported, giving a 35% rate of chromosomal aneuploidy in the setting of cleft with multiple anomalies. The associated malformations involved the central nervous system (11 cases), heart (9), kidneys (9), skeleton (10), and abdomen (2). Among the 15 fetuses without associated anomalies, 4 were terminated electively, 1 spontaneously aborted, 1 died from pulmonic stenosis and vertebral anomalies, and 9 survived and underwent successful postnatal surgical correction.

In postnatal studies, approximately 25% of infants with clefts have associated malformations (Kraus et al., 1963). Isolated cleft lip has the lowest frequency (range 7–45% of cases). The highest incidence of multiple and complex anomalies occurs with isolated cleft palate (range 13–72% of cases) (Gorlin et al., 1971; Shprintzen et al., 1985; Jones, 1988a; Ademiluyi et al., 1989). Shprintzen et al. (1985) described an extensive study of 1000 patients attending a craniofacial clinic, all of whom were seen by a clinical geneticist for a thorough dysmorphology examination. Associated anomalies were documented in 63.4% of patients. Craniofacial anomalies were most frequently represented, but short stature, microcephaly, and mental retardation (in 28% of cases) were also common findings.

MANAGEMENT OF PREGNANCY

The suspected diagnosis of orofacial cleft necessitates a thorough search for associated anomalies, ideally at a sonographic facility with experience in prenatal diagnosis of anatomic defects. Prenatal karyotyping should be considered in all cases following the diagnosis of orofacial clefing, but in particular if a facial cleft and additional anomalies are demonstrated. Orofacial clefting is seen in 75% of cases of trisomy 13 (particularly midline clefting), 15% of cases of trisomy 18, 1.5% of cases of trisomy 21, and as stated earlier, approximately 0.1% to 0.15% of chromosomally normal fetuses (Warkany, 1971). In a study of 263 fetuses and neonates with cleft lip +/− cleft palate performed by the Utah Birth Defect Network, 15 (5.7%) had aneuploidy (Walker et al., 2001). Aneuploidy was more likely to be present if there was bilateral cleft lip and palate. If a karyotype is performed, additional consideration should be given to fluorescence in situ hybridization (FISH) studies to rule out a microdeletion of chromosome 22 that is associated with DiGeorge and Shprintzen syndromes or molecular cytogenetic studies using array-CGH. Because the infant will require multiple operations postnatally, the

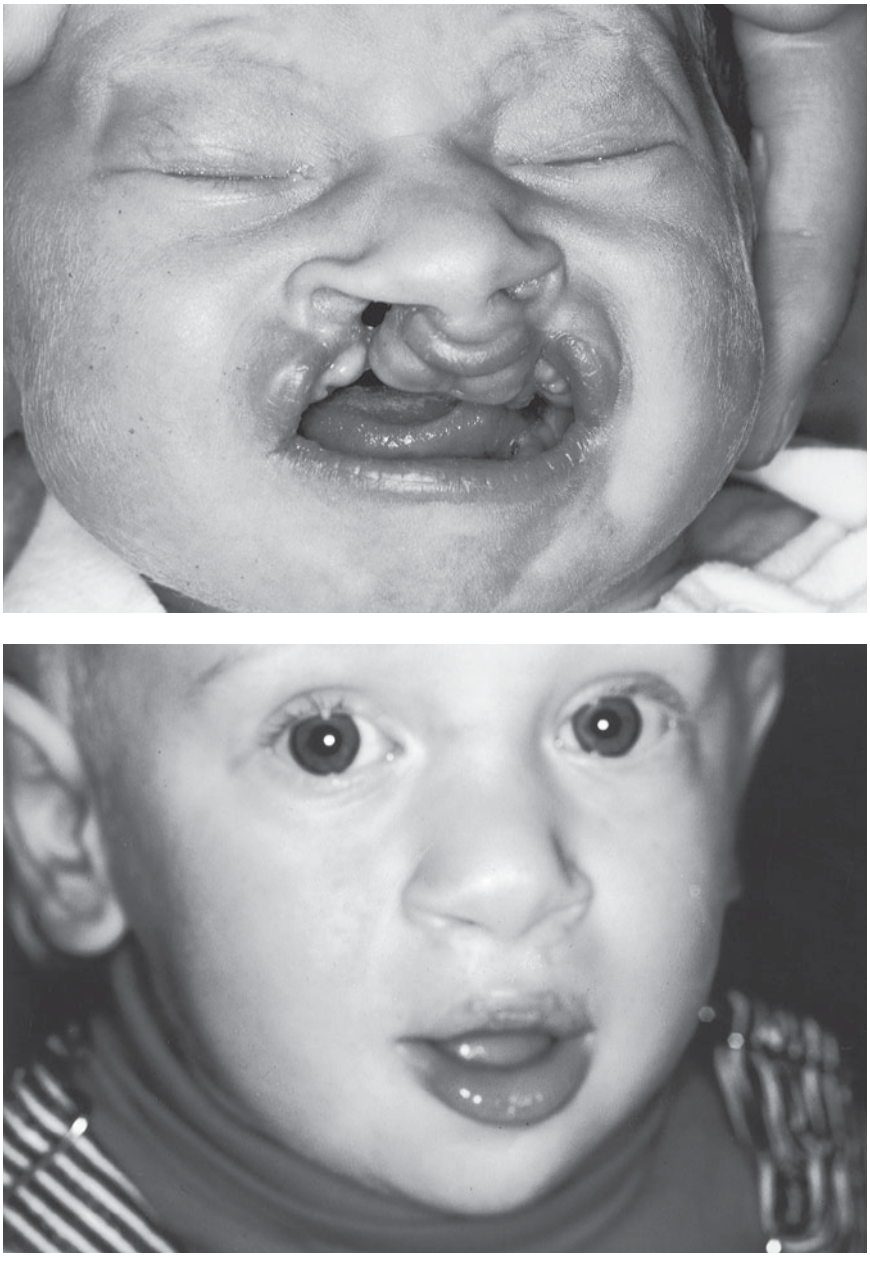

Figure 23-4 *Top*: Postnatal photograph of an infant who was diagnosed at 20 weeks of gestation with a bilateral cleft lip and palate. *Bottom*: Follow-up photograph of the same patient at 1 year of age following complete surgical repair. (*Courtesy of Dr. Michael Lewis.*)

presence of an abnormal karyotype may influence the parents' decisions regarding continuation of the pregnancy.

For the fetus with an apparently isolated cleft lip located lateral to the midline, the recommendations are less clear. There is no evidence in the medical literature of a case of unilateral isolated cleft lip diagnosed antenatally associated with an abnormal karyotype. On the other hand, even cleft lip has a significant rate of associated major anomalies in postnatal studies [7% in the Walker et al. (2001) study]. Thus, while the yield of cytogenetic abnormal results is likely to be extremely low, we recommend discussing with prospective parents the risk of the amniocentesis procedure versus the perceived benefits of knowing that the fetal chromosomes are normal.

Other than sonographic examination and karyotype, management of the pregnancy should continue in a routine manner. Fetuses with isolated cleft lip and palate can be delivered in a community hospital. Fetuses with multiple anomalies should be delivered in a setting where qualified subspecialists are available for newborn resuscitation, syndromic diagnosis, and therapy. We recommend that the prospective parents meet with a pediatric craniofacial surgeon soon after the antenatal diagnosis of facial cleft to discuss the steps involved in surgical treatment. Parents can then have the opportunity to observe the physical appearance of children with repaired facial clefts (Figure 23-4).

FETAL INTERVENTION

Because the fetal skin has unique scarless wound-healing properties, in utero repair of fetal facial clefts has been

proposed (Dado et al., 1990; Strauss and Davis, 1990; Longaker et al., 1991). It is well recognized that the characteristic facies following repair of cleft lip and palate, with midface retrusion and maxillary deficiency, are often the result of surgical scar formation that inhibits facial and maxillary growth. Because studies of mice and sheep have demonstrated that scarless cleft lip repair is possible antenatally, some have postulated that in the presence of normal functional maturity in the growing fetus, human facial appearance would be enhanced by the absence of scar and unimpaired facial growth.

To date, most research has focused on the use of animal models, such as the goat and sheep. The successful in utero repair of a teratogen-induced congenital cleft palate has been described in the goat (Weinzweig et al., 1999). In a sheep model, Papadopulos et al. (2005) have described the use of bone regenerating implants such as collagen lypophilisate, to fill in the maxillary alveolar defect created by cleft palate.

TREATMENT OF THE NEWBORN

Studies have shown that infants with clefting disorders have lower mean birth and placental weights than normal infants (Lilius and Nordstrom, 1992). The immediate concerns in treatment of the newborn infant with a cleft involve clearing of the airway and the ability to feed. Many hospitals have specialized feeding teams or individuals available with expertise in feeding infants with orofacial clefts. It is wise to involve these specialists early to help select a nipple and advise parents on feeding techniques. Breast feeding is possible but considerably more difficult than for the infant without a cleft palate. Infants with isolated cleft lip feed most easily and grow the most quickly. The mean weekly weight gain for all infants with clefts is 145 g, which is lower than the rate in normal infants (Jones, 1988b). This may be due to the nipple rubbing against the delicate nasal mucosa, which causes ulceration.

The infant with a cleft requires a thorough physical examination to look for associated anomalies that may have been missed on sonographic examination. If additional anomalies are detected, the infant should be referred to a medical geneticist. One author recommends consideration of an ophthalmologic evaluation during the first year of life in all infants with cleft palate because of the relatively high frequency of Stickler syndrome (Jones, 1988a). Severe myopia, glaucoma, and retinal detachment can develop in individuals affected with Stickler syndrome, but the disorder may be extremely difficult to diagnose during infancy. Chromosome analysis, including a FISH test to rule out microdeletion of chromosome 22, should be considered in all infants with cleft palate.

Subsequent treatment of the infant should occur in the setting of a cleft palate multidisciplinary team approach (NIH Consensus Panel, 1993). Hearing should be assessed as soon as possible. A plan should be made in conjunction with the primary pediatrician to ensure weekly assessment of nutritional intake and weight gain during the first month of life.

SURGICAL TREATMENT

The exact time of the first surgical repair depends on the anatomy of the malformation. For a unilateral complete cleft, a preliminary lip–nasal adhesion is often performed within the first month of life, followed by the more definitive repair at 4 to 6 months of age. For a unilateral or bilateral incomplete cleft, nose and lip correction can be performed any time within the first 6 months of life. For a bilateral complete cleft lip and palate, presurgical maxillary orthodontics may be indicated prior to surgical closure of the lip within the first few weeks (see Figure 23-3A). Bilateral cleft lip and nose correction and closure of the alveolar cleft are performed at 4 to 6 months (see Figure 23-3B) (NIH Consensus Panel, 1993). For lip repairs, the infant stays in the hospital for 1 day; for palate repairs, 2 days. In otherwise healthy infants, there is virtually no mortality associated with these procedures (Dado et al., 1990).

Surgical closure of the hard and soft palate is usually complete by 1 year of age. The goal of palate surgery is to restore normal function. Generally, speech results are excellent in 75% to 85% of children, with no need for further surgical procedures. In the small percentage of children in whom velopharyngeal insufficiency persists, secondary surgical procedures can be performed at 3 to 7 years of age, bringing the percentage of children with normal speech to 90% to 95%.

LONG-TERM OUTCOME

The salient long-term issues for a child with cleft lip and palate include midface hypoplasia, appearance (and related psychologic problems), dental abnormalities, speech disorders, and hearing problems (Felix-Schollaart et al., 1992). Cleft palate has also been shown to be associated with olfactory deficits, more often in boys than in girls (Richman et al., 1988). Children with cleft lip and palate are prone to multiple progressive problems as they grow. As many as 25% to 35% have speech abnormalities requiring secondary palate surgery and speech therapy. All children with cleft palate require speech evaluation, and some will need therapy. Speech and language evaluations are recommended at least annually until 4 years of age (NIH Consensus Panel, 1993). In addition, there are secondary defects that result from the surgical corrective procedures. In patients with unilateral cleft lip and palate, a secondary nasal deformity from a depressed alar base and tip and deviation of the septum can exist. Bilateral cleft lip–cleft palate deformity predisposes to bilateral widening of the alar base and a short columella. Scarring from surgical repair results in midface growth deficiency, with maxillary retrusion and relative mandibular prognathism (Hallock, 1985).

Infants with cleft lip and palate have hearing abnormalities that begin surprisingly early in postnatal life. They require frequent and ongoing audiologic surveillance (NIH Consensus Panel, 1993). In one study of 23 infants younger than 1 year of age, only 2 had normal hearing at age 6 months (Hélias et al., 1988). Of the 19 infants affected by hearing abnormalities, evidence of conduction deafness was documented by abnormal brainstem auditory-evoked responses. Fifteen infants had chronic otitis media with effusion, presumably due to the fact that the eustachian tube is smaller in patients with cleft palate. Obstruction of the eustachian tube is related to the inability of the tensor veli palatine muscle to dilate the eustachian tube actively during swallowing (Hélias et al., 1988). Early myringotomy with placement of bilateral tympanotomy tubes improved hearing acuity and consonant articulation in patients with cleft palate (Hubbard et al., 1985; Grant et al., 1988).

Common dental anomalies include missing, extra, or malpositioned teeth. In infants with cleft lip and palate, deciduous tooth formation and eruption is normal, but permanent dentition may be delayed (Poyry and Ranta, 1986; Poyry et al., 1989). Almost all children with cleft palate defects will require fixed orthodontic appliances (braces) on their permanent teeth. During the period of mixed dentition, removable or fixed appliances may be necessary for expansion and alignment of the incisors (Asher-McDade and Shaw, 1990).

Regular psychologic screening, preferably by an expert in craniofacial disorders, is also recommended to assess the child's cognitive development, behavior, and self-image (NIH Consensus Panel, 1993).

GENETICS AND RECURRENCE RISK

Cleft lip and palate are classified as isolated (nonsydromic) (70% of cases) or syndromic (30% of cases), based on the presence of other anomalies and/or developmental delay. The Online Mendelian Inheritance in Man (OMIM) catalog lists more that 400 single-gene causes of cleft lip and/or palate (Lidral and Murray, 2004) (see Table 23-2). It is therefore important to rule out a syndromic diagnosis before discussing the risk of recurrence. A complete family history should indicate other cases occurring within the same pedigree.

When counseling families regarding recurrence risk, it is important to examine parents for the so-called microforms of cleft palate, including a bifid uvula, submucous cleft of the soft palate, hypodontia, and linear-lip indentations. This latter finding is characteristic of Van der Woude syndrome, a dominantly inherited disorder in which there is a high penetrance of cleft lip and palate but no extrafacial associated anomalies. The incidence of Van der Woude syndrome is 1 in 33,600 livebirths (Sander et al., 1995). The finding of lip pits in a parent and an affected infant with a cleft disorder strongly suggests Van der Woude syndrome and a 50% risk of

Table 23-2

Major Genes Involved in Syndromic Cleft Lip and Palate

Gene	Syndrome	Inheritance Pattern	Chromosomal Location
PTCH1	Basal cell nevus (Gorlin Goltz)	Autosomal dominant	9q22
MID1	Opitz	X-linked	Xp22
MSX1	Cleft lip/palate and oligodontia	Autosomal dominant	4p16
PVRL1	Margarita Island cleft lip/palate and ectodermal dysplasia (CLPED1)	Autosomal recessive	11q23
P63	Ectrodactyly-ectodermal dysplasia, cleft (EEC)	Autosomal dominant	3q28
IRF6	Van der Woude	Autosomal dominant	1q32
TBX22	Cleft palate and ankyloglossia	X-linked	Xq21
FGFR1	Hypogonadotropic hypogonadism, anosmia, and cleft (Kallmann)	Autosomal recessive	8p11
COL2A1	Stickler	Autosomal dominant	12q13

Table 23-3

Empirical Recurrence Risk Figures for Orofacial Clefts

			Cleft Lip and Palate (%)	Cleft Palate Alone (%)
Normal parents	Number of affected children	Number of normal children		
	1	0	4.0	3.5
	1	1	4.0	3.0
	2	0	14.0	13.0
One parent affected	Number of affected children	Number of normal children		
	0	0	4.0	3.5
	1	0	12.0	10.0
	1	1	10.0	9.0
	2	0	25.0	24.0
Both parents affected	Number of affected children	Number of normal children		
	0	0	35.0	25.0
	1	0	45.0	40.0
	1	1	40.0	35.0
	2	0	50.0	45.0

recurrence. Mutations in the interferon responsive factor 6 (*IRF6*) gene are the underlying basis for Van der Woude syndrome (Kondo et al., 2002). Knowledge of the disease-causing mutation makes DNA-based prenatal diagnosis for the condition available. Embryoscopy has also been used to diagnose cleft lip as early as 11 weeks of gestation in a fetus at risk for Van der Woude syndrome (Dommergues et al., 1995).

If the parents have a negative physical examination and family history, the empiric risk for a second affected child is 4% (Lynch and Kimberling, 1981; Tenconi et al., 1988). Table 23-3 summarizes empiric recurrence risks for several clinical scenarios.

Nonsyndromic cleft lip with or without cleft palate is a complex trait that is determined by multiple loci that interact and are affected by environmental exposures. Point mutations in *FOXE1*, *GLI2*, *JAG2*, *LHX8*, *MSX1*, *MSX2*, *SATB2*, *SKI*, *SPRY2*, and *TBX10* are additional rare causes of isolated clefts (Stainer and Moore, 2004; Vieira et al., 2005). The results of direct sequencing of *MSX1* suggest that point mutations in this gene may be responsible for as many as 2% of nonsyndromic clefts.

Hemifacial Microsomia

24 CHAPTER

Key Points

- Second most common facial anomaly after cleft lip and palate.
- Characteristic findings include hypoplasia of malar, maxillary, and/or mandibular regions of the face with associated anomalies of the ears and vertebrae.
- Incidence is as high as 1 in 3,000-5,000 livebirths if mild cases are included.
- Associated with eye, ear, vertebral, cardiac, renal, and urinary anomalies.
- Karyotype is indicated.
- Deliver infant in tertiary care center if polyhydramnios is present.
- Perform complete audiologic evaluation on all infants postnatally.
- Rule out syndromic causes.

CONDITION

Hemifacial microsomia is the second most common facial anomaly after cleft lip and palate. It is a predominantly unilateral malformation of craniofacial structures that originally develop from the first and second branchial arches. The characteristic findings of hemifacial microsomia include hypoplasia of the malar, maxillary, and/or mandibular regions of the face with associated abnormalities of the ears and vertebrae (Burck, 1983). The term *hemifacial microsomia* was first used by Gorlin and Pindborg (1964), who described a condition consisting of unilateral microtia, macrostomia, and failure of formation of the mandibular ramus and condyle. Since then, hemifacial microsomia has been considered one phenotypic manifestation of a group of disorders that affect the face, ears, eyes, vertebrae, heart, and kidneys. This spectrum of disorders has been called "oculoauriculovertebral dysplasia," although this is technically incorrect because the term *dysplasia* refers to abnormalities of cellular differentiation. An association between hemifacial microsomia, auricular malformations, and specific malformations of the eye known as epibulbar dermoids was first recognized by Goldenhar in 1952 (Heffez and Doku, 1984). Although the name *Goldenhar syndrome* is widely used, the use of the word *syndrome* is also incorrect because there is no known unique cause for this phenotype.

At present, hemifacial microsomia is considered to be part of a complex developmental field defect known as the oculoauriculovertebral (OAV) anomaly. There is no agreement on the minimal diagnostic criteria and the phenotypic spectrum for this condition (Rollnick, 1988). It is not known whether OAV anomaly represents one entity with variability in the phenotype or whether there are several different entities with similar phenotypes. Causal heterogeneity for this group of conditions has been described (Rollnick, 1988). However, any fetus identified with asymmetry of the facial structures or hemifacial microsomia should be considered to be at risk for associated eye, ear, vertebral, cardiac, and renal malformations.

INCIDENCE

The incidence of hemifacial microsomia varies considerably according to the minimal diagnostic criteria used to define the condition. When the most mildly affected individuals are included, the incidence is on the order of 1 in 3000 to 1 in 5000 livebirths (Benacerraf and Frigoletto, 1988). When only the most severely affected patients are included, the incidence was on the order of 1 in 45,000 livebirths in one study performed in Northern Ireland (Morrison et al., 1992). Approximately two-thirds of cases of hemifacial microsomia

are unilateral (Singer et al., 1994). When unilateral, the right side is more commonly involved (Poon et al., 2003). When the condition is bilateral, one side is more severely affected than the other (Heffez and Doku, 1984). In one report of 294 patients affected with the oculoauriculovertebral anomaly, a male to female ratio of 2:1 was observed (Rollnick et al., 1987). In the same study, 78% of affected individuals were white. In this study, 154 patients (52%) had no other congenital anomaly in addition to the anomalies required for diagnosis, which consisted of microtia, mandibular hypoplasia, anomalies of the cervical spine, and/or anomalies of the eye, including epibulbar dermoids or lipodermoids. Of the remaining patients, 51 (18%) had one additional anomaly and 89 (30%) had two or more additional anomalies (Rollnick et al., 1987).

Figure 24-1 Postnatal photograph of a newborn who was noted antenatally to have hemifacial microsomia and a bilateral cleft lip and palate. Note the lack of ear development but the presence of two small ear tags.

SONOGRAPHIC FINDINGS

Relatively few reports of prenatal sonographic diagnosis of hemifacial microsomia have been described. In 1986, Tamas et al. described a fetus with polyhydramnios, unilateral anophthalmia, and a malformed, low-set ipsilateral ear. This was followed by a report in 1988 from Benacerraf and Frigoletto, who described a fetus at 29 weeks of gestation with moderate polyhydramnios, an abnormal fetal facial profile with micrognathia, a right kidney hydronephrosis and hydroureter, an enlarged echogenic left lung, a ventriculoseptal cardiac defect, and a two-vessel umbilical cord. Prenatally, a cystic adenomatoid malformation of the lung was suspected, but this was refuted postnatally when it was found that the right lung was absent and the left lung was hyperexpanded. The infant died during the newborn period. Physical examination at birth revealed a right-sided mandibular hypoplasia, an abnormal right ear, and vertebral anomalies that were not appreciated antenatally. Goldenhar syndrome was diagnosed postnatally (Benacerraf and Frigoletto, 1988).

Potential sonographic findings in cases of hemifacial microsomia or OAV anomaly might include polyhydramnios due to impaired fetal swallowing. This is likely to be the result of either unilateral mandibular hypoplasia or micrognathia due to hypoplasia of the condyle and ramus, which has been documented in 60% of infants affected with these conditions (Heffez and Doku, 1984). Some infants with OAV anomaly have intrauterine growth restriction (Kobrynski et al., 1993). In one fetus with Goldenhar syndrome, a lipoma of the corpus callosum, which presented as a hyperechoic midline structure, was described (Jeanty et al., 1991). In another case, the prenatal sonographic diagnosis of OAV anomaly at 15 weeks' gestation was suggested by the presence of a maxillary cleft in association with unilateral microophthamia (DeCatte et al., 1996). More recently, Goldenhar syndrome was diagnosed in a fetus at 24 weeks due to marked hemifacial microsomia and ipsilateral cerebellar hemisphere hypoplasia (Martinelli et al., 2004).

In any fetus in whom facial asymmetry is suspected, an attempt should be made to sonographically examine the fetal ears, because microtia or other ear abnormalities are frequently seen in association with the mandibular hypoplasia (Figure 24-1). The spine should be observed closely, as skeletal anomalies are the most common associated malformations (due to hemivertebrae and scoliosis) (Poon et al., 2003). The prevalence of associated congenital heart disease in infants with OAV anomaly is increased (Kumar et al., 1993; Poon et al., 2003). Two-thirds of these cases are either tetralogy of Fallot or a ventriculoseptal defect. In one study, 19% (6 of 32) of patients with OAV anomaly had congenital heart disease. The cardiac lesions in this study were varied and more complex than previously reported, including double outlet ventricle, pulmonary atresia with ventriculoseptal defect, and total anomalous pulmonary venous return. Five of the six cases were conotruncal malformations. Pulmonary and renal anomalies were noted to be more common in the patients with congenital heart disease. Morrison et al. (1992) also reported that 8 of their 25 patients with OAV anomaly had congenital heart disease. In fetuses with hemifacial microsomia, the presence of congenital heart disease is an important prognostic factor because of the very high neonatal mortality rate when congenital heart disease exists. In Morrison et al.'s study (1992), six of eight infants died before 2 years of age, and in Kumar et al.'s study (1993), four of six infants died during the newborn period.

A high incidence of urinary tract abnormalities has also been demonstrated in infants with OAV anomaly. Of 20 infants with OAV anomaly, 14 were demonstrated to have a variety of renal and urinary anomalies, including ectopic or fused kidneys, renal agenesis, vesicoureteral reflux, ureteropelvic obstruction, ureteral duplication, and multicystic kidneys (Ritchey et al., 1994). Therefore, any fetus identified with hemifacial microsomia should undergo a detailed

sonographic study with particular attention paid to the ears, heart, vertebrae, and kidneys.

Hemifacial microsomia, initially detected by prenatal sonography, has also been demonstrated by magnetic resonance imaging at 20 weeks of gestation (Hattori et al., 2005).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes conditions that are considered to be part of the phenotypic spectrum of hemifacial microsomia and OAV anomaly, as well as other syndromes that include hemifacial microsomia as one component. The differential diagnosis of hemifacial microsomia variants includes microtia, hemifacial microsomia, Goldenhar syndrome, OAV dysplasia, and otomandibular dysostosis. The minimal criteria for these conditions are given in Table 24-1. Other conditions associated with the hemifacial microsomia phenotype include branchio-oto-renal syndrome, a dominantly inherited disorder that consists of hemifacial microsomia, preauricular and branchial sinuses and kidney anomalies; Townes–Brocks syndrome, another dominantly inherited disorder that consists of hemifacial microsomia and anal and digital anomalies; and hemifacial microsomia/radial limb defects, which include the additional finding of triphalangeal thumbs. There have been other case reports of hemifacial microsomia in association with other, more severe anomalies (Dodinval, 1979; Rollnick, 1988).

Table 24-1

Minimal Criteria for Diagnosis of Hemifacial Microsomia Variants

Diagnosis	Minimal Criteria
Microtia	Isolated microtia
Hemifacial microsomia	Unilateral microtia Small and/or malformed mandible Anomalies of cervical spine
Goldenhar syndrome	Unilateral microtia Small and/or malformed mandible Epibulbar dermoids and/or lipodermoids
Oculoauriculo-vertebral dysplasia	Unilateral microtia Small and/or malformed mandible Epibulbar dermoids and/or lipodermoids Anomalies of the cervical spine

From Rollnick BR, Kaye CI. Hemifacial microsomia and variants: pedigree data. Am J Med Genet. *1983;15:233-253.*

ANTENATAL NATURAL HISTORY

Little is known about the antenatal natural history for fetuses with hemifacial microsomia. More information is available regarding its pathogenesis. Experiments performed in animals have suggested that abnormalities of blood flow to the first and second branchial arches may produce malformations similar to those found in hemifacial microsomia and its variants (Poswillo, 1974). Poswillo showed that the presence of an expanding hematoma in the region of the ear and jaw produced a branchial arch abnormality that destroyed the differentiating tissues in that region. Additional studies using triazene in the pregnant rat or thalidomide in the pregnant monkey produced hemorrhage and formation of a hematoma in the anatomic distribution of the stapedial artery. A clinical correlation in humans has been documented by Robinson et al. (1987), who described three unrelated children with unilateral craniofacial defects. Abnormal carotid artery blood flow studies were documented in two of the three patients described. This group hypothesized that the craniofacial defects were the result of an in utero vascular accident, most likely due to interruption of blood flow to structures supplied by the stapedial artery. Interestingly, these patients also had unilateral cerebral atrophy. In one patient, a decreased right carotid pulse was documented. This patient also had colonic stenosis, which has also been postulated to be the result of an in utero vascular compromise.

A large-scale epidemiologic study of 230 children with hemifacial microsomia and 678 controls was performed to identify whether vasoactive exposures or vascular events during early pregnancy affected the incidence of this malformation (Werler et al., 2004). An increased risk of hemifacial microsomia was associated with vasoactive medication use (such as pseudoephedrine and phenylpropanolamine), multiple gestation, diabetes, and second trimester vaginal bleeding. These findings appeared to collectively support the hypothesis that vascular disruption is one etiology for hemifacial microsomia.

While the vascular theory for the pathogenesis of hemifacial microsomia and OAV anomaly explains the abnormalities of the facial features, it does not explain some of the associated findings, including epibulbar dermoids and other eye malformations and congenital heart disease. These associated abnormalities could be explained by an abnormality in the interaction of neural crest cell derivatives with branchial arch mesenchyme. This could be the result of exposure to a teratogen such as retinoic acid (Lammer et al., 1985). Abnormalities of cranial neural crest cell derivatives also affect conotruncal development of the heart and the anterior chamber of the eye. Teratogens that are known to cause anomalies of the first and second branchial arches in humans and animals

are primidone, thalidomide, and maternal diabetes (Rollnick, 1988). Another theory regarding the cause of hemifacial microsomia is that this condition is the result of a local deficit of oxygen or a brief, total hypoxic insult to the embryo, resulting in decreased oxygen for tissue formation.

MANAGEMENT OF PREGNANCY

When a fetus is identified with hemifacial microsomia, a detailed sonographic survey should be performed to examine the fetus for the aforementioned associated anomalies, including microtia, micrognathia, vertebral malformations (most commonly hemivertebrae), congenital heart disease (especially conotruncal defects), and renal abnormalities. An attempt should be made to examine the parents for subtle manifestations of OAV anomaly, such as preauricular tags or fistulae, small or abnormally shaped ears, narrow external auditory canals, or micrognathia. Isolated microtia is considered to be a minimal expression of OAV anomaly (Llano-Rivas et al., 1999). The parents should be asked if there is any history of hearing deficit in the family. If hemifacial microsomia is demonstrated in the fetus, consideration should be given to obtaining a fetal karyotype. Many chromosomal abnormalities have been described in association with facial asymmetry and the OAV anomaly (Table 24-2) (Rollnick, 1988). In addition, complete or mosaic trisomy 22 should be considered. This can be diagnosed using fluorescence in situ hybridization studies (Kobrynski et al., 1993). Knowledge of the fetal karyotype will certainly help in establishing a prognosis for the infant and in guiding further treatment. There is no indication for cesarean delivery other than for standard obstetric reasons. We recommend that these infants be delivered in a tertiary care center if polyhydramnios is present, suggesting micrognathia, which indicates the potential for airway compromise at birth. Most infants with OAV anomaly can be delivered in a community hospital, but should receive multispecialty evaluation, including a clinical genetics examination shortly after birth.

FETAL INTERVENTION

There are no fetal interventions indicated for hemifacial microsomia.

TREATMENT OF THE NEWBORN

The overall goal in the treatment of the newborn with hemifacial microsomia is to determine whether the anatomic defects are localized to the head or whether there are associated anomalies that will influence long-term health. The most important aspect of newborn treatment is a detailed physical examination, with specific attention to the ears, documenting the presence of auricular or preauricular appendages, blind-ending preauricular fistula, abnormalities in ear size or shape, presence of epibulbar dermoids or lipomas, colobomas (notching) of the upper eyelid, hemivertebrae, congenital heart disease, and renal anomalies (Thomas, 1980). If the vertebrae were not adequately visualized antenatally, we recommend obtaining a postnatal radiograph of the vertebrae to look for malformations of the spine. In addition, we recommend obtaining a postnatal echocardiogram, because of the relatively high incidence of congenital heart lesions. It is especially important to document cardiac anatomy, because of the relatively high postnatal mortality for infants identified with hemifacial microsomia and congenital heart disease (Morrison et al., 1992; Kumar et al., 1993). In addition, because of the high incidence of genitourinary malformations in infants with the OAV anomaly, we recommend that a screening ultrasound examination be performed in the neonatal period to identify significant urologic abnormalities before functional consequences ensue (Ritchey et al., 1994).

In one study, conductive hearing loss was observed in 85% of patients (Rahbar et al., 2001). However, there was no correlation between the severity of the dysmorphic features and the degree or type of hearing loss. A complete audiologic evaluation should be performed on every infant with hemifacial microsomia.

SURGICAL TREATMENT

The goals of surgical treatment include improving facial symmetry, stimulating further facial growth, correcting maxillary deficiency, providing a growth center in the temporomandibular joint, improving chewing, allowing for early soft tissue expansion, and minimizing psychologic trauma associated with an asymmetric facial appearance (Heffez and Doku, 1984). The surgical treatment depends on the severity of the mandibular hypoplasia. Mandibular hypoplasia has been classified according to its severity. Grade 1 is a small but normal temporomandibular joint and ramus; Grade 2 is an abnormal but functional temporomandibular joint and ramus; and Grade 3 is an absent temporomandibular joint and ramus. With increasing severity of the bony abnormalities, there is more severe hypoplasia of the associated facial and lingual muscles, which exaggerates the asymmetry of the facial appearance. In addition, there is generally a correlation between severity of the microtia and the mandibular anomalies. The mandibular deformity is surgically corrected in two or more stages. The first operation generally is performed when the child is between 5 and 12 years of age and can cooperate with the required postoperative orthodontic therapy. For severely affected patients who have an absent mandibular ramus, an augmentation procedure is performed using costochondral bone grafts (Heffez and Doku, 1984). A second operation is generally required during the teenage years, after the majority of facial growth has occurred.

LONG-TERM OUTCOME

For patients with hemifacial microsomia or the OAV anomaly, the long-term health outcome is good. More than 90% of these patients have normal intelligence. Except for those who have severe conotruncal cardiac defects, the general health and life expectancy of these patients are excellent. Long-term problems, however, are hearing abnormalities and facial nerve weakness.

GENETICS AND RECURRENCE RISK

The cause of hemifacial microsomia and OAV anomaly is heterogeneous. The majority of patients with hemifacial microsomia occur sporadically within a family. A scarcity of reports of concordance of the defects in monozygotic or dizygotic twins supports this interpretation of the genetics (Setzer et al., 1981; Burck, 1983; Boles et al., 1987). However, there have been multiple reports of autosomal dominant inheritance with variable expression of the phenotype (Burck, 1983; Singer et al., 1994). There also have been multiple case reports of this finding with two affected siblings and unaffected parents, suggesting autosomal recessive inheritance (Rollnick, 1988). As previously mentioned, many chromosomal abnormalities have been associated with hemifacial microsomia. Therefore, if a chromosome study was not obtained prenatally, it should be obtained during the newborn period. Rollnick and Kaye (1983) described 97 individuals affected with hemifacial microsomia. Of these, 44 (45%) had relatives with either ear anomalies, mandibular hypoplasia, or early onset hearing loss. The most frequent malformations included preauricular skin tags. In this study, 8% of first degree relatives had at least a minor manifestation of hemifacial microsomia.

When counseling the family for recurrence of hemifacial microsomia, a syndrome must be ruled out. If a medical geneticist suggests a diagnosis of Townes–Brocks syndrome, DNA should be studied for the presence of a mutation in the *SALL1* gene (Keegan et al., 2001). In addition, the physician must examine the parents and siblings and obtain a complete family history. If the family history is negative and the parental physical examination is negative for the milder forms of hemifacial microsomia, the recurrence risk is 2% to 3% (Burck, 1983; Rollnick and Kaye, 1983).

25 CHAPTER Hypertelorism

Key Points

- Defined as an increased distance between inner and outer canthi.
- Prenatal sonographic measurements are obtained from either the outer-to-outer or inner-to-inner bony orbital margins.
- Unknown incidence but rare.
- Main concern is its association with median facial and/or brain defects as well as syndromes.
- Offer karyotype and FISH analysis for 22q11.2 deletion (associated with autosomal dominant form of Opitz syndrome).
- Prognosis depends on severity of associated anomalies and/or if a syndrome is present.
- DNA analysis is available for a number of the single-gene disorders associated with hypertelorism.

CONDITION

Hypertelorism is a condition in which a larger-than-average distance exists between the orbits. The distances between the medial canthi and pupils are also increased (Kirkham et al., 1975). The term was first used by Greig in 1924, who described hypertelorism as a "great breadth between the eyes." The orbits represent a bridge between the face and the cranium. Seven different bones are required to form the orbit (frontal, zygomatic, sphenoid, ethmoidal, maxillary, lacrimal, and palatine) (Dollfus and Verloes, 2004).

Ocular hypertelorism is defined as an increased distance between the medial orbital walls. This can be demonstrated either radiographically or clinically by an increased interpupillary distance. If the interpupillary distance is greater than 2 SD above the mean for the patient's age, hypertelorism is said to exist (Brodsky et al., 1990). More recently, it has been recommended that the diagnosis of hypertelorism be made

radiographically by interorbital measurements. The difficulty with using intercanthal distance to define hypertelorism is that soft tissue changes of the face can increase the intercanthal distance without affecting the interorbital distance (Trout et al., 1994). Telecanthus is an increased distance between the inner canthi. This can either be primary, defined as an increase in soft tissue with normal interpupillary and interbony distance, or secondary, which is really orbital hypertelorism, with an increased interbony or interpupillary distance (Murphy and Laskin, 1990). The major concern regarding the fetal finding of hypertelorism is its association with median facial and brain defects, such as encephalocele, facial cleft, and craniosynostosis.

INCIDENCE

Hypertelorism is rare. Its exact incidence is unknown. Hypertelorism may occur as an isolated condition or in association with other anomalies.

SONOGRAPHIC FINDINGS

Imaging of the fetal orbits and measurements of the interorbital distance are not routinely performed in most centers that offer targeted fetal sonographic studies. Measurement of the fetal interorbital distance is not included in either the American Institute of Ultrasound in Medicine (AIUM) or American College of Obstetrics and Gynecology (ACOG) guidelines for obstetrical sonography (American College of Obstetrics and Gynecology, 2008). Fetal orbital measurements should be performed in any pregnant woman known to have had a previously affected child with a condition associated with hypertelorism, such as Waardenburg, Opitz or Noonan syndromes. Detection of fetal hypertelorism in any structural survey should alert the sonographer to the possibility of other anomalies.

In 1985, de Elejalde and de Elejalde studied 1108 pregnant women and measured the interorbital distances in fetuses between 7 and 38 weeks of gestation. They derived normal growth percentiles for the intermalar and interethmoidal distances for fetuses between 10 and 40 weeks of gestation. The intermalar and interethmoidal distances were comparable to the postnatal measurements of inner and outer canthal distances. In 1982, Mayden et al. described fetal inner and outer orbital diameter measurements in 180 normal pregnancies. The outer orbital diameter was demonstrated to be closely related to the biparietal diameter. Fetal orbits were identified in three different head positions, including occipitotransverse, occipitoposterior, and occipitoanterior. Twelve years after this report, the validity of this nomogram was tested in a high-risk antenatal population by another group of investigators, who obtained inner and outer orbital measurements from 422 fetuses between 12 and 37 weeks of gestation (Trout et al., 1994). This group identified three cases of hypertelorism, with inner orbital measurements above the 95th percentile for gestational age and outer orbital distances within the normal limits but near the 95th percentile for gestational age. In the three cases of hypertelorism identified, all fetuses had serious associated abnormalities, including cleft palate, diaphragmatic hernia, imperforate anus, porencephaly, encephalocele, and truncus arteriosus. The three fetuses with hypertelorism were all diagnosed between 20 and 33 weeks of gestation. These investigators recommended routine measurement of the interorbital distance at the level of the thalamus at the same time that the conventional biparietal diameter measurement was taken. They measured outer orbital diameter from outer-to-outer bony margins of the orbit, whereas the inner orbital diameter was measured from inner-to-inner bony margin of the orbits. The bony orbits were seen reliably from 12 weeks of gestation onward. These investigators stressed that it was the inner orbital diameter measurement that was most clearly associated with postnatal hypertelorism. The three affected fetuses described in this study had inner orbital diameter measurements that were more than 2 SD from the mean for gestational age, whereas the outer orbital diameter measurements were borderline high.

In another report of 1600 fetuses screened by transvaginal sonography at 12 to 18 weeks of gestation, 8 ocular abnormalities were found, but no cases of hypertelorism were described (Bronshtein et al., 1991). To date, there have been no reports of fetal hypertelorism in the first trimester.

In one case report, a fetus at 20 weeks of gestation was diagnosed with Opitz syndrome (Hogdall et al., 1989). This syndrome consists primarily of hypertelorism and hypospadias, with either X-linked or autosomal dominant patterns of inheritance. In this report, the fetus was described as an "at-risk" member of a large kindred affected with the autosomal dominant form of Opitz syndrome. At 18 weeks of gestation, a prenatal sonogram was within normal limits. At that time, the outer orbital measurement was 30 mm (the normal mean for gestational age is 29 mm; range, 24–33 mm). The inner orbital measurement was 15 mm (mean for gestational age, 11 mm; range, 8–15 mm). At 20 weeks, the study was repeated and a small phallus with hypospadias was noted. In addition, the outer orbital measurement was 36 mm (mean for gestational age, 33 mm; range, 28–37 mm) (Figure 25-1). The inner orbital measurement was 17 mm (mean for gestational age, 13 mm; range, 10–16 mm). Because of the provisional diagnosis of an affected fetus with Opitz syndrome, the pregnancy was terminated. Perinatal autopsy studies revealed widely separated eyes and an enlarged fourth ventricle, as well as hypospadias, and imperforate anus. Thus, the fetus was confirmed as affected. This study also reinforced the findings of Trout et al. (1994), who determined that the inner orbital measurement is the more sensitive indicator of hypertelorism.

More recently, three-dimensional (3D) ultrasound imaging has been used to improve visualization of the fetal face. This has been especially helpful in the diagnosis of frontonasal dysplasia (Sleurs et al., 2004) and Binder syndrome (Cook et al., 2000).

DIFFERENTIAL DIAGNOSIS

Hypertelorism occurs in more than 550 disorders (Dollfus and Verloes, 2004). Hypertelorism is strongly associated with other abnormalities, especially of the frontal part of the brain, such as encephalocele and dacrocystocele. A number of conditions are associated with hypertelorism, and these are summarized in Table 25-1. Most significantly, these consist of chromosomal abnormalities, single-gene disorders, developmental abnormalities of the skull, such as craniosynostosis, and midface abnormalities such as frontonasal dysplasia.

Table 25-1

Conditions Associated with Hypertelorism

Chromosomal abnormalities
- 45,X (Chrousos et al., 1984)
- 22q11.2 deletion (Fryburg et al., 1996)
- Trisomy 9p (Centerwall and Beatty-DeSana, 1975)
- Interstitial deletion of chromosome 1 (Sarda et al., 1992)
- Interstitial deletion of chromosome 13 (Dean et al., 1991)
- Interstitial deletion of chromosome 17 (Park et al., 1992)

Single-gene disorders
- Aarskog syndrome
- Apert syndrome
- Coffin–Lowry syndrome
- Crouzon syndrome
- LEOPARD syndrome (*PTPN11*)
- Noonan syndrome (*PTPN11*)
- Opitz syndrome, autosomal dominant
- Opitz syndrome, X-linked (*MID1*)
- Robinow syndrome
- Waardenburg syndrome, type 1 (*PAX3*)
- Waardenburg syndrome, type 2 (*MITF*)

Developmental abnormalities
- Anterior cephalocele
- Craniosynostosis
- Dacrocystocele
- Frontal, ethmoidal, sphenoidal meningoencephalocele
- Frontonasal dysplasia
- Median cleft face
- Megaloencephaly

Rare syndromes
- Sclerocornea, hypertelorism, syndactyly, ambiguous genitalia (Martinez-Frias et al., 1994)
- Diaphragmatic hernia, exomphalos, absent corpus callosum, hypertelorism, myopia, deafness (Donnai and Barrow, 1993)
- Hypertelorism, hypospadias, Tetralogy of Fallot (Farag and Teebi, 1990)
- Hypertelorism, downslanting palpebral fissures, malar hypoplasia, low-set ears, joint and scrotal abnormalities (Seaver and Cassidy, 1991)

ANTENATAL NATURAL HISTORY

Ocular hypertelorism occurs by three pathogenic mechanisms: (1) early ossification of lesser wings of the sphenoid bone, fixing orbits in the fetal position; (2) failure of development of the nasal capsule, which allows the primitive brain to protrude into space normally occupied by the nasal capsule, as in frontal encephalocele; (3) a disturbance in the development of the skull base due to craniosynostosis or midfacial malformations (Cohen et al., 1995).

The antenatal natural history depends on the underlying condition responsible for the hypertelorism. For example,

there is a higher-than-normal rate of miscarriage in fetuses affected with Opitz syndrome (Patton et al., 1986). The natural history for isolated fetal hypertelorism is unknown.

Hypertelorism has occurred as the result of first trimester fetal trauma. In one report, two fetuses were described who were exposed to dilation and curettage during the first trimester of pregnancy (Holmes, 1995). The cause of hypertelorism was hypothesized to be the result of exposure to marked and acute mechanical forces on the fetal circulatory system. This resulted in shear stress with release of vasoactive modulators and potentially resulted in the multiple congenital abnormalities described in these two fetuses.

MANAGEMENT OF PREGNANCY

When fetal orbital hypertelorism is documented, a detailed anatomic survey should be performed to look for associated malformations, especially in the central nervous system. Strongly associated findings include anterior cephalocele; clefts of the face, lip, palate, and nose; megaloencephaly; and craniosynostosis. Because multiple chromosomal abnormalities have been documented in association with fetal hypertelorism, a karyotype should be offered. An association between the autosomal dominant form of Opitz syndrome and microdeletion of chromosome 22q11.2 has been demonstrated (Fryburg et al., 1996; Lacassie and Arriaza, 1996). Both parents should have their inner and outer canthal distances measured and compared with normal standards for adults (Figure 25-2). If the fetal hypertelorism is apparently isolated, there is no indication for a change in the standard management of pregnancy. If, however, the orbital hypertelorism is found to be associated with a severe brain defect, the parents should be counseled regarding the grim prognosis for this condition. Termination of pregnancy can be discussed if the abnormality is found before 24 weeks of gestation.

Families at risk for the single-gene disorders listed in Table 25-1 should have fetal orbital measurements taken during serial sonographic studies. In one study, hypertelorism was considered as a marker of brain involvement in neurofibromatosis. In this report, 11 patients with neurofibromatosis were described who had hypertelorism. All the patients had severe central nervous system abnormalities. In an additional 23 patients with neurofibromatosis but no hypertelorism, no central nervous system abnormalities were demonstrated, despite extensive skin involvement (Westerhof et al., 1984). Although this finding has not been validated prenatally, it would be of interest to routinely measure orbital distances in fetuses at risk for neurofibromatosis, and to correlate those distances with neurologic abnormalities observed postnatally.

FETAL INTERVENTION

There are no fetal interventions recommended for hypertelorism.

Figure 25-2 The mother of the fetus in Figure 25-1 also had hypertelorism. (*From Hogdall C, Siegel-Bartelt J, Toi A, Ritchie S. Prenatal diagnosis of Optiz (BBB) syndrome in the second trimester by ultrasound detection of hypospadias and hypertelorism.* Prenat Diagn. *1989;9:783-793. Copyright 1989 John Wiley & Sons, Inc. Reprinted, by permission, of John Wiley & Sons, Ltd.*)

TREATMENT OF THE NEWBORN

The infant with isolated hypertelorism should have a detailed physical examination, including postnatal measurements of the inner and outer canthal distances. If a fetal chromosomal analysis was not obtained antenatally, it should be obtained in the immediate postnatal period. In addition, consultation with a medical geneticist is recommended. Consideration should be given to postnatal assessment of the affected infant's intracranial anatomy by computed tomographic (CT) scan or magnetic resonance imaging (MRI). In the absence of documentation of cerebral abnormalities, or in the setting of a family with isolated hypertelorism as a physical trait, the infant affected with isolated hypertelorism should require only routine newborn care.

Infants with hypertelorism and hypospadias should be considered to be at risk for Opitz syndrome (Figure 25-3) (Cappa et al., 1987). Infants with Opitz syndrome have a 30% chance of having laryngotracheal or esophageal clefts. These infants are at high risk for stridor, wheezing, and choking upon feeding. Infants who are clinically diagnosed with

Figure 25-3 A 14-month-old boy with hypertelorism and hypospadias, who was given a clinical diagnosis of Opitz G/BBB syndrome. He had a chromosome deletion of 22q11.2. (*From Fryburg JS, Lin KY, Golden WL. Chromosome 22q11.2 deletion in a boy with Opitz (G/BBB) syndrome*. Am J Med Genet. *1996;62:274-275. Copyright ©1996 John Wiley & Sons, Inc. Reprinted, by permission, of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.*)

this condition should have a barium swallow examination and endoscopy to rule out the presence of these clefts. Many affected infants require tracheostomy, feeding gastrostomy, or a Nissen fundoplication.

SURGICAL TREATMENT

Surgical treatment is not indicated during the newborn period or during very early childhood. Surgical treatment should be contemplated only after evaluation by a craniofacial team. The surgical treatment for hypertelorism was first described by Tessier (1974). This treatment involves mobilization of the orbits and their contents to the midline to achieve normal separation between the orbits (Ortiz-Monasterio et al., 1990). In Tessier's description of the surgical technique for hypertelorism, it was demonstrated that:

1. extensive areas of the craniofacial skeleton could be completely devascularized and repositioned and still survive;
2. the orbits could be circumferentially mobilized and repositioned without affecting the patient's vision;
3. intracranial and extracranial surgery could be combined to treat serious deformities of physical appearance (Tessier, 1974; Whitaker and Vander Kolk, 1988).

Plastic surgery for hypertelorism is generally not performed before 24 months of age because of the small size of the facial structures and the position of the tooth buds in the maxilla (Whitaker and Vander Kolk, 1988). In one report, however, McCarthy et al. (1990) described surgical treatment of hypertelorism as safe, desirable, and effective even in a child less than 5 years of age.

LONG-TERM OUTCOME

The long-term outcome for a child with isolated hypertelorism is good. If the hypertelorism is associated with severe cerebral abnormalities, the prognosis will depend on the extent of the severity of the associated anomalies. Many of the single-gene disorders that have been described in association with hypertelorism (Table 25-1) do involve mental retardation or mild developmental disabilities. The reader is referred to Chapter 10 for further information on disorders such as Apert and Crouzon syndromes, which include hypertelorism and craniosynostosis as physical findings.

GENETICS AND RECURRENCE RISK

The genetics of hypertelorism will depend on the underlying cause for this finding. If a chromosomal abnormality such as an interstitial deletion or partial trisomy is detected, parental chromosomes must be studied. Further genetic counseling will depend on whether the parents are shown to be carriers of a balanced translocation. Ten percent of cases of Turner syndrome (45,X) have hypertelorism (Chrousos et al., 1984). The recurrence risk for Turner syndrome is not considered to be increased above background, and it is independent of maternal age.

A number of single-gene disorders are associated with hypertelorism. Opitz syndrome is a multiple congenital anomaly disorder that primarily affects midline structures and presents with hypertelorism, hypospadias, laryngotracheoesophageal defects, the central nervous system (particularly vermis hypoplasia or agenesis), and the heart (De Falco et al., 2003; Pinson et al., 2004). Interestingly, Opitz syndrome is genetically heterogeneous, meaning that at least two different genes are known to cause an essentially identical phenotype. In the autosomal dominant form there is an unknown gene that maps to chromosome 22q11.2 and can be detected using the DiGeorge syndrome FISH probes. Another form is X-linked, and is caused by mutations in the gene *MID1*. *MID1* encodes a protein containing a RING, B-box-coiled-coil motif that belongs to the tripartite motif (TRIM)

gene family (De Falco et al., 2003). Clinical testing for *MID1* mutations is available.

Noonan syndrome is an autosomal dominant syndrome characterized by hypertelorism, short stature, and heart defects. Mutations in the gene *PTPN11*, located on chromosome 12q24, are thought to be the molecular etiology for this condition. A related but much rarer dominant disorder, LEOPARD syndrome (*L*entigines, *E*KG abnormalities, *O*cular hypertelorism, *P*ulmonary stenosis, *A*bnormal genitalia, *R*etardation of growth, *D*eafness) is also caused by mutations in *PTPN11* (Legius et al., 2002). Waardenburg syndrome, another autosomal dominant disorder, is characterized by dystopia canthorum, which is lateral displacement of the inner canthi and lacrimal puncta (Dollfus and Verloes, 2004). Clinically, affected individuals present with variable deafness, a white patch of hair, and eye color that differs between the two eyes (iridal heterochromia).

Waardenburg syndrome (WS) is also genetically heterogeneous. WS type 1 is caused by mutations in *PAX3*, the paired-box 3 gene. WS type 2 is caused by mutations in *MITF*, the microphthalmia-associated transcription factor gene.

In the infant with hypertelorism, every attempt should be made to make a definitive diagnosis, either clinically or by molecular analysis. This will permit accurate estimates of recurrence risk and counseling, as many of the conditions associated with hypertelorism described in Table 25-1 are inherited as autosomal dominant traits. If one of the parents is diagnosed retrospectively as having a single-gene disorder, such as Noonan syndrome, the parents can be counseled about the 50% recurrence risk in future children.

If a gene mutation has been identified as part of a syndrome associated with hypertelorism, prenatal diagnosis in subsequent pregnancies can be performed by DNA analysis. Otherwise, prenatal diagnosis in future pregnancies can be made by sonographic measurement of the fetal orbits.

26 CHAPTER Hypotelorism

Key Points

- Defined as a decreased distance between the medial aspects of the orbital walls.
- Incidence is approximately 1 in 1220 livebirths.
- Main concern is its strong association with brain anomalies (especially holoprosencephaly).
- A fetal karyotype should be offered due to its association with aneuploidy, most commonly trisomy 13.

CONDITION

The term *hypotelorism* was used as early as 1960 to indicate a decrease in interorbital distance (Judisch et al., 1984). *Ocular hypotelorism* is defined as a decreased distance between the eyes or pupils, whereas *orbital hypotelorism* is defined as a shortened distance between the medial aspects of the orbital walls, with reduced inner and outer canthal distances (Converse et al., 1975; Judisch et al., 1984). The major concern regarding the finding of fetal hypotelorism is its association with midline craniofacial defects and major cerebral anomalies.

Orbital hypotelorism results from developmental abnormalities of the telencephalon, which is a derivative of the forebrain. It is strongly associated with holoprosencephaly (see Chapter 14) (Converse et al., 1975; Achiron et al., 1995). Frequently, hypotelorism is more obvious radiographically or sonographically than clinically. In one study, the normal range of interorbital distances was documented in anteroposterior facial radiographs obtained in 250 normal children. The mean values ranged from 15 mm in infancy to 23 mm at 12 years of age. The interorbital distance was found to be narrower for girls than for boys. The interorbital distance normally remains small until 18 months of age, when distance gradually increases in both sexes. Interorbital growth levels off in females at age 13 years, but in males this distance continues to increase until 21 years of age (Converse et al., 1975). Interorbital distances are closely related to ethnic background. Individuals who trace their ancestry to Eskimos or Mongolians may have hypotelorism as a normal genetic variation (Awan, 1977).

INCIDENCE

Hypotelorism is uncommon. Most references list the incidence of hypotelorism as unknown, but one reference documented hypotelorism in 1 in 1220 deliveries in Taiwan (a frequency of 0.08% livebirths) (Kuo et al., 1990).

SONOGRAPHIC FINDINGS

Imaging of the fetal orbits and measurements of the interorbital distance are not routine in most centers that provide antenatal sonography. Measurement of the interorbital distance is not included in the American Institute of Ultrasound

in Medicine (AIUM) or American College of Obstetrics and Gynecology (ACOG) guidelines for obstetrical sonography (American College of Obstetrics and Gynecology, 2008). Fetal orbital measurements should be taken in any pregnant woman with a previously affected child, or in the setting of a facial cleft, or with a central nervous system malformation such as hydrocephalus or holoprosencephaly. When orbital hypotelorism is discovered, the finding should be taken seriously, because of its strong association with cerebral abnormalities (Trout et al., 1994). In 1982, Jeanty and colleagues determined the ocular diameter, interocular distances, and binocular distances in a group of fetuses. They proposed the use of inner and outer canthal distances as an indication of fetal growth. In another study of 1108 pregnant women, the interorbital distances were analyzed in fetuses between 7 and 38 weeks of gestation. A chart consisting of normal growth percentiles for the intermalar and interethmoidal distances was created for fetuses between 10 and 40 weeks of gestation (de Elejalde and de Elejalde, 1985). These investigators thought that the intermalar and interethmoidal distances were comparable to postnatal measurements of inner and outer canthal distances. In 1982, Mayden and colleagues constructed a nomogram from measurements of fetal inner and outer orbital diameters obtained in 180 normal pregnancies. These investigators demonstrated that the outer orbital diameter was closely related to the biparietal diameter. After constructing this nomogram, they studied an additional 463 fetuses considered to be at high risk for anomalies. They diagnosed three cases of hypotelorism with fetal orbital measurements below the 95% confidence limits. In two of these three fetuses, hypotelorism was confirmed postnatally, and the other was lost to follow-up. This nomogram was also used to examine six fetuses at risk for ocular abnormalities due to prior affected children in the family. In all six cases, normal antenatal measurements were predicted and correlated with normal neonatal interocular distances (Mayden et al., 1982). Twelve years after this report, the validity of this nomogram was tested in a high-risk antenatal population. These later investigators obtained inner and outer canthal measurements of 422 fetuses studied prospectively at gestational ages of 12 to 37 weeks (Trout et al., 1994). Six cases of hypotelorism and two cases of cyclopia were identified. For all of these affected fetuses, both the inner and outer canthal measurements fell clearly more than 2 SD below the mean. Most cases had measurements that were 3 or 4 SD below the mean and were very clearly abnormal. In all the cases of hypotelorism, there were associated intracranial or extracranial abnormalities, including holoprosencephaly, encephalocele, cleft palate, cardiac anomalies, imperforate anus, congenital diaphragmatic hernia, and digital anomalies. These investigators recommended measurement of the interorbital distance at the level of the thalamus at the same time that the biparietal diameter was measured (Figure 26-1). They stated that bony orbits were seen reliably in transabdominal scans from 12 weeks of gestation and later.

Other investigators recommend a coronal view of the fetus to demonstrate both orbits, the maxilla, and the anterior portion of the mandible in a vertical plane. They recommend moving the transducer posteriorly to image both bony orbits (Meizner et al., 1987). In one case report, a fetus at 38 weeks of gestation was demonstrated to have hypotelorism in association with microphthalmia, microcephaly, and alobar holoprosencephaly (Kuo et al., 1990). These investigators stressed the importance of using measurements based on normal standards for the patient's specific ethnic group, which in this case was Chinese.

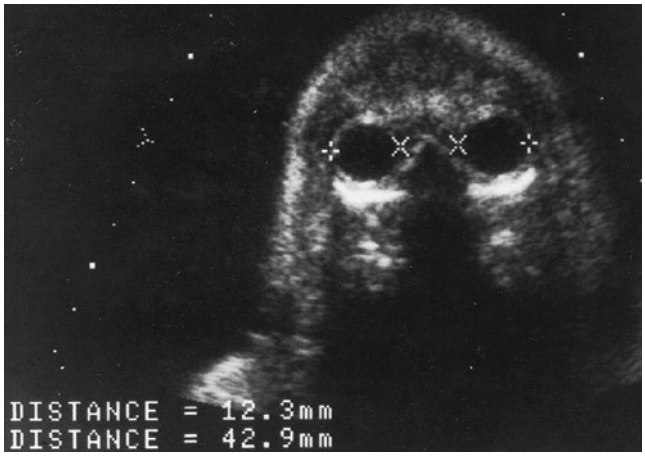

Figure 26-1 Antenatal sonogram demonstrating the presence of hypotelorism. The Xs mark the inner orbital measurement (12.3 mm) and the +s mark the outer orbital measurement (42.9 mm). Both of these measurements are abnormal for gestational age. (*Photograph courtesy of Dr. Marjorie C. Treadwell.*)

Transvaginal sonography has also been used to detect fetal ocular abnormalities. In one report of 1600 cases screened at 12 to 18 weeks of gestation, 8 cases of ocular abnormalities were seen (Bronshtein et al., 1991). There were associated defects of the central nervous system in 5 of the 8. These authors recommended that the optimal section in a transvaginal scan consists of a transverse image of the fetal skull at the orbital plane. They also recommended an oblique tangential section from the nasal bridge, which can also detect hypoechogenic circles lateral to the nose in the anterior part of the orbits representing the fetal lens. Using this approach, Bronshtein et al. (1991) were able to detect the fetal eyes within the orbits in 40% of cases at 11 weeks of gestation and 100% of cases at 12 weeks of gestation. A more recent report summarized normal binocular and intraocular distances for fetuses scanned transvaginally between 11 and 16 weeks of gestation (Rosati and Guariglia, 2003).

DIFFERENTIAL DIAGNOSIS

Fetal hypotelorism is strongly associated with abnormalities of the brain, specifically telencephalon derivatives, including the spectrum of malformations seen in holoprosencephaly (see Chapter 14) (Wong et al., 1999). Other associated conditions include arrhinencephaly, cebocephaly, ethmocephaly,

otocephaly, and cyclopia (Lin et al., 1998). Many chromosomal abnormalities are associated with orbital hypotelorism. The most common is trisomy 13 (Rosati and Guariglia, 2003) but trisomy 20p, partial trisomy 15p, trisomy 21, chromosome 5p deletion, and trisomy 4 mosaicism (Gentile et al., 2005) have also been reported. In one study, three of six fetuses with orbital hypotelorism had chromosomal abnormalities including trisomy 13, ring 21, and chromosome 7 short arm deletion (Trout et al., 1994). Hypotelorism is also associated with abnormalities of head shape, including microcephaly and trigonocephaly. Syndromes associated with hypotelorism include Meckel–Gruber, Williams, Coffin–Siris, Langer–Giedion, oculodentodigital dysplasia, nasal maxillary dysostosis (Binder syndrome), and craniosynostosis-medial aplasia (Jeanty et al., 1982; Judisch et al., 1984). Hypotelorism occurs in more than 60 syndromes (Dollfus and Verloes, 2004). It can be the result of an underlying skull or central nervous system malformation.

ANTENATAL NATURAL HISTORY

The antenatal natural history depends on the underlying condition responsible for the hypotelorism. The natural history for isolated fetal hypotelorism is unknown.

MANAGEMENT OF PREGNANCY

When orbital hypotelorism is documented, a detailed anatomic survey should be performed to look for associated malformations, particularly in the central nervous system. Holoprosencephaly should be ruled out. In addition, because of the multiple chromosomal abnormalities seen in association with hypotelorism, a fetal karyotype should be offered. Both parents should have their inner and outer canthal distances measured and compared with normal standards for adults. If the hypotelorism is apparently isolated, there is no indication for a change in the standard management of pregnancy. If the orbital hypotelorism is found to be associated with holoprosencephaly, the parents should be counseled regarding the poor prognosis for this condition. Termination of pregnancy should be discussed if the abnormality is found before 24 weeks of gestation.

FETAL INTERVENTION

There are no fetal interventions for hypotelorism.

TREATMENT OF THE NEWBORN

The infant with isolated hypotelorism should have a detailed physical examination, including postnatal measurements of the inner and outer canthal distances. If a chromosomal analysis was not obtained antenatally, it should be obtained during the postnatal period. In addition, consultation with a medical geneticist is recommended. Consideration should be given to postnatal assessment of the infant's intracranial anatomy by computed tomographic (CT) scan or magnetic resonance imaging (MRI). In the absence of documentation of cerebral abnormalities, the infant with isolated hypotelorism should require only routine newborn care.

SURGICAL TREATMENT

Surgical treatment is not indicated during the newborn period or during early childhood. For the patient who has isolated severe orbital hypotelorism resulting from a mass effect, such as a frontoethmoidal encephalocele, plastic surgery is possible later in life. In one report, severe orbital hypotelorism was successfully corrected surgically in a 15-year-old girl (Cavina et al., 1999).

LONG-TERM OUTCOME

The long-term outcome for a child with isolated hypotelorism is expected to be good. If the hypotelorism is associated with severe cerebral abnormalities, prognosis will depend on the severity of the associated anomalies.

GENETICS AND RECURRENCE RISK

The genetics of hypotelorism will depend on the underlying cause for this finding. If a chromosomal deletion or partial trisomy is detected, parental chromosomes should be studied. Further genetic counseling will depend on whether the parents are shown to be carriers of a balanced translocation. If the underlying diagnosis is trisomy 13, the parents should be counseled that there is a recurrence risk of 1% in addition to the maternal age–related risk. Hypotelorism has been reported as an isolated trait inherited as an autosomal dominant in a three-generation pedigree (Judisch et al., 1984). In this family, intelligence was completely normal. If parental measurements are consistent with a familial trait of hypotelorism, the parents can be counseled about the 50% recurrence risk. At present, no specific gene has been identified for isolated hypotelorism. However, multiple genes have been identified that cause hypotelorism as a result of holoprosencephaly, including sonic hedgehog (*SHH*), sine oculis homeobox (*SIX3*), TG interacting factor (*TGIF*), and zinc finger protein of cerebellum (*Z1C2*) (Dollfus and Verloes, 2004).

27 Macroglossia

CHAPTER

Key Points

- Defined as "true" and "relative." In "true" macroglossia histologic abnormalities are present. In "relative" macroglossia, the tongue is normal but appears large due to jaw underdevelopment or oropharyngeal hypotonia.
- Incidence is 1/11,000 to 1/25,000 livebirths.
- Differential diagnosis includes overgrowth syndromes, trisomy 21, congenital hypothyroidism, inborn errors of metabolism, lymphatic and vascular malformations, and tumors.
- A karyotype is indicated to rule out trisomy 21.
- Prevent airway obstruction at birth.
- Partial glossectomy in childhood is curative.
- Recurrence risks depend on underlying etiology.

CONDITION

In children, *macroglossia* is defined as a resting tongue that protrudes beyond the teeth or the alveolar ridge (Weiss and White, 1990;Weissman et al., 1995). The antenatal diagnosis of macroglossia is somewhat subjective. In the neonate, the tongue grows faster than the other oral structures; it is not limited by the presence of teeth. At rest, some normal neonates may exhibit apparent enlargement of the tongue and protrusion through the lips. For the majority of these newborns, however, the tongue recedes into place with normal anatomic growth of the mouth (Myer et al., 1986). The first scientific report of macroglossia occurred in 1854, when Virchow and Uber described a lingual lymphatic malformation that arose

from dilation of lymphatic spaces in the tongue (Vogel et al., 1986).

Vogel et al. (1986) have defined two types of macroglossia: "true" and "relative." *True macroglossia* means that histologic abnormalities of the tongue are present that correlate with the clinical findings of tongue enlargement. Examples of such findings include vascular malformations, muscular hypoplasia, tumor infiltrate, or the presence of abnormal elements within the tongue, including edema, inflammation, or storage material. In Beckwith–Wiedemann syndrome, the histology of the tongue is normal, and the macroglossia is due to hyperplasia of the muscle fibers. In lymphangioma, histologic analysis reveals numerous endothelial-lined cystic spaces that contain lymphatic fluid, erythrocytes, and lymphocytes in a thin stroma of connective tissue. The striated muscle in the tongue subsequently atrophies where compression has occurred from dilated lymphatics (Rice and Carson, 1985). *Relative macroglossia* means that there is apparent tongue enlargement, but no histologic changes within the tongue are demonstrated. An example of relative macroglossia is in trisomy 21, in which the tongue is normal but appears large due to mandibular or maxillary underdevelopment or generalized oropharyngeal hypotonia.

INCIDENCE

Macroglossia is a rare fetal finding (Weissman et al., 1995). To our knowledge, there are no published reports of the true incidence of macroglossia presenting in utero. An estimate of the incidence of macroglossia may be calculated indirectly from the incidences of three common conditions that are associated with macroglossia—Beckwith–Wiedemann syndrome, congenital hypothyroidism, and trisomy 21. The incidence of Beckwith–Wiedemann syndrome is 1 in 13,500 births (Patterson et al., 1988). Approximately 82% to 99% of infants with Beckwith–Wiedemann syndrome have macroglossia (McManamny and Barnett, 1985; Elliott and Maher, 1994). Taking the more conservative estimate of macroglossia

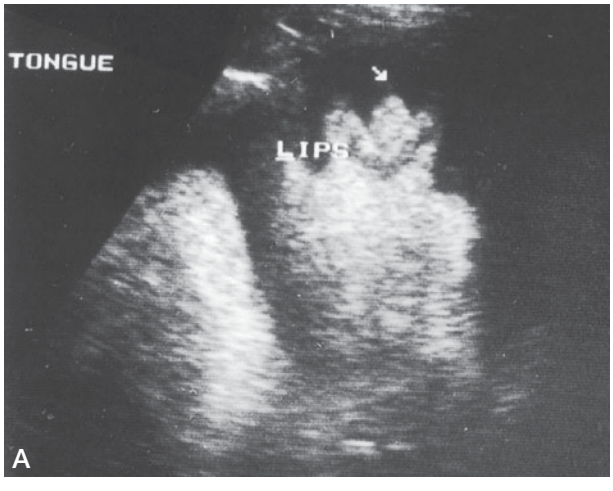

Figure 27-1 **A**. Prenatal sagittal scan performed at 34 weeks of gestation, demonstrating a large tongue that protrudes beyond the fetal lips. **B**. Postnatal photograph of same individual at 2 months of age. The macrosomia, macroglossia, and lax abdominal musculature were consistent with a diagnosis of Beckwith–Wiedemann syndrome. (*From Viljoen DL, Jaquire Z, Woods DL. Prenatal diagnosis in autosomal dominant Beckwith–Wiedemann syndrome.* Prenat Diagn. *1991;11:167-175. Copyright 1991 John Wiley & Sons Ltd. Reprinted, by permission, of John Wiley & Sons Ltd.*)

in Beckwith–Wiedemann syndrome (82%), this would give an approximate incidence of 1 in 16,000 livebirths with macroglossia due to Beckwith–Wiedemann syndrome. Overall, trisomy 21 occurs in 1 in 1000 livebirths. Approximately 8.9% of fetuses with trisomy 21 have macroglossia (Weissman et al., 1995). This would give a livebirth incidence of macroglossia due to trisomy 21 of 1 in 11,000. Congenital hypothyroidism occurs in 1 in 5,000 livebirths (Kourides et al., 1984). Approximately 20% of newborns with hypothyroidism have macroglossia (Grant et al., 1992). This would equal a livebirth incidence of 1 in 25,000 livebirths with hypothyroidism and macroglossia. Summation of these studies gives a range of 1 in 11,000 to 1 in 25,000 livebirths presenting with macroglossia as a symptom.

SONOGRAPHIC FINDINGS

The tongue can be successfully imaged by an inferior coronal view of the fetal face. The tongue can also be visualized by the sagittal profile face view, if the tongue is extending from the mouth (Figure 27-1A) (Weissman et al., 1995). Fetuses with macroglossia have a large protruding tongue (Figure 27-2A). In normal fetuses, the growth of the tongue is linear between 13 and 18 weeks of gestation (Bronshtein et al., 1998). Although nomograms have been published for both first and second trimester fetal tongue size (Achiron et al., 1997; Bronshtein et al., 1998), the diagnosis is usually subjective. Additional sonographic findings include polyhydramnios due to impairment in fetal swallowing. Considerations in the further assessment of fetuses with macroglossia include a detailed search for associated anomalies. Specifically, it is important to rule out fetal goiter (Kourides et al., 1984). A large for gestational age fetus with polyhydramnios might also suggest maternal diabetes, or one of the overgrowth syndromes (see Chapter 124). A macrosomic fetus with macroglossia and other findings, such as omphalocele, increased abdominal circumference, adrenal gland cyst, nephromegaly, and cardiovascular abnormalities, is most likely to have Beckwith–Wiedemann syndrome (Cohen, 2005). Table 27-1 summarizes the prenatal ultrasonographic findings in six cases of Beckwith–Wiedemann syndrome. Macrosomia due to Beckwith–Wiedemann syndrome is a constant finding and can be diagnosed between 16 and 22 weeks of gestation (Viljoen et al., 1991). Prenatal diagnosis of Beckwith–Wiedemann syndrome has been reported at 19 weeks of gestation (Winter et al., 1986), 28 weeks of gestation (Wieacker et al., 1989), and 30 weeks of gestation (Cobellis et al., 1988). Prenatal sonographic diagnosis is not always conclusive for this condition. Even in the setting of a positive family history and multiple prenatal sonograms, the diagnosis was missed in a fetus who presented with severe hydronephrosis, cardiomegaly, and hepatomegaly in utero (Nowotny et al., 1994). Furthermore, there is clinical overlap between Beckwith–Wiedemann syndrome and an X-linked overgrowth syndrome, Simpson Golabi Behmel syndrome (DeBaun et al., 2001).

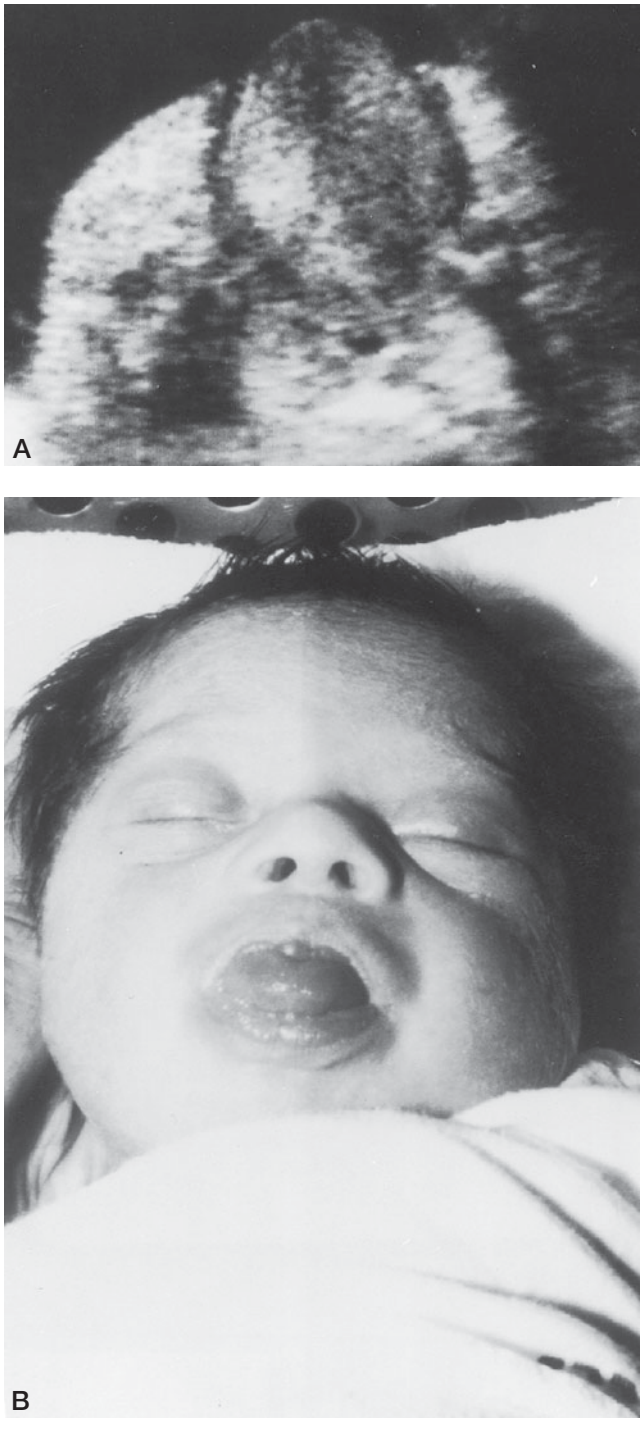

Figure 27-2 **A**. Axial scan through the floor of the fetal mouth, performed at 22 weeks of gestation, demonstrating a large tongue that extends outside of the mouth. This was the only abnormal finding. **B**. Postnatal photograph of same infant during the neonatal period, showing an enlarged tongue. The karyotype revealed trisomy 21. Birth weight (g)	4285	4600	—	5100	—	5300	

**wga = Gestational age in weeks. (From Viljoen et al., 1991.)*

An additional important consideration in fetal sonographic assessment of macroglossia is the possibility of lingual lymphatic malformations, often seen in association with other lymphatic malformations, such as cystic hygroma. Prenatal sonographic assessment should also specifically exclude abnormalities associated with trisomy 21, such as shortening of the long bones, an increased nuchal fold, cardiovascular defects, widening of the space between the first and second toes, and renal pyelectasis.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of conditions associated with macroglossia is given in Table 27-2. The most important considerations in the differential diagnosis include the overgrowth syndromes, such as Beckwith–Wiedemann (Figure 27-1B) and Simpson-Golabi-Behmel, trisomy 21 (Figure 27-2B), congenital hypothyroidism, lingual lymphatic malformations, tumor/epignathus (Figures 27-3A and 27-3B), and hemangiomas/vascular malformations. Prior to the recognition of Beckwith–Wiedemann syndrome in 1963, lymphangioma was the most common cause of macroglossia presenting during the newborn period. Sixty percent of lymphangiomas that involve the tongue present at birth (Rice and Carson, 1985). Lingual lymphatic malformations are the most common vascular abnormalities of the tongue and are frequently localized to the anterior two-thirds of the tongue. Inborn errors of metabolism that can be associated with macroglossia include Hunter, Hurler, Maroteaux–Lamy, and Sanfilippo syndromes, as well as Pompe (glycogen storage disease, type II) I-cell disease, and GM_1

Table 27-2

Differential Diagnosis of Conditions Associated with Micrognathia

- Chromosome abnormalities
  - Trisomy 21
  - Pallister–Killian syndrome (mosaic trisomy 12p)
- Inborn error of metabolism
  - Congenital hypothyroidism
  - Hurler syndrome
  - I-cell disease
  - GM_1 gangliosidosis
  - Pompe disease
  - Farber's lipogranulomatosis
- Overgrowth syndromes
  - Beckwith–Wiedemann syndrome
  - Simpson-Golabi-Behmel syndrome
  - Maternal diabetes
- Anatomic abnormalities
  - Lymphangioma
  - Hemangioma
  - Epignathus
  - Teratoma

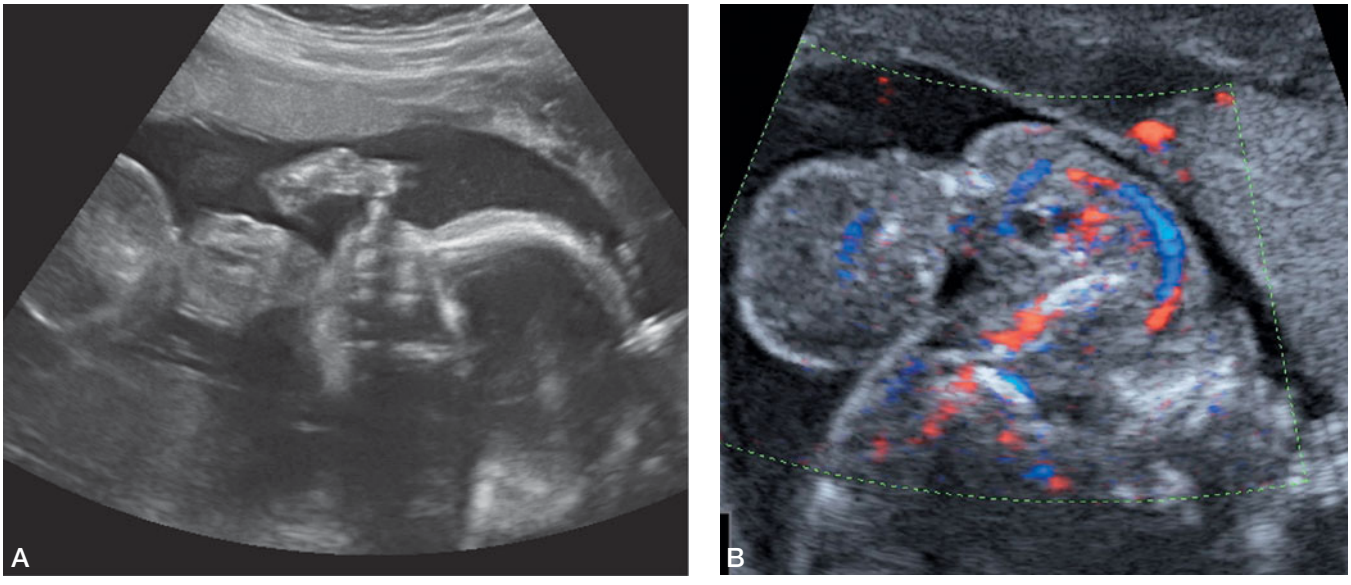

Figure 27-3 **A**. Sagittal view of a fetus at 19 weeks showing a teratoma protruding from the tip of the tongue into the amniotic cavity. **B**. Transverse view of the same fetus showing vascular supply through the tongue mass.

gangliosidosis. Of these, the disorders that can present during the newborn period are Hurler, I-cell, GM_1 gangliosidosis, and possibly Pompe. Patients with I-cell disease are typically growth-restricted and have abnormal neurologic signs. Farber's lipogranulomatosis, in its most severe form, can also present during the neonatal period. These infants will have the classic triad of subcutaneous nodules, hoarseness, and joint involvement.

ANTENATAL NATURAL HISTORY

The antenatal natural history of macroglossia is unremarkable. As an isolated finding, there is no evidence for in utero lethality due to the presence of macroglossia. However, macroglossia due to trisomy 21 does have an increased risk for pregnancy loss. As stated earlier, there can be polyhydramnios associated with macroglossia due to impairment of swallowing.

MANAGEMENT OF PREGNANCY

When macroglossia is documented in utero, a detailed fetal sonographic anatomical evaluation is indicated to look for associated anomalies. It is important to rule out the anomalies associated with Beckwith–Wiedemann syndrome, such as omphalocele, macrosomia, and nephromegaly. It is also important to rule out trisomy 21. Nicolaides et al. (1992, 1993) described a series of 13 fetuses with macroglossia. In 10, a chromosomal abnormality was found, and 9 of the 10 had trisomy 21. None of these patients had isolated macroglossia; additional anomalies were always documented. However, Weissman et al. (1995) have described a case of isolated macroglossia due to trisomy 21 (see Figure 27-2). Given the fact that macroglossia is a relatively rare finding, we recommend obtaining a chromosomal analysis on the fetus with macroglossia. This is important for two reasons: one is to rule out trisomy 21 or mosaic trisomy 12p as the cause of the macroglossia. The other consideration is that in some cases of Beckwith–Wiedemann syndrome, there are abnormalities seen in chromosome 11p15.

If hypothyroidism is suspected in the fetus, particularly in the presence of a goiter, it has been recommended to obtain amniotic fluid thyroid-stimulating hormone (TSH) levels to confirm the diagnosis. According to Kourides et al. (1984), the normal TSH levels in amniotic fluid at 26 and 38 weeks of gestation are 0.44 ± 0.21 μU per milliliter and 0.27 ± 0.15 μU per milliliter, respectively. The fetus reported by Kourides et al. had markedly elevated TSH values of 2.4 and 2.9 μU per milliliter at 26 and 38 weeks. These authors advocate the early diagnosis of hypothyroidism to permit treatment of the infant on day 1 of life. Although newborn screening for hypothyroidism is routine in most states, the diagnosis is not usually communicated to the pediatrician until 2 to 3 weeks after birth. Thus, the infant does not generally receive treatment until approximately 3 to 4 weeks of age. If hypothyroidism is prenatally diagnosed, treatment can begin immediately after birth and reduce symptoms. If the macroglossia is due to Beckwith–Wiedemann syndrome, the fetus may be large for gestational age, and cesarean delivery may be necessary because of dystocia.

FETAL INTERVENTION

There are no fetal interventions indicated for macroglossia.

TREATMENT OF THE NEWBORN

The immediate considerations in treatment of the newborn with macroglossia include preventing airway obstruction, monitoring for difficulties in feeding and swallowing, and monitoring for hypoglycemia if a clinical diagnosis of Beckwith–Wiedemann syndrome is suspected. Physical examination should confirm the macroglossia. During the newborn period this will be notable for the tongue protruding through the lips. Palpation of the tongue is generally unremarkable and unrevealing. The diagnosis of Beckwith–Wiedemann syndrome is important to make because of the increased rate of infant mortality associated with this condition. Babies with Beckwith–Wiedemann syndrome are at risk for severe neonatal hypoglycemia, seizures, and congestive heart failure (Viljoen et al., 1991).

The most common neonatal findings in infants with Simpson-Golabi-Behmel syndrome are a birth weight and length >95% for age, macroglossia, coarse facial features, extramammary nipple, and genitourinary anomalies (DeBaun et al., 2001).

As mentioned earlier, in infants with trisomy 21, the tongue is not actually enlarged. In a radiographic study of the tongue of several patients with Down syndrome, Ardran et al. (1972) demonstrated that the problem in Down syndrome was due to large lingual tonsils, which narrowed the airway. They hypothesized that the gaping mouth of the patient with Down syndrome related to the need to provide an airway. The major problems in Down syndrome relate to oropharyngeal hypotonia and midface underdevelopment. The tongue protrusion present during the first year of life in infants with trisomy 21 tends to disappear with improved muscular tone as the patients grow older. Limbrock et al. (1991) advocate the use of a palatal plate to stimulate oral muscular tone to improve spontaneous tongue positioning, drooling, and the open-mouthed posture seen in infants and children with trisomy 21.

If no prenatal studies have been obtained, the physical examination is the most important component of the assessment of the newborn with macroglossia. If physical findings suggest Down syndrome, a chromosomal analysis should be performed. If physical findings suggest Beckwith–Wiedemann syndrome, a chromosomal study should also be performed to look for abnormalities of 11p15 (Slavotinek et al., 1997). Special efforts should be made to verify the results of newborn screening thyroid function tests. In the absence of any other diagnosis, consideration should be given to the diagnosis of inborn errors of metabolism. Urine for mucopolysaccharides, oligosaccharides, and sialyloligosaccharides will identify most metabolic diseases. Pompe (glycogen storage disease, type II) would not be identified by the urine tests, but the clinical findings of cardiomyopathy and significant hypotonia should suggest the diagnosis. Similarly, the clinical findings present in Farber lipogranulomatosis should help in diagnosis, although the assay for acid ceramidase in leukocytes, fibroblasts, and amniocytes will be definitive.

SURGICAL TREATMENT

Many infants with macroglossia will have spontaneous resolution of the problem due to normal growth of the oropharynx, mandible, and maxilla. The major treatment for this condition is a partial glossectomy early in life to restore adequate breathing and swallowing, and to leave a tongue capable of normal speech, taste sensation, and further orofacial development (Rice and Carson, 1985). Most surgeons recommend operative intervention by 6 months of age to prevent dental abnormalities such as prognathism and malocclusion. McManamny and Barnett (1985), who are strong advocates for partial glossectomy, state that macroglossia is unsightly, predisposes to drooling, and gives a false impression of mental retardation. Macroglossia affects dentition and prevents orthodontic treatment until the tongue is reduced. Macroglossia also affects the pronunciation of consonants, thereby impairing clarity of speech.

The goals of surgery include preservation of normal taste sensation, restoration of normal size and shape of the tongue for proper articulation after incision, and correction of a dental arch deformity and malocclusion of the teeth by later orthodontics (Gupta, 1971). Surgical methods include an anterior V-shaped wedge resection, a bilateral marginal resection, a U-shaped resection with the open end facing posteriorly, and a combined transoral–transcervical approach for an extremely large lesion (Myer et al., 1986; Wang et al., 2003). Partial glossectomy is curative, and postoperatively there is no recurrence. In occasional cases in which the initial resection is inadequate, a second procedure is performed to remove more of the tongue. For most patients, however, the treatment is completely curative and these lesions heal well. Even in cases of Beckwith–Wiedemann syndrome, there is no evidence that the muscular hyperplasia causes the tongue to increase in size after surgery.

LONG-TERM OUTCOME

Patients with macroglossia need to be followed for evidence of chronic alveolar hypoventilation, which has been documented in patients with Beckwith–Wiedemann syndrome and has been noted to cause a secondary reversible pulmonary hypertension syndrome (Smith et al., 1982). If there is a suggestion of airway obstruction, patients should be monitored closely for evidence of hypoventilation with intermittent blood gas evaluation. In rare cases, tracheostomy has been recommended. Symptomatic macroglossia can lead to noisy breathing, difficulty with chewing and swallowing, drooling, slurred speech, an open bite deformity, a dry cracked tongue, and ulceration and secondary infection of the tongue (Vogel et al., 1986). In patients who are diagnosed with either Beckwith–Wiedemann or Simpson-Golabi-Behmel syndrome, close follow-up for development of embryonal tumors is warranted (Schneid et al., 1997; DeBaun et al., 2001).

These include frequent postnatal sonographic studies to assess for Wilms tumor, hepatoblastoma, and nephroblastoma (McManamny and Barnett, 1985).

In a long-term follow-up of 13 children with Beckwith–Wiedemann syndrome ascertained by congenital macroglossia, Hunter and Allanson (1994) described normalization of the craniofacial appearance by adolescence, leaving little clue as to the original diagnosis. None of the patients described in this series had mental retardation.

GENETICS AND RECURRENCE RISK

Isolated macroglossia has been described as a familial trait inherited as an autosomal dominant manner in two unrelated families (Reynoso et al., 1986). Recurrence risks for trisomy 21 are described more fully in Chapter 131. Beckwith–Wiedemann syndrome is a complex and genetically heterogeneous condition. Most cases are chromosomally normal. The gene has been localized to chromosome 11p15 by linkage analysis in the 15% of families that appear to have a familial transmission of this condition (Slavotinek et al., 1997). Chromosomal analysis is recommended in cases of Beckwith–Wiedemann syndrome to rule out duplications or abnormalities of chromosome 11p15, although this is only found in 1% to 2% of cases (Rump et al., 2005). Although most cases of Beckwith–Wiedemann syndrome are sporadic, recessive and multifactorial inheritance has also been suggested (Viljoen et al., 1991). Overexpression of insulinlike growth factor 2 (*IGF2*), the gene involved in Beckwith–Wiedemann syndrome, is maternally imprinted and functions as a growth factor and tumor suppressor (Weksberg et al., 1993). In 28% of parents who carry informative DNA polymorphisms, uniparental disomy has been demonstrated (Slatter et al., 1994). In all the cases studied by Slatter et al., there was paternal uniparental disomy present as a mosaic cell line. Therefore, there is good evidence in sporadic cases that uniparental disomy of chromosome 11 occurs as a postzygotic event. In families in which this is demonstrated, there should theoretically be no recurrence risk. In parents who have an affected infant with Beckwith–Wiedemann syndrome, a family history should be obtained to rule out dominant patterns of inheritance.

Germline mutations in the cyclin-dependent kinase inhibitor gene *CDKN1C* (p57KIP2) are found in approximately 40% of familial cases of Beckwith–Wiedemann syndrome (Rump et al., 2005). A higher frequency of omphalocele has been shown in the cases associated with *CDKN1C* mutations (Lam et al., 1999).

Simpson Golabi Behmel syndrome is an X-linked condition that arises as a result of deletions or point mutations in the *glypican-3* gene at Xq26 (DeBaun et al., 2001).

Macroglossia due to inborn errors of metabolism is inherited in a pattern consistent with a single-gene defect. Recurrence risk is related to the underlying disorder, whether it is an autosomal recessive or X-linked condition.

28 CHAPTER Micrognathia and Agnathia

Key Points

- Facial malformation characterized by mandibular hypoplasia and a small receding chin that fails to maintain the tongue in a forward position.
- Incidence is 1 in 1600 fetuses.
- Very high incidence of associated anomalies.
- Differential diagnosis includes Pierre Robin, Stickler, Treacher Collins, and Nager syndromes.
- Fetal karyotype, including FISH studies for DiGeorge syndrome, is indicated.
- DNA studies may be indicated if a syndrome is suspected.
- Delivery should occur in a tertiary center due to the potential for neonatal airway problems.

CONDITION

Micrognathia is a facial malformation characterized by mandibular hypoplasia and a small, receding chin that fails to maintain the tongue in a forward position (Figure 28-1).

Early in embryonic development, the mandible grows slowly. Between 4 and 8 weeks of gestation, the developing tongue remains in the nasal cavity, between the palatine shelves, and a physiologic micrognathia is present. Around the 8th week of gestation, the mandible grows rapidly, and the tongue is normally pulled downward and forward. This allows the palatine shelves to come together to form the secondary palate. At this point in gestation, the mandible extends beyond the maxilla, but continued growth of the maxilla once again produces a relative micrognathia in the fourth and fifth months of gestation. The mandible continues to grow during the third trimester. If the compensatory growth of the mandible is incomplete at birth, a relative micrognathia can exist (Hawkins and Simpson, 1974).

Micrognathia may result from environmental or genetic factors. For example, sharp flexion of the fetal neck in utero results in continuous pressure of the chin against the sternum, which impedes mandibular growth (Hawkins and Simpson, 1974). Micrognathia is also one component of many chromosomal and genetic syndromes (see "Differential Diagnosis").

Figure 28-1 Three-dimensional image demonstrating micrognathia.

Micrognathia is commonly thought of as one component of the Pierre Robin syndrome. This clinical triad consists of micrognathia, upper airway obstruction, and a U-shaped cleft palate. The name derives from a 1923 report by Pierre Robin, a French stomatologist, who described the association between newborn micrognathia and upper airway obstruction caused by glossoptosis (posterior displacement of the tongue). The symptoms associated with this "syndrome" are primarily due to an underlying mandibular abnormality (Figure 28-1). During fetal life, when the mandible is hypoplastic, the tongue cannot descend normally into the oral cavity at 7 to 11 weeks of gestation. If the tongue does not descend, it will remain pressed against the base of the cranium. This will then interfere with fusion of the medially growing palatal shelf and ultimately result in a cleft palate (Shprintzen, 1988).

Normal mandibular growth may depend on the presence of mandibular movement during intrauterine development. In one study, Sherer et al. (1995) examined the correlation between lack of mandibular movement, manifested by the absence of fetal swallowing and the development of subsequent micrognathia. For more than a 4-year period, these investigators studied 28 fetuses with polyhydramnios, defined as an amniotic fluid volume of >20 cm^3. The study group consisted of 14 fetuses studied sonographically with absent mandibular movement and a nonvisualized stomach. These findings were interpreted as being consistent with absent fetal swallowing. The control group consisted of 14 fetuses with polyhydramnios but who had sonographic evidence of swallowing. In the study group, 2 fetuses were stillborn. Of the 12 liveborn infants, 11 died in the neonatal period between 1 hour and 7 days of life. All the fetuses in the study group had micrognathia confirmed at birth, whereas none of the fetuses in the control group had micrognathia. These authors concluded that lack of fetal swallowing movements were likely to be important in the development of micrognathia. In this study, four major groups of underlying anomalies were identified in cases of absent fetal swallowing:

1. Complete absence of any fetal movements (fetal hypokinesia/akinesia sequence).
2. Major central nervous system abnormalities with neurologic impairment of the swallowing mechanism.
3. Abnormal karyotype.
4. Isolated absent swallowing due to Moebius sequence (sixth and seventh cranial nerve palsy) (Sherer et al., 1995).

The most severe form of micrognathia is agnathia—total or virtual absence of the mandible. This extremely rare and lethal anomaly also known as otocephaly, is the result of a developmental field defect thought to be secondary to an insult to developing neural crest cell derivatives (Persutte et al., 1990). Prenatal sonographic diagnosis has been reported for this condition (Persutte et al., 1990) (Figures 28-2A and 28-2B).

INCIDENCE

The incidence of mild-to-moderate micrognathia in the general population is unknown. In a high-risk referral center, 56 cases of micrognathia were identified in 2086 fetuses (2.6%) studied in a tertiary sonographic unit for more than 8 years (Nicolaides et al., 1993). More recently, the incidence of micrognathia in a single center was estimated to be 1 in 1600 fetuses (Vettraino et al., 2003).

SONOGRAPHIC FINDINGS

The first prenatal diagnosis of micrognathia was made in a patient deemed to be at risk for Pierre Robin syndrome because the parents already had an affected child. At 23 weeks of gestation, the facial structures were studied and considered to be within normal limits. The same patient returned at 35 weeks of gestation, when polyhydramnios and a striking micrognathia were demonstrated. This report indicated that significant fetal mandibular growth occurs during the third trimester (Pilu et al., 1986). In a later study of 2086 high-risk fetuses, severe micrognathia was diagnosed by the presence of a prominent upper lip and a small chin in 56 cases (Nicolaides et al., 1993). Significantly, all cases with micrognathia in this study had additional malformations or evidence of intrauterine growth restriction. A review of 20 prenatally diagnosed cases of Pierre Robin sequence noted a high incidence of associated polyhydramnios (60% of cases) and cleft palate (45% of cases) (Hsich et al., 1999). Micrognathia has been diagnosed in the first trimester (Teoh and Meagher, 2003).

Three-dimensional image of same fetus showing the absence of lower facial structures. Due to the craniofacial abnormality the ears cannot migrate upward from the fetal neck. (*Photograph courtesy of Prenatal Diagnosis Center, Women and Infant's Hospital.*)

All reports of sonographic studies performed on fetuses with micrognathia stress the extremely high incidence of associated anomalies and the grim prognosis for this finding. Bromley and Benacerraf (1994) described their experience with 20 fetuses diagnosed with micrognathia between 15 weeks of gestation and full term. Thirteen of these fetuses had polyhydramnios (a 70% incidence). These authors hypothesized that the polyhydramnios was due to difficulty in fetal swallowing. These authors recommended a full sonographic evaluation of the fetal face, which optimally includes a midsagittal profile, coronal sections of the lower face, and axial evaluation of the orbital area. In this report, micrognathia was subjectively defined as an unusually small mandible with a receding chin demonstrated on the midsagittal view of the fetal face (Figure 28-3). The fetal mandible was not measured.

Several reports have attempted to establish sonographic nomograms of fetal mandibular length in relationship to gestational age (Otto and Platt, 1991; Paladini et al., 1999). To provide objective evidence of micrognathia, Chitty et al. (1993) created a growth chart for mandibular length in 184 normal fetuses between 12 and 27 weeks of gestation. The fetal mandible was measured from the proximal end of the ramus at its insertion site into the temporomandibular joint to its distal end where it meets the cartilaginous symphysis mentis. The measurement was made in a plane that visualized one ramus of the jaw. The ultrasound beam was placed at a right angle to the plane of the mandible. A single measurement was recorded. Normal values obtained in this study are given in Table 28-1. At more than 28 weeks of gestation, it became difficult to identify and define fetal facial landmarks. This was due to change in fetal positioning and adjacent bony structure shadowing. These authors, as well as others, stated that accurate and reliable measurements of the mandible were not possible in the third trimester. In another study, fetal mandibular measurements were obtained in a scan plane parallel to the mandible that included the fetal hypopharynx. In this report of 204 women with uncomplicated pregnancies and reliable gestational dating, the anterior, posterior, and transverse fetal jaw measurements were shown to increase with gestational age (Watson and Katz, 1993).

Paladini et al. (1999) also showed that mandibular growth correlated linearly with gestational age and biparietal diameter. This group developed the jaw index

(anteroposterior mandibular diameter/BPD × 100) to objectively diagnose micrognathia. In a population of 198 fetuses with malformations, they compared the jaw index to subjective assessment of micrognathia. The jaw index had a 100% sensitivity and a 98.1% specificity in diagnosing micrognathia at a cutoff level of less than 23, which was better than the 73% sensitivity when using a subjective approach. More recently 3D ultrasound imaging has been recommended, as it provides a true midline sagittal view of the fetal face (Lee et al., 2002).

Fetal micrognathia is highly associated with the presence of additional structural abnormalities, including intrauterine growth restriction, skeletal dysplasias, congenital heart disease, and polyhydramnios. A diagnosis of isolated micrognathia is unlikely. Vettraino et al. (2003) performed a retrospective review of outcome for 15 fetuses diagnosed with "isolated" micrognathia; 14 of 15 had additional anomalies, including 11 cases of cleft palate, and 3 cases of syndromes or associations.

DIFFERENTIAL DIAGNOSIS

Micrognathia is diagnosed either subjectively or objectively, by comparing individual fetal jaw measurements with the nomograms for fetal mandible measurements as a function of gestational age. The differential diagnosis must include conditions that are known to be associated with micrognathia. These are summarized in Table 28-2, and include chromosomal abnormalities, neuromuscular abnormalities,

Table 28-2

Conditions Associated with Micrognathia

Chromosomal abnormalities
- Trisomy 18
- Triploidy
- Trisomy 13
- Trisomy 9
- Trisomy 8

Neuromuscular abnormalities
- Pena–Shokeir syndrome
- Fetal akinesia/hypokinesia syndrome
- Arthrogryposis multiplex congenita

Single-gene disorders
- Familial trait (autosomal dominant)
- Stickler syndrome (autosomal dominant)
- Treacher Collins syndrome (autosomal dominant)
- Diastrophic dysplasia (autosomal recessive)
- Campomelic dysplasia (autosomal recessive)
- Saethre Chotzen syndrome (autosomal recessive)
- Nager acrofacial dysostosis (autosomal dominant)
- Multiple pterygium syndrome (autosomal recessive)
- Thrombocytopenia–absent radius syndrome (autosomal recessive)

Other syndromes
- Congenital ichthyosis
- Beckwith–Wiedemann

Teratogen
- Isotretinoin exposure

single gene (Mendelian) disorders, other syndromes, and teratogen exposure. Stickler syndrome, an autosomal dominant disorder consisting of micrognathia, myopia, epiphyseal dysplasia, juvenile arthropathy, cleft palate, mild sensorineural hearing loss, and airway obstruction, is frequently missed during the newborn period. In a retrospective review of patients with micrognathia and symptoms consistent with the Robin malformation, Shprintzen (1988) found a very high incidence of Stickler syndrome. Most of these cases were diagnosed later in childhood. Treacher Collins syndrome, a dominantly inherited disorder consisting of micrognathia, small ears, downslanting palpebral fissures, malar hypoplasia, lower eyelid coloboma, and abnormal hair growth, has been diagnosed prenatally by noting the presence of a hypoplastic mandible, absent ears, and severe polyhydramnios (Crane and Beaver, 1986; Meizner et al., 1991; Cohen et al., 1995). Similarly, Nager syndrome (acrofacial dysostosis), a dominantly inherited disorder that consists of mandibulofacial abnormalities and shortened upper extremities, has also been diagnosed by prenatal sonography via the demonstration of markedly hypoplastic mandible, malformed external ear, poorly ossified long bones of the arm, and polyhydramnios (Benson et al., 1988; Paladini et al., 2003).

ANTENATAL NATURAL HISTORY

Fetal micrognathia is frequently associated with severe underlying abnormalities (Figure 28-4). At least three separate studies suggest that increased lethality is associated with this malformation. In a study by Turner and Twining (1993) of 3200 fetuses scanned at a single institution, 9 were identified with micrognathia. The underlying diagnosis for these 9 fetuses included 3 cases of trisomy 18, 4 cases of skeletal dysplasias (including short rib-polydactyly, 2 cases of campomelic dysplasia, and 1 case of diastrophic dysplasia), 1 case of Roberts syndrome, and 1 case of multiple anomalies. Nicolaides et al. (1993) described their experience with 56 cases of fetal micrognathia. Thirty-seven (66%) of these had abnormal chromosomes. Surprisingly, the prognosis was equally poor for the 19 fetuses with normal chromosomes. Of the 19, 10 were terminated electively, 4 had died during the neonatal period, and 5 died in utero. Only 1 infant was born alive. Most of the fetuses affected with micrognathia had associated abnormalities, including ventriculomegaly (8 cases), hydronephrosis (9 cases), and diaphragmatic hernia (2 cases). In the study performed by Bromley and Benacerraf (1994), 80% of fetuses with micrognathia (16 of 20) did not survive postnatally. Of these, 6 were terminated electively and 10 died in utero or during the immediate neonatal period. After reviewing the autopsy diagnoses on the products of conception these authors concluded that at least four of the six cases in the electively terminated fetuses would definitely have been lethal had the pregnancy continued to term.

Figure 28-4 Milder micrognathia demonstrated in a fetus terminated at 19 weeks of gestation due to multiple anomalies detected sonographically. (*Photograph courtesy of Dr. Joseph Semple.*)

MANAGEMENT OF PREGNANCY

An attempt should be made to examine both parents, because a significant number of mild-to-moderate cases of micrognathia are inherited as familial traits. A family history should be obtained to seek specific evidence of other cases of micrognathia (especially family members affected with Stickler syndrome), or exposure to drugs such as isotretinoin. Following a diagnosis of micrognathia, a targeted fetal anatomy scan should be performed, with particular attention paid to the diagnosis of cardiac or skeletal defects. Fetal magnetic resonance imaging may provide additional information regarding the fetal face (Robson and Barnewolt, 2004). It is recommended that the fetal ears be examined to rule out Treacher Collins syndrome or oculoauriculovertebral dysplasia (Goldenhar syndrome) (see Chapter 24) (Bromley and Benacerraf, 1994).

When micrognathia is diagnosed, fetal karyotyping is indicated, and consideration should be given to ruling out the 22q11 microdeletion associated with DiGeorge syndrome by fluorescent in situ hybridization analysis (see Chapter 139).

In an 8-year survey of 2086 high-risk fetuses, 56 were shown to have micrognathia (Nicolaides et al., 1993). Of these 56 affected fetuses, 37 (66%) had chromosomal abnormalities. These karyotypes included 21 cases of trisomy 18, 9 cases of triploidy, and 3 cases of trisomy 13, but no cases of trisomy 21. Similar results were reported by Bromley and Benacerraf (1994), who demonstrated that 5 of 20 (25%) with micrognathia had an abnormal karyotype. Of the 5, 3 had trisomy 18, 1 had trisomy 13, and 1 had trisomy 9. Conversely, in sonographic studies of 83 fetuses with a known diagnosis of trisomy 18 and 42 fetuses with triploidy, micrognathia was detected in only 21 (25%) and 9 (21%), respectively. Therefore, only the most severe jaw defects are demonstrable by prenatal sonography in aneuploid fetuses (Nicolaides et al., 1993).

In the setting of a known family history of Stickler syndrome, DNA diagnosis for mutations in *COL2A1*, *COL11A1*, or *COL 11A2* may be indicated. Furthermore, if the fetal face suggests Treacher Collins syndrome, mutations in the *TCOF1* gene may be diagnostic.

If a fetus is diagnosed with micrognathia and an additional anomaly, the parents should be counseled regarding the expected poor prognosis for the fetus. Agnathia is uniformly fatal at birth. Termination of pregnancy can be offered if the fetus is at less than 24 weeks of gestation.

Infants with micrognathia need to delivered in a tertiary care center because the micrognathia can cause severe respiratory distress and the anatomy of the jaw makes orotracheal intubation difficult. Neonatologists and pediatric anesthesiologists should be available to resuscitate an infant expected to have micrognathia (Figure 28-5). The ex utero intrapartum treatment (EXIT) procedure has been described to allow airway management of a newborn with dysgnathia complex (Baker et al., 2004). Cesarean delivery is not necessary other than for standard obstetric indications.

FETAL INTERVENTION

There are no fetal interventions for micrognathia.

TREATMENT OF THE NEWBORN

Infants with micrognathia are at serious risk for airway obstruction because the anterior attachment of the tongue is displaced posteriorly, so the tongue tends to fall back into the pharynx. The tongue can therefore act as a ball–valve mechanism in the pharynx. These infants are at serious risk for regurgitation and aspiration due to difficulties in breathing and feeding simultaneously. Most patients can maintain an adequate airway as long as they are awake and actively moving their tongue. When they fall asleep, however, the tongue musculature relaxes and the airway can become obstructed. Relief of obstruction can be achieved by pulling the tongue forward or by placing the patient in the prone position (Hawkins and Simpson, 1974). Any infant with micrognathia should be admitted to a special care nursery and observed by pulse oximetry. The propensity for respiratory obstruction can then be monitored while the infant is under supervision in the prone position.

Affected infants also have difficulty with oral feedings (Vettraino et al., 2003). Feedings should be offered with a soft nipple in an almost upright position. In some centers, these infants are offered a nasopharyngeal positive-pressure tube with nasogastric feedings to promote weight gain and maintain patency of the airway. If the infant appears to be stable and pulse oximetry is normal, conservative (nonoperative) treatment is best.

Figure 28-5 Infant depicted in Figure 28-3, who was delivered after a full-term gestation. He required immediate placement of a tracheostomy tube in the delivery room due to the inability to orally intubate him.

Infants with micrognathia should be closely examined for the presence of associated anomalies. If present, consultation with a medical geneticist is indicated. If a syndrome is under consideration, blood or skin fibroblasts should be obtained as a source of DNA for mutation analysis.

SURGICAL TREATMENT

There are multiple options for surgical treatment, including glossopexy (anchoring of the tongue to the mandible and lower lip) and tracheostomy. Most infants are given an initial trial of conservative management, but if multiple pneumonias develop, consideration should be given to performing tracheostomy to maintain the airway. Monroe and Ogo (1972) described their experience with 65 infants with micrognathia. Of these, nine had a tracheostomy tube placed for an average of 19.2 months. Two of these nine infants died. There was a very high incidence of associated abnormalities. They described the case histories of an additional seven patients who did not have a tracheostomy tube placed. These authors concluded that five of the deaths could have been prevented by performing tracheostomy. If the infant is failing to thrive because of difficulties with swallowing, gastrostomy tube placement may be considered to allow improved nutrition.

LONG-TERM OUTCOME

Monroe and Ogo (1972) reviewed records of 65 patients with micrognathia treated at the Children's Memorial Hospital in Chicago between the years 1950 and 1969. Eight deaths occurred in this group of patients. All were due to aspiration with or without pneumonia. Of the 65 patients, 51 (78%) failed to thrive. In addition, there was a high incidence of associated anomalies (56% of patients). These included congenital heart disease (14 patients), ear abnormalities (7), clubfoot (4), congenital hip dislocation (3), and syndactyly (3). Of the long-term survivors in the Bromley and Benacerraf (1994) study, one had Treacher Collins syndrome, one had Pierre Robin malformation, one had intrauterine growth restriction but is now normal, and one had multiple congenital anomalies but survived postsurgical repair.

The long-term outcome for many infants with micrognathia will depend on the extent and severity of the associated malformations. For the infant with isolated micrognathia, the potential for mandibular growth means that symptoms will potentially disappear over the first few years of life. If any long term concerns exist due to the child's physical appearance, orthodontic therapy and jaw advancement can be offered during adolescence (Kennett and Curran, 1973).

GENETICS AND RECURRENCE RISK

The recurrence risk for the syndromes listed in Table 28-2 with a known pattern of inheritance will be 25% or 50%, depending on whether the syndrome is autosomal recessive or dominant, respectively. Both parents should be examined, as it is possible that one of them has an undiagnosed syndrome. The recurrence risk for a fetal chromosomal abnormality will be 1%, or the age-related maternal risk, whichever is higher.

A few reports suggest that a single gene exists that predisposes to micrognathia or related orofacial defects. In one report, 10 of 65 patients with micrognathia had at least one family member with cleft palate (Monroe and Ogo, 1972). In another case report of a consanguineous Middle Eastern family (in which the parents were first cousins), three children with polyhydramnios and micrognathia were noted. This family apparently had an autosomal recessive gene that predisposed them to lethal micrognathia. All three fetuses affected by this condition died during the newborn period because of hyaline membrane disease and asphyxia. Amniography performed during pregnancy in affected infants showed that no contrast material was swallowed into the fetal intestinal tract (Berant et al., 1978).

Microphthalmia/ Anophthalmia

29 CHAPTER

Key Points

- Microphthalmia, anophthalmia, and coloboma represent a spectrum of developmental anomalies of the eye known as MAC.
- Prevalence is 1 in 10,000 births. Approximately 10% of affected children have a chromosome abnormality. There may be an increased incidence of MAC in mothers older than age 40 and in multiple gestation.
- Nomograms exist for normal fetal eye measurements at 12 to 37 weeks' gestation. Refer for targeted fetal anatomical evaluation because of high likelihood of associated anomalies.
- Strongly associated with chromosome abnormalities and single-gene disorders.
- Karyotype is indicated. If bilateral anophthalmia is present, consider DNA testing for *SOX2* mutations.
- Refer for consultation with medical geneticist and pediatric ophthalmologist.
- Progress depends on severity of eye defects and presence of associated anomalies. Recurrence risk depends on syndromic diagnosis.
- Many developmental gene mutations are being identified as underlying basis of MAC.

CONDITION

Microphthalmia is one stage in a spectrum of developmental abnormalities that affect the eye, with coloboma at the milder end and anophthalmia at the severe end. Collectively the eye defect is known as MAC (microphthalmia, anophthalmia, coloboma). Although microphthalmia and anophthalmia can present as isolated findings, they are more commonly appreciated as part of syndromes involving multiple malformations (Bronshtein et al., 1991). Both are associated with abnormalities of the central nervous system.

Warburg (1993) proposed a phenotypic classification of microphthalmia that consists of three groups: genetic (monogenic and chromosomal), prenatally acquired (teratologic agents and intrauterine deformations), and associations. Genetic disorders commonly result in malformations of the eye, whereas prenatally acquired insults result in disruption or deformation of an initially normal eye.

The eye derives from three embryologic germ layers. Neuroectoderm gives rise to the optic vesicle; neural crest cells are responsible for migration to the anterior chamber of the developing eye. Ectoderm is responsible for the formation of the lens placode. Neuroectodermal and mesodermal

Posterior segment

cells participate in the closure of the optic fissure. The variety of cells and tissue types involved explains variability of phenotypic abnormalities of the eye (see Table 29-1) (Warburg, 1993). The embryonic optic fissure is formed from invagination along the inferior aspect of the optic cup and optic stalk at the 5- to-8-mm stage of gestation. This fissure allows the ingress of the hyaloid artery and egress of retinal axons through the optic nerve. In the normal eye, the embryonic optic fissure closes at 33 to 44 days after conception. If the fissure fails to fuse, a defect in the neuroectodermal and uveal tissues will be produced, forming a coloboma. The coloboma is a layer of sclera lined by maldeveloped neuroectoderm (Leatherbarrow et al., 1990). Colobomas of the uvea are frequently associated with microphthalmia and microcornea. Congenital cystic eye is a malformation that results from failure of invagination of the optic vesicle. Cysts frequently develop from proliferation of neuroectodermal tissue at the edge of the persistently open embryonic fissure. The optic cup originates from localized evagination of forebrain. The optic cup is the supporting framework for further optic development. Thus, conditions that result in abnormalities of the forebrain also potentially affect the optic cup (Weiss et al., 1989).

Microphthalmia is a deformity that results from arrest of ocular growth and development. The eye is considered microphthalmic at birth if its greatest diameter is smaller than 15 mm. The normal newborn eye has a diameter of 16 to 19 mm (Price et al., 1986). Anophthalmia results from a failure in development or early involution of the primary optic vesicle during the 2nd or 3rd week of gestation. In degenerative anophthalmia, the optic tract and vesicles develop normally initially, but subsequently undergo degeneration and result in severe microphthalmia. Because the lens depends on the optic vesicle for its differentiation, it is usually absent. In anophthalmia, the non-neuroectodermal structures are usually normally formed. Thus, the orbits, eyelids, cilia, lacrimal apparatus, conjunctiva, and extraocular muscles are usually normal (Figure 29-1).

INCIDENCE

A national birth registry in the United Kingdom noted a prevalence of either anophthalmia or microphthalmia of 1.0 per 10,000 births (Busby et al., 1998). Thirty-four percent

Figure 29-1 Absence of the globe with a normal appearance to the eyelids and eyelashes in anophthalmos. (*From Matsui H, Hayasaka S, Setogawa T. Congenital cataract in the right eye and primary clinical anophthalmos of the left eye in a patient with cerebellar hypoplasia.* Ann Ophthalmol *1993;25:315-318.*)

of affected infants had mild microphthalmia. Of the severely affected infants, 51% of cases were bilateral, other non-eye malformations were present in 65% of cases, and 72% had other eye malformations.

A Swedish health registry covering births during the years 1965 to 2001 observed a rate of 1.5/10,000 births for microphthalmia and 0.2/10,000 births for anophthalmia. Approximately 10% of the 432 children identified in this study had a chromosome abnormality (Källén and Tornquist, 2005). A recent epidemiologic study performed in California showed a twofold relative risk of bilateral anophthalmia if maternal age was 40 or more or if there was a multiple gestation (Shaw et al., 2005). After adjusting for other study factors, the relative risk was substantially lower if the mother has >12 years of education.

SONOGRAPHIC FINDINGS

The ability to measure the human fetal eye and orbits antenatally was first documented in 1982, when in two separate reports, sonographic measurements of fetal ocular diameters, interocular distance, and binocular distance were published (Jeanty et al., 1982; Mayden et al., 1982). Using transvaginal sonography, Bronshtein et al. (1991) detected fetal eyes within their orbits in 40% of screened fetuses at 11 weeks of gestation and 100% of fetuses at 12 weeks of gestation. They also noted the presence of a hypoechogenic ring that represented the fetal lens in 75% of fetuses at 12 weeks and 100% of fetuses at 14 weeks of gestation. Fetal eyelid motion was detectable by the beginning of the second trimester. This group recommended that the optimal section for the examination of the fetal eye is a transverse plane taken at the level of the skull at the orbits. An oblique tangential section taken from the fetal nasal bridge may detect hypoechogenic circles lateral to the nose consistent with the developing lens (Bronshtein et al., 1991).

Nomograms have been established for measurements of the fetal eye taken from 12 to 37 weeks of gestation using a combination of transvaginal and transabdominal high-resolution ultrasound techniques (Achiron et al., 1995). In this study, the fetal eye was evaluated by a coronal–facial view with the ultrasound probe positioned lateral to the fetal orbit. This group measured the transverse and superoinferior diameters of the vitreous, and the outer-edge to outer-edge measurement of the lens as a function of gestational age. Only one observer made the measurements, but three separate measurements were obtained on each fetal eye. An intraobserver variation of $3.1 \pm 1.5\%$ existed. This group studied 12 fetuses at risk for eye abnormalities and found 3 with vitreous and lens measurements above or below the 95% confidence intervals for gestational age (Achiron et al., 1995). An additional study documented the normal growth percentiles for intermalar and interethmoidal distances from 10 to 40 weeks of gestation (de Elejalde and de Elejalde, 1985).

Although routine study of the fetal face with prenatal sonography is recommended by most professional organizations, current guidelines do not recommend routine views of the fetal orbits or eyes (American College of Obstetricians and Gynecologists, 2008). Microphthalmia, even in the setting of a fetal face examination, may be difficult to detect antenatally. Bronshtein et al. (1991) reported two false-negative results for fetuses at prior genetic risk for microphthalmia. The sonographic diagnosis of anophthalmia can be equally challenging. Abnormalities in the fetal orbits are more easily recognized than abnormalities in the fetal globe. A specific finding appears to be flattened or concave eyelids when the fetal globes are missing (Figure 29-2).

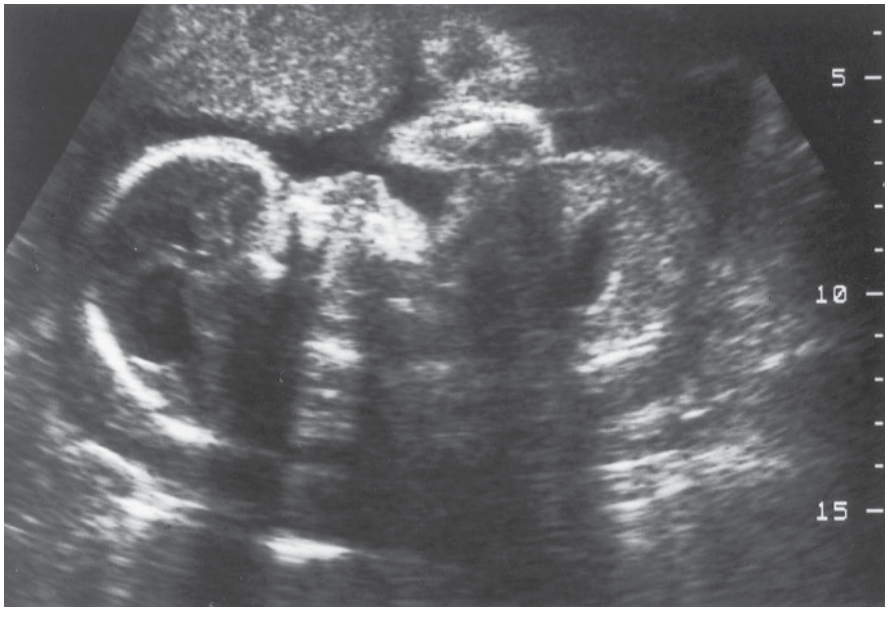

Figure 29-2 Antenatal sonogram, performed at 27 weeks of gestation, demonstrating anophthalmia and severe midface hypoplasia in a fetus with trisomy 13.

Table 29-2

Etiologic Classification of Microphthalmia

Genetic		Prenatally Acquired		Unknown	
Malformations and syndromes		Disruptions		Deformations	Associations
Single-gene disorder	Chromosomal abnormality	Drugs/radiation	Maternal disease	Encephalocele	VATER
Autosomal dominant Autosomal recessive CHARGE X-linked	Trisomy 13 Trisomy 18 18p− 13q− 4p− Triploidy Other deletions/duplications	Ionizing radiation (4–11 wk) Ethanol Thalidomide Isotretinoic acid	Diabetes Cytomegalovirus Rubella Toxoplasmosis Parvovirus B19 Influenza	Tumors

DIFFERENTIAL DIAGNOSIS

The major consideration in the differential diagnosis is to determine whether the eye defects are isolated or part of a syndrome or association. Table 29-2 lists the etiologic classification of MAC. If the condition is isolated, it is important to determine whether other family members are also affected. Many chromosomal abnormalities include eye defects as part of a multiple congenital anomaly syndrome; trisomy 13 is one of the more common ones (Allen et al., 1977). MAC can be the consequence of exposure to certain drugs, ionizing radiation, or infectious agents. MAC can also be due to single-gene multiple congenital abnormality syndromes (Table 29-3), including Walker–Warburg syndrome (Crowe et al., 1986; Dobyns et al., 1990), Fraser syndrome (Schauer et al., 1990; Berg et al., 2001), Meckel–Gruber syndrome (Bateman, 1983), cerebro-oculo-facio-skeletal syndrome (Paladini et al., 2000), Lenz syndrome (Traboulsi et al., 1988), focal dermal hypoplasia (Goltz syndrome) (Gottlieb et al., 1973), Norrie disease, Hallermann–Streiff syndrome, oculodentodigital syndrome, frontonasal dysplasia, Fryns syndrome (Pierson et al., 2004), and microphthalmia with linear skin defects (Morleo et al., 2005). Any fetus diagnosed with MAC should have consideration of specific studies performed to rule out holoprosencephaly (see Chapter 14; Artman and Boyden, 1990). MAC can result from masses, such as encephalocele and tumors, pressing on the developing eye. Finally, MAC is seen in associations of congenital anomalies, such as CHARGE and VATER.

ANTENATAL NATURAL HISTORY

The overall fetal prognosis will depend to a large extent on the underlying cause of the microphthalmia or anophthalmia. Fetuses that have isolated eye malformations do well during gestation. Fetuses that have an underlying chromosomal abnormality will have a much worse prognosis. In a Japanese study, Amemiya and Nishimura (1977) studied 60 intact human fetal specimens that were selected on the basis of the presence of nonocular abnormalities. This study showed a very high association of eye abnormalities with other malformations. Overall, 18 (30%) of the fetuses had eye malformations and 12 (16.7%) had an asymmetric insertion of the recti muscles that would predispose the infant to severe strabismus later in life. The incidence of ocular malformation in fetuses with heart abnormalities was 40%, and central nervous system abnormalities was 37.5%. Abnormalities in the endocrine organs had a 31.6% chance of having associated ocular malformations. This study suggested that when severe malformations of other organs were detected early in fetal life, a specific study of the fetal eye was also indicated.

Microphthalmia is one of the most common consequences of ionizing radiation delivered to the pregnant woman. In a review of 26 cases of pregnant women who received large doses of radiation during pregnancy, Dekaban (1968) demonstrated that the fetus was especially vulnerable to development of severe microphthalmia between 4 and 11 weeks of gestation. Radiation after 12 weeks resulted in microcephaly, severe brain abnormalities, and growth restriction, but after 12 weeks the eyes were relatively protected. Maternal TORCH infections (herpes, varicella, and cytomegalovirus) are associated with MAC. More recently, maternal parvovirus B19 and influenza infection have also been shown to be positively associated with anophthalmia/microphthalmia (Busby et al., 2005). Any condition that affects development of the forebrain, such as maternal diabetes or maternal ingestion of ethanol, will also put the fetus at risk for abnormal eye development.

Table 29-3

Syndromes Associated with Microphthalmia

Syndrome	Associated Findings	Inheritance
Walker–Warburg	Pachygyria, cerebellar hypoplasia encephalocele, Dandy–Walker cyst, hydrocephalus, cataract	Autosomal recessive
Fraser	Mental retardation, syndactyly, genital abnormalities	Autosomal recessive
Meckel–Gruber	Microcephaly, encephalocele, polydactyly, cystic renal dysplasia, cleft lip and palate	Autosomal recessive
Cerebro-oculo-facio-skeletal	Microcephaly, cataracts, micrognathia, flexion contractures	Autosomal recessive
Fryns	Coarse face, cleft lip and palate, diaphragmatic hernia, genital malformations	Autosomal recessive
Lenz	Microcephaly, mental retardation, digital, skeletal, dental abnormalities	X-linked
Focal dermal hypoplasia (Goltz)	Microcephaly, syndactyly, skin lesions, dental anomalies	X-linked (lethal in males)
Microphthalmia with linear skin defects	Linear skin defects	X-linked
Norrie	Cataracts, deafness, mental retardation	X-linked
Hallermann–Streiff	Brachycephalus, micrognathia, cataracts, thin small nose, skin atrophy, hypotrichosis	Autosomal recessive
Oculodentodigital	Small nares, enamel hypoplasia, syndactyly, sparse hair	Autosomal dominant
Frontonasal dysplasia (median cleft face)	Hypertelorism, defect in midline frontal bone, cleft lip, notched nose	Unknown

MANAGEMENT OF PREGNANCY

Microphthalmia and anophthalmia are more commonly seen as part of a multiple malformation syndrome than as an isolated finding. In one study, six of eight cases of ocular malformations were associated with intracranial defects or other organ malformations (Bronshtein et al., 1991). It is therefore important to refer a patient in whom fetal microphthalmia is suspected to a center experienced in the detection of congenital malformations. In addition, a referral center is more likely to be familiar with the normal measurements of the fetal eye (Achiron et al., 1995). It is important to obtain a history from the mother regarding medication exposures, ethanol ingestion, and the results of glucose-tolerance testing to rule out maternal diabetes as a cause for microphthalmia. Isotretinoic acid, a commonly prescribed acne medication, can cause microphthalmia, so consideration should be given to the possibility of exposure to this medication in teenage patients or in older patients with severe cystic acne.

In the setting of isolated eye defects, it is important to examine both parents and to ask specifically about the history of visual difficulties and/or consanguinity. Because of the rarity of MAC and its association with severe abnormalities, we recommend obtaining a fetal karyotype to rule out the large number of chromosomal abnormalities that can result in microphthalmia. We also recommend obtaining TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes virus) titers.

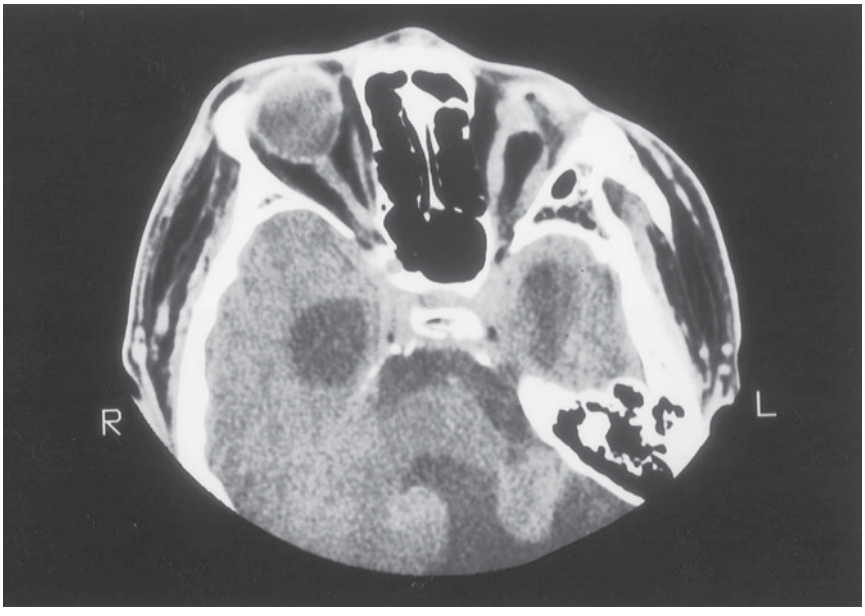

Figure 29-3 Postnatal CT scan showing, on the patient's left side, a small nodular mass with well-developed extraocular muscles in a case of primary anophthalmia. A normal eye is present on the right. (*From Matsui H, Hayasaka S, Setogawa T. Congenital cataract in the right eye and primary clinical anophthalmos of the left eye in a patient with cerebellar hypoplasia.* Ann Ophthalmol *1993;25:315-318.*)

FETAL INTERVENTION

There are no fetal interventions indicated for microphthalmia or anophthalmia.

TREATMENT OF THE NEWBORN

The newborn with unilateral or bilateral anophthalmia should have a complete physical examination to rule out associated congenital anomalies. A computed tomographic (CT) or magnetic resonance imaging (MRI) scan should be performed (Figure 29-3). If a fetal karyotype was not performed antenatally, it should be done postnatally. TORCH titers (if not obtained antenatally) should be performed on mother and infant. Newborn urine should be collected for cytomegalovirus culture. DNA should be analyzed for the presence of *SOX2* mutations, which are found in approximately 11% of individuals with bilateral anophthalmia (Fantes et al., 2003). A medical genetics consultation should be obtained. Consultation with a pediatric ophthalmologist should also be obtained to discuss plans for prosthetic fitting and plastic surgery.

Microphthalmia can be a subtle finding that can be missed during the newborn period. Asymmetry of the globes or an abnormal red reflex should prompt a pediatric ophthalmologic consultation. A newborn that has microphthalmia and a corneal diameter of 5 mm or less has a very poor prognosis for useful vision (Elder, 1994). The globe serves as a scaffold for further development of eyelids. Infants who have had severe microphthalmia in utero will have foreshortening of the palpebral fissure and flattening of the eyelids. The abnormal appearance becomes more apparent as facial growth occurs over the first year of life. Price et al. (1986) recommend fitting infants who have unilateral microphthalmia with cosmetic scleral shells. This permits the development of a symmetric ocular appearance without any need for surgery. They recommend initial fitting of the prosthesis at 2 months of age, with refittings twice or more yearly during the first 2 years of life. The adult eye size is normally reached at age 13 years, so fittings are required only throughout the childhood years.

SURGICAL TREATMENT

The normal development of the orbital region depends on orbital growth. Anophthalmia or severe microphthalmia leads to severely underdeveloped bony orbital growth and overall facial development (Chen and Heber, 2004). The resulting facial asymmetry is usually apparent at birth. The normal infant eye is approximately 70% of its adult size and grows most rapidly during the first 12 months of life. Therefore the long-term goal is to create a suitable pocket for a cosmetically acceptable prosthesis. Treatment usually consists of tissue expanders, orbital implants, and orbital reconstruction (Chen and Heber, 2004).

When microphthalmia is present with a cyst, the cyst may be aspirated repeatedly or surgically excised. Enucleation should be performed only if the cyst aspiration is unsuccessful. Once the eye is enucleated, laser orbital and eyelid reconstruction will become necessary. A lensectomy can be performed for congenital cataract if present. Corneal transplantation has successfully restored vision in some infants with microphthalmia (Feldman et al., 1987).

LONG-TERM OUTCOME

In a review of 15 patients with anophthalmia, those who had prosthetic therapy initiated during the first year of life had acceptable cosmetic results (Figure 29-4) (O'Keefe et al., 1987).

Figure 29-4 Patient with unilateral anophthalmos treated with early prosthetic therapy but no surgical eyelid revisions, demonstrating an acceptable cosmetic result. (*From O'Keefe M, Webb M, Pashby RC, et al. Clinical anophthalmos.* Br J Ophthalmol. *1987;71: 635-638.*)

Elder (1994) described 27 patients with bilateral microphthalmia, who had visual acuity of less than 6/60. All patients had nystagmus. Of the 27, 12 had congenital cataracts as their primary cause of blindness. An additional 6 had chorioretinal colobomas; 2 had degenerative myopia. There was no light perception in 8 of the 27. This study was performed in a very poor Middle Eastern area, where patients had no access to surgical treatment. Most patients with microphthalmia have high hyperopia and require lens correction. During adulthood, microphthalmic eyes are at high risk for glaucoma, retinal detachment, and spontaneous uveal effusion (Weiss et al., 1989). A retrospective follow-up study of 30 children with microphthalmia revealed that 7 had mental retardation, but a surprisingly high number of the others were described as extremely good students (Whiteman and Crawford, 1980). Long-term follow-up by a pediatric ophthalmologist is recommended.

GENETICS AND RECURRENCE RISK

Isolated microphthalmia usually occurs sporadically, although there have been reports of autosomal dominant inheritance (Vingolo et al., 1994) and autosomal recessive inheritance in a large inbred Arab kindred (Kohn et al., 1988), a Swiss Anabaptist kindred (Cross and Yoder, 1976), and an Iranian Jewish inbred community (Zlotogora et al., 1994). Additionally, X-linked forms have been reported (Warburg, 1981). Shulman et al. (1993) described a family initially thought to have microphthalmia presenting as an autosomal recessive condition, but later found to be autosomal dominant with incomplete penetrance.

Multiple chromosomal abnormalities have been associated with microphthalmia. These include triploidy; trisomies 13 and 18; deletion of the short arm of chromosome X (Xp22.2 to ter) (Ogata et al., 1998; Temple et al., 1990); deletion of 4p−, 4q−, 13q− (Gul et al., 2005), ring 13, ring 18q−, and 18 ring; and duplications of 4q+, 7p+, 9+, 10q+, 13q+, 22q+, and partial trisomy 22. In addition, microphthalmia has been found in at least 10 patients with trisomy 4p (Lurie and Samochvalov, 1994). Common chromosomal abnormalities to be suspected in the setting of microphthalmia with coloboma are trisomy 13, 13q−, triploidy, and trisomy 4p.

Many single gene (Mendelian disorders) are associated with microphthalmia and anophthalmia. Any patient with MAC should be referred to a medical genetics unit for complete pedigree interpretation and counseling regarding recurrence risk. Specific genetic counseling will depend on the underlying cause of the eye defect. If unbalanced chromosomal abnormalities are detected, parental blood samples should be obtained to study the parental karyotypes. Infants with MAC should be examined by a clinical geneticist to seek additional dysmorphic features to permit diagnosis of a genetic syndrome.

Recently, mutations in a number of developmental genes have been shown to be the cause of anophthalmia or microphthalmia. These include *SOX2*, *CHX10*, *RAX*, and *SIX3*. *PAX6* is considered to be a master control gene in eye development; mutations in *PAX6* and *PAX2* are more likely to result in colobomas than anophthalmia or microphthalmia (Morrison et al., 2002). *SOX2* is a transcription factor expressed in the early developing eye and nervous system. De novo heterozygous mutations in *SOX2* are present in 11% of individuals with bilateral anophthalmia (Fantes et al., 2003). Furthermore, it is now recognized that there are consistent nonocular abnormalities associated with *SOX2* mutations, including brain malformations, mild facial dysmorphism, seizures, learning disability, postnatal growth failure, and male genital abnormalities (Ragge et al., 2005). *SOX2*

mutation analysis is recommended for fetuses with bilateral anophthalmia. *CHX10* mutations are associated with an autosomal recessive syndrome of microphthalmia/anophthalmia that presents with iris colobomas and cataracts (Percin et al., 2000; Bar-Yosef et al., 2004).

The mouse microphthalmia (mi) gene encodes a protein whose mutations result in early onset deafness, reduced eye size, and loss of pigmentation in the eye, inner ear, and skin. A human homolog of this gene exists, microphthalmia-associated transcription factor gene, *MITF*, which maps to human chromosome 3p12–14 (Tachibana et al., 1994). *MITF* is responsible for Waardenburg syndrome, type 2, a dominantly inherited disorder with sensorineural hearing loss and heterochromic irides but no microphthalmia (Hughes et al., 1994). The gene for microphthalmia with linear skin defects (MLS) has been cloned and mapped to chromosome Xp22 (Ogata et al., 1998; Wapenaar et al., 1993; Morleo et al., 2005).

Congenital High Airway Obstruction Syndrome

30
CHAPTER

Key Points

- Congenital high airway obstruction syndrome (CHAOS) is characterized by bilaterally enlarged lungs, flat or inverted diaphragms, dilated tracheobronchial tree, and massive ascites due to complete airway obstruction.
- CHAOS is often mistaken for bilateral congenital pulmonary airway malformations.
- MRI is helpful in diagnosing CHAOS and excluding potential associated findings.
- CHAOS can be associated with syndromes such as Fraser syndrome.
- The natural history of CHAOS may be divided in thirds: 1/3 die in utero; in 1/3 the hydrops remains stable; and in 1/3 the hydrops resolves following spontaneous perforation.
- Fetoscopic treatment of the tracheal or laryngeal obstruction is possible in select cases.
- EXIT procedure is indicated to deliver all cases of CHAOS due to critical airway obstruction.

CONDITION

Congenital high airway obstruction syndrome (CHAOS) is a prenatally diagnosed clinical syndrome manifested by the presence of extremely large echogenic lungs, flattened or inverted diaphragms, a dilated tracheobronchial tree, ascites, and other manifestations of nonimmune hydrops due to complete obstruction of the fetal airway (Hedrick et al., 1994). No fetus diagnosed prenatally with CHAOS associated with hydrops and complete airway obstruction has survived without intervention. The exception to this occurs when there is spontaneous perforation of the laryngeal or tracheal atresia, which may occur in up to one-third of cases and results in resolution of the hydrops.

The airway obstruction in CHAOS may be due to one of several causes, including laryngeal atresia, tracheal atresia, or laryngeal cyst, but the fetal clinical presentation is the same. Three types of laryngeal atresia are recognized: type I, in which the supraglottic and infraglottic parts of the larynx are atretic; type II, in which the atresia is infraglottic; and type III, which is glottic. A wide range of anomalies can be seen in association with laryngeal atresia (Table 30-1). Some fetuses, however, have atresia as an isolated anomaly (Fox and Crocker, 1964).

INCIDENCE

Congenital obstruction of the fetal airway resulting in CHAOS was initially thought to be extremely rare (Hedrick et al., 1994). Only 55 cases of this syndrome have been reported since 1989 (Wigglesworth et al., 1987; Delechotte et al., 1988; Silver et al., 1988; Tournier et al., 1988; Arizawa et al., 1989; Fang et al., 1989; Scurry et al., 1989; Didier et al., 1990; Schauer et al., 1990; Watson et al., 1990; Richards et al., 1992;

Genitourinary anomalies
Uterine anomalies
Imperforate anus
Cardiac anomalies
Anophthalmia

Weston et al., 1992; Hedrick et al., 1994). However, this syndrome may be more common than generally appreciated because many of the affected fetuses die in utero or are stillborn (Fox and Crocker, 1964; Smith and Bain, 1965; Cohen, 1971; Wigglesworth et al., 1987; Fang et al., 1989; Scurry et al., 1989; Schauer et al., 1990; Watson et al., 1990; Richards et al., 1992). The true incidence of this syndrome is unknown.

SONOGRAPHIC FINDINGS

The sonographic findings of CHAOS are due to complete obstruction of the upper airway. The lungs normally produce fluid that leaves the trachea at a rate estimated at 4 mL per kilogram of body weight per day as a result of fetal breathing movements. Complete obstruction of the upper trachea or larynx results in elevated intratracheal pressure and distention of the tracheobronchial tree due to accumulation of fetal lung fluid. The lungs become distended and appear sonographically to be extremely echogenic and diffusely enlarged (Tournier et al., 1988; Watson et al., 1990; Richards et al., 1992; Weston et al., 1992; Hedrick et al., 1994). The diaphragm becomes inverted and the mediastinal structures compressed (Figure 30-1). The heart may appear elongated, with a shift in its axis, and the chambers small and compressed by the large lungs (Figure 30-2). The dilation of the tracheobronchial tree can be traced up to the larynx or level of the tracheal obstruction. In a rare form of CHAOS, there may

Figure 30-1 Sagittal sonographic image of a fetus with CHAOS at 20 weeks of gestation demonstrating extremely large homogenously echogenic lungs with inversion of the diaphragm.

be complete absence of the trachea (Vaikunth et al., 2009). In advanced cases, signs of nonimmune hydrops, including ascites, placentomegaly, and anasarca may be seen as a result of compromised venous return to the heart. Polyhydramnios may also be observed secondary to esophageal compression. The fetus with CHAOS may also exhibit qualitatively abnormally vigorous breathing movements. Baarsma et al. (1993) observed that a fetus with complete laryngeal atresia exhibited high-amplitude vigorous jerky breathing movements as it tried in vain to move tracheal fluid through an atretic larynx.

The cause of CHAOS may vary from laryngeal or tracheal obstruction or stenosis to an intraluminal web or cyst (Figure 30-3). However, it may be difficult, if not impossible, to distinguish these conditions sonographically. Recently, the use of half-Fourier acquisition single shot turbo spin echo sequence (HASTE) and echoplanar magnetic resonance imaging (MRI) has aided in the diagnosis of CHAOS. In the report by Crombleholme et al. (2000), fetal MRI was helpful in excluding bilateral cystic adenomatoid malformation as well as determining the level of obstruction (Figure 30-4).

Figure 30-2 Cross-sectional view of same fetus in Figure 30-1, demonstrating extremely large echogenic lungs with narrowed compressed mediastinum and elongated heart.

Figure 30-3 Autopsy of a 23-week-old fetus with CHAOS due to laryngeal cyst occluding the airway. The posterior view of the trachea and larynx is shown, with the back wall completely opened to reveal the laryngeal cyst.

DIFFERENTIAL DIAGNOSIS

The main diagnosis mistaken for CHAOS is bilateral cystic adenomatoid malformation (see Chapter 35). This is an even rarer finding than CHAOS, as cystic adenomatoid malformation is usually lobar, not involving the entire lung, and less than 2% of cases are bilateral. Cases of CHAOS are commonly misdiagnosed as bilateral CCAMS and this should raise suspicion that the diagnosis may, in fact, be CHAOS. An important distinguishing feature is the compressed rim of normal lung that can usually be seen in cystic adenomatoid malformation but not in CHAOS. The uniformly echogenic lungs, which are massively enlarged and associated with flattened or inverted diaphragms, a compressed mediastinum, and dilated trachea and mainstem bronchi allow CHAOS to be distinguished from cystic adenomatoid malformation.

CHAOS may be one fetal presentation of Fraser syndrome (cryptophthalmos–syndactyly syndrome) (see Chapter 29). This inherited disorder is characterized by variable expression of cryptophthalmos, renal agenesis, syndactyly, abnormalities of ears and external genitalia, and laryngeal stenosis or atresia (Fraser, 1962; Schauer et al., 1990). This syndrome has only been correctly diagnosed twice during the second trimester (Schauer et al., 1990; Feldman et al., 1995). Often a previously affected pregnancy will prompt sonographic surveillance for Fraser syndrome. The sonographic features of cryptophthalmos, renal agenesis, and syndactyly in a fetus with CHAOS suggest the diagnosis of Fraser syndrome.

ANTENATAL NATURAL HISTORY

Our understanding of the natural history of CHAOS is limited by the rarity of this entity. Only 48 cases of complete laryngeal

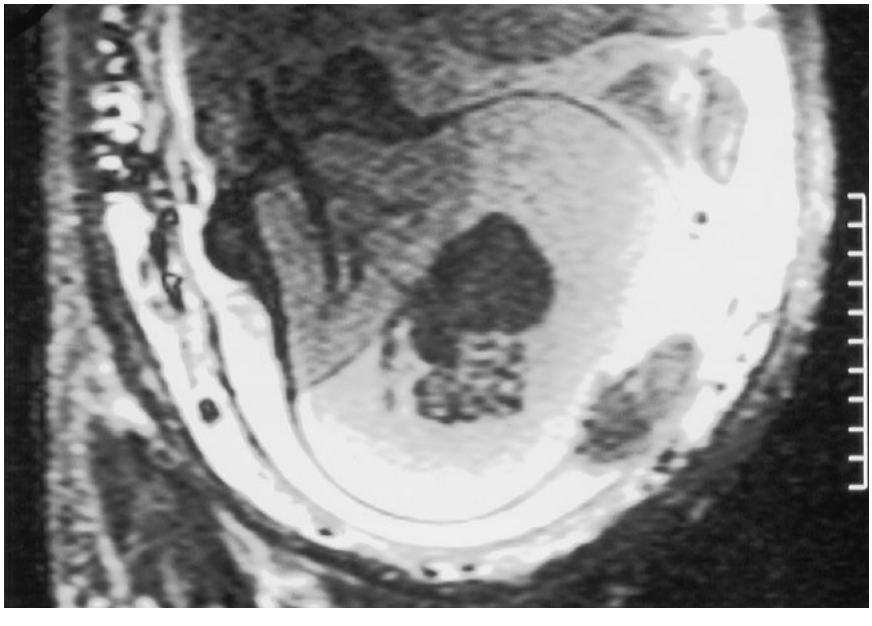

Figure 30-4 Fetal MRI demonstrating massively enlarged lungs, dilated tracheobronchial tree, inverted diaphragms, and massive ascites.

atresia and CHAOS have been reported to date. In 10 of these cases, the fetus was stillborn, suggesting that the fetus may be compromised in utero, not just at birth (Fox and Crocker, 1964; Smith and Bain, 1965; Cohen, 1971; Wigglesworth et al., 1987; Fang et al., 1989; Scurry et al., 1989; Schauer et al., 1990; Richards et al., 1992). Postnatal survivors with laryngeal atresia have been rare. Among the 16 most recently reported cases of prenatally diagnosed CHAOS, only 1 patient survived the immediate postdelivery period. In contrast to the nonsurvivors, this patient had incomplete subglottic stenosis, which may have lessened the effects of airway occlusion and contributed to the patient's survival.

A fetus identified with sonographic features of CHAOS should be presumed to be at significant risk of intrauterine fetal death and faces a high mortality should the pregnancy progress to delivery. Diagnosis in the middle of the second trimester appears to correlate with poor outcome. At least one case has been reported in which a 23-week-old fetus presented with CHAOS and polyhydramnios and fetal ascites, but no other manifestations of nonimmune hydrops. However, at 30 weeks of gestation, the amniotic fluid volume normalized and the ascites resolved. At birth, the infant was found to have a severe subglottic stenosis with only a 1-mm hole allowing passage of lung fluid (Richards et al., 1992).

Malformations of the esophagus and trachea, including tracheoesophageal fistula, which are commonly associated with laryngeal atresia, allow decompression of the obstructed tracheobronchial tree. With CHAOS, these fetuses are more commonly present at birth, as opposed to in utero.

The fetus with the characteristic features of diffusely enlarged lungs, polyhydramnios, and nonimmune hydrops is at high risk for perinatal death if no intervention takes place. Only one case has been reported in which CHAOS accompanied by ascites at 23 weeks of gestation progressed to delivery. Crombleholme et al. (2000) reported a case of CHAOS associated with massive ascites and other features of nonimmune hydrops at 20 weeks. The infant delivered by the ex utero intrapartum treatment (EXIT) procedure 11 weeks later. A fetus in the middle of the second trimester with isolated CHAOS presents a dilemma, as there is insufficient information about this condition to predict with certainty that fetuses will progress to hydrops and intrauterine fetal death versus premature delivery because of polyhydramnios, or will spontaneously perforate with resolution of hydrops.

Clinical experience suggests that fetuses diagnosed with CHAOS fall into one of three categories. Approximately one-third will develop progressive nonimmune hydrops and die in utero. Another third will spontaneously perforate through the tracheal or laryngeal atresia or less commonly decompress via a tracheoesophageal fistula. The remaining third tolerate hydrops reasonably well and remain hydropic until 30 to 32 weeks' gestation, at which point preterm labor or fetal distress prompt the need for an EXIT procedure.

A fetus presenting in the third trimester with CHAOS but without associated anomalies or hydrops likely has incomplete obstruction and will do well until delivery by EXIT procedure. These fetuses need to be managed by the EXIT procedure to secure the airway while being maintained on placental support, as laryngoscopy, bronchoscopy, and tracheostomy will be required immediately prior to delivery.

MANAGEMENT OF PREGNANCY

The fetus presenting with CHAOS should have a detailed sonographic examination to determine if there are associated anomalies present (see Table 30-1). Of particular interest are the features of Fraser syndrome, including cryptophthalmos, syndactyly, and genitourinary anomalies (see Chapter 29). An echocardiogram should be obtained because of the possibility of structural heart disease. A karyotype analysis should also be obtained to rule out aneuploidy or other serious chromosomal abnormalities that might preclude fetal intervention. The fetus should be followed closely for early signs of hydrops. Consultation with a medical geneticist and a pediatric surgeon is indicated.

Delivery in a tertiary care center experienced with the EXIT procedure is indicated. Under deep general anesthesia, which allows uterine relaxation and preserves uteroplacental circulation, a bloodless hysterotomy is performed using a uterine stapling device and the fetal head and chest are delivered in order to secure an airway (Figure 30-5). Stable uteroplacental gas exchange can be maintained for up to 60 minutes while an airway is secured (Liechty et al., 1997; Crombleholme et al., 2000). Previous reports in which vaginal delivery was performed without clamping the cord, to allow an airway to be secured, did not preserve uteroplacental circulation. Similarly, standard cesarean delivery results in uterine contraction and loss of uteroplacental circulation. Once the fetus is delivered, there is uterine contraction that shuts down uteroplacental gas exchange. During the EXIT procedure, laryngoscopy is performed initially to evaluate the larynx. In most instances, the level of obstruction will be distal to the vocal cords, and attempts to pass an endotracheal tube will be unsuccessful. Bronchoscopy should then be performed. The obstruction may be due to a simple laryngeal cyst or web, which may be amenable to bronchoscopic disruption, allowing passage into the trachea (Sylvester et al., 1998). If these efforts are unsuccessful, a formal tracheostomy should be performed. Once an airway is secured, the cord is clamped and the infant is handed over to the neonatologists. It is crucial that the timing of the delivery of the baby, after obtaining an airway, is carefully orchestrated with the anesthesiologist, because uterine relaxation is essential for an EXIT procedure. After delivery of the baby and placenta, massive uterine bleeding may occur unless uterine tone is rapidly reestablished. This is best accomplished by turning off the halogenated anesthetic agent to allow uterine tone to return to normal, as well as beginning an oxytocin infusion. After the infant and placenta are delivered, vigorous massage of the uterus stimulates contraction and minimizes blood loss (Langer et al., 1992; Skarsgard et al., 1996; Mychatisha et al., 1997; Sylvester et al., 1998).

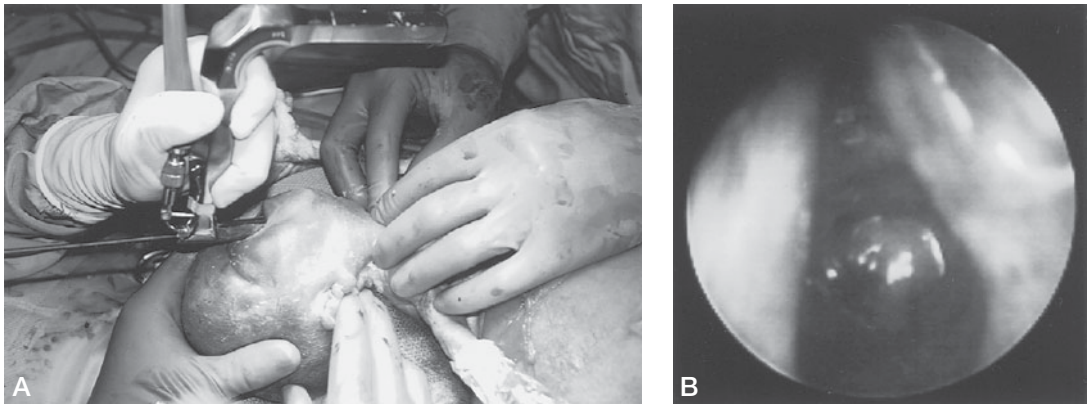

Figure 30-5 EXIT procedure for a fetus with CHAOS at 31 weeks of gestation. **A**. The fetus is monitored by pulse oximetry while undergoing laryngotracheoscopy. **B**. The tracheoscopic view of the obstructing tracheal atresia.

Crombleholme et al. (2000) reported the first successful salvage and long-term survival of a fetus with CHAOS due to complete tracheal atresia. The fetus was originally diagnosed with bilateral cystic adenomatoid malformation of the lung and nonimmune hydrops at 19 weeks of gestation. Although intrauterine fetal death was anticipated, 12 weeks after diagnosis the fetus was doing well, albeit with massive ascites and severe polyhydramnios. The EXIT procedure, performed at 31 weeks of gestation, demonstrated complete tracheal occlusion due to subglottic atresia (see Figure 30-5). A tracheostomy was performed and the newborn did well, requiring ventilatory support due to diaphragmatic dysfunction, but was weaned to room air in 24 hours. The child is developing normally now at 10 years of age.

FETAL INTERVENTION

The pathophysiology of CHAOS has been reproduced in a fetal lamb model (Crombleholme and Albanese, 2000). Tracheal ligation at 80 days of gestation produces extremely large hyperplastic fetal lungs, with secondary nonimmune hydrops and polyhydramnios. The fetal lambs die in utero if left untreated. Release of the tracheal ligation in utero reverses these changes and allows the lambs to be delivered at term. Fetal surgery to correct the airway obstruction has been performed by Kohl, et al. (2006). In this 25-week gestation fetus with characteristic signs of CHAOS, a fetoscopic laryngoscopy was performed. A balloon catheter was passed through the obstruction and pulled back. The catheter passed easily, which suggests that in this case, spontaneous perforation had already occurred and resolution of hydrops was due to the spontaneous perforation and not the fetoscopic procedure. Despite the likely spontaneous relief of obstruction, this case demonstrates the feasibility of treating CHAOS in utero. S. Hirose (personal communication, September 12, 2008) reported a similar case in which fetoscopic laryngoscopy allowed passage of a guide wire across the tracheal atresia. The importance of conversion of complete airway obstruction to partial airway obstruction should not be underestimated. In both instances an EXIT procedure will be necessary, but resolution of hydrops results in a much more easily managed premature infant. The baby with CHAOS has a profound capillary leak syndrome that may take weeks to resolve, with severe respiratory distress syndrome, hepatic and gastrointestinal dysfunction, all of which may contribute to significant morbidity and mortality. In marked contrast, the fetus with complete tracheal or laryngeal atresia and resulting CHAOS that spontaneously perforates or is fetoscopically decompressed will have resolution of hydrops and will be remarkably stable at birth. These infants do not have capillary leak syndrome, or respiratory distress, and are quite stable. Often their most significant clinical problem is diaphragmatic dysfunction due to stretch injury from massive lung enlargement and diffuse tracheobroncheomalacia due to softening of cartilage from distention of the trachea. Because of the possibility of a simple laryngeal web or cyst, in utero bronchoscopy should be performed first. If a more significant airway obstruction exists, laser perforation of the larynx or trachea can then be performed. CHAOS due to thick cartilaginous plaque is unlikely to respond to simple perforation, and fetal tracheostomy may be necessary to allow resolution of hydrops. Although there are many unanswered questions about the long-term effects of in utero tracheostomy on lung development, it is clear that CHAOS, when associated with hydrops carries a high risk of intrauterine fetal death. In addition, in a fetal lamb model of this condition, tracheostomy reversed the pathophysiology. However, the case reported by Crombleholme et al. (2000) suggests that in some cases hydrops can be tolerated for prolonged periods. If close monitoring is available, intervention may be deferred until after 30 weeks of gestation, when an EXIT procedure can be considered with acceptable risks of prematurity.

TREATMENT OF THE NEWBORN

In cases of CHAOS in which an EXIT procedure is performed, the infant should have an airway in place before being handed over to the neonatologist. It is important that a medical

geneticist examines the infant for possible associated anomalies. Blood for karyotype analysis should be sent if a karyotype was not obtained during the pregnancy. Depending on physical findings, plain radiography to exclude vertebral anomalies, sonography to exclude genitourinary anomalies, and echocardiography should all be considered. The possibility of a communication between trachea and esophagus must be excluded in all patients with CHAOS. The pathophysiology of CHAOS results in a capillary leak syndrome after delivery by EXIT procedure. Affected neonates require careful fluid management because of their capillary leak, and the massive ascites that may initially be refractory to diuretic therapy. Because of chronic tracheal obstruction, diffuse tracheobronchial malacia should be anticipated, which may require 7 to 12 cm H_2O positive end-expiratory pressure (PEEP) to maintain patency of the airway. In addition, diaphragmatic dysfunction, secondary to in utero stretch injury as a result of lung overdistention, may be severe at birth. Phrenic nerve stimulation can confirm that the neuromuscular unit is intact. Progressive improvement can be anticipated during the first 5 months of life. The infant can be weaned from mechanical as soon as diaphragmatic function is restored and tracheal reconstruction can be considered at 6 to 12 months of age. Because of the unusual nature of CHAOS, these patients are best managed at centers not only experienced in EXIT procedures, but also with the neonatal care of infants with CHAOS and the complex airway reconstructive surgery that will be required.

SURGICAL TREATMENT

The most important aspect of the care of the newborn diagnosed with CHAOS is securing and maintaining the airway. Once potential associated anomalies have been excluded, and the infant's cardiorespiratory status is stable, an elective approach to evaluating the newborn's airway can be taken. In the absence of tracheoesophageal fistula, the surgical management of CHAOS is elective. The initial evaluation should be directed toward diagnosing the level of obstruction to allow planning of definitive surgical repair. It is important that prospective parents understand that, depending on the nature of the malformation, perfect laryngeal reconstruction and adequate speech may not be possible. The ideal timing of reconstruction in these extremely rare cases has not been established. However, bronchoscopy performed during the newborn period will exclude simple causes of laryngeal obstruction, such as laryngeal cyst or web. The majority of webs are located at the level of the glottis or immediately subglottic and are readily diagnosed by laryngoscopy or bronchoscopy. These webs can occasionally be lysed endoscopically with a knife or laser. Although lasers can be used, the small airway of the newborn may make it difficult to avoid thermal damage to surrounding tissues. An infant urethral resectoscope with a narrow cutting loop can be used with brief bursts of cutting current. There are only anecdotal reports of successful reconstruction and long-term outcome in this condition (Smith and Bain, 1965; Richards et al., 1992; Crombleholme et al., 2000; Rutter, 2006; Vaikunth et al., 2009).

LONG-TERM OUTCOME

Because of the nature of the malformation in CHAOS, very little information exists regarding the long-term outcome for affected children. In cases of simple laryngeal cyst or web, normal laryngeal function can be anticipated. The outcome in cases of more significant laryngeal malformation is less certain. Most infants with this problem have not survived. The few long-term survivors of isolated CHAOS have had excellent glottic and airway function with normal neurodevelopmental outcome.

GENETICS AND RECURRENCE RISK

Most cases of CHAOS occur as sporadic, isolated malformations without a known risk of recurrence. In cases of CHAOS associated with Fraser syndrome, there is a 25% chance of recurrence, as this syndrome is inherited as an autosomal recessive disorder (Fraser, 1962). Two different genes have been shown to be associated with Fraser syndrome, *FRAS1* and *FREM2* (McGregor et al., 2003; Jadeja et al., 2005)

Cystic Hygroma in Early Pregnancy

31 CHAPTER

Key Points

- Septated cystic hygroma in the first trimester is defined by extensive nuchal thickening extending along the entire length of the fetal back and in which septations are clearly visible.
- This finding is seen frequently in the first trimester, affecting more than one in 300 pregnancies.
- Given the 50% risk of fetal aneuploidy, definitive diagnostic testing with CVS should be offered immediately.
- Amongst the 50% of cases without aneuploidy, there is a one in two risk of major structural malformation, typically cardiac or skeletal abnormalities.
- If complete prenatal evaluation reveals no evidence of additional abnormality, a residual risk for abnormal pediatric outcome of 5% should be quoted.

CONDITION

Cystic hygroma refers to the finding of marked skin thickening extending along the entire length of the fetus at early ultrasound examination (Benacerraf and Frigoletto, 1987; Langer et al., 1990; Thomas, 1992; Gallagher et al., 1999). This finding is to be differentiated from simple increased nuchal translucency in which skin thickening is noted at the posterior aspect of the fetal neck only. Additionally, cystic hygroma in the first trimester has clearly visible septations running transversely between the fetal skin and underlying subcutaneous tissue. It

appears that the diagnosis of this finding early in pregnancy represents a completely different entity than the diagnosis of cystic hygroma in later pregnancy (Chapter 32). The latter condition is typically an isolated structural abnormality of lymphatic drainage and appears to have little or no association with chromosomal abnormality or other malformation.

The importance of this sonographic finding is its contribution to general population screening for fetal abnormalities and fetal aneuploidy in the first trimester of pregnancy. Given the pivotal role that nuchal translucency sonography at 11 to 13 weeks' gestation currently plays in general population screening for fetal abnormalities (Chapter 2), the finding of cystic hygroma will likely become more common. Once identified it is clear that such pregnancies are at significantly increased risk for a range of adverse outcomes. This includes up to a 50% chance of fetal aneuploidy (Malone et al., 2005a). Amongst euploid pregnancies there is almost a 50% chance of cardiac malformation or other major structural abnormality. Additionally, about one in four pregnancies with cystic hygroma in which a fetal abnormality has been excluded will result in spontaneous intrauterine fetal demise. Ultimately, only 15% to 20% of all cases of cystic hygroma identified in the first trimester will result in the birth of a healthy neonate at term (Malone et al., 2005a).

INCIDENCE

Until recently it was difficult to assess the population prevalence of first trimester cystic hygroma as most studies have included only selected patients identified from high-risk referral centers (Bernstein et al., 1991). However, a recent general population screening study evaluated more than 38,000 unselected pregnancies from throughout the United States with first trimester ultrasonography. The prevalence of cystic hygroma in this group was 1 in 285 first trimester pregnancies (Malone et al., 2005a). It is therefore likely that in a busy clinical practice performing routine first trimester ultrasonography, septated cystic hygroma will be encountered frequently.

SONOGRAPHIC FINDINGS

The key sonographic criteria for diagnosing cystic hygroma in the first trimester of pregnancy include the presence of a markedly enlarged nuchal translucency measurement that extends along the entire length of the fetal back, and in which septations are clearly visible in transverse section through the fetal neck. Figure 31-1 demonstrates a sagittal view through a fetus at 12 weeks' gestation in which skin thickening is seen to extend from the fetal head to the base of the fetal spine. Figure 31-2 illustrates the septations that are clearly visible in a transverse view through the fetal neck. Such septations tend to be more easily noted using the higher frequency imaging

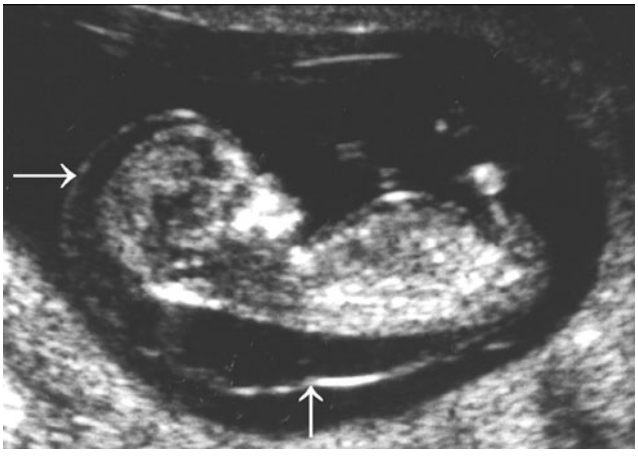

Figure 31-1 Septated cystic hygroma at 12 weeks' gestation, demonstrating midsagittal view through the fetus with increased nuchal translucency extending along the entire length of the fetal back.

provided by a transvaginal transducer. Figure 31-3 demonstrates a 3D ultrasound image of a septated cystic hygroma.

Given the strong association between first trimester cystic hygroma and various structural malformations, it is recommended that a careful sonographic evaluation is performed of the fetus following the diagnosis of cystic hygroma. Transvaginal sonography can be utilized to evaluate fetal long bones, skull, cardiac situs, cardiac axis, cardiac structure, and abdominal wall integrity in the first trimester.

DIFFERENTIAL DIAGNOSIS

The main differential diagnosis for first trimester enlarged nuchal thickening is to consider whether it meets criteria to

Figure 31-2 Septated cystic hygroma at 12 weeks' gestation, demonstrating transverse view through the fetal neck with septations being clearly visible between the fetal skin and underlying nuchal tissue.

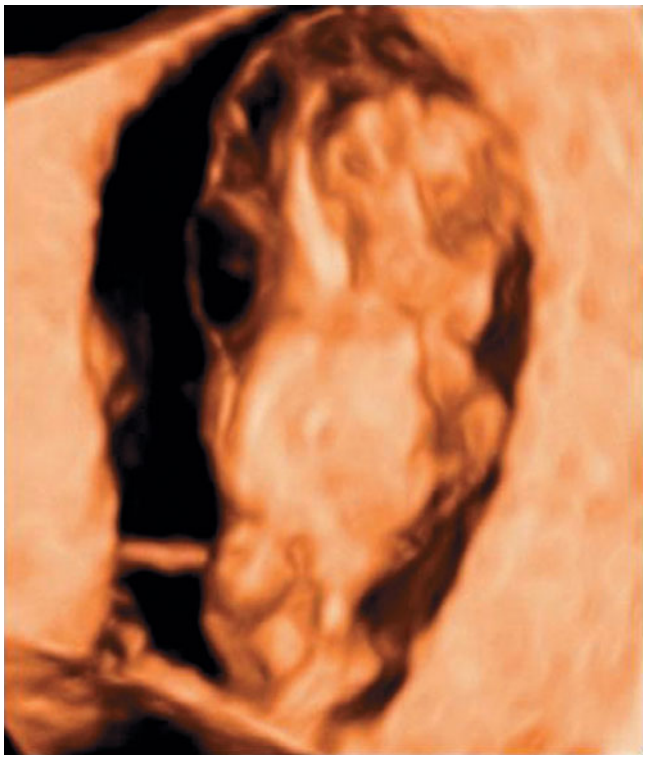

Figure 31-3 Three-dimensional surface-rendered view of fetus with septated cystic hygroma at 12 weeks' gestation.

be termed cystic hygroma or whether it should be considered a simple enlarged nuchal translucency. While some would consider these two entities to be part of the same spectrum of sonographic abnormalities, it is now clear that the outcomes following these two findings are clearly different. Septated cystic hygroma, using the definition as described above, can be easily identified in the first trimester and does not need the same degree of quality assurance required with general nuchal translucency screening programs. If the nuchal thickening does not extend along the entire length of the fetal back, and if transverse septations are not clearly visible, then the term nuchal translucency should be used. When an enlarged nuchal translucency is identified, it is generally advised that maternal serum markers, including free beta hCG and PAPP-A, be obtained before using risk-interpretative software to provide a patient-specific risk of fetal aneuploidy (Malone et al., 2005b). However, if a simple nuchal translucency measurement of 3 mm or greater is noted, there is little value in obtaining serum markers, and it is reasonable to immediately offer the patient definitive diagnostic testing with CVS (Comstock et al., 2006).

In a direct comparison of outcomes of cases of septated cystic hygroma and simple increased nuchal translucency, it is clear that the natural history of these two conditions is different (Table 31-1). Cystic hygroma has a fivefold higher risk of fetal aneuploidy compared with simple increased nuchal translucency, has a 12-fold increased risk of cardiac malformation, and a sixfold increased risk of spontaneous fetal or neonatal death (Malone et al., 2005a).

ANTENATAL NATURAL HISTORY

The natural history of septated cystic hygroma identified in the first trimester reveals a generally poor outcome (Table 31-1). In one series of 132 cases of cystic hygroma, 50% of fetuses were found to be aneuploidy (Malone et al., 2005a). Amongst aneuploidies, 40% were trisomy 21, 30% Turner syndrome, 20% trisomy 18, and 10% trisomy 13 or triploidy. Amongst the 50% of cases that are found to be euploid, approximately one-third will have a major structural malformation, most commonly cardiac malformation or skeletal abnormality. The most common cardiac malformations include hydrops, hypoplastic left heart syndrome, tetralogy of Fallot, and ventricular septal defect. The most common skeletal abnormalities include Roberts syndrome and Cornelia de Lange syndrome (Malone et al., 2005a). Additionally, amongst euploid fetuses

Table 31-1

Comparative Outcome of Septated Cystic Hygroma and Simple Increased Nuchal Translucency

	Septated Cystic Hygroma	Simple Nuchal Translucency $\geq$ 3.0 MoM	*P*	OR (95% CI)
Number	132	140		
Aneuploidy	67/132 (51%)	23/140 (16%)	<0.001	5.2 (2.9–9.6)
Cardiac malformation	16/65 (25%)	3/117 (3%)	<0.001	12.4 (3.2–56.3)
Fetal or neonatal death	5/20 (25%)	6/114 (5%)	0.003	6.0 (1.4–26.2)

MoM = multiples of median; OR = odds ratio.
From Malone FD, Ball RH, Nyberg DA, et al. First trimester septated cystic hygroma. Prevalence, natural history, and pediatric outcome. Obstet Gynecol. *2005a;106:288-294.*

without structural malformation, there is a 25% risk of spontaneous fetal demise. Ultimately, only 15% to 20% of all cases of septated cystic hygroma diagnosed in the first trimester will result in a normal liveborn neonate at term.

Also of note, in almost 80% of cases of first trimester cystic hygroma followed expectantly, the cystic hygroma can be expected to resolve spontaneously at a mean gestational age of 18 weeks (Malone et al., 2005a).

MANAGEMENT OF PREGNANCY

Following the diagnosis of septated cystic hygroma in the first trimester, counseling regarding pregnancy management can be provided in three steps. Once the initial diagnosis is made, patients should be counseled of a one in two risk of fetal aneuploidy and therefore should be offered the opportunity for immediate definitive diagnostic testing by means of CVS. There is no benefit in delaying diagnosis further by awaiting first trimester serum markers or performing computerized risk assessment. If CVS confirms no evidence of aneuploidy, patients should then be counseled of a one in two residual risk of major structural malformation. Since these malformations are most likely to be cardiac or skeletal, a targeted ultrasound evaluation of fetal anatomy and fetal echocardiography should be provided at 16 to 20 weeks' gestation. Finally, if such targeted fetal evaluation confirms a structurally normal fetus, patients should be counseled of a 95% likelihood of normal short-term pediatric outcome. A residual risk of 5% for abnormal pediatric outcome, despite complete prenatal evaluation, should be described.

FETAL INTERVENTION

Other than prenatal diagnostic testing by means of CVS in the first trimester and appropriate detailed fetal anatomical evaluation at 16 to 20 weeks' gestation, there is no indication for specific fetal intervention following the diagnosis of cystic hygroma.

TREATMENT OF THE NEWBORN

Once prenatal evaluation has confirmed normal fetal karyotype and no evidence of structural cardiac or skeletal malformation, there is generally no need for specific treatment or intervention in the neonatal period. It is recommended that all such neonates should be examined carefully by a pediatric geneticist or dysmorphologist as rarer genetic conditions such as Noonan syndrome have been described following cystic hygroma (Achiron et al., 2000). This is especially important given the acknowledged difficulties in making the diagnosis of Noonan syndrome in the neonatal period. Additionally, despite a normal fetal echocardiogram it would be reasonable to repeat an echocardiographic examination for the neonate, given the difficulties in excluding certain cardiac abnormalities prenatally, such as ventricular septal defect and aortic or pulmonary stenosis.

SURGICAL TREATMENT

In contrast to the third trimester diagnosis of cystic hygroma (Chapter 32), no specific surgical intervention is recommended following the early pregnancy diagnosis of cystic hygroma.

LONG-TERM OUTCOME

Minimal data are currently available to counsel patients regarding the long-term outcome of first trimester cystic hygroma, once fetal aneuploidy and major structural malformation are excluded. In a study of 132 cases of first trimester cystic hygroma, median longer term outcome extended to 25 months of age, with a range of 12 to 50 months (Malone et al., 2005a). In only 1 of 23 cases followed for this length of time was an additional pediatric abnormality diagnosed (one case of spastic diplegia with developmental delay). It seems reasonable therefore to counsel patients with cystic hygroma and normal prenatal evaluation of a 5% residual risk of longer term abnormal pediatric outcome. However, caution should be exercised in implying normal outcome beyond 2 years of age.

GENETICS AND RECURRENCE RISK

It is clear that 50% of cases of first trimester cystic hygroma are associated with fetal aneuploidy. Recurrence risk for such cases should be provided based on the individual chromosomal abnormality. For example, for cases of fetal trisomy, recurrence risk is generally quoted as 1%, or the maternal age–related risk, whichever is higher. In contrast, for cases of fetal Turner syndrome, patients should generally be counseled that there is no significant increased risk of recurrence beyond the general population risk (Chapter 134). Similarly, if a cardiac malformation is diagnosed, specific recurrence risks should be quoted based on the individual cardiac abnormality.

There have been a number of case reports of recurrence of first trimester cystic hygroma, both in the setting of normal fetal karyotype and as a sonographic marker of other recurrent fetal abnormalities. One report described three consecutive pregnancies complicated by cystic hygroma with nonimmune hydrops with normal karyotype (Teague et al., 2000). Another described recurrent cases of Fryns syndrome (diaphragmatic hernia and digital hypoplasia) presenting in the first trimester as cystic hygroma (Hosli et al., 1997). It has

been suggested that there may be rare cases of recurrent cystic hygroma inherited in an autosomal recessive pattern (Dallapiccola et al., 1984).

Cystic Hygroma in Late Pregnancy

32 CHAPTER

Key Points

- Cystic hygroma and lymphangioma are older commonly used terms for a specific type of vascular malformation.
- Most often seen in the soft tissue of the neck, axilla, thorax, and lower extremities.
- Different prenatal natural history if diagnosed in the first trimester versus the third.
- Lymphangiomas presenting in the third trimester usually seen in the anterior or anterolateral neck are not usually associated with other anomalies or hydrops.
- Lymphatic vascular malformations consisting of cysts separated by fine septa.
- While the mortality of lymphatic vascular malformations prior to 30 weeks' gestation is high, due to hydrops and karyotype abnormalities, those presenting later have an excellent prognosis.
- Cervical lymphangiomas are at risk for airway compromise, and an EXIT procedure should be considered if there is evidence of airway compression or displacement.

CONDITION

Traditionally referred to as lymphangioma or if in the neck cystic hygroma, these are currently considered a form of vascular malformation of the lymphatic system characterized by localized or diffuse malformations of lymphatic channels that can be characterized as microcystic, macrocystic, or both (Christison and Fishman, 2006).

Lymphangioma is a benign type of vascular malformation composed predominantly of dilated cystic lymphatics (Isaacs, 1997). These malformations are often present at birth and are second only to hemangioma as a cause of

soft tissue mass in the newborn (Potter and Craig, 1975; Isaacs, 1983, 1991, 1997). Lymphangiomas can occur in almost any location but are most commonly seen in the soft tissue of the neck, axilla, thorax, and lower extremities (Isaacs, 1997). Isaacs reported a series of 97 consecutive lymphangiomas seen at Children's Hospital of Los Angeles in which 45 occurred in the neck, 22 in the chest wall, 12 in the extremities, and 4 in the abdominal wall. Other less common sites included the omentum, mesentery, larynx, tongue, bowel, retroperitoneum, mediastinum, conjunctiva, and mouth (Isaacs, 1991). These lesions can vary in size from tiny subepidermal skin blebs to large dilated cystic fluid filled–masses that, when presenting in the neck, are commonly referred to as cystic hygromas.

There is a disparity between lymphangiomas that are diagnosed at birth as isolated findings in otherwise healthy infants and those detected prenatally during the first or second trimester (see chapter 31). Prenatal sonographic examination in the first and second trimester identifies a group of fetuses with cystic hygroma in which 60% have associated chromosomal abnormalities and are often associated with other structural anomalies that have an extremely high mortality rate (Romero et al., 1988; Cohen et al., 1989; Welborn and Timm, 1994). In this group of fetuses, cystic hygromas are distinguished by posterior triangle location of the lymphangioma, chromosomal abnormalities, structural anomalies, hydrops fetalis, a high incidence of intrauterine death, and rare postnatal survival. In contrast, isolated cystic hygroma presenting during the third trimester, often with previously normal sonographic studies earlier in gestation, is usually located anteriorly or anterolaterally in the anterior cervical triangle. These two groups of fetuses appear to have lymphangiomas of differing origin, pathophysiology, natural history, and most importantly, prognosis (Lyngbye et al., 1986; Benacerraf and Frigoletto, 1987; Langer et al., 1990).

The lymphatic system develops at the end of the 5th week of gestation with sprouting from the six primary lymph sacs situated in the neck, iliac region, and retroperitoneum. Goetsch (1938) suggested that lymphangiomas are developmental defects secondary to sequestration of lymphatic tissue in early embryonic life. Cystic hygromas are thought to arise because of the failure of the jugular lymph sacs to join the lymphatic system. The hygroma develops fibrillike sprouts from the existing cystic spaces. These endothelial-lined cystic spaces secrete lymphlike fluid, which causes local distention and gradual enlargement of cysts. The walls may become thicker with time, with connective tissue septae separating large cysts (Chervenak et al., 1983; Isaacs, 1997).

Lymphangiomas diagnosed in utero are commonly seen in association with Turner syndrome, hydrops, oligohydramnios, single-vessel umbilical cord, Noonan syndrome, fetal alcohol syndrome, Fryns syndrome, and trisomies 18 and 21 (Stephens and Shepard, 1980; Chervenak et al., 1983; Pijpers et al., 1988; Golden et al., 1989; Welborn and Timm, 1994). Chromosomal abnormalities are found in more than 60% of fetuses with cystic hygroma. The majority have a 45,X karyotype (Romero et al., 1988; Cohen et al., 1989; Welborn and Timm, 1994), although Trisomies 13, 18, and 21 and Klinefelter syndrome have all been reported (Chervenak et al., 1983; Greenberg et al., 1983; Marchese et al., 1985; Stephens and Shepard, 1980). Conversely, fetuses with a normal karyotype appear to have a much higher incidence of consanguinity or a previous family history of abnormal fetuses (Langer et al., 1990). Cystic hygromas in these patients are more likely to be associated with familial conditions such as Noonan syndrome, multiple pterygium syndrome, polysplenia syndrome, Roberts syndrome, or an isolated autosomal recessive trait (Chen et al., 1982; Cowchock et al., 1982; Graham et al., 1983; Zarabi et al., 1983; Zelante et al., 1984).

Isolated cystic hygromas presenting late in gestation appear to be a completely different entity (Lyngbye et al., 1986; Benacerraf and Frigoletto, 1987; Langer et al., 1990; Fujita et al., 2001; Tanriverdi et al., 2005; Gedikbasi, 2007). These cases had cystic hygromas located in the anterior and lateral location and were not generally associated with other anomalies or hydrops. Langer et al. suggested that in these cases lymphangioma developed much later in gestation. In one of his cases, the fetus had a normal sonographic examination at 17 weeks of gestation (Langer et al., 1990). If this is true, it is unlikely that the mechanism would be similar in the late presenting group of cystic hygromas and the early gestation group. Cystic hygromas may also regress in utero, presumably due to development of collateral lymphatic and venous connections. Webbing of the neck and puffiness of the hands and feet are characteristic features of Turner syndrome, which is thought to be due to fetal cystic hygromas that spontaneously resolve.

INCIDENCE

Precise estimates of the incidence of cystic hygroma and lymphangioma are difficult to come by and depend on whether prenatal or postnatal data are evaluated. Fonkalsrud estimated the incidence of cystic hygroma to be 1 in 12,000 births, with 50% to 65% of cases presenting at birth, and 80% to 90% presenting by the second year of life (Bill and Sumner, 1965; Fonkalsrud, 1980). A total of 52 confirmed diagnoses of cystic hygroma were reported to the South East Thames Regional Congenital Malformation Registry in a region with an annual birth rate of 52,000, yielding an incidence of 1 in 1000 births. This series included terminations, intrauterine fetal death, stillbirths, and postnatal deaths to give a more accurate account of the incidence of cystic hygroma (Fisher et al., 1996). The incidence of cystic hygroma was as high as 1 in 300 among spontaneous abortuses reported by Byrne et al. (1984).

SONOGRAPHIC FINDINGS

The sonographic features of cystic hygroma include fluid-filled cystic spaces divided by fine septae commonly observed in the nuchal region and anterior and posterior triangles of the neck (Figure 32-1). They often have a dense midline posterior

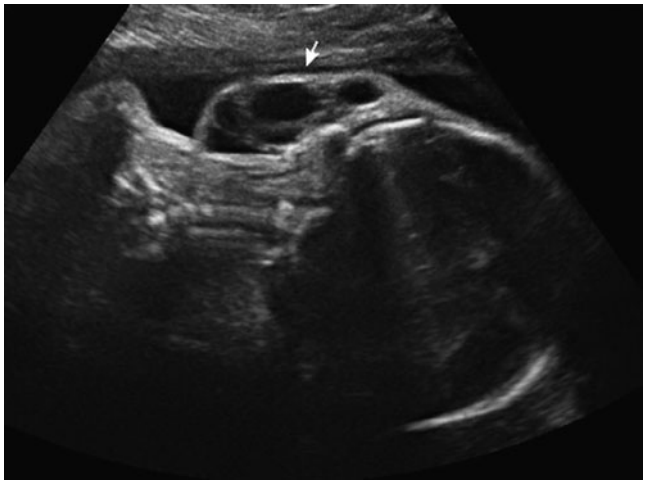

Figure 32-1 Cystic mass along lateral aspect of fetal head at 31 weeks consistent with cystic hygroma.

septum extending from the fetal neck across the full width of the hygroma. This septum is the sonographic equivalent of the nuchal ligament (Chervenak et al., 1985). In order to differentiate cystic hygroma from other diagnoses, it is important to exclude a bony defect in the skull or vertebral column as would be seen with encephalocele. Solid components should be excluded to distinguish cystic hygroma from a cystic teratoma. Cysts separated by septae are helpful in distinguishing nuchal edema from cystic hygroma.

Lymphatic malformations may be diagnosed in the chest, abdomen, retroperitoneum or inguinal region. Rasidaki et al. (2005) have reported a chest wall lymphatic malformation in which MRI in addition to ultrasound was used to make the diagnosis. Similarly, there have been several reports of prenatal diagnoses of axillary lymphatic malformations (Song et al., 2002; Zanotti et al., 2001).

Once cystic hygroma has been detected, a search for other potential associated signs of nonimmune hydrops such as fetal skin edema, ascites, and pleural or pericardial effusions should be sought. In addition, structured anomalies seen in association with cystic hygroma should be sought, including cardiac, facial, vertebral, and genitourinary anomalies and diaphragmatic hernia (Bulas et al., 1992) (Table 32-1).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of cystic neck masses includes nuchal edema, encephalocele or other neural tube defects, cystic teratoma, and twin sac of a blighted ovum. The approach to each of these conditions differs, highlighting the importance of accurate prenatal diagnosis. The presence of skull or vertebral column defects suggests the diagnosis of encephalocele, especially if associated with hydrocephalus. The distinction between cystic hygroma and cervical teratoma can be extremely difficult. Teratomas usually have a more complex sonographic appearance, with solid as well as cystic components. Calcifications within the mass are thought to be diagnostic of teratoma (see Chapter 110). Fetal magnetic resonance imaging (MRI) may be very helpful in distinguishing cystic hygroma from cervical teratoma (Liechty et al., 1997; Hubbard et al., 1998) (Figures 32-2A and 32-2B). Nuchal edema is usually without septae except the midline nuchal ligament and is a few millimeters in thickness (see Chapter 31).

Table 32-1

ANTENATAL NATURAL HISTORY

The natural history of prenatally diagnosed cystic hygroma appears to depend on gestational age at diagnosis, location of the cystic hygroma, and most particularly, whether or not there are associated chromosomal or structural abnormalities (Langer et al., 1990).

The mortality rate for cystic hygromas diagnosed prior to 30 weeks of gestation, with posterior location, is extremely high because of the high incidence of nonimmune hydrops and associated chromosomal defects (see Chapter 128). In the report by Langer et al. of 27 cases diagnosed prior to 30 weeks of gestation, all but 2 fetuses died. Of the 25 that did not survive, nonimmune hydrops developed in 21, 4 spontaneously aborted, and 21 were electively terminated. The only 2 survivors had spontaneous regression and were subsequently diagnosed with Noonan syndrome at birth (Langer et al., 1990). Cystic hygroma associated with nonimmune hydrops is almost uniformly fatal. There are chromosomal abnormalities in approximately 80% of these cases. Fetuses with normal chromosomes have a higher incidence of consanguinity (Langer et al., 1990). These cases of cystic hygroma are also

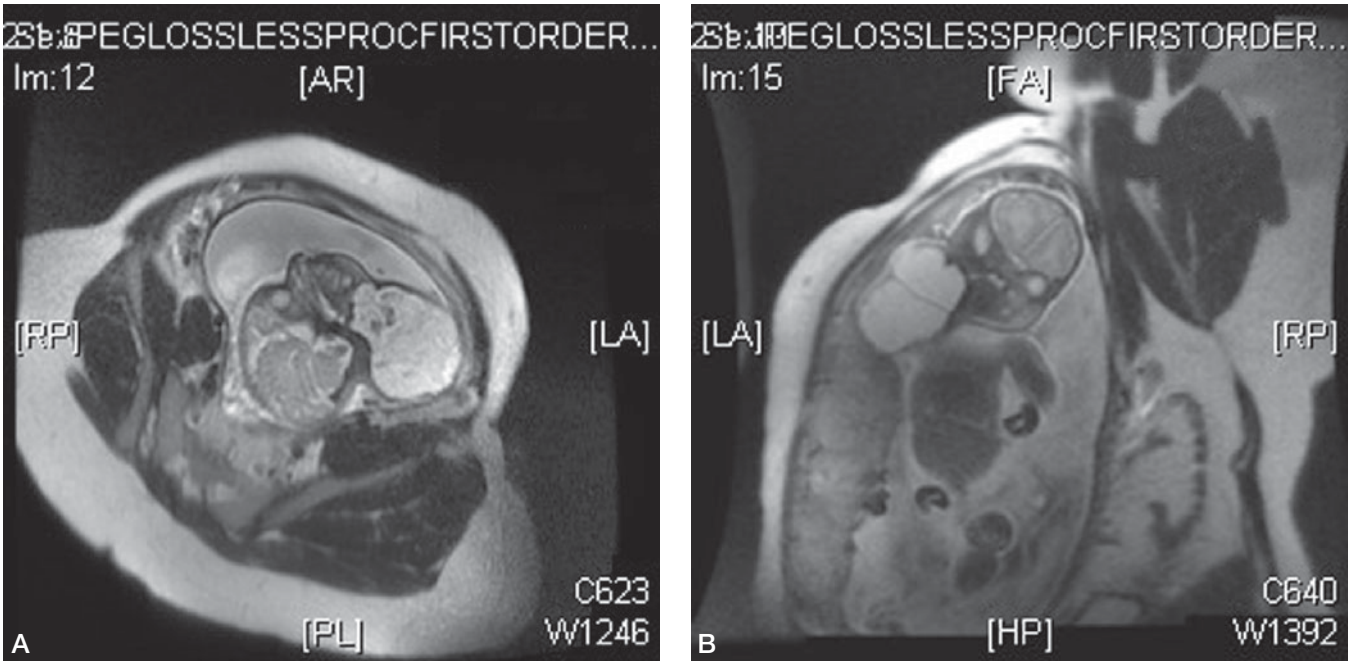

Figure 32-2 **A**. Sagittal view of fetus with large right-sided lymphangioma resulting in hyperextension of the neck and compression and distortion of the airway. **B**. Coronal view of the same fetus with a large lymphangioma.

more likely to be associated with familial conditions, such as Noonan syndrome (Zarabi et al., 1983), multiple pterygium syndrome (Chen et al., 1982), polysplenia syndrome, Roberts syndrome (Graham et al., 1983), or an isolated recessive trait (Cowchock et al., 1982). In a review of 100 fetuses with nuchal thickening or cystic hygroma detected sonographically at 10 to 15 weeks of gestation, Nadel et al. (1993) found that a good prognosis could be expected if the karyotype was normal, there were no separations in the mass, and there were no associated hydrops.

In marked contrast to cystic hygromas with associated karyotypic abnormalities, there is a small group of fetuses with an isolated cystic hygroma without chromosomal abnormality, structural anomaly, or familial condition and in which hydrops does not develop. These cystic hygromas usually develop in the third trimester and have an excellent prognosis. The major concern in fetuses with large cystic cervical masses later in gestation is airway compromise at birth. The fetuses often require delivery by EXIT procedure (see below).

MANAGEMENT OF PREGNANCY

The management of a pregnancy complicated by a fetus with cystic hygroma depends on the presence or absence of nonimmune hydrops, chromosomal abnormalities, or other associated anomalies. Once a cystic hygroma has been detected, a detailed sonographic examination should be performed to search for fetal skin edema, ascites, and pleural or pericardial effusions. In addition, other structural anomalies should be excluded, especially genitourinary and cardiac defects. Genetic amniocentesis is recommended in all cases of cystic hygroma because of the high incidence of associated chromosomal abnormalities. In the presence of nonimmune hydrops the prognosis is grim, and appropriate counseling is indicated. In the presence of severe associated anomalies or a chromosomal abnormality prior to 24 weeks of gestation, elective termination may be offered. Echocardiography should be obtained in cases in which no chromosomal abnormalities are detected to exclude cardiac defects. An isolated cystic hygroma diagnosed in the third trimester has a much more favorable prognosis, and attention should be focused on site and mode of delivery. Because of risks of airway compromise, delivery in a tertiary care center with neonatologists and pediatric surgeons standing by is recommended. Because of the risks of airway compromise, consideration should be given to the EXIT procedure (Liechty et al., 1997; Marwan and Crombleholme, 2006). While a cervical mass of any size can cause airway compromise, masses sufficiently large enough to cause polyhydramnios can obstruct the pharynx or larynx, making intubation exceedingly difficult. Pregnancies with a cystic hygroma should be followed closely for the development of polyhydramnios and secondary uterine irritability. Polyhydramnios in fetuses with large cystic hygromas may be so severe as to require amnioreduction to treat maternal respiratory difficulties and preterm labor.

FETAL INTERVENTION

A few cases of lymphangioma have undergone in utero drainage by ultrasound-guided cyst aspiration. Chen et al. (1996) reported two fetuses that underwent multiple cyst aspirations. In each case karyotype analysis was normal and

there were no associated structural anomalies. The rationale for this approach is to prevent polyhydramnios, irreversible facial deformity, and progression to hydrops fetalis. It is unclear, however, that these multiple cyst aspirations had any effect on outcome. While cyst aspiration as an adjunct to securing an airway at birth may be indicated, there are few data to support in utero decompression to prevent progression to nonimmune hydrops or facial deformity. The lack of benefit and risk of repeated aspirations make this fetal intervention difficult to justify. Kaufman et al. (1996) did report successful percutaneous decompression of a large axillary lymphangioma that would have caused skeletal dystocia. Ultrasound-guided aspiration was followed by normal spontaneous vaginal delivery. Figure 32-3 demonstrates an axillary lymphangioma detected antenatally and aspirated prior to birth to allow vaginal delivery.

Several groups in Japan have attempted intrauterine sclerotherapy using OK-432 between 27 and 28 weeks' of gestation (Wattori et al., 1996; Ogita et al., 2001). OK-432 is a lyophilized mixture of a low-virulence strain of *Streptococcus pyogenes* of human origin incubated with penicillin G. The fetuses had involution of the cystic hygroma, and at birth only a slight skinfold was noted. Cases of lymphatic vascular malformations with normal chromosomes and no associated anomalies with hydrops were considered candidates for in utero sclerotherapy with OK-432 (Ogita et al., 2001). Those lesions with very large lymphangiomas even in the absence of hydrops may also be candidates for OK-432 in Japan. To date there have been no reports of in utero sclerotherapy with OK-432 being used in this country. There are few data on the use of this agent postnatally and none are available on its potential effects in the developing fetus. Currently, the only

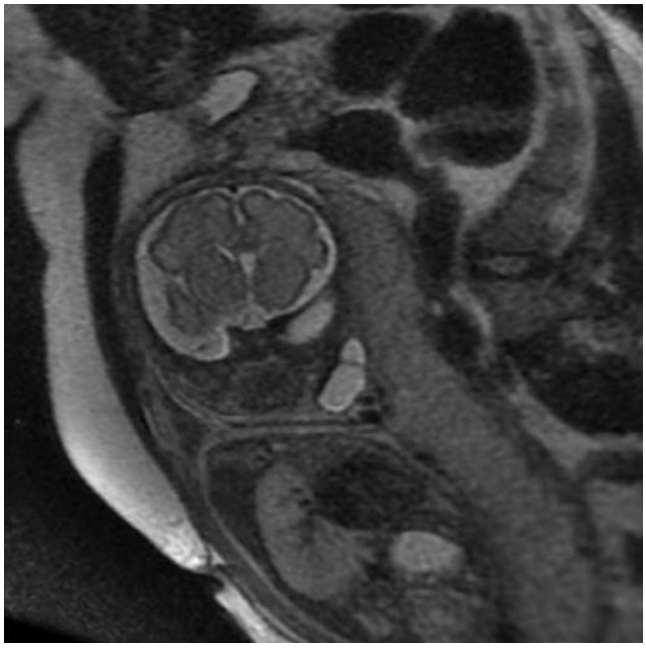

Figure 32-3 Fetal MRI demonstrating unilateral cystic mass at lateral aspect of fetal neck consistent with cystic hygroma.

fetal procedure indicated for large cystic hygromas is EXIT (ex utero intrapartum treatment), which involves placement of an endotracheal tube before the fetus is separated from placental support (Liechty et al., 1997).

Treatment of the fetus with a large cystic hygroma includes an EXIT procedure to secure the airway (Liechty et al., 1997). The EXIT procedure allows up to 1 hour with excellent uteroplacental gas exchange for laryngoscopy, bronchoscopy and, if necessary, tracheostomy with or without partial resection of the mass (Liechty et al., 1997). As fetuses with prenatally diagnosed fetal airway obstruction reach viability, they should be monitored closely for the development or progression of hydrops or cardiac decompensation. If the development or progression of hydrops is noted sonographically, open fetal surgery may be necessary to salvage patients younger than 30 weeks' gestation. If hydrops is noted later than 30 weeks' gestation, the fetus should be delivered by using the EXIT strategy.

A number of important considerations must be taken into account when applying the EXIT procedure in the setting of giant fetal neck masses. The most pressing issue is the successful securing of the fetal airway. Although fetal neck masses can cause polyhydramnios and preterm labor, the most significant aspect of their management is treating a compromised airway at the time of delivery. The timing of the EXIT is often dictated by severity of polyhydramnios and preterm labor. The mean gestational age of fetuses with neck masses undergoing EXIT procedure is 34 weeks. Airway compromise is a function of the location of the mass and distortion of the airway, not necessarily the absolute size of the neck mass. As mentioned previously, the surgeon must be prepared for every possible airway contingency. All the available modalities to secure the fetal airway are detailed under the description of the EXIT procedure and are outlined in the algorithm in Figure 32-4. Other important issues to consider when performing an EXIT procedure for giant neck masses include: (1) the possibility of wedging of the lungs in the apex of the chest as a result of the neck hyperextension (despite the fact that a successful EXIT strategy can be applied in these cases, significant morbidity and mortality should be anticipated because of the associated lung hypoplasia); (2) the chance of the trachea being pulled up into the neck may lead to the underestimation of the site of tracheostomy, leading to an inappropriately low tracheostomy site; (3) the occurrence of polyhydramnios as a result of esophageal compression (this may lead to underestimation of the proximity of the placental edge to the site of hysterotomy with increased risk of bleeding); and (4) some fetal neck masses are caused by a cystic mass lesion. In such cases, decompression of the mass before the hysterotomy under US guidance will help in fashioning the hysterotomy and in delivering the fetal head and neck. Based on our cumulative experience in the application of the EXIT procedure in different clinical situations, we have summarized pitfalls and lessons learned to provide guidance when applying the EXIT approach (See Chapter 5, Table 5-6). If the fetus is premature and at increased risk for respiratory distress syndrome, surfactant replacement therapy can be administered while on

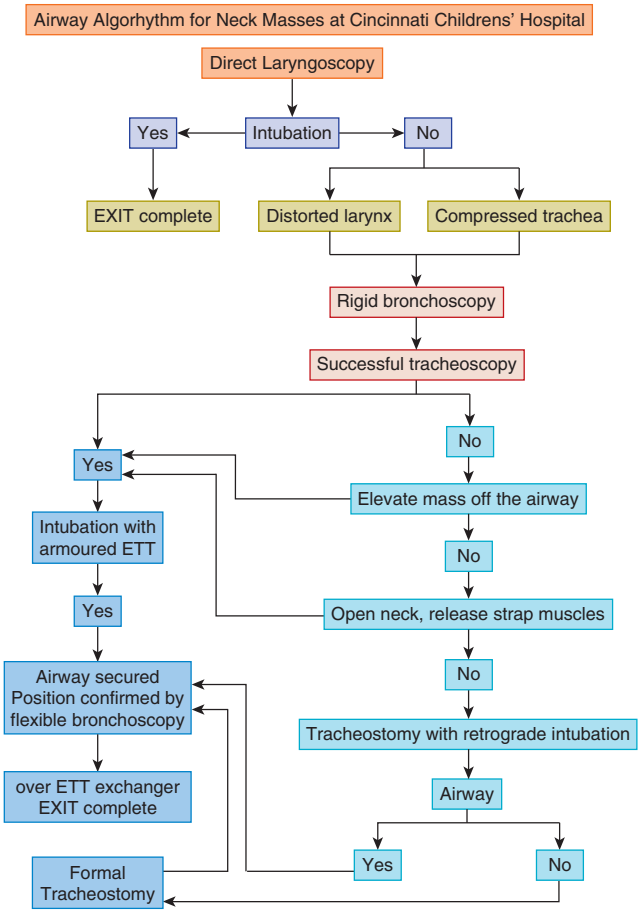

Figure 32-4 Algorithm for EXIT-to-Airway intraoperative decision-making.

placental support. In addition, in a three-vessel cord, and umbilical artery catheter, and even an umbilical venous catheter can be placed while on placental support to facilitate newborn resuscitation.

Once an airway has been established, the care of the newborn should focus on any underlying lung disease and exclusion of any associated anomalies and chromosomal abnormalities, if this has not already been done. Once the newborn is able to be transported to a tertiary care facility, a computed tomographic (CT) scan and MRI scan with magnetic resonance angiography should be obtained of the infant's head and neck to confirm the diagnosis of lymphangioma and to determine the extent of the hygroma (Figures 32-5A and 32-5B). Of particular concern is to define whether there is extension into the mediastinum or the floor of the mouth and tongue.

TREATMENT OF THE NEWBORN

The infant with a large cystic hygroma has an intrinsically unstable airway, and resection should proceed as soon as the diagnostic evaluation is completed. Cystic hygromas of a modest size can be dealt with on a more elective basis if they do not pose a risk for airway compromise. The nature of the lymphangioma often precludes a complete resection. The surgical approach is focused on resection of as much of the mass as possible without sacrificing vital structures. Some surgeons have recommended a conservative approach in asymptomatic lymphangiomas because of occasional spontaneous regression. More commonly, these lesions grow proportionately with the growth of the infant. There may also be acute increases in the size of the cyst due to hemorrhage or infection. Because of difficulty in achieving a complete resection, alternative treatments have been tried with variable results.

SURGICAL TREATMENT

Cystic aspiration is of little benefit except in the rare instance of a large dominant cyst as a means of emergency decompression. However, the cysts rapidly reaccumulate. Sclerosing agents have been used as an alternative to resection, using boiling water or sodium morrhuate, with disappointing results. Bleomycin has been used as microspheres in oil bleomycin fat emulsions (BLM), and seems more effective than other preparations (Tanigawa et al., 1987; Tanaka et al., 1990). After cyst aspiration, injection into the lymphangioma via fine needle of 0.3 to 0.6 mg of BML per kilogram of body weight is recommended. This treatment requires admission to the hospital for observation and is contraindicated in infants younger than 6 months or in the presence of airway compromise or mediastinal involvement due to significant tissue edema that results. Side effects of bleomycin include fever, diarrhea, vomiting, infection, and bleeding. In addition, the incidence of long-term complications such as pulmonary fibrosis is unknown.

The sclerosing agent OK-432 is the product of incubating *S. pyogenes* of human origin with penicillin G (Ogita et al., 1996). Intracystic injection of 0.1 mg of OK-432 in 10 mL of saline solution following cyst aspiration is recommended. If necessary, the treatment can be repeated 3 to 4 weeks later. No prospective trials confirming the efficiency of this treatment have been reported. Laser treatment of lymphangioma has also been reported, but again with mixed results (Ogita et al., 1996).

LONG-TERM OUTCOME

The mortality of cystic hygroma diagnosed prior to 30 weeks of gestation and associated with nonimmune hydrops is virtually 100%. There is also a high incidence of associated chromosomal abnormalities that may, as in trisomy 18 and 13, be lethal. The outcome for isolated cystic hygroma presenting in the third trimester, however, is quite different. The overall mortality in this group is very low. However, complete resection is possible in only 75% of cases (Hancock et al., 1982). Despite complete resection, recurrence can occur in as many as 10% to 27% of cases. In cases in which only a partial

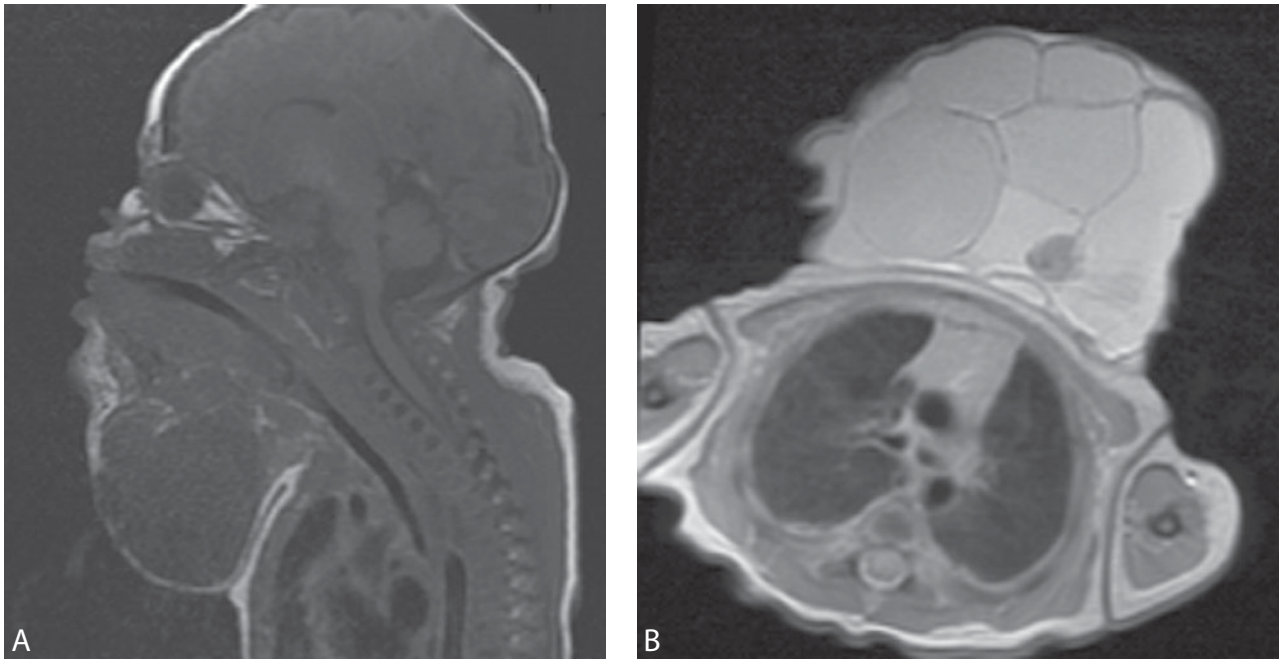

Figure 32-5 **A and B.** Postnatal MRI images demonstrating large submental cystic mass resting on the anterior surface of the fetal chest.

resection can be achieved, recurrence is observed in 50% to 100% of patients. Significant complications can occur in up to 30% of patients. Significant neurologic problems can result from injury to cranial nerves, especially the facial nerve (VII). However, injuries to the 9th, 10th, 11th, and 12th cranial nerves have also been reported. In addition, Horner syndrome due to injury to the sympathetic chain and diaphragmatic paralysis from phrenic nerve injury has occurred during resection of the cystic hygroma. Extensive involvement of the larynx, trachea, or extensive involvement of the floor of the mouth may necessitate tracheostomy tube placement. Often multiple operations are required to bring lymphangiomas under control. The long-term outcome depends on the ability to achieve a complete resection. This becomes unlikely in the face of extensive involvement of the floor of the mouth, tongue, larynx, or trachea.

GENETICS AND RECURRENCE RISK

Prenatally diagnosed cystic hygroma has a 50% to 60% incidence of abnormal karyotype. The most common associated chromosomal abnormalities are listed in Tables 32-1 and 32-2. Because some fetuses with cystic hygroma may have chromosomal mosaicism, it may be necessary to study several tissues to make a diagnosis. There are two reports of familial cystic hygroma occurring in eight patients in three families (Tricoire et al., 1993; Teague et al., 2000). In the first family, two fetuses with normal karyotypes and cystic hygromas had camptomelic dysplasia (see Chapter 91). Only one other fetus had anomalies—meningomyelocele and cleft palate. In all cases parental consanguinity was found, suggesting an autosomal recessive mode of inheritance. In another report, a 19-year-old gravida 3 para 0 was diagnosed with a large cystic hygroma at 11 weeks' gestation. The fetal subsequently developed increasing sign of a septated nuchal mass and ascites. A 46XX fetal karyotype had been noted on two prior pregnancies, both of which had also been complicated by cystic hygroma and hydrops. Cystic hygroma associated with a normal karyotype can be inherited as an autosomal recessive (Teague et al., 2000).

33 Goiter

CHAPTER

Key Points

- Goiter in the fetus, a rare condition, can occur as part of a hypothyroid, hyperthyroid, or euthyroid state.
- Hypothyroid fetal goiter may be secondary to transplacental passage of antithyroid medication, iodine deficiency, iodine intoxication, transplacental passage of antithyroid antibodies, congenital metabolic disorders of thyroid hormone synthesis, or hypothalamic-pituitary hypothyroidism.
- Congenital hypothyroidism is a serious condition, which if not treated in the first 3 months of life is likely to result in irreversible mental retardation.
- Hyperthyroid fetal goiter is most often caused by transplacental passage of a thyroid-stimulating IgG antibody from the mother. Such antibodies are present in approximately 95% of women with Graves disease.
- Thyroid-stimulating antibody levels in Graves disease may not reflect maternal thyroid status because they are detectable in women who are clinically hyperthyroid, euthyroid, or hypothyroid.
- The typical sonographic appearance of a fetal goiter is a symmetric, homogenous mass in the anterior neck, with an echogenic consistency, and with some lobulation.
- The diagnosis of fetal goiter is rarely made prior to 24 weeks' gestation. The fetal neck may be hyperextended and the trachea and esophagus may become compressed or displaced resulting in polyhydramnios.
- It is extremely important to thoroughly evaluate and treat a fetal goiter.
- Because ultrasound methods of differentiating between hypothyroidism and hyperthyroidism may not be reliable, fetal cord blood sampling may be required. Amniotic fluid thyroid hormone values may not be reliable.
- If fetal hypothyroidism is diagnosed, intra-amniotic injection with levothyroxine will be required.
- Little information is available to guide patient counseling regarding the antenatal natural history of fetal goiter. The clinical course will depend on whether or not the fetus is hyperthyroid, euthyroid, or hypothyroid.
- Serial sonographic surveillance is suggested due to the fact that fetal goiter may be associated with polyhydramnios, intrauterine growth restriction, hydrops, and intrauterine fetal demise.
- A neonatologist should be present in the delivery room because problems securing an airway may be encountered. In the most severe cases of fetal goiter, the ex utero intrapartum treatment (EXIT) procedure may be needed to maximize the ability to promptly secure an airway at delivery.
- There is little data available to counsel patients on the long-term prognosis of antenatal fetal goiter.

CONDITION

Fetal goiter, or thyromegaly, is a diffuse enlargement of the fetal thyroid gland. Goiter in the fetus can occur as part of a hypothyroid, hyperthyroid, or euthyroid state. Hypothyroid fetal goiters are more common than those associated with either the hyperthyroid or euthyroid states.

Goiter associated with fetal hypothyroidism can be caused by transplacental passage of antithyroid medications being used by a mother with hyperthyroidism, iodine deficiency, iodine intoxication, transplacental passage

of antithyroid antibodies, congenital metabolic disorders of thyroid hormone synthesis, or hypothalamic-pituitary hypothroidism (Weiner et al., 1980; Romero et al., 1988; Noia et al., 1992; Soliman et al., 1994; Van Loon et al., 1995; Bruner and Dellinger, 1997; Vicens-Calvet et al., 1998). Most cases of hypothyroid goiter will not become apparent until the neonatal period. When goiter associated with hypothyroidism is recognized in utero it is most likely to be secondary to transplacental passage of drugs or congenital dyshormonogenesis because of an inherited enzymatic deficiency (Romero et al., 1988). Congenital hypothyroidism is a serious condition, which if not treated within the first 3 months of life is likely to result in irreversible mental retardation. Although newborn screening programs for congenital hypothyroidism have been extremely successful in reducing the incidence of mental retardation associated with this condition, it is possible that the presence of a hypothyroid state in utero may result in some degree of hearing, speech, and other intellectual impairment, despite early neonatal therapy (Rovet et al., 1987). This emphasizes the importance of thorough evaluation and treatment of fetal goiter whenever it is suspected prenatally.

Goiter associated with fetal hyperthyroidism is almost always caused by transplacental passage of a thyroid-stimulating IgG antibody from the mother (Wenstrom et al., 1990; Belfar et al., 1991; Hatjis, 1993; Hadi and Strickland, 1995; Heckel et al., 1997). Such antibodies are present in at least 95% of women with Graves disease. Thyroid-stimulating antibody levels in Graves disease may not reflect maternal thyroid status, as they are detectable in women who are clinically hyperthyroid, euthyroid, or hypothyroid. Therefore, whenever a patient with a history of Graves disease becomes pregnant, the fetus is at risk for hyperthyroid goiter, irrespective of the mother's clinical thyroid state. The fetal thyroid gland becomes fully responsive to thyroid-stimulating substances, such as maternal IgG, only in the second trimester, so the detection of a fetal goiter before 20 to 24 weeks of gestation is unlikely.

INCIDENCE

Fetal goiter is extremely rare, with no published series sufficient to allow an estimation of its incidence. Hypothyroid goiter is more common than hyperthyroid goiter. Congenital hypothyroidism has an incidence of 1 in 4000 livebirths. Only a small fraction of these will be complicated by fetal goiter, because in the vast majority of cases goiter becomes clinically apparent only during neonatal life (Fisher et al., 1979). Inborn errors of thyroid hormone biosynthesis that result in congenital dyshormonogenesis and cause hypothyroid fetal goiter are rare, being present in 1 in 30,000 livebirths. Graves disease is seen in approximately 1% of pregnant women, and hyperthyroidism or hypothyroidism will develop in 2% to 12% of these fetuses or neonates (Hatjis, 1993). However, only a small fraction of this number of at-risk fetuses will be diagnosed prenatally with a fetal goiter.

Figure 33-1 Prenatal sonographic image of a fetal neck demonstrating symmetric bilateral enlargement of the thyroid gland.

SONOGRAPHIC FINDINGS

The typical sonographic appearance of a fetal goiter is a symmetric, homogeneous mass in the anterior neck, with an echogenic consistency, and with some lobulation (Figure 33-1) (Heckel et al., 1997). The diagnosis is rarely made prior to 24 weeks of gestation. The fetal neck is often maintained in a state of hyperextension (Figure 33-2), and the

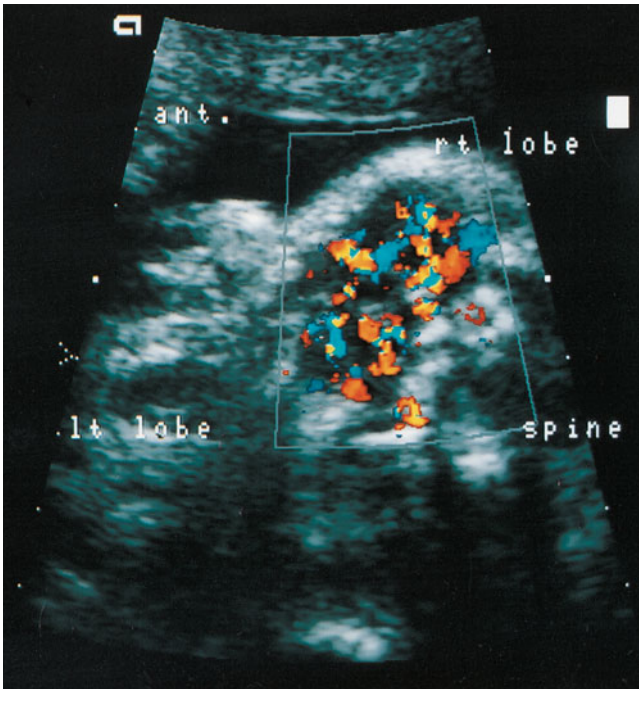

Figure 33-2 Sonographic image of the same fetal goiter shown in Figure 33-1 demonstrating increased vascularity in the neck mass.

trachea and esophagus may be compressed or displaced. Later in gestation, this compression may be associated with polyhydramnios, as swallowing becomes more difficult (Abuhamad et al., 1995). Color Doppler sonography can be used to aid in the diagnosis of a fetal goiter. The presence of a high flow pattern helps to confirm the diagnosis of goiter but does not necessarily imply a hyperthyroid state, as hypothyroid fetal goiters may also have increased vascularity (Soliman et al., 1994). Color Doppler sonography may also be useful in monitoring the response of a hyperthyroid fetus to antithyroid therapy, with a decrease in vascularity accompanying the resolution of the hyperthyroid state (Luton et al., 1997).

Sonographic screening for fetal goiter may be difficult because of problems in accurately identifying the fetal thyroid during early gestation. Nevertheless, normograms have been published for thyroid volume across a range of gestational ages, including transverse width and circumference of the gland, which may be helpful in diagnosing fetal goiter in patients at high risk for fetal thyroid dysfunction (Bromley et al., 1992).

After the sonographic diagnosis of a fetal goiter, a careful sonographic survey should be performed for other features suggestive of hyperthyroidism or hypothyroidism. Sonographic signs suggestive of fetal hyperthyroidism include cardiac hypertrophy, fetal tachycardia, hydrops, intrauterine growth restriction, advanced bone age with craniosynostoses, and hepatosplenomegaly. Sonographic signs of fetal hypothyroidism include cardiomegaly and fetal heart block. However, none of these additional sonographic features are sufficiently specific to reliably predict the fetal thyroid status. Magnetic resonance imaging (Figure 33-3) and 3D ultrasound imaging may help confirm the diagnosis (Figure 33-4) (Karabulut et al., 2002; Nath et al., 2005).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for a fetal goiter includes a determination of whether the fetus is hypothyroid, hyperthyroid, or euthyroid. A presumptive diagnosis of fetal hyperthyroidism may be considered in the setting of a fetal goiter in a mother with autoimmune Graves disease. Sonographic findings suggestive of fetal hyperthyroidism include cardiac hypertrophy, hydrops, or fetal tachycardia. Sonographic findings suggestive of fetal hypothyroidism include cardiomegaly and fetal heart block. Because other methods of differentiation between hypothyroidism and hyperthyroidism may not be reliable, fetal blood sampling may be required to evaluate the fetal thyroid state. Amniotic fluid thyroid hormone values may also not be reliable (Abuhamad et al., 1995; Van Loon et al., 1995; Heckel et al., 1997).

Other structural abnormalities that may mimic a fetal goiter include a thyroid cyst, hemangioma, cervical neuroblastoma, teratoma, ectopic thymus, branchial cleft cyst, cervical meningocele, or cystic hygroma (Heckel et al., 1997). Anterior neck masses other than a fetal goiter, such as a teratoma

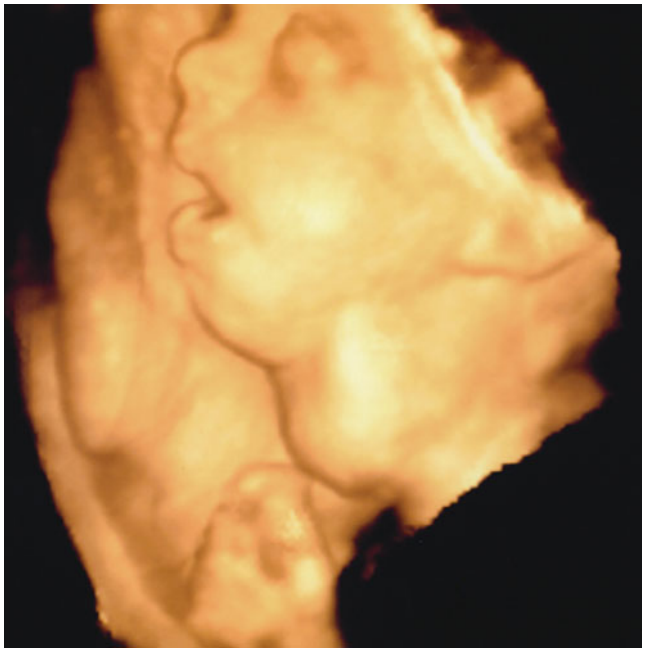

Figure 33-4 Twenty-seven-week fetus with goiter: three-dimensional multiplanar surface-rendered image of the fetal neck and face. *(From Nath CA, Oyelese Y, Yeo L, et al. Three-dimensional sonography in the evalution and management of fetal goiter.* Ultrasound Obstet Gynecol. *2005;25:312-314.)*

or neuroblastoma, tend to be asymmetric and extend above or below the thyroid region.

ANTENATAL NATURAL HISTORY

Little information is available to guide patient counseling regarding the antenatal natural history of fetal goiter. The literature to date consists almost entirely of single case reports. The antenatal natural history of a goiter will depend in large part on the thyroid status of the fetus. In the euthyroid fetus, the main potential problem associated with the presence of a goiter is obstruction of trachea and/or esophagus as the goiter enlarges in later pregnancy. This may lead to polyhydramnios, which may precipitate preterm contractions that are due to uterine overdistention (Abuhamad et al., 1995). In addition, fetal goiter may result in hyperextension of the fetal neck, which can result in dystocia (Romero et al., 1988).

Fetal goiter associated with hyperthyroidism may result in significant fetal changes in utero as the pregnancy progresses. Fetal effects may include tachycardia, cardiac hypertrophy, hydrops, fetal death, intrauterine growth restriction, craniosynostoses, advanced bone age, intellectual impairment, and preterm birth (Wenstrom et al., 1990; Belfar et al., 1991; McKenzie and Zakarija, 1992; Hatjis, 1993; Heckel et al., 1997). Fetal tachycardia is the most common presentation of fetal hyperthyroidism, and the most common cause of intrauterine death is secondary to hydrops. Congenital hyperthyroidism is associated with a 15% to 25% mortality rate.

Fetal goiter secondary to hypothyroidism may result in fetal bradycardia, heart block, or cardiomegaly. However, in the majority of cases of fetal hypothyroidism there are no additional sonographic findings other than the presence of a goiter. Given the strong association between mental retardation and untreated neonatal hypothyroidism, there is logical concern that prolonged untreated fetal hypothyroidism may also lead to intellectual impairment during the prenatal period (Abuhamad et al., 1995; Bruner and Dellinger, 1997).

MANAGEMENT OF PREGNANCY

After the prenatal diagnosis of a fetal goiter, a careful sonographic survey of the entire fetal anatomy is indicated to evaluate for sonographic signs consistent with fetal hypothyroidism or hyperthyroidism. A detailed maternal history should be obtained to evaluate for an antecedent diagnosis of thyroid dysfunction and for any exposure to drugs that may affect fetal thyroid function, such as propylthiouracil, iodide preparations, or amiodarone. It should be noted that the mother may be unaware of possible iodide exposure in the form of expectorant medications or certain radiopaque dyes (Romero et al., 1988). A physical examination of the mother should be performed to evaluate for clinical signs of hypothyroidism or hyperthyroidism. Maternal serum should be assayed for thyroxine (T_4) levels, thyroid-stimulating hormone (TSH) levels, and for the presence of thyroid-stimulating antibodies.

Because of the difficulty in predicting fetal thyroid status in the absence of clear sonographic signs of thyrotoxicosis, serious consideration should be given to percutaneous fetal blood sampling to evaluate fetal serum thyroid hormone levels directly. A maternal history of Graves disease does not imply that fetal goiter will be associated with fetal hyperthyroidism, as goiter may be secondary to either fetal hypothyroidism from transplacental passage of antithyroid medications or fetal hyperthyroidism from transplacental passage of thyroid-stimulating antibodies. An alternative to fetal blood sampling may be amniocentesis, which in the presence of severe fetal hypothyroidism may demonstrate elevated TSH levels. However, this approach is controversial, with many authors suggesting that there is no reliable correlation between amniotic fluid thyroid hormone levels and fetal serum levels (Abuhamad et al., 1995; Van Loon et al., 1995; Bruner and Dellinger, 1997; Heckel et al., 1997).

When the fetal thyroid status is known, decisions can be made regarding options for fetal intervention. These options are described in detail in the section on "Fetal Intervention." Prenatal consultation with a neonatologist is recommended to discuss potential difficulties with neonatal airway management. Careful sonographic surveillance every 2 weeks is recommended following the diagnosis of fetal goiter, because of the association with polyhydramnios, growth restriction, hydrops, and intrauterine death. Antenatal testing with twice-weekly nonstress tests or biophysical profiles is recommended in the presence of fetal hyperthyroidism.

Because of the possibility of significant tracheal compression, all fetuses with a goiter should be delivered in a tertiary care center with the immediate availability of experienced neonatology, pediatric anesthesiology, or pediatric otolaryngology personnel. Securing an adequate airway is crucial and, in cases of severe tracheal compression from a goiter, may require maintenance of the uteroplacental circulation until intubation, bronchoscopy, or tracheotomy procedures are performed (Stocks et al., 1997). The timing of delivery should not be altered simply because a fetal goiter is present. However, if the fetus has significant hypothyroidism or hyperthyroidism, consideration should be given to elective induction of labor at 39 weeks of gestation, because of the potential adverse pregnancy outcome associated with these conditions. The mode of delivery should be dictated by standard obstetric indications, although there may be a high likelihood of cesarean delivery in cases of severe fetal neck hyperextension leading to dystocia.

FETAL INTERVENTION

After the diagnosis of a fetal goiter, consideration should be given to percutaneous fetal blood sampling to accurately document the thyroid status of the fetus, and to guide options

for fetal intervention. Many case reports have described successful prenatal therapy of fetal hyperthyroid goiter, with resolution or improvement in the size of the thyroid gland (Wenstrom et al., 1990; Hatjis, 1993; Hadi and Strickland, 1995; Heckel et al., 1997; Yanai and Shveiky, 2004; Lembert et al., 2005). Propylthiouracil (PTU) is considered the drug of choice for the treatment of hyperthyroidism in pregnancy, because of an apparently slightly better safety profile as compared with carbimazole or methimazole. However, carbimazole and methimazole have much more rapid and complete transplacental transfer as compared with PTU (Marchant et al., 1977). If carbimazole or methimazole is used for fetal therapy, the lowest possible dose that produces a clinical effect should be used. All three agents are considered class D for use in pregnancy. Adequacy of dose can be documented by return of fetal heart rate to a normal range. Repeat fetal blood sampling may also be considered after therapy to confirm normalization of fetal serum thyroid hormone profiles. If the mother is clinically euthyroid, maternal thyroxine replacement may also be required, as an antithyroid medication used for fetal therapy may render the mother hypothyroid.

Many case reports have also described successful prenatal therapy of fetal hypothyroid goiter, with resolution or improvement of the goiter (Weiner et al., 1980; Noia et al., 1992; Abuhamad et al., 1995; Van Loon et al., 1995; Bruner and Dellinger, 1997; Vicens-Calvet et al., 1998). However, since thyroxine does not cross the placenta, more invasive methods of therapy are required to treat fetal hypothyroidism. The most commonly used approach is the periodic intra-amniotic injection of levothyroxine, 90% of which is adsorbed in animal models within 24 hours of instillation (Abuhamad et al., 1995). The dose used in the various reports described to date has varied from 250 to 500 mg of levothyroxine. The intra-amniotic injection of levothyroxine can be repeated weekly as often as needed until sonographic resolution of the fetal goiter occurs, or until repeat fetal blood sampling has confirmed normalization of the fetal thyroid hormone status. In one case report, intra-amniotic injections of levothyroxine were repeated for seven consecutive weeks, from 29 to 37 weeks of gestation, with documented normalization of fetal thyroid hormone status and reduction in size of the fetal thyroid gland (Abuhamad et al., 1995).

TREATMENT OF THE NEWBORN

A neonatologist should be present in the delivery room whenever a prenatal diagnosis of fetal goiter is suspected, as problems securing an adequate airway may be encountered. Although it is possible that emergency tracheotomy or bronchoscopy may be required in cases of severe tracheal compression from a large goiter, such occurrences are extremely rare. Once an airway is secured the neonate should be transferred to a neonatal intensive care unit for a thorough evaluation of thyroid status. This should include careful physical examination and serum thyroid hormone profiles.

Neonatal thyrotoxicosis can be treated with PTU, carbimazole, or methimazole, as in the adult patient. Additional therapy with a β-blocker such as propranolol may also be required to control heart rate. Iodide should be administered, in the form of Lugol solution. In most cases of maternal Graves disease with subsequent neonatal thyrotoxicosis, the hyperthyroid features are transient and ameliorate over time, as there is no longer a source of thyroid-stimulating autoantibodies. Therefore, medical supportive therapy is generally needed only for a short period, usually for no longer than 12 weeks. Neonatal features of hyperthyroidism may not appear during the first week of life, presumably due to a residual therapeutic effect of any maternal antithyroid medications that may be present in the neonatal circulation during the first days of life. Infants with hyperthyroid goiter should therefore be followed closely during the first 2 weeks of life to evaluate for possible clinical deterioration. The infant should be examined for any evidence of premature craniosynostoses, which can accompany fetal hyperthyroidism and may require surgical correction.

The infant with hypothyroid goiter is usually asymptomatic at birth, but may also present with profound lethargy, hypotonia, hyporeflexia, and bradycardia. Subsequent development may be delayed, with delayed bone age and epiphyseal dysgenesis. Replacement therapy with levothyroxine should be started immediately and is usually successful at reducing the incidence of intellectual impairment and developmental delay associated with congenital hypothyroidism. Any delay in therapy may lead to a significantly poorer neurologic outcome for the child.

SURGICAL TREATMENT

Surgical treatment for fetal goiter is rarely required. Occasionally, a massive fetal goiter may cause such extreme compression of the trachea that an adequate airway cannot be secured. In that case, surgical options include emergency tracheotomy in the delivery room or bronchoscopy. In the most severe cases of fetal goiter, the EXIT (ex utero intrapartum treatment) procedure may be another option to maximize the ability to promptly secure an airway at delivery. Using this technique during cesarean delivery, the fetal face and neck are exposed at the uterine incision prior to delivery of the fetus, thus preserving uteroplacental perfusion for up to 1 hour and allowing time for surgical attainment of an adequate airway (Liechty et al., 1997). Additional surgical resection of an enlarged thyroid gland in infancy may be required rarely, if interference with swallowing and breathing continues despite medical therapy.

LONG-TERM OUTCOME

Minimal data are available to counsel parents on the long-term prognosis in childhood following the prenatal diagnosis

of a fetal goiter. In almost all cases however, it can be expected that shrinkage of the goiter will occur during the neonatal period as appropriate medical therapy is initiated. In addition, most cases of hyperthyroid goiter will improve spontaneously during the first 1 to 3 months of life as thyroid-stimulating antibodies from a mother with Graves disease are no longer present. Failure to replace levothyroxine adequately in a timely fashion in infants with congenital hypothyroidism will greatly increase the risk of profound and irreversible intellectual impairment and developmental delay.

GENETICS AND RECURRENCE RISK

Recurrence of fetal goiter in subsequent pregnancies is a significant possibility when a mother has thyroid dysfunction. It is estimated that there will be some hypothyroid effects on the fetus in 1% of all mothers with hyperthyroidism who are taking PTU (Romero et al., 1988). Between 2% and 12% of all infants of mothers with Graves disease will have hypothyroidism or hyperthyroidism (Hatjis, 1993). Inborn errors of thyroid hormone biosynthesis that result in congenital dyshormonogenesis and cause hypothyroid fetal goiter are rare, but are inherited as an autosomal recessive trait. Therefore, the recurrence risk for such conditions is 25%.

Bronchopulmonary Sequestration

34
CHAPTER

Key Points

- Bronchopulmonary sequestration (BPS) is a mass of nonfunctioning lung tissue that does not communicate with the bronchial tree.
- Prenatal diagnosis is possible by noting an echodense triangular area of tissue, often with an obvious systemic feeding vessel, such as from the descending aorta.
- BPS can be intralobar (same pleural cover as normal lung) or extralobar (separate pleural cover), and can be intrathoracic or extrathoracic.
- Main differential diagnosis for intrathoracic BPS includes type III CCAM, teratoma, and diaphragmatic hernia, while the differential for intra-abdominal BPS includes mesoblastic nephroma and neuroblastoma.
- At least 75% of prenatally diagnosed cases of BPS resolve spontaneously, while those associated with hydrops, pleural effusions, or mediastinal shift have a much worse prognosis.
- Fetal intervention by means of thoracoamniotic shunting may be an option for cases with coexisting pleural effusions prior to 30 weeks' gestation.
- For large lesions that persist prenatally, and for those associated with hydrops, delivery should occur in a tertiary care center.
- Elective surgical excision is recommended for most cases of asymptomatic BPS that persist postnatally.

CONDITION

Bronchopulmonary sequestration (BPS) is a mass of nonfunctioning pulmonary tissue that lacks an obvious communication with the tracheobronchial tree and receives all or most of its blood supply from anomalous systemic vessels (Carter, 1959). There appears to be a spectrum of sequestration with, at one extreme, an abnormal vessel supplying a nonsequestered lung and, at the other extreme, abnormal pulmonary tissue but without anomalous vascular supply. Terminology has become increasingly complicated with terms such as congenital bronchopulmonary foregut malformation (CBPFM) and malinosculation used (Gerle et al., 1968; Heithoff et al., 1976; Clements and Warner, 1987). CBPFM refers to intralobar or extralobar BPS associated with a communication with the gastrointestinal tract. The spectrum of CBPFM includes intralobar sequestration, extralobar sequestration, congenital cystic adenomatoid malformation (CCAM), bronchogenic cyst, Scimitar syndrome, and duplication cyst. Malinosculation describes the spectrum of congenital lung anomalies, in which there is abnormal connection of one or more of the four major components of the lung tissue (Clements and Warner, 1987). While much emphasis has been placed in the past in differentiating between

BPS and CCAM, it is now clear that both can coexist in the same lesion, where it is referred to as a hybrid lesion. Extralobar sequestration and CCAM type II coexisting together has been reported in 25% to 50% of extralobar sequestration cases (Conran and Stocker, 1999) (see Chapter 35).

There are two forms of BPS: intralobar and extralobar. Intralobar is the more common malformation seen in infants and children, accounting for 75% of cases of BPS, and it shares the same pleural investment with the normal lung (Savic et al., 1979; Collin et al., 1987). Extralobar BPS accounts for 25% of cases in infants and children, has a separate pleura from the lung, and may be either intrathoracic or subdiaphragmatic in location (Savic et al., 1979; Collin et al., 1987).

The most widely accepted theory about the embryogenesis of BPS is that a supernumerary lung bud arises caudal to the normal lung bud and migrates caudally with the esophagus. If this lung bud arises prior to the development of the pleura, the bud is invested with adjacent lung and becomes an intralobar BPS. If supernumerary development occurs subsequent to pleura formation, the bud will grow separately and become invested with its own pleura, forming an extralobar BPS (Carter, 1959).

INCIDENCE

BPS is seen in 0.8% to 1.4% of all pulmonary resections (Carter, 1959). There is no familial predisposition. There is a slight male predominance, which is more obvious in extralobar BPS (male to female ratio of 3:1) compared with intralobar BPS (male to female ratio of 1.5:1) (Warner et al., 1958; Carter, 1959; Williams and Enumah, 1968). Extralobar BPS is much more common in the fetus and neonate than intralobar BPS (Buntain et al., 1977; Moulik et al., 1987; Panicek et al., 1987; Felker and Tonkin, 1990; Sauerbrei, 1992).

Intralobar BPS is located within the lower lobe in 98% of cases. Extralobar BPS is usually located in the posterior lower chest and 90% of extralobar BPS is located on the left side. Up to 15% of extralobar BPS can be found either within or below the diaphragm (Berrocal et al., 2004).

SONOGRAPHIC FINDINGS

BPS is a solid, highly echogenic mass (Figure 34-1) with a clearly defined systemic feeding vessel (Figure 34-2). There have now been many reports of the prenatal sonographic diagnosis of BPS (Newman, 1970; Jaffe et al., 1982; Romero et al., 1982; Jouppila et al., 1983; Kritstoffersen and Ipsen, 1984; Mariona et al., 1986; Thomas et al., 1987; Adzick et al., 1998; Baumann et al., 1988; Davies et al., 1989a; Morin et al., 1989; Siffling et al., 1989; Weinbaum et al., 1989; Slotnick et al., 1990; Stern et al., 1990; Boiskin et al., 1991; Heranz-Schulman et al., 1991; Dolkhart et al., 1992; Eisenberg et al., 1992; Sauerbrei, 1992; Luetic et al., 1995). The sonographic hyperechogenicity of BPS is thought to result from the interfaces created by numerous dilated bronchioles (Jaffe et al., 1982). The demonstration of the systemic blood supply to the mass by color Doppler sonography usually confirms the diagnosis (Figures 34-2 to 34-4). Occasionally, these vessels cannot be demonstrated sonographically, making it difficult to distinguish BPS from type III congenital cystic adenomatoid malformation (CCAM) of the lung (see Chapter 35). Even if an anomalous systemic blood supply to a thoracic mass can be demonstrated, which confirms the diagnosis of BPS, intralobar and extralobar BPS usually cannot be distinguished by prenatal ultrasound. Several cases of extralobar BPS have been reported prenatally because of the finding of echogenic suprarenal abdominal masses (Mariona et al., 1986; Baumann et al., 1988; Davies et al., 1989b; Dolkhart et al., 1992).

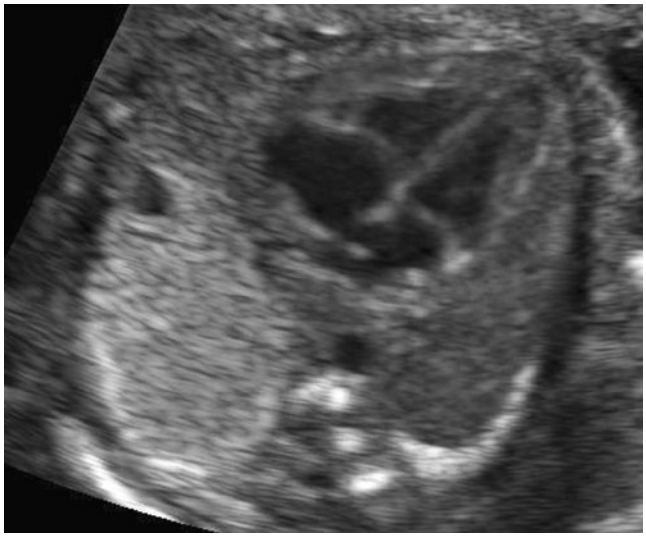

Figure 34-1 Ultrasound of the fetal chest at 23 weeks' gestation, demonstrating a homogeneous echodense triangular wedge-shaped thoracic mass, consistent with either type III cystic adenomatoid malformation or bronchopulmonary sequestration.

Additional sonographic findings seen in association with BPS include pleural effusion, mediastinal shift, hydrops, and polyhydramnios (Morin et al., 1989, 1994a, 1994b; Gross et al., 1992). Extralobar BPS may undergo torsion of its vascular pedicle, causing venous and lymphatic obstruction, leading to pleural effusion and hydrops due to systemic venous obstruction (Vode and Kramer, 1989; Morin et al., 1994a). Fetal hydrops may result from a compressive effect of the sequestration on the inferior vena cava with venous obstruction and compromised cardiac output. Polyhydramnios may be seen in association with BPS due to esophageal obstruction or decreased swallowing. BPS associated with hydrops uniformly results in fetal or neonatal death if untreated. There have been anecdotal reports of cases treated successfully in utero by thoracoamniotic shunting of the associated pleural effusion. To date, open fetal surgery has not been reported for a BPS in contrast to hybrid CCAM (see Chapter 35).

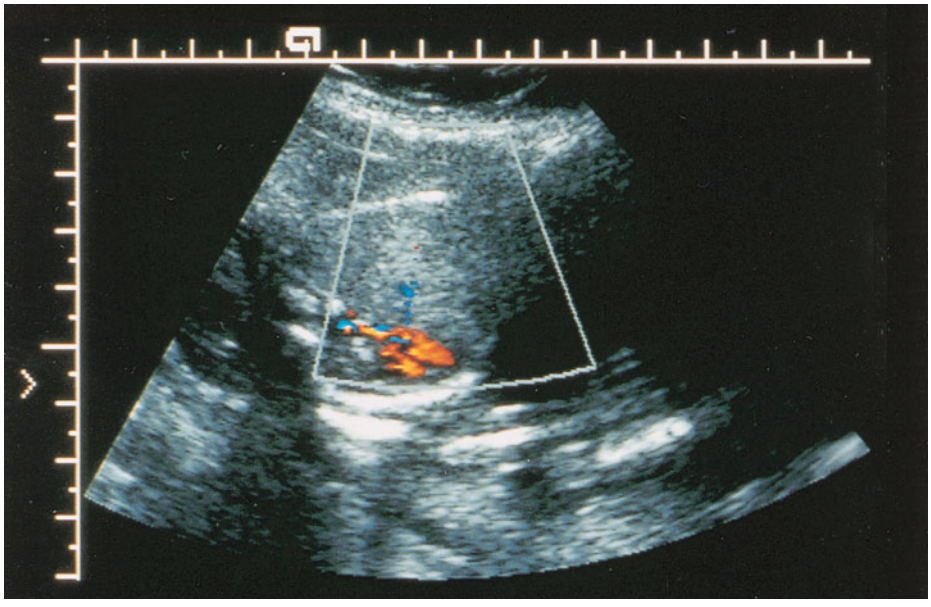

Figure 34-2 Color flow Doppler examination of the same fetus as in Figure 34-1, demonstrating systemic blood supply to the mass arising from the descending aorta, confirming the diagnosis of bronchopulmonary sequestration. (*Reprinted, with permission, from Morin L, Crombleholme TM, Louis F, et al. Bronchopulmonary sequestration: prenatal diagnosis with chinisopathologic correlation*. Curr Opin Obstet Gynecol. *1994b;6:479-481.*)

In postnatal series of BPS, there is a high incidence of associated anomalies, especially in extralobar BPS (60% of cases) (Warner et al., 1958; Carter, 1959; Gerle et al., 1968; Sade et al., 1974; Buntain et al., 1977; Savic et al., 1979; Collin et al., 1987). The most commonly associated anomalies include congenital diaphragmatic hernia (CDH), pectus excavatum, tracheoesophageal fistula, esophageal duplication, and congenital heart disease (Warner et al., 1958; Carter, 1959; Gerle et al., 1968; Buntain et al., 1977). The intralobar type has a lower incidence of associated anomalies (10% of cases) (Carter, 1959; Gerle et al., 1968; Sade et al., 1974; Buntain et al., 1977).

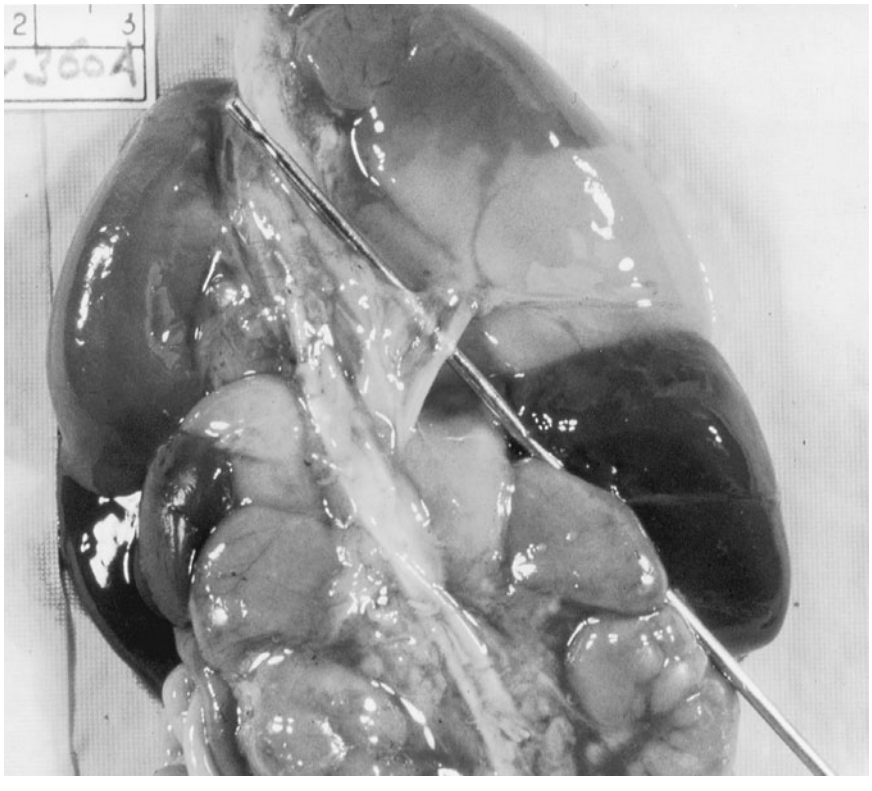

Figure 34-3 Autopsy confirmation of the systemic blood supply to an intralobar bronchopulmonary sequestration. The vessel is demonstrated by the probe.

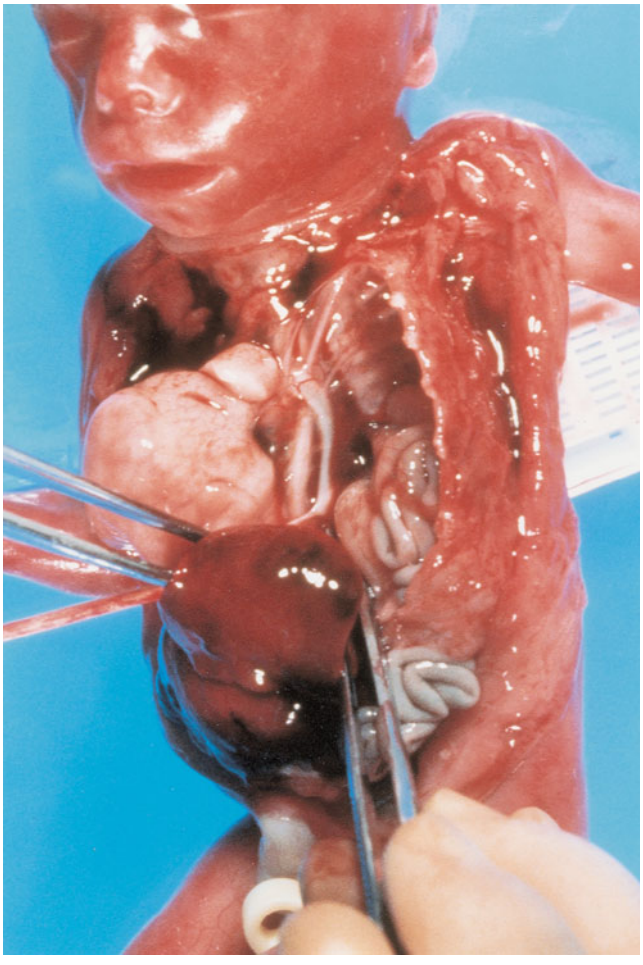

Figure 34-4 Photograph taken at autopsy, demonstrating systemic blood supply arising from the descending thoracic aorta to supply an extralobar BPS.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of intrathoracic BPS includes type III CCAM, mediastinal or thoracic teratoma, and CDH (Moulik et al., 1987; Morin et al., 1994a) (Table 34-2). Type I or II CCAMs have a characteristic cystic appearance that clearly distinguishes them sonographically from BPS, while type III CCAMs have a dense hyperechoic appearance that may be indistinguishable from BPS. Mediastinal teratomas usually have a higher density, causing acoustic shadowing behind the mass (Golladay and Mollitt, 1984). Prenatal diagnosis of BPS may be quite difficult. In a review of cases diagnosed antenatally, only 29% were diagnosed correctly (Dolkhart et al., 1992). The other cases of BPS were documented variously as tumor, diaphragmatic hernia, CCAM, neuroblastoma, collapsed lung, and abdominal mass (Siffling et al., 1989; Dolkhart et al., 1992). The distinction between CCAM and BPS when a systemic feeding vessel is not demonstrated usually comes down to the echotexture of the mass. The presence of cysts suggests CCAM, whereas solid triangular lesions are more consistent with BPS, especially in the lower thoracic region. In lesions that are without cysts, it may not be possible to distinguish type III hybrid CCAM from BPS.

The main considerations in the differential diagnosis of intra-abdominal extralobar BPS are mesoblastic nephroma and neuroblastoma (see Chapters 112 and 113) (Mariona et al., 1986; Baumann et al., 1988; Davies et al., 1989b; Ohnichi et al., 1989; Weinbaum et al., 1989; Sauerbrei, 1992). Intra-abdominal extralobar BPS can occur on as a discrete suprarenal echogenic mass with a systemic blood supply. This mass can be mistaken for neuroblastoma or mesoblastic nephroma (Ohnichi et al., 1989; Oh et al., 1993). However, mesoblastic nephroma can usually be seen arising from the kidney (Ohnichi et al., 1989). Neuroblastomas arising from the adrenal glands are most commonly cystic lesions, which distinguish them from BPS (Oh et al., 1993). There has been one case of gastric duplication in association with BPS that gave a cystic appearance to the intra-abdominal BPS (Thilenius et al., 1983).

ANTENATAL NATURAL HISTORY

The natural history of BPS depends on whether it is an intralobar or an extralobar BPS, whether it has a thoracic or abdominal location, and the presence or absence of hydrops and other associated anomalies (Adzick et al., 1993). Older reports suggested survival among cases of prenatally diagnosed intrathoracic BPS of only 36% (van Nayenberg, 1914; Williams and Enumah, 1968; Newman, 1970; Buntain et al., 1977; Rodgers et al., 1986; Panicek et al., 1987; Felker and Tonkin, 1990; Stern et al., 1990). However, a more recent report from the Children's Hospital of Philadelphia reported a survival of 95% (Adzick et al., 1998). This difference likely reflects the fact that today's more advanced ultrasound techniques are picking up milder cases that would never have been apparent prenatally in the past, as well as the fact that older case reports described successful prenatal diagnosis in only the most severe cases. BPS associated with hydrops is uniformly fatal if untreated (Weiner et al., 1986). The survival rate for BPS associated with pleural effusions was 22%, but the only survivors were those in whom the pleural effusions were decompressed in utero by thoracoamniotic shunts (Kritstoffersen and Ipsen, 1984; Boiskin et al., 1991; Dolkhart et al., 1992). The survival rate for BPS associated with polyhydramnios was only 30%.

Our understanding of the natural history of this lesion when diagnosed prenatally is still evolving. It was once thought that in fetuses with BPS, hydrops invariably developed and the fetus died in utero or during the neonatal period (Warner et al., 1958; Williams and Enumah, 1968). However, MacGillivray et al. (1993) subsequently reported six cases of BPS associated with contralateral mediastinal shift that dramatically decreased in size over the course of the pregnancy and spontaneously resolved, leading to a good neonatal outcome. Postnatally, the lesions could be detected only by computed tomographic (CT) scan or magnetic resonance imaging (MRI). There were no signs of hydrops in any of these cases.

Adzick et al. (1994, 1998) subsequently reported that 75% of cases of BPS diagnosed prenatally resolve spontaneously. The mechanism by which these lesions shrink is unknown. Adzick (1993) speculated that the lesions may decompress themselves into the normal tracheobronchial tree or that the lesions outgrow their vascular supply and partially involute (Rodgers et al., 1986). Another possibility is that the "disappearing" malformations are actually extralobar BPSs that undergo complete torsion about their vascular pedicle and infarct (Morin et al., 1994a).

Intra-abdominal extralobar BPS has an outcome that is somewhat better than that for intrathoracic lesions and is rarely associated with hydrops. However, polyhydramnios may still develop secondary to esophageal or gastric compression.

The BPS associated with hydrothorax is usually of the extralobar type. It is thought that torsion of the extralobar BPS about its vascular pedicle may result in venous and lymphatic obstruction, causing fluid accumulation in the ipsilateral hemithorax (Golladay and Mollitt, 1984). Tension hydrothorax in the fetus with BPS is fatal unless there is intervention. An alternative explanation for nonimmune hydrops, especially in intralobar BPS, is the "left-to-left" shunting that may occur due to anomalous systemic artery and venous drainage via the pulmonary veins (Thilenius et al., 1983). This "left-to-left" shunt, which occurs in no other clinical entity, results in high-output failure and nonimmune hydrops (White et al., 1974).

MANAGEMENT OF PREGNANCY

The fetus with an echodense chest mass should be evaluated to exclude CDH (see Chapter 37), mediastinal teratoma, and CCAM (see Chapter 35). In most cases of BPS, the vascular supply from the aorta can be defined with color Doppler studies (see Figure 34-2). The adrenal glands and kidneys should be delineated to distinguish an abdominal extralobar BPS from mesoblastic nephroma (see Chapter 112) and neuroblastoma (see Chapter 113). It is noteworthy that most cases of BPS diagnosed prenatally are isolated sequestrations without associated anomalies (Felker and Tonkin, 1990). Despite this observation, it is recommended that a detailed sonographic survey for possible associated anomalies be performed in every case.

Ultrafast fetal MRI may be very useful in sorting out the differential diagnosis, demonstrating the feeding vessels and excluding other potential associated anomalies. Normal fetal lungs are homogenous and, on MRI, have a relatively high T2 signal intensity because they are filled with amniotic fluid. A sequestration cyst typically appears as a well-defined mass in the chest with a T2 signal intensity that is higher than that of the normal lung (Hubbard et al., 1999). The efficacy of MRI for detecting systemic feeding vessels is no better than that of Doppler ultrasonography. However, MRI has some advantages over ultrasound in differentiating complex cases associated with other anomalies (Table 34-1).

Table 34-1

Anomalies Associated with Bronchopulmonary Sequestration

Scimitar syndrome
Goldenhar syndrome
Gastrointestinal duplications
Hirschsprung's disease
Esophageal atresia with tracheoesophageal fistula
Neuroenteric cysts
Vertebral anomalies
Pulmonary hypoplasia
Congenital diaphragmatic hernia
Diaphragmatic eventration
Cardiac anomalies
Aberrant pancreatic tissue
Pectus excavatum
Bronchogenetic cyst
Pericardial malformation
Cardiac anomalies
Congenital lobar emphysema

A fetal karyotype should be obtained to exclude associated chromosomal anomalies if they might influence the decision to continue the pregnancy or for cases in which fetal treatment is contemplated (see Table 34-2). Because of the reported association of BPS with congenital heart disease, fetal echocardiography should be performed (White et al., 1974). The family may choose not to continue the pregnancy if the diagnosis of BPS is made prior to 24 weeks and there are other life-threatening anomalies.

Arrangements should be made for delivery at a center with appropriate neonatal and pediatric surgical expertise. The fetus with isolated BPS, of either the intrathoracic or intra-abdominal type, has a good chance of survival in the absence of hydrops, polyhydramnios, or pleural effusion and when there is a planned delivery at an appropriately staffed facility with immediate resuscitation and surgery available. BPS may regress in size in 75% of cases, even when it is associated

Table 34-2

Differential Diagnosis for Fetuses with Chest Masses

Anterior mediastinum	Thymoma, teratoma, cystic hygroma
Posterior mediastinum	Gastric duplication, teratoma, neuroblastoma, Wilms' tumor
Left hemithorax	CCAM, accessory lobe
Right hemithorax	Bronchogenic cyst, hamartoma, CDH, CCAM, teratoma, accessory lobe
Diaphragm	CDH, duplication cyst
Left upper quadrant	Gastric duplication, adrenal cyst and tumors, accessory spleen, neuroblastoma, Wilms' tumor
Right upper quadrant	Adrenal cyst and tumors, liver tumor, neuroblastoma, Wilms' tumor

with mediastinal shift (MacGillivray et al., 1993; Adzick et al., 1995).

FETAL INTERVENTION

The management of intrathoracic BPS in the fetus with hydrops depends on the gestational age (Figure 34-5). Fetuses at 30 weeks' gestation or more should be considered for early delivery and resection ex utero. The fetus with hydrops and intrathoracic BPS diagnosed prior to 30 weeks' gestation may however be a candidate for fetal intervention. Hydrops may be seen in cases of BPS with tension hydrothorax, causing mediastinal shift, compromised venous return to the heart, and cardiac output. Thoracoamniotic shunting in these cases may correct the pleural effusion, mediastinal shift, polyhydramnios, and hydrops. Shunting is not an option for the fetus with intrathoracic BPS associated with mediastinal shift and hydrops from a large thoracic mass without pleural effusion. Because BPS associated with hydrops is uniformly fatal, fetal surgery should be considered in these cases. Adzick et al. have reported excellent results with fetal surgery for pulmonary resection in cases of CCAM. It is anticipated that similar results may be observed with BPS (Adzick, 1993; Adzick et al., 1998).

The prognosis for isolated intra-abdominal BPS is better than that for intrathoracic BPS because the intra-abdominal location does not result in pulmonary hypoplasia. Polyhydramnios may be observed due to compression of the esophagus or stomach, which may cause preterm labor and delivery. The role of reduction amniocentesis remains undefined but may be considered in such cases.

TREATMENT OF THE NEWBORN

Ideally, a fetus diagnosed with a large BPS should be delivered in a setting where vigorous resuscitation and appropriate therapy for a newborn with pulmonary hypoplasia can be initiated immediately. In contrast, small lesions do not require a change in delivery plans, and delivery in a community setting may be appropriate. The infant should be examined carefully to confirm the presence or absence of associated anomalies. There is a wide range of severity with BPS; the degree of pulmonary hypoplasia is the primary determinant of outcome. The newborn with intra-abdominal BPS usually has no respiratory compromise and can undergo elective resection. The treatment of the newborn with an intrathoracic BPS is determined by the severity of pulmonary hypoplasia. Therapeutic needs may vary from minimal (not requiring ventilatory support) to severe [requiring ventilatory and vasopressor support, high-frequency oscillatory ventilation, and/or extracorporeal membrane oxygenation (ECMO)]. Large pleural effusions should be treated immediately by tube thoracostomy. In the infant with pulmonary hypoplasia secondary to BPS, thoracotomy should be deferred until it is clear the infant has stabilized, as in the management of CDH (see Chapter 37) (Hazebrock et al., 1989; Langer et al., 1989). The infant's condition often deteriorates after surgery because of changes in chest wall compliance, pulmonary vascular resistance, and pulmonary hypertension superimposed on pulmonary hypoplasia.

SURGICAL TREATMENT

The surgical approach to BPS is straightforward, with the exception of the management of anomalous blood supply. These vessels are often huge, thin-walled, and elastic, rather than muscular, arteries. In 20% of cases, these vessels are subdiaphragmatic in origin; in 15%, more than one vessel is present (Carter, 1959). Subdiaphragmatic origin of anomalous vessels is more common with right-sided lesions (Gottrup and Lund, 1978). These vessels can retract into the mediastinum or diaphragm and continue to bleed. Intraoperative death due to hemorrhage from unrecognized anomalous vessels has been reported (Harris and Lewis, 1940). Of note, one series reported that 60% of right-sided intralobar sequestrations had anomalous venous return compatible with the Scimitar syndrome (Collin et al., 1987). The importance of preoperative assessment of venous drainage, as well as arterial supply, is underscored by the reports of postoperative fatalities due to ligation of anomalous veins that constituted the sole or major venous drainage of the entire ipsilateral lung (O'Mara et al., 1978; Thilenius et al., 1983).

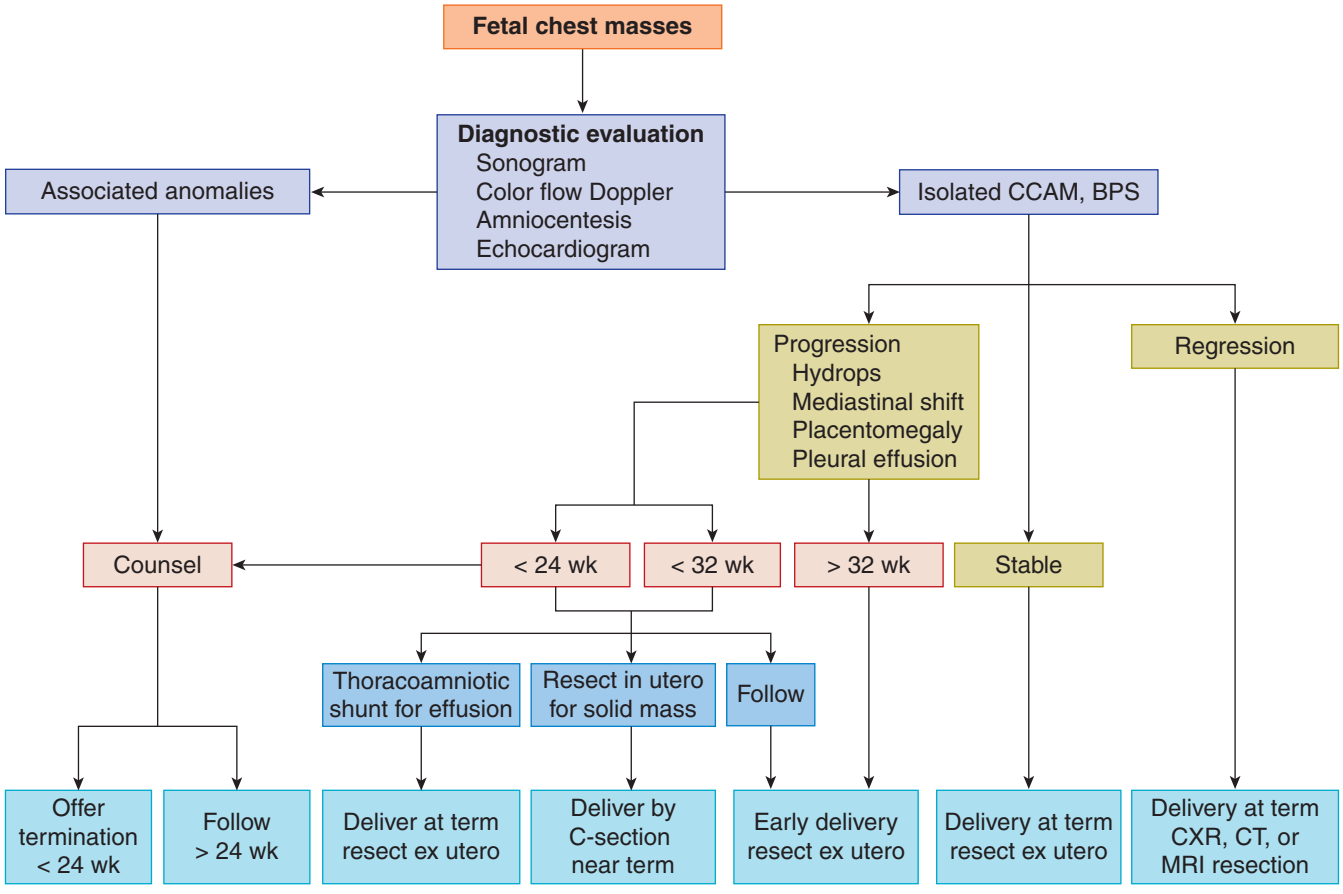

Figure 34-5 Algorithm for the management of fetal chest masses.

In the rare case of the prenatally diagnosed BPS that appears to regress, postnatal imaging studies should be obtained. If the lesion is evident on plain chest radiography, surgical resection should be planned. If chest radiography does not demonstrate the malformation, a CT or MRI scan should be performed. Even though these lesions are asymptomatic, postnatal resection should be considered because of the risks of infection, hemorrhage, and malignant transformation (Elias and Aufses, 1960; Juettner et al., 1987). When cardiac decompensation is the result of BPS, embolization of the feeding vessels may be considered. This technique can be used either as definitive treatment or in combination with resection. Complications reported after embolization include pain and pyrexia, pleural effusion, transient ischemia of the lower limb, recanalization of the artery, and persistent chest radiography changes (Corbett et al., 2004).

LONG-TERM OUTCOME

The resection of the intra-abdominal extralobar BPS has no affect on the pulmonary parenchyma, and the operative risks and long-term complications are the same as those for laparotomy in the newborn. The long-term outcome of intrathoracic BPS is determined by the extent of pulmonary hypoplasia. In extralobar BPS, resection results in no loss of pulmonary parenchyma. Resection of intralobar BPS requires at least segmentectomy or lobectomy, and the loss of pulmonary tissue may compound the underlying pulmonary hypoplasia in the short term. In the long term, removal of the BPS will provide room for compensatory lung growth in the remaining pulmonary tissue. It has been suggested that infants treated for BPS are at increased risk for gastroesophageal reflux, pneumonia, and pectus exconation (Corbett et al., 2004).

GENETICS AND RECURRENCE RISK

There is no known genetic predisposition to the development of BPS. Although BPS is not known to have a familial pattern of recurrence and occurs as a sporadic anomaly, there has been a case reported of BPS recurring in male siblings (Abuhamed et al., 1996).

Cystic Adenomatoid Malformation

35 CHAPTER

Key Points

- CCAM is cystic malformation of pulmonary tissue and, unlike BPS, typically has a pulmonary blood supply.
- CCAM has been subdivided into five types, depending on the number and size of cystic changes; additionally hybrid lesions in which features of BPS coexist have been described.
- Prenatal ultrasound can detect either cystic or solid mass in the chest without a systemic vascular supply.
- Differential diagnosis includes BPS, diaphragmatic hernia, and bronchogenic cyst.
- Cases of CCAM with a dominant large cyst, or with a CCAM volume ratio greater than 1.6, appear to be at most risk of developing hydrops in utero, which is associated with very poor prognosis; in contrast, some cases of CCAM also regress spontaneously in utero.
- Fetal intervention is possible by means of thoracoamniotic shunting for cases of hydrops with a dominant cyst, or by means of open fetal surgical resection for cases of hydrops with a microcystic appearance; additionally a course of antenatal corticosteroids may also be beneficial.
- Delivery should occur electively, at term, in a tertiary care center with adequate pediatric surgical facilities available.

CONDITION

Congenital cystic adenomatoid malformation (CCAM) of the lung is a lesion characterized by a multicystic mass of pulmonary tissue with a proliferation of bronchial structures (Stocker et al., 1977; Miller et al., 1980). It may represent a failure of maturation of bronchiolar structures, occurring at approximately the 5th or 6th week of gestation during the pseudoglandular stage of lung development (Stocker et al., 1977; Miller et al., 1980; Shanji et al., 1988). Alternatively, it may represent focal pulmonary dysplasia, since skeletal muscle has been identified within the cyst walls (Leninger and Haight, 1973). Others have suggested that it may be the result of airway obstruction (Demos and Teresi, 1975; Cochia and Sobonya, 1981; Moerman et al., 1992; Langston, 2003). The gestational age and location of the airway obstruction may determine whether CCAM, bronchopulmonary sequestration, or lobar emphysema results (Keswani et al., 2005; Kunisaki et al., 2006).

CCAM is slightly more common in males and may affect any lobe of the lung (Hernanz-Schulman, 1993). The lesion is unilobar in 80% to 95% of cases and bilateral in fewer

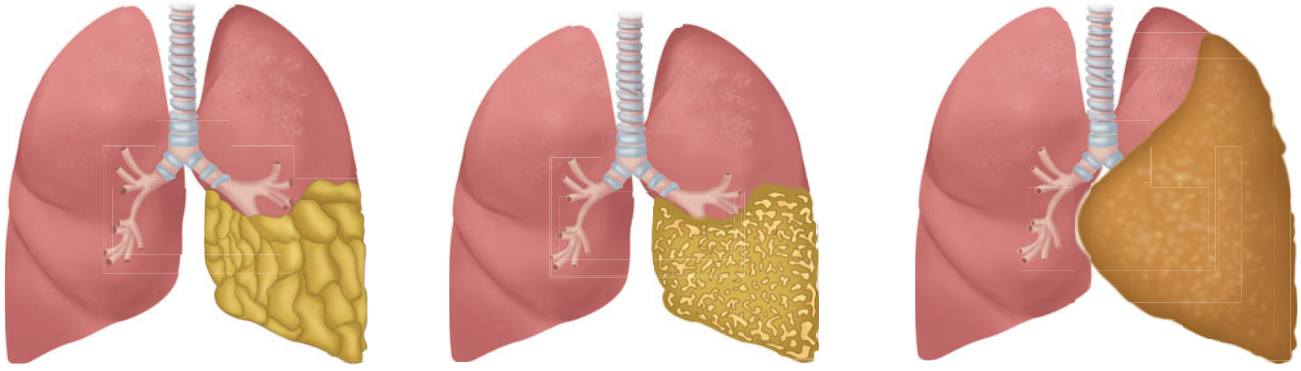

Figure 35-1 Depiction of Stocker's classification of type I, II, and III CCAM.

than 2% (Stocker et al., 1977). Unlike bronchopulmonary sequestration (BPS), CCAMs have a communication with the tracheobronchial tree, albeit via a minute tortuous passage. In contrast to BPS, CCAMs derive their arterial blood supply and venous drainage from normal pulmonary circulation, but anomalous arterial and venous drainage of CCAM have also been reported (Rashad et al., 1988) as well as the so-called "hybrid" CCAMs that have a systemic blood supply (Cass et al., 1997).

Stocker et al. (1977) originally subdivided CCAM into three types based on their pathologic characteristics (Figure 35-1). More recently, Stocker revised this classification to include five types. Stocker initially recommended that CCAM be classified as type I, II, and III and later added type 0 and IV (Stocker et al., 1977; Stocker, 2002). The five types were intended to represent the spectrum of malformations of five successive groups of airways. Type 0, a condition previously described as acinar dysplasia (Davidson et al., 1998) is described as bronchial; type I as bronchial/bronchiolar; type II as bronchiolar; type III as bronchiolar/alveolar dust; and type IV as peripheral. Because of the broad spectrum of malformations covered by this expanded classification system, Stocker (1994) suggested the term congenital pulmonary airway malformation (CPAM), and both CCAM and CPAM are in common usage. Stocker's classification is a histologic one, although commonly applied to sonographic appearance.

Type I lesions account for 50% of postnatal cases of CCAM, and consist of single or multiple cysts lined by ciliated pseudostratified epithelium. These cysts are usually quite large (3–10 cm) and few in number (1–4). Type I lesions are usually associated with a favorable outcome. Type II lesions account for 40% of postnatal cases of CCAM and consist of more numerous cysts of smaller diameter (usually less than 1 cm) lined by ciliated, cuboidal, or columnar epithelium. Respiratory bronchioles and distended alveoli may be present between these cysts. There is a high frequency of associated congenital anomalies with type II lesions. The prognosis for type II lesions often depends on the severity of associated anomalies. The most commonly associated anomalies include genitourinary, such as renal agenesis or dysgenesis; cardiac, including truncus arteriosus and tetralogy of Fallot; jejunal atresia; diaphragmatic hernia; hydrocephalus; and skeletal anomalies (Stocker et al., 1977). The high incidence of associated anomalies has led to speculation that this type of CCAM may occur as a result of events occurring prior to 31 days of gestation (Walker and Cudmore, 1990). The type III lesions account for only 10% of cases and are usually large homogeneous microcystic masses that cause mediastinal shift. These lesions have bronchiole-like structures lined by ciliated cuboidal epithelium, separated by masses of alveolar-sized structures lined by nonciliated cuboidal epithelium. The mixture of epithelial and mesenchymal structures in type III lesions has led to speculation that its development is related to events occurring prior to 28 days of gestation, after the formation of the lung buds (Walker and Cudmore, 1990). The prognosis in type III CCAMs is variable but can in severe cases present with nonimmune hydrops in utero and cardiorespiratory compromise in the newborn (Adzick et al., 1985b; Harrison et al., 1990a). Type IV CCAMs account for approximately 15% of cases and are characterized by very large cysts up to 10 cm lined by flattened epithelium resting on loose mesenchyme. These lesions can have areas of focal stromal hypercellularity with histologic overlap with grade I pleuropulmonary blastoma (McSweeney et al., 2003; Hill and Dehner, 2004).

Adzick et al. (1985b) have proposed a modification of Stocker's classification of CCAMs based on anatomy and sonographic appearance to assist in predicting prenatal outcome. In this classification, macrocystic CCAMs have single or multiple cysts >5 mm in diameter. Microcystic CCAMs are more solid and bulky, with cysts that are <5 mm in diameter. This distinction can easily be made sonographically in the fetus. Macrocystic lesions appear sonographically as fluid-filled cysts, while microcystic lesions appear solid with an almost homogeneous appearance (Adzick et al., 1985b). This is a useful sonographic distinction, because microcystic lesions are at increased risk for the development of hydrops. The high mortality rate of microcystic lesions is due to the large size these lesions attain and secondary sequelae, including mediastinal shift, pulmonary hypoplasia, polyhydramnios, and nonimmune hydrops (Adzick et al., 1985b, 1993, 1998; Harrison et al., 1990a).

INCIDENCE

CCAM has been considered a relatively rare lesion, although in more recent years, with the widespread use of obstetrical ultrasound, there has been a rapid increase in the number of cases detected prenatally (Nicolaides et al., 1987; Adzick et al., 1998). A commonly quoted incidence of CCAM lesions is between 1:25,000 and 1:35,000 livebirths (Laberge et al., 2001).

SONOGRAPHIC FINDINGS

CCAM is diagnosed by prenatal ultrasound demonstrating a lung tumor that may be solid or cystic, and with an absence of systemic vascular flow (Figure 35-2) (Dann et al., 1981; Bezzuti and Isler, 1983; Diwan et al., 1983; Cone and Adam, 1984; Johnson et al., 1984; Morcos and Lobb, 1986; Mendoza et al., 1986; Deacon et al., 1990). Types I and II CCAM appear as cystic or echolucent pulmonary masses, and may appear similar to diaphragmatic hernia, cystic hygroma, and other cystic lesions, such as bronchogenic or enteric cysts, and pericardial cysts (Boulot et al., 1991). In contrast, type III CCAM typically appears as a large hyperechogenic mass, often associated with mediastinal shift and, in advanced cases, hydrops (Adzick et al., 1985b).

The sonographic appearance of CCAMs can range from solid echodense mass filling the chest to a lesion with a single dominant cyst with a compressive effect on the mediastinum. The vast majority of CCAMs derive their blood supply from the pulmonary circulation and drain via the pulmonary veins. However, color Doppler should be used to search for the presence of a systemic feeding vessel. This may be observed in most BPSs (the main differential diagnosis in CCAMs) and in "hybrid" CCAM lesions (Cass et al., 1997). The systemic feeding vessel in hybrid CCAM lesions usually comes directly off the descending aorta; however, transdiaphragmatic systemic feeding vessels have also been observed in CCAMs.

A change in the echogenicity of type III CCAMs may occur between 30 and 34 weeks in which they become isoechogenic with adjacent normal lung. Although sonographically invisible, such cases of CCAM are still readily apparent on MRI. Occasionally, postnatal imaging with CT scanning reveals no evidence of CCAM, which may be due to the presence of lobar emphysema instead.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of fetal thoracic masses includes congenital diaphragmatic hernia (CDH) (see Chapter 37), bronchogenic or enteric cysts, BPS (see Chapter 34), mediastinal cystic hygroma (see Chapter 32), bronchial atresia or stenosis, neuroblastoma, and brain heterotopia (Adzick et al., 1985a; Hobbins et al., 1979; Gonzalez-Cuezzi et al., 1980; Romero et al., 1982; Chinn et al., 1983). The sonographic appearance of CCAM will influence the differential diagnosis. Type I CCAMs are more likely to be confused with a CDH. Observing peristalsis in the loops of herniated intestine or emptying of the stomach herniated through the diaphragm may help to differentiate the two (May et al., 1993). Fetal magnetic resonance imaging (MRI) may be helpful in evaluating fetal chest masses and distinguishing them from diaphragmatic hernia (Figure 35-3) (Hubbard and Crombleholme, 1998). It is also worth noting that CCAM can coexist with CDH (Stocker et al., 1977). The microcystic type III CCAMs are highly echogenic. This is helpful in distinguishing CCAM from solid tumors such as neuroblastoma. Bronchogenic cysts

Figure 35-2 Prenatal sonographic cross-sectional image of the fetal chest, demonstrating a large homogeneous type III CCAM filling the right chest, displacing the mediastinum to the left. The four-chamber view of the heart is seen displaced against the left chest wall. (*Courtesy of Dr. Marjorie Treadwell.*)

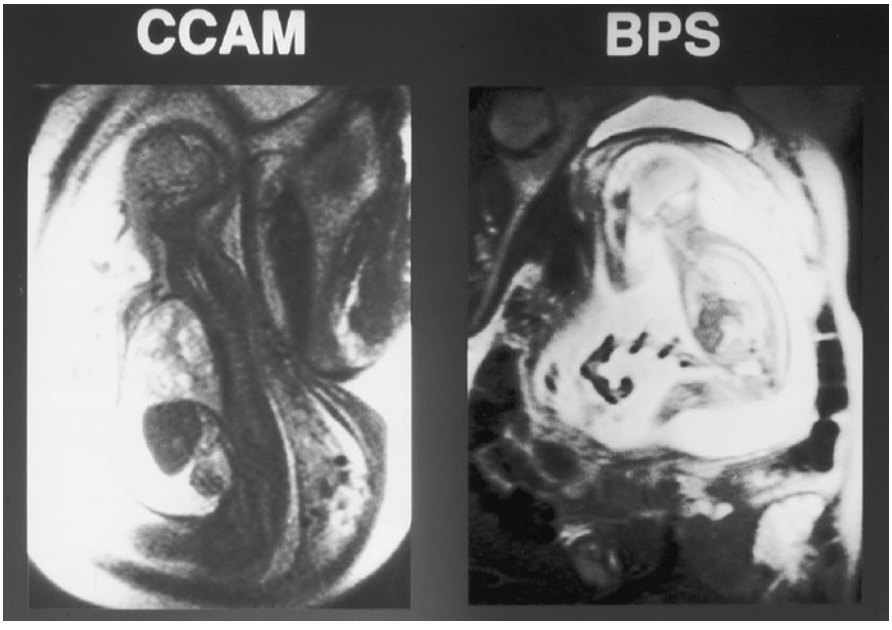

Figure 35-3 Fetal MRI in CCAM and BPS. The left panel is a sagittal section of a fetus with complex multicystic adenomatoid malformation with associated hydrops and ascites. The right panel is a sagittal section of a fetus with a hyperechogenic, homogeneous, wedge-shaped mass due to bronchopulmonary sequestration.

are unilocular and are usually adjacent to major bronchi, which may be confused with a type I CCAM. However, the main differential diagnosis in type III CCAM is usually BPS. Unlike most CCAMs, BPS derives its blood supply from the systemic circulation (Carter, 1959). This systemic blood supply to BPS can often be demonstrated with the use of color flow Doppler studies (Figure 35-4) (Hernanz-Schulman et al., 1991; Morin et al., 1994). There has been an anecdotal report of CCAM associated with anomalous blood supply (Rashad et al., 1988). With the exception of this case, the demonstration of systemic blood supply to a thoracic mass has been thought to be pathognomonic of BPS. More recently, Cass et al. (1997) described six cases of cystic adenomatoid malformation that had systemic blood supply. These lesions were called "hybrid" lesions as they had features of both CCAMs and BPSs and their natural history was also a mixture of the two lesions. The prognosis in hybrid CCAM is much more favorable than "pure" CCAM (Crombleholme et al., 2002).

ANTENATAL NATURAL HISTORY

The postnatal natural history of CCAM can be quite variable (Adzick, 1993, 1998). The lesion can be completely asymptomatic and come to medical attention only when chest radiography is performed for other reasons, such as a history of mild respiratory complaints with recurrent infections in infancy or childhood. However, most postnatal patients will present at birth with severe cardiorespiratory compromise

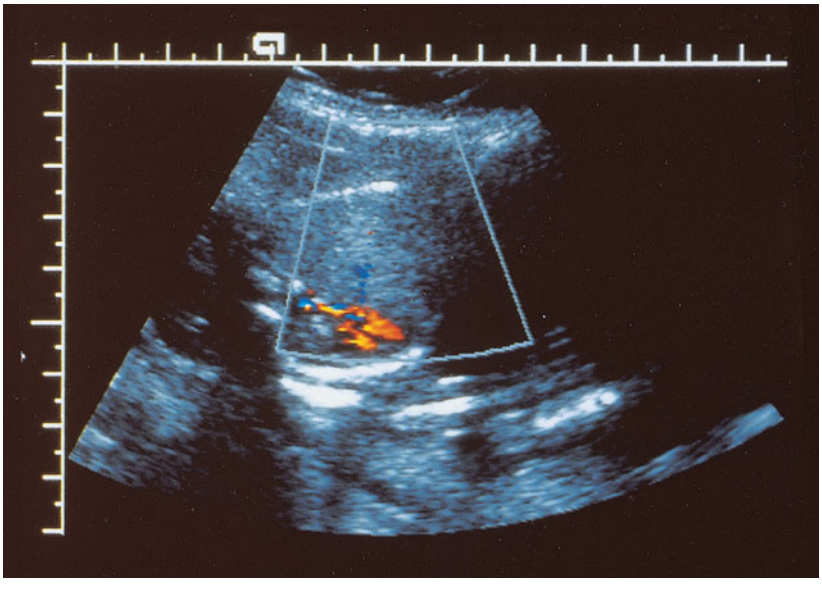

Figure 35-4 Color Doppler sonogram demonstrating systemic feeding vessel arising from the aorta supplying an echogenic lung mass, in this case a bronchopulmonary sequestration.

due to severe pulmonary hypoplasia (Atkinson et al., 1972; Stocker et al., 1977; Nishibayashi et al., 1981; Pulpeiro et al., 1987; Heij et al., 1990; Hernanz-Schulman et al., 1991; Neilson et al., 1991; Kuller et al., 1992; Cloutier et al., 1993). Even before the advent of obstetrical sonography, it was recognized that up to 14% of cases of CCAM result in stillbirths (Stocker et al., 1977). This observation hinted at the different prenatal natural history of CCAM.

Our understanding of the natural history of CCAM is still evolving. The worst outcome is observed in fetuses in which hydrops develops (Adzick et al., 1985b, 1998; Harrison et al., 1990a; Adzick, 1993). Hydrops is usually seen in very large lesions, often type III lesions, which cause mediastinal shift and vena caval obstruction (Figure 35-5). Hydrops may also be exacerbated by the loss of protein from the CCAM into the amniotic fluid, thus reducing the fetal colloid oncotic pressure from hypoproteinemia (Hernanz-Schulman et al., 1991). Anecdotal reports exist of fetuses with CCAM surviving after the onset of hydrops (Golladay and Mollitt, 1984; Graham et al., 1982; Glaves and Baker, 1983; Heydanus et al., 1993; Meagher et al., 1993; Etches et al., 1994; Dommergues et al., 1997; Higby et al., 1998; Bunduki et al., 2000; Diamond et al., 2003). Diamond et al. (2003) suggested that resolution by 30 weeks' gestation may be more common than is appreciated. The reason for this unexpected resolution of hydrops in CCAM was not apparent until the natural history of CCAM was defined by Crombleholme (Crombleholme et al., 2002). CCAMs plateau in their growth at an average of 26 weeks' gestation after which the fetus grows around the CCAM allowing hydrops to resolve (Crombleholme et al., 2002).

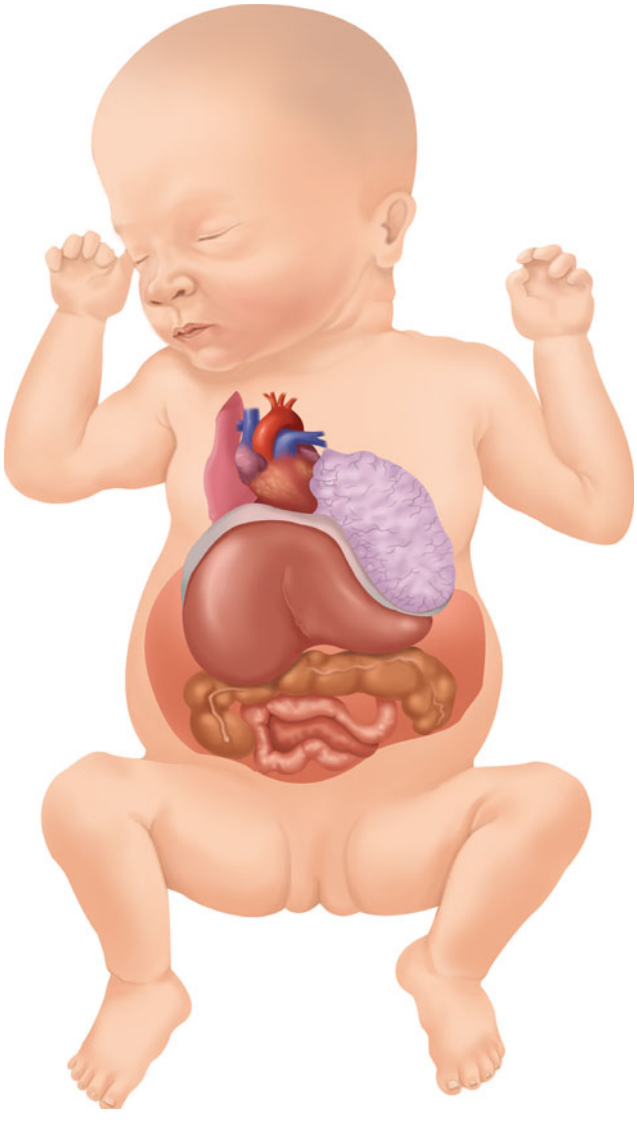

Figure 35-5 Schematic illustration of the pathophysiology of large CCAMs. The rapid growth of the chest mass compresses the lungs, depresses the diaphragm, and shifts the mediastinum, compromising venous return to the heart. Ascites, placentomegaly, and nonimmune hydrops develop.

The overall prognosis depends primarily on the size of the lesion, as well as whether it is predominantly macrocystic or microcystic. Polyhydramnios is seen in up to 70% of CCAMs diagnosed antenatally (Adzick et al., 1998). The pathogenesis of polyhydramnios is not completely understood but is thought to relate to esophageal obstruction from mediastinal shift and interference with fetal swallowing of amniotic fluid (Miller et al., 1980; Murayama et al., 1987). This is supported by the absence of fluid in the fetal stomach in such cases.

The diagnosis of CCAM may also have implications for the health of the mother. The mother with a fetus with CCAM may develop the "mirror syndrome," a hyperdynamic pre-eclamptic state that may be life-threatening. The "mirror syndrome" has also been seen in molar pregnancies, sacrococcygeal teratoma, and in fetal conditions that result in poor placental perfusion, which leads to endothelial cell injury (Creasy, 1979; Roberts et al., 1989). The only treatment for this syndrome is immediate delivery of the baby and placenta.

The antenatal diagnosis of a large CCAM might at first appear to be an ominous finding; however, several reports have described disappearing fetal lung masses (Fine et al., 1988; Saltzman et al., 1988; Budorick et al., 1992; Adzick and Harrison, 1993; Adzick et al., 1993; MacGillivray et al., 1993). MacGillivray et al. (1993) have reported six cases of large CCAM with associated mediastinal shift that progressively decreased in size over the course of gestation. These lesions were all of the microcystic, or type III, variety but none was associated with hydrops. The percentage of cases that will undergo spontaneous regression is not known, but may occur in 6% to 11% of cases (MacGillivray et al., 1993; Adzick et al., 1998). The reason for regression of fetal CCAM is not understood. Decompression of the fluid from the CCAM into the tracheobronchial tree or outgrowing its blood supply has been suggested as possible mechanisms (Adzick et al., 1993). There has been no biochemical or sonographic marker that allows differentiation between a CCAM that will regress and one that will progress to hydrops.

Recently, Crombleholme et al. (2002) reported the use of CCAM volume and the CCAM volume ratio as a predictor of the development of hydrops. The CCAM volume

is calculated using the formula for the volume of an ellipse ($h \times w \times l \times 0.52$ in cm^3) with the measurement of the greatest length in the sagittal section and the width and height taken at 90 degrees to the sagittal measurement. The CCAM volume ratio (CVR) is obtained by dividing the CCAM volume by the head circumference (in cm) to correct for any differences in gestational age. Based on 32 fetuses with CCAMs, the CCAM volume and the CVR were found to be significantly higher in fetuses destined to develop hydrops. Of those fetuses with CVRs > 1.6, 80% developed hydrops. The CVR may therefore be a useful criterion to select fetuses at greatest risk for the development of hydrops and those at low risk for development of hydrops (Crombleholme et al., 2002).

One of the largest experiences with prenatally diagnosed CCAMs has been reported by Adzick et al. (1998) who described 134 fetuses with CCAM. Of these, 14 pregnancies were terminated, 101 cases were managed expectantly, 13 women underwent open fetal surgery, and 6 fetuses underwent thoracoamniotic shunt placement. In the fetuses that did not develop nonimmune hydrops, the postnatal survival was 100%. In contrast, of 25 large CCAMs that developed hydrops and were managed expectantly, there was 100% mortality, with death in utero or immediately after birth. Among the 76 fetuses with CCAMs that were not associated with hydrops, the uniform survival was, in part, due to planned near-term delivery at a tertiary care center. Many of the babies with large lesions required substantial ventilatory support, and four needed treatment with extracorporeal membrane oxygenation (ECMO).

Fifteen CCAM lesions appeared large at 20 to 26 weeks of gestation with an associated contralateral mediastinal shift, but then clearly decreased in size during the third trimester with return of the position of the heart toward midline. Although four of these shrinking lesions were associated with polyhydramnios, including one case with fetal ascites, these phenomena resolved as the masses decreased in size.

MANAGEMENT OF PREGNANCY

The initial evaluation of the patient with a suspected fetal CCAM should include a detailed ultrasound examination to confirm the diagnosis, including color flow Doppler studies to demonstrate or exclude systemic blood supply as seen in BPS (see Chapter 34). The size of the cysts within the lesion should be noted, as well as the size and location of the CCAM. Evidence of mediastinal shift and subtle signs of hydrops should be sought. The incidence of chromosomal anomalies in CCAM is uncertain. In the report by Adzick et al. (1998), among 134 prenatally diagnosed CCAMs, there was only one fetus with a chromosomal abnormality (trisomy 21), for an incidence of only 0.7%. Amniocentesis for karyotype analysis may be reasonable if fetal treatment is anticipated (D'Alton and DeCherney, 1993). Fetal echocardiography should be performed in all cases of suspected CCAM because of an increased incidence of associated cardiac anomalies, particularly truncus arteriosus and tetralogy of Fallot (Stocker et al., 1977; Miller et al., 1980). In addition, there is impaired cardiac function in large CCAMs that shifts the mediastinum causing compression of the ventricles, elevating central filling pressures, altering ventricular inflow patterns, and causing reversal of IVC flow with atrial contractions. This pattern of restrictive ventricular filling associated with flow reversals in the IVC with atrial contractions may be a harbinger of the development of hydrops (Mahle et al., 2000). Prenatal consultation should be obtained from a pediatric surgeon, a neonatologist, and a pediatric cardiologist.

If there are associated life-threatening congenital anomalies, the family may choose not to continue the pregnancy. The development of the maternal "mirror syndrome" warrants immediate delivery. A fetus with an isolated CCAM but no hydrops should be followed closely by serial sonography. Occasionally, these lesions will regress during gestation, but this is not predictable, and CCAMs should be observed for signs of hydrops. All fetuses with CCAMs should be referred for delivery at a tertiary care center, preferably with ECMO capability, where a planned delivery with appropriate resuscitation and surgery can be performed. There is no need for cesarean delivery of a baby with CCAM except for standard obstetrical indications.

FETAL INTERVENTION

The management of CCAM and hydrops depends on the CVR value that is obtained at presentation. If the CVR is less than 1.6 and there is no evidence of a dominant cyst, the CCAM has only a 2% risk for the development of hydrops (Crombleholme et al., 2002). The fetus should have weekly sonograms to measure the CAM volume and CVR in order to identify early signs of hydrops or more likely that the plateau in growth has been reached. Once the growth plateau is reached, the pregnancy is no longer at risk for the development of hydrops. The surveillance of the fetus can be reduced but one should continue to assess the size of the CCAM, the risk of pulmonary hypoplasia, or air trapping that would influence delivery management.

If there is a dominant cyst, even if the CVR is less than 1.6, the fetus remains at significant risk for acute enlargement of the cyst and development of hydrops. A thoracoamniotic shunt may be considered in these cases at the very earliest sign of hydrops.

If the CVR is more than 1.6 at presentation, with or without a dominant cyst, there is an 80% chance of hydrops developing. Twice weekly sonographic surveillance should be started to help detect the earliest signs of hydrops, in which case fetal surgery may be considered. Maternal administration of antenatal corticosteroids should be considered in all cases with a CVR of 1.6. There are now two small series of apparent resolution of hydrops in patients with CCAMs that were not candidates for open fetal surgery (Tsao et al., 2003;

Perenteau et al., 2008). It is thought that steroids may arrest the growth of the solid component of the CCAM inducing an early growth plateau allowing the fetus to grow around the CCAM and hydrops to resolve. However, it is not proven that steroids truly affect the growth of CCAMs and the observations reported may simply reflect CCAMs naturally entering a growth plateau regardless of steroid administration.

Fetuses with CCAM and a dominant cyst in which hydrops develops prior to 32 weeks can be considered for treatment in utero. There now have been at least 28 CCAMs treated by thoracoamniotic shunting (Clark et al., 1987; Nicolaides et al., 1987; Bernaschek et al., 1994; Miller et al., 1996; Dommergues et al., 1997; Bunduki et al., 2000; Laberge, 2001; Wilson et al., 2004; Viggiano et al., 2006) with survival of 19 (70%) fetuses. However, these survivors often have marked respiratory insufficiency and some have required ECMO or high-frequency ventilation. The most challenging antenatal presentation is large microcystic CCAM with hydrops that does not lend itself to catheter decompression. Fetal surgical resection of massively enlarged microcystic CCAM with associated hydrops has been performed in at least 25 patients at 21 to 29 weeks' gestation (Figure 35-6) (Harrison et al., 1990b; Adzick et al., 1993, 1998). In this series, of the 16 fetuses that survived, CCAM resection led to hydrops resolution in 1 to 2 weeks, return of the mediastinum to the midline within 3 weeks, and impressive in utero lung growth. There were also nine fetal deaths in this series.

While open fetal surgery remains the best treatment option for type III CCAMs associated with hydrops, some patients may not be suitable or may decline such intervention. In these cases, a course of maternal steroids (betamethasone or dexamethasone) may be effective in arresting the growth of the CCAM (Tsao et al., 2003; Peranteau et al., 2008; Morris et al., 2009). We have treated several patients in the Fetal Care Center of Cincinnati with resolution of hydrops. The fetus remains at high risk, however, for significant pulmonary hypoplasia. In some instances, the size of the CCAM remains substantial with significant mediastinal shift and cardiac compression. In these cases, delivery by EXIT-to-Resection may be indicated. The rationale for this approach is that the mediastinal shift and compression by the CCAM will make ventilation difficult and will similarly impair venous return if ECMO was attempted. During EXIT-to-Resection, a thoracostomy for resection of the CCAM is performed on placental support during an EXIT procedure. In this approach when the infant is born the trachea is decompressed facilitating ventilation, and if ECMO is needed venous return will be unobstructed (Hedrick et al., 2005).

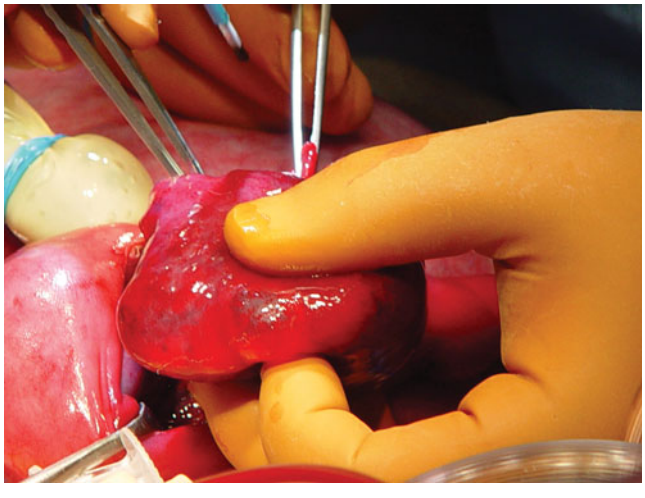

Figure 35-6 Intraoperative view of a fetus at 23 weeks' gestation undergoing resection of a large left lower lobe CCAM. The uterus has been opened, and the left fetal chest has been opened through a left thoracoabdominal incision; the left lower lobe CCAM has been delivered from the chest and is held in the surgeon's fingers. The forceps hold the tip of the hypoplastic left upper lobe. The 7 Hz fetal echocardiography probe seen in the background is used for continuous intraoperative fetal cardiac monitoring.

TREATMENT OF THE NEWBORN

The fetus with CCAM should be referred for delivery at a center with an intensive care nursery and appropriate staff available to resuscitate a newborn with potentially severe pulmonary hypoplasia. The newborn should be evaluated in the nursery to confirm the prenatal diagnosis and exclude other associated anomalies. The infant with type I or II CCAM may be at significant risk for air trapping in the CCAM, which may acutely worsen the respiratory status (Stocker et al., 1977; Bailey et al., 1990). In cases of unilateral CCAM, selective intubation of the contralateral bronchus may be a useful temporizing measure until resection of the CCAM can be accomplished. Pneumothorax is an additional concern in CCAM, especially in the type I or II lesions, and may require tube thoracostomy (Bentur et al., 1991).

SURGICAL TREATMENT

CCAM is usually confined to a single lobe. Rare cases have been reported of multilobar involvement of one lung or bilateral lesions (Rempen et al., 1987). Complete resection of the CCAM, usually by lobectomy, is the treatment of choice in CCAM. In cases of extensive involvement of nearly the entire lung, resection of multiple lobes or pneumonectomy may be necessary. There are several reports, however, detailing potentially lethal problems associated with pneumonectomy in newborns resulting from mediastinal shift with vascular compression of the trachea and remaining bronchus (Szarnicki et al., 1978). Because of these risks, some groups advocate a nonanatomic resection to preserve as much pulmonary parenchyma as possible to allow postoperative compensatory growth and avoid postpneumonectomy complications (Mentzer et al., 1992).

The newborn with a CCAM detected antenatally that subsequently regresses, also needs careful postnatal evaluation (MacGillivray et al., 1993; Adzick et al., 1998). Often

subtle abnormalities will be evident on chest radiography, but chest CT or MRI scanning may be necessary to detect residual CCAM tissue. Several authors have recommended that as long as these lesions are asymptomatic, they be observed closely and managed without resection (Adzick et al., 1993; MacGillivray et al., 1993; Aziz et al., 2004; Hsieh et al., 2005). The argument against this approach includes the reported cases of myxosarcoma, embryonal rhabdomyosarcoma, pleuropulmonary blastoma, and bronchoalveolar carcinoma arising in CCAMs (Stephanopoulos and Catsaros, 1963; Wecla et al., 1977; Benjamin and Cahill, 1991; d'Agostino et al., 1997). While primary lung tumors are rare during the first two decades of life, 4% of those reported were associated with congenital cystic lesions of the lung, including CCAM (Benjamin and Cahill, 1991). While CCAM-associated malignancies often arise only after decades, the youngest patient reported with a malignancy was only 13 months of age (Ozcan et al., 2001). Because there is an anomalous connection to the tracheobronchial tree, infection is an additional potential complication (Stephanopoulos and Catsaros, 1963; Ueda et al., 1977; Weinberg et al., 1980; Krous and Sexauer, 1981; Weinblatt et al., 1982; Prichard et al., 1984; Sheffield et al., 1987; Hedlund et al., 1989; Domizio et al., 1990; Benjamin and Cahill, 1991; Morresi et al., 1995; Ribet et al., 1995; d'Agostino et al., 1997; Kaslovsky et al., 1997; Granata et al., 1998; de Perrot et al., 2001; Federici et al., 2001; Ozcan et al., 2001; Hasiotou et al., 2004; Doladzas et al., 2005; Pai et al., 2005). Some have argued that asymptomatic CCAMs should be followed expectantly, and that the risks of surgery in infancy outweigh the potential benefits (Aziz et al., 2004). However, the continued presence of CCAM represents a lifelong risk of both infection and malignant transformation. In centers with significant experience in lung resection in infants, CCAMs can be safely resected with no mortality and virtually no morbidity (Tsai et al., 2007). Our approach is to obtain a postnatal CT scan and perform a muscle-sparing thoracotomy for lobectomy or nonanatomic resection whenever possible to retain normal lung tissue. An added benefit to resection over observation is that the remaining lung undergoes significant compensatory growth within months of the surgery. This does not occur if the CCAM is left in situ.

LONG-TERM OUTCOME

The long-term outcome of infants with CCAM following resection is excellent. If residual CCAM is left behind or the mass is not resected, the child will be at risk for infectious and potentially malignant complications. Also as noted above, infants usually have remarkable compensatory growth of the residual lung following resection, with continued alveolization for several years. We also recommend prophylaxis against respiratory syncytial virus (RSV) in infancy in children with significant pulmonary hyperplasia, pulmonary hypertension, or chronic lung disease. Children who survived open fetal surgery for CCAMs associated with hydrops appear to be still doing well from 1 to 7 years postoperatively.

GENETICS AND RECURRENCE RISK

CCAM has no known genetic defect responsible for its development and is thought to be an early developmental anomaly of uncertain cause. CCAM is not known to be specifically associated with chromosomal abnormalities, although one case of the 134 CCAMs reported by Adzick et al. (1998) had trisomy 21. No cases of recurrence of CCAM in a sibling or offspring have been reported.

Other Cystic Lesions of the Chest

36 CHAPTER

Key Points

- Differential diagnosis includes bronchogenic cyst, pericardial cyst, thymic cyst, esophageal duplication, and neurenteric cysts.
- Sonographic features may be used to differentiate between various cystic masses that may be found in the fetal chest.
- MRI scanning is often a useful adjunctive imaging modality to ultrasound that may allow more accurate diagnosis and recognize mass effect on adjacent structures.
- Fetal intervention may be indicated by thoracoamniotic shunting for hydrops.
- EXIT-to-ECMO or EXIT-to-Resection may be indicated in cases in which the cystic lesion is very large and the airway is compromised.

CONDITION

Cystic lesions of the fetal chest include a broad list of anomalies that differ in origin, prenatal natural history, pathophysiology, and implications for management of the fetus. The most common lesions of the fetal chest include congenital pulmonary airway malformation (CPAM) (see Chapter 35) and bronchopulmonary sequestration (BPS) (see Chapter 34). This chapter focuses on other less common causes of fetal thoracic cysts including bronchogenic cysts, congenital lobar emphysema, pericardial cyst, thymic cyst, esophageal duplication cysts, and neurenteric cysts.

Bronchogenic cysts result from premature foregut remnants that originate in embryonic bud tissue prior to the formation of the bronchi. While bronchogenic cysts can share common features with esophageal duplication cysts, they are histologically characterized by the presence of cartilage, smooth muscle, and glands in the cyst wall (McAdams et al., 2000; Stocker, 2002; Langston, 2003). Most bronchogenic cysts occur in the mediastinum adjacent to the distal trachea or mainstem bronchi (McAdams et al., 2000; Stocker, 2002). Bronchogenic cysts can also be found within the lung parenchyma (McAdams et al., 2000; Langston, 2003). However, this is a controversial point, as some have considered these lesions a form of type I CPAM (Stocker, 2002). Bronchogenic cysts are unilocular and do not communicate with the tracheobronchial tree and are usually filled with mucus. Bronchogenic cysts can enlarge to produce airway compression and may ulcerate the cyst wall lining due to ectopic gastric mucosa (Eber, 2007). Histologically, bronchogenic cysts are lined with ciliated columnar epithelium and contain bronchial mucous glands, elastic tissue, and hyaline cartilage (Maier, 1948) (Figure 36-1).

Congenital lobar emphysema is characterized by overinflation, either by retained fluid produced in the lobe or segment prenatally or by air trapped in the lobe or segment postnatally (Clements, 1999). Congenital lobar emphysema is thought to be a consequence of bronchial valve mechanism from localized malformations or deficiencies of bronchial cartilage, mucosal folds, or extrinsic bronchial compression (Clements, 1999). This same appearance may be due to an increase in the number of normally expanded alveoli, called a polyalveolar lobe (Hislop and Reid, 1970; Mani et al., 2004). Almost half of all cases involve the left upper lobe (Eber, 2007), and the right middle lobe is the next most often affected. These lesions rarely contain cysts and appear homogeneous by ultrasound and MRI.

Some authors have suggested that both congenital lobar emphysema and polyalveolar lobe may be two outcomes of a similar inciting lesion during lung development (Mani et al., 2004). The timing of the lesion during lung development may account for different anatomical and functional bronchial abnormalities (Mani et al., 2004). Prenatally, lobar emphysema appears as a homogeneously enlarged lobe or segment that may be impossible to distinguish from a type III CPAM. Lobar emphysema tends to follow a different prenatal history from type III CPAM and can continue to enlarge slowly throughout gestation with resulting mediastinal shift and compression of

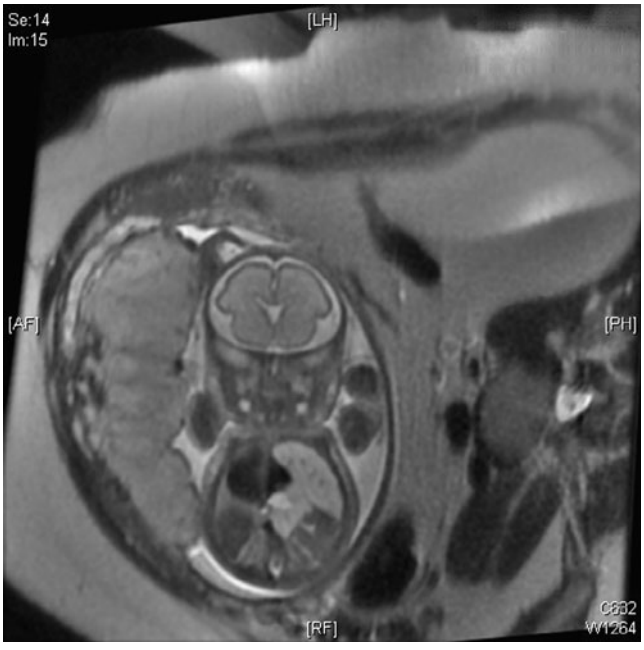

Figure 36-1 A T_1-weighted fetal MRI attained at 28 weeks' gestation demonstrating lobar emphysema of the LUL that was due to a bronchogenic cyst compressing the left mainstem bronchus and the take off of the left upper lobe bronchus. The bronchogenic cyst could not be detected prenatally as the cyst fluid was of the same signal intensity as that of adjacent mediastinal tissues.

adjacent normal lungs. Congenital lobar emphysema may be associated with other anomalies including cardiac anomalies in 12% to 14% of patients (Stocker et al., 1977; Kuga et al., 2001).

Pericardial cysts are rare lesions that are typically located at the cardiophrenic angle. Approximately 50% to 70% of pericardial cysts occurring in the costophrenic angle occur on the right side, whereas 28% to 38% occur on the left. More rarely, pericardial cysts may occur in other mediastinal locations not adjacent to the diaphragm (8–11%) (Stoller et al., 1986; Patel et al., 2004). Pericardial cysts are mesothelial lined with clear watery fluid. Pericardial cysts are usually asymptomatic but may cause compression of adjacent structures. Bernasconi et al. (2007) reported a small case series of prenatally diagnosed pericardial cysts that all spontaneously resolved without intervention by 28 weeks' gestation. However, there have been larger pericardial cysts that have been associated with fetal hydrops or with cardiac or respiratory compromise at birth due to impaired cardiac filling or airway compression (Fernandes et al., 1991; Muraskas et al., 1993; Rizalar et al., 1995; Daher et al., 1996; Macaulay et al., 1997; Wilkinson et al., 1999; Jung et al., 2000). Aspiration of cyst fluid has been associated with resolution of hydrops caused by a pericardial cyst (Gulrajani et al., 1993; Muraskas et al., 1993; Macaulay et al., 1997).

Thymic cysts are rare, accounting for less than 4% of all anterior mediastinal masses postnatally (Kelley et al., 1997; Tollefson et al., 2001). Thymic cysts arise from remnants of the thymopharyngeal duct that can occur anywhere from the hyoid bone to mediastinum (McEwing and Chaoui, 2005). Thymic cysts are usually asymptomatic and are usually an incidental finding but respiratory complications, vocal cord paralysis, and dysphagia have been reported (Rudick and Wood, 1980; Dunne and Weksberg, 1983; Graeber et al., 1984; Wernicke and Diederich, 1994; Tollefson et al., 2001). Prenatal diagnosis of asymptomatic thymic cysts has been reported (de Miguel Campos et al., 1997; McEwing and Chaoui, 2005).

Enteric duplication cysts of the mediastinum may or may not communicate with the gastrointestinal lumen, either in the chest or below the diaphragm (Jaggers and Balsara, 2004). There can be associated vertebral anomalies, but there is no communication with the spinal cord or meninges. Enteric duplication cysts may have ectopic gastric mucosa that can cause pain or bleeding due to peptic ulceration. In contrast, a neurenteric cyst that contains both ectodermal and endodermal or neurogenic elements is characterized by a connection to the meninges and spinal cord by a narrow stalk. Neurenteric cysts are associated with spinal anomalies such as congenital scoliosis, hemivertebrae, or spina bifida.

INCIDENCE

All of the cystic lesions described above are rare conditions for which only anecdotal reports of prenatal diagnosis exist. There are no reliable estimates of their incidence.

SONOGRAPHIC FINDINGS

Bronchogenic cysts are rarely diagnosed prenatally but may be suspected from the sonographic appearance of a unilocular fluid-filled cyst in the middle or posterior mediastinum (Avni et al., 1986). Alternatively, a bronchogenic cyst may be suggested by mass effect on adjacent structures (Figure 36-1). Patel et al. (2004) diagnosed a cystic mass at the time of fetal echocardiogram compressing the left atrium. Bronchogenic cysts can also present in atypical locations such as in the neck or subdiaphragmatic but retain the unilocular fluid-filled cystic appearance (Bagolan et al., 1999).

Esophageal duplication cysts are second only to those of the ileum comprising 15% to 20% of all reported duplications (Benson et al., 1985; Berrocal et al., 1999). Esophageal duplications may be tubular or sausage-shaped but most often are spherical cysts that have a thick wall of smooth muscle and an inner lining of gastrointestinal mucosa that may include gastric mucosa (Tam et al., 1987). These duplications are intimately associated with the esophagus but may appear as an isolated posterior mediastinal unilocular cyst on ultrasound. On T_1-weighted fetal MRI images, esophageal duplications may appear as a discrete, sharply defined low signal intensity mass and high signal intensity on T_2-weighted images (Berrocal et al., 2003). Esophageal duplications may enlarge sufficiently to obstruct the esophageal lumen and cause polyhydramnios (Gul et al., 2004).

Only a few thymic cysts have been diagnosed prenatally, usually recognized as an intrathoracic cyst and confirmed

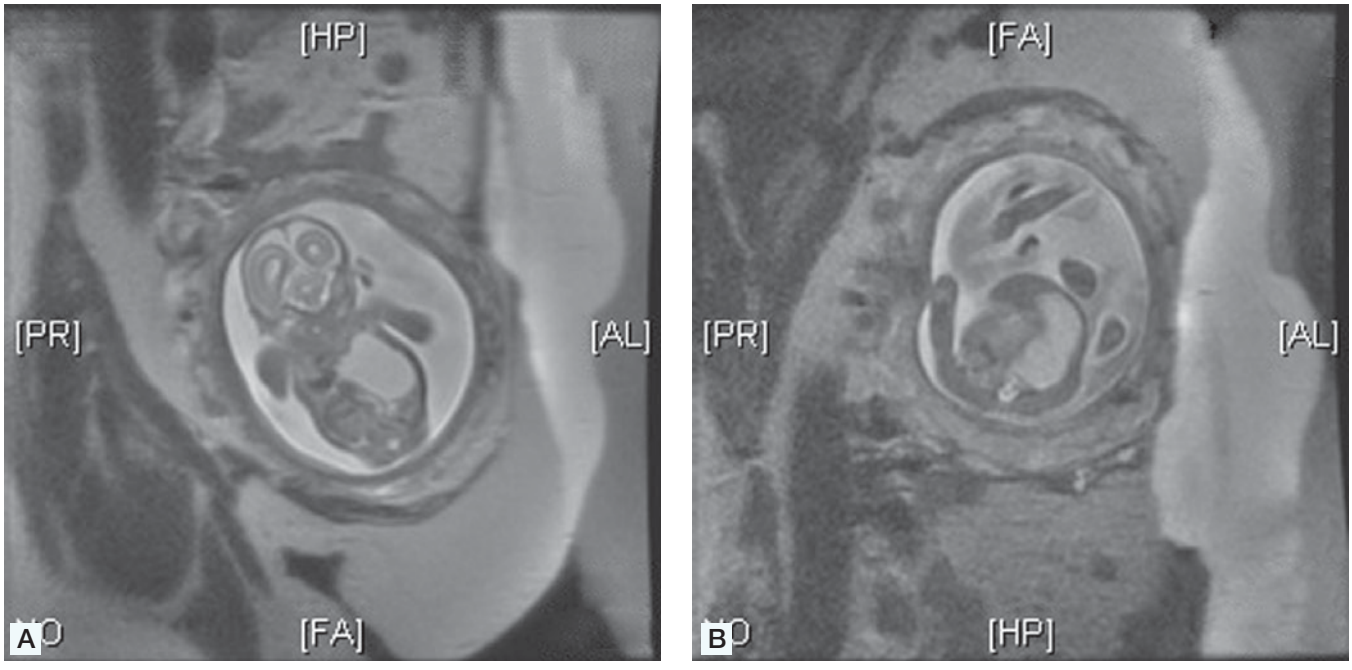

Figure 36-2 **A**. A T_1-weighted fetal MRI demonstrating a very large neurenteric cyst compressing adjacent structures. **B**. A narrow stalk communicating with the spinal canal can be seen.

to be thymic postnatally (de Miguel Campos et al., 1997; McEwing and Chaoui, 2005). The normal fetal thymus, lying immediately posterior to the sternum, can be either hyperechoic or hypoechoic with a tendency to become more hypoechoic as the gestation progresses (Felker et al., 1989). Thymic cysts arise from remnants of the thymopharangeal duct and may appear from the level of the hyoid bone to the carina (Han et al., 2001). These cysts tend to present in the anterior mediastinum and are usually small. If completely surrounded by thymic tissue, a diagnosis of thymic cyst can be made. However, in a large mediastinal cyst, it may be difficult to differentiate a thymic cyst from other etiologies such as lymphangioma, thyroid cyst, parathyroid cyst, bronchogenic cyst, or pericardial cyst (Tollefson et al., 2001).

Pericardial cysts are rare lesions adjacent or originating from the pericardium that are thin-walled anechoic masses (Bernasconi et al., 2007). There have been a number of prenatally diagnosed cases (Newnham et al., 1984; Zalel et al., 1992; Muraskas et al., 1993; Rahmani et al., 1995; Wu et al., 1995; Lewis et al., 1996; Jung et al., 2000; Simsek et al., 2003; Bernasconi et al., 2007) allowing some understanding of their presentation and natural history. Pericardial cysts are usually diagnosed at midgestation during routine sonography. In the report from Bernasconi et al. (2007), all had a benign course without impingement on adjacent structures and half resolved by 28 weeks' gestation. In contrast, other case reports have documented large cysts with secondary impaired cardiac filling and hydrops or airway compression (Muraskas et al., 1993; Jung et al., 2000). Pericardial cysts are characteristically unilocular, fluid filled arising from pericardial fat along the left or right cardiophrenic angle either inside or outside the pericardium or both (Feigin et al., 1977). The cyst wall consists of a single layer of mesothelial cells surrounded by fibroconnective tissue and may communicate with the pericardial space. It has been speculated that spontaneous resolution may occur as a result of rupture into the pericardial space (Bernasconi et al., 2007).

Neurenteric cysts are presumed to arise from incomplete separation of the notochord from the foregut during embryogenesis. The extraspinal neurenteric cysts are usually located in the right posterior chest and are associated with vertebral anomalies with a stalklike connection to the meninges or spinal canal (Figure 36-2). At least eight cases of neurenteric cysts have been diagnosed prenatally (Fernandes et al., 1991; Gulrajani et al., 1993; Rizalar et al., 1995; Daher et al., 1996; Macaulay et al., 1997; Perera and Milne, 1997; Wilkinson et al., 1999; Bernasconi et al., 2007). Neurenteric cysts may become quite large with impingement on adjacent structures. In five of the prenatally diagnosed cases, respiratory distress occurred soon after delivery due to mass effect on the airway resulting from posterior mediastinal cysts up to 6 cm in diameter (Fernandes et al., 1991; Rizalar et al., 1995; Daher et al., 1996; Wilkinson et al., 1999). In addition, two of these prenatally diagnosed neurenteric cysts developed hydrops from cardiac compression (Macaulay et al., 1997; Wilkinson et al., 1999).

DIFFERENTIAL DIAGNOSIS

The location, size, and involvement of adjacent structures may be used to help distinguish the underlying etiology of cystic thoracic masses. Bronchogenic cysts are almost uniformly found in close proximity to the trachea or mainstem bronchi. In some cases, a bronchogenic cyst may be found completely surrounded by lung parenchyma that may make it difficult to distinguish from a type I CPAM (Stocker, 2002).

The typical location of pericardial cysts is in the cardiophrenic angle on the right more often than left and rarely seen in sites not adjacent to the diaphragm (Stoller et al., 1986). These cysts may have an intra- and extrapericardial sac component and can seriously compromise fetal cardiac function. These lesions may spontaneously resolve by 28 weeks' gestation. In contrast to other cystic lesions, thymic cysts are usually confined to the anterior mediastinum and are often completely surrounded by thymic tissue allowing a specific diagnosis to be made (de Miguel Campos et al., 1997; McEwing et al., 2004).

Thoracic enteric duplication cysts can communicate with the enteric lumen and extend below the diaphragm. They are most commonly seen intimately involved with the esophagus. Neurenteric cysts are usually seen in the posterior mediastinum and are characterized by their associated vertebral anomalies. Although communication with the meninges or spinal canal is typical of these lesions, this may be difficult to demonstrate on prenatal imaging. Although ultrasound is the primary imaging modality to help with the differential diagnosis of cystic thoracic masses, MRI may be extremely helpful in defining involvement of adjacent structures and may provide clues to the true etiology of the cysts.

ANTENATAL NATURAL HISTORY

The rare occurrence of cystic lesions of the chest limits our understanding of the natural history of these congenital anomalies. Most are likely to be asymptomatic, but some will pose a risk for development of complications usually due to compression of adjacent structures. For example, esophageal duplication cysts can cause polyhydramnios from esophageal obstruction. Bronchogenic cysts may increase in size and cause compression on the trachea or mainstem bronchi, but this does not cause symptoms in utero. After birth, however, these compression effects may result in airway compromise and respiratory distress at the time of delivery. Pericardial cysts and neurenteric cysts have both been reported to result in hydrops due to compression of the fetal heart. The pericardial cysts by their location do not need to be excessively large to compromise fetal cardiac function. In the case of pericardial cysts, up to half of these may spontaneously resolve by 28 weeks of gestation (Bernasconi et al., 2007). In contrast, neurenteric cysts have resulted in hydrops because they can be extremely large. Thoracic cysts of other etiologies such as thymic cysts infrequently cause any symptoms and are usual incidental findings. A precise diagnosis may not always be possible but is helpful in defining complications if any, from the cyst for which the fetus is at risk.

MANAGEMENT OF PREGNANCY

The pregnancy in which a cystic lesion of the chest is diagnosed should be evaluated by a combination of ultrasound, echocardiography, and MRI. The latter may be useful in narrowing the differential diagnosis and help define impingement on adjacent structures. If the cyst is in close proximity to the heart and a pericardial cyst is suspected, fetal echocardiography is indicated. However, a large cyst in close proximity to the heart should prompt fetal echocardiography to exclude cardiac compromise no matter the suspected etiology. Prenatal consultation with a pediatric surgeon, cardiac surgeon, or neurosurgeon may be indicated depending upon whether the cyst is thought to be bronchogenic or a duplication cyst, pericardial cyst or neurenteric cyst. Orthopedic consultation may be indicated if there are associated hemivertebrae or kyphoscoliosis. The indications for genetic amniocentesis should be based on maternal age and associated anomalies detected as none of the cysts discussed have a particular association with karyotype anomalies. Close sonographic and echocardiographic surveillance should be recommended for signs of progressive cyst growth, polyhydramnios, or the development of hydrops until the cyst size stabilizes or resolves. Ultrasound close to the time of delivery is indicated to be certain that there is no impingement on the fetal airway that may have implications for delivery management.

FETAL INTERVENTION

There are few reports of fetal interventions for thoracic cysts. To date, there have only been three reports of cyst decompression in utero with resolution of hydrops (Muraskas et al., 1993; Macauley et al., 1997; Wilkinson et al., 1999). In one case, the etiology was a mediastinal lymphatic vascular malformation (Muraskas et al., 1993). In the other two cases, large neurenteric cysts causing hydrops responded to cyst drainage at 25 and 28 weeks' gestation, respectively. Kunisaki et al. reported the use of EXIT-to-ECMO to manage a fetus with a bronchogenic cyst completely obstructing the carina resulting in bilateral lung distention. The use of the EXIT strategy allowed the newborn to be evaluated by CT scan, undergo a right thoracotomy resection of the bronchogenic cyst, and repair of the trachea while on ECMO support (Kunisaki et al., 2007). The anecdotal nature of fetal interventions for thoracic cysts precludes defining indications for interventions. However, the presence of hydrops or significant airway compromise as in the cases noted above appears to be reasonable indications for treatment in utero.

TREATMENT OF THE NEWBORN

The newborn with a thoracic cyst should be evaluated to exclude airway compromise prior to delivery. Postnatal studies to evaluate the cyst will depend on the nature of the cyst. Cases of bronchogenic cysts, thymic cysts, duplication cysts may be best evaluated by bronchoscopy and chest CT or MRI. Echocardiography may be better to evaluate a suspected pericardial cyst and its effect on cardiac function.

In some instances, such as in known thymic cysts or pericardial cysts, simple observation alone is indicated in the

absence of significant compression on adjacent structures. In some instances such as neurenteric cysts, plane radiographs may also be indicated to evaluate possible associated vertebral anomalies. Potential communication with the meninges or spinal cord should also be evaluated by CT scan. In most instances, surgery to resect the cyst is indicated to prevent complications including infection or hemorrhage into the cyst or simply cyst growth with impingement on adjacent structures. If a complete resection can be performed, this reduces the chances of cyst recurrence.

SURGICAL TREATMENT

In most instances, surgical resection of cystic thoracic lesions will be indicated due to risk of infection, cyst enlargement, airway compromise, impingement on the heart, esophageal obstruction, or because the etiology of the cyst is unknown. In some instances, observation alone is indicated when the diagnosis is known and the risk of cyst enlargement is small as in thymic cysts. The operative approach to resecting these cysts depends on location and involvement of adjacent structures. Bronchogenic cysts can involve the trachea or mainstem bronchi and resection may require cross-field ventilation or cardiopulmonary bypass. Thoracoscopic resection may be possible in some cases but most will require open thoracotomy. The assistance of a pediatric neurosurgeon may be required for resection of a neurenteric cyst because of communication with meninges or spinal canal. In virtually all instances, complete excision of neurenteric cysts is possible that eliminates the risk of cyst recurrence. In the case of duplication cysts and neurenteric cysts, communication with the lumen of the gastrointestinal tract should be sought and addressed to avoid postoperative complications. Unless a decision has been made to observe as in the case of pericardial or thymic cysts, resection should be performed as early as practical in order to prevent complications.

LONG-TERM OUTCOME

In almost all instances, these cystic lesions do not recur and cause no other problems once resected. In some instances, as in large bronchogenic cysts or large neurenteric cysts tracheobronchial malacia may take 1 to 2 years to improve. In the case of neurenteric cysts, the associated vertebral anomalies may require spinal surgery to prevent progressive kyphoscoliosis.

In most instances, complete resection of the cyst prevents long-term complications and these children do very well long-term follow-up. Those patients with spinal abnormalities may have problems related to these vertebral anomalies such as kyphosis or scoliosis but not related to the cyst itself.

GENETICS AND RECURRENCE RISK

None of the cystic lesions discussed in this chapter are associated with karyotype abnormalities or recognized syndromes. There has been only a single report of familial thymic cysts (Joshua et al., 2004). In all other cases, these lesions are thought to be sporadic and recurrence with subsequent pregnancies has not been reported.

37 CHAPTER Congenital Diaphragmatic Hernia

Key Points

- Defect in formation of diaphragm that is associated with pulmonary hypoplasia.
- Incidence is around 1 in 2200 with 85% to 90% being left sided, 10% to 15% right sided, and 2% bilateral.
- Approximately 60% of cases are isolated and 40% are complex or syndromic.
- Multiple sonographic and MRI techniques have been described to predict lung volume, which is an important predictor of survival. Liver position is also very important with regard to outcome.
- In the most severe cases of congenital diaphragmatic hernia (CDH), the fetal tracheal occlusion (FETO) with a balloon is removed prior to delivery "or EXIT-to-ECMO offers the best hope for survival."
- All fetuses with CDH should be delivered in a tertiary center with specific neonatal and surgical expertise in this condition and ECMO capability.

Key Points (cont.)

- Cesarean section delivery is indicated only for standard obstetrical reasons.
- Approximately a dozen single-gene disorders have CDH as a major feature. With increased cytogenetic resolution through array cGH, more syndromic cases are being recognized as being associated with a chromosome abnormality. Fetal karyotype is indicated.

CONDITION

Congenital diaphragmatic hernia (CDH), a defect in the diaphragm, is thought to be due to failure of the pleuroperitoneal canal to close by 9 to 10 weeks of gestation and results in varying degrees of pulmonary hypoplasia from compression of the developing lungs by the herniated viscera (Harrison et al., 1993b). The traditional view that the diaphragm forms by fusion of the septum transversum, the esophageal mesentery, the pleuroperitoneal folds, and ingrowth of musculature from the lateral body wall, is now being questioned (Pober, 2008). In model organisms, recent work suggests that a nonmuscular diaphragmatic anlage first develops, and that the diaphragmatic musculature derives from muscle precursors that migrate through the pleuroperitoneal folds at approximately day 37 of gestation (Babiuk and Greer, 2002; Pober, 2008).

During the development of the diaphragm, the peritoneal cavity is quite small and the midgut is normally present in the umbilical cord as physiologic herniation of the cord. If closure and muscularization of the pleuroperitoneal canal has not occurred by 9 or 10 weeks of gestation, when the midgut returns to the abdomen to undergo its normal 270-degree rotation, the viscera may herniate into the thorax through the posterolateral diaphragmatic defect because of limited intra-abdominal space (Areechon et al., 1963). If herniation occurs before the closure of the pleuroperitoneal canal there is no hernia sac. However, if pleuroperitoneal membrane has formed but is not muscularized, a hernia sac will be present and is observed in 10% to 15% of cases (Areechon et al., 1963). Occasionally, a "transient" herniation may occur later in gestation, with little effect on pulmonary development (Adzick et al., 1985a; Stringer et al., 1995).

The clinical course of an infant with isolated CDH depends entirely on the degree of pulmonary hypoplasia and severity of pulmonary hypertension. The degree of pulmonary hypoplasia depends on the timing of herniation during development, the volume of viscera herniated, and duration of herniation, that is, whether or not the viscera slide in and out of the thorax (Harrison et al., 1993a; Stringer et al., 1995).

An appreciation of the pathophysiology of CDH requires an understanding of the normal growth and development of the tracheobronchial tree and pulmonary vasculature. Reid (1977) has described four overlapping stages of normal histologic development: embryonic (from conception to 5 weeks); pseudoglandular (5–16 weeks); canalicular (16–24 weeks); and terminal sac or alveolar (24 weeks to postnatal life). The bronchial tree is almost completely developed by 16 weeks of gestation, at which time the adult complement of airways is established. However, alveoli continue to develop after birth, increasing in number until about 8 years of age (Boyden, 1977).

The severity of pulmonary developmental abnormalities depends on the time and the extent to which the herniated viscera compress the adjacent lung. A large intrathoracic mass effect that develops during the formation of the conducting airways (pseudoglandular stage) will reduce the number of bronchial divisions, decreasing the thoracic volume available for lung development (Geggel and Reid, 1984). The herniation of viscera in CDH usually occurs during the pseudoglandular stage of lung development (5–16 weeks) (Reid et al., 1977). In fetuses with CDH, the major bronchial buds are already present, but the number of bronchial branches is pruned and greatly reduced (Companale et al., 1955). The number of alveoli per acinus may be normal, but the absolute number of alveoli is decreased because of the reduced number of bronchial divisions. These morphologic changes are more pronounced in the lung ipsilateral to the diaphragmatic hernia, but the contralateral lung is similarly affected by compression from the shifted mediastinum (Figure 37-1) (Harrison et al., 1980a, 1980b, 1981, 1990, 1993a; O'Rourke et al., 1984; Adzick et al., 1985b; Hasegawa et al., 1990). Persistent mass lesions during later stages of lung development (canalicular or alveolar stages) will result in a reduction not only in airway size, but in the number and size of saccules, alveoli, and preacinar and intra-acinar vessels (Areechon et al., 1963). Concomitant with these changes in the fetal tracheobronchial tree is an increase in the thickness of the arterial media and extension of muscle peripherally into the small preacinar arteries (Levin et al., 1978). The pulmonary hypoplasia that is associated with CDH is one of the major determinants of morbidity and mortality (Figure 37-1). Some have suggested a "two-hit" theory in which pulmonary underdevelopment occurs first but is then made worse by subsequent mechanical compression (Keijzer et al., 2000). In addition, the pulmonary vasculature is abnormal with overmuscularized vessels. In addition to the increased muscularization of the preacinar arteries, Geggel et al. have demonstrated that there is a reduction in size of the pulmonary vascular bed in CDH (Geggel et al., 1985). These changes in the pulmonary vascular bed are the histologic correlate of the pulmonary hypertension seen in experimental models of CDH and newborns with pulmonary hypoplasia.

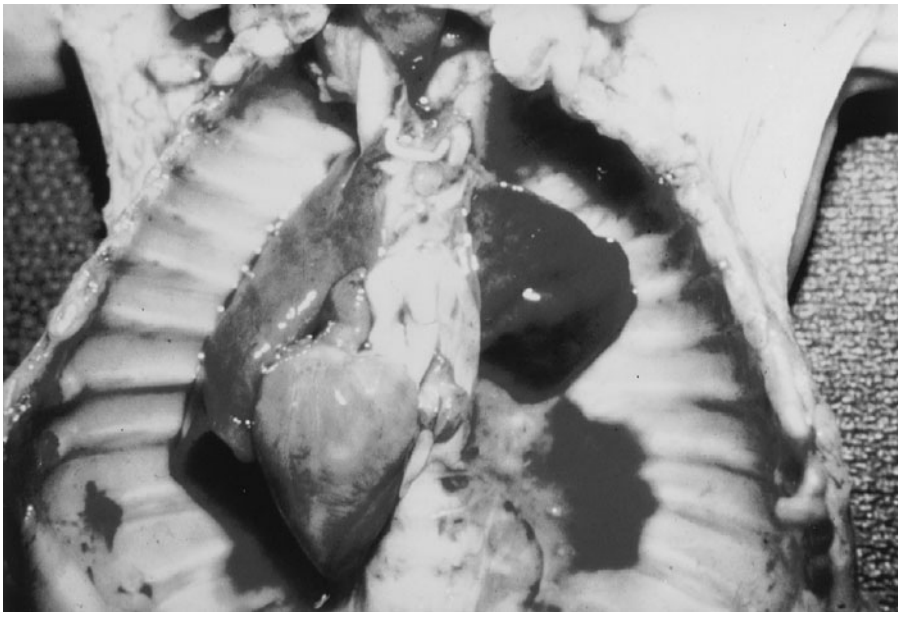

Figure 37-1 Autopsy photograph demonstrating the shift of the heart to the right side of the chest and bilateral lung hypoplasia due to diaphragmatic hernia.

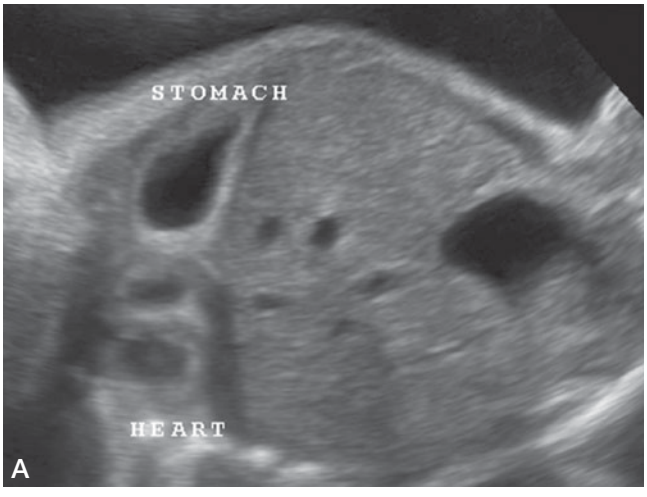
There is evidence that mutations in specific genes that are involved in diaphragmatic development and/or the vitamin A pathway may play a role in the etiology of CDH and pulmonary hypoplasia (Ackerman and Pober, 2007). Key genes that are mutated in teratogenic mouse models of CDH include the transcription factors *Fog2*, *couptf2*, *wt1*, *slit3*, and *GATA4*, and molecules involved in cell migration and signaling such as *slit3* (Bielinska et al., 2007). It is not clear that this teratogenic model from which these mutations have been identified apply to human CDH. Interestingly, in the human, these genes map to areas that have been consistently shown to have chromosome abnormalities that are associated with CDH. There has also been one case in a human mutation in *FOG2* in which there was pulmonary hypoplasia and a diaphragmatic abnormality consistent with eventration, but no CDH (Ackerman et al., 2005).

INCIDENCE

Approximately 85% to 90% of diaphragmatic hernias occur on the left side, 10% to 15% are on the right side, and a few are bilateral. In 60% of cases, the diaphragmatic hernia is either isolated or associated with malformations that are due to hemodynamic or mechanical consequences of the CDH. In 40% of cases the CDH is nonisolated or part of a syndrome. All studies have shown that infants with syndromic (or "complex") CDH have higher mortality (Pober, 2007). The incidence of CDH has been estimated at between 1 in 3000 and 1 in 5000 livebirths (Puri and Gorman, 1984). These estimates ignore the significant numbers of intrauterine fetal death, stillbirths, and neonatal deaths that occur before transfer to a tertiary care facility. An accurate incidence of CDH is more likely around 1 in 2200 births (Fitzgerald, 1979; Harrison et al., 1979; Reynolds et al., 1984; Puri, 1989). In years past, the postnatal survival rate of infants with CDH has traditionally been quoted as 50% (Adzick et al., 1981), but this figure represents survival in a favorably selected group of patients who survive not only to term, but also transfer to a referral center for further treatment (Harrison et al., 1979, 1990, 1993a, 1994; O'Rourke et al., 1984; Adzick et al., 1985a). The most severely affected neonates die before they are transferred to a tertiary care center. Harrison has referred to this discrepancy as the "hidden mortality" of CDH (Harrison et al., 1979). A more recent meta-analysis found that the average mortality for prenatally diagnosed cases was 75%, for cases ascertained as part of a population-based study it was 48%, and for cases transferred to a tertiary facility it was 45% (Skari et al., 2000).

The cause of CDH is unknown but it has been reported in association with maternal ingestion of thalidomide, Bendectin, quinine, and antiepileptic drugs (Hobolth, 1962; Kup, 1967; Hill, 1974; Greenwood et al., 1976; Tubinsky et al., 1983). Associated anomalies are seen in 25% to 57% of all cases of CDH, but this figure rises to 95% in stillborn infants (Crane et al., 1979; Tubinsky et al., 1983; Puri, 1984). The associated anomalies may include congenital heart defects, hydronephrosis or renal agenesis, intestinal atresias, extralobar sequestrations, and neurologic defects, including hydrocephalus, anencephaly, and spina bifida (Crane et al., 1979; Tubinsky et al., 1983). CDH has been described as a finding in Fryns, Beckwith–Wiedemann, and Pierre–Robin syndromes as well as in congenital choanal atresia (Thorburn et al., 1970; Evans et al., 1971; Harrison et al., 1991). Chromosomal anomalies are diagnosed in 10% to 20% of cases of CDH diagnosed prenatally. The most common diagnoses include



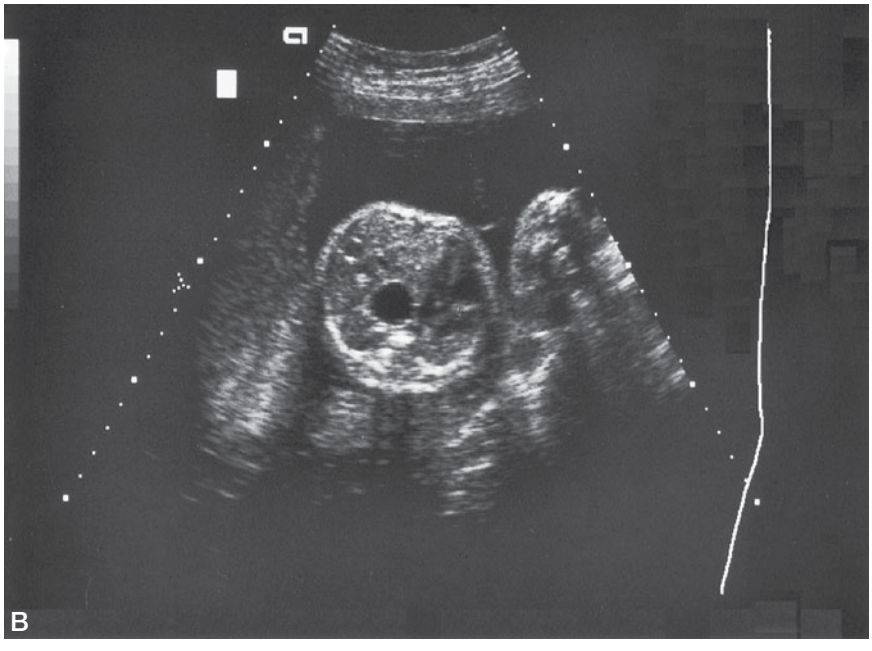


Figure 37-2 **A.** Coronal image of a fetus with a left congenital diaphragmatic hernia demonstrating the stomach in the left chest and the heart deviated into the right chest. **B.** An axial image demonstrating the four-chamber view of the heart and adjacent herniated loops of bowel. (*Reprinted, with permission, from Morin L, Crombleholme TM, Dalton ME. Prenatal diagnosis and management of fetal thoracic lesions.* Semin Perinatol. *1994;18:228-253.*)

trisomies 21, 18, and 13 (Lesk et al., 1959; Crane et al., 1979; Tubinsky et al., 1983).

SONOGRAPHIC FINDINGS

Approximately 60% to 90% of cases of CDH are detected prenatally by sonography or MRI depending on the center reporting ascertainment (Pober, 2008). The diagnosis of CDH should be suspected if the stomach bubble is not observed in its normal intra-abdominal location. The fetal chest should be viewed in the true transverse plane, and landmarks such as the inferior margin of the scapula should be used to identify the abdominal viscera in the chest (Lesk et al., 1959). Abdominal viscera that are seen cephalad to the inferior margin of the scapula or at the same level of the four-chamber view of the heart are herniated, confirming a diagnosis of CDH (Figures 37-2 to 37-4). The herniated abdominal viscera associated with a left-sided CDH may be the easiest to detect. The fluid-filled stomach and small bowel contrast strikingly with the more echogenic fetal lung.

Liver Herniation

The position of the fetal liver is one of the most significant and reproducible independent prognostic factors, with liver herniation predictive of poor outcome (Harrison et al., 1990; Cannie et al., 2006; Hedrick et al., 2007; DePrest et al., 2009). Kinking of the sinus venosus is a reliable sign of left-sided CDH with herniated left lobe of the liver (Figure 37-5). In a retrospective review of 16 fetuses with left CDH, Boostaylor et al. (1995) found that bowing of the umbilical segment of the portal vein (the portal sinuses) to the left of midline and coursing of portal vessels to the lateral segment of the left hepatic lobe toward or above the diaphragmatic ridge are the best predictors for liver herniation into the left chest. Another subtle finding is an echodense space between the left border

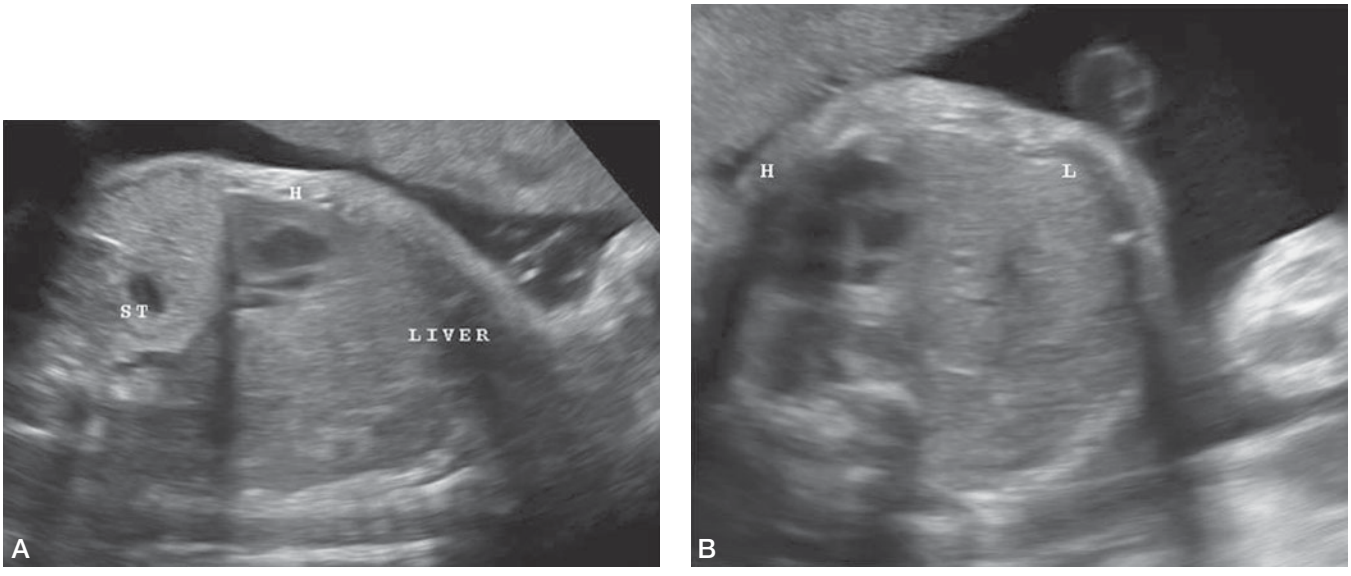

Figure 37-3 **A.** Sagittal image of a fetus with a right congenital diaphragmatic hernia demonstrating the liver above the diaphragm. **B.** An axial image demonstrating a right congenital diaphragmatic hernia with the liver filling the right fetal thorax and the heart deviated against the left chest wall.

of the heart and the stomach, which is due to interposed herniation of the left lobe of the liver. Sonographic or MRI delineation of the diaphragm is not always possible. Even identifying the diaphragm cannot exclude CDH because only a portion of the diaphragm may be missing.

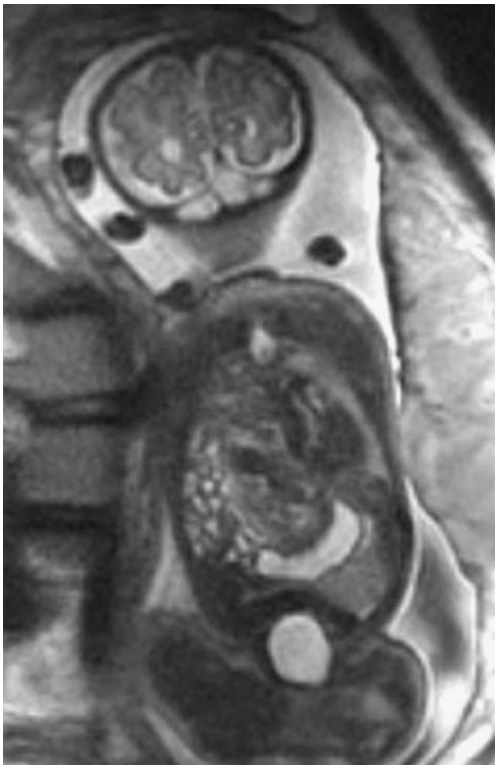

Figure 37-4 Fetal MRI demonstrating a right diaphragmatic hernia; note the liver, gallbladder, and small intestine filling the right thorax and the stomach below the diaphragm.

The location of the gallbladder may also be helpful in diagnosing CDH because it may be herniated in the right chest in right-sided CDH or displaced to the midline or left upper quadrant with left-sided CDH. A large-volume herniation will result in mediastinal shift with polyhydramnios. Mediastinal shift is thought to interfere with swallowing, thus resulting in polyhydramnios (Harrison et al., 1991). Since the stomach is often rotated 180 degrees counterclockwise from its normal anatomic position up into the chest, it is more likely that there is partial gastric outlet obstruction due to kinking at the gastroduodenal junction. The stomach position is also a good predictor if observed in a posterior or midthoracic location if the liver is herniated (Boostaylor et al., 1995). CDH has been also reported in association with concomitant bronchopulmonary sequestration cystic adenomatoid malformation, and teratomas. These may be noted as echogenic masses seen in association with the CDH.

The extent of pulmonary hypoplasia is the most important determinant of survival in CDH. Hasegawa et al. (1990) have proposed using a ratio of the cross-sectional area of the lung to thorax (L:T ratio) in sonographic transverse section of the fetal chest at the level of the four-chamber view of the heart to assess the likelihood of pulmonary hypoplasia. They found, in a small series of eight fetuses with CDH, that the L:T ratio was below 2 SD from the mean ratio obtained in 156 normal controls. There was also an inverse correlation between the L:T ratio in the fetus and in the postnatal A-aDO_2 (alveolar-to-alveolar oxygen difference) values (Hasegawa et al., 1990).

Metkus et al. (1996) reported the use of the right-lung to head circumference ratio (LHR) as a sonographic predictor of survival in fetal diaphragmatic hernia. The LHR is the two-dimensional area of the right lung taken at the level of the four-chamber view of the heart. This is divided by the

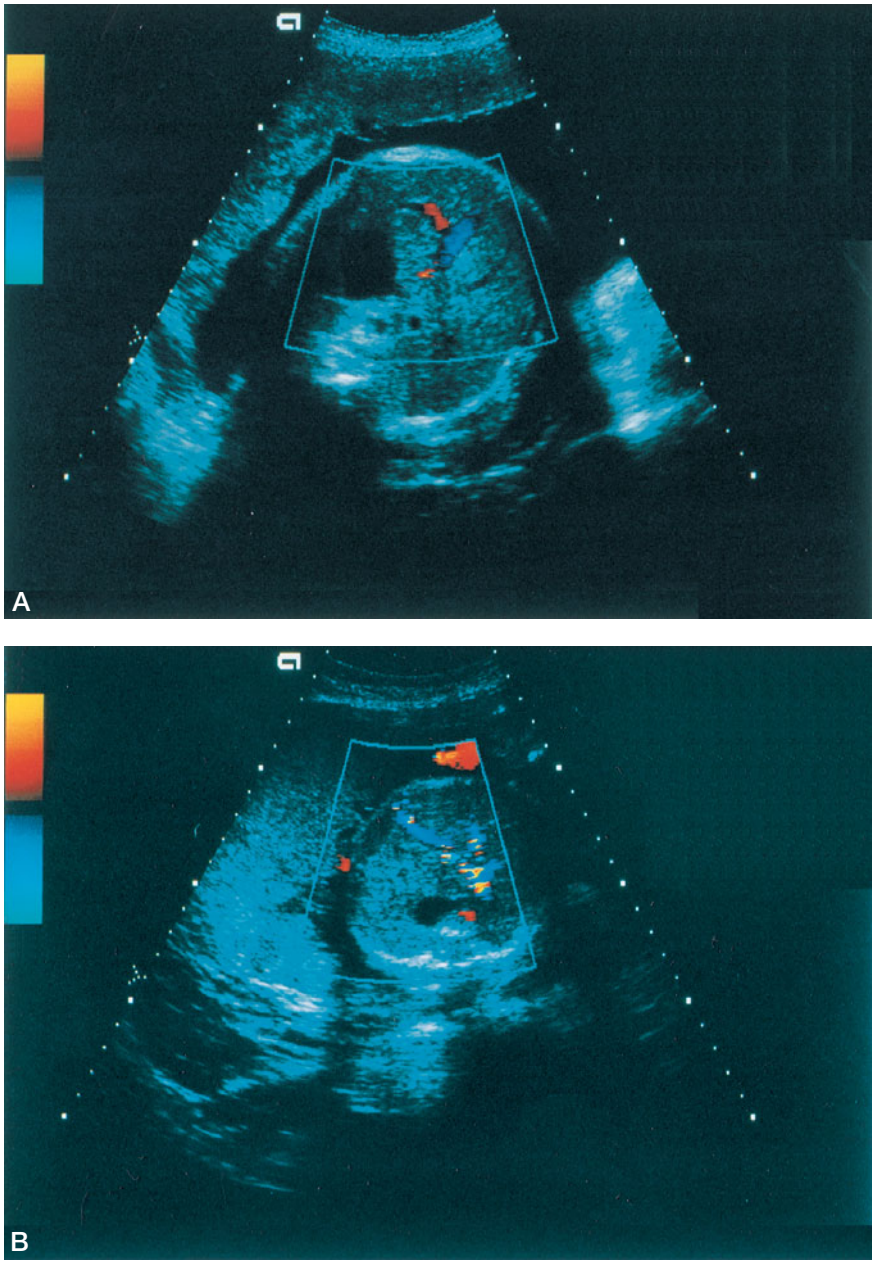

Figure 37-5 **A.** Color flow Doppler images demonstrating normal course of sinus venosus on left. **B.** ''Kinked" sinus venosus on right in CDH.

head circumference. In a retrospective review of 55 fetuses diagnosed with left-sided CDH, the LHR was found to be predictive at its extremes. At low values (i.e., small right lung), fetuses with LHRs <0.6 did not survive with postnatal therapy. But in fetuses with LHRs >1.35, survival was 100% with conventional postnatal therapies, including ECMO (Cannie et al., 2006; DePrest et al., 2006). The survival of fetuses with LHRs between 0.6 and 1.35 was 61%. At an NIH symposium, Harrison et al. (2003) provided additional data in the group of fetuses with values between 0.6 and 1.35. Survival with an LHR <1.0 was only 11%. The accuracy of the LHR described by Metkus et al. (1996) was validated in two subsequent prospective studies (Flake et al., 2000). The LHR has not been widely adopted due to the difficulty in accurately and reproducibly obtaining the LHR.

There now have been three different techniques reported for obtaining lung:head circumference ratio and a fourth modification in which the observed LHR is normalized to an expected LHR. The only two of these methods have been validated in prospective studies. In the technique first reported by the University of California San Francisco (UCSF) group, the largest transverse width of the right lung is obtained from the cross-sectional view of fetal chest at the level of the four-chamber view of the heart. This transverse measurement is taken parallel to the sternum from the right side of the Ao to the edge of the lung at the right chest wall. The anterior-posterior (AP) measurement is obtained perpendicular to this measurement. A second technique obtains the longest transverse measurement at the level of the four-chamber view of the heart independent of the orientation

of the sternum. The third technique captures the image of the cross-sectional view of the chest at the level of the four-chamber view and traces the outline of the right lung to obtain the area and divides by the head circumference. Each of these techniques yields slightly different results that may alter the perceived prognosis. These techniques are not only highly user-dependent, but the prognosis based on these results may not translate from one center that sees a high volume of fetuses with CDH to one that sees only a few cases each year. Case in point, Crombleholme et al. (2009) have reported the Cincinnati Children's experience with LHR, finding a survival of 100% when LHR was >1.0 and 50% with LHR <1.0. These findings are in contrast to older reports of prognosis based on LHR that indicates the institutional-specific nature of the utility of LHR in predicting survival. The accuracy of the LHR in predicting outcome has been challenged by the Columbia group (Arkovitz et al., 2007), who reported that the LHR in their series was not predictive of outcome. Methodical problems with LHR acquisition may be an issue, but this does point to concern regarding how easily translatable use of LHR is from one center to another.

Between 12 and 32 weeks' gestation, normal lung area increases four times more than head circumference (DePrest et al., 2009). For this reason, Jani et al. (2007) proposed referencing LHR to gestational age by expressing the observed LHR as a ratio to the expected mean LHR for that gestational age. In a study from the CDH antenatal registry of 354 fetuses with isolated left and right CDH between 18 and 38 weeks, Jani et al. found that observed/predicted LHR predicted postnatal survival. The O/E LHR tended to be more accurate at 32 to 33 weeks than at 22 to 23 weeks' gestation. The O/E LHR was also found to correlate with short-term morbidity indicated (Jani et al., 2007).

A novel approach was reported by Mahieu-Caputo et al. (2001) using the thoracic volume minus the mediastinal volume to yield an estimate of what the lung volume would be expected to be if there was no CDH and dividing the actual lung volume by this estimate to yield the percent predicted lung volume (PPLV). Mahieu-Caputo et al. (2001) found that the observed/expected fetal lung volume ratio was significantly lower in CDH patients who died with a mean of 26% compared to those who survived with a mean of 46%. This same group reported a larger experience from a 4-year prospective multicenter study of 77 fetuses with isolated CDH diagnosed between 20 and 33 weeks' gestation (Gorincour et al., 2005). They found that the observed/expected lung volume was significantly lower in fetuses with CDH that died (23%) compared to those that survived (36%). When the observed to expected fetal lung volume ratio was below 25%, there was a significant decrease in postnatal survival to 19% versus 40.3%. While these survival rates are lower than usually reported in the United States, they still support the utility of this prognostic technique.

Using this same technique that she termed PPLV, Barnewolt et al. (2007) reported their preliminary experience in Boston with 14 patients with CDH in which there was a clear break point at a PPLV of 15%. Fetuses with PPLV more than 20% had 100% survival while those with PPLV <15% had a 40% survival and all required prolonged ECMO. However, Crombleholme et al. (2009), in reporting the Cincinnati Children's experience with PPLV with 28 patients, found that PPLV was not as predictive of outcome as LHR (Crombleholme et al., 2009). In this series, three of the four deaths occurred in patients with PPLV more than 15%. In contrast, survival with LHR >1.0 was 100% and all deaths occurred in patients with LHR <1.0.

Fetal MRI has been also applied to directly measure total lung volumes to predict outcome in CDH. Hubbard et al. (1997) found that fetal lung volumes obtained by MRI at midgestation did not accurately predict postnatal outcome. Kilian et al. (2006) reported a series of fetal MRI-derived lung volumes at 34 to 35 weeks' gestation. They noted that most of the growth in lung volume occurs in late gestation, as reflected in the later sharp upward sweep of lung volume normograms. They reasoned that in the presence of a large CDH there would not be the normal increase in lung growth. In a series of 38 cases of CDH, both right-sided and left-sided, they correlated lung volume with survival and the need for ECMO. They found that the mean lung volume of survivors was 35 cc, while mean lung volume of nonsurvivors was 9 cc. The mean lung volume of those infants requiring ECMO was 18 cc, while 25 cc was the mean lung volume of those that did not require ECMO.

At the time of 34 weeks' gestation MRI, measurement of the branch pulmonary artery diameter and the descending Ao allows calculation of the modified McGoon index. Vuletin et al. (2009) have shown that the modified McGoon <1.0 and the prenatal pulmonary hypertensive index (PPHI, branch pulmonary arteries divided by the cerebellum to normalize for age) correlates with severe postnatal pulmonary hypertension at 3 weeks of age.

Cystic diseases of the chest, such as type I congenital cystic adenomatoid malformation (CCAM) of the lung, bronchogenic cysts, neurenteric cysts, and cystic mediastinal teratoma, may also be mistaken for the herniated bowel of CDH (Harrison et al., 1991). The demonstration of normal upper gastrointestinal anatomy helps to distinguish cystic thoracic masses from CDH. Peristalsis of bowel loops within the chest may also help distinguish these two diagnoses. In right-sided lesions the liver is often the only organ herniated. This may be more difficult to identify, due to the similar echodensities of the fetal liver and lung. It may also be difficult to distinguish herniation of the liver into the chest from a type III CCAM.

ANTENATAL NATURAL HISTORY

It was once thought that prenatal detection of CDH might improve outcome by allowing transport of the mother to an appropriate facility, planned delivery, immediate resuscitation, and sophisticated postnatal intervention with "gentilation" strategies, high-frequency ventilation and/or ECMO. Reviews of prenatally diagnosed CDH, however, have consistently shown a 76% to 80% mortality rate despite this

optimized approach to management (Adzick et al., 1981; O'Rourke et al., 1984; Reynolds et al., 1984; Harrison et al., 1990, 1993a, 1993b, 1994; Puri and Gorman, 1984).

There has been a trend toward improved survival even among the most severely affected fetuses with CDH in which there is liver herniation and LHR <1.0. In the NIH study reported by Harrison et al. (1997), the survival in fetuses regardless of treatment was 30%. Although the numbers were small, this is an improvement from 11% previously reported by this group. Similarly, the CHOP group has reported 40% survival in this high-risk category. The improvement in survival in general for CDH has shifted innovative strategies of management to only those patients with LHR <1.0 and liver herniation. These innovative strategies include reversible tracheal balloon occlusion (DePrest, 2007; DePrest et al., 2009), EXIT-to-ECMO (Kunisaki et al., 2007), and aggressive management of pulmonary hypertension with off-label use of inhaled nitric oxide and inhaled prostacyclin (Lim, 2007). This aggressive management of pulmonary hypertension in CDH has resulted in 100% survival in isolated CDH with LHR >1.0. Even with LHR ≤1.0, the group at Cincinnati Children's have observed a 50% survival and have reduced the need for ECMO to only 8% in patients not sufficiently severe for EXIT-to-ECMO.

MANAGEMENT OF PREGNANCY

The evaluation of the fetus with suspected CDH should include a detailed ultrasound examination to confirm the diagnosis and detect possible associated anomalies. If possible, measurement of LHR should be obtained. Prenatal karyotyping is indicated in all cases of CDH because of the high incidence of associated chromosomal anomalies (16–37% of cases) (Adzick et al., 1981; Puri, 1984; Sharland et al., 1992). Even if termination of the pregnancy is not an option because of gestational age or parental choice, the diagnosis of a chromosomal anomaly may influence the management of labor and the plan for neonatal resuscitation. Array comparative genomic hybridization (CGH) has also been recommended by some for all cases of prenatally diagnosed CDH due to limitations in completely ascertaining all anomalies in utero (Pober, 2008).

The most common chromosome abnormalities associated with CDH are trisomy 18 (see Chapter 130), and tetrasomy 12p (Pallister–Killian syndrome) (see Chapter 138), and trisomy 21 (see chapter 131). Other chromosome rearrangements that have been reported in association with multiple cases of CDH include del(15)(q26.1-q26.2), del (8)(p23.1), del (4)(p16), partial and full trisomy 22, del (1)(q41-q42.12), and rearrangement of 8q23 (Holder et al., 2007; Pober, 2008).

CDH is found in at least a dozen single-gene disorders, including Cornelia de Lange syndrome, craniofrontonasal syndrome, Donnai–Barrow syndrome, multiple vertebral segmentation defects, Simpson–Golabi–Behmel syndrome, Denys–Drash syndrome, and Frasier syndrome. Although a diagnosis of Fryns syndrome is commonly made, there is likely to be etiologic heterogeneity with Fryns, and no gene that causes this condition has been identified to date (Pober, 2008). If the CDH is suggested to be syndromic, consultation with a medical geneticist is advised.

Fetal echocardiography is also recommended in all cases because of the 16% incidence of associated congenital heart disease (Sharland et al., 1992).

The diagnosis of CDH at less than 25 weeks of gestation with long-standing large-volume herniation (indicated by mediastinal shift and dilated intrathoracic stomach, herniated liver, or LHR <1.0 and associated polyhydramnios) indicates a fetus at risk for severe pulmonary hypoplasia and a poor outcome. The severity of pulmonary hypoplasia and CDH seems to correlate with the timing, duration, and volume of herniation. A few mildly affected fetuses will have minimal developmental effects on the lungs because of herniation late during gestation, small-volume hernia, minimal mediastinal shift, and greater lung volume as indicated by an L:T ratio >0.5 or LHR >1.4 (Hasegawa et al., 1990; Metkus et al., 1996; Stringer et al., 1995). These fetuses should be followed closely by serial ultrasound examinations and delivered at term in an ECMO center staffed with pediatric surgeons and neonatologists, expert in management of infants with CDH.

The majority of fetuses with prenatally diagnosed CDH are detected early in gestation (less than 25 weeks), with a large-volume herniation with mediastinal shift and intrathoracic stomach, polyhydramnios, low L:T ratio (<0.5), and low LHR (<1.35). The management of the fetus depends on the gestational age at diagnosis. If the fetus is less than 24 weeks, then the parents may choose to terminate the pregnancy, continue the pregnancy with conventional postnatal care at term, or consider fetoscopic tracheal balloon occlusion procedure in utero (if available). At the time of publication, no FDA-approved device for fetal tracheal balloon occlusion was available in the United States, and tracheal occlusion is being offered in Europe. Several centers including UCSF and Cincinnati Children's are offering this therapy on an FDA-approved investigational device exemption. After 28 weeks of gestation, CDH is managed by conventional postnatal management or EXIT-to-ECMO (Figure 37-6).

Cesarean delivery is not indicated for CDH. There are no data to support elective preterm delivery. However, elective induction at 37 weeks allows a planned delivery in the appropriate center with suitable resources for the care of a fetus with severe pulmonary hypoplasia. There has been controversy as to whether CDH fetuses are surfactant deficient with reports on both sides of the argument. Recently however, Benachi (2007) from France reported definitive results in autopsy specimens in fetuses with CDH near term, as demonstrated by the presence of type II pneumocytes both bronchoalveolar lavage and histology that were no different from normal-term control fetuses. There is, however, another reason to administer prenatal steroids within 48 hours up to 7 days prior to delivery. Davey et al. (2007) have demonstrated in a sheep model of CDH that steroid administration close to the time of delivery can reverse the extensive muscularization of the preacinar capillary bed responsible for pulmonary.

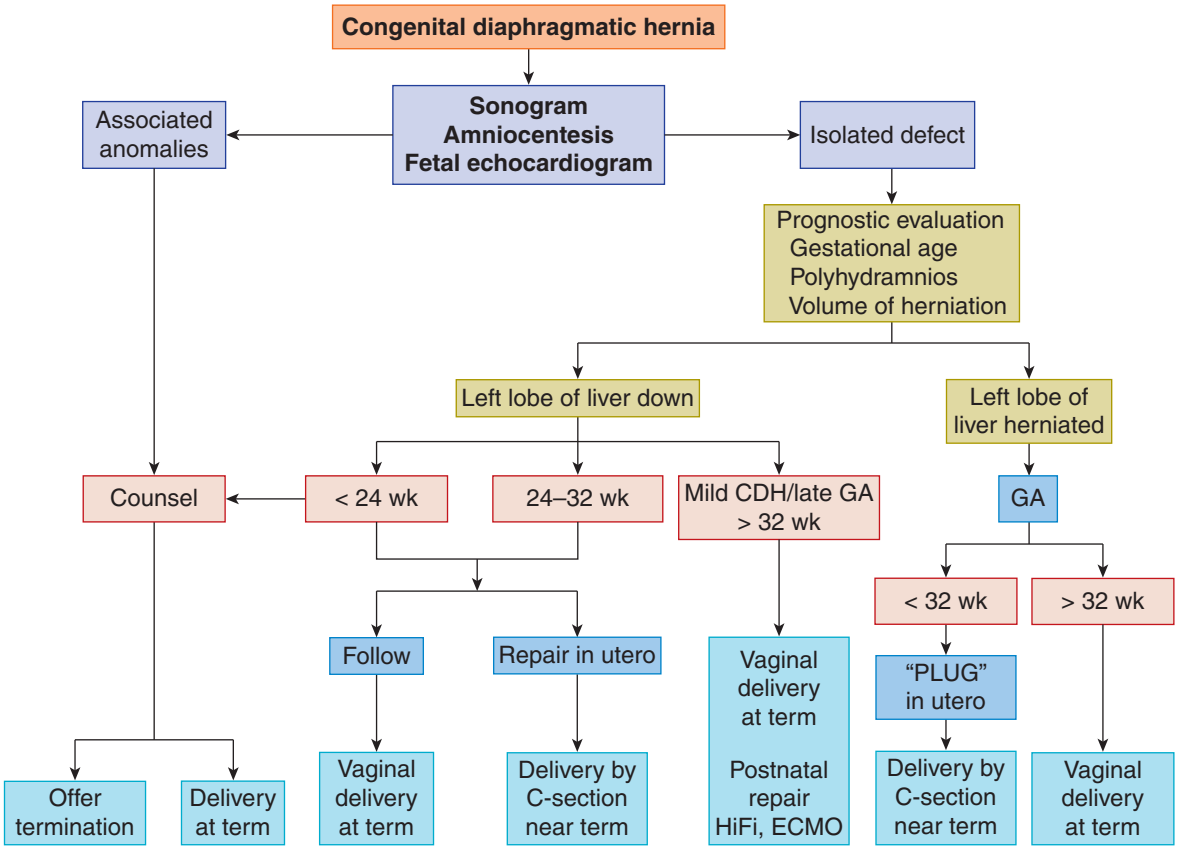

Figure 37-6 Algorithm for the management of prenatally diagnosed CDH.

FETAL INTERVENTION

Compensatory lung growth and development are possible after repair of CDH, but weeks or months may be required to achieve this. Postnatal support by ECMO is usually limited to 2 to 6 weeks, which may be an inadequate period of support for the most severely affected infants (O'Rourke et al., 1984). It has been demonstrated experimentally that reduction and repair of the hernia in utero allows the lungs adequate time for compensatory growth (Harrison et al., 1980a, 1980b, 1981; Adzick et al., 1985b). In a series of experiments in fetal sheep and rhesus monkeys, the techniques of open fetal surgery and perioperative tocolytic therapy were established before clinical trials of open fetal surgery for CDH were undertaken (Harrison et al., 1980a, 1980b, 1981, 1991; Adzick et al., 1985b; Adzick and Harrison, 1994).

Although the survival rate with in utero repair of CDH in initial clinical trials was not encouraging (Harrison et al., 1990, 1993a, 1993b), the dramatic results observed in surviving infants prompted an NIH-sponsored trial (Harrison et al., 1997). The results of this trial, limited to diaphragmatic hernia without herniation of the left lobe of the liver, showed no survival benefit of fetal surgery over postnatal treatment. As a result, there is currently no indication for complete repair of diaphragmatic hernia without herniation of the left lobe of the liver. However, cases of diaphragmatic hernia associated with herniation of the left lobe of the liver remain the most severely affected cases, with profound pulmonary hypoplasia. Ironically, although considered an exclusion criterion for complete repair of diaphragmatic hernia, it is now one of the selection criterions for fetal tracheal occlusion (FETO; Deprest et al., 2009).

It was recognized long ago that occlusion of the fetal trachea results in markedly enlarged and hyperplastic lungs (Carmel et al., 1965; Lanman et al., 1971; Alcorn et al., 1976). This observation was applied to the problem of diaphragmatic hernia. Throughout gestation the fetal lung produces fluid that exits the trachea during normal breathing movements. External drainage of this fluid, bypassing the glottic mechanism, results in retarded lung growth and pulmonary hypoplasia (Carmel et al., 1965; Lanman et al., 1971; Alcorn et al., 1976). Conversely, tracheal occlusion results in accelerated lung growth and pulmonary hyperplasia (Carmel et al., 1965; Alcorn et al., 1976; Moessinger et al., 1990; Hedrick et al., 1993; Hooper et al., 1993; DeFiore et al., 1994; Bealer et al., 1995; Luks et al., 1995; Beierle et al., 1996). In the fetal lamb model of diaphragmatic hernia, tracheal obstruction accelerates lung growth, pushing the viscera back into the abdomen resulting in larger lungs with significant functional improvement at birth as compared with controls (Hedrick et al., 1993; Wilson et al., 1993; DeFiore et al., 1994; Bealer et al., 1995; Luks et al., 1995; Beierle et al., 1996). The results of experimental work were so impressive that this strategy was employed by Harrison in fetuses with herniation of the left lobe of the liver (Harrison et al., 1997).

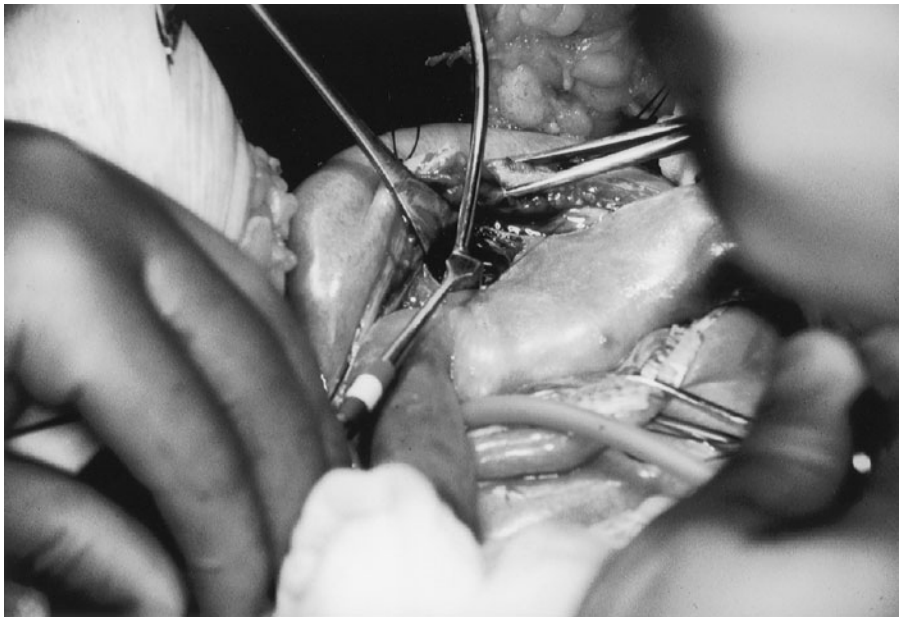

Figure 37-7 Intraoperative view of a fetus at 26 weeks of gestation undergoing fetal tracheal clip application. The fetal arms are retracted down through the hysterotomy and the head is extended within the uterus. The fetal neck is opened above the sternal notch to expose the fetal trachea.

Despite an excellent biologic response with complete tracheal occlusion, there was only one survivor in the initial series of patients treated by tracheal occlusion. The group at The Children's Hospital of Philadelphia had similar problems when the procedure was performed at 28 weeks of gestation (Figure 37-7). Survival increased to 40% in fetuses with a predicted mortality rate in excess of 90% when fetal tracheal clip application was performed at 26 weeks of gestation (Flake et al., 2000).

Due to difficulties with open fetal surgery for tracheal clip application as well as fetoscopic tracheal clip application, the UCSF group began performing tracheal occlusion by detachable endoluminal balloon placement.

The results with fetoscopic balloon tracheal occlusion were evaluated by the UCSF group in an NIH-sponsored randomized trial that compared fetoscopic tracheal occlusion to conventional postnatal therapy in fetuses with isolated left-sided CDH with liver herniation and LHR <1.4 (Harrison et al., 2003). The investigators' preliminary data suggested an anticipated survival with conventional therapy of 50% and with fetoscopic tracheal occlusion of 75%. A crucial aspect of the trial was that patients from both arms of the trial were born and treated postnatally at UCSF. The trial was stopped after randomization of only 24 patients because of an unexpectedly high survival rate with standard care. Eight of the 11 fetuses (73%) randomized to tracheal occlusion survived and 10 of 13 fetuses (77%) randomized to standard care survived to 90 days of age. There was a significant difference in gestational age at delivery for FETO (30.8 weeks) compared to conventional therapy (37 weeks). This trial demonstrated a significant improvement in survival compared to historical controls in the same center. However, the inclusion of fetuses with LHR > 1 < 1.4 biased the study toward the less severe end of the spectrum with insufficient power to analyze the effects in the subset of patients with LHR <1.0.

The tracheal occlusion procedure currently in use in Europe is done using maternal percutaneous access under local or regional anesthesia with a single 3.3 mm port and a balloon to occlude the trachea (DePrest et al., 2009). The balloon is inserted at 26 to 28 weeks and removed at 34 weeks. If patients deliver prior to 34 weeks they require emergency peripartum balloon removal, which requires the availability of trained clinicians at all times. The Eurofoetus group reports in their experience of more than 150 cases a survival rate with tracheal occlusion of 50% to 57% (DePrest et al., 2009). However, these studies have been criticized due to lack of contemporary controls. Nonetheless, no maternal complications have been reported, but iatrogenic preterm rupture of the membranes has occurred in 20% of cases. Long-term follow-up study of infants is in progress. DePrest and his Eurofoetus colleagues have achieved survival of 83% with tracheal occlusion at 26 to 28 weeks' gestation followed by reversal of tracheal occlusion performed either by popping the balloon by an ultrasound-guided needle or by a second fetoscopic procedure. While no randomized trial comparing fetoscopic tracheal occlusion to conventional care is planned. The Eurofoetus study will soon begin randomizing patients to different gestational ages to determine the best timing of tracheal occlusion. In the United States, no center is currently offering FETO due to the lack of an FDA-approved device. The only fetal surgery offered for high-risk CDH is EXIT-to-ECMO. In preliminary results reported by Kunisaki et al. (2007), fetuses with liver herniation and PPLV or <20% are offered EXIT-to-ECMO, with a 65% survival. Similar results have been observed at Cincinnati Children's and Vanderbilt. This therapeutic innovation remains unproven but may hold

promise in these high-risk CDH cases given survival with conventional treatment is significantly lower.

TREATMENT OF THE NEWBORN

All fetuses with CDH are at high risk for severe pulmonary hypoplasia and are optimally managed by delivery in a perinatal center with neonatal and pediatric surgical expertise in CDH immediately available, preferably in a center capable of performing ECMO (Harrison et al., 1990; Marwan and Crombleholme, 2006). The resuscitation of a newborn includes immediate endotracheal intubation, "gentilation" limited, positive-pressure ventilation with PIPs. The infant should have a sump-style nasogastric tube inserted in the delivery room to perform continuous suction to avoid dilation of the intrathoracic bowel from the infant swallowing air. In the delivery room the infant should have umbilical arterial and umbilical venous catheters placed to monitor arterial blood gases and provide venous access. In the face of liver herniation, however, umbilical venous lines are rarely successfully placed. Preductal and postductal transcutaneous oxygen saturation monitors can help to continuously monitor right-to-left shunting across the ductus arteriosus.

Judicious volume resuscitation is important, and many infants with diaphragmatic hernia require vasopressor support with dopamine, milrinone, or epinephrine. Occasionally vasopressor refractory hypotension may require the use of steroids or even vasopressin.

The use of inhaled nitric oxide in CDH has met with mixed results. Inhaled nitric oxide has not clearly been shown to benefit newborns with diaphragmatic hernia. However, inhaled nitric oxide has been beneficial in preventing the need for ECMO during the postoperative period (Frostell et al., 1993; Dillon et al., 1995). At Cincinnati Children's an aggressive approach for pulmonary hypertension includes inhaled nitric oxide combined with inhaled prostacyclin. While this approach has not been proven yet to affect outcome, preliminary results with this approach have been promising, and resulted in 90% overall survival in CDH and 100% survival in cases with LHR >1.0. (Crombleholme et al., 2009)

SURGICAL TREATMENT

It was once believed that immediate operation to decompress the chest was necessary. However, in recent years, it has been recognized that this is not the case. The more important variable is the degree of underlying pulmonary hypoplasia. Emergency surgical repair may, in fact, be detrimental to the infant's tenuous pulmonary and hemodynamic status after birth and relative pulmonary artery hypertension (Hazebrock et al., 1989; Langer et al., 1989). It is better to delay repair until the infant has stabilized. This may take hours, days, or weeks. If the infant deteriorates during this so-called "honeymoon" period, ECMO can be initiated. The infant can undergo repair of CDH while on ECMO and be weaned from the circuit postoperatively (Connors et al., 1990). An alternate strategy is to perform early repair on ECMO to facilitate remodeling of the hypoplastic lung following repair of the diaphragmatic defect. The rationale here is that relieving compression of the lung is beneficial for pulmonary hypertension. The risk of this approach is postoperative bleeding while anticoagulated on ECMO prior to a time when ECMO decannulation would be possible.

Repair of CDH is usually performed via a left-upper-quadrant transverse or subcostal incision, which allows exposure of the defect and reduction of the herniated viscera. The diaphragm can occasionally undergo primary repair, but in severe cases, the defect is large or there may be complete diaphragmatic aplasia, both of which require a prosthetic patch. Because reherniation may occur in up to 50% of cases with gortex patch repair, there is growing interest in the use of the transversus abdominus muscle flap as a patch. Because the tissue is autologous there is decreased risk of infection, and because it grows with the infant, it is believed to prevent dehiscence and reherniation. A chest tube may be inserted after repair of CDH. If used, the chest tube is placed only to water seal, and no suction is applied.

LONG-TERM OUTCOME

The long-term outcome of infants with isolated CDH who survive the neonatal period depends on the severity of pulmonary hypoplasia, and the degree of bronchopulmonary dysplasia resulting from long-term ventilatory support (Bales and Anderson, 1979). In addition, extrapulmonary complications are noted more commonly in survivors of CDH (Glass et al., 1989; Lund et al., 1994). There is a high incidence of neurologic problems in children with CDH, independent of exposure to ECMO. Other complications such as reactive airway disease, sensorineural hearing loss due to prolonged need for antibiotics and/or furosemide (Lasix), seizures, and developmental delay, may be seen in up to 20% to 30% of patients (Lund et al., 1994). Long-term follow-up evaluation and early intervention are indicated in this group of high-risk patients.

Failure to thrive has been noted in many survivors of diaphragmatic hernia (Cunniff et al., 1990; Atkinson and Poon, 1992; Van Meers et al., 1993; D'Agostino et al., 1995). Many infants with isolated diaphragmatic hernia have feeding difficulties that may require gavage feedings and may contribute to failure to thrive. The causes of failure to thrive may be multifactorial, but Nobuhora et al. (1996) noted that 30% of infants remained below the fifth percentile despite optimization of caloric intake; 68% of the patients in this group were ECMO survivors. Van Meers et al. (1993) also noted a high percentage (50%) of CDH survivors supported with ECMO who had failure to thrive.

Gastroesophageal reflux may affect as many as 50% to 62% of diaphragmatic hernia survivors (Koot et al., 1993; Kieffer et al., 1995). While some have reported good response to medical therapy (Stolar et al., 1990), the need for antireflux

surgery varied from 9.6% to 14.8% (Nagaya et al., 1994; Kieffer et al., 1995).

Musculoskeletal deformities, such as pectus excavatum and scoliosis, may also develop in survivors of diaphragmatic hernia. The cause of these deformities may be the asymmetric lung size, the diaphragmatic repair, or the increased work of breathing some patients may have. In the series reported by Nobuhora et al. (1996), the incidence of pectus excavatum was 21% and scoliosis was 10.5%.

The most worrisome finding is the incidence of neurodevelopmental delays, which may be present in up to 40% of survivors with CDH. While in general the risk of neurodevelopmental delay is thought to be proportional to the severity of the infant's NICU course, this has not been proven.

GENETICS AND RECURRENCE RISK

In recent years, there have been multiple lines of evidence that suggest that many cases of CDH may have a genetic etiology. These include: (1) recurring chromosome abnormalities in unrelated individuals that reveal CDH "hot spots"; (2) single-gene disorders in which the causative gene is known and provides insight into pathways that are critical for diaphragmatic development; (3) multiple families in which CDH recurs (Pober, 2008).

For all fetuses in which a CDH is detected, a complete family history should be obtained and the parents should be examined. The first consideration should be whether the CDH is isolated or nonisolated. Anomalies such as pulmonary hypoplasia, bowel malrotation, patent ductus arteriosus, dextraposition of the heart, tricuspid or mitral valve regurgitation, or undescended are considered to be mechanical or hemodynamic consequences of the CDH, so if present, they do not preclude a diagnosis of isolated CDH (Pober, 2008). A truly isolated CDH carries a multifactorial recurrence risk of at most 2% (Pollock and Hall, 1979; Norio et al., 1984).

All fetuses with CDH should have a minimum of a metaphase karyotype, and ideally, an array cGH study. If a chromosome abnormality is detected, the prognosis and recurrence risk will be those of the specific abnormality.

If associated anomalies are detected the prospective parents should meet with a medical geneticist. The single-gene disorders in which CDH is a major feature are listed in Table 37-1. If the geneticist suspects one of the conditions listed, DNA diagnosis is possible on amniocytes. Special note

Table 37-1

Major Single-Gene Disorders Associated with CDH

Syndrome	Pattern of Inheritance	Causative Gene	Chromosome Location	Prenatal Sonographic Findings*
Cornelia de Lange	Autosomal dominant X-linked	*NIPBL* *Smc1 A*	5p13.1 Xp11.2	Growth restriction Limb anomalies
Craniofrontonasal dysplasia	X-linked	*EFNB1*	Xq12	Craniosynostosis, hypertelorism
Donnai–Barrrow	Autosomal recessive	*LRP2*	2q24.3-2q31.1	Agenesis of corpus callosum, hypertelorism
Fryns	Unknown Autosomal recessive			CNS, renal, cardiac anomalies
Matthew–Wood	Autosomal recessive	*STRA6*	15q24.1	Micro- or anophthalmia, cardiac and GU anomalies
Multiple vertebral segmentation defects	Autosomal recessive	*DLL3*	19q13	Hemivertebrae, fused vertebrae, rib anomalies
Simpson–Golabi–Behmel	X-linked	*GPC3*	Xq26	Overgrowth, limb, and renal anomalies
Denys–Drach/ Frasier/Meacham	Autosomal dominant	*WT1*	11p13	Ambiguous genitalia, cryptophthalmos, renal anomalies

** In addition to diaphragmatic hernia.*

should be made of Fryns' syndrome, an autosomal recessive condition that is commonly considered for fetuses with CDH (Moerman et al., 1988; Bamforth et al., 1989; Cunniff et al., 1990). The gene responsible for this condition is not known. For a diagnosis of Fryns syndrome to be made, Lin et al. (2005) propose that at least four of the following six findings are present: diaphragmatic defect, pulmonary hypoplasia, specific facial dysmorphic features, distal digital hypoplasia, and affected sibling, or "other anomalies" (typically, septal or conotruncal cardiac defects, renal cystic dysplasia, or agenesis of the corpus callosum). If a single-gene disorder is diagnosed, either by molecular testing or by physical examination of the neonate, the recurrence risk and prognosis are that of the condition.

In cases of perinatal loss, every attempt should be made to have autopsy studies performed to document the presence of additional anomalies not detected on sonographic examination. A follow-up meeting with a clinical geneticist is useful to summarize autopsy results and discuss possible genetic diagnoses. A fibroblast cell line should be established as a source of DNA for molecular studies. If karyotype and CGH analysis were not performed earlier, they should be done on cultured cells.

38 CHAPTER Hydrothorax

Key Points

- May be primary, due to chylous leak, or secondary, in which effusions are part of generalized fluid retention. Secondary hydrothorax is more common in the fetus than the neonate.
- Sonography demonstrates an anechoic space peripherally around the compressed lungs. If effusion is large there may be mediastinal shift. Polyhydramnios is present in 60% to 70% of cases. Extrathoracic anomalies are frequently present.
- Prior to 32 weeks of gestation fetal treatment options include: thoracentesis, thoracoamniotic shunting, and thoraco-maternal cutaneous drainage. Thoracentesis should be performed to determine if the effusion is chylous and to obtain a cell count, differential, and culture.
- Decompression of the fetal chest immediately prior to delivery is controversial.
- Delivery should occur in a tertiary care center.
- Up to 5% of cases are associated with a chromosome abnormality, such as Down and Turner syndromes.

CONDITION

Fetal hydrothorax (FHT), either unilateral or bilateral, is a pleural effusion that may be primary, due to chylous leak, or secondary, in which the effusions are part of a generalized fluid retention associated with immune or nonimmune hydrops (Holzgreve et al., 1985; Longaker et al., 1989; Laberge et al., 1991). The management of pleural effusion in the fetus is complicated by the difficulty in distinguishing primary from secondary FHT. Secondary FHT is far more common in the fetus than in the neonate (Holzgreve et al., 1985; Hagay et al., 1993). Secondary FHT may be due to a wide variety of maternal and fetal disorders, including chromosomal anomalies, cardiovascular, hematologic, gastrointestinal, pulmonary, metabolic, infectious, and neoplastic, and malformations of the placenta and umbilical cord (Chernick and Reed, 1970; Petres et al., 1982; Gardner et al., 1983; Grena-Ansotegui et al., 1984; Van Gerde et al., 1984; Foote and Vickers, 1986; Nicolaides and Azar, 1990). While the underlying cause of a secondary FHT may be evident from detailed sonographic examination and karyotype analysis, in many instances the cause of the effusion remains obscure even after a postmortem examination (Keeling et al., 1983; Nicolaides et al., 1985).

INCIDENCE

Cases of secondary FHT may occur as frequently as 1 in 1500 livebirths (Hutchison et al., 1982; Im et al., 1984; Castillo et al., 1986). The true incidence of primary FHT is uncertain. In a review of cases from five obstetrical hospitals in Montreal between 1980 and 1987, Longaker et al. (1989) estimated that the incidence of primary FHT is 1 case per 12,000 livebirths. The actual incidence of primary FHT may be even higher if one considers that in many cases the condition may remain undiagnosed, it may resolve spontaneously, the fetus may be aborted, or death may occur soon after birth in outlying hospitals before transfer to a tertiary care center (Longaker et al., 1989; Laberge et al., 1991). In a review of reported cases of FHT, Weber and Philipson (1992) found that there was a 2:1 male to female ratio, which is similar to the ratio in neonates with chylothorax (Chernick and Reed, 1970; Broadman, 1975; Weber and Philipson, 1992).

SONOGRAPHIC FINDINGS

The first sonographic diagnosis of FHT was made by Carroll in 1977, followed shortly thereafter by Defoort and Thiery (1978). Although the earliest gestation age at which prenatal diagnosis has been made sonographically is 17 weeks, the majority of cases are not diagnosed until after 30 weeks (Laberge et al., 1991). Reports of prenatally diagnosed FHT have continued to appear, and hundreds of cases have been described in the literature (Defoort and Thiery, 1978; Peleg et al., 1985; Wilson et al., 1985; Benacerraf et al., 1986; Calisti et al., 1986; Roberts et al., 1986; Weiner et al., 1986; Castillo et al., 1987; Murayoma et al., 1987; Reece et al., 1987; Adams et al., 1988; Blott et al., 1988; Bruno et al., 1988; Yaghoobian and Comrie, 1988; Longaker et al., 1989; Landy et al., 1990; Lien et al., 1990; Eddleman et al., 1991; Hernanz-Schulman et al., 1991; Parker and James, 1991).

In FHT, sonography demonstrates an anechoic space located peripherally around the compressed lungs (Figure 38-1). If the effusion is sufficiently large, there may be some degree of tension noted, with shift of the mediastinum away from the FHT and flattening or eversion of the ipsilateral diaphragm. The heart may be shifted into the contralateral hemithorax and appear smaller than normal. The presence of septations or solid components within the intrathoracic fluid collection suggests alternative diagnoses (Sydorak et al., 2002; Tsao et al., 2003). FHT has been reported in association with congenital diaphragmatic hernia, congenital cystic adenomatoid malformation of the lung, and bronchopulmonary sequestration, but it can usually be differentiated from simple hydrothorax by its more echogenic appearance (Smith, 1982; Longaker et al., 1989; Hernanz-Schulman et al., 1991; Laberge et al., 1991). Blott et al. (1988) reported FHT in association with a right-sided congenital diaphragmatic hernia and ascites. The hydrothorax resulted from a fluid-filled peritoneal sac in the right chest. The association with FHT has been reported in up to 20% of cases of congenital diaphragmatic hernia and should be considered in the differential diagnosis of FHT (Liew, 1974; Sydorak et al., 2002; Khalil et al., 2005), although the effusion in these cases is usually small.

FHT may be the first sign of nonimmune hydrops, and a careful sonographic inspection should be made to detect subtle signs of this. Congenital heart disease is observed in up to 5% of cases of prenatally diagnosed FHT (Hagay et al., 1993). Large effusions with shift of the mediastinum and compression of the heart may limit delineation of cardiac anatomy on fetal echocardiography (Rodeck et al., 1988). Evacuation of the pleural cavity by fetal thoracentesis will shift the heart to the midline, which may facilitate adequate imaging of the heart (Bigras et al., 2003).

Polyhydramnios is associated with FHT in 60% to 70% of cases (Defoort and Thiery, 1978; Peleg et al., 1985; Wilson et al., 1985; Calisti et al., 1986; Roberts et al., 1986; Weiner et al., 1986; Castillo et al., 1987; Murayoma et al., 1987; Reece et al., 1987; Adams et al., 1988; Blott et al., 1988; Bruno et al., 1988; Yaghoobian and Comrie, 1988; Lien et al., 1990; Longaker et al., 1989; Landy et al., 1990; Nicolaides and Azar, 1990; Eddleman et al., 1991; Parker and James, 1991). This often prompts referral for prenatal sonography because of discordant size and dates. The cause of polyhydramnios in FHT is not known for certain, but it has been suggested that large FHT associated with mediastinal shift may interfere with fetal swallowing (Hagay et al., 1993). This view is supported by one study that demonstrated a lack of contrast agent in the gastrointestinal tract after intra-amniotic instillation (Urografin) (Murayoma et al., 1987). Alternatively, Petres et al.

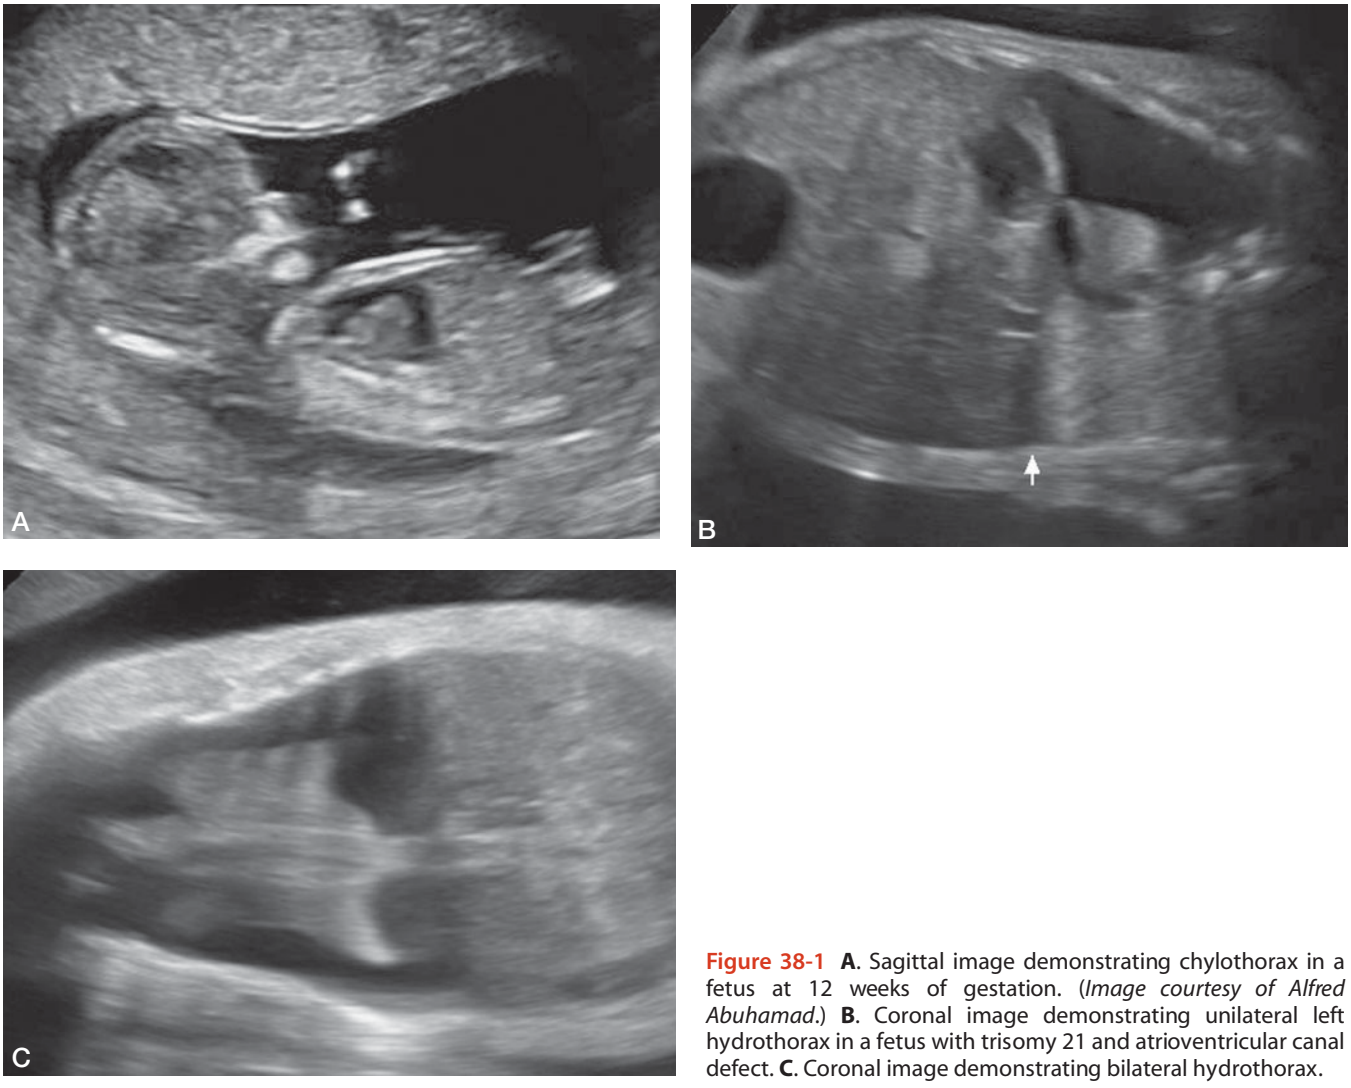

Figure 38-1 **A**. Sagittal image demonstrating chylothorax in a fetus at 12 weeks of gestation. (*Image courtesy of Alfred Abuhamad.*) **B**. Coronal image demonstrating unilateral left hydrothorax in a fetus with trisomy 21 and atrioventricular canal defect. **C**. Coronal image demonstrating bilateral hydrothorax.

(1982) suggested that the cause of polyhydramnios in FHT may be an alteration in the production of amniotic fluid by the compressed lungs.

A thorough search should be made for associated extrathoracic malformations, such as cystic hygroma or other features suggesting Turner syndrome (Smith, 1982; Foote and Vickers, 1986). Down syndrome has been associated with congenital pleural effusion (Puntis et al., 1987). Both Turner and Noonan syndromes include malformations of lymphatic vessels, but only rarely are these syndromes associated with congenital chylothorax (Van Gerde et al., 1984).

DIFFERENTIAL DIAGNOSIS

The most important factor in the differential diagnosis of fetal pleural effusions is distinguishing primary from secondary FHT. A detailed sonographic examination will reveal a major congenital anomaly in up to 40% of cases of secondary FHT (Hutchison et al., 1982). In most instances, however, a fetal thoracentesis is needed to distinguish primary from secondary FHT (Broadman, 1975). A pleural-fluid differential cell count that consists of more than 80% lymphocytes is considered pathognomic for chylothorax, which is a characteristic finding in neonates (Puntis et al., 1987; Longaker et al., 1989; Pijpess et al., 1989). Eddleman et al. (1991) have questioned the accuracy of a lymphocyte count as an indicator of chylothorax in the presence of a viral infection. However, the serositis that results from viral infection is usually not limited to the pleural cavities, and pericardial effusion and ascites are also often observed. A predominance of atypical lymphocytes on differential cell count may also suggest a viral infection.

Chylothorax has been described in association with diffuse congenital lymphangiomatosis (Berberich et al., 1975; Roth, 1984; Smelzer et al., 1986), diffuse hemangiomata, chylopericardium (Bhatti et al., 1985), congenital lymphedema (Pearl and Wilson, 1981; Kitohara, 1985; Lev-Sagie et al., 2003), pulmonary lymphangiectasia (Jauppela et al., 1983; Hunter and Becroft, 1984; Kerr-Wilson et al., 1985), bronchopulmonary sequestration (Kristofferson and Ipsen, 1984; Hook et al., 1987), congenital diaphragmatic hernia (Liew,

1974; Sydorak et al., 2002; Khalil et al., 2005) atresia of thoracic duct, generalized pleural oozing, and other malformations (Manning and O'Brien, 1983; Lazarus and McCurdy, 1984). In many cases no underlying cause for the chylothorax is found.

ANTENATAL NATURAL HISTORY

The natural history of FHT is significantly different from chylothorax in the newborn and carries a much poorer prognosis. The mortality rate for chylothorax in the newborn is at most 15%, but the mortality rate for prenatally diagnosed FHT is 53% (Broadman, 1975; Longaker et al., 1989; Klam et al., 2005).

Several features of primary FHT are associated with a more favorable outcome. Unilateral FHT, without evidence of tension, such as mediastinal shift or diaphragmatic eversion, is associated with 100% survival (Longaker et al., 1989; Laberge et al., 1991). This contrasts with a survival rate of only 52% in bilateral FHT (Longaker et al., 1989). Survival is also observed in all cases of FHT that spontaneously resolve (Longaker et al., 1989; Laberge et al., 1991). Spontaneous resolution of FHT has occurred in approximately 5% to 22% of cases (Carroll, 1977; Jaffe et al., 1986; Blott et al., 1988; Yaghoobian and Comrie, 1988; Longaker et al., 1989; Landy et al., 1990; Lien et al., 1990; Nicolaides and Azar, 1990; Eddleman et al., 1991; Klam et al., 2005). Because of the possibility of spontaneous regression, a period of observation is warranted in all cases of FHT.

The development of hydrops in the fetus with primary FHT is a poor prognostic sign, with a mortality rate of up to 52% (Longaker et al., 1989). It is thought that hydrops develops from mediastinal shift, cardiac compression, and vena caval obstruction, which diminishes venous return to the heart, resulting in a low-cardiac-output state (Bessone et al., 1971). The mortality rate associated with primary FHT is still significantly better than the 95% to 98% mortality rate observed in secondary FHT (Inselman and Mellins, 1981). In cases of FHT diagnosed prior to 33 weeks, the survival rate is only 43%, versus 80% if it was diagnosed after 33 weeks (Carroll, 1977; Longaker et al., 1989). Similarly, a gestational age of less than 35 weeks at delivery has a survival rate of only 30%, versus 79% if delivered after 35 weeks (Carroll, 1977; Longaker et al., 1989; Laberge et al., 1991). Polyhydramnios has no independent prognostic significance, except that it can result in uterine overdistention, which predisposes to preterm labor and delivery (Broadman, 1975; Carroll, 1977; Defoort and Thiery, 1978).

Even in the absence of hydrops, large pleural effusions can cause pulmonary hypoplasia due to compression. Pulmonary hypoplasia is a well-known complication of space-occupying lesions in the chest, such as cystic adenomatoid malformation of the lung and congenital diaphragmatic hernia (Areechon and Reid, 1963; Levin, 1978; Geggel and Reid, 1984; Adzick et al., 1985; Geggel et al., 1985; Lange et al., 1989; Morin et al., 1994). It is likely that the time of onset, size, and duration of the pleural effusion probably influence the development of pulmonary hypoplasia. The earlier in gestation a large pleural effusion develops, the greater the degree of pulmonary hypoplasia is likely to be. Klam et al. (2005) suggested that unrelieved compression of the lung by bilateral FHT for 8 to 9 weeks associated with hydrops was sufficient to cause lethal pulmonary hypoplasia. The most common cause of neonatal death in patients diagnosed with FHT is respiratory insufficiency due to pulmonary hypoplasia (Carroll, 1977; Longaker et al., 1989; Laberge et al., 1991).

MANAGEMENT OF PREGNANCY

FHT is frequently associated with extrathoracic anomalies. The risk of an abnormal karyotype in FHT is small but significant (Chen, 2005). Prenatal karyotyping is recommended, especially if fetal intervention is considered. The incidence of Down syndrome in FHT is 4.9% (Weber and Philipson, 1992). Because the incidence of associated congenital heart disease may be as high as 5%, we recommend that every fetus diagnosed with FHT undergoes fetal echocardiography. Rodeck reported treating a fetus with a thoracoamniotic shunt. The fetus was subsequently shown to have congenital heart disease that was appreciated only after the effusion was drained (Rodeck et al., 1988).

The fetus with a pleural effusion is at risk for the development of polyhydramnios and preterm labor. We recommend that these pregnancies be followed closely, with ultrasound examination every 1 to 2 weeks for early detection of signs consistent with tension hydrothorax, such as mediastinal shift, diaphragmatic eversion, development of hydrops, and polyhydramnios.

The fetus with FHT is at significant risk for pulmonary hypoplasia and respiratory distress following delivery. We recommend that the fetus with a large pleural effusion be delivered in a tertiary care center. Prenatal consultations with a pediatric surgeon, neonatologist, geneticist, and pediatric cardiologist are indicated. The presence of FHT does not influence the mode of delivery. Cesarean delivery should be reserved for obstetrical indications. There have been several reports of fetal thoracentesis prior to delivery to improve respiratory function. Some neonatologists believe that prenatal decompression facilitates resuscitation of the newborn (Bessone et al., 1971; Petres et al., 1982). Others believe that the fluid reaccumulates so rapidly that the patient will be hypovolemic at birth and that this will compromise resuscitation. The latter group advocates thoracentesis after delivery, when venous access can be established and boluses of colloid or crystalloid can be given. There are no data to support one approach over the other, but delay of thoracentesis until after delivery will minimize maternal and fetal risks (Wilson et al., 1985). If the effusion is large and long-standing, thoracentesis is unlikely to have much benefit because of underlying pulmonary hypoplasia. The benefit at the time of delivery, before

or after, is to facilitate ventilation by removing compression of the lung by the hydrothorax.

The development of polyhydramnios may precipitate preterm labor. Antenatal treatment of the FHT may reduce the amniotic fluid and eliminate the preterm labor. In cases in which treatment of the FHT fails to improve the polyhydramnios, reduction amniocentesis may be considered. If tocolysis is necessary, it may be appropriate to administer indomethacin (Lange et al., 1989).

FETAL INTERVENTION

There are several options in the management of the fetus with isolated FHT; the options depend on gestational age, severity of effusion, evidence of progression, and the presence or absence of hydrops, polyhydramnios, or mediastinal shift (Figure 38-2). A period of observation is recommended in each fetus with FHT because of the real possibility of spontaneous resolution. Simple observation may be the best option when the effusion is small and unilateral and there is no evidence of tension. In a fetus diagnosed with FHT prior to 24 weeks of gestation, termination of pregnancy is an option. In the fetus of greater than 32 weeks' gestational age, observation with postnatal thoracentesis may be the best option, but shunting may still be considered.

There are three forms of treatment available for managing the fetus with FHT prior to 32 weeks: thoracentesis, thoracoamniotic shunting, and thoraco-maternal cutaneous drainage. Thoracentesis is a diagnostic maneuver to obtain pleural fluid for cell count, differential, and culture and to establish whether the effusion is chylous. Even repeated thoracenteses provide inadequate decompression of the fetal chest.

Figure 38-2 Axial image demonstrating unilateral right hydrothorax with significant mediastinal shift.

There have been several reports of thoracentesis for FHT, performed with either complete resolution or a good outcome despite reaccumulation (Petres et al., 1982; Kurjak et al., 1985; Benacerraf et al., 1986). Others have had disappointing results with repeated thoracentesis for FHT because of rapid accumulation of the effusion and neonatal death from respiratory insufficiency (Longaker et al., 1989; Nicolaides and Azar, 1990; Weber and Philipson, 1992). Thoracentesis cannot adequately decompress the fetal chest to allow pulmonary expansion and prevent pulmonary hypoplasia (Longaker et al., 1989).

Thoracoamniotic shunting provides continuous decompression of the fetal chest, allowing lung expansion (Figure 38-3). If instituted early enough, this allows compensatory lung growth and prevents neonatal death from pulmonary hypoplasia. In a review of reported cases of thoracoamniotic shunting for FHT, the survival rate was 38 of 59 (65%) (Weber and Philipson, 1992). Nicolaides and Azar (1990) subsequently reported 48 cases of thoracoamniotic shunting, but there was no attempt to distinguish isolated primary FHT from secondary FHT. Despite intervention, the mortality rate was high. Four of the deaths were due to termination of pregnancy after a chromosomal abnormality was diagnosed. In addition, there were 12 neonatal deaths despite thoracoamniotic shunt placement, but these fetuses appeared to have severe nonimmune hydrops and secondary FHT. Two fetuses that died in utero also appeared to have had secondary FHT and severe hydrops. If the cases of secondary FHT are eliminated, the survival of cases with thoracoamniotic shunting is 38 of 41 (92%) (Gardner et al., 1983; Nicolaides and Azar, 1990; Weber and Philipson, 1992). This is a striking improvement as compared with the survival rate without treatment (50%). Wilson et al. (2004) recently reviewed experiences with thoracoamniotic shunting for pleural effusions reporting a survival rate of 67%. A similarly lower survival rate is observed if secondary cases of FHT are excluded.

The initial step in the management of all fetuses with FHT is a diagnostic thoracentesis for cell count, differential, and culture. The rapidity with which the effusion reaccumulates provides an indication of the severity of the FHT. Drainage of FHT also provides a better view of the heart for fetal echocardiogram. If hydrops is present and thought to be due to mediastinal shift from a unilateral FHT under tension, then thoracoamniotic shunting should be performed without delay. Since spontaneous regression is possible, a second thoracentesis should be performed in cases without hydrops. Drainage of the pleural effusion may allow apposition of visceral and parietal pleura to seal the chylous leak. If the effusion rapidly reaccumulates despite the second thoracentesis, then more definitive drainage is indicated.

The indications for thoracoamniotic shunting are not well defined. Most authors consider the presence of FHT-induced hydrops or polyhydramnios to be indications for shunting (Rodeck et al., 1988; Longaker et al., 1989; Weber and Philipson, 1992). In addition, we recommend

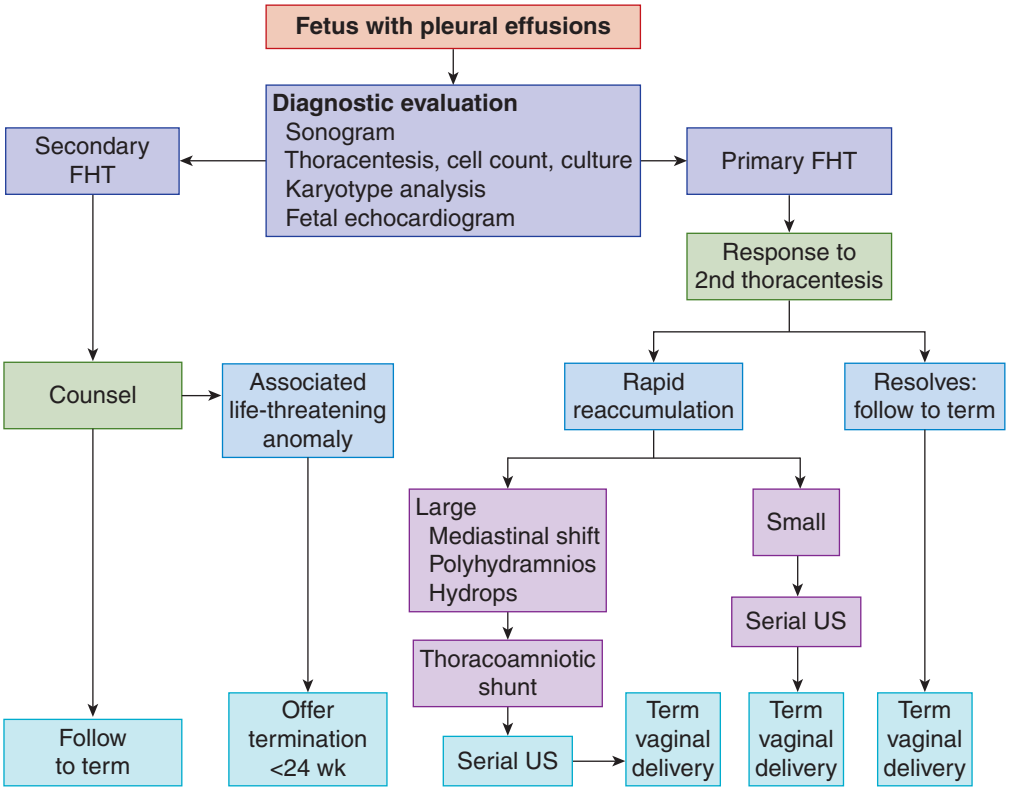

Figure 38-3 Algorithm for the management of fetal pleural effusions.

thoracoamniotic shunting for primary FHT with evidence of effusion under tension even in the absence of hydrops or polyhydramnios (Rigsby et al., 1998). Because spontaneous resolution has been observed even in severe cases of FHT, we reserve thoracoamniotic shunting for cases in which a tension hydrothorax persists after two thoracenteses. The two currently available catheters are the Harrison double-pigtail catheter (Cook Inc., Bloomington, IN) and the Rocket catheter (Rocket Co. Inc., Branford, CT). We have had excellent results with both catheters, which have pigtails at 90 degrees to each other so that the outer coil sits flush against the fetal chest. The trocar used for insertion is smaller for the Cook catheters that make it preferable to the Rocket catheter for earlier gestation fetuses. Laceration of an intercostal artery is possible with either catheter system. This is usually lethal (Wilson et al., 2004). The thoracoamniotic shunt is placed under ultrasound guidance after administering prophylactic tocolytic agents (terbutaline) to the mother; antibiotics (cefazolin, 1 g) are delivered to the amniotic cavity at the conclusion of the procedure. The mother may be admitted to the hospital overnight for serial ultrasound examinations to assess regression of FHT and improvement of hydrops and to be monitored for preterm labor. Weekly sonography is recommended to ensure continued function of the shunt.

Another therapeutic option is thoraco-maternal cutaneous drainage, as reported by Roberts et al. (1986). Adapting a technique first used by Liggins (1986) for intraperitoneal blood transfusions, a catheter was inserted into the fetal pleural cavity. This single case report is of historical interest, in which a chylothorax was successfully decompressed and external drainage maintained for 7 days, with complete resolution. The catheter was subsequently removed and there was a good neonatal outcome. Although no adverse effects were reported, infection remains a significant risk of this procedure and no other cases have been reported.

Large effusions, diagnosed early in gestation, are likely to progress to tension hydrothorax, hydrops, and neonatal death from pulmonary hypoplasia. We do not yet know what percentage of second trimester FHTs require intervention. We believe that evidence of tension, hydrops, or polyhydramnios indicates a worse prognosis. The limited experience with thoracoamniotic shunts suggests that they are extremely effective in decompressing the effusion and improving survival. The risks of thoracentesis and shunt placement to mother and fetus have been minimal and far outweighed by the potential benefits. Few complications have been reported for either fetal thoracentesis or thoracoamniotic shunts. There have even been cases of FHT occurring in twins that have been successfully treated (Grisaru-Granovsky et al., 2000; Lam et al., 2003; Van Mieghem et al., 2006). There has been a procedure-related fetal death due to torsion of the umbilical cord as a result of thoracentesis (Longaker et al., 1989). One case of migration of the shunt under the fetal skin has been reported, but required no intervention when the infant was born (Rodeck et al., 1988). There has been one reported case in which the trocar used to place the shunt lacerated the intercostal artery resulting in fetal demise (Wilson et al., 2004). There have been

no maternal complications reported with either thoracentesis or thoracoamniotic shunting. It should be recognized, however, that these procedures have the potential for infection, bleeding, premature rupture of membranes, preterm labor, and injury to the fetus (Rodeck et al., 1988; Longaker et al., 1989; Tsao et al., 2003; Wilson et al., 2004).

TREATMENT OF THE NEWBORN

We recommend delivery of the fetus with FHT in a tertiary-care setting, where appropriate neonatal resuscitation can be instituted immediately. The infant with an undrained pleural effusion may have pulmonary hypoplasia and is at risk for respiratory insufficiency. We do not see any advantage to fetal thoracentesis immediately prior to delivery. We recommend neonatal thoracentesis in the delivery room to avoid risk to mother and fetus. Fluid shifts caused by thoracentesis can be treated with volume infusion once intravenous access is established in the newborn. The infant who undergoes thoracoamniotic shunt placement should have the shunt clamped or removed during the delivery to prevent pneumothorax. Occasionally, the shunt will become dislodged during delivery. After the infant is resuscitated, chest radiography should be performed to exclude pneumothorax and evaluate the size of residual effusion.

SURGICAL TREATMENT

In the infant with congenital chylothorax without respiratory distress, a period of close observation is indicated. The majority of patients treated in utero do not require postnatal treatment. In the infant with modest effusions, a period of observation and diet manipulation should be initiated. A formula high in medium-chain triglycerides (e.g., Portogen) will bypass the lymphatic system by direct absorption into the bloodstream. This reduces thoracic duct lymphatic flow, which normally has a basal rate of 4 mL per kilogram of body weight per hour (Acevedo, 1943). In some patients, even modest enteral feedings may stimulate marked increases in lymphatic flow. If the chylothorax rapidly reaccumulates and requires repeated thoracentesis on this diet, then central access for total parenteral nutrition and bowel rest are indicated. This regimen is successful in the majority of cases of chylothorax. Tube thoracostomy should be reserved for large effusions that cause respiratory embarrassment despite repeated thoracentesis. Octreotide can be used as an adjunct to bowel rest and total parenteral nutrition and has been successful in treating chylous effusions. Prolonged continuous chest tube drainage can result in relative lymphopenia and an immunocompromised state. In the rare instances in which the chylothorax fails to resolve, thoracotomy for thoracic-duct ligation becomes necessary if chest tube drainage, bowel rest, total parenteral nutrition, and octreotide fail. The duration of nonoperative management in newborns should be at least 1 month because congenital chylothorax tends to close spontaneously. If severe lymphopenia results from long-term chest tube drainage or difficulty maintaining lung inflation is encountered, surgical intervention should be undertaken sooner.

The approach to ligation of the thoracic duct should be on the side of the chylothorax. The surgical objective should be ligation of the leaking tributary or ligation of the main trunk of the thoracic duct above and below the site of the leak, in addition to the overlying pleura at the site of the leak (Reynolds, 1998). In some instances, tissue adhesions such as fibrin glue may be helpful in sealing thoracic duct leaks in congenital chylothorax (Stenzl, 1983). In cases in which thoracic duct ligation fails, the use of pleuroperitoneal shunts for chylothorax has been effective in up to 75% of cases and can be accomplished thoracoscopically (Milsom et al., 1985; Murphy et al., 1989).

LONG-TERM OUTCOME

The majority of cases of congenital chylothorax due to primary FHT resolve spontaneously (Laberge et al., 1991). In Broadman's series, 19 of 20 patients were normal at an average follow-up period of 15 months (Broadman, 1975).

GENETICS AND RECURRENCE RISK

Primary FHT may be associated with a chromosomal abnormality in up to 5% of cases (Weber and Philipson, 1992). This is most often Down syndrome, but cases of Noonan and Turner syndromes have also been reported in FHT (Van Gerde et al., 1984). To date there have been no reports of primary FHT occurring in siblings or the subsequent offspring of an affected fetus.

39 CHAPTER Pulmonary Agenesis

Key Points

- Pulmonary agenesis is defined as complete absence or severe hypoplasia of one or both lungs.
- Pulmonary agenesis may be found in isolation or in association with other malformations.
- Bilateral agenesis of the lung is rare, and is incompatible with life; unilateral agenesis occurs more commonly, and may be compatible with normal life.
- Sonographically, the mediastinum is shifted toward the affected side and the diaphragm on the ipsilateral side is elevated.
- Detailed sonography and fetal magnetic resonance imaging (MRI) may distinguish unilateral pulmonary agenesis from other causes of mediastinal shift.
- Unilateral or bilateral pulmonary agenesis is not thought to be associated with chromosomal abnormalities.

CONDITION

Pulmonary agenesis is a rare developmental condition in which there is complete absence or severe hypoplasia of one or both lungs (Oyamada et al., 1953; Valle, 1955; Booth and Berry, 1967; Borja et al., 1970; Yaghmai, 1970; Costas et al., 1977; Boxer et al., 1978; McCormick and Kuhns, 1979; Shenoy et al., 1979; Mygind and Paulsen, 1980). Although quite rare, it was initially recognized by dePozzi in 1673 (Skandalakis and Gray, 1994). Munchmeyer was the first to diagnose unilateral agenesis of the lung clinically in 1885 (Ferguson and Neuhauser, 1944). There have since been more than 200 cases of unilateral agenesis of the lung reported. However, only 14 cases have been reported of bilateral agenesis of the lung (Allen and Affelbach, 1925; Tuynman and Gardner, 1952; Claireaux and Ferreira, 1957; Devi and More, 1966; Ostor et al., 1978; Faro et al., 1979; Diaz et al., 1989; Engellenner et al., 1989). In some cases, bilateral pulmonary agenesis was an isolated finding. In other cases, pulmonary agenesis was found in association with other anomalies in the gastrointestinal, genitourinary, and ocular systems (Tuynman and Gardner, 1952; Claireaux and Ferreira, 1957; Devi and More, 1966; Ostor et al., 1978).

A number of theories have been advanced to explain the pathogenesis of lung aplasia. Lung aplasia has been observed in experimental animals fed a diet deficient in vitamin A (Warkany et al., 1948). Some authors have suggested that there may be a vascular cause of pulmonary agenesis, similar to that invoked for intestinal atresia (Louw, 1959). Other authors have suggested a genetic cause for the pulmonary agenesis. Booth and McKenzie and their colleagues linked unilateral pulmonary agenesis to ipsilateral facial and jaw abnormalities, an association noted more recently by several authors (McKenzie and Craig, 1955; Booth and Berry, 1967; Kenawi and Dickson, 1976; Maymon et al., 2001; Dorchy, 2004; Priolo et al., 2004). The gene involved may have a variable expressivity and penetrance. However, the actual cause of this type of pulmonary agenesis remains obscure.

Bilateral agenesis of the lung is incompatible with life and, fortunately, is exceedingly rare (Engellenner et al., 1989). Unilateral agenesis occurs approximately 25 times more commonly, and it may be compatible with a normal life (Booth and Berry, 1967; Maltz and Nadas, 1968). Maymon et al. (2001) proposed a classification for the degree of underdevelopment of the lung that has been adopted by many authors. In Class I, there is agenesis of the lung or total absence of the bronchus and lung. In Class II, there is aplasia in which there is a rudimentary bronchus without lung tissue. In Class III hypoplasia there is bronchial hypoplasia and a variably reduced amount of lung tissue present. This classification scheme is most appropriately referred to as agenesis and hypoplasia, with Class I and II representing cases of agenesis, and Class III representing cases of hypoplasia.

Unilateral pulmonary agenesis is associated with a broad range of anomalies of other organ systems. The most common cardiac defect associated with unilateral agenesis is patent ductus arteriosus (PDA). Although PDA is a common neonatal finding, it may or may not relate directly to the nature of the underlying cause of the pulmonary agenesis. Another common finding is anomalous pulmonary venous drainage, either to the azygos vein or to a persistent left superior vena cava. Other cardiovascular anomalies that have been reported include left pulmonary artery posterior to the left bronchus, aorta anterior to the trachea and compressing it with the left pulmonary artery posterior to the trachea, an anomalous pulmonary venous drainage of the left lung to the right atrium, and four pulmonary veins on the right side. In addition, atrial and ventricular septal defects have been reported in association with pulmonary agenesis.

Although tracheoesophageal anomalies may accompany unilateral pulmonary agenesis, only 14 cases have been recorded thus far, one of which was tracheoesophageal fistula (Kitagawa et al., 1995; Steadland et al., 1995; Vittraino et al., 2003). Other gastrointestinal anomalies associated with pulmonary agenesis include duodenal atresia, annular pancreas, malrotation, Meckel diverticulum, and imperforate anus. Barium contrast studies may demonstrate deviation of the esophagus to the agenetic side, particularly when the right lung is absent. Occasionally the diaphragm may be deficient on either the ipsilateral or contralateral side, allowing eventration of the abdominal viscera. However, this diaphragmatic anomaly is more commonly seen accompanying pulmonary hypoplasia than agenesis.

The most common spinal abnormality seen in association with pulmonary agenesis is hemivertebrae (see Chapter 88). This can be seen in both agenesis of the lung and hypoplasia of the lung. The resulting scoliosis may be quite severe and produce an additional handicap in the child already suffering from recurrent respiratory infection. Such scoliosis may also be due to a rudimentary rim of lung tissue on the affected side. An abnormality of the spine or ribs in the cervical or thoracic regions may be attended by a more prominent scapula on the affected side.

In at least six cases, there have been associated facial or jaw abnormalities ipsilateral to the side of the pulmonary agenesis or hypoplasia (David et al., 1996; Cunningham and Mann, 1997). These abnormalities have included hemifacial microsomia, deformed left external ear, seventh nerve paralysis, small deformed right ear without a patent external auditory canal, facial asymmetry, torticollis, and unilateral mandibulofacial dysostosis (see Chapter 24).

Ipsilateral limb abnormalities have also been observed in many of these cases. These usually involve the upper extremity on the ipsilateral side (Cunningham and Mann, 1997; Aggarwal et al., 2002). While abnormalities of both the ulna and the radius and malformation of the carpus result in a smaller, less powerful hand and arm, the most characteristic abnormalities have been noted in the ipsilateral thumb. These included triphalangia; angulated thumb, in which the middle phalanx is hypoplastic; a preaxial polydactyly; and an abnormal thumb with a short first metacarpal. Some of these digital radial dysplasias fit the pattern of the Holt–Oram syndrome (Holt and Oram, 1960) and the ventriculoradial

dysplasia syndrome (Harris and Osborn, 1966). Because of the association of pulmonary agenesis, or vascular anomalies, gastrointestinal anomalies (tracheoesophageal fistula, imperforate anus), vertebral anomalies (fetal vertebrae or hemivertebrae), urogenital anomalies (renal agenesis, horseshoe kidney, hemiuterus), radial ray anomalies, and ipsilateral craniofacial anomalies (microtic facial asymmetry and hemifacial microsomia) have suggested that pulmonary agenesis should be considered part of the VACTERL Association (Knowles et al., 1988; David et al., 1996; Cunningham and Mann, 1997). At least 13 cases of unilateral pulmonary agenesis have now been reported as part of the VACTERL Association (Knowles et al., 1988; David et al., 1996; Bromley and Benacerraf, 1997; Cunningham and Mann, 1997; Chen et al., 2003).

INCIDENCE

The incidence of agenesis, either unilateral or bilateral, is uncertain. Based on a report of four cases among 114,569 hospital admissions Borja et al. (1970) suggested a prevalence of 0.0034%. During a 6-year period, four other patients were noted with unilateral agenesis among 41,403 admissions to the King Feisel Specialist Hospital and Research Center, which would represent a prevalence of 0.0097% or approximately 1 in 10,000 admissions, or 0.67% of the 596 patients who underwent cardiac catherization at that center (Mardini and Nyhan, 1985). Agenesis of the right lung and agenesis of the left lung are about equally common. Females are affected slightly more commonly than males, and the condition may be inherited (Schechter, 1968; Mardini and Nyhan, 1985).

There is no estimate of the prenatal incidence of pulmonary aplasia; however, Schechter (1968) has estimated an incidence of 1 in 15,000 based on autopsies. Both lungs are affected with equal frequency, although patients with left lung aplasia are thought to have a much better prognosis.

SONOGRAPHIC FINDINGS

The diagnosis of pulmonary agenesis is often made only at the time of autopsy. However, in recent years cases of unilateral pulmonary agenesis have been recognized prenatally (Engellenner et al., 1989; Becker et al., 1993; Yancey and Richards, 1993; Bromley and Benacerraf, 1997; Maymon et al., 2001; Viora et al., 2002; Chen et al., 2003). Sonographically, the mediastinum is shifted toward the affected side and the diaphragm on the ipsilateral side is elevated. Care should be taken to distinguish pulmonary hypoplasia caused by compression from a diaphragmatic hernia or cystic adenomatoid malformation from unilateral agenesis. The sonographic features of unilateral pulmonary agenesis include medial mediastinal shift to the agenetic side and enlarged echogenic lung herniating into the contralateral chest anterior and/or posterior to the mediastinum. There may be associated scoliosis with a curve toward the agenetic side with or without hemivertebrae. Because of the frequency of associated anomalies in pulmonary agenesis affecting other organ systems, a careful sonographic examination should be performed, including scanning of the vertebrae, heart, and limbs and the genitourinary and central nervous systems. There is an association with ipsilateral radial ray defects and hemifacial microsomia. The presence of bilateral facial or radial ray anomalies may be seen in bilateral pulmonary agenesis (Cunningham and Mann, 1997). Renal abnormalities including dysplasia, pelvic kidney, and horseshoe kidney have been reported with unilateral pulmonary agenesis, as has encephalocele (Becker et al., 1993; Cunningham and Mann, 1997; Eroglu et al., 2005). Both polyhydramnios and oligohydramnios have been reported in pulmonary agenesis (Engellenner et al., 1989). In the single case of nonimmune hydrops reported in a fetus with unilateral pulmonary agenesis, it was thought to be due to partial closure of the ductus arteriosus in an otherwise structurally normal heart (Engellenner et al., 1989).

While opacification of the ipsilateral hemithorax occurs with displacement of the mediastinum in the direction of the agenetic lung, Roque et al. (1997) reported a postnatal patient in which this was not the case. In that patient the mediastinum was not displaced, but the liver and the intact diaphragm were displaced cephalad. Fetal magnetic resonance imaging (MRI) has been helpful in distinguishing unilateral pulmonary agenesis from other causes of mediastinal shift (Hubbard and Crombleholme, 1998). MRI clearly demonstrates the compensatorily enlarged unilateral lung shifting over into the contralateral hemithorax with shift of the heart and mediastinal structures to the agenetic side (Figures 39-1 and 39-2).

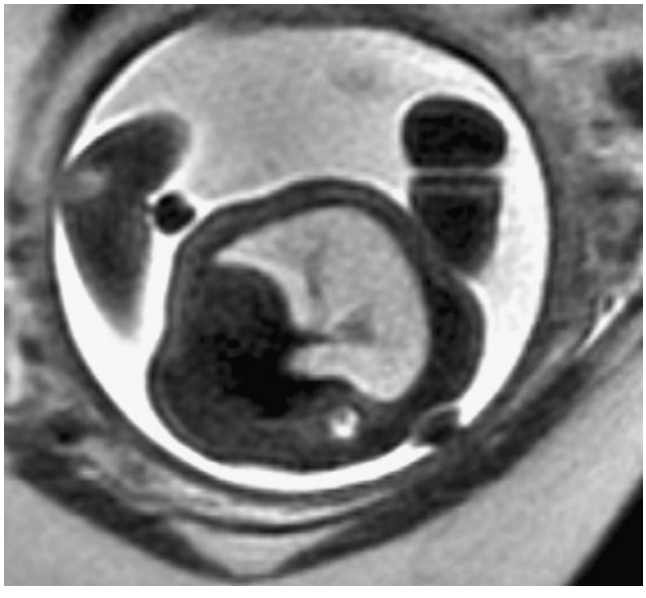

Figure 39-1 Axial image on fetal MRI demonstrating the compensatorily enlarged single lung with shift of mediastinum away from the lung toward the side of the agensis.

Figure 39-2 The same fetus on sagittal MRI image demonstrating the shift of the heart to the right.

DIFFERENTIAL DIAGNOSIS

Bilateral pulmonary agenesis is not generally mistaken for other conditions. However, at least one case report raised bilateral diaphragmatic hernia in the differential of bilateral pulmonary agenesis (Vittraino et al., 2003). Unilateral agenesis, however, must be distinguished from other conditions that cause mediastinal shift, including diaphragmatic hernia, cystic adenomatoid malformation, and bronchopulmonary sequestration (Bromley and Benacerraf, 1997) (see Chapters 34–37) as well as emphysema.

ANTENATAL NATURAL HISTORY

The coexistence of pulmonary agenesis with other malformations suggests that an interference with embryologic development in the 4th week of fetal life is responsible for these defects. The primitive lung buds are forming at the fourth week of embryonic life, when the pulmonary venous system is changing from its early association with systemic venous circulation to make a connection with the left atrium. An insult occurring at this time, along with the laryngotracheal groove on the ventral surface of the foregut, could interrupt lung-bud development and interfere with the establishment of normal pulmonary venous return. This could account for the frequently observed anomalous pulmonary venous return seen in association with pulmonary agenesis. While the bilateral cases of lung agenesis are incompatible with life, a better prognosis exists for unilateral agenesis. As noted by Maltz and Nadas (1968), 24 of 36 patients followed since 1954 were alive at the time of their report in 1968. In unilateral agenesis there is an uncertain incidence of fetal death, stillbirth, and death during the immediate neonatal period from respiratory distress. These infants remain at risk for recurrent bronchopulmonary infections, which is the leading cause of death. The second most common cause of death is related to associated congenital anomalies, primarily cardiac in cause. While studies have demonstrated that resting pulmonary arterial pressures are normal in these infants, there have been questions raised about the ability for the pulmonary vascular bed to accept increases in cardiac output when stressed. However, it has been recognized that, in the absence of increased pulmonary blood flow related to anomalous pulmonary venous return or other congenital heart defect, the pulmonary vascular bed behaves relatively normally in these children. Ryland and Reid (1971) have performed detailed morphometric analysis of a child who died at 3 months of age from infectious causes with unilateral pulmonary agenesis (Ryland and Reid, 1971). The findings that they reported included a decrease in the number of pulmonary vascular generations, as well as tracheobronchial divisions. However, there was a normal complement of alveoli for two lungs that had been concentrated in the single lung. Right-sided pulmonary agenesis carries a worse prognosis than that of left-sided lesions (Oyamada et al., 1953; Schaffer and Rider, 1957; Smith and Beck, 1958; Steinberg and Stein, 1966; Gabarre et al., 2005). Right-sided lesions result in death earlier and at a greater frequency. This is thought to be due to the fact that 50% of cases of right-sided pulmonary agenesis have associated anomalies—including severe cardiac abnormalities (Gabarre et al., 2005), whereas left-sided lesions are more often isolated. This higher mortality may also be due to the greater mediastinal shift produced by right-sided agenesis, leading to more significant distortion of the tracheobronchial and vascular structures (Thurlbeck, 1975).

MANAGEMENT OF PREGNANCY

Any fetus in which bilateral pulmonary agenesis is suspected should have a detailed sonographic assessment to confirm the diagnosis. MRI may be particularly helpful in distinguishing pulmonary agenesis from congenital cystic adenomatoid malformation of the lung and labor emphysema. In addition, MRI may complement ultrasound in distinguishing unilateral pulmonary agenesis from aplasia (in which, unlike agenesis, the bronchial trunk is seen as a rudimentary stump) and hypoplasia, in which there is arrest of fetal bronchial development (Gabarre et al., 2005). If bilateral pulmonary agenesis is confirmed, the parents should be advised of the uniformly

fatal outcome. Termination is an option if the pregnancy is at less than 24 weeks. If the diagnosis is made at a later gestational age, the delivery should be planned without monitoring for fetal distress. In addition, the neonatologist should be aware of the diagnosis so that no futile heroic resuscitative efforts are made.

In the case of unilateral pulmonary agenesis, detailed sonographic and MRI examination should be performed to confirm the diagnosis and to exclude any associated abnormalities. Of particular interest is the ipsilateral upper extremity, kidneys, face, and mandible. In addition, spinal and rib abnormalities may be seen in unilateral agenesis. The volume of amniotic fluid is important to note, as both esophageal atresia and tracheoesophageal fistula have been reported with unilateral pulmonary agenesis, which may cause polyhydramnios (Thomas and Boyden, 1952). Conversely, oligohydramnios has been observed in one case of unilateral pulmonary agenesis associated with bilateral renal agenesis. Because of the frequency of associated cardiac anomalies in unilateral pulmonary agenesis, echocardiography should be performed in every patient. Unless there are other indications, such as an abnormal serum screen or sonographic markers of aneuploidy, there is no need to perform amniocentesis because pulmonary agenesis is not associated with an increased incidence of chromosomal abnormalities.

FETAL INTERVENTION

There are no fetal interventions for pulmonary agenesis.

TREATMENT OF THE NEWBORN

Fifty percent of children with pulmonary aplasia are stillborn or die within the first few years of life. Because of potential problems with the airway or pulmonary hypoplasia, delivery in a tertiary care center with neonatologists in attendance and a pediatric surgeon available is advisable. Once respiratory status has been assessed, a nasogastric tube should be inserted to exclude esophageal atresia. A detailed physical examination should be performed to evaluate possible VACTERL-associated anomalies. A plain chest radiogram will show shift of the mediastinum toward the affected side (Figure 39-3). There may be bony spinal anomalies and a thoracic asymmetry not appreciated on the physical examination. The diaphragm may be quite high on the ipsilateral side, but it is not paralyzed and it functions normally. The agenetic hemithorax is opaque in contrast to the contralateral side, which may appear overinflated. In contrast, in cases of cystic adenomatoid malformation of the lung and bronchopulmonary sequestration, the ipsilateral hemithorax is cystic or opaque. In addition, unilateral pulmonary agenesis should be distinguished from severe scoliosis by the presence of two lungs. Symptoms may develop in infants with

Figure 39-3 Plain chest radiogram of an infant with unilateral right pulmonary agenesis. The left lung appears hyperinflated and rotated into the right hemithorax. The agenetic side is radiopaque and there is mediastinal shift toward the agenetic side.

lung agenesis because of distortion of the airway from severe shift or vascular compression (Harrison and Hendren, 1975; Newman and Gandor, 1997). Three-dimensional chest computed tomography (CT) or MRI scanning may be valuable in defining airway and vascular anatomy for planning a surgical strategy (Wu et al., 1996).

LONG-TERM OUTCOME

Patients who survive with unilateral lung aplasia are thought to be at risk for recurrent respiratory infections due to the rudimentary bronchus. Patients with pulmonary agenesis do not appear to be at increased risk of infectious complications. There have been at least three children with pulmonary aplasia who have died from aspiration of a foreign body, which obstructed their only bronchus (Thomas and Boyden, 1952). Schaffer and Rider (1957) suggested that the survival of patients with pulmonary aplasia was worse with absence of the right lung as compared with absence of the left. The incidence of respiratory infections is higher in patients with Class II and III defects, in which there is interrupted formation of the bronchial tree with absence of alveoli or the entire lung is reduced in size or one lobe of the lung is absent. Schaffer (1960) suggested that the remaining bronchi on the affected side provide a constant source of infection for the contralateral normal lung.

In a detailed morphometric analysis of a child with right pulmonary aplasia, Ryland and Reid found several abnormalities in the remaining lung. There was a reduction in the number of branches in the tracheobronchial tree, which they suggested may be due to an intrinsic abnormality that had affected the two lung buds unequally (Ryland and Reid, 1971). However, despite abnormalities in this lung, it achieved a compensatory cell population appropriate for two normal lungs. The patients with pulmonary agenesis may be at risk for the development of progressive mediastinal shift over time that may present as the equivalent of postpneumonectomy syndrome (Dobremez et al., 2005).

GENETICS AND RECURRENCE RISK

Unilateral or bilateral pulmonary agenesis is not thought to be associated with chromosomal abnormalities. An exception to this is a single case of unilateral pulmonary agenesis associated with velocardiofacial syndrome due to deletion of 22q 11.2 (Conway et al., 2002). While no familial tendency has been recognized, there is one case reported in which pulmonary agenesis occurred in offspring of an affected patient. In addition, unilateral pulmonary aplasia has been reported in both members of two sets of identical twins (Yount, 1948).

40 CHAPTER Esophageal Atresia and Tracheoesophageal Fistula

Key Points

- Occurs in 1 in 3000 livebirths.
- Fifty percent of cases have associated anomalies, most commonly cardiac, but also genitourinary, anorectoal, and musculoskeletal.
- Sonographic diagnosis is inferred by absence of the fetal stomach with polyhydramnios.
- Differential diagnosis includes congenital diaphragmatic hernia, situs inversus, and musculoskeletal or neurologic abnormalities.
- Chromosome abnormalities are present in 6% to 10% of cases. Fetal karyotype is indicated. Fetal echocardiogram should be performed.
- Delivery is not mandated at a tertiary care center.
- Long-term outcome may be complicated by esophagitis, recurrent strictures, and the development of Barrett's mucosa.
- Mutations in the genes *N-MYC*, *CHD7*, and *SOX2*, which cause Feingold syndrome, CHARGE syndrome, and anophthalmia, esophageal atresia, and genital (AEG) syndrome, respectively, are important genetic causes of esophageal atresia.

CONDITION

Tracheoesophageal anomalies probably arise as a result of events that occur around the 4th week of gestation. The trachea and esophagus first develop as a ventral diverticulum off of the foregut at 22 to 23 days of gestation (Skandalakis et al., 1994). This diverticulum elongates and there is an influx of endodermal cells that form ridges of tissue, which divide the foregut into esophageal and tracheal lumens beginning at the carina and progressing cephalad. By the 26th day of gestation the esophagus and trachea have become completely separated up to the level of the larynx. Interruption in the ingrowth of ectodermal ridges is thought to result in tracheoesophageal fistula. However, the cause of esophageal atresia when associated with tracheoesophageal fistula is less well understood. One theory suggests that rapid caudal elongation of the trachea, in the presence of a distal tracheoesophageal fistula, produces fixation of the distal esophagus to trachea (Smith, 1957; Moore and Pessaud, 1993). The dorsal wall of the esophagus is drawn forward and downward to be incorporated with the trachea, and esophageal atresia results. Consequently, the esophageal atresia associated with tracheoesophageal fistula occurs as a direct result of the presence of the fistula. In contrast, isolated, or pure, esophageal atresia is thought to arise as a result of a vascular deficiency.

More recently, mutations in the hedgehog (Hh) signaling pathway have been implicated in the development of tracheoesophageal fistula (Lees et al., 2005). Studies in transgenic mouse models examining the effects of homozygous sonic hedgehog (*Shh*) knockout mutations demonstrate esophageal atresia and tracheoesophageal fistula (Litingtung et al., 1998; Ramalho-Santos et al., 2000). The foregut abnormalities become evident as early as embryonic day 9.5 in the mouse when the tracheal diverticulum is developing. The role of hedgehog signaling in esophageal atresia and tracheoesophageal fistula is further supported by *Gli* 2−/− and *Gli* 3+/− double knock out mice. These mutations are downstream from sonic hedgehog and also result in esophageal atresia and tracheoesophageal fistula (Lees et al., 2005). Studies performed on biopsies of proximal and distal esophagus in infants undergoing repair of esophageal atresia (EA) and tracheoesophageal fistula (TEF) demonstrated that *Shh* expression was present in the proximal esophagus, but absent in the distal esophagus by both immunohistochemistry and RT-PCR (Spilde et al., 2003).

INCIDENCE

The various forms of esophageal atresia constitute one of the most common gastrointestinal anomalies, occurring in 1 in 3000 livebirths (Holder et al., 1964). The embryologic events at approximately 28 days of gestation that result in esophageal atresia can result in a spectrum of anomalies (Figure 40-1). Isolated esophageal atresia occurs in only 1 in 15,000 livebirths (Figure 40-1A), but esophageal atresia is most commonly seen in association with distal esophageal fistula (Figure 40-1C), in 86% of the observed cases (Holder et al., 1964). Approximately one half of patients with esophageal atresia have anomalies of other organs. Cardiac malformations are the most common, occurring in approximately 25% of cases. They are responsible for most of the mortality and morbidity associated with esophageal atresia (Landing, 1975; Greenwood and Rosenthal, 1976). Atrial and ventricular septal defects are the most common cardiac abnormalities. Genitourinary, additional gastrointestinal, anorectal, and musculoskeletal anomalies occur in approximately 10% of the cases (David and O'Collaghan, 1975; Manning et al., 1986; Spitz et al., 1993) (Table 40-1). These anomalies tend to cluster in groups as part of the "VACTERL" association—*v*ertebral, *a*norectal, *c*ardiac, *t*racheal, *e*sophageal, *r*enal, and *l*imb anomalies.

Maternal exposure to the teratogen methimazole is associated with esophageal and tracheal defects (Shaw-Smith, 2006).

SONOGRAPHIC FINDINGS

It is important to recognize that the diagnosis of esophageal atresia is inferred from the presence of polyhydramnios and

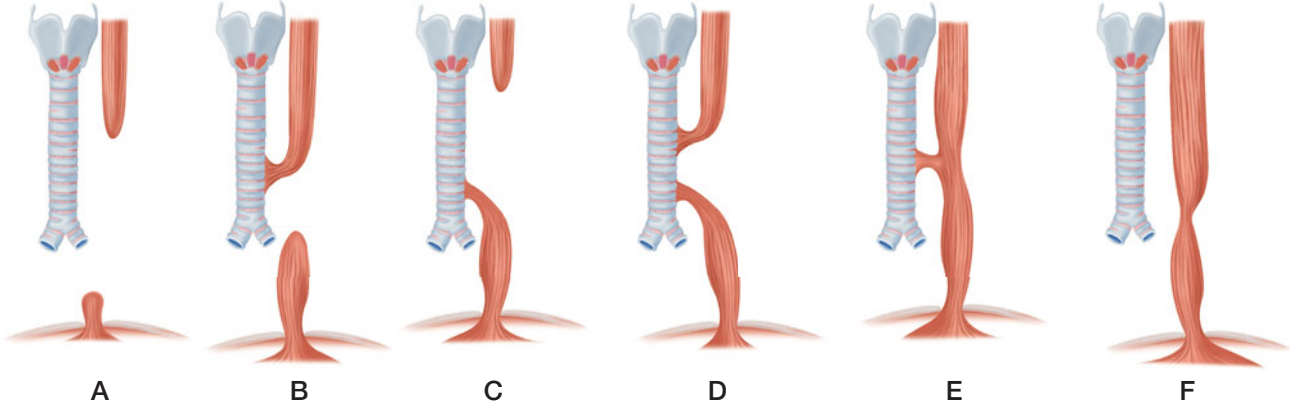

Figure 40-1 Types of esophageal anomalies.

Table 40-1

Incidence of Associated Anomalies in Esophageal Atresia

Anomalies	Percent
Cardiovascular	35
Gastrointestinal	15
Neurologic	5
Genitourinary	5
Skeletal	2
VACTERL association	25
Overall incidence	50–70

the absence of a fetal stomach. This combination of findings has a positive predictive value ranging from 30% to 70% for esophageal atresia (Pretorius et al., 1987; Stringer et al., 1995; Crombleholme et al., 1996). Observation of the dilated proximal pouch is a far more specific finding for esophageal atresia, but this is difficult to see in most fetuses with esophageal atresia (Figure 40-2).

Sonographic observation of fetal breathing movements, swallowing, and general muscular activity should be assessed whenever the stomach bubble is not observed, in order to exclude a neuromuscular cause. Failure to observe the fetal stomach may also occur in normal fetuses because of variations in swallowing and gastric emptying. Serial ultrasound examinations are useful to distinguish this cause of absent fetal stomach. However, visualization of a normal-appearing stomach does not exclude the diagnosis of esophageal atresia. Even in isolated esophageal atresia, gastric secretions alone may be sufficient to distend the stomach and make it visible on prenatal sonography. In esophageal atresia associated with a distal tracheoesophageal fistula, amniotic fluid may be inhaled and passed into the stomach. When the size of the tracheoesophageal fistula is small and limits flow of fetal lung fluid, polyhydramnios develops (Bovicelli et al., 1983).

DIFFERENTIAL DIAGNOSIS

Prenatal diagnosis of esophageal atresia is suspected when polyhydramnios is seen in association with an absent stomach bubble (Figure 40-3) (Farrant, 1980; Zemlyn, 1981; Bovicelli et al., 1983). Considerations in the differential diagnosis of these findings include congenital diaphragmatic hernia,

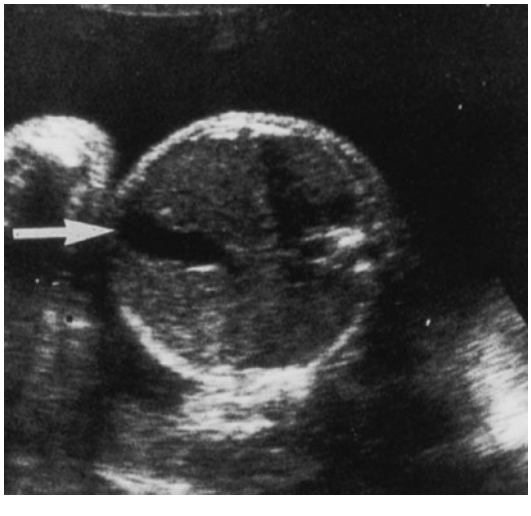

Figure 40-3 Sonographic image of absent stomach with polyhydramnios in fetus with esophageal atresia. *(From Robertson FM, Crombleholme TM, Paidas M, et al. Prenatal diagnosis and management of gastrointestinal anomalies.* Semin Perinatol. *1994;18:182-195.)*

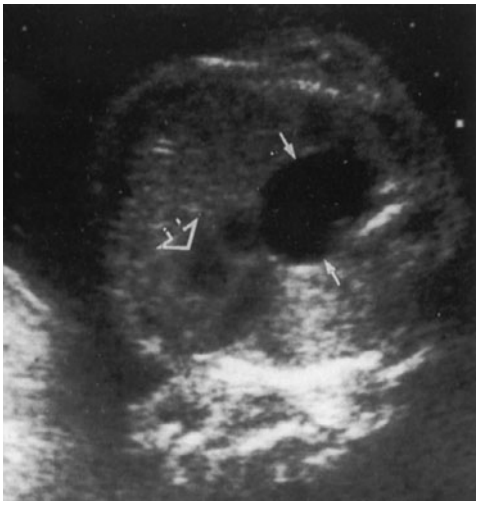

Figure 40-4 Sonographic image of a fetus with esophageal atresia, demonstrating dilated proximal esophageal pouch. *(From Estroff JA, Parad RB, Share JC, et al. Second trimester prenatal findings in duodenal and esophageal atresia without tracheoesophageal fistula.* J Ultrasound Med. *1994;13:375-379.)*

situs inversus, and musculoskeletal or neurologic anomalies that result in fetal inability to swallow. Some authors argue that prenatal diagnosis of esophageal atresia is possible only in isolated esophageal atresia, which accounts for only 10% to 15% of esophageal anomalies. Rarely, a dilated proximal esophageal pouch may be visualized, which is diagnostic of esophageal atresia (Estroff et al., 1994) (Figure 40-4). A dilated proximal esophageal pouch ending at the point of atresia with regurgitation after swallowing has been observed on prenatal ultrasound examination in cases of pure esophageal atresia (Bowie and Clair, 1982; Eyheremendy and Pfister, 1983). Absence of the stomach on ultrasound examination is commonly seen in isolated esophageal atresia, but may also be observed in esophageal atresia with tracheoesophageal fistula. Prenatal sonographic absence of the fetal stomach may also be seen in neuromuscular disorders due to absence of normal fetal swallowing. Severe central nervous system disorders can diminish fetal swallowing and breathing, resulting in an absent stomach bubble and polyhydramnios (Bowie and Clair, 1982).

ANTENATAL NATURAL HISTORY

It remains controversial as to whether prenatal diagnosis of EA with or without TEF alters the prognosis of this condition. Some have argued that early detection allows appropriate counseling of parents, screening for potential associated anomalies, and appropriate delivery setting for postnatal care (Kalish et al., 2003). Despite these theoretical advantages of prenatal diagnosis, some studies have shown no improvement in neonatal outcomes. Increases in perinatal loss rates have been demonstrated among antenatally detected cases of EA/TEF (Nicolaides et al., 1992; Stringer et al., 1995). It has therefore been suggested that prenatally diagnosed cases have a higher incidence of associated anomalies and attendant morbidity. Sparey et al. (2000) also attributed the worse prognosis in prenatally detected cases to the high incidence (60%) of associated anomalies, including cardiac, genitourinary, skeletal, and chromosomal abnormalities. These additional abnormalities may make it more likely that the cases would be identified prenatally.

MANAGEMENT OF PREGNANCY

All pregnant women in whom a fetus with esophageal atresia is suspected because of observed polyhydramnios and absent stomach or dilated proximal pouch should undergo a thorough sonographic survey for potential associated anomalies (see Table 40-1). In particular, evidence of spinal, limb, genitourinary, and cardiac anomalies should be sought. Each fetus should undergo echocardiography to exclude associated structural heart disease.

The fetal karyotype should be determined because chromosomal abnormalities in 6% to 10% of cases (Shaw-Smith, 2006). The most common chromosomal abnormalities observed have been trisomies 18 and 21 (Felix et al., 2007). Esophageal atresia and/or tracheoesophageal fistula are found in 1% of infants with trisomy 21 and up to 25% of infants with trisomy 18. Other chromosome abnormalities that are associated with esophageal atresia and tracheoesophageal fistula include deletions of bands 17q22-23, 13q32, and 22q11 (Shaw-Smith, 2006).

Polyhydramnios may complicate up to 62% of cases of esophageal atresia. This usually develops during the third trimester (Pretorius et al., 1987). Polyhydramnios predisposes to preterm labor, and active measures to continue the pregnancy may be required, including bed rest, administration of tocolytic agents, and/or reduction amniocenteses. The role of reduction amniocentesis in this setting is undefined, but in general is reserved for cases of maternal respiratory compromise. In cases of uterine irritability caused by polyhydramnios, betamethasone can be administered to hasten fetal lung maturity before delivery. The overall prognosis of tracheoesophageal anomalies depends on the presence of associated anomalies, the infant's physiologic status, respiratory complications, and gestational age. In the absence of severe cardiac anomalies and chromosomal abnormalities, survival is greater than 95% in infants weighing more than 2.5 kg following repair of esophageal atresia and tracheoesophageal fistula (Spitz et al., 1993).

The pregnancy should be monitored during the third trimester for the development of worsening polyhydramnios and secondary preterm labor. Once appropriate screening has been performed to exclude potential associated anomalies, the delivery plan can be made. In general, there is no need to transfer care to a tertiary care center. However, the patient should be aware that if esophageal atresia is confirmed postnatally the newborn will require immediate transport to a tertiary care center with pediatric surgeons capable of

reconstructing the anomaly. The presence of esophageal atresia has no implications for the mode of delivery. Cesarean section should be reserved for obstetric indications and there is no need to alter the timing of delivery.

FETAL INTERVENTION

There are no fetal interventions for esophageal atresia and tracheoesophageal fistula.

TREATMENT OF THE NEWBORN

At birth, Replogle sump tube should be positioned in the proximal esophageal pouch and placed to low, continuous suction to prevent aspiration of secretions. Chest radiography showing the sump tube coiled in the proximal pouch is consistent with a diagnosis of esophageal atresia. Rarely a Replogle tube will coil in the pharynx of a normal infant. In isolated esophageal atresia, plain radiography reveals a gasless abdomen. If a tracheoesophageal fistula is present, bowel gas will be seen. The infant should be maintained in an upright position and given antibiotics, and H_2 blockers intravenously. Because of the reported 7% incidence of proximal esophageal pouch–tracheal fistulas (Figure 40-1D) and the possibility of coiling of a sump tube in the pharynx, despite a normal esophagus, some groups perform contrast studies or bronchoscopy/esophagoscopy at the time of repair.

SURGICAL TREATMENT

After considering gestational age, birth weight, pulmonary function, and the presence of other associated anomalies, a decision is made whether to perform a reconstructive procedure or a staged repair. In the extremely premature infant, or a newborn of any gestational age with tracheoesophageal fistula complicated by pneumonia, a feeding gastrostomy can be performed, with or without closure of the tracheoesophageal fistula, and definitive repair can be deferred until the infant's clinical status improves (Louhimo and Lindahl, 1983; Spitz, 1996; Orford et al., 2004).

In cases of isolated esophageal atresia, the gap between proximal and distal pouches is usually prohibitively long (Figure 40-1A). In these cases, a gastrostomy tube is placed to allow enteral feeding. Bolus feedings are employed to encourage gastroesophageal reflux to facilitate growth and dilation of the distal pouch. The growth of the proximal and distal pouches will be maximal between 10 and 12 weeks of postnatal age (Puri et al., 1981). In the meantime, nasopharyngeal suction is maintained to clear saliva, and H_2 blockers are administered to prevent severe esophagitis. Serial contrast studies are performed every few weeks to assess growth of the pouches so that reconstruction may be undertaken as soon as possible. One risk of this approach is aspiration pneumonia. If the infant's respiratory status has been compromised because of aspiration of secretions, this form of therapy must be abandoned. A cervical esophagostomy is then performed to drain salivary secretions. This results in foreshortening of the proximal esophageal pouch and necessitates an esophageal replacement procedure using either colon interposition or a gastric tube. These procedures are usually not performed until approximately 1 year of age.

The prolonged hospitalization, expense, risk of salivary aspiration, and, most importantly, lost opportunity to reconstruct the infant's native esophagus have led some surgeons to attempt a primary repair during the newborn period. Spitz et al. (1987) have reported some success with the gastric pullup of so-called long-gap esophageal atresia. The advantages of this approach include briefer hospitalization, lower cost, and early return to normal feeding. The use of this procedure in the United States is not widespread because of the ongoing risk of aspiration from pooling of secretions in the intrathoracic gastric reservoir and compromise of respiratory function secondary to mass effect of the gastric pullup in the posterior mediastinum.

A basic tenet of all reconstructive esophageal surgery is the preservation of the native esophagus whenever possible. True to this tenet, Kimura and Soper (1994) have proposed an ingenious operation for long-gap esophageal atresia. The infant's proximal esophagus is mobilized through an incision into the right neck and a spiral myotomy is performed to lengthen the esophagus. The esophagus telescopes like a "barber shop pole" and the muscular layers are reapproximated. This gives sufficient length to create an esophagostomy at the level of the nipples. A gastrostomy tube is placed for enteral feeding, but sham feedings can be commenced to preserve the coordination of normal swallowing. In addition, an esophagostomy positioned on the chest instead of at the clavicle allows placement of an ostomy appliance for ease of care. Normal neck movement then stretches the proximal esophagus. In a series of two or three procedures, the stoma is advanced 1.5 to 2.5 cm to lengthen the proximal esophagus. When sufficient length has been obtained, the esophagus can be reconstructed through a right thoracotomy. The advantages of this approach include discharge from hospital within the first 10 days of life, maintenance of normal swallowing coordination by sham feedings, cost reduction, and, most importantly, a reconstruction that preserves the infant's native esophagus. There is limited experience with this approach and no data on long-term outcome are yet available.

LONG-TERM OUTCOME

In cases of esophageal atresia, the motor function of the distal esophageal pouch never becomes normal because of its interruption during embryologic life. Manometric studies of the distal esophageal pouch have demonstrated that it lacks normal peristalsis and the stripping activity usually observed after

reflux of acid into the distal esophagus. In addition to motor disturbances, the sensory innervation of the distal esophagus does not appear to be as robust as that of the normal esophagus. Also, due to foreshortening of the intra-abdominal esophagus, the lower esophageal sphincter appears to be less competent than in normal infants. All these factors predispose to gastroesophageal reflux and the potential for severe esophagitis. A more significant consequence is the development of strictures at the anastomosis, which occurs as a result of acid injury in this area. To prevent these complications, all infants with tracheoesophageal fistula should be on H_2-blocker therapy to prevent injury from gastroesophageal reflux. In instances in which recurrent anastomotic strictures occur despite repeated dilation and adequate medical therapy, antireflux procedures, such as Nissen fundoplication, are often indicated.

As experience has grown with repair of esophageal atresia and tracheoesophageal fistula, it has become more widely recognized that these children are at risk for the subsequent development of Barrett's mucosa from prolonged and severe gastroesophageal reflux. Barrett's mucosa is the result of metaplastic changes in the mucosa of the distal esophagus. This is a premalignant condition and requires close endoscopic surveillance with biopsies to detect dysplastic changes that precede the development of esophageal carcinoma. Esophageal carcinoma has developed after repair of tracheoesophageal fistula in patients as young as 21 years of age (Adzick et al., 1989). It is presumed that these malignancies arose within areas of Barrett's mucosa, which were caused by severe untreated gastroesophageal reflux. While both Barrett's mucosa and esophageal carcinoma are rare in children with repair of esophageal atresia and tracheoesophageal fistula, the incidence is uncertain. It is recommended that all children with this anomaly undergo endoscopic surveillance periodically to ensure that clinically silent gastroesophageal reflux has not resulted in severe esophagitis predisposing to the development of Barrett's mucosa.

Because of the abnormal motility in the reconstructed esophagus of the child with esophageal atresia with tracheoesophageal fistula, the motility in this organ is never quite normal. These children are prone to the impaction of food boluses at the anastomosis. This may occur even in the absence of a true anastomotic stricture. The reason for this is the disordered motility in the distal esophageal pouch, which does not move the food bolus normally into the stomach. All parents should be advised that once their infant begins eating solid food the pieces should be small and that they should learn to chew their food very well. This problem with impaction of food in the esophagus usually becomes less frequent as the child grows and the caliber of the esophagus increases.

GENETICS AND RECURRENCE RISK

The birth of an infant with an isolated esophageal atresia and/or tracheoesophageal fistula and a negative family history carries a low recurrence risk, on the order of 1% (Van Staey M et al., 1984; Pletcher et al., 1991; Shaw-Smith, 2006). The recurrence risk for a chromosome abnormality depends on the parental age and their chromosome status, if a chromosome deletion was found in the fetus or infant.

Recently, mutations in three different genes, *N-MYC*, *CHD7*, and *SOX2*, have been shown to be causative in syndromes that include esophageal atresia as one feature. The first condition, Feingold syndrome, is an autosomal dominant disorder in which 40% of patients have a gastrointestinal atresia. Esophageal atresia is the most frequent GI atresia in this syndrome. Affected individuals have other subtle anomalies, including microcephaly, shortening of the second and fifth fingers, hypoplastic thumbs, and syndactyly of the toes (Brunner and van Bokhoven, 2005; Shaw-Smith, 2006). The condition results from heterozygous mutations in the *N-MYC* gene. It is thought that this syndrome is underdiagnosed (Layman-Pleet et al., 2007). Diagnostic DNA mutation testing is available. If a mutation is identified, the parents should have their DNA studied.

Approximately 10% of patients with CHARGE syndrome (coloboma, heart malformation, choanal atresia, growth and/or mental retardation, genital abnormalities, ear anomalies and/or deafness) have esophageal atresia. Charge syndrome is due to haploinsufficiency of the gene *CHD7*. DNA testing is also available for this condition. Lastly, anophthalmia, esophageal atresia, and genital (AEG) syndrome have been shown to be due to loss of function mutations in the *SOX2* gene.

Tachyarrhythmias

41
CHAPTER

Key Points

- Fetal tachyarrhythmias include isolated extrasystoles, supraventricular tachycardia, and atrial flutter.
- Approximately 1% of fetuses are diagnosed with an arrhythmia.
- Isolated extrasystoles are the most common tachyarrhythmias and are for the most part benign.
- Supraventricular tachycardia is the most common serious dysrhythmia detected prenatally. The majority are re-entrant and are identified by a fetal heart rate of greater than 200 beats per minute with one-to-one atrial-to-ventricular activity. Congenital heart disease is associated with this arrhythmia 5% to 10% of cases.
- The rate with atrial flutter is usually between 300 and 500 beats per minute. The ventricular response depends on the degree of atrioventricular block. This dysrhythmia has a poor prognosis due to the fact that it is associated with hydrops and with congenital heart defects.
- Fetal dysrhythmias have the potential for serious sequelae including fetal hydrops.
- Fetal arrhythmias are diagnosed by fetal echocardiography that includes M-mode assessment and Doppler analysis. A full anatomical survey including a detailed survey of the fetal heart should also be performed.
- Although premature atrial and ventricular contractions are considered benign, sustained tachyarrhythmia may develop in up to 1% of fetuses diagnosed with this condition. Thus, serial fetal heart rate auscultation is suggested.
- Spontaneous resolution of supraventricular tachycardia has been reported.
- For the most part, fetal supraventricular tachycardia associated with congenital heart defects has been associated with a poor prognosis.
- Gestational age is an important factor when determining how best to manage a fetal dysrhythmia.
- Digoxin is the first-line therapy for isolated fetal tachyarrhythmia. Procainamide, flecainide, and sotolol are reserved for second-line treatment.
- If hydrops is concomittent, the tachyarrhythmia may take longer to resolve.
- Intermittent fetal tachycardia without evidence of fetal hemodynamic compromise can be observed closely instead of undergoing medical therapy.
- Refractory cases to maternal medical management have been treated with direct fetal therapy.
- The newborn should be evaluated thoroughly for signs of cardiac abnormalities. Approximately 50% of infants will relapse after birth.

CONDITION

Fetal tachyarrhythmias detected in utero include irregular cardiac rhythm resulting from isolated extrasystoles, supraventricular tachycardia, and atrial flutter. The most common of the above arrhythmias is an irregular cardiac rhythm resulting from isolated extrasystoles (Silverman et al., 1985; Kleinman, 1986; Copel et al., 2000). Most of these extrasystoles originate in the atria and resolve spontaneously (Kleinman, 1986; Reed et al., 1987). An increased frequency of premature beats has been attributed to the maternal use of caffeine, tobacco, and alcohol (De Vore, 1984). Although premature atrial or ventricular contractions have not been considered a risk factor for anomalies in the past, more recent reports suggest that a fetal structural cardiac abnormality may be found in up to 2% of such cases (Beall and Paul, 1986; Reed, 1991).

Supraventricular tachycardia is the most common serious dysrhythmia detected prenatally (Bergmans et al., 1985; Kleinman et al., 1985a). The majority of supraventricular tachycardias are considered to be re-entrant dysrhythmias and are identified by a fetal heart rate of more than 200 beats per minute (bpm) with one-to-one atrial-to-ventricular activity (Figure 41-1) (Simpson and Marx, 1994). Paroxysmal supraventricular tachycardia may also occur as part of the Wolff–Parkinson–White syndrome, together with a short P–R interval, prolonged QRS, and presence of a delta wave on electrocardiogram. Typically, supraventricular tachycardia has not been associated with congenital heart disease; however, in 5% to 10% of cases, structural cardiac abnormalities can be found (Beall and Paul, 1986; Reed, 1989). The presence of structural heart disease in addition to supraventricular tachycardia is associated with a poor fetal outcome (Bergmans et al., 1985).

Fetal atrial flutter has been diagnosed and reported less commonly than supraventricular tachycardia (Kleinman, 1986). The atrial rate in flutter can be estimated between 300 and 500 bpm with a variable ventricular response dependent on the degree of atrioventricular block (Figure 41-2). Fetal atrial flutter has a poor prognosis, due in part to its association with structural heart disease (in up to 20% of cases) and with the development of hydrops fetalis (Kleinman, 1986; Reed, 1991; Simpson and Marx, 1994).

In contrast to benign arrhythmias such as isolated extrasystoles, fetal dysrhythmias have the potential for serious sequelae. It has been well described that fetuses with tachyarrhythmias have decreased cardiac output and are at risk for hydrops fetalis (Reed et al., 1987; Reed, 1989). Protracted supraventricular tachycardia can lead to cardiac failure in a matter of days (Allan, 1984). The exact mechanism for the development of cardiac failure and hydrops remains unclear. The progression to hydrops in utero seems to follow right heart failure with tricuspid regurgitation and right ventricular dilatation, signifying impending decompensation (Allan et al., 1983; Chao et al., 1992; Gembruch et al., 1993). It has been postulated that either passive liver congestion associated with cardiac failure or decreased hepatic perfusion from decreased cardiac output may result in hypoalbuminemia, leading to decreased oncotic pressure and transudation of fluid into interstitial spaces (Johnson et al., 1992). Pericardial and pleural effusions, fetal ascites, and subcutaneous edema are probably late manifestations of cardiac decompensation.

INCIDENCE

Arrhythmias are identified in approximately 1% of all fetuses; however, the actual incidence of fetal arrhythmias is expected

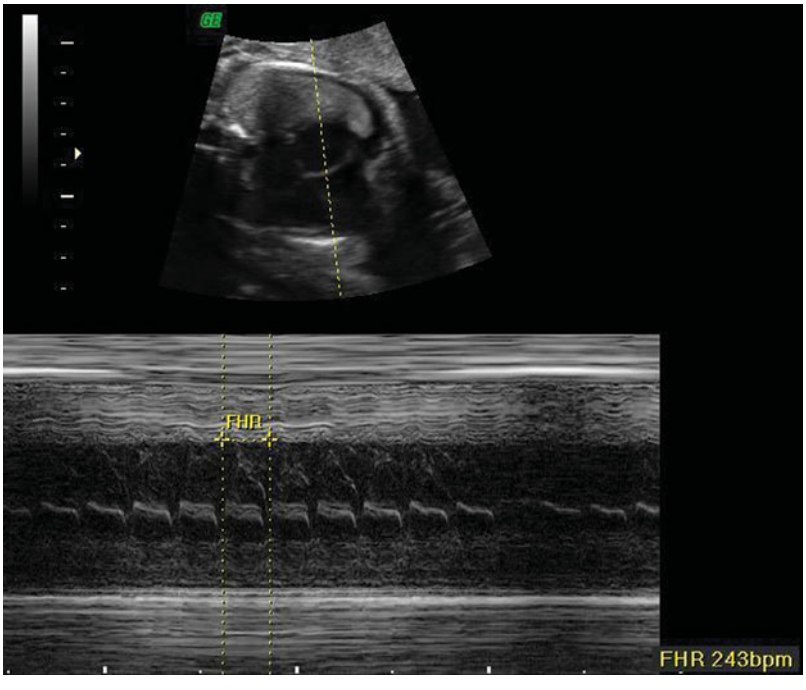

Figure 41-1 M-mode imaging in a fetus with supraventricular tachycardia demonstrating a ventricular rate of 243 bpm.

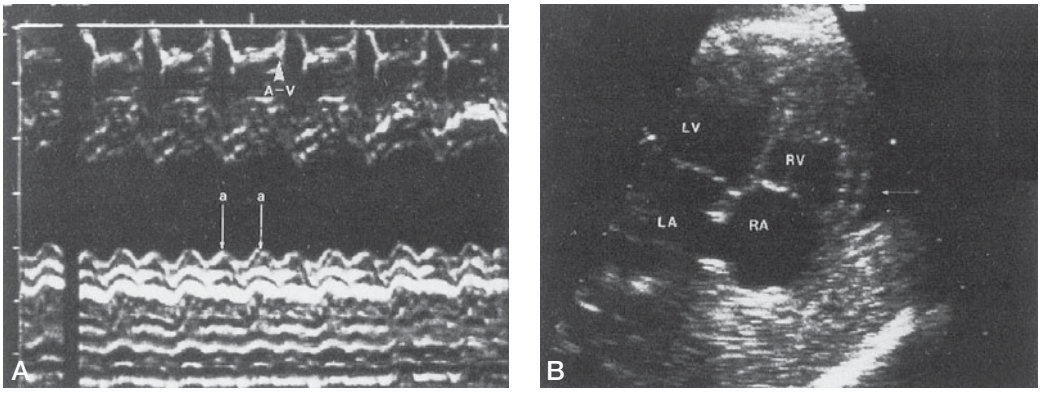

Figure 41-2 **A**. Fetus in atrial flutter as shown by an atrial contraction rate of 480 bpm (arrowhead labeled A-V for atrioventricular-valve opening). **B**. Four-chamber view in the same fetus in atrial flutter showing dilated right atrium and pericardial effusion (arrow). LA = left atrium; LV = left ventricle; RV = right ventricle; RA = right atrium. *(From Simpson LL, Marx GR. Diagnosis and treatment of structural fetal cardiac abnormality and dysrhythmia.* Semin Perinatol. *1994;18:215-227.)*

to be higher because a significant proportion of them can be intermittent or resolve spontaneously (Reed, 1989; Simpson and Marx, 1994). The most common and clinically significant tachyarrhythmias identified in utero are supraventricular tachycardia and atrial flutter.

SONOGRAPHIC FINDINGS

Ultrasound evaluation should include a complete fetal survey and a survey of the cardiac anatomy to confirm absence of structural malformations. The incidence of abnormal cardiac anatomy varies with the type of arrhythmia. The fetus should also be examined for evidence of hydrops as defined by fluid collections in the pericardium, the pleural spaces, ascites, or skin edema. Amniotic fluid may also be increased. An increase in fetal cardiac size or wall thickness may be an indication of abnormal cardiac hemodynamics (Reed, 1989).

Echocardiography, including M-mode assessment and Doppler analysis, is an important tool in the diagnosis and evaluation of fetal dysrhythmias (Kleinman et al., 1980; De Vore et al., 1983; Silverman et al., 1985). The atrial and corresponding ventricular activity can be viewed by two-dimensional echocardiography and the rates determined by placement of the M-mode cursor perpendicular to the atrial and ventricular walls. M-mode echocardiography can also be used to identify pericardial effusions and to measure wall thickness, chamber size, and fractional shortening (see Figures 41-1 and 41-2). Doppler evaluation of atrioventricular and semilunar valve flows can be used to time the ventricular contractions (Strasburger et al., 1986). The hemodynamic effects of a dysrhythmia are assessed by determining the size and function of the four chambers, the magnitude of the semilunar and atrioventricular flow-velocity integrals, and the presence of mitral or tricuspid regurgitation or nonimmune hydrops fetalis. Color flow mapping may also be used to identify flow disturbances. The approach to the ultrasound evaluation of arrhythmias is summarized in Table 41-1.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of fetal tachyarrhythmias includes benign isolated extrasystoles and more significant dysrhythmias such as atrial flutter and supraventricular tachycardia. M-mode echocardiography is useful in differentiating these conditions, as described above.

ANTENATAL NATURAL HISTORY

Premature atrial and ventricular contractions are considered to be benign and do not require treatment. However, it has

Table 41-1

Evaluation of Arrhythmias

been reported that a sustained tachyarrhythmia may subsequently develop in up to 1% of fetuses with premature beats (Kleinman, 1986).

The natural history of isolated in utero supraventricular tachycardia remains unclear. Although intermittent supraventricular tachycardia may be of no clinical significance, sustained supraventricular tachycardia may be life-threatening (Southall et al., 1980; Bergmans et al., 1985). Spontaneous resolution of supraventricular tachycardia has been reported (Newburger and Keane, 1979; Santulli, 1990). Complete resolution of protracted supraventricular tachycardia with subsequent normal fetal development has been observed (Simpson et al., 1997). In a small series of isolated fetal supraventricular tachycardia, hydrops developed in only one of nine cases managed conservatively without medical therapy (Simpson et al., 1997). Interestingly, the fetus in which signs of hydrops developed had intermittent supraventricular tachycardia at a rate of 200 bpm occurring less than 50% of the time. In the remaining eight fetuses in which hydrops did not develop, five had intermittent episodes of supraventricular tachycardia occurring less than 50% of the time and two had more sustained supraventricular tachycardia occurring between 50% and 75% of the time. Spontaneous resolution of the supraventricular tachycardia in these remaining eight fetuses occurred within 10 days of diagnosis, with no recurrence in the antepartum or newborn period. Antiarrhythmic agents were not administered to these eight mothers or their infants, who were all delivered at term. However, sustained supraventricular tachycardia can be associated with the development of congestive heart failure and hydrops and the potential for fetal death.

The presence of structural heart disease in association with fetal supraventricular tachycardia has been reported to have a poor outcome (Bergmans et al., 1985). However, a case of fetal supraventricular tachycardia and congenital heart disease has been observed in an infant, who is now 3 years old, without any recurrence of the dysrhythmia after surgery for a double inlet single left ventricle, subaortic stenosis, and coarctation of the aorta (Simpson et al., 1995).

Although rapid progression to fetal hydrops can occur with sustained supraventricular tachycardia of 24 to 48 hours' duration, signs of cardiac failure will not develop in all fetuses (Newburger and Keane, 1979; Kleinman et al., 1985a). In approximately 25% of cases, there seems to be no associated hemodynamic compromise. However, 55% to 60% of fetuses with supraventricular tachycardia will have evidence of cardiac decompensation in utero or during the newborn period (Newburger and Keane, 1979; Bergmans et al., 1985). At the time of diagnosis of supraventricular tachycardia, Kleinman (1986) detected hydrops fetalis in 16 of 18 cases. Fortunately, even in the presence of cardiac failure, supraventricular tachycardia has a favorable prognosis (Kleinman, 1986). In utero medical treatment can result in conversion to normal sinus rhythm within 48 hours (Sarno et al., 1989). Conversion to sinus rhythm seems to occur more easily in the absence of fetal hydrops (Kleinman et al., 1985a). It has also been shown that because of impaired placental transfer of antiarrhythmic agents, fetuses with hydrops could require 2 to 3 weeks of therapy before converting to normal sinus rhythm (Maxwell et al., 1988). Atrial flutter seems to have a poor in utero prognosis, with two of three fetuses with atrial flutter and associated hydrops dying in one series (Kleinman, 1986; Simpson and Marx, 1994).

MANAGEMENT OF PREGNANCY

The typical presentation of fetal tachyarrhythmia involves the auscultation of a rapid fetal heart rate in an asymptomatic woman at a routine prenatal visit. Such a finding should prompt a thorough prenatal evaluation, including a detailed ultrasound examination for fetal anatomy, growth, and biophysical status, in addition to an echocardiogram with M-mode and Doppler evaluation to characterize the arrhythmia fully and evaluate its impact on myocardial function. The latter studies are generally performed in consultation with a pediatric cardiologist. The finding of structural cardiac abnormalities in 5% to 10% of cases of supraventricular tachycardia reaffirms the need for careful anatomic assessment of the fetal heart (Beall and Paul, 1986; Reed, 1989).

In the absence of additional structural cardiac malformation, it is well accepted that in utero medical therapy or delivery, or both, is appropriate in cases of fetal supraventricular tachycardia with evidence of hemodynamic compromise. Gestational age is a significant factor in deciding appropriate intervention. In one series, use of digoxin alone or digoxin with verapamil or propranolol achieved in utero control in 13 of 14 cases of supraventricular tachycardia with associated hydrops (Kleinman et al., 1985b). Higher doses of digoxin are often necessary to achieve therapeutic levels because of the variable absorption, large volume of distribution, and rapid clearance associated with pregnancy. Conversion to sinus rhythm seems to occur more easily in the absence of fetal hydrops (Kleinman et al., 1985a). This may be because of impaired placental transfer of antiarrhythmic agents in hydropic fetuses (Maxwell et al., 1988). In a retrospective study of 11 cases of supraventricular tachycardia and 4 cases of atrial flutter with hydrops, a median of 12.5 days was required for in utero conversion to sinus rhythm, as compared with a median of 3 days in the absence of hydrops (van Engelen et al., 1994). In this series, indications were that flecainide was more effective than digoxin in achieving rhythm control. Oudijk retrospectively reviewed the charts of 21 patients treated with sotalol during the prenatal period (Oudijk et al., 2000). Ten patients had fetal supraventricular tachycardia, 10 had atrial flutter, and 1 had ventricular tachycardia. Hydrops was present in 9 cases. In the supraventricular tachycardia group, sinus rhythm was established in 6/10 of cases. In the atrial flutter group, sinus rhythm was established in 8/10 patients. The mortality rate was 19% (4/21 patients; 3 with supraventricular tachycardia and 1 with atrial flutter).

Two patients (2/17; 12%) who converted to sinus rythm in utero were diagnosed with adverse neurological outcomes postnatally. The authors suggested that sotolol may cause a proarrhythmic event in the fetus that may contribute to the high mortality rate in this study. The authors also recommend that sotalol be reserved for cases of fetal atrial flutter or refractory cases of supraventricular tachycardia.

We recommend digoxin for first-line therapy of isolated fetal tachyarrhythmia, with procainamide, flecainide, and sotolol reserved for second-line treatment when delivery is not desirable because of gestational age and when conversion to normal sinus rhythm with digoxin has been unsuccessful. It is important to note that both flecainide and sotolol have been associated with a risk for fetal death (Oudijk et al., 2000, 2002; Pradhan et al., 2006). Amiodarone has been used in refractory cases with good results but must be used with caution due to the fact that it has been associated with fetal hypothyroidism (Pradhan et al., 2006).

Successful in utero conversion from supraventricular tachycardia to atrial flutter with a variable ventricular response after maternal administration of digoxin has been described (Simpson et al., 1995). Atrial flutter has been found to be more difficult to treat successfully in utero, and this is partly responsible for the reported poor prognosis associated with this dysrhythmia (Simpson and Marx, 1994). In one series, antiarrhythmics were effective for in utero control of supraventricular tachycardia in 88% of cases, as compared with 66% of cases of atrial flutter (van Engelen et al., 1994). Although second-line antiarrhythmic agents may be tried, elective preterm delivery may be necessary in cases of supraventricular tachycardia alternating with atrial flutter that are refractory to digoxin. On the basis of the adverse outcomes reported in the literature, we recommend that atrial flutter with or without hydrops be promptly treated with an antiarrhythmic if delivery is not a reasonable option because of gestational age (Simpson et al., 1995).

In contrast, in the absence of hydrops or hemodynamic compromise, conservative management without medical therapy may be a reasonable option for fetuses with supraventricular tachycardia. Spontaneous resolution of protracted supraventricular tachycardia with subsequent normal fetal development has been observed (Stewart et al., 1983; Bergmans et al., 1985; Simpson et al., 1997). A review of the literature has identified seven cases of supraventricular tachycardia that converted to normal sinus rhythm spontaneously during parturition, with no recurrences after delivery (Bergmans et al., 1985). It is postulated that vagal stimulation during delivery slows conduction through the atrioventricular node, resulting in conversion to normal sinus rhythm.

A close follow-up of cases of isolated fetal supraventricular tachycardia without hydrops is warranted because of the potential for hydrops if conservative management without medical therapy is undertaken. Initially, daily assessments with ultrasound and fetal echocardiography are necessary. The interval between fetal evaluations can be extended, and resolution of the supraventricular tachycardia has been documented with individualization of follow-up thereafter. This regimen requires a reliable and compliant patient. If frequent evaluations are not possible or if compliance is questionable, medical therapy with antiarrhythmics is more appropriate.

When supraventricular tachycardia is diagnosed, the perinatologist and pediatric cardiologist together formulate a treatment plan (Simpson and Marx, 1994). Initially the fetus is assessed by the perinatologist for any signs of biophysical compromise. A detailed sonographic examination to determine fetal growth, development, and biophysical status is performed, with careful examination for the presence of pericardial, pleural, or abdominal fluid. The pediatric cardiologist then confirms the atrial and ventricular rate of contraction, atrial and ventricular size and function, and the presence and magnitude of atrioventricular valve regurgitation. Aortic and pulmonary flow-velocity integrals are determined during episodes of tachycardia and episodes of normal sinus rhythm. Immediate medical therapy is undertaken if there are signs of hemodynamic compromise, fetal distress, or hydrops fetalis. In all other cases, the mother is admitted to hospital and the fetus is monitored for 24 hours to determine the duration of the dysrhythmia. Expectant management without immediate medical therapy is considered if there are no signs of compromise, if the fetal tachycardia is not sustained, and if the patient is compliant (Simpson and Marx, 1994).

When fetal supraventricular tachycardia is persistent despite digoxin, and the gestational age precludes delivery, an additional antiarrhythmic drug should be tried. Procainamide, flecainide, quinidine, verapamil, propranolol, sotolol, and amiodarone have all been given for fetal tachyarrhythmias, with variable success (Bergmans et al., 1985; Kleinman et al., 1985b; Wladimiroff and Stewart, 1985; Oudijk et al., 2000). Unlike digoxin, however, these drugs can be associated with significant toxicity to the mother and fetus. Both procainamide and quinidine have the potential for proarrhythmic effects in the fetus and gastrointestinal toxicity in the mother (Kleinman et al., 1985a). Verapamil has been associated with cardiac decompensation and sudden fetal demise (Epstein et al., 1985; Owen et al., 1988). Intrauterine growth restriction and subsequent neonatal bradycardia and hypoglycemia have been observed with the use of propranolol (Gladstone et al., 1975; Rubin, 1981). Amiodarone can be considered for more protracted dysrhythmias, but both maternal and fetal thyroid dysfunction are potential complications. At our institution, flecainide or procainamide are most commonly used as the second-line treatment when delivery is not desirable. Procainamide can be administered orally or intravenously to the mother, and serum levels can be closely monitored. Procainamide has a short half-life, which is an important characteristic if maternal or fetal toxicity is experienced. Delivery is planned at term when conversion to normal sinus rhythm is successful, or sooner if conversion fails to occur and there is evidence of cardiac decompensation or fetal compromise.

When the diagnosis of fetal tachyarrhythmia is first made at term, medical therapy may be used in order

to facilitate a trial of labor and possible vaginal delivery (Silverman et al., 1985). Vaginal delivery should be possible in most cases; however, when conversion to normal sinus rhythm is unsuccessful or hydrops is present, delivery by cesarean section may be more appropriate. Intrapartum fetal monitoring may not be reliable with supraventricular tachycardia, and the fetus with hydrops may not tolerate labor. Intermittent sonographic surveillance of fetal well-being may be necessary in such cases.

FETAL INTERVENTION

For fetuses with evidence of hemodynamic compromise or hydrops prior to term, treatment of the rhythm disturbance is accomplished by administering antiarrhythmic medications to the mother. This approach is described in detail in the section for management of pregnancy. Maternal administration of digoxin, flecainide, procainamide, quinidine, and verapamil has been successfully used.

If an adequate trial of maternal medical therapy fails despite appropriate drug levels and time for effect, direct fetal therapy may be considered. This may be achieved by direct intravenous infusion of digoxin or amiodarone into the umbilical vein. Amiodarone may be helpful in this regard due to its prolonged duration of action.

In very rare cases, direct fetal intramuscular injection of medications may be possible, but this approach should be considered less optimal than direct fetal intravascular infusion (Weiner and Thompson, 1988; Hallak et al., 1991). Direct fetal therapy should be reserved for the preterm fetus that has evidence of heart failure and has not responded to maternally administered therapy. In one case, supraventricular tachycardia at 24 weeks of gestation was successfully controlled with direct fetal therapy after more traditional transplacental therapy with digoxin, verapamil, and procainamide had failed (Weiner and Thompson, 1988). In this case report, the fetus received 70 μg of digoxin in three divided doses administered intramuscularly over a period of 24 hours. In a further case, a 25-week-old fetus with severe hydrops fetalis secondary to supraventricular tachycardia was successfully treated with fetal intramuscular injections of digoxin together with maternal digoxin (Hallak et al., 1991). Fetal umbilical blood sampling had revealed poor placental transfer of digoxin even after 2 weeks of therapeutic maternal levels.

TREATMENT OF THE NEWBORN

Because 50% of infants have a relapse of tachycardia after birth, it is important to assess the neonatal rate with an electrocardiogram (van Engelen et al., 1994). Neonatal echocardiography should also be performed to confirm the absence of structural cardiac malformation and to evaluate cardiac function. Cardioversion, transvenous atrial overdrive pacing, or antiarrhythmic drugs have been used postnatally to convert the heart rate of infants who have tachycardia at birth to normal sinus rhythm (van Engelen et al., 1994). In the absence of hemodynamic instability, it is reasonable to either observe neonates closely without medical therapy, or begin prophylactic medical therapy for up to 1 year.

SURGICAL TREATMENT

No surgical treatments for tachyarrhythmias have been described.

LONG-TERM OUTCOME

In a group of 51 cases presenting with fetal tachycardia, 50% of all surviving infants had a relapse of tachycardia after birth (van Engelen et al., 1994). Relapse appeared to be more common in those with atrial flutter; 60% of infants with fetal atrial flutter had a relapse, as compared with 42% of infants with fetal supraventricular tachycardia. In the group of 33 infants with supraventricular tachycardia, a re-entry mechanism could be seen on the electrocardiogram in eight cases: four with Wolff–Parkinson–White syndrome and four with permanent junctional reciprocating tachycardias. At 1 month of age, 78% of the patients with a history of fetal supraventricular tachycardia or atrial flutter were receiving anti-arrhythmic drugs, usually digoxin, and sometimes in combination with propranolol, verapamil, or flecainide either for recurrent tachycardia or as prophylaxis. At 3 years of age, 14% were taking antiarrhythmic drugs (van Engelen et al., 1994). Of the three patients who were still receiving medications, one had Wolff–Parkinson–White syndrome and two had permanent junctional reciprocating tachycardia. The need for drug therapy seems to diminish as childhood advances, with re-entry tachycardia proving to be the most therapy-resistant form before and after birth as well as during later childhood.

Adverse neurological outcome has been associated with successful in utero treatment of fetal dysrhythmias (Oudijk et al., 2000). For example, in a series by Oudijk where patients were treated with transplacental sotolol two patients (2/17; 12%) who had converted to sinus rhythm in utero were diagnosed with adverse neurological outcomes postnatally. Both of these cases had been complicated by hydrops.

GENETICS AND RECURRENCE RISK

We are unaware of any reported cases of a recurrence of fetal arrhythmias in subsequent pregnancies. An exception is Wolff–Parkinson–White syndrome, which involves

paroxysmal supraventricular tachycardia and has a well-documented familial occurrence (Harnischfeger, 1959).

42 CHAPTER Bradyarrhythmias

Key Points

- The most common fetal bradyarrhythmia diagnosed prenatally is congenital complete heart block (CHB), usually occurring in association with circulating maternal anti-Ro or anti-La antibodies, but also occurring together with structural fetal cardiac malformation.
- Sonographic diagnosis of complete heart block (CHB) is made using M-mode echocardiography, demonstrating complete dissociation between atrial and ventricular rates; varying degrees of cardiac failure and hydrops may also be present.
- Immune-mediated CHB usually leads to permanent damage to the fetal cardiac conduction system, and controversy exists as to whether subsequent prenatal therapy by maternal administration of corticosteroids will have any meaningful benefit.
- Other options for prenatal therapy include maternal betamimetic administration, although its role is generally limited by maternal side effects; additionally experimental approaches to fetal cardiac pacing have also been described in cases with very poor prognosis.
- While vaginal delivery is possible with appropriate intensive fetal surveillance, for practical reasons, most such fetuses are delivered elective by cesarean; delivery should occur in a tertiary care facility with appropriate pediatric cardiology backup available.

CONDITION

The diagnosis of fetal arrhythmias has become increasingly common as echocardiographic evaluation of the fetal heart has improved and been pursued earlier in gestation. Two-dimensional echocardiography can distinguish normal from disordered cardiac anatomy as early as 16 weeks of gestation (Kleinman et al., 1980; Allan et al., 1983, 1984a). Similarly, fetal arrhythmias can be accurately characterized with the addition of M-mode echocardiography (Allan et al., 1983; Devore et al., 1983). Although the vast majority of fetal arrhythmias reported are either extrasystoles (75%) or tachyarrhythmias (15%), fetuses with bradyarrhythmia due to complete heart block (CHB) account for 9% of all cases (Kleinman and Evans, unpublished data, 1988). CHB is seen in association with severe congenital heart disease in up to 53% of cases (Schmidt et al., 1991). In this setting the prognosis is poor, with a survival rate of less than 15% (Shenker, 1979; Teteris et al., 1979; Allan et al., 1983; Crawford et al., 1985; Cameron et al., 1989). However, CHB complicates structural congenital heart disease in only 0.4% to 0.9% of the cases (Camm and Bexton, 1984; Olah and Gee, 1993). CHB is observed with normal cardiac anatomy in up to 50% of cases (Kleinman and Evans, unpublished data, 1988). CHB with normal cardiac anatomy is usually associated with transplacental passage of maternal antibodies, anti-SSA or anti-SSB (anti-Ro or anti-La), in mothers with connective-tissue diseases (McCue et al., 1977; Scott et al., 1983; Litsey et al., 1985; Taylor et al., 1988).

The most common form of congenital heart block seen in the fetus is third-degree, or complete, atrioventricular (AV) block. First-degree AV block is the prolongation of the P–R interval and is difficult to detect prenatally. Second-degree AV block occurs either as a progressive lengthening of the P–R interval, with resulting dropped beats (Wenckebach phenomenon), or as a fixed P–R interval with a ratio of transmission of atrial beats to ventricular beats of 2:1, 3:1, 4:1, etc. Third-degree AV block occurs when there is complete dissociation of atrial and ventricular rates with no transmission of atrial beats to the ventricles.

Antibodies to soluble ribonuclear proteins, anti-Ro (Sjögren syndrome antigen-A, SS-A) and anti-La (Sjögren

syndrome antigen-B, SS-B) have been demonstrated in the serum of affected fetuses and their mothers (Franco et al., 1981; Kephart et al., 1981; Miyagowa et al., 1981). CHB in fetuses with structurally normal hearts is almost uniformly associated with the presence of anti-Ro or anti-La antibodies. Anti-Ro and anti-La antibodies have been demonstrated to bind to fetal heart conduction tissue (Deng et al., 1987; Harsfield et al., 1991). The pathophysiology of CHB involves the transplacental passage of maternal autoantibody, anti-Ro, which binds to an antigen in the fetal heart conduction system with consequent inflammation and fibrosis. The fetal and neonatal heart contains the body's highest concentration of Ro antigen (Wolin and Steitz, 1984; Harley et al., 1985; Deng et al., 1987). IgG deposits have been demonstrated in the cardiac tissues of affected infants (Litsey et al., 1985; Lee et al., 1987). Studies in vitro, using anti-Ro and anti-La antibodies, have demonstrated that anti-Ro antibodies selectively bind to newborn myocardium but not to adult myocardium and that this binding inhibits repolarization (Alexander et al., 1992).

Although it is thought that anti-Ro and anti-La antibodies play an important role in the pathogenesis of fetal CHB, some authors have suggested that there must be a cofactor (Taylor et al., 1988). The mothers of infants with CHB almost always have anti-Ro and anti-La antibodies. Fetal CHB, however, develops in only 1% to 2% of anti-Ro/anti-La antibody positive mothers, and usually occurs between 20 and 24 weeks' gestation. Since the majority of mothers with these antibodies have normal pregnancies, this implies that a second factor is necessary for the development of CHB. It has been suggested that viral infections may initiate immune damage by influencing antigenic expression. Ro and La ribonucleoproteins may become immunogenic by forming complexes with viral genomes (Venables et al., 1983). Interestingly, an increased frequency of antibodies to cytomegalovirus has been observed in mothers of babies with CHB (Peckham et al., 1983; Taylor et al., 1988).

In cases in which maternal anti-Ro/anti-La antibodies are not responsible for CHB, prolonged QT syndrome or viral infection may be responsible (Peckham et al., 1983).

The presence or absence of subendocardial fibroelastosis should be noted in cases of CHB. This is an echogenic appearance to the inner lining of the cardiac chambers, most often affecting the ventricles but also can affect the atria. This is thought to be due to subendocardial ischemia and is usually a sign of more severe myocardial injury, which without treatment is associated with a poor prognosis (Jaeggi et al., 2004).

INCIDENCE

CHB during fetal life is uncommon, with an incidence of approximately 1 in 20,000 to 1 in 25,000 livebirths (McHenry and Coyler, 1969; Michaelson and Engle, 1972; Gochberg, 1984). However, because many fetuses with CHB die in utero, the true incidence of fetal CHB is likely to be somewhat higher than this.

SONOGRAPHIC FINDINGS

The most common reason for referral for evaluation for fetal CHB is the detection of a slow or irregular heart rate on routine obstetric examination (Schmidt et al., 1991). The median gestational age at referral for fetal CHB is 26 weeks, but may range from 17 to 38 weeks (Schmidt et al., 1991). More than half of fetuses with CHB will have associated structural heart disease, making assessment of fetal cardiac anatomy essential. The diagnosis of CHB can be confirmed sonographically by demonstrating atrial and ventricular rate discrepancies. If detected early, type 1 or 2 second-degree AV block may be observed. M-mode examination may be particularly useful to independently confirm atrial and ventricular rates (Crowley et al., 1983). It is also important to sonographically assess myocardial function, as immune complex deposition and fetal inflammatory reaction may result in myocarditis and significant myocardial dysfunction.

A complete fetal survey should be performed, with special attention paid to the presence or absence of hydrops, as indicated by pericardial or pleural effusions, ascites, or skin edema. Echocardiographic assessment should include measurement of ventricular escape rate and atrial rate. An atrial rate of less than 120 beats per minute (bpm) should raise the possibility of a missed structural heart defect. In addition, assessment of stroke volume, left and right ventricular ejection fraction, combined ventricular output, and the presence and severity (or absence) of AV valvular insufficiency should be noted (Takomiya et al., 1989; Veille et al., 1990). Valvular insufficiency can be diagnosed by Doppler echocardiography. Peak systolic flow velocities in the ascending aorta and diastolic umbilical flow velocities should be assessed as indirect indicators of cardiac output, and should be measured as a basis for comparison for serial echocardiographic assessment.

Doppler ultrasound assessment of the umbilical artery has been used to estimate impedance to flow in the placental circulation. However, because calculations depend on the time taken for the velocity of flow to decay in diastole, the prolonged diastolic component in CHB limits the value of this technique (Olah et al., 1991; Olah and Gee, 1993). Complete absence or reversal of flow during diastole in CHB, however, has the same clinical significance as in cases in which the heart rate is normal (Olah et al., 1991). This form of sonographic assessment is thought to be particularly useful in CHB because of its association with anti-Ro antibodies and antibodies in connective-tissue disease, such as systemic lupus erythematosus, in which placental infarction and immunoglobulin deposition are frequently encountered (Guzman et al., 1987; Veille et al., 1990). Increases in placental resistance may be sufficient to precipitate cardiac decompensation, even

in the absence of further slowing in the ventricular escape rate.

Growth restriction may occur as a result of fetal CHB. Therefore, serial measurements of biparietal diameter, abdominal circumference, and long bones should be performed at bimonthly intervals to assess fetal growth.

Measurement of the cardiothoracic ratio should also be performed by two-dimensional echocardiography (Paladini et al., 1990). An increase in the cardiothoracic index beyond the normal range may assist in predicting the extent of lung compression and possible pulmonary hypoplasia, as well as the severity of cardiac failure as indicated by cardiac enlargement (Olah and Gee, 1993).

DIFFERENTIAL DIAGNOSIS

When evaluating a fetus with bradycardia, the differential diagnosis includes heart block as a complication of structural heart disease, heart block in a structurally normal heart (most often due to transplacental passage of maternal antibodies in connective tissue disease), and sinus bradycardia in a premorbid fetus. The most common structural defects seen in association with CHB are listed in Table 42-1. Although pregnant women with connective tissue disease are at significantly increased risk for having a fetus with CHB, only 50% of fetuses with bradycardia are born to women with a history of collagen vascular disease (Petri et al., 1989; McCauliffe, 1995). Fetal CHB may be the first manifestation of maternal collagen vascular disease.

A fetus diagnosed early in the development of heart block may present with irregular heart rhythm due to second-degree AV block. This may occur either as partial progressive AV block, (the Wenckebach phenomenon), or as second-degree AV block in which the P–R interval is relatively fixed and the ratio of transmission may be 2:1, 3:1, or 4:1, etc. Schmidt et al. (1991) have observed progression from normal sinus rhythm to second-degree block to CHB.

Table 42-1

Structural Heart Defects Most Commonly Associated with Fetal Complete Heart Block

Left atrial isomerism
Transposition of the great arteries
Atrioventricular septal defect
Pulmonic atresia
Anomalous pulmonary venous connection
Double outlet right ventricle
Atrioventricular discordance
Absent right atrioventricular connection
Double inlet ventricle
Right atrial isomerism
Pulmonic stenosis

ANTENATAL NATURAL HISTORY

While bradycardia is well tolerated by most fetuses, nonimmune hydrops will develop in up to 25% as a result of cardiac decompensation (Kleinman et al., 1982; Stewart et al., 1983; Holzgreve and Golbus, 1984; Crowley et al., 1985; Carpenter et al., 1986; Machado et al., 1988). In 90% of cases associated with a structurally normal heart, the infant is born with neonatal lupus erythematosus (McCauliffe, 1995).

Fetal CHB usually presents during the second trimester in the setting of a structurally normal heart. Although fetal CHB has been diagnosed as early as 17 weeks, the mean gestational age at presentation is closer to 26 weeks (Schmidt et al., 1991). There is some evidence to suggest that a progressive rise in transplacental passage of immunoglobulin occurs after 22 weeks' gestation, which correlates with progressive immune-mediated injury to the fetal conduction system (Stiehm, 1975).

The majority of the fetuses with CHB tolerate the slower ventricular rate relatively well and progress to term without incident. However, in 15% to 25% of fetuses with CHB nonimmune hydrops will develop and the fetus will die in utero or shortly after delivery. In a multicenter review, Schmidt et al. (1991) found that fetuses with structurally normal hearts and CHB with ventricular rates of less than 55 bpm had only a 14% survival rate. The presence of nonimmune hydrops was a poor prognostic feature, with only a 15% survival rate. Similarly, when CHB complicated structural heart disease, the survival was only 14%. The development of AV valve incompetence is also a harbinger of fetal cardiac decompensation and nonimmune hydrops (Schmidt et al., 1991). AV valve incompetence appears to be due to distortion at the valve rings by progressive ventricular dilation with the slow ventricular rate. In the fetal-sheep model of CHB, slower ventricular rates cause progressive diastolic distention of the ventricles distorting the AV valve rings, resulting in regurgitation (Crombleholme et al., 1991). The AV valve incompetence can be immediately reversed by increasing the ventricular rate by pacing the heart, which reduces the diastolic ventricular distention. AV valve incompetence tends to precede the development of nonimmune hydrops because it results in venous hypertension and passive hepatic congestion, leading to pericardial and pleural effusions, ascites, and anasarca.

Figure 42-1 Four-chamber view of the heart in a fetus with complete heart block due to transplacental passage of SSA antibodies in a mother with systemic lupus erythematosis. The atrial rate was 135 beats per minute with a ventricular response rate of 54 beats per minute. There is evidence of endocardial fibroelastosis (EFE) in this heart most notably in the papillary muscle and in the interventricular septum.

In addition to progressive destruction of the fetal conduction system by an inflammatory response to maternal autoantibody deposition, a generalized myocarditis may also be seen in fetal CHB. In these cases, antibody deposition occurs throughout the heart, and the inflammatory reaction results in progressive myocardial decompensation. Subendocardial fibroelastosis may result, which can be an indicator of end-stage myocardial injury. These may appear as echogenic papillary muscles or areas of subendocardial myocardium in the ventricle or atria (Figure 42-1).

MANAGEMENT OF PREGNANCY

A woman with no previous history of collagen vascular disease who presents carrying a fetus with CHB should have a formal rheumatologic evaluation. On close questioning, such women often report dry eyes/mouth or arthralgias, which suggest collagen vascular disease (McCauliffe, 1995). The fetus should undergo a complete anatomic sonographic survey, including Doppler waveform studies of umbilical arterial diastolic flow. Echocardiography should be performed, not only to exclude structural heart disease, but also to confirm AV dissociation and document the atrial and ventricular rates. In addition, assessment of ventricular contractility, presence or absence of increased myocardial echogenicity suggestive of subendocardial fibroelastosis, AV valve incompetence, and stroke volume should be noted and serve as a baseline for comparison with future studies.

The diagnosis of immune-mediated fetal heart block should be treated by maternal steroid administration. During the third trimester there may be progressive slowing of ventricular rate, and increased frequency of surveillance is indicated in fetuses with ventricular rates of less than 65 bpm. Heart rates less than 60 bpm may prompt a twice-weekly ultrasound examination to detect AV valve incompetence or early signs of nonimmune hydrops. Similarly, serial echocardiography is indicated to detect subtle changes in contractility, stroke volume, myocardial echogenicity, and onset of AV valve incompetence. Diastolic flow in the umbilical arteries is also a useful marker to follow because it indicates impedance to flow in the placental circulation. Increased resistance due to deposition of immune complexes in the placental bed may precipitate heart failure. Because of the progressive dilation of heart chambers, cardiothoracic ratios may be useful indicators of possible pulmonary hypoplasia. Because of the lack of heart rate variability, standard nonstress tests are not helpful.

The indications for delivery in fetal CHB include obvious signs of deteriorating cardiac status, with the subsequent development of nonimmune hydrops. The mode of delivery in fetal CHB is controversial. If the fetus is being delivered for signs of cardiac decompensation, the stress of vaginal delivery may cause further hemodynamic compromise (Paladini et al., 1990). In addition, detection of nonreassuring fetal heart rate status in the setting of fetal CHB is very difficult. Some authors have delivered noncompromised fetuses with CHB vaginally, using continuous heart rate monitoring and fetal blood sampling during labor (Olah and Gee, 1993). Some authors have advocated continuous monitoring of ventricular rate by scalp electrodes, atrial rate by external transducers, or fetal pulse oximetry by scalp probes or transcutaneous pCO_2 (Todras et al., 1989; Chan et al., 1990a, 1990b). Other authors have suggested continuous intrapartum echocardiography.

While such intensive surveillance is possible, we recommend cesarean delivery for any fetus at more than 30 weeks' gestation with CHB and evidence of hemodynamic compromise, manifested by nonimmune hydrops, a ventricular rate of less than 55 bpm, AV valve insufficiency, or poor contractility. In fetuses in which CHB is well tolerated, vaginal delivery may be considered, but only if appropriate intrapartum monitoring is available. Delivery should be performed at a center with pediatric cardiologists and surgeons who are available for placement of either temporary transvenous or epicardial pacing leads.

FETAL INTERVENTION

Numerous antenatal treatments, both medical and surgical, have been proposed in the management of the fetus with CHB. The medical therapies are divided into those intended

to minimize the immunologic injury to the fetal heart and those geared toward increasing the ventricular rate.

Controversy exists over the prenatal treatment of CHB. The form of treatment used most often is administration of steroids to the mother to limit the fetal inflammatory response (Barclay et al., 1987; Bunyan et al., 1987; Fox and Hawkins, 1990; Jaeggi et al., 2004). Dexamethasone is preferred over prednisone. Because of the fear of adverse side effects due to steroids, such as maternal insulin resistance, lowered resistance to infection, and poor wound healing, some authors have recommended against prophylactic treatment for anti-Ro antibody positive mothers. However, once antibody-mediated damage to the fetal conduction system has occurred, it is permanent. Because myocardial injury is likely permanent at the time of presentation with CHB, it has been argued that there is minimal role for steroid therapy once that stage has been reached.

Jaeggi et al. published a protocol for the management of prenatally diagnosed CHB without structural heart disease (Figure 42-2). This report included 37 patients treated by this approach divided into two groups based on year of diagnosis. Patients received maternal dexamethasone or maternal betamimetics. The survival of the earlier group treated from 1990 to 1996 was 80% at birth and 47% to 1 year of life. In contrast, the more recent group of patients treated between 1997 and 2003 had a survival to birth and 1 year of 95% ($p < 0.01$). The use of the glucocorticoid dexamethasone appeared to be the primary reason for this improved survival. Among these mothers receiving dexamethasone, the survival was 90% versus 46% without dexamethasone.

This group therefore recommended maternal dexamethasone administration (4–8 mg/d) and with betamimetics (ritodrine 30–60 mg/d or salbutamol 10 mg/d) for cases in which ventricular response rate is below 55 bpm or in which there is evidence of abnormal ventricular function. In the dexamethasone-treated mother, adverse effects attributed to steroid included oligohydramnios (19%), and one mother developed hypertension. It is unclear whether the addition of betamimetics to dexamethasone conferred any additional benefit. It is possible that in this setting betamimetics either prevented further decrease in heart rate or improved myocardial function. The QT interval should be assessed in all patients prior to starting betamimetics and should be avoided in prolonged QT syndrome. Betamimetics may alter ventricular depolarization and dramatically lengthen QTc that may trigger cardiac events. The use of magnetocardiography may be useful in the diagnosis of prolonged QT syndrome and assist management of CHB (Hosono et al., 2001).

Betamimetic agents, such as terbutaline, ritodrine, and isoproterenol have been used in attempts to accelerate the fetal heart rate (Carpenter et al., 1986; Martin et al., 1988; Schmidt et al., 1991; Jaeggi et al., 2004). The responses to these agents have been variable, and no definite benefit has been proven (Crowley et al., 1985; Carpenter et al., 1986; Machado et al., 1988). In addition, doses sufficient to cause an increase in fetal ventricular rate are often poorly tolerated by the mother.

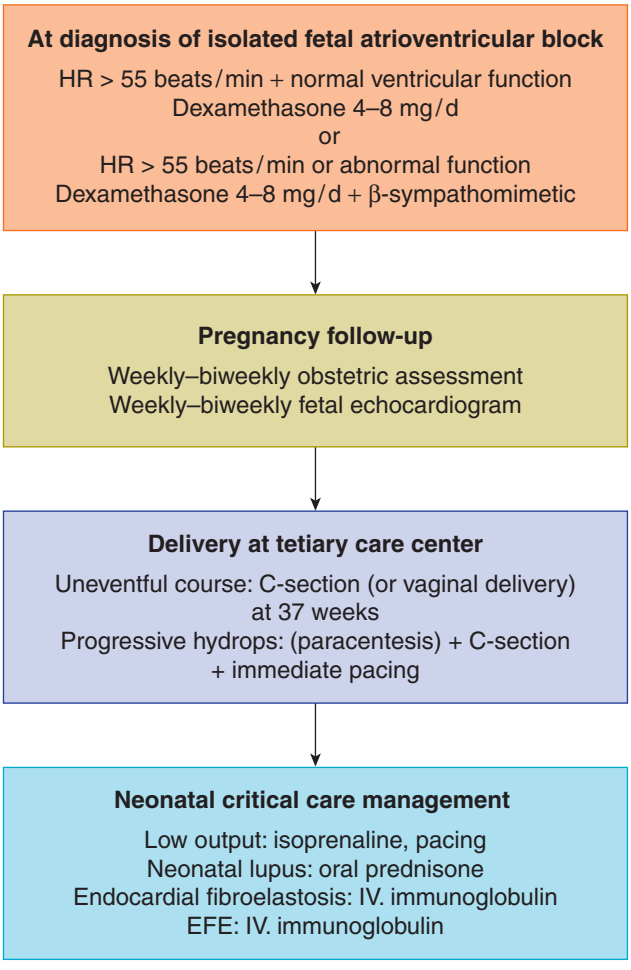

Figure 42-2 Suggested protocol for the management of prenatally diagnosed complete heart block without structural heart disease.

The use of intravenous immunoglobulin (IVIG) in fetal CHB has been described. IVIG is thought to bind circulating anti-Ro antibody in the maternal circulation to prevent transplacental passage, by increasing immune clearance of the antibody. It may also downregulate anti-Ro antibody production. Limited data are available to support this intervention.

Plasmapheresis has also been recommended to limit cardiac damage once pericardial effusion, heart enlargement, or conduction disturbance develops (Bunyan et al., 1987). However, plasmapheresis cannot reverse fetal CHB once it is established (Heurman and Golezewski, 1985). Bunyan et al. (1988) have suggested that plasmapheresis be used prior to 20 weeks' gestation, before increased antibody passage occurs across the placenta. This requires plasmapheresis three times a week, in addition to steroid treatment. The use of plasmapheresis is based on the idea of removing maternal anti-Ro antibody and decreasing transplacental passage, although damage to the fetal conduction system might not

be reversed using this regimen. None of these immunologic strategies has any proven efficacy in preventing or reversing the consequences of fetal CHB due to anti-Ro antibodies.

Early cesarean delivery for temporary pacemaker placement has been associated with a mortality rate that approaches 80% (Kleinman and Downerstein, 1985; Martin et al., 1988). The lack of effective medical treatment for the fetus with CHB and evidence of cardiac decompensation and poor outcome with early delivery have prompted some groups to attempt pacing the fetal heart in utero (Carpenter et al., 1986; Crombleholme et al., 1989, 1990, 1991; Harrison et al., 1993). While technically successful in individual human and animal model cases, such intervention is still considered experimental.

In order for fetal cardiac pacing to be effective, appropriate case selection is essential. Fetuses without hydrops do not need cardiac pacing. Fetuses with advanced hydrops are unlikely to benefit from cardiac pacing. However, a fetus with CHB with ventricular escape rates of less than 50 bpm despite corticosteroid and betamimetic therapy is at especially high risk. These fetuses should be followed closely for development of early signs of hydrops, such as pericardial or pleural effusion or AV valve insufficiency, which usually precedes hydrops. These fetuses are at high risk, and may be candidates for fetal cardiac pacemaker placement. Open fetal surgery for fetal CHB may be preferable because a percutaneously placed pacing lead may become dislodged, cause cardiac tamponade, chorioamnionitis, or cord enlargement. The contraindications to open fetal surgery for pacemaker placement include uterine irritability, maternal illness, structural fetal heart disease, massive hydrops, or poor ventricular function that is sometimes associated with subendocardial fibroelastosis. It may be reasonable for corticosteroids to be administered to the pregnant woman for fetuses with CHB to minimize ongoing immune-mediated myocardial cardiac injury. While the injury to the fetal conduction system is permanent and irreversible, it is possible that progressive myocarditis may be averted by maternal steroid treatment. Except for one anecdotal case, there are no data to support the use of plasmapheresis in fetal CHB.

TREATMENT OF THE NEWBORN

Neonatal lupus erythematosus (NLE) is a misnomer, as these newborns do not have systemic lupus erythematosus, but a constellation of clinical disorders associated with, and probably in part caused by, autoantibodies that are passively acquired by the fetus transplacentally (McCauliffe, 1995). The majority of newborns with NLE exhibit cutaneous or cardiac disease (Table 42-2).

In the absence of structural heart disease, the newborn with congenital CHB has NLE, which is associated with a distinctive skin rash of erythematous round eruptions due to antibody disposition on basal keratinocytes (McCauliffe, 1995). This rash may be increased by light exposure, especially phototherapy for hyperbilirubinemia. Parents are advised to keep affected infants out of direct sunlight for the first 6 months of life, after which the NLE resolves. In addition to cardiac and dermatologic manifestations, NLE may present with thrombocytopenia or anemia, as well as hepatosplenomegaly, hepatitis or cholestasis, aseptic meningitis, myopathy, or myasthenia (McCauliffe, 1995).

In the delivery room, an isoproterenol drip should be initiated as soon as intravenous access is secure. Corticosteroids may be administered to prevent ongoing myocardial injury. Some neonatologists have performed exchange transfusions to eliminate circulating maternal antibody, but no data are available to support its use. Cardiac pacing is the definitive treatment. If the child is unstable or delivered for cardiac decompensation, a transvenous or transthoracic temporary pacing lead should be placed. This may not be possible in a premature infant, in whom a left anterior thoracotomy for placement of temporary epicardial pacing leads should be performed until the infant is sufficiently large to undergo

Table 42-2

Clinical Manifestations of Neonatal Lupus Erythematosus

System	Description	Presentation
Cutaneous	Erythematous round, oval, and annular patches	Weeks to months after delivery. Resolves after 6 months, occasional residual pigmentation
Cardiac	Complete heart block, myocarditis, congestive heart failure	Usually third trimester, but as early as 17 weeks, invisible heart block
Hematologic	Thrombocytopenia, anemia, leukopenia	At birth, usually self-limited
Hepatic	Hepatomegaly, hepatitis, cholestasis	At birth, usually self-limited

permanent placement of a cardiac pacemaker. If the fetus is hydropic, delivered for cardiac decompensation, or has a ventricular rate less than 55 bpm, some form of cardiac pacemaker should be placed urgently. The degree of heart block is permanent and if the heart is decompensating, medical therapy such as isoproterenol is unlikely to prevent progressive deterioration.

LONG-TERM OUTCOME

The mortality rate for infants presenting in the newborn period with CHB is at least 25%. In a long-term follow-up study Vetter and Rashkind (1983) documented 90% survival after the neonatal period. Most deaths were due to pacemaker failure. These children need to be followed for the later development of rheumatologic disease. McCauliffe (1995) described seven patients with congenital CHB who went on to develop collagen vascular diseases, either systemic lupus erythematosus or Sjögren syndrome. Whether this is due to NLE is unknown. More likely, this represents familial predisposition or inheritance of an HLA type associated with collagen vascular disease.

GENETICS AND RECURRENCE RISK

There is no known genetic predisposition for the development of fetal CHB. The woman who has previously had a fetus with NLE is at greatest risk for recurrence. The manifestations of NLE tend to be the same in subsequent pregnancies. Petri et al. (1989) found that mothers of infants with NLE manifested by CHB had a 64% chance of a subsequent fetus being similarly affected. However, McCune et al. (1987) found only a 25% recurrence of CHB.

Women with a history of an autoimmune disorder and anti-Ro antibodies constitute the next highest risk category. Ramsey-Goldman et al. (1986) found that only 8% of infants born to mothers with SLE who had anti-Ro antibodies were affected by NLE. Among mothers with SLE but no anti-Ro antibodies, the incidence of NLE was only 0.6%. Normal women, or those with ill-defined symptoms who produce anti-Ro antibodies, are probably at even lower risk. Unfortunately, this latter category accounts for 50% of cases of NLE, which are impossible to identify before the fetus or newborn is symptomatic (Petri et al., 1989; McCauliffe, 1995).

Olah and Gee (1993) have defined four known risk factors: a previous child with CHB, a high titer of anti-Ro antibody (>1:16), presence of anti-La antibody in addition to anti-Ro antibody, and maternal HLA-DR3.

43 CHAPTER Atrial Septal Defects

Key Points

- Atrial septal defects are relatively common congential cardiac malformations, but are difficult to diagnose prenatally due to problems differentiating the normal patent foramen ovale from an anatomic defect of the septum.
- Many cases close spontaneously within 2 years of life, while persistence of a large defect, especially with evidence of right ventricular overload, is an indication for elective closure.
- Open surgical approaches to closure have been replaced in most cases with minimally invasive transcatheter occlusion techniques.
- While the medium-term outcome of such transcatheter occlusion techniques appears favorable, it will likely be some time before sufficient data are available to confirm long-term safety and efficacy.

CONDITION

Atrial septal defect (ASD) refers to a congenital malformation in the development of the interatrial septum. In embryonic life, the interatrial septum begins as a septum primum, growing from the atrial walls to the endocardial cushions, which contains a temporary opening known as the foramen primum (Romero et al., 1988). Subsequently, a septum secundum grows on the right side of the septum primum and contains a normal opening known as the foramen ovale. The lower part of the septum primum forms a flap valve for this foramen ovale. Soon after birth, increased left atrial pressure closes this flap, normally resulting in complete closure of the foramen ovale within 2 years of life (Kerut et al., 2006).

Three different types of ASDs are possible, depending on the location within the heart (Romero et al., 1988). An inlet ASD is located near the entrance of the superior vena cava; a secundum ASD occurs in the body of the interatrial septum; a primum or outlet ASD is located near the atrioventricular junction and usually behaves similarly to an AV canal defect (see Chapter 45). Secundum ASDs typically occur because of absence of the foramen ovale flap valve. ASDs usually cause no hemodynamic effects in utero because of the normal right-to-left shunting of blood across the patent foramen ovale. If an ASD persists after birth it may allow for a left-to-right shunt, which can result in congestive heart failure or pulmonary hypertension.

INCIDENCE

Because of the difficulties in differentiating ASDs from asymptomatic patency of the foramen ovale, the precise incidence of ASD in neonatal life is difficult to establish. A patent foramen ovale may be present in up to 30% of normal adults (Kerut et al., 2006). ASDs comprise 7.5% of all congenital cardiac malformations (Ferencz et al., 1987). In one population series, the incidence of ASD was 6 in 10,000 total births (Mitchell et al., 1971).

SONOGRAPHIC FINDINGS

Prenatal sonographic diagnosis of ASD is problematic because the differentiation between a normal patent foramen ovale and true ASD may be difficult. The foramen ovale normally increases in size linearly with advancing gestational age (Phillipos et al., 1994). Large defects of the septum secundum are visualized as dropout of echoes at the level of the interatrial septum (Romero et al., 1988). If an apical four-chamber view is used it may be difficult to confirm an intact interatrial septum. For adequate visualization, the ultrasound probe should be perpendicular to the septum, which can be achieved through the use of a subcostal approach to the four-chamber view (Romero et al., 1988).

The accuracy of sonographic screening for prenatal detection of ASD is poor. In a series of 7459 fetuses who were screened at 18 weeks of gestation, there were 10 ASDs, none of which were identified prenatally (Tegnander et al., 1995). In another series, only 5% of the 761 ASDs that were present in a single large population were detected prenatally (Montana et al., 1996).

DIFFERENTIAL DIAGNOSIS

The main differential diagnosis to consider following the prenatal diagnosis of an ASD is the possibility of a normal patent foramen ovale.

ANTENATAL NATURAL HISTORY

In the majority of cases, an isolated ASD will not cause any significant hemodynamic compromise in utero because of the normal right-to-left shunting of blood across the patent foramen ovale. It is also possible for ASDs to close spontaneously in utero, although the exact frequency of this occurrence is unclear because the accuracy of prenatal diagnosis of isolated ASD is so poor.

MANAGEMENT OF PREGNANCY

Following prenatal diagnosis of an ASD, a careful sonographic fetal anatomy survey is recommended to exclude additional complex cardiac malformations. A sonographic search for extracardiac malformations should also be performed. Fetal echocardiography should be performed by an appropriately trained specialist to confirm the diagnosis and to exclude other cardiac malformations. Invasive fetal testing for karyotype analysis is recommended following the prenatal diagnosis of ASD because the incidence of chromosomal abnormalities may be up to 10% (Ferencz et al., 1987). Referral for prenatal consultation with a pediatric cardiologist is also recommended.

If expectant management is desired, sonographic surveillance to confirm appropriate fetal growth and to evaluate for the development of fetal hydrops is recommended, although the chances of significant hemodynamic disturbances occurring in utero are extremely low with isolated ASD. Although delivery need not necessarily occur at a tertiary care center if the ASD is isolated and uncomplicated, arrangements should be in place for a prompt careful examination of the infant soon after delivery and for referral to a pediatric cardiologist during the newborn period. There is no indication to alter the timing or method of delivery based on the prenatal diagnosis of isolated ASD.

FETAL INTERVENTION

No fetal intervention has been described for the prenatal management of an isolated ASD.

TREATMENT OF THE NEWBORN

Almost all infants with isolated ASD are asymptomatic at the time of delivery and do not require any alteration to usual neonatal care or resuscitation practices. A careful physical examination is mandatory to confirm hemodynamic stability immediately following delivery and again during the neonatal period. Consultation with a pediatric cardiologist should be obtained promptly and echocardiography performed to confirm the prenatal diagnosis and to rule out additional cardiac malformations. Confirmation of a significant patent foramen ovale is generally performed using transthoracic echocardiography. Injection of bacteriostatic saline containing benzyl alcohol can be performed, and the appearance of contrast bubbles in the left heart within three cardiac cycles confirms the diagnosis. Appearance of contrast after more than three cardiac cycles is not consistent with ASD or patent foramen ovale, as the contrast will likely have already passed through the pulmonary circulation (Kerut et al., 2006). It should be noted that physiological size and functional significance of an ASD are not directly correlated. It is important also to evaluate for the presence of an atrial septal aneurysm, as its presence together with a patent foramen ovale puts the patient at significantly higher risk for cryptogenic stroke (Overell et al., 2000).

SURGICAL TREATMENT

Most infants with an isolated ASD will remain completely asymptomatic during the first decade of life. Initially, there is a fall in pulmonary vascular resistance at the time of birth, which leads to left-to-right shunting of blood across the ASD. However, because of the distensibility of the ventricles during infancy, this shunt leads to progressive distention of the right ventricle rather than a sudden increase in pulmonary blood flow. In general, this situation persists throughout the second decade of life, at which time pulmonary artery blood flow increases significantly, leading to symptoms of right heart failure. In addition, as pulmonary flow increases, pulmonary vascular resistance can increase again, eventually leading to Eisenmenger syndrome, which results from cyanosis due to right-to-left shunting of blood.

The rate of spontaneous closure of isolated ASDs is 22% for infants younger than 1 year, 33% for children aged 1 to 2 years, and 3% for children older than 4 years (Cockerham et al., 1983). Because of the risks of heart failure and pulmonary hypertension, it has been recommended that

children with significant ASDs that persist beyond 4 years of age undergo elective surgical closure of the defect (Cockerham et al., 1983). Surgical repair is generally performed on cardiopulmonary bypass, through a median sternotomy incision, and by the use of pericardium or prosthetic material to close the defect (Merrill and Bender, 1985). Other open surgical approaches include right thoracotomy and submammary incisions, the latter being cosmetically preferable. The operative mortality rate for this procedure is currently less than 1% (Ward, 1994).

More recently however, transcatheter approaches for closure of ASDs have been perfected to the extent that in many centers, open surgical correction has been replaced for all but the largest ASDs. The great advantage of these approaches is the lack of open incisions and the ability to avoid cardiopulmonary bypass and stopping the heart. While there is controversy between interventional pediatric cardiologists and cardiac surgeons on the criteria to select between open surgical and transcatheter approaches to ASD closure, it is generally considered acceptable to rely on transcatheter devices if at least 5 mm of rim around the ASD is present (Holzer and Hijazi, 2004). With the latest transcatheter septal occlusion devices, 100% closure rates 1 month postoperatively are expected (Patel and Hijazi, 2005).

Because of the limitations of most of the studies of the natural history of isolated ASD, it has also been argued that only children with symptomatic ASDs should be offered surgical repair (Ward, 1994). There are virtually no good data on the natural history of asymptomatic children with ASDs because almost none of these children will have a diagnosis, so it is difficult to warrant routine surgical repair in the asymptomatic state. In addition, ASDs diagnosed prenatally may represent yet another patient group with a completely different natural history during childhood.

LONG-TERM OUTCOME

The long-term outcome following surgical repair for isolated ASD is excellent, with a 92%, 25-year actuarial survival (Morris and Menashe, 1991). It is possible that right ventricular enlargement and arrhythmias may persist postoperatively, but the long-term consequences of these conditions are unclear (Merrill and Bender, 1985). Almost all patients have a normal life span and a normal level of activity following surgical repair of ASD.

Long-term outcome results following transcatheter septal occlusion appear reassuring, although there have been sporadic reports of erosion of the device into the adjacent ascending aorta (Patel and Hijazi, 2005). The other major long-term adverse event with these minimally invasive devices is thrombus formation, which may occur in 2% to 7% of cases 6 months postoperatively (Krumsdorf et al., 2004; Patel and Hijazi, 2005).

GENETICS AND RECURRENCE RISK

Almost all cases of ASD are sporadic in occurrence. However, there is some evidence of familial occurrence, with siblings of women with a patent foramen ovale being more likely to also have patent foramen ovale (Arquizan et al., 2001). The recurrence risk if one previous sibling has an ASD is 2.5%; this increases to 8% if two previous siblings were affected (Nora and Nora, 1988). If the mother has an ASD, the recurrence risk for offspring is 4%; the recurrence risk is only 1.5% if the father has an ASD (Nora and Nora, 1988).

Ventricular Septal Defects

44 CHAPTER

Key Points

- Ventricular septal defects are the most common congential cardiac malformations, and often occur as part of more complex abnormalities, such as tetralogy of Fallot or transposition.
- Prenatal diagnosis should be straightforward using a long axis view of the ventricles, followed by a short axis sweep from apex to base.
- Many isolated small VSDs, especially of the muscular type, will close spontaneously in utero, or in infancy.
- Significant VSDs that contribute to failure to thrive, or those associated with increased pulmonary vascular flow, should be surgically repaired by 6 months of age.
- Recent advances in minimally invasive transcatheter septal occlusion devices hold great promise as an alternative to open surgical repair with cardiopulmonary bypass.

CONDITION

Ventricular septal defect (VSD) refers to a congenital malformation in the development of the interventricular septum. VSDs can occur in the muscular or membranous portions of the septum. Muscular VSDs may be further subdivided into inlet, trabecular, or infundibular defects (Soto et al., 1980; Minette and Sahn, 2006). VSDs may also be classified as being either subvalvular or muscular (Capelli et al., 1983). Subvalvular VSDs are directly related to the atrioventricular or semilunar valves, without interposed muscle between the defect and the valve cusps. Such subvalvular defects may be further subclassified as inlet, subtricuspid, subaortic, subpulmonary, or double-committed subarterial, in which the defect is below the pulmonary and aortic valves. Muscular VSDs are bordered on all sides by muscle and are not directly related to the valves. Such defects may be further subclassified as being apical, central, or outlet in location. Most of these VSD types can be defined by echocardiography, although it is important to realize that small muscular defects can be missed by sonography during both the prenatal and the postnatal periods (Capelli et al., 1983).

VSDs usually cause no hemodynamic effects in utero because of the similarity in pressures between the right and left sides of the heart during prenatal life. Most VSDs are also asymptomatic immediately following birth. If the VSD persists after birth, it may allow for the development of a left-to-right shunt, which can result in congestive heart failure or pulmonary hypertension.

INCIDENCE

VSDs are the most common single congenital cardiac malformation, accounting for 26% of all structural cardiac abnormalities (Ferencz et al., 1987). In an earlier population series, the incidence of VSD was 2 in 10,000 total births (Mitchell et al., 1971). However, with the increasing use of prenatal and neonatal echocardiography, the birth incidence of VSDs seems to be much higher than previously suggested (Minette and Sahn, 2006). In one series, 5% of all newborns were found to have an isolated muscular VSD (Roguin et al., 1995). The most accurate estimate of birth prevalence of VSD is 3.5 per 1000 livebirths (Hoffman and Kaplan, 2002). In addition, VSDs are frequently found in association with other cardiac malformations, such as tetralogy of Fallot (see Chapter 52) and transposition of the great arteries (see Chapter 55).

SONOGRAPHIC FINDINGS

As with an ASD, prenatal sonographic diagnosis of a VSD can be difficult because it relies on visualization of dropout

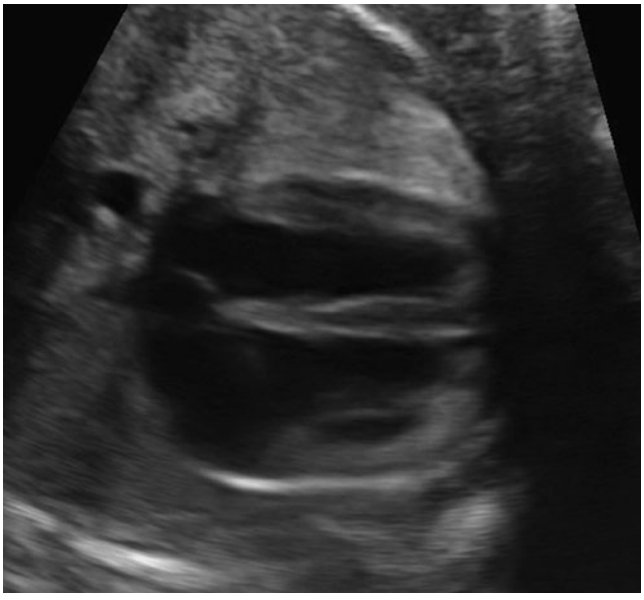

Figure 44-1 Long-axis view demonstrating intact ventricular septum.

of echoes at the level of the interventricular septum, which is best achieved using a subcostal approach to the four-chamber view. In order to confirm an intact interventricular septum, the septum should also be visualized by means of a long-axis view of the left and right ventricles, together with an apex-to-base sweep along the short axis of the heart (Figures 44-1 to 44-3) (Romero et al., 1988). Small membranous VSDs are still commonly missed on prenatal sonography, despite adequate views of all parts of the interventricular septum. In addition, artifactual areas of hypoechogenicity in the septum during the apical four-chamber view may give the false impression of a VSD; therefore a true VSD is confirmed only when it is

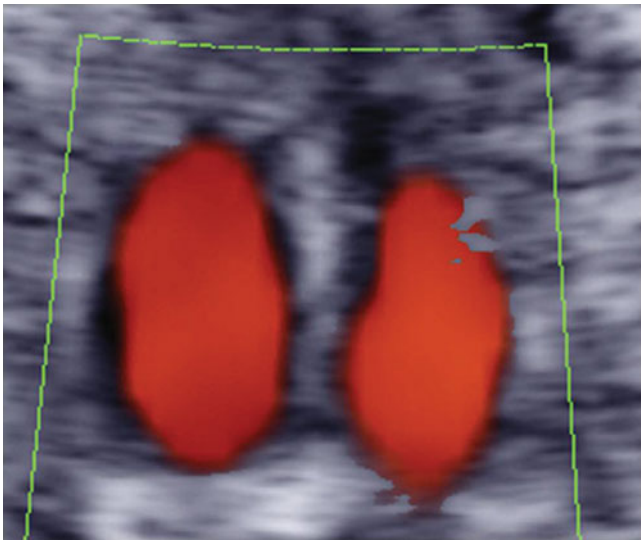

Figure 44-2 Axial image with color Doppler showing forward flow across the atrioventricular valves with an intact interventricular septum.

Figure 44-3 Axial image demonstrating a membranous ventricular septal defect.

visible in at least two different planes (Romero et al., 1988). Color Doppler sonography may also be used to demonstrate flow across the area of defect (Figure 44-4) (Sanders et al., 1996).

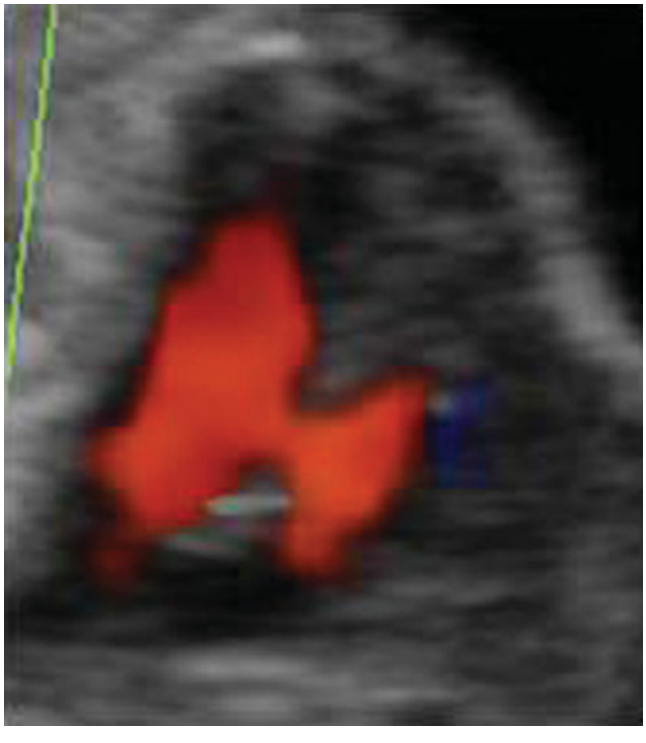

Figure 44-4 Axial image with color Doppler demonstrating forward flow across the atrioventricular valves and flow across a ventricular septal defect.

The accuracy of prenatal sonographic screening for VSDs is poor. In a series of 7459 fetuses that were screened at 18 weeks of gestation, there were 53 VSDs, none of which were identified prenatally (Tegnander et al., 1995). In another series, only 5% of the 486 VSDs present in a single large population were detected prenatally (Montana et al., 1996). The accuracy of targeted fetal echocardiography for prenatal detection of isolated VSDs is also poor. In one series of targeted fetal echocardiograms, only 4 (31%) of 13 ASDs or VSDs were correctly identified (Benacerraf et al., 1987). In another series of fetal echocardiograms, there were 29 VSDs, 19 (66%) of which were correctly identified; the vast majority of these were associated with other more complex cardiac malformations (Crawford et al., 1988). In one further series, only 11 (44%) of 25 isolated VSDs were correctly identified prenatally, with small and moderate-sized VSDs the most likely to be missed (Kirk et al., 1997).

DIFFERENTIAL DIAGNOSIS

As with ASD, it is important to consider a normal interventricular septum in all cases following the prenatal diagnosis of VSD because false-positive diagnoses are possible, especially if the septum is visualized by means of an apical four-chamber view. Other diagnoses to consider include the presence of additional, more complex cardiac malformations that may involve a VSD, such as tetralogy of Fallot, transposition of the great arteries, double outlet right ventricle, and tricupsid atresia.

ANTENATAL NATURAL HISTORY

As with ASDs, almost all isolated VSDs cause no significant hemodynamic compromise in utero; the pressures in both ventricles are similar, so shunting of blood between ventricles is not a problem. Many isolated VSDs, especially small muscular types, close spontaneously, either in utero or soon after birth (Nir et al., 1994). Muscular VSDs may close as a result of muscular occlusion, while membranous VSDs may close by tricuspid valve aneurysm formation (Minette and Sahn, 2006). In one series, 26 (74%) of 35 isolated VSDs diagnosed prenatally closed spontaneously before birth, and there was no correlation between the size of the defect and probability of closure (Orie et al., 1994). In another series, 89% of all muscular VSDs were asymptomatic and resulted in spontaneous closure within 1 to 10 months of neonatal life (Roguin et al., 1995). However, because prenatal diagnosis of VSDs is so poor, it is possible that VSDs successfully diagnosed in utero may be larger and may represent a group that has a more unfavorable prognosis.

In a series of 14 fetuses with VSDs diagnosed prenatally, 6 (43%) were terminated, 2 (14%) died in utero, 1 (7%) died postnatally, and 5 (36%) survived (Smythe et al., 1992). In another series of 19 fetuses with VSDs diagnosed prenatally, 1 (5%) died in utero, 10 (53%) died postnatally, and 8 (42%) survived (Sharland et al., 1990).

MANAGEMENT OF PREGNANCY

Following prenatal diagnosis of a VSD, a careful sonographic fetal anatomy survey is recommended to exclude additional complex cardiac malformations, such as tetralogy of Fallot, transposition of the great arteries, or double outlet right ventricle. Although most VSDs diagnosed after birth are isolated, the majority of prenatally diagnosed VSDs occur in association with more complex cardiac malformations (Crawford et al., 1988). A sonographic search for extracardiac malformations should also be performed. Fetal echocardiography should be performed by an appropriately trained specialist to confirm the diagnosis and to exclude other cardiac malformations.

Invasive fetal testing for karyotype analysis is recommended following the prenatal diagnosis of VSD because the incidence of chromosomal abnormalities may be up to 18%, although in one series of 7 prenatally diagnosed VSDs, 5 (71%) were associated with aneuploidy (Ferencz et al., 1987; Paladini et al., 1993). Referral for prenatal consultation with a pediatric cardiologist is also recommended.

Elective termination of pregnancy may be considered by some patients, especially if the VSD is part of a more complex cardiac malformation. However, the chances of spontaneous closure, both in utero and postnatally, should be emphasized before a decision on terminating the pregnancy is made. If expectant management is desired, sonographic surveillance to confirm appropriate fetal growth and to evaluate for the development of fetal hydrops is recommended, although the chances of significant hemodynamic disturbances occurring in utero are extremely low with isolated VSD.

Even though delivery need not necessarily occur at a tertiary care center if the VSD is isolated and uncomplicated, arrangements should be in place for a prompt, careful examination of the infant soon after delivery and for referral to a pediatric cardiologist during the early newborn period. If there is a suspicion that the VSD may be large and may become clinically significant soon after birth, consideration should be given to delivery in a tertiary care center. There is no indication to alter the timing or method of delivery based on the prenatal diagnosis of isolated VSD.

FETAL INTERVENTION

No fetal intervention has been described for the prenatal management of isolated VSD.

TREATMENT OF THE NEWBORN

Most infants with isolated VSD are asymptomatic at the time of delivery and do not require any alteration to usual neonatal

care or resuscitation practices. A careful physical examination is mandatory to confirm hemodynamic stability immediately following delivery and again during the neonatal period. Consultation with a pediatric cardiologist should be obtained promptly and echocardiography performed to confirm the prenatal diagnosis and to rule out additional cardiac malformations. More recently, three-dimensional echocardiography has been used successfully to quantify the left-to-right shunt, which aids in assessing the severity and prognosis (Ishii et al., 2001). If required, subsequent cardiac catheterization can be used to measure pulmonary vascular resistance and shunt volume, as well as confirming cardiac anatomy in complex cases.

Infants with large, membranous VSDs tend to become progressively more symptomatic during the first months of life as the pulmonary vascular resistance falls and left-to-right shunting increases. This can lead to right ventricular failure, which may require digoxin, fluid restriction, and diuretics. The use of hydralazine to achieve afterload reduction may also decrease the left-to-right shunt. As pulmonary vascular congestion worsens, lung compliance decreases, and such infants have difficulty feeding, which may require caloric supplementation or tube feedings.

SURGICAL TREATMENT

The majority of isolated VSDs tend to close spontaneously, and therefore the most common indication for surgical repair of a VSD is failure of medical treatment in a symptomatic patient. Other indications for surgical repair include pulmonary hypertension, aortic insufficiency, recurrent respiratory infections, persistent failure to thrive, and prior bacterial endocarditis. Most infants who become symptomatic from a VSD tend to demonstrate congestive heart failure at 1 to 2 months of life. If growth failure cannot be improved by medical therapy by 6 months of age, surgical repair should be considered (Ohye and Bove, 2001). If optimal medical treatment fails to relieve symptoms, definitive primary surgical repair should be performed. The repair is usually done by means of cardiopulmonary bypass, through a right atrial approach and the use of a Dacron patch to close the defect (Merrill and Bender, 1985). Operative mortality currently should be less than 5%.

Controversy exists about whether all asymptomatic VSDs should be surgically repaired. In one series of 141 patients with restrictive VSDs, elective surgical repair was performed, with no operative mortality, and the authors concluded that the accepted indications for VSD closure should be expanded (Backer et al., 1993). However, given that there is a 50% chance that a small VSD will close spontaneously by 5 years of age and an 80% chance that it will close by adolescence, it is difficult to recommend elective surgical repair in childhood for small asymptomatic VSDs (Waldman, 1993). Other indications for surgery may include infundibular VSDs, increased pulmonary vascular flow, or multiple "Swiss cheese" type defects refractory to medical therapy, in which case a palliative pulmonary artery band may be required (Minette and Sahn, 2006).

As with atrial septal defect repair, more recent trends are toward catheter device closure, thereby avoiding cardiopulmonary bypass. While currently considered investigational, early studies of transcatheter techniques, (such as the Amplatzer VSD occluder), have suggested 96% VSD closure success at 6 months, with a serious adverse event rate of 9% (Patel and Hijazi, 2005; Fu et al., 2006).

LONG-TERM OUTCOME

The long-term outcome following surgical repair for isolated VSD is also excellent, with an 86%, 25-year actuarial survival (Morris and Menashe, 1991). The risk of bacterial endocarditis remains significant following surgical repair of VSD, although it is twice as likely to occur before VSD closure than subsequently (Waldman, 1993). Other long-term problems include heart block, in 3% of cases, which may require pacemaker placement (Minette and Sahn, 2006). The majority of patients have a normal life span and normal level of activity following surgical repair of VSD.

GENETICS AND RECURRENCE RISK

While almost all cases of VSD are sporadic in occurrence, VSDs can be seen as part of a range of genetic conditions, including chromosomal disorders (such as trisomy 21 or DiGeorge syndrome), and single-gene disorders (such as Holt–Oram syndrome). In such cases, the recurrence risk is related to the underlying genetic abnormality. The recurrence risk if one previous sibling has a VSD is 3%; this increases to 10% if two previous siblings were affected (Nora and Nora, 1988). If the mother has a VSD, the recurrence risk for offspring is 6% to 10%; the recurrence risk is only 2% if the father has a VSD (Nora and Nora, 1988).

Atrioventricular Canal Defect

45 CHAPTER

Key Points

- Atrioventricular (AV) canal defect is the most common form of congenital heart disease detected prenatally and usually involves both a lower atrial and an upper ventricular septal defect, together with a common AV valve orifice.
- In 70% of cases there will be additional cardiac malformations, and in the majority of isolated cases additional chromosomal abnormality will be diagnosed, most commonly trisomy 21.
- Prenatal diagnosis of complete AV canal defect should be straightforward, by failure to visualize the normal crux on a four-chamber cardiac view.
- Management of pregnancy includes detailed echocardiographic and general fetal anatomic evaluation, amniocentesis, and planned delivery with complete pediatric cardiology backup.
- Overall prognosis is variable as prenatally diagnosed AV canal defects represent a heterogenous group.

CONDITION

Atrioventricular (AV) canal defect is also known as an AV septal defect, common AV canal, endocardial cushion defect, ostium primum atrial septal defect, or persistent ostium atrioventriculare commune. Complete AV canal defect consists of an unrestrictive atrial septal defect, an unrestrictive ventricular septal defect, and a single common AV valve. It occurs because of failure of development of the endocardial cushion during embryogenesis and persistence of the primitive single AV canal beyond 6 weeks of gestation. Although the AV canal defect may involve a wide spectrum of abnormalities of the atrial and ventricular septa and the AV valves, the complete form with associated AV valve regurgitation is the one that most commonly presents during the neonatal period (Chin et al., 1982).

AV canal defects can be partial or complete. With a partial AV canal defect, there are two separate AV orifices, with communication between two atria or between the left ventricle and the right atrium. While the right AV valve is usually normal, the left valve usually has three leaflets (Becker and Anderson, 1981). With a complete AV canal defect, there is a defect in the inferior portion of the atrial septum and the superior portion of the ventricular septum, together with a single AV valve orifice, which usually has five valve leaflets. The anterior and posterior valve leaflets are inserted on the anterior and posterior surfaces of the ventricular septum, respectively; the degree of bridging of the anterior leaflet across the ventricular septum determines the type of defect (Rastelli et al., 1966). For type A complete AV canal defects, the anterior leaflet does not bridge the ventricular septum and is attached on both sides of the septum by chordae tendineae (Silverman et al., 1986). For type B complete AV canal defects, the anterior leaflet somewhat bridges the ventricular septum and is attached to the right ventricle by an anomalous papillary muscle. For type C complete AV canal defects, the anterior leaflet is not attached to the septum, and completely bridges it, being attached at either side by papillary muscles. Type A is commonly seen in trisomy 21, and type C is commonly seen with atrial isomerism (Mann et al., 2004).

INCIDENCE

Complete AV canal defect accounts for 1% to 5% of all cases of congenital heart disease (Rowe et al., 1981). It is the most common cardiac defect detected prenatally. In one series of 357 cases of congenital heart disease 13% were AV canal defects, almost 70% of which were of the complete type (Fontana and Edwards, 1962). In a series of 49 AV canal defects from a single center, 88% were of the complete type and 12% were partial (Allan, 1999). Familial clustering of AV canal defects has also been described (Tennant et al., 1984; Disegni et al., 1985). Review of population-based series of congenital heart disease suggests that the incidence of AV canal defect is 0.3 per 1000 livebirths (Hoffman and Kaplan, 2002).

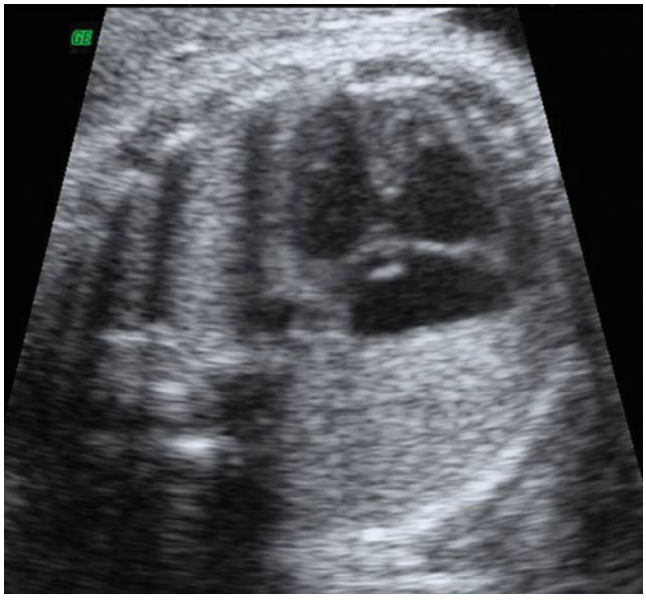

Figure 45-1 Axial image demonstrating defect in the crux of the fetal heart consistent with an atrioventricular canal defect.

SONOGRAPHIC FINDINGS

Prenatal diagnosis of a complete AV canal defect is relatively straightforward, because a large defect or hole is easily visualized at the crux of the heart during diastole on the four-chamber view (Figure 45-1). This hole represents the defects in the inferior portion of the atrial septum, the superior portion of the ventricular septum, and the single AV valve orifice. In the normal four-chamber view of the heart, the tricuspid valve inserts more apically than the mitral valve, leading to an offset appearance at the crux of the heart. With an AV canal defect, this offset appearance may be lost, with both valves forming a straight line across the crux of the heart when closed (Figure 45-2).

Because the defect can be large, the cardiac conduction apparatus is frequently abnormal, resulting in an increased frequency of bradyarrhythmias. In one series, 11 of 29 fetuses with AV canal defects also had complete heart block (Machado et al., 1988). In addition, all 11 of these fetuses also demonstrated features of the heterotaxy syndrome (see Chapter 56). Prenatal echocardiography should focus on the structure of the AV valve. The presence of a common leaflet at the level of the AV valve is suggestive of complete AV canal defect, while in its partial form the only abnormality may be a small defect in the inferior portion of the atrial septum (Romero et al., 1988).

Color and pulsed Doppler echocardiography may demonstrate turbulent systolic flow on the atrial side of the common AV valve because of significant valvular regurgitation (Barber and Chin, 1990). The presence of significant valvular regurgitation can be quantified, and when present throughout systole, it may be predictive of hydrops fetalis (Gembruch et al., 1991). In contrast, valvular regurgitation confined to early systole is not associated with hydrops and may be an indicator of improved prognosis.

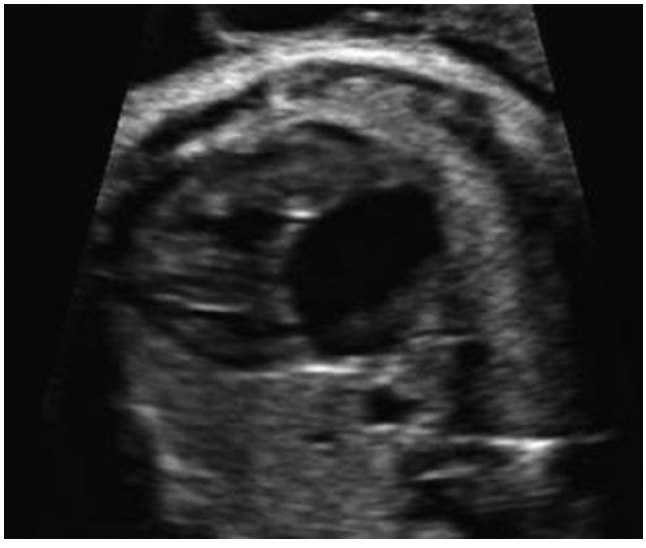

Figure 45-2 Axial image through the fetal heart with an atrioventricular canal defect demonstrating the abnormal positioning of the AV valves.

Prenatal sonography should also focus on excluding other abnormalities, such as malformations associated with aneuploidies or additional cardiac malformations. Sonographic markers associated with aneuploidy should be specifically sought, as approximately 50% of cases of AV canal defects have a chromosomal abnormality, the majority of which are due to trisomy 21 or 8p deletion (Machado et al., 1988). Additional cardiac malformations may be present in more than 70% of cases, such as tetralogy of Fallot, coarctation, pulmonary stenosis, and double outlet right ventricle (Machado et al., 1988). In a series of 49 cases of AV canal defect from a single center, 31 (63%) had additional cardiac malformations, typically heterotaxia or isomerism, but also including hypoplastic left ventricle and tetralogy (Allan, 1999). In the Baltimore–Washington infant study, 336 children were identified with an endocardial cushion defect. Of these, 76% were identified as having a syndromic diagnosis (78% of these had trisomy 21) (Carmi et al., 1992). A more recent review of 301 cases of AV canal defect from a single center in London demonstrated that approximately 50% with known karyotype had aneuploidy, with the vast majority (80%) of these being trisomy 21, and others including trisomy 18, trisomy 13 (Huggon et al., 2000). In this series, 155 of 301 (52%) had normal atrial arrangement and no other evidence of additional cardiac abnormalities, while 40 of 301 (13%) had significant extracardiac abnormalities (Huggon et al., 2000). Chromosomal abnormality appears to be much more likely in the setting of AV canal defect with normal atrial connections.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for complete AV canal defects includes a large atrial or ventricular septal defect, or a single ventricle (Barber and Chin, 1990). While complete AV canal defects can usually be easily distinguished from these lesions by prenatal echocardiography, differentiation from partial AV canal defects may be more problematic. Genetic considerations in the differential diagnosis include trisomy 21 (see Chapter 131), heterotaxy (Ivemark syndrome; see Chapter 56), Ellis–van Creveld syndrome (see Chapter 94), Holt–Oram syndrome, and CHARGE association.

ANTENATAL NATURAL HISTORY

Few data are available on the antenatal natural history of isolated complete AV canal defects and none are available for partial forms of this condition. In one series, 3 of 36 (8%) cases with AV canal defect that were managed expectantly resulted in spontaneous intrauterine demise (Allan, 1999). In another series of 301 cases of AV canal defect from a single center, 19 of 123 (15%) expectantly managed cases ended with spontaneous intrauterine demise (Huggon et al., 2000). If chromosomal abnormalities are also present, the rate of intrauterine loss is significantly increased. The worst antenatal prognosis seems to be associated with complete forms of the AV canal defect, in which there is also significant regurgitation across the common AV valve, as well as cases with bradycardia (Huggon et al., 2000). Such cases are mostly associated with hydrops fetalis (Gembruch et al., 1991). The partial forms of the AV canal defect tend to present clinically after 1 month of postnatal life because volume overload does not occur until pulmonary vascular resistance has dropped significantly (Chin et al., 1982).

MANAGEMENT OF PREGNANCY

If an AV canal defect is suspected on prenatal sonographic studies, a referral to a pediatric cardiologist or other specialist skilled in fetal echocardiography is recommended. Careful sonographic imaging to assess for the presence of additional cardiac malformations is also recommended. Because of the strong correlation between AV canal defects and trisomy 21, all patients should be offered prenatal karyotype evaluation, typically by means of amniocentesis. Prenatal consultation with a pediatric cardiac team, (including cardiology, cardiothoracic surgery, and neonatology), may also be helpful for planning immediate neonatal intervention.

Early delivery is not recommended because a low birth weight carries a less favorable prognosis for neonatal cardiac surgery as compared with a higher birth weight. Delivery should take place under controlled circumstances at a tertiary care center with an on-site pediatric cardiology team immediately available. The mode of delivery should be dictated by obstetric indications. However, the presence of hydrops may make vaginal delivery problematic because of soft-tissue dystocia. Weighing the benefits of cesarean delivery to avoid dystocia against the very poor prognosis for infants with hydrops secondary to structural cardiac malformations represents a difficult choice.

FETAL INTERVENTION

No fetal intervention has been described for prenatally diagnosed cases of AV canal defect.

TREATMENT OF THE NEWBORN

Some infants with partial AV canal defect are detected during the newborn period but the majority are asymptomatic at birth. The presence of a complete AV canal defect usually results in symptoms at birth, such as a heart murmur. In other infants with complete AV canal, tachycardia, tachypnea, and failure to thrive develop during early infancy. The development of clinical symptoms prior to 3 months of age may be delayed because pulmonary vascular resistance remains high, which limits left-to-right shunting. If symptomatic presentation occurs prior to 3 months it is usually due to the presence of severe valvular regurgitation or additional cardiac malformations. Infants presenting with these symptoms need appropriate medical and surgical intervention to avoid the development of significant pulmonary hypertension. Left untreated, infants with complete AV canal defects have a 50% chance of survival beyond 6 months, and only a 30% chance of survival beyond 1 year (Berger et al., 1978).

Initial medical treatment of the newborn with a complete AV canal defect includes cardiorespiratory support and complete cardiac work-up, including electrocardiography. The administration of digoxin to enhance myocardial contractility and diuretics to optimize preload is recommended (Barber and Chin, 1990). Appropriate caloric supplementation is also recommended to make up for the high metabolic state associated with an intracardiac shunt and pulmonary edema. Two-dimensional echocardiography with pulsed and color Doppler studies should be performed soon after birth to confirm the cardiac malformation and to assess the morphology of the valve leaflets. With careful echocardiographic evaluation and optimal visualization of cardiac anatomy, cardiac catheterization and angiography may be avoided (Zellers et al., 1994).

SURGICAL TREATMENT

Primary surgical repair of complete AV canal defect is usually performed electively between 3 and 6 months of age, or earlier if significant symptoms are present (Sand and Pacifico, 1990). Delay beyond this time may expose the infant to significant risk for the development of pulmonary hypertension and eventually Eisenmenger syndrome. Correction of partial AV canal defects is performed electively during the first few years of life.

Primary repair of AV canal defects is facilitated by the establishment of cardiopulmonary bypass. Repair usually involves closure of the atrial septal defect with a patch of pericardium, closure of the interventricular defect with a Dacron patch, and attachment of the common AV valve leaflets to this patch. Care must be taken to avoid surgical injury to the AV node or bundle of His to prevent surgically induced complete heart block. The use of a double-patch technique may produce less distortion of the valve, although it may be possible to achieve similar results using a single patch and ventricular distention (Santos et al., 1986). The precise details of surgical repair, especially if additional cardiac malformations are present, are beyond the scope of this textbook but are easily available in the literature (Capouya and Laks, 1991).

Poor prognostic factors for the surgical repair of AV canal defects include the presence of significant valvular regurgitation, poor overall functional capability, ventricular hypoplasia, presence of a ventricular septal defect, accessory valve orifice, or additional cardiac malformations (Studer et al., 1982). Unbalanced AV canal defect, in which the AV valve sits more over one ventricle with relative hypoplasia of the other ventricle, represents a much higher risk surgical scenario that may require a single ventricle repair (Cohen and Spray, 2005). Mortality directly related to surgery is approximately 0.6% for partial and 2% for complete AV canal defects (Kirklin et al., 1986; Sand and Pacifico, 1990). In another more recent series, overall operative mortality was 3.6% for complete AV canal defects (Tweddell et al., 1996). Higher operative mortality rates described in other series (up to 30%) may reflect different surgical techniques in earlier eras or the presence of additional complex cardiac malformations (Clapp et al., 1987).

LONG-TERM OUTCOME

Surgical series suggest that long-term survival after repair of AV canal defects is excellent. Almost 90% of survivors can be expected to be normally functioning at long-term follow-up, and survival at 12 years after surgery is approximately 85% (Sand and Pacifico, 1990). Valve failure occurs in 10% of cases following repair, which may necessitate valve replacement. Long-term follow-up in a series of 334 cases of surgical repair of partial AV canal defect demonstrated 94% and 87% 5-year and 20-year actuarial survival (El-Najdawi et al., 2000).

However, there seems to be some discrepancy with regard to the long-term survival rates reported by series including prenatally diagnosed AV canal defects and series including only postnatal surgical cases. In a study of 301 AV canal defect cases from London, only 57 (19%) children were still alive at 4 years of age (Huggon et al., 2000). Postnatal surgical series are likely favorably biased as they tend to only include uncomplicated cases, and those suitable for biventricular repair.

Controversy exists about whether the presence of trisomy 21 affects survival after surgical repair of AV canal defects. Caution is necessary in comparing outcomes following repair in infants with and without trisomy 21, as most infants with trisomy 21 tend to have complete AV canal defects and an earlier tendency for pulmonary hypertension

to develop as compared with chromosomally normal infants with AV canal defects. In one series comparing 47 cases of complete AV canal defects in chromosomally normal infants with 12 cases in infants with trisomy 21, there was a trend toward higher mortality in the trisomy 21 group (Morris et al., 1992). However, in a larger series comparing 94 infants with trisomy 21 with 127 chromosomally normal infants with AV canal defects, trisomy 21 was not found to be an independent risk factor for adverse outcome, after controlling for disease severity (Rizzoli et al., 1992). In another series, infants with AV canal defects and trisomy 21 did even better than chromosomally normal infants with AV canal defects (Vet and Ottenkamp, 1989). In view of these findings, most pediatric cardiology centers do not treat infants with AV canal defects and trisomy 21 differently than the way they treat chromosomally normal infants.

GENETICS AND RECURRENCE RISK

A strong correlation exists between the presence of AV canal defects and chromosomal abnormalities, particularly trisomy 21 and 8p deletion. If trisomy 21 is also present, the recurrence risk is related more to the aneuploidy than to the structural cardiac defect. Familial clustering of isolated AV canal defects has also been described, which suggests the possibility of a single-gene defect (Tennant et al., 1984; Disegni et al., 1985). The recurrence risk of AV canal defects in siblings of those affected ranges from 1.5% to 8.7% (Sanchez-Cascos, 1978). In general, with one affected child, we quote a recurrence risk of 3%, and with two affected children we quote a recurrence risk of 10% (Nora and Nora, 1988). The recurrence risk in offspring of chromosomally normal parents with AV canal defects is approximately 10% (Emanuel et al., 1983). This risk is higher when the mother has an AV canal defect as compared to when the father is affected.

In a large study of 103 individuals with isolated AV canal defect, Digilio et al. (1993) found 4 of 111 siblings to be similarly affected (3.6%), 4 of 206 parents affected (1.9%), and 5 of 644 uncles and aunts affected (0.8%). None of the grandparents were affected. Prenatal diagnosis in a subsequent pregnancy is by fetal echocardiography.

CHAPTER

Ebstein Anomaly

Key Points

- Ebstein anomaly is a malformation of the tricuspid valve, causing tricuspid insufficiency and atrialization of a significant portion of the right ventricle.
- When it progresses it can be associated with right ventricular outflow tract obstruction and arrhythmias.
- It is rarely associated with extracardiac malformations or fetal aneuploidy.
- Prognosis for prenatally diagnosed cases is much worse than for those diagnosed later in childhood, with less than 50% of cases surviving to 5 years of age.
- Pregnancy management rarely needs to be altered significantly, other than to arrange for prompt referral for postnatal cardiac evaluation and likely surgical repair, either by means of valve repair or replacement.

CONDITION

Congenital downward displacement of the septal and posterior leaflets of the tricuspid valve is known as Ebstein anomaly. This downward displacement is associated with valvular dysplasia, resulting in tricuspid insufficiency (Schiebler et al., 1968). The displaced septal and posterior leaflets become adherent to the right ventricular walls, which may also be dysplastic. This results in division of the right ventricle into two segments, a proximal atrialized portion that forms a common enlarged chamber with the right atrium and a distal functional right ventricular chamber (Attenhofer Jost et al., 2007). Significant right atrial enlargement is common, and atrial septal defects or patent foramen ovale is commonly seen during neonatal life (Attenhofer Jost et al., 2007). Other cardiac malformations coexist with Ebstein anomaly in approximately one-third of cases (Celermajer et al., 1994). The most common additional malformations are pulmonary stenosis, pulmonary atresia with intact ventricular septum, ventricular septal defect, mitral-valve prolapse, aortic coarctation, patent ductus arteriosus, and right ventricular hypoplasia. Rarer coexisting malformations include tetralogy of Fallot, atrioventricular septal defect, aortic atresia, mitral dysplasia, and left ventricular diverticulum (Celermajer et al., 1994).

INCIDENCE

The incidence of Ebstein anomaly in the general population is approximately 1 in 10,000 livebirths (Hoffman and Kaplan, 2002). It accounts for 0.3% to 0.6% of congenital heart defects in children and occurs equally in males and females (Rao, 1990).

First trimester maternal lithium ingestion has been implicated in the occurrence of Ebstein anomaly for more than 20 years. Based on data from an international registry of mothers exposed to lithium during pregnancy it was suggested that the risk of Ebstein anomaly was 400 times greater

in lithium-exposed infants than in the general population (Weinstein, 1976). From the registry of 225 infants born to women treated with lithium during the first trimester, there was an 8% incidence of all cardiac malformations and a 2.7% incidence specifically of Ebstein anomaly.

Subsequent controlled studies have suggested that the actual risk of Ebstein anomaly is considerably less than originally estimated from population registries. A total of two cohort studies and four case–control studies did not demonstrate as high a risk of Ebstein anomaly as was suggested from population registries, although the precise magnitude of the risk of Ebstein anomaly following first trimester lithium exposure is unclear (Cohen et al., 1994). It was estimated that first trimester lithium exposure is associated with a 4% to 12% incidence of congenital anomalies, as compared with a general population risk of from 2% to 4%.

SONOGRAPHIC FINDINGS

Prenatally, Ebstein anomaly is suggested by an abnormal four-chamber cardiac view, in which the right atrium appears grossly enlarged (Figure 46-1) and the tricuspid valve is displaced downward toward the apex and below the level of the atrioventricular junction. Dysplasia of the valve appears as abnormal thickening, nodularity, and irregularity of the leaflets. The right ventricular wall may become dysplastic and appear thin (Roberson and Silverman, 1989). Pulsed and color Doppler evaluation may also demonstrate significant tricuspid regurgitation. As tricuspid regurgitation worsens, congestive heart failure may develop, leading to cardiac enlargement and eventually hydrops. On prenatal sonography, supraventricular tachycardia may also be noted in association with Ebstein anomaly (Sharf et al., 1983), and accessory conduction pathways resulting in Wolff–Parkinson–White syndrome may be common.

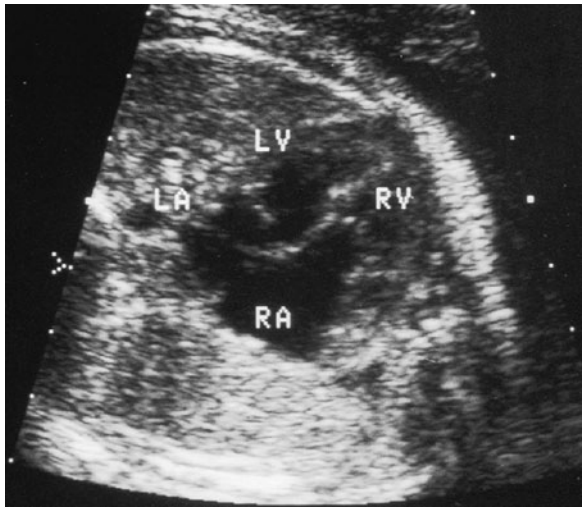

Figure 46-1 Antenatal four-chamber view of a fetal heart, demonstrating abnormally enlarged right atrium (RA) and downward displacement of tricuspid valve toward an abnormally small right ventricle. LA = left atrium; LV = left ventricle; RV = right ventricle.

Ebstein anomaly has been graded in severity based on the volume of the right ventricle and degree of restriction of the anterior leaflet of the triscupid valve. With type A, the volume of the right ventricle is adequate; type B involves a significant amount of atrialization of the right ventricle but with no restriction in movement of the anterior triscupid leaflet; type C involves severe restriction in movement of the anterior tricuspid leaflet, with obstruction of the right ventricular outflow tract; type D demonstrates almost complete atrialization of the right ventricle (Carpentier et al., 1988). Another system for grading severity involves calculation of the ratio of the area of the right atrium plus atrialized right ventricle to the functional right ventricle area (Celermajer et al., 1994).

Prenatal sonographic diagnosis of Ebstein anomaly is accurate. In one series of 17 fetuses diagnosed prenatally with Ebstein anomaly, the diagnosis was confirmed postnatally in 15, either by autopsy, surgery, or neonatal imaging (Hornberger et al., 1991). In another series of 19 cases of prenatally identified tricuspid abnormalities, 6 of 10 cases of Ebstein anomaly were correctly diagnosed by fetal echocardiography; the remaining 4 were incorrectly described prenatally as valvular dysplasia without displacement (Oberhoffer et al., 1992).

DIFFERENTIAL DIAGNOSIS

The sonographic detection of right atrial enlargement should prompt a search for abnormalities of the tricuspid and pulmonary valves. The differential diagnosis of Ebstein anomaly includes isolated tricuspid valve dysplasia without significant downward displacement of valve leaflets. In its most severe form, such valve dysplasia may represent an unguarded tricuspid valve orifice. In each of these conditions, significant tricuspid regurgitation and cardiomegaly will most likely be present, but only in Ebstein anomaly will there be an abnormally located insertion site for the valve. However, the differentiation between Ebstein anomaly and tricuspid dysplasia is largely academic; both conditions can present clinically with heart failure and additional cardiac malformations (Sharland et al., 1991).

Echocardiography should easily distinguish pulmonary stenosis, anatomic pulmonary atresia, tricuspid atresia, transposition of the great vessels, Uhl anomaly, and tetralogy of Fallot from Ebstein anomaly (Rao, 1990). With pulmonary stenosis or atresia, significant right ventricular hypertrophy should be visible, together with a small pulmonary artery. Functional pulmonary atresia with diminished pulmonary flow may occur secondary to Ebstein anomaly, tricuspid dysplasia, and tricuspid insufficiency; these may be difficult to differentiate without neonatal imaging (Rao, 1990). In cases of tricuspid atresia, marked right atrial enlargement will be present, but forward flow across the site of the tricuspid valve

will not be present. Uhl anomaly involves severe hypoplasia of the myocardium of the right ventricle, which may present with right atrial enlargement but with the tricuspid valve in a normal position (Benson et al., 1995).

ANTENATAL NATURAL HISTORY

Infants with Ebstein anomaly diagnosed in utero have a significantly worse prognosis as compared with patients diagnosed later in childhood (Celermajer et al., 1994). In one series of 16 cases of Ebstein anomaly diagnosed prenatally, 11 were managed expectantly, 4 of which resulted in intrauterine death (Sharland et al., 1991). Another 6 infants died within 3 months of birth, with only 1 infant surviving. All of 6 fetuses with Ebstein anomaly followed sequentially with ultrasound examination had significant increases in cardiac size, as measured by cardiothoracic ratio, as pregnancy progressed (Sharland et al., 1991).

In a further series of 17 fetuses diagnosed prenatally with Ebstein anomaly, 14 were managed expectantly, and in this group there were 6 intrauterine deaths, 5 early neonatal deaths, and only 3 survivors (Hornberger et al., 1991). Eight of the 17 fetuses had pulmonary hypoplasia, and hydrops developed in 3. Therefore, the prognosis in prenatally diagnosed Ebstein anomaly is poor: one-third die in utero and only one-tenth survive the neonatal period.

MANAGEMENT OF PREGNANCY

If the diagnosis of Ebstein anomaly is suspected after prenatal ultrasonography, the patient should be referred to a tertiary care center for careful sonographic evaluation of fetal anatomy to exclude additional noncardiac malformations and fetal echocardiography to confirm the diagnosis. However, no obvious pattern of extracardiac malformations has been described in association with Ebstein anomaly, and karyotypic abnormalities are rare (Siebert et al., 1989). In one series of 16 infants with Ebstein anomaly no karyotypic abnormalities were found (Ferencz et al., 1987). In another series of 16 fetuses with Ebstein anomaly, one case of Down syndrome was found (Roberson and Silverman, 1989), and a further series of 17 fetuses with Ebstein anomaly included 1 fetus with trisomy 13 (Hornberger et al., 1991). Prenatal consultation with a pediatric cardiologist is recommended. If the diagnosis is made prior to fetal viability, termination of pregnancy may be offered because of the significant neonatal mortality and surgical morbidity.

Following prenatal diagnosis, serial evaluation with obstetric ultrasonography is recommended to confirm adequate fetal growth and to exclude the development of congestive heart failure. If hydrops develops, the option of early delivery may be considered; however, it is unclear that this will alter the expected high mortality rate (Romero et al., 1988). In the absence of hydrops there is no indication to alter obstetric management, including timing and route of delivery. Delivery should occur in a tertiary care center, with the immediate availability of appropriately trained neonatologists, pediatric cardiologists, and pediatric cardiothoracic surgeons.

FETAL INTERVENTION

No fetal intervention has been described following the prenatal diagnosis of Ebstein anomaly.

TREATMENT OF THE NEWBORN

Many cases of Ebstein anomaly are completely asymptomatic and do not present until adolescence. Such postnatally diagnosed cases commonly present with cyanosis, right-sided heart failure, arrhythmias, or sudden cardiac death (Attenhofer Jost et al., 2007). By contrast, most cases diagnosed prenatally tend to have tricuspid regurgitation and cardiomegaly, which usually results in the development of congestive heart failure during the newborn period. Infants with Ebstein anomaly diagnosed in utero have a significantly worse overall prognosis as compared with patients diagnosed later in childhood (Radford et al., 1985).

Careful evaluation by a pediatric cardiologist is recommended during the immediate newborn period, including echocardiography, to confirm the diagnosis and to exclude the presence of additional cardiac malformations. Electrocardiography typically reveals evidence of right atrial enlargement, right bundle-branch block, and possibly first-degree atrioventricular block (Attenhofer Jost et al., 2007). For patients with arrhythmias such as Wolff–Parkinson–White syndrome, electrophysiologic mapping may also be required to localize any accessory conduction pathways. Clinical improvement of cyanosis is likely in many cases during the initial newborn period as pulmonary vascular resistance falls, thereby reducing right-to-left shunting of blood.

If severe hypoxemia is also present, infusion of prostaglandin E_1 to maintain patency of the ductus arteriosus may also improve pulmonary vascular flow. This requirement for prostaglandin infusion usually decreases as pulmonary vascular resistance continues to fall following delivery (Rao, 1990). Treatment with diuretics and digoxin may also be needed if congestive heart failure is present, and lidocaine or procainamide may be needed if arrhythmias develop. If tachyarrhythmias are present, radiofrequency ablation of accessory pathways may be performed.

SURGICAL TREATMENT

Indications for surgical repair of Ebstein anomaly are unclear but include the presence of New York Heart Association functional class III or IV disease, severe or progressive cyanosis,

paradoxical emboli, right ventricular outflow tract obstruction, progressive cardiac enlargement, and development of atrial arrhythmias due to the presence of accessory conduction pathways (Danielson et al., 1992; Dearani et al., 2006; Attenhoffer Jost et al., 2007). Sudden death postoperatively can occur secondary to ventricular arrhythmias. Preoperative electrophysiologic studies, with prophylactic lidocaine therapy followed by procainamide for 3 months, are recommended to reduce this complication (Danielson et al., 1992). Permanent pacing may be necessary in a small percentage of patients (4%) (Attenhoffer Jost et al., 2007).

Surgical technique for Ebstein anomaly involves repairing the tricuspid valve, which should be possible in many cases (Danielson et al., 1992). In one series of 540 consecutive operations for Ebstein anomaly at a single center, 34% of patients had a valve reconstruction procedure, while 66% underwent valve replacement (Attenhofer Joet et al., 2007). Following median sternotomy and cardiopulmonary bypass, redundant right atrial tissue is excised and a patch closure of any atrial septal defect is performed. The portion of the right ventricle is plicated, and an annuloplasty is performed to narrow the tricuspid annulus, allowing the single anterior leaflet to function as a monocuspid valve. If the tricuspid valve cannot be repaired, complete valve replacement is performed. Corrections of associated anomalies are also made, such as relief of pulmonary stenosis and ablation of accessory conduction pathways (Danielson et al., 1992).

In one large study from a single center, 189 patients with Ebstein anomaly underwent surgical repair (Danielson et al., 1992). There was a 7.3% incidence of early death within 30 days in the group who underwent valvuloplasty and a 5.8% incidence of early death in the group who underwent complete valve replacement.

Another approach to the surgical repair of Ebstein anomaly involves vertical plication of the right ventricle with reimplantation of the tricuspid valve leaflets (Quaegebeur et al., 1991). In a series of 10 patients treated with this technique, 9 demonstrated significant clinical improvement and 8 showed diminished tricuspid regurgitation on echocardiography. One patient continued to have significant tricuspid regurgitation and required prosthetic valve replacement. All 10 patients in this series survived (Quaegebeur et al., 1991).

LONG-TERM OUTCOME

The long-term outcome for Ebstein anomaly depends on the timing of clinical presentation and diagnosis. Patients diagnosed during the fetal and early neonatal periods almost always have severe disease, with tricuspid regurgitation and significant cardiomegaly. Up to 50% of infants diagnosed with Ebstein anomaly during the neonatal period die within the first year of life (Rowe et al., 1981). Approximately 20% to 40% of neonates do not survive past 1 month, and less than 50% are alive at 5 years (Celermajer et al., 1992; McElhinney et al., 2005).

In a series of 189 patients with Ebstein anomaly managed surgically, there were 10 late deaths, 4 of which were presumed secondary to arrhythmias and 3 of which were secondary to congestive cardiac failure (Danielson et al., 1992). More than 90% of survivors were in New York Heart Association functional class I or II, and 9 affected adult women had a total of 12 successful pregnancies. Four (3.6%) of the patients treated by valvuloplasty required subsequent tricuspid valve replacement, in one case 14 years after the initial surgical repair. In another series of 191 patients with repair of the abnormal tricuspid valve, the mean survival rate at 20 years was 82% (Carpentier et al., 1988).

In another series of 220 cases of Ebstein anomaly, actuarial survival was 67% at 1 year and 59% at 10 years of age (Celermajer et al., 1994). Significant predictors of death included severe tricuspid regurgitation at presentation, diagnosis in utero, and right ventricular outflow tract obstruction. Of 155 survivors overall, 83% remained in New York Heart Association functional class I, and 67% required no ongoing medical therapy.

Long-term data allowing comparison of outcome for tricuspid valve repair versus valve replacement are now available. In one series of 294 patients followed up for 12 years postoperatively, there was no significant difference in freedom-from-operation rates between valve repair versus valve replacement patients (Kiziltan et al., 1998; Attenhoffer Jost et al., 2007). It appears as if valve repair is preferable for neonatal patients, while valve replacement may be a better option for adult therapy (Chen et al., 2004; Attenhoffer Jost et al., 2007).

GENETICS AND RECURRENCE RISK

Ebstein anomaly usually occurs as an isolated lesion or together with an additional cardiac malformation. It does not seem to occur with karyotypic abnormalities or as part of a recognizable genetic syndrome or association. Although most cases are sporadic, there have been several familial reports, including occurrence in two sisters born to consanguineous Sri Lankan parents (Gueron et al., 1966; Donegan et al., 1968; McIntosh et al., 1992). Estimates of recurrence risk suggest a 1% rate of recurrence if one previous sibling has been affected and a 3% rate of recurrence if two siblings have been affected (Nora and Nora, 1988).

47 CHAPTER Hypoplastic Right Ventricle

Key Points

- Hypoplastic right ventricle is considerably rarer than hypoplastic left heart syndrome.
- It is a complex cardiac malformation with a wide spectrum of presentations, the most serious of which frequently results in a single-ventricle functionality.
- Prenatal sonographic features include pulmonary atresia with an intact ventricular septum, varying degrees of tricuspid atresia and tricuspid regurgitation, and varying degrees of hypoplasia of the right ventricular walls.

Key Points (cont.)

- Neonates will be ductal-dependent and therefore delivery should be carefully coordinated in a center that can provide immediate pediatric cardiology intervention, prostaglandin infusion to maintain a patent ductus arteriosus, and ability to provide prompt catheter-based interventions such as pulmonary valvotomy, ductus arteriosus stenting, and balloon atrial septostomy.
- Optimal management is individualized between catheter-based approaches that allow blood flow from right to left sides of the heart, together with open surgical systemic-pulmonary shunting.
- Long-term outcome depends on whether a biventricular or univentricular repair is achieved.

CONDITION

Hypoplastic right ventricle (HRV) is also known as pulmonary atresia with intact ventricular septum (PA:IVS). The normally formed right ventricle becomes hypoplastic, in association with pulmonary atresia, and occasionally tricuspid atresia. The competence of the tricuspid valve determines the size of the right ventricle, with type I HRV being associated with a competent valve and small ventricle and type II HRV being associated with an incompetent valve and normal or large right ventricle (Romero et al., 1988). Another classification system is based on the degree of severity of right ventricular hypoplasia (Alwi, 2006). Group A patients have only mild right ventricular hypoplasia, with a well-developed infundibulum, beyond which the pulmonary arterial outflow tract is atretic. Group C patients have severe right ventricular hypoplasia, with an atretic infundibulum. Group B patients have a moderately HRV, but may have a reasonably well-developed infundibulum. Patients in Group C tend to have poor prognosis with long-term outcome being dependent on a single-ventricle repair.

In the setting of right ventricular hypoplasia, blood flows from the right to the left atria through the foramen ovale, and the left ventricle supplies both systemic and pulmonary circulations, the latter by retrograde flow through the ductus arteriosus. Additional cardiac malformations that may coexist include atrial and ventricular septal defects and transposition of the great vessels. Additionally, coronary arterial anatomy is frequently abnormal, and there may be varying degrees of tricuspid regurgitation or Ebstein malformation (see Chapter 46) (Daubney et al., 2002).

INCIDENCE

HRV is extremely rare, accounting for less than 3% of all cases of congenital heart disease diagnosed during the first year of life (Fyler et al., 1980). The overall population incidence is likely to be 1 to 2 per 10,000 livebirths (Hoffman and Kaplan, 2002). In another series, the livebirth prevalence was estimated at 4.1 per 100,000 livebirths (Daubney et al., 1998).

SONOGRAPHIC FINDINGS

Prenatal diagnosis of HRV is relatively straightforward if there is a significant disproportion in size between the two ventricular cavities (Figure 47-1) (McGahan et al., 1991). However, if the right ventricle is normal in size (due to an incompetent tricuspid valve) prenatal diagnosis may be extremely difficult and may depend on identification of isolated pulmonary atresia (Romero et al., 1988). While the right ventricular cavity is usually very small, the right ventricular wall is often hypertrophied (Grundy et al., 1987). Although adequate visualization of the right ventricular outflow tract may be difficult, Doppler echocardiography may demonstrate absence

Figure 47-1 Axial image demonstrating ventricular disproportion with hypoplastic right ventricle.

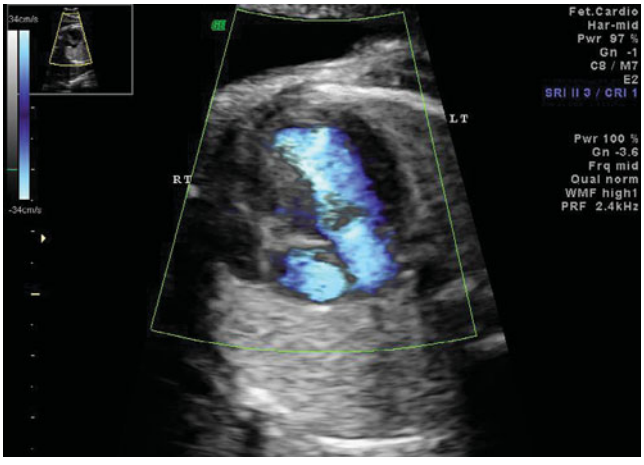

Figure 47-2 Power Doppler showing lack of filling of the hypoplastic right ventricle.

of flow across the pulmonary valve (Figure 47-2). As with hypoplastic left heart syndrome (see Chapter 48), the diagnosis of HRV may not be clear at an initial second trimester ultrasound examination, but instead may evolve over time so that true hypoplasia may not be visible until late in the third trimester (Hornberger et al., 1996). At fetal echocardiography, detailed evaluation of tricuspid valve annulus size, ratio of right to left ventricular size, and presence or absence of tricuspid regurgitation are essential.

DIFFERENTIAL DIAGNOSIS

When only one ventricle is clearly visible during fetal echocardiography, the differential diagnosis is similar to that for hypoplastic left heart syndrome and includes right-sided cardiac masses, pulmonary stenosis, and univentricular heart. Doppler echocardiography may be helpful in demonstrating absence of antegrade flow through the pulmonary valve, therefore confirming the presence of complete pulmonary atresia.

ANTENATAL NATURAL HISTORY

Congestive heart failure can often develop in utero with HRV because of significant tricuspid regurgitation. In one series of 28 cases of prenatally diagnosed pulmonary atresia with intact ventricular septum, antenatal predictors of poor outcome included a small tricuspid valve annulus (<5 cm) after 30 weeks' gestation, a ratio of right to left ventricular length or width of less than 0.5, and absence of tricuspid regurgitation (Peterson et al., 2006). Growth of the fetal tricuspid valve during gestation, and calculation of tricuspid valve z scores may also be useful for predicting outcome and which infants will ultimately survive with a biventricular anatomy (Salvin et al., 2006).

FETAL INTERVENTION

No fetal intervention has been described for the management of HRV.

MANAGEMENT OF PREGNANCY

Following the prenatal diagnosis of HRV, a careful sonographic fetal anatomy survey is recommended to exclude additional cardiac and extracardiac malformations. Fetal echocardiography should be performed by an appropriately trained specialist to confirm the diagnosis and to exclude other cardiac malformations. Particular attention should be paid to morphology of the tricuspid and pulmonary valves, and growth of the tricuspid valve should be monitored throughout gestation. It is unclear if invasive fetal testing for karyotype analysis is needed, because in one series of 48 cases of tricuspid or pulmonary atresia there were no chromosomal abnormalities (Ferencz et al., 1987). There may be a higher prevalence of chromosomal abnormalities in fetuses with prenatally diagnosed right ventricular hypoplasia, although minimal data are available to confirm the need for karyotype analysis.

Referral for prenatal consultation with a pediatric cardiologist and cardiothoracic surgeon is also recommended. If the diagnosis is made prior to fetal viability, termination of pregnancy may be offered because of the significant neonatal mortality and surgical morbidity. If expectant management is desired, sonographic surveillance to confirm appropriate fetal growth and to evaluate for the development of fetal hydrops is recommended. If fetal hydrops occurs, the prognosis deteriorates further, and the optimal management of such pregnancies is uncertain. In the absence of tricuspid regurgitation, or if the tricuspid valve is small, prognosis worsens with likely outcome being a single-ventricle repair (Peterson et al., 2006; Salvin et al., 2006). Delivery should occur at a tertiary care center, with the immediate availability of a neonatologist, pediatric cardiologist, and cardiothoracic surgeon. There is no indication to alter the timing or method of delivery based on the prenatal diagnosis of HRV.

TREATMENT OF THE NEWBORN

The infant should be transported to a neonatal intensive care unit, and prostaglandin E_1 infusion should be started as soon as possible to maintain blood flow across the ductus arteriosus. Care should be taken with the administration of supplemental oxygen to an infant with HRV, so as to avoid significant reduction in pulmonary vascular resistance, which may decrease the amount of blood shunted across the ductus arteriosus. Consultation with a pediatric cardiologist should be obtained promptly, and echocardiography should be performed to confirm the prenatal diagnosis and to exclude additional

cardiac malformations. Echocardiography should document patency of the ductus, size of the right ventricular cavity, and size of the tricuspid annulus. If inadequate atrial communication is present, balloon atrial septostomy may be considered to maximize cardiac output during the initial treatment phase. Consultation with a pediatric cardiothoracic surgeon should be obtained to decide on timing and method of surgical intervention.

Initial management of infants with pulmonary atresia and intact ventricular septum has moved toward prompt intervention with catheter-based therapies to allow blood flow from the right to the left sides of the heart (McLean and Pearl, 2006). Pulmonary valvotomy (laser assisted) and balloon pulmonary valvuloplasty are becoming increasingly common for the initial management of select patients (Mi et al., 2005).

SURGICAL TREATMENT

The choice of surgical procedure for right ventricular hypoplasia depends on the size of the tricuspid valve, the severity of outflow tract/infundibular atresia, and the presence of right ventricular-dependent coronary circulation. Because of the significant anatomic variation between patients, there is no agreement on a single best surgical approach to right ventricular hypoplasia. Management should be individualized for each infant depending on size and function of the right ventricle as well as on the presence of other abnormalities.

Group A patients, in which right ventricular hypoplasia is mild and membranous pulmonary atresia is present, are usually managed primarily with a catheter-based approach such as laser-assisted valvotomy and balloon pulmonary valvuloplasty (Mi et al., 2005; Alwi, 2006). In contrast, Group C patients, in which ventricular hypoplasia is severe and the infundibulum is almost completely atretic, are not candidates for the more conservative catheter-based approaches. Such patients will also likely have major right ventricular-coronary arterial connections and should be managed as a univentricular heart. These infants are ductal-dependent, may require prolonged prostaglandin infusion, and will likely need an initial systemic-pulmonary shunt during the neonatal period (Alwi, 2006). Options in such cases may include patent ductus arteriosus (PDA) stenting or modified Blalock–Taussig (BT) shunt (Armstrong, 1995). While further surgical intervention is uncommon for patients in Group A, most patients in Group C with severe hypoplasia will require multiple further interventions.

Patients with moderate right ventricular hypoplasia, (Group B), generally have individualized surgical intervention depending on the degree of infundibular hypoplasia and extent of right ventricular-coronary arterial connections. Such patients may do well with pulmonary valvotomy (laser assisted or radiofrequency), together with stenting of the PDA and balloon atrial septostomy (Alwi, 2006).

Depending on the anatomic variation with right ventricular hypoplasia, the operative mortality may range from 27% to 50% (DeLeval et al., 1982). In one series of 25 neonates with pulmonary atresia with intact ventricular septum, initial catheter-based intervention occurred at a mean of 3 days of life, but the majority of these required subsequent open surgical intervention within further 8 days (McLean and Pearl, 2006).

LONG-TERM OUTCOME

Data on long-term outcome following surgery for HRV are conflicting. In one series of 17 infants who were treated with both pulmonary valvotomy and systemic-pulmonary shunt, the long-term survival rate was 53% (Moulton et al., 1979). In another series of 60 patients with HRV, 5-year actuarial survival was only 36% (DeLeval et al., 1982). However, more recent data are more encouraging. In a series of 106 pateints with pulmonary atresia and intact ventricular septum managed at a single center in Los Angeles from 1982 to 2001, the 10-year actuarial survival was 86% (Odim et al., 2006). Over half of these patients underwent a biventricular repair, with initial severity of the ventricular hypoplasia being the best predictor for such a good outcome.

GENETICS AND RECURRENCE RISK

HRV occurs in a sporadic pattern. No recurrence risk data are available for counseling parents with a previously affected infant.

48 CHAPTER Hypoplastic Left Ventricle

Key Points

- Hypoplastic left heart syndrome (HLHS) is a spectrum of disorders involving aortic atresia with or without mitral atresia or stenosis.
- The condition may be diagnosed as severe ventricular hypoplasia before 20 weeks' gestation, or it may evolve from aortic stenosis to HLHS during the second half of pregnancy.
- Prenatal diagnosis of classic HLHS is straightforward as the ventricular disproportion is obvious, leading to prenatal detection rates as high as 85%.
- Delivery needs to be carefully planned to optimize the availability of pediatric specialists, and will include immediate prostaglandin infusion and referral to cardiothoracic surgeons for initial palliation.
- Surgical management includes a choice between traditional three-stage Norwood procedure leading ultimately to a single ventricle repair, versus hybrid palliation involving open surgical and interventional catheterization until cardiac transplantation is available.

CONDITION

Hypoplastic left heart syndrome (HLHS) represents a spectrum of abnormalities in which there is underdevelopment of the left-sided cardiac structures, such as the left ventricle, the mitral valve, and aortic valve, such that the systemic circulation cannot be adequately supported (Rychik, 2005). Classic HLHS involves both aortic valve atresia, and either atresia or stenosis of the mitral valve (Simpson, 2000).

The spectrum of malformations can include congenital hypoplasia of the left ventricular wall, atresia of the aortic and/or mitral valves, and coarctation or hypoplasia of the aortic arch. Critical aortic stenosis can evolve into HLHS (see Chapter 50), and unbalanced atrioventricular canal defects (see Chapter 45) in which the left ventricle is quite underdeveloped and can also behave similar to HLHS (Simpson, 2000). Each of the components of HLHS may occur with varying degrees of severity, ranging from aortic stenosis with a small left ventricle to complete aortic and mitral atresia with a slit-like left ventricular remnant. Hypoplastic left ventricle and mitral atresia may also occur without aortic atresia, but such an anomaly is rare (Kiel, 1990). The cause of HLHS is unknown, but it may be due to abnormal intracardiac streaming during weeks 5 to 8 of embryonic life

(Harh et al., 1973). HLHS may also evolve during prenatal life from isolated severe aortic stenosis (see Chapter 50), which may result in decreased right-to-left shunting between the atria, and subsequent hypoplasia of the left ventricle (Sharland et al., 1991).

Postnatally, left-to-right shunting occurs in the newborn, returning oxygenated blood from the pulmonary veins through a patent foramen ovale into the right atrium. The right ventricle provides both pulmonary and systemic circulations, the latter through a patent ductus arteriosus with retrograde flow to the aortic arch and coronary vessels. The mitral valve is hypoplastic; the tricuspid valve is often large and regurgitant. The aortic outflow tract may end blindly below the coronary arteries, and the aortic valve and arch may be hypoplastic. Associated cardiac anomalies are common with HLHS. Other associated cardiac anomalies include ventricular septal defect, aortic-arch interruption, and transposition of the great vessels (Kiel, 1990). Central nervous system abnormalities have also been described in association with HLHS, including microcephaly, holoprosencephaly, and agenesis of the corpus callosum (Sanders et al., 1996).

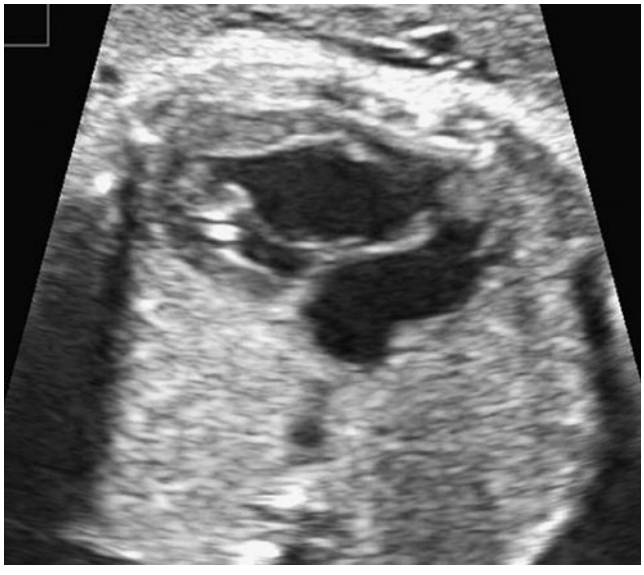

Figure 48-1 Axial image through fetal chest demonstrating ventricular disproportion and small left ventricle consistent with hypoplastic left heart syndrome.

INCIDENCE

HLHS accounts for up to 9% of all cases of congenital heart disease, with an incidence of 1 to 2 per 10,000 livebirths (Kiel, 1990; Hoffman and Kaplan, 2002). Twice as many males as females may be affected.

SONOGRAPHIC FINDINGS

HLHS is generally easy to detect prenatally by means of the standard four-chamber cardiac view. This should demonstrate an inequality in ventricle size, with the left ventricular cavity often appearing as a small remnant to the left of the right ventricle (Figure 48-1) (Silverman et al., 1984). The left ventricular wall may be hypocontractile or immobile and may also appear echogenic (Kluckow et al., 1993). The apex of the left ventricle will usually end more proximally than the right ventricular apex, and the ventricular cavity may be in a globular shape rather than in the normal elliptical shape. The right ventricular cavity is often enlarged, and the left atrium is usually small, with left-to-right bowing of the interatrial septum (Sanders et al., 1996). The aortic outflow tract may be atretic, with hypoplasia of the ascending aorta. However, the aortic arch and descending aorta should be visible because of retrograde filling through the ductus arteriosus. Doppler echocardiography may also be helpful in demonstrating a lack of antegrade flow into the left ventricle, abnormal flow through the foramen ovale, and retrograde flow in the ascending aorta (Figure 48-2) (Blake et al., 1991).

Even though these findings should be detectable at 18 to 20 weeks of gestation, it is possible that isolated aortic stenosis (see Chapter 50) may evolve over time into HLHS, so that the typical features of HLHS may not become visible until the late second trimester or the third trimester (Sharland et al., 1991). The detection rate of prenatal ultrasonography for HLHS is unclear in the general population, with only 28% of all cases of HLHS being detected prenatally in one series (Montana et al., 1996). However, as sonographer experience has improved over the past decades, it is likely that a much higher prenatal detection rate is now possible. In another population-based study from Australia, 66 of 78 cases (85%) of HLHS were correctly diagnosed antenatally (Chew et al., 2007). Additionally,

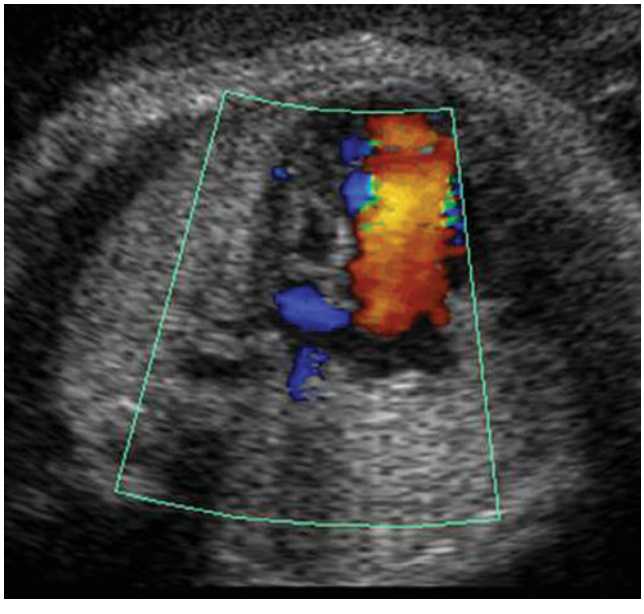

Figure 48-2 Axial image with color Doppler demonstrating absence of forward flow across mitral valve consistent with hypoplastic left heart syndrome.

the positive predictive value of prenatal ultrasonography for HLHS is high, with up to 95% of cases of prenatally diagnosed HLHS confirmed on postnatal examination (Chang et al., 1991).

DIFFERENTIAL DIAGNOSIS

Other conditions that should be included in the differential diagnosis of HLHS include left-sided cardiac masses, aortic stenosis, and univentricular heart (Sanders et al., 1996). Large cardiac masses, such as rhabdomyomas (see Chapter 58), may completely obliterate the left ventricular cavity, thus mimicking the sonographic appearance of HLHS. However, normal ventricular dimensions will be present, and Doppler echocardiography should demonstrate normal flow through the mitral and aortic valves. Severe aortic stenosis may be difficult to differentiate from HLHS because complete obliteration of the left ventricle may occur as the stenosis worsens (see Chapter 50). It is possible that aortic stenosis in early fetal life may progress to hypoplastic left ventricle as gestation advances (Sharland et al., 1991; Wilkins-Haug et al., 2005). Differentiation should be possible based on Doppler echocardiography demonstrating antegrade flow in the ascending aorta with aortic stenosis, as compared with retrograde flow in HLHS. Univentricular heart is a condition in which the entire atrioventricular junction is connected to a single ventricle. There is little agreement on the precise definition of univentricular heart, which makes prenatal differentiation difficult.

ANTENATAL NATURAL HISTORY

HLHS may evolve in utero from critical aortic stenosis (Sharland et al., 1991; Kluckow et al., 1993; Wilkins-Haug et al., 2005). The precise antenatal natural history of HLHS is therefore very variable. This malformation has several degrees of severity, ranging from critical aortic stenosis with normal left ventricular size to complete atresia of the aortic and mitral valves with near absence of the left ventricle. Previously, because of the lack of adequate pediatric surgical intervention, the vast majority of cases diagnosed prior to 24 weeks of gestation resulted in termination of pregnancy. In a series of 77 cases of HLHS diagnosed prior to 24 weeks, 72 resulted in termination of the pregnancy (Allan et al., 1991). However, as pediatric surgical management options have improved over the last 20 years and as the potential for in utero intervention has appeared, it is likely that the voluntary pregnancy termination rate may be significantly less in contemporary practice.

Expectant management of prenatally diagnosed HLHS is associated with a poor prognosis. In one series of 20 cases of prenatally diagnosed HLHS, 9 pregnancies were terminated (Blake et al., 1991). Four of the 11 expectantly managed pregnancies resulted in intrauterine fetal death, 7 resulted in livebirths, and 5 of these 7 infants died within 1 week of birth. Intrauterine congestive heart failure may occur with HLHS because of right ventricular overload. In another series, nonimmune hydrops developed in 4 of 20 cases of prenatally diagnosed HLHS. Only one of these cases resulted in a liveborn infant, following administration of digoxin to the mother (Blake et al., 1991).

When classic HLHS is diagnosed before 24 weeks' gestation, little in utero change is likely to occur to the already extremely hypoplastic left ventricle. However, in cases in which aortic outflow tract restriction is diagnosed before 24 weeks' gestation, it is possible that the left ventricle may not yet be hypoplastic, and this may evolve over subsequent months in utero (Wilkins-Haug et al., 2005). The rate of growth of left ventricular dimensions may be quite slow, and there may be limited growth of aortic and mitral valves. Additionally, reversed flow across the foramen ovale (from left to right) and retrograde flow in the aortic arch are predictors of subsequent severe HLHS that will unlikely support systemic circulation in postnatal life (Hornberger et al., 1996; Wilkins-Haug et al., 2005).

FETAL INTERVENTION

The only fetal intervention that has been described for HLHS is in utero balloon dilation for critical aortic stenosis (see Chapter 50), but if the stenosis has progressed to the development of HLHS it is unlikely that such an intervention will be of any benefit. Recently, attempts have been made to identify fetuses with hallmarks of potential HLHS at a sufficiently early gestational age to warrant in utero intervention in an attempt to optimize postnatal outcome. Prevention of in utero evolution of HLHS such that a biventricular repair is possible would represent a significant step forward in our management of this condition. The largest series of such interventions, by means of in utero balloon dilation of the aortic valve, is from the Children's Hospital, Boston. In a series of 20 cases operated on at a mean gestational age of 24 weeks, technical success was achieved in 14, and of these 9 resulted in either fetal loss or subsequent development of classic HLHS (Tworetzky et al., 2004). Overall, only 5 of the original 20 cases resulted in postnatal survival with a two-ventricle circulation. This study underlines the challenges in prenatal selection of cases in which the natural history can be modified. Currently, in utero balloon aortic dilation should be considered an unproven experimental intervention for the prevention of HLHS.

MANAGEMENT OF PREGNANCY

Following prenatal diagnosis of HLHS, a careful sonographic fetal anatomy survey is recommended to exclude additional

cardiac and extracardiac malformations. This evaluation should include a search for sonographic markers of Turner syndrome and trisomies 13, 18, and 21. Invasive fetal testing for karyotype analysis is recommended because of the association between HLHS and chromosomal abnormalities. Chromosomal abnormalities were found in 2 of 85 cases of HLHS in infants in one study (Ferencz et al., 1987) and in 9 of 83 cases in a later study, including trisomies 13, 18, and 21 (Natowicz et al., 1988). In a series of 20 cases of HLHS diagnosed prenatally, 1 fetus also had trisomy 13 and 2 had Turner syndrome (Blake et al., 1991). The incidence of karyotypic abnormalities is likely dependent on the exact form of HLHS diagnosed, as there appears to be a higher incidence in the setting of coarctation or unbalanced atrioventricular canal defect, compared with isolated aortic stenosis (Simpson, 2000). A detailed sonographic survey of the fetal anatomy should be performed to exclude extracardiac abnormalities, and fetal echocardiography should be performed by an appropriately trained specialist to confirm the diagnosis. Referral for prenatal consultation with a pediatric cardiologist and cardiothoracic surgeon is also recommended.

If the diagnosis is made prior to fetal viability, termination of pregnancy may be offered because of the significant neonatal mortality and surgical morbidity. If expectant management is desired, sonographic surveillance to confirm appropriate fetal growth and to evaluate for the development of fetal hydrops is recommended. If fetal hydrops occurs, the prognosis deteriorates further and the optimal management of such pregnancies is uncertain. Delivery should occur at a tertiary care center, with the immediate availability of a neonatologist, pediatric cardiologist, and cardiothoracic surgeon. There is no indication to alter the timing or method of delivery based on the prenatal diagnosis of HLHS. In one series of 13 cases of HLHS, all spontaneous or induced labors resulted in normal vaginal deliveries and there was only one case of an abnormal fetal heart rate pattern (Jackson et al., 1991). Routine labor management therefore does not need to be modified when the fetus has HLHS.

TREATMENT OF THE NEWBORN

All infants with HLHS will die soon after birth without surgical intervention. For many years the options for surgery were limited and, when available, the outcome from surgical intervention was very poor. Because of this poor prognosis, comfort care without aggressive resuscitation efforts was a common method of treatment for infants with HLHS. The provision of comfort measures only has been challenged recently as more centers become skilled in surgical palliation of HLHS and as survival from such surgery has improved (O'Kelly and Bove, 1997). Decisions regarding the aggressiveness of treatment for newborns with HLHS should be made during the antenatal period, and, depending on the results from the local pediatric cardiothoracic surgery center, such decisions should include options for surgical intervention and provision of only comfort care (Thwaites, 1997; Simpson, 2000).

Following delivery of an infant with HLHS, supplemental oxygen should be administered judiciously so as to avoid significant reduction in pulmonary vascular resistance, which may decrease the amount of blood shunted across the ductus arteriosus. The infant should be transported to a neonatal intensive care unit, and prostaglandin E_1 infusion should be started as soon as feasible to maintain patency of the ductus arteriosus. Other supportive measures that are essential include correction of metabolic acidosis and use of inotropic agents, such as dopamine, to maintain adequate cardiac output. If inadequate atrial communication is present, efforts to maximize cardiac output by balloon atrial septostomy may be considered during the initial resuscitative efforts (Kiel, 1990; Theilen and Shekerdemian, 2005).

Postnatal consultation with a pediatric cardiologist should be obtained promptly, and echocardiography should be performed to confirm the prenatal diagnosis and to exclude additional cardiac malformations. Echocardiography should document patency of the ductus, presence of coarctation, size of an atrial septal defect, and presence of significant tricuspid regurgitation (Sanders et al., 1996). Consultation with a pediatric cardiothoracic surgeon should then be obtained to decide on timing and method of surgical intervention.

SURGICAL TREATMENT

All infants with HLHS will require surgical intervention to permit postnatal survival. Contraindications to surgery include a decision by parents to receive comfort care only or the presence of significant hemodynamic instability, such as severe hypoperfusion, metabolic acidosis, or coagulopathy. These conditions should be aggressively corrected prior to surgical intervention. Two surgical choices are present for infants with HLHS: the Norwood three-stage procedure and neonatal cardiac transplantation.

The Norwood procedure is a complex operation, the precise surgical details of which are beyond the scope of this chapter (Simpson, 2000; Rychik, 2005; Alsoufi et al., 2007). Stage 1 is usually performed within the first week of life. It involves connecting the systemic circulation to the pulmonary circulation to maintain adequate pulmonary flow, together with an atrial septectomy to allow adequate mixing of pulmonary venous and systemic venous blood flows. Stage 2 is performed at 6 months of age. It involves connecting the superior vena cava to the pulmonary arteries in an effort to reduce ventricular volume overload. The final stage 3 procedure is performed at 2 years of age, and involves connecting the inferior vena cava to the pulmonary arteries, further reducing ventricular volume overload. Ultimately, this staged Norwood palliation treatment results in systemic venous return passing directly to the pulmonary arteries;

oxygenated pulmonary venous blood is then returned to the single ventricle and is pumped around the body through a reconstructed aortic arch (Simpson, 2000; Alsoufi et al., 2007).

Stage 1 is performed as soon as possible after birth and after initial medical stabilization. While pulmonary blood flow is generally controlled by a modified Blalock–Taussig shunt (which anastomoses the subclavian to the pulmonary arteries), more recent modifications have suggested use of a direct conduit from the right ventricle to the pulmonary artery (Ohye et al., 2007). It is unclear at this stage whether this so-called Sano modification to the stage 1 procedure is preferential to the more traditional modified Blalock–Taussig shunt.

The results for the Norwood procedure are variable, depending on the institution, operator experience, and modifications to the procedure to account for anatomic variations. The greatest surgical mortality seems to be related to the first stage of the Norwood procedure, with recent surgical mortality rates typically exceeding 70% for this first stage (Alsoufi et al., 2007). While interim mortality remains significant, once survivors become candidates for the second stage of the Norwood procedure, prognosis improves significantly. For example, among 23 patients who completed the second stage of the Norwood procedure, there was only 1 death, and among 12 patients who completed the third stage there was 1 further death (Kern et al., 1997). In one of the largest series from a single center, 120 of 158 patients survived the first stage of surgery, 103 of 106 patients subsequently survived the second stage, and 53 of 62 survived the final stage of the Norwood procedure (Bove and Lloyd, 1996).

It is now recognized that a major contributor to operative mortality and surgical morbidity is the requirement for cardiopulmonary bypass to complete the Norwood procedures. An alternative management has recently evolved that is known as the "hybrid" strategy, which avoids the need for cardiopulmonary bypass. This uses a combination of more limited surgery together with interventional catheterization to achieve HLHS palliation until a suitable donor heart for transplantation is obtained. With this approach, both pulmonary arteries are banded to control pulmonary blood flow, a stent is placed in the ductus arteriosus, and an atrial septal defect is created (Alsoufi et al., 2007). Initial results have suggested results comparable to those with the traditional Norwood procedure.

The alternative surgical management for HLHS is neonatal cardiac transplantation. As discussed above, this option will almost certainly require an initial interventional procedure to stent the ductus arteriosus or to enlarge the interatrial communication as a palliative step until a suitable donor heart is found. In a large series of cardiac transplantations as a primary treatment for HLHS, 176 infants were listed for transplantation, 34 of whom (19%) died during the waiting period (Razzouk et al., 1996). Of the 142 infants who underwent successful transplantation in this series, the median age at surgery was 26 days and there was a 9% operative mortality rate. Overall, transplant waiting list mortality is approximately 20% to 25%, and operative mortality is approximately 10% (Alsoufi et al., 2007).

LONG-TERM OUTCOME

The long-term outcome for infants with HLHS has improved in recent years, with the modifications to the original Norwood procedure as described above. In one series of 53 infants operated on from 1990 to 1996 the 5-year actuarial survival was 61% (Kern et al., 1997). In one of the largest series of Norwood procedures from a single center, 5-year actuarial survival was 58% from an initial cohort of 158 infants (Bove and Lloyd, 1996). The 5-year actuarial survival for primary neonatal cardiac transplantation was 76% from another initial cohort of 176 infants with HLHS (Razzouk et al., 1996). However, in this cohort, half of these late deaths were due to organ rejection, and approximately 4% required retransplantation. Although long-term outcome may appear better after transplantation compared with the Norwood procedure, this is tempered by the short supply of suitable neonatal donor hearts and the long-term need for medications to manage organ rejection.

Both survival and long-term outcome data for infants with HLHS should include neurodevelopmental information and quality-of-life outcomes. In one series of 11 survivors of staged repair of HLHS, 64% had major developmental disabilities (Rogers et al., 1995). Conversely, in another series of 14 survivors of pediatric heart transplantation for HLHS or cardiomyopathy, only 1 had a significant neurologic deficit (Lynch et al., 1994). More data are needed to adequately assess the long-term neurologic and quality-of-life outcome for infants following surgical management of HLHS. However, as modifications to palliation improve, including options that avoid cardiopulmonary bypass (such as the "hybrid" strategy, it is likely that neurologic deficits can be minimized. The majority of HLHS survivors will demonstrate long-term exercise intolerance, up to 50% will have arrhythmias, and there is a 10% ongoing risk of thromboembolism (Rychik, 2005). Overall incidence of neurocognitive disabilities, ranging from learning difficulties to attention deficit hyperactivity disorder, may range from 10% to 70% (Rychik, 2005).

GENETICS AND RECURRENCE RISK

The inheritance pattern for HLHS is not clear, and in the majority of cases it occurs sporadically. HLHS has been reported as an autosomal recessive condition, which would imply a recurrence risk as high as 25% (Shokeir, 1971; Grobman and Pergament, 1996). Other reports suggest HLHS is inherited in a polygenic pattern, with a recurrence risk of only 2% if one previous sibling was affected (Brownell and Shokeir, 1976). The recurrence risk increases to 6% if two previous siblings have been affected by HLHS (Nora and Nora, 1988). In

another series, a recurrence risk of 13.5% has been quoted for HLHS (Boughman et al., 1987). It is possible that different subsets of HLHS may have different patterns of inheritance, which may explain the wide range of recurrence risks quoted for HLHS (Brenner et al., 1989). If a chromosome abnormality is documented, the recurrence risks are related to the chromosomal findings.

49 CHAPTER Pulmonary Stenosis and Atresia

Key Points

- Pulmonary stenosis and atresia refer to congenital narrowing or complete occlusion of the right ventricular outflow tract respectively.
- It may occur in isolation or as part of Williams or Noonan syndrome, or secondary to teratogenic exposure such as congenital rubella syndrome.
- Prenatal diagnosis relies upon identification of asymmetry in ventricular size, right atrial enlargement, thickening of the pulmonary valve and Doppler abnormalities across the pulmonary valve.
- Obstetric management generally does not need to be changed following this diagnosis, although in cases of critical pulmonary stenosis or atresia, delivery should occur in a controlled manner in a center with pediatric cardiology backup and ability to provide prostaglandin infusion.
- Neonatal management depends on the pressure gradient across the pulmonary valve, with invasive intervention reserved generally for those cases with pressure gradients greater than 30 to 50 mm Hg.
- While open surgical valvotomy or valve replacement represents definitive treatment, contemporary management is moving toward percutaneous approaches using balloon valvuloplasty and valve replacement.

CONDITION

The term *pulmonary stenosis* refers to narrowing of the right ventricular outflow tract; *pulmonary atresia* implies complete occlusion of the right ventricular outflow tract. Pulmonary atresia, when associated with an intact ventricular septum, is also considered as a hypoplastic right ventricle and is described in detail in Chapter 47. Pulmonary atresia with coexistent ventricular septal defect is generally considered part of the spectrum of tetralogy of Fallot and is described in detail in Chapter 52. Pulmonary stenosis usually results from fusion of the three cusps of the pulmonary valve. Other causes of pulmonary stenosis include narrowing of the infundibular portion of the right ventricular outflow tract, hypoplasia of the pulmonary artery, or pulmonary valve dysplasia, in which the valve leaflets are thickened and immobile. Pulmonary artery hypoplasia and supravalvar pulmonary stenosis may occur in association with Williams syndrome or with congenital rubella or toxoplasmosis (Gutgesell, 1990; Rhodes et al., 2008). Supravalvar pulmonary valve stenosis may also occur in association with Noonan syndrome, which has a phenotype similar to Turner syndrome, but a normal karyotype (Mendez and Opitz, 1985; Rhodes et al., 2008). Approximately 60% of cases of Noonan syndrome will have a dysplastic pulmonary valve (Bashore, 2007).

Pulmonary stenosis may lead to right ventricular hypertrophy, a decrease in right ventricular chamber size, and poststenotic dilation of the pulmonary artery (Romero et al., 1988). Poststenotic dilation of the pulmonary artery is rarely present in utero and usually takes several months of neonatal life to develop (Gutgesell, 1990). In cases of critical pulmonary stenosis, hypoplasia of the right ventricular cavity may occur together with hypertrophy of the ventricular wall and dilation of the right atrium. In such cases, neonates usually have an interatrial communication through either a patent foramen ovale or a secundum atrial septal defect. Other associated cardiac defects that may be seen with pulmonary stenosis include ventricular septal defect, total anomalous pulmonary venous return, and aortic stenosis (Romero et al., 1988).

Congenital pulmonary stenosis may be subdivided into three anatomical types: (1) a dome-shaped pulmonary valve with a narrow opening but preservation of mobile valve leaflets, (2) a dysplastic thickened pulmonary valve with a narrow outflow tract, and (3) a unicuspid or bicuspid

pulmonary valve (Bashore, 2007). Differentiation of these types by prenatal sonography is quite limited.

INCIDENCE

Pulmonary stenosis is a relatively common congenital cardiac defect, and in many mild forms the diagnosis may not be made until late in childhood. The incidence of congenital pulmonary stenosis is approximately 1 in 1500 livebirths, while pulmonary atresia occurs in approximately 1 in 10,000 livebirths (Hoffman and Kaplan, 2002). Pulmonary stenosis may account for 5% to 10% of all pediatric cardiology patients at tertiary care centers (Gutgesell, 1990).

SONOGRAPHIC FINDINGS

Prenatal sonographic features of congenital pulmonary stenosis include decreased size of the right ventricular chamber, thickening of the right ventricular walls, right atrial enlargement, increased diameter of the pulmonary artery, thickening of the pulmonary valve, and incomplete valvular opening (Figure 49-1). However, several of these features may be extremely difficult, if not impossible, to demonstrate reliably with two-dimensional echocardiography in the fetus. Duplex and color flow Doppler sonography may be used in the prenatal diagnosis of pulmonary stenosis to demonstrate poststenotic turbulence of flow in the pulmonary artery as well as significant tricuspid regurgitation. The demonstration of reversed flow across the ductus arteriosus is also suggestive of severe pulmonary stenosis or atresia and in one study was found in all seven fetuses with this prenatal diagnosis (Mielke et al., 1997).

The ability of routine prenatal sonography to detect pulmonary stenosis or atresia in unselected populations seems limited. In the largest study evaluating the prenatal detection rates for various congenital cardiac malformations, only 9 of 180 cases of pulmonary stenosis or atresia were detected prenatally (Montana et al., 1996). In another series of 11,984 fetuses examined by prenatal sonography, there were 19 cases of pulmonary stenosis or atresia of varying severity, only two of which were detected prenatally (Tegnander et al., 1995). However, if the diagnosis of pulmonary stenosis or atresia is made by targeted prenatal sonography, it appears to be accurate, with all seven cases in one series confirmed on postnatal examination (Mielke et al., 1997). In another series of 12 cases of prenatally diagnosed pulmonary stenosis or atresia, the four-chamber view was abnormal in all cases, and 10 of the 12 cases were confirmed on postnatal examination (Hornberger et al., 1994). Another problem in prenatal diagnosis of pulmonary stenosis is the possibility of late appearance of the typical sonographic features, which may lead to the diagnosis being missed during a second trimester survey of fetal anatomy (Todros et al., 1988).

Figure 49-1 Short axis view of the right ventricular outflow tract demonstrating a thickened pulmonic valve and post stenotic dilation of the pulmonary artery in a fetus with pulmonic stenosis.

DIFFERENTIAL DIAGNOSIS

Differentiation of pulmonary stenosis from pulmonary atresia through the use of prenatal sonography is difficult, with the only reliable feature allowing differentiation being the presence of antegrade pulmonary blood flow in pulmonary stenosis. In cases of pulmonary stenosis without documented antegrade pulmonary flow, it may be impossible to differentiate prenatally between stenosis and atresia (Hornberger et al., 1994). Tetralogy of Fallot should be considered in the differential diagnosis of all cases of pulmonary stenosis or atresia. Hypertrophy of the right ventricular walls is almost always present in both isolated pulmonary stenosis and tetralogy of Fallot. The presence of a ventricular septal defect and an overriding aorta, together with the sonographic features of pulmonary stenosis should be sufficient to lead to the diagnosis of tetralogy of Fallot (see Chapter 52). Pulmonary atresia with intact ventricular septum should be considered as part of hypoplastic right ventricle (see Chapter 47).

ANTENATAL NATURAL HISTORY

Pulmonary stenosis may evolve in utero, leading to hypoplasia of the right ventricle or to worsening tricuspid regurgitation and congestive heart failure or hydrops (Romero et al., 1988). Few data are available describing the antenatal natural history of pulmonary stenosis or atresia. In a series of 222 cases of prenatally diagnosed cardiac malformations that were managed expectantly, there were 4 cases of pulmonary stenosis and 9 cases of pulmonary atresia (Sharland et al., 1990). All 4 fetuses with pulmonary stenosis survived through the neonatal period. However, 2 of the 9 fetuses with pulmonary atresia died in utero, and 2 more died during the neonatal period. In another series of 3 fetuses with pulmonary stenosis and

3 with pulmonary atresia managed expectantly, 1 fetus with pulmonary atresia died in utero (Smythe et al., 1992).

MANAGEMENT OF PREGNANCY

Following prenatal diagnosis of pulmonary stenosis or atresia, careful assessment of the remainder of the fetal anatomy is recommended to rule out associated cardiac and noncardiac malformations. Fetal echocardiography should be performed by an appropriately trained specialist to confirm the prenatal diagnosis and to exclude additional cardiac malformations such as ventricular septal defect, total anomalous pulmonary venous return, and aortic stenosis. Referral for prenatal consultation with a pediatric cardiologist and neonatologist is recommended.

Invasive testing to evaluate the fetal karyotype is generally recommended for most cases of prenatally diagnosed cardiac malformations, although the incidence of chromosomal abnormalities with isolated pulmonary stenosis or atresia is low. In 1 series of 105 infants with pulmonary stenosis there was only 1 abnormal karyotype (Ferencz et al., 1987). In another series of 7 fetuses with pulmonary stenosis or atresia, 1 fetus had a balanced translocation that was also present in the mother (Mielke et al., 1997). In a further series of 3 fetuses with pulmonary atresia and ventricular septal defect, 1 fetus had trisomy 13 (Paladini et al., 1996). Additionally, pulmonary stenosis is found in only a small percentage of cases with the DiGeorge 22q11 deletion (Bashore, 2007).

Following confirmation of diagnosis, termination of pregnancy may be considered for eligible patients. For expectantly managed patients, the fetus should be monitored with serial ultrasound examinations to confirm appropriate fetal growth and to detect early signs of hydrops. There is no reason to alter timing or mode of delivery based on a prenatal diagnosis of isolated pulmonary stenosis; therefore, in these cases the delivery plan should be for standard obstetric indications. Delivery of fetuses with critical pulmonary stenosis or pulmonary atresia should occur at a tertiary care center, with the immediate availability of a neonatologist and pediatric cardiologist.

FETAL INTERVENTION

Unlike aortic stenosis (see Chapter 50), no fetal intervention has been described following the prenatal diagnosis of pulmonary stenosis or atresia.

TREATMENT OF THE NEWBORN

Most infants with mild-to-moderate pulmonary stenosis are asymptomatic during the newborn period. Those with severe stenosis or atresia present with congestive heart failure, cyanosis, and severe hypoxia (Figure 49-2). If critical pulmonary stenosis or pulmonary atresia has been diagnosed during the antenatal period, maintenance of a patent ductus arteriosus may be achieved by starting a prostaglandin E_1 infusion and limiting oxygen supplementation to maintain reasonably normal perfusion. Immediately following delivery the neonate should be evaluated by a pediatric cardiologist. Echocardiography should be performed to confirm the diagnosis, assess the severity of stenosis, and rule out additional cardiac malformations. Medical stabilization may require the use of diuretics and digoxin.

Newborns with critical pulmonary stenosis may be treated with right-sided cardiac catheterization and balloon pulmonary valvuloplasty. By positioning a balloon across the

Figure 49-2 Lateral projection of a right ventricular angiogram in a symptomatic 1-day-old newborn with severe pulmonary valve stenosis. Arrow indicates the narrowed valve. (*Courtesy of Ziyad Hijazi, MD.*)

pulmonary valve and inflating to 100 lb per square inch (psi) for 10 seconds, a significant decrease in pressure gradient across the valve can be achieved (Lababidi, 1990). In a series of 23 infants with pulmonary stenosis good short- and medium-term relief of stenosis was achieved (Sullivan et al., 1985). In that series of 23 infants and children with pulmonary stenosis, repeat pulmonary-valve dilation was required on only four occasions. However, there are insufficient data to determine precisely which infants are treated best by balloon valvuloplasty and which infants will require surgical valvotomy.

Decisions on intervention for pulmonary stenosis depend on the gradient across the pulmonary valve. The latest recommendations from the American College of Cardiology/American Heart Association Task Force suggest that the vast majority of cases with a gradient of <30 mm Hg do not require any intervention (Bonow et al., 1998; Bashore, 2007).

SURGICAL TREATMENT

Surgical approaches to critical pulmonary stenosis include transarterial pulmonary valvotomy, closed transventricular pulmonary valvotomy, and open pulmonary valvotomy using cardiopulmonary bypass. The need for surgical treatment of pulmonary stenosis depends on the pressure gradient across the pulmonary valve. With gradients of less than 25 mm Hg, 5% of children require surgery; 20% of those with gradients of 25 to 49 mm Hg and 76% of those with gradients of 50 to 79 mm Hg require surgical treatment (Hayes et al., 1993). Catheter-based approaches using a percutaneous balloon valvuloplasty have also evolved such that this is now considered by many to be a viable alternative to open surgical valvotomy (Bashore, 2007).

The most commonly performed surgical procedure is a closed transventricular pulmonary valvotomy, with or without a modified Blalock–Taussig shunt from the subclavian to the pulmonary artery (Coles and Trusler, 1990). Following thoracotomy or sternotomy, a stab incision is made in the right ventricular wall and a valvulotome, or Hegar dilator, is inserted to open the pulmonary valve. In one series of 16 infants younger than 3 months of age who had critical pulmonary stenosis, 14 survived following closed transventricular valvotomy, and all survivors demonstrated clinical improvement (Srinivasan et al., 1982).

Presence of a dysplastic pulmonary valve, or significant pulmonary insufficiency, usually requires complete pulmonary valve replacement. Replacement is typically with a bioprosthetic valve or pulmonary homograft, rather than a mechanical valve (Bashore, 2007).

LONG-TERM OUTCOME

Late results after treatment of pulmonary stenosis seem favorable. Estimates of 25-year actuarial survival range from 90% to 95% (Morris and Menashe, 1991; Hayes et al., 1993). In a series of 14 infants who survived closed transventricular pulmonary valvotomy for critical pulmonary stenosis, 2 required repeat surgery with 1 needing open valvotomy for restenosis and 1 needing closure of a secundum atrial septal defect (Srinivasan et al., 1982). It seems that in the majority of patients, adequate growth of the right ventricle and pulmonary annulus occurs following surgical repair. If the infundibular portion of the right ventricular outflow tract is hypoplastic on initial evaluation, the requirement for late reoperation to repair residual stenosis increases significantly and may be as high as 50% at 10 years postoperatively (Coles and Trusler, 1990).

Comparison of balloon valvuloplasty versus open surgical valvotomy for pulmonary stenosis suggests similar long-term outcome, with perhaps higher rates of pulmonary insufficiency among the surgical group (Peterson et al., 2003; Bashore, 2007). Pulmonary valve replacement is now also possible as a percutaneous catheter-based technique, raising the possibility of hybrid approaches in the treatment of congenital heart disease in which interventional cardiologists and cardiothoracic surgeons jointly repair a range of defects (Holzer and Hijazi, 2004).

GENETICS AND RECURRENCE RISK

Pulmonary stenosis may occur as part of Williams syndrome, which may also involve supravalvular aortic stenosis, developmental delay, and unusual facies. Williams syndrome is due to the deletion of one copy of the elastin gene on chromosome 7. Pulmonary stenosis may also occur as part of Noonan syndrome. Noonan syndrome is autosomal dominant and appears to be associated with mutations in the *PTPN11* gene in 45% to 60% of cases (Tartaglia et al., 2002). At least one case report describing familial clustering of cases of pulmonary stenosis has also been reported (Manetti et al., 1990). Without a history suggestive of a mendelian or chromosomal disorder, the recurrence risk for a couple with one previously affected child having another child with pulmonary stenosis is 2% but is increased to 6% if two previous children have been affected (Nora and Nora, 1988). The chance of having an affected infant if the mother has pulmonary stenosis is 4% to 6.5%, but if the father is affected, it is only 2% (Nora and Nora, 1988).

50 CHAPTER Aortic Stenosis

Key Points

- Prenatal diagnosis of aortic stenosis is unreliable.
- Aortic stenosis should be suspected whenever there is asymmetry of the cardiac ventricles including either left ventricular enlargement or left ventricular hypoplasia.
- Evaluation with serial fetal echocardiography should include consideration of coarctation of the aorta and the possibility of progression to hypoplastic left heart syndrome.
- In utero balloon dilation of the aortic valve has been described but is of questionable value.
- While pediatric balloon valvuloplasty is very successful, the high rate of reintervention required suggests that definitive surgical repair leads to best long-term outcome.

CONDITION

Aortic stenosis is the congenital obstruction of the left ventricular outflow tract of the heart. Stenosis can occur at, above, or below the aortic valve (Becker and Anderson, 1981). Subvalvular aortic stenosis can be either fixed or dynamic. Fixed aortic stenosis is due to the presence of a discrete membranous diaphragm or a diffuse fibromuscular ring below the valve. Dynamic subvalvular aortic stenosis demonstrates a constantly changing pressure gradient across the valve and is most commonly due to muscular thickening of the septum. This form of subvalvular aortic stenosis is often called "asymmetric septal hypertrophy" (ASH), "idiopathic hypertrophic subaortic stenosis" (IHSS), or "hypertrophic obstructive cardiomyopathy" (HOCM). A transient form of dynamic subvalvular aortic stenosis has also been described, secondary to fetal hyperglycemia (Gutgesell et al., 1976).

Valvular aortic stenosis occurs secondary to abnormalities of the cusps of the aortic valve. Congenital unicuspid or bicuspid aortic valves may be stenotic at birth or they may become stenotic later in adult life. Other causes of valvular aortic stenosis include dysplastic or thickened cusps and fusion of the commissures that separate the cusps.

Supravalvular aortic stenosis can occur secondary to a localized narrowing of the ascending aorta, the presence of a membrane just superior to the origin of the coronary arteries, or a diffuse narrowing of the aortic arch and great arteries. Because the obstruction occurs above the origin of the coronary arteries at the sinuses of Valsalva, the coronary arteries are also exposed to the elevated left ventricular pressures.

With all types of congenital aortic stenosis, if the stenosis becomes severe, secondary endocardial fibroelastosis can occur, leading to thickening of the endocardium and subsequent mitral insufficiency or cardiomyopathy. Aortic stenosis diagnosed early in gestation may evolve over time into hypoplastic left heart syndrome (Sharland et al., 1991).

INCIDENCE

The overall incidence of congenital heart disease is 4 in 1000 to 10 in 1000 livebirths (Hoffman, 1990). Aortic stenosis accounts for 3% to 6% of all congenital cardiovascular malformations, although it makes up 1% to 3% of all cardiac lesions in newborns presenting with significant cardiac defects (Rowe et al., 1981; Kitchener et al., 1993). It occurs up to four times more commonly in males than in females, although this sex predominance may be less marked in newborn populations. Overall, aortic stenosis has an incidence of 3.5 in 10,000 livebirths, while congenital bicuspid aortic valve may be as common as 1 in 100 livebirths.

SONOGRAPHIC FINDINGS

Prenatal diagnosis of aortic stenosis is unreliable. Because supravalvular and subvalvular forms of aortic stenosis are usually not clinically apparent during the newborn period, prenatal diagnosis of these conditions is rarely successful. Prenatal sonographic features suspicious for aortic stenosis include enlargement or hypoplasia of the left ventricle. However, it is important to realize that left ventricular size can also be normal despite the presence of significant aortic stenosis. The right ventricle is also usually dilated with critical aortic stenosis, as blood flow is redistributed to the right ventricle and through the ductus arteriosus. In addition, critical aortic stenosis is usually associated with poststenotic aortic root dilation.

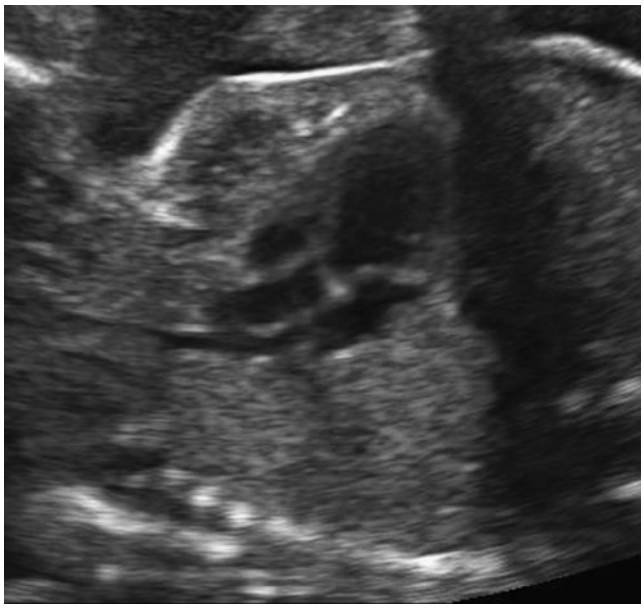

Figure 50-1 Long-axis view of the left ventricular outflow tract demonstrating a thickened and echogenic aortic valve consistent with aortic stenosis.

Incomplete opening of the aortic valve and increased aortic turbulence on Doppler echocardiography are both sonographic signs consistent with aortic stenosis during the newborn period (Figures 50-1 and 50-2), but prenatal

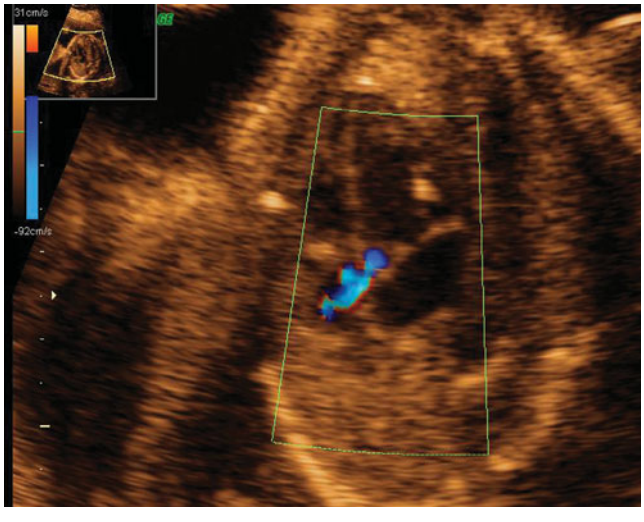

Figure 50-2 Color Doppler demonstrating high-velocity flow through the narrow aortic valve in a fetus with aortic stenosis.

visualization of these signs is extremely difficult because of the small size of the fetal aortic root. Prenatal diagnosis of a significant pressure drop (more than 50 mm Hg) across the valve is also suggestive of aortic stenosis (Jouk and Rambaud, 1991). Prenatal visualization of abnormal thickening of the interventricular septum in aortic stenosis has been documented (Stewart et al., 1986). In severe cases of congenital aortic stenosis, antenatal Doppler studies may demonstrate significant mitral regurgitation. Aortic stenosis may also be the underlying cause of some cases of hydrops fetalis or intrauterine growth restriction, and therefore aortic stenosis should be considered during the sonographic assessment of these conditions.

DIFFERENTIAL DIAGNOSIS

The main alternatives that must be considered in the prenatal diagnosis of aortic stenosis include primary cardiomyopathy (see Chapter 57) and hypoplastic left heart (see Chapter 48) (Huhta et al., 1987). In addition, coarctation of the aorta must be considered, but the prenatal diagnosis of this condition is also very limited (see Chapter 51). Unlike aortic stenosis, primary cardiomyopathy is usually associated with a normal aortic valve and no evidence of poststenotic dilation. Such primary cardiomyopathies may be secondary to endocardial fibroelastosis, viral or bacterial myocarditis, or some glycogen storage diseases.

Hypoplastic left heart syndrome is usually associated with both mitral- and aortic-valve atresia. In addition, the hypoplastic left ventricle may be globular in shape, rather than ellipsoid, which can be demonstrated on a four-chamber cardiac view by the left ventricle failing to reach the apex of the heart. In some cases, differentiation of aortic stenosis from hypoplastic left heart syndrome can be difficult because the enlarged right ventricle seen with aortic stenosis may make the left ventricle appear small or even hypoplastic. Other features that aid in differentiating aortic stenosis from hypoplastic left heart syndrome include failure of growth in left ventricular, aortic, or mitral dimensions on serial examinations, as well as severe restriction of interatrial shunting in cases of hypoplastic left heart syndrome (McCaffrey and Sherman, 1997). Of note, aortic stenosis and hypoplastic left heart syndrome are now considered part of a clinical spectrum with many cases of early fetal aortic stenosis evolving as gestation advances into the classic hypoplastic left heart syndrome. Therefore, attempts to differentiate between these two clinical conditions in utero may be purely academic (Hornberger et al., 1995).

ANTENATAL NATURAL HISTORY

The antenatal natural history of congenital aortic stenosis can be quite varied, with almost all cases of subvalvular and supravalvular aortic stenosis resulting in no fetal compromise, while critical valvular aortic stenosis can lead to intrauterine growth restriction, hydrops fetalis, and severe hemodynamic compromise during the early newborn period. The presence of hydrops with a structural cardiac malformation is usually considered an ominous finding.

Left ventricular pressure overload may lead to ventricular enlargement, relative coronary hypoperfusion, subendocardial ischemia, and consequently, significant impairment of cardiac function. This can result in severe metabolic acidosis, leading to death in a significant number of cases, either before or soon after birth (Sharland et al., 1991). Sustained elevated left ventricular pressure secondary to outflow tract obstruction can also lead to the intrauterine development of endocardial fibroelastosis and subsequent cardiomyopathy, which also increases the mortality rate for congenital aortic stenosis. In cases of aortic stenosis diagnosed prenatally, left ventricular volume and aortic root dimensions tend to fall off from the normal percentiles as gestation progresses, and this information may be useful in predicting the appropriate form of repair during the newborn period (Simpson and Sharland, 1997).

In one series of 30 cases of prenatally diagnosed left ventricular dysfunction, an initial appearance of aortic stenosis evolved over time into complete hypoplastic left heart syndrome in five cases (Sharland et al., 1991). There may be a spectrum of diseases in the fetus, involving primary left ventricular endocardial fibroelastosis, critical aortic stenosis, and hypoplastic left heart syndrome. Therefore, if screening takes place early enough, an initial clinical presentation of aortic stenosis may evolve over time into hypoplastic left heart syndrome (Sharland et al., 1991). For this reason, it is important to evaluate the appearance of the fetal heart whenever obstetric ultrasound examinations are performed in gestation.

MANAGEMENT OF PREGNANCY

Following the prenatal diagnosis of aortic stenosis, careful assessment of the remainder of the fetal anatomy is mandatory to rule out associated cardiac and noncardiac abnormalities. A referral for prenatal consultation with a pediatric cardiologist and neonatologist is recommended. Fetal echocardiography should be performed by an appropriately trained specialist if it has not already been done, as associated defects that may also be present include coarctation of the aorta, ventricular septal defect, and endocardial fibroelastosis. Karyotyping is also recommended because of the association between aortic stenosis and chromosomal abnormalities such as Turner syndrome. The fetus should be monitored with serial ultrasound examinations to detect early signs of congestive heart failure or hydrops fetalis. If hydrops develops, the prognosis is usually poor, although there are insufficient data at present to recommend changes in obstetric management. While it may be reasonable to offer early delivery in the setting of aortic stenosis with hydrops, it is as yet unclear if such an intervention will

change the already poor fetal prognosis. As described in the section on fetal intervention, there has been growing interest in balloon dilation of the aortic valve in utero in an attempt to improve the in utero natural history of this condition.

In the absence of hydrops, continued sonographic surveillance is recommended, followed by delivery for standard obstetric reasons in a tertiary care facility, with the immediate availability of a pediatric cardiologist and cardiothoracic surgeon. Although some pediatric specialists have recommended elective cesarean delivery in the presence of critical aortic stenosis (Robertson et al., 1989), there are insufficient data at present to support routine cesarean delivery in this setting.

FETAL INTERVENTION

Because of the high neonatal mortality rate associated with critical aortic stenosis, invasive attempts have been made in utero to correct the underlying valve abnormality. In one case report, a 16-gauge needle was placed transabdominally at 27 weeks of gestation and then inserted through the apex of the fetal heart, followed by a balloon catheter, which was threaded through the left ventricle into the ascending aorta (Lopes et al., 1996). Inflation of the balloon reportedly improved flow through the aortic valve, resulting in sonographic resolution of hydrops. The fetus was delivered by cesarean section but died from recurrent ventricular fibrillation soon after birth. In another case report, in utero balloon dilation for aortic stenosis was technically successful in one of two fetuses, but did not affect fetal outcome (Maxwell et al., 1991). One survivor has been described following in utero balloon dilation of a stenotic aortic valve (Allan et al., 1995).

The largest series of fetal aortic balloon valvuloplasties described to date has been from the Children's Hospital of Boston. In 20 fetuses with severe aortic stenosis and left ventricular dysfunction ranging from 21 to 29 weeks' gestation, technically successful aortic valve dilation was achieved in 14 cases (70%) (Tworetzky et al., 2004). Balloon insufflation with an oversized balloon seemed to provide more reliable degree of aortic regurgitation, with the goal being to improve left ventricular blood flow, thereby allowing the left ventricle to grow (Marshall et al., 2005). In their most recently updated series of 26 attempted valvuloplasties, 4 of 21 (19%) liveborn infants maintained a two-ventricle circulation postnatally (Marshall et al., 2005). It is, of course, uncertain whether these four cases would have had a two-ventricle repair postnatally if they were managed expectantly. Of note, in almost 50% of their cases maternal laparotomy was required to optimize fetal positioning following failed percutaneous access to the apex of the fetal heart.

The criteria to select appropriate fetal candidates for in utero intervention are not yet clear, although the presence of endocardial fibroelastosis may contraindicate intervention. The Boston group has suggested that cases of fetal aortic stenosis in which significant left ventricular dysfunction is present in the second trimester and in which retrograde flow is noted in the transverse aortic arch may be the best candidates for consideration for intervention as such fetuses almost invariably progress to hypoplastic left heart syndrome (Makikallio et al., 2006). The ethical challenges with this approach are also significant as potential morbidity to the mother needs to be balanced against an experimental procedure in which perhaps only 20% of fetuses gain significant benefit. Fetal intervention by means of in utero balloon dilation should therefore be considered experimental at this time, and should be limited to situations in which nondirective counseling is provided by a number of independent specialists in this area.

In addition to balloon dilation, the only other form of in utero intervention described for aortic stenosis is digoxin therapy for the mother, which was reported in two cases of hydrops fetalis secondary to severe aortic stenosis, followed by postnatal balloon valvuloplasty (Bitar et al., 1997).

TREATMENT OF THE NEWBORN

The initial treatment of newborns with congenital aortic stenosis involves diagnosing the severity of the condition followed by medical stabilization. Postnatal echocardiography should be performed promptly to confirm the diagnosis, establish its severity, and rule out other associated cardiac malformations. Echocardiography with Doppler studies should be sufficient to obtain this information without having to perform cardiac catheterization (Figure 50-3) (Huhta et al., 1987).

Medical management of aortic stenosis centers around stabilizing the infant while awaiting surgical intervention. Supplemental oxygen therapy, with or without mechanical

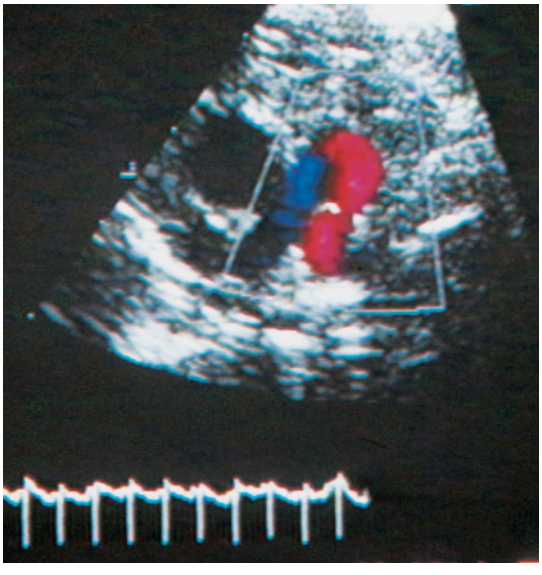

Figure 50-3 Color Doppler studies in a newborn with aortic stenosis, pulmonic atresia, and intact ventricular septum.

ventilation, correction of metabolic acidosis, maintenance of normal hematocrit, inotropic support with digoxin, and cautious use of diuretics to alleviate pulmonary edema are all recommended (Kiel, 1990). Prostaglandin E_1 infusion is recommended to maintain patency of the ductus arteriosus and improve tissue perfusion (Leoni et al., 1984). Balloon valvuloplasty via the umbilical artery may be useful as either a palliative procedure until definitive surgical repair takes place or as the primary repair procedure (Kiel, 1990).

Definitive therapeutic options for the repair of critical aortic stenosis include biventricular repair, univentricular repair, or cardiac transplantation. Biventricular repair involves aortic valvulotomy (either open surgical or percutaneous balloon approaches). Univentricular repair is by means of a Norwood-type surgical procedure (anastomosis of the main pulmonary artery to the aorta followed later by creation of an atriopulmonary connection). Often within hours or days of birth the physician must decide which of these therapeutic options to follow. The presence of multiple small left heart structures may suggest improved survival following a Norwood-type repair rather than a valvulotomy (Rhodes et al., 1991). Aortic valvulotomy may yield better results when the aortic root measures 5 mm or greater (Turley et al., 1990).

SURGICAL TREATMENT

Aortic valvulotomy is indicated when congestive heart failure is present or when the valve area is less than 0.5 cm^2 per square meter. Valvulotomy can be successfully performed via a closed, percutaneous approach, using a no. 5 Cook balloon catheter, which avoids the need for open surgery and cardiopulmonary bypass (Lababidi et al., 1984). In one series of 87 cases, balloon dilation of aortic stenosis is highly successful with a 98% technical success rate of reducing the pressure gradient across the valve being described (Pedra et al., 2004). However, repeat intervention may be required in more than 40% of these cases, with many requiring reintervention within 6 months of the original balloon dilation.

Alternatively, an open surgical approach can be performed with the aid of hypothermia and cardiopulmonary bypass. This approach involves making of commissural incisions in the stenotic valve, relieving stenosis but avoiding aortic incompetence. The disadvantage of this surgical approach is the need for cardiopulmonary bypass, which can significantly add to the morbidity for an already critically ill infant (Beeman and Hammon, 1990). An alternative surgical approach involves closed valvulotomy through a median sternotomy with insertion of a valvulotome through a left ventricular stab wound. The Norwood-type surgical repair is described in more detail in the chapter on hypoplastic left ventricle (see Chapter 48). More detailed description of surgical techniques for repair of congenital aortic stenosis is beyond the scope of this textbook, but is readily available in the literature (Gaynor and Elliott, 1993).

Operative mortality for aortic stenosis typically occurs within 48 hours of surgery. The operative mortality rate for corrective surgery has been given as 1.9% for valuvar stenosis, 6% for fixed subvalvular stenosis, and 5.5% for dynamic subvalvular stenosis (Jones et al., 1982). An overall operative mortality of 9% to 18% has been quoted for valvulotomy in cases of severe neonatal aortic stenosis (Messina et al., 1984; Gildein et al., 1996).

LONG-TERM OUTCOME

Without treatment, almost all clinically significant cases of congenital aortic stenosis result in death. Even when aortic stenosis is mild at presentation, it may become progressive, eventually requiring surgery (Kitchener et al., 1993). Later complications after repair include aortic incompetence or regurgitation and bacterial endocarditis. The long-term mortality rate from aortic stenosis is 23% during the first year of life and falls to 1.2% during the first two decades, 3% in the third, 3.5% in the fourth, 6% in the fifth, and 8.5% in the sixth decade of life (Campbell, 1968). In a more recent series, survival was 90% at age 10 years and 73% at age 25 years (Elkins et al., 1997). Twenty-five-year survival for aortic stenosis is 76% (Morris and Menashe, 1991).

Long-term outcomes described from a series of 87 balloon valvuloplasties demonstrated freedom from reintervention in 86% at 1 year, 67% at 5 years, and 46% at 12 years (Pedra et al., 2004). Approximately 50% to 70% of neonates who had surgical correction of aortic stenosis had satisfactory results when evaluated 5 to 14 years postoperatively (Jones et al., 1982). Almost one-third of patients will require repeat aortic valve repair within 15 to 20 years of the original operation (Beeman and Hammon, 1990; Gaynor et al., 1995). In another series, there was a 28% reoperation rate after a median duration of 8.7 years (Kitchener et al., 1993). A further 5% of patients may require a third operation later in childhood for aortic valve stenosis (Wheller et al., 1988). Sudden deaths comprise more than one-third of all late cardiac deaths for aortic stenosis (Morris and Menashe, 1991). One of the longest follow-up series of aggressive management of congenital aortic stenosis followed 88 cases and reported a 76% 12-year reoperation-free survival (Erentug et al., 2005).

GENETICS AND RECURRENCE RISK

Between 5% and 8% of all cases of congenital heart disease involve a chromosomal abnormality, usually trisomy 21, and therefore the recurrence risk is that of the chromosomal defect itself (Hoffman, 1990). Only a minority of cases of congenital heart disease (approximately 3%) are inherited in a classical Mendelian pattern. The dynamic form of subvalvular aortic stenosis (IHSS or HOCM) is most often inherited in an autosomal dominant pattern. Subvalvular aortic stenosis

may also occur as part of Turner and Noonan syndromes. Noonan syndrome is inherited as an autosomal dominant gene, and Turner syndrome is most commonly sporadic. Isolated supravalvular aortic stenosis may be inherited in an autosomal dominant pattern. Supravalvular aortic stenosis may also occur as part of Williams syndrome, together with developmental delay and an unusual facies. Williams syndrome is due to the deletion of one copy of the elastin gene and may be diagnosed using a fluorescence in situ hybridization probe that maps to the elastin gene on chromosome 7.

Without a history suggestive of a Mendelian or chromosomal disorder, the recurrence risk for a couple with one previously affected child with aortic stenosis is 2%. If there have been two affected children, the risk is 6%. Interestingly, the chance of having an affected infant if the mother has aortic stenosis is 13% to 18%, but if the father is affected, it is only 3% (Nora and Nora, 1988).

51 CHAPTER Coarctation of the Aorta

Key Points

- Coarctation of the aorta refers to a congenital narrowing of the aorta and is relatively common, accounting for 7% of cases of congenital heart disease.
- Prenatal diagnosis is generally possible following the discovery of asymmetry of the ventricles and outflow tracts.
- There is a strong association with chromosomal abnormalities, particularly Turner syndrome, as well as other cardiac and extracardiac malformations.
- Prenatal diagnosis is critical, as it leads to significantly improved neonatal morbidity and mortality.
- Following prenatal diagnosis, the infant should be delivered under controlled circumstances with prompt pediatric cardiology backup and the ability to start a prostaglandin infusion.
- Definitive therapy in infancy involves surgical correction by means of aortic resection and end-to-end anastomosis, although there is a growing role for catheter-based therapy with a combination of balloon dilation and stent placement.

CONDITION

Coarctation of the aorta refers to narrowing of a segment of the aorta along the aortic arch, usually near the origin of the ductus arteriosus (Figure 51-1A and 51-1B). The narrowed segment of the aorta can be of any length and can be preductal, juxtaductal, or postductal in location. The area of narrowing can be caused by a discrete soft tissue shelf, or can be due to hypoplasia of a segment of the arch, leading to complete aortic arch interruption. Previously, coarctation was divided into infantile and adult forms. The infantile form classically occurred in a preductal location, was associated with other cardiac malformations, and was more likely to be associated with neonatal congestive heart failure. The adult form classically occurred in juxtaductal or postductal locations and was associated with a better prognosis. This distinction now seems to be imprecise and is of little relevance, with both forms of coarctation presenting at various ages.

The pathogenesis of coarctation is unclear. It may be due to a developmental defect of the aortic arch, possibly because of failure of connection of the fourth and sixth branchial arches to the descending aorta. Another possible mechanism is the development of abnormal blood flow patterns in utero, leading to decreased aortic-arch flow and increased flow in the pulmonary artery and ductus arteriosus. The consequence of this imbalance in flow may be the development of relative hypoplasia of the aortic arch. A third possible mechanism for the pathogenesis of coarctation is the presence of aberrant ductal tissue in the arch, leading to narrowing of the aortic arch after closure of the ductus (Whitley and Perry, 1990).

Associated cardiac malformations are present in up to 90% of cases of coarctation, including bicuspid aortic valve, aortic stenosis (see Chapter 50) or insufficiency, septal defects (see Chapters 43 and 44), transposition of the great vessels (see Chapter 55), double outlet right ventricle (see Chapter 53), postnatal patent ductus arteriosus, and truncus arteriosus (see Chapter 54) (Romero et al., 1988). In one series of 68 cases of prenatally diagnosed coarctation of the aorta, 43% had a ventricular septal defect, and 15% had a bicuspid aortic valve (Paladini et al., 2004). Additional noncardiac malformations are present in 40% of cases (Paladini et al., 2004). A strong association exists between Turner syndrome and coarctation, with 10% of Turner syndrome patients being affected (see Chapter 134). Overall, 35% of cases of aortic coarctation will have an abnormal karyotype (Paladini et al., 2004).

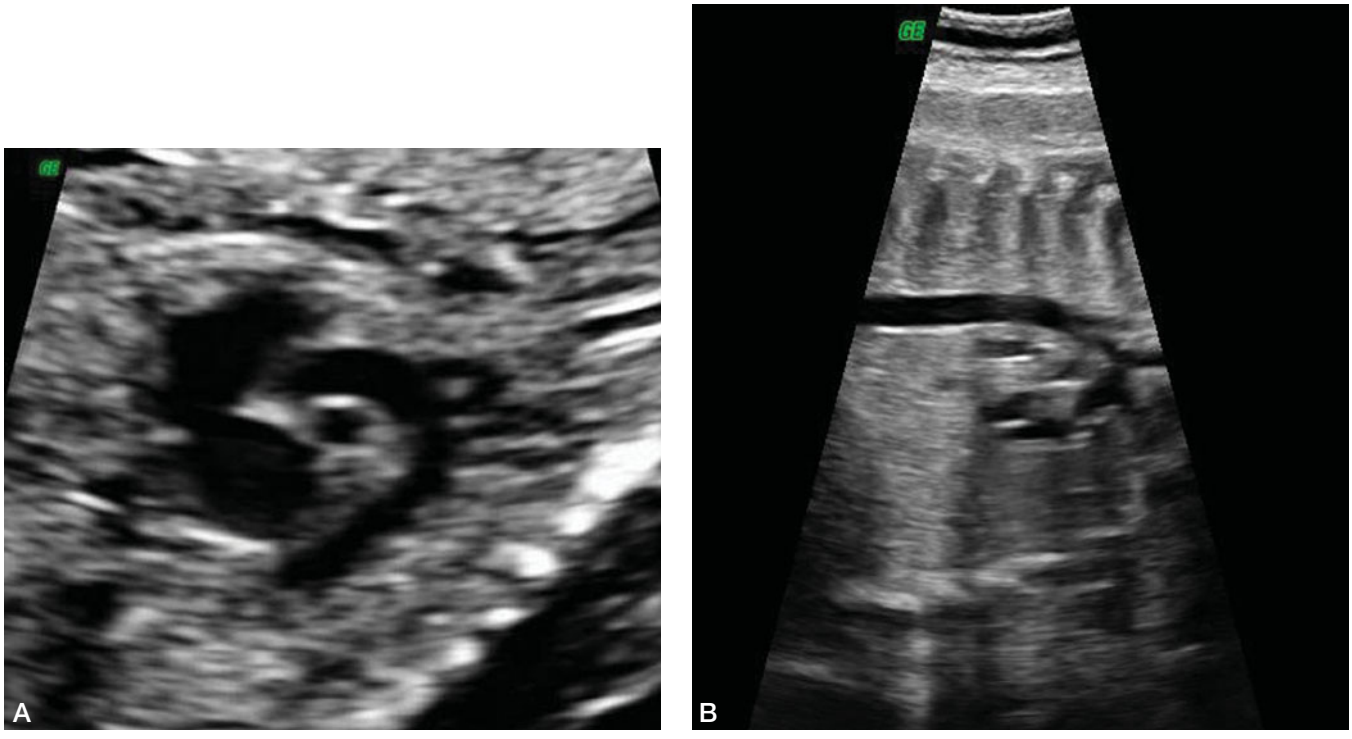

Figure 51-1 **A.** Parasagittal image of a normal aortic arch; **B.** Parasagittal view of the aortic arch demonstrating narrowing in the distal portion of the transverse arch consistent with coarctation of the aorta.

INCIDENCE

Coarctation of the aorta is present in approximately 2.5 per 1000, or 4 per 10,000, livebirths (Hoffman and Kaplan, 2002). While there is a significant male preponderance for coarctation in the entire population, there appears to be an equal incidence in both genders at birth. Coarctation accounts for up to 8% of all cases of congenital heart disease.

SONOGRAPHIC FINDINGS

Prenatal diagnosis of coarctation of the aorta using ultrasound examination is controversial. Some believe that it cannot be reliably diagnosed prenatally because in most cases the hemodynamic complications depend on closure of the ductus. Although it is true that coarctation of the aorta can be entirely a postnatal event, several series of prenatally diagnosed cases of coarctation have been documented (Allan et al., 1988; Sharland et al., 1994). However, in a population-based study of prenatal diagnosis of congenital heart disease from Australia, correct identification of coarctation prenatally was possible in only 26% of cases (Chew et al., 2007). This study ranked coarctation as the second most difficult form of congenital heart disease to accurately diagnose prenatally, after simple transposition of the great arteries (see Chapter 55).

An increased nuchal translucency measurement may be an early marker for aortic coarctation (Moselhi and Thilaganathan, 1996). Pathologic examination of fetuses with increased nuchal translucency thickness has demonstrated a high prevalence of cardiac defects and abnormalities of the great arteries. This has been shown in both trisomic and chromosomally normal fetuses (Hyett et al., 1995, 1996). In fetuses with trisomy 21, the aortic valve and ascending aorta are wider than in normal fetuses, while the aortic isthmus is narrower. In chromosomally normal fetuses, the aorta is narrowed at both the level of the isthmus and immediately above the aortic valve.

Later in gestation, prenatal visualization of a shelf or discrete area of narrowing in the aortic arch is extremely difficult. However, if there is complete hypoplasia or arch interruption, Doppler evaluation may demonstrate a disturbance of flow (Figure 51-2). Prestenotic or poststenotic dilation of the aortic arch may also be present. Growth curves for the transverse aortic arch at various gestational ages have been published, with the suggestion that cases of coarctation are associated with measurements at or below the third percentile (Hornberger et al., 1992). However, no data are available on the reliability or sensitivity of these techniques for the prenatal diagnosis of coarctation.

Relative enlargement of the right ventricle and pulmonary artery, when compared with the left ventricle and aorta, may be more easily detectable signs consistent with coarctation. The combination of ventricular disproportion and great vessel disproportion probably represents a more sensitive marker for coarctation (Rosenthal, 2005). In one series of prenatally diagnosed dilation of the right ventricle

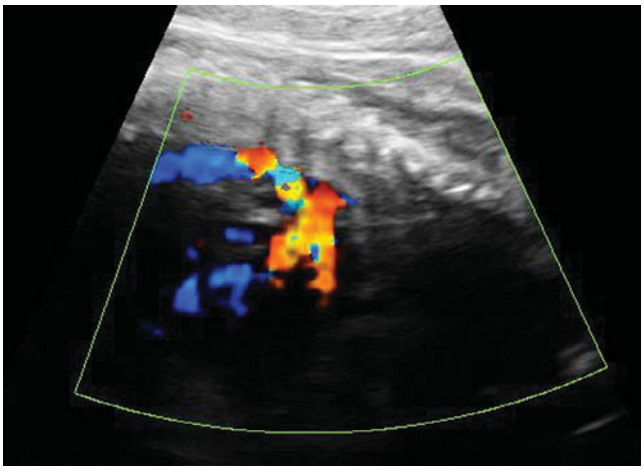

Figure 51-2 Color Doppler image of the same fetus showing turbulent flow in distal portion of the transverse aortic arch.

and pulmonary artery, 18 of 24 fetuses had coarctation (Allan et al., 1988). Doppler visualization of reduced aortic blood flow was present in most cases of coarctation, but was also present in some normal fetuses. Discrepancy in the size of the ventricles, caused by relative hypoplasia of the left heart structures, has a poor positive predictive value for coarctation, with the false-positive rate being higher after 34 weeks of gestation (Brown et al., 1997). Overall, 62% of cases of coarctation may have ventricular discrepancy recognizable on fetal echocardiograms. The higher false-positive rate at later gestational ages may be due to the normal relative increase in right heart size as gestation advances (Sharland and Allan, 1992). At present, no prenatal sonographic signs—taken either individually or in combination—can reliably distinguish true cases of coarctation from false-positive results (Sharland et al., 1994).

DIFFERENTIAL DIAGNOSIS

The main differential diagnosis for isolated coarctation of the aorta diagnosed prenatally is pulmonic stenosis, which may also present with a dilated right ventricle. However, in cases of pulmonic stenosis the pulmonary artery is small or hypoplastic as compared with the typical dilation of the pulmonary arterial dilation seen with coarctation. Other cardiac malformations commonly coexist with coarctation, so their presence cannot exclude coarctation.

ANTENATAL NATURAL HISTORY

The antenatal course of fetuses with coarctation of the aorta is usually benign, since the presence of an open ductus arteriosus carries blood supply from the heart to the aorta. However, in cases of severe coarctation or arch hypoplasia, progressive dilation of the right ventricle may result in right ventricular hypertrophy. The antenatal course may also be influenced by the presence of additional cardiac and noncardiac malformations, which frequently coexist with coarctation. As pregnancy advances, it is possible that isolated coarctation initially caused by a discrete shelf in early gestation may progress into complete arch hypoplasia (Allan et al., 1984). The prognosis for an individual fetus may therefore change as pregnancy progresses and the arch abnormality evolves. Congestive heart failure may occur early during the newborn period following closure of the ductus, especially in infants with an intact ventricular septum.

In one series of 68 cases of prenatally diagnosed coarctation of the aorta, the only independent predictor of poor outcome was the coexistence of fetal growth restriction (Paladini et al., 2004). It appears as if prenatal diagnosis of aortic coarctation confers a significant advantage on the infant. In one series of 10 cases of prenatally diagnosed cases of aortic coarctation, which were compared with 22 cases in which the diagnosis was not made until postnatal life, there was a significant improvement in neonatal mortality and morbidity amongst prenatally diagnosed cases (Franklin et al., 2002).

MANAGEMENT OF PREGNANCY

If the diagnosis of coarctation is suspected on obstetric ultrasound evaluation, fetal echocardiography should be performed by an appropriately trained specialist to confirm the diagnosis and to evaluate for the presence of additional cardiac malformations. In addition, careful sonographic evaluation should be performed for other noncardiac abnormalities, such as diaphragmatic hernia or sonographic signs of Turner or DiGeorge syndrome. Because of the significant association (up to 35%) with chromosomal abnormalities, karyotype evaluation should be offered, including fluorescence in situ hybridization analysis for chromosome 22 deletions (Paladini et al., 2004). Pediatric cardiology and neonatology consultations should also be arranged to facilitate neonatal treatment.

Serial ultrasound evaluation during pregnancy is recommended because the appearance and severity of the coarctation may change as pregnancy advances. Progressive obstruction will be evidenced by increasing right ventricular dilation with hypertrophy and possibly congestive cardiac failure. Additionally, the development of fetal growth restriction may be an independent marker for poor prognosis (Paladini et al., 2004). It is rare for coarctation to require early delivery, as the presence of an open ductus during intrauterine life usually delays significant hemodynamic disturbances until after birth. Because there is no absolute indication for cesarean delivery with coarctation, the mode of delivery should be dictated by standard obstetric circumstances. Delivery should occur at a tertiary care center, with the immediate availability of a pediatric cardiologist.

FETAL INTERVENTION

No fetal intervention has been described for isolated coarctation of the aorta.

TREATMENT OF NEWBORN

Immediate neonatal resuscitation is essential in the management of significant aortic coarctation. This is evidenced by the significantly higher morbidity and mortality amongst cases of aortic coarctation in which the correct diagnosis is not made prenatally (Franklin et al., 2002). Medical stability depends on the presence of continued patency of the ductus arteriosus with a right-to-left shunt supporting systemic perfusion. Because hyperventilation and supplemental oxygen therapy reduce pulmonary vascular resistance, these interventions may reduce the right-to-left shunt, thereby reducing systemic perfusion. Supplemental oxygen therapy should therefore be avoided unless absolutely necessary and, when used, should be limited to 40% to 60% maximum fractional inspired oxygen (Fio_2).

Prostaglandin E_1 infusion should be started to maintain patency of the ductus in severe cases of aortic coarctation. This will improve perfusion of the lower body, increase urinary output, and improve metabolic acidosis (Whitley and Perry, 1990). Prostaglandin E_1 infusion has been shown to improve surgical survival in left-sided obstructive congenital cardiac disease (Leoni et al., 1984). Diuresis and inotropic support with dopamine or dobutamine may be necessary if severe congestive cardiac failure develops.

Additional treatment of the newborn includes complete echocardiographic evaluation to confirm the diagnosis, to evaluate the severity of the coarctation, and to exclude any additional coexisting cardiac malformations. The involvement of a pediatric cardiologist and pediatric cardiac surgeon is essential.

The definitive neonatal treatment of coarctation is primary surgical repair. Balloon angioplasty has been advocated as an alternative to surgical repair, but it is associated with increased risks of restenosis at the site of coarctation. In one randomized comparison of balloon dilation with surgical repair of coarctation, subsequent aortic aneurysm occurred in none of those undergoing surgery, compared with 20% of those having balloon dilation (Shaddy et al., 1993). Long-term follow-up of these cases also revealed that significantly more of the patients who underwent surgery were symptom-free compared to those having balloon dilation (Cowley et al., 2005). In addition, since most cases of coarctation presenting during the newborn period are complex, or demonstrate aortic hypoplasia, balloon angioplasty is often not possible (Whitley and Perry, 1990). Isolated coarctation that is not symptomatic may be managed expectantly, with close surveillance of Doppler gradients across the area of narrowing or examination of the femoral pulse.

More recently, the development of endovascular stents appears to have improved the success of catheter-based interventions for coarctation. Balloon dilation of the area of coarctation need not be as extensive if a stent can be subsequently placed. This has resulted in balloon dilation and stent placement taking a more prominent first-line role for aortic coarctation in some centers, especially after the first year of life (Rosenthal, 2005; Wong et al., 2008).

SURGICAL TREATMENT

Surgical repair of symptomatic isolated coarctation of the aorta is generally delayed until at least 6 months of age, unless there is complete interruption of the aortic arch, which requires urgent correction (Beeman and Hammon, 1990). The presence of poor peripheral perfusion or congestive heart failure refractory to initial medical therapy may prompt earlier primary surgical repair. The timing of surgery also depends on the diagnosis of additional cardiac malformations, with the presence of a coexisting ventricular septal defect often considered an indication for immediate operation.

The most common surgical procedure used to repair isolated coarctation of the aorta is resection with an end-to-end anastomosis (Rosenthal, 2005; Abbruzzese and Aidala, 2007). Alternative surgical approaches include subclavian flap aortoplasty, and patching with a Dacron or pericardial patch (Beeman and Hammon, 1990; Rosenthal, 2005). These approaches are generally performed through a left thoracotomy. The main complications associated with patch repairs and subclavian flap aortoplasty are aneurysm formations at the flap site and weakening of the left arm with subclavian steal symptoms, respectively. For cases of aortic arch interruption, direct end-to-end anastomosis of the two aortic ends is performed using an endogenous vessel or graft.

Operative mortality for primary repair of isolated coarctation is less than 5% and probably approaches zero (Beeman and Hammon, 1990; Rosenthal, 2005). Mortality increases with the presence of additional complex cardiac malformations and the presence of medical complications such as congestive heart failure, metabolic acidosis, and prolonged preoperative ventilation.

LONG-TERM OUTCOME

Long-term survival after coarctation of the aorta depends on the presence of additional cardiac malformations. For isolated coarctation, 92% of patients are alive 15 years after repair, as compared with 81% with coexisting ventricular septal defect; 41% are alive at 3 years with more complex cardiac malformations (Kirklin and Barratt-Boyes, 1986). Survival 25 years after repair has been estimated at 79% of affected individuals (Morris and Menashe, 1991). Restenosis at the site of coarctation repair may occur in up to 50% of cases, depending on

the type of correction (Beekman et al., 1981). However, some centers have reported extremely low rates of recurrence of the coarctation following subclavian flap aortoplasty (Moulton et al., 1984). Aortic stenosis may also occur in up to 7% of cases following repair in infancy (Kirklin and Barratt-Boyes, 1986). Additionally, as many as 70% of survivors face long-term problems with chronic hypertension (Rosenthal, 2005). Other long-term problems include aortic dilation, dissection and rupture, which may occur in up to 16% of survivors (Oliver et al., 2004).

GENETICS AND RECURRENCE RISK

There is a strong association between Turner syndrome (45,X) and coarctation of the aorta, with 10% of patients with this syndrome also having coarctation. The occurrence of Turner syndrome is generally sporadic (see Chapter 134). In addition, coarctation has been described as part of the DiGeorge sequence (see Chapter 139). Inheritance patterns for most cases of coarctation of the aorta are considered polygenic. Estimates of recurrence risk for children with one parent diagnosed with coarctation range from 2.7% to 4.4%. The recurrence risk for siblings of an affected child is 2% (Nora and Nora, 1988; Whitley and Perry, 1990). The recurrence risk if two siblings are affected is 6% (Nora and Nora, 1988). At least one familial cluster of coarctation of the aorta, possibly consistent with autosomal dominant inheritance, has also been described (Gerboni et al., 1993). In this family, four members of three generations had mild or severe coarctation of the aorta, either isolated or in association with other congenital heart defects. Prenatal diagnosis was successfully performed in this family using fetal echocardiography, which at 26 weeks of gestation demonstrated severe narrowing of the aortic isthmus and hypoplastic left heart.

52 CHAPTER

Tetralogy of Fallot

Key Points

- Tetralogy of Fallot is a complex congenital cardiac malformation consisting of varying degrees of right ventricular outflow tract obstruction, ventricular septal defect, overriding aorta and right ventricular hypertrophy (although the latter is generally not present in fetal life).
- Prenatal diagnosis generally requires careful evaluation of cardiac outflow tracts, including discontinuity between ventricular septum and aortic outflow, as well as a relatively small pulmonary outflow.
- Testing for fetal karyotype and 22q11 deletion is recommended.
- Infants should be delivered in a controlled setting with ability to provide prostaglandin infusion and prompt pediatric cardiology availability.
- While initial palliation with a systemic-to-pulmonary arterial shunt may be required, many centers today perform definitive complete surgical correction within the first 6 months of life.

CONDITION

Tetralogy of Fallot is a cardiac malformation comprising ventricular septal defect (VSD), right ventricular outflow tract obstruction, aorta overriding the interventricular septum, and right ventricular hypertrophy. This malformation presumably occurs because of unequal division of the conotruncus or incorrect alignment of the ascending aorta during embryogenesis (Romero et al., 1988). A wide spectrum of severity exists for this condition, ranging from mild right ventricular outflow tract obstruction to complete pulmonary atresia, and aortic override ranging from minimal to 75% (Pinsky and Arciniegas, 1990). In addition, the hypoplasia may involve simply the infundibulum of the right ventricle or it may also involve the pulmonary valve or pulmonary arteries. Tetralogy may therefore also include pulmonary stenosis, pulmonary atresia or absent pulmonary valve, with this degree of right ventricular tract obstruction determining the amount of right-to-left shunting and cyanosis in infancy (Bashore, 2007). Approximately 3% to 6% of all cases of tetralogy will present with absent pulmonary valve (Shinebourne et al., 2006). The VSD is most often in a superior or perimembranous location, and it is usually large and nonrestrictive. The diameter of the aortic root is generally inversely proportional to that of the pulmonary artery, so that in cases of pulmonary atresia the aorta is very wide, with more than 50% committed to the right ventricle (Graham and Gutgesell, 1990).

In general, tetralogy of Fallot does not cause significant intrauterine hemodynamic compromise for the fetus because of similarities in the pressure between the systemic and pulmonary circulations. Right ventricular hypertrophy is therefore usually not seen until after birth. In cases of tetralogy with complete absence of the pulmonary valve, significant regurgitation may cause congestive cardiac failure in utero and ultimately, hydrops (Romero et al., 1988). Following birth, the closure of the ductus arteriosus, together with the narrowed right ventricular outflow tract, results in development of a significant right-to-left shunt. This leads to blood flow bypassing the pulmonary bed, resulting in hypoxemia in the systemic circulation. Because the right ventricular outflow-tract obstruction is fixed, the degree of right-to-left shunt is almost entirely dependent on the systemic vascular resistance (Graham and Gutgesell, 1990). In times of low systemic resistance, such as during exercise, fever, or following feeding, the right-to-left shunt becomes more pronounced, which leads to cyanotic spells in the child. These can be treated by knee–chest positioning and by the use of peripheral vasoconstrictors.

Additional abnormalities that may coexist with tetralogy of Fallot include chromosomal abnormalities (such as trisomies 13, 18, and 21), syndromes (such as velocardiofacial), and associations (such as CHARGE and VATER)

(Sanders et al., 1996). In one series, 3 of 6 cases (50%) of prenatally diagnosed tetralogy were associated with trisomy 18 (Crawford et al., 1988). In another series of prenatally diagnosed cardiac malformations, 3 of the 18 fetuses (17%) with tetralogy and known karyotype had trisomy 13 (Paladini et al., 1996). In a series of 138 liveborn infants with tetralogy, 17 (12%) had chromosomal abnormalities (Ferencz et al., 1987).

INCIDENCE

Tetralogy of Fallot is one of the most common congenital cardiac malformations, occurring in approximately 2 to 3 per 10,000 livebirths (Hoffman and Kaplan, 2002). It accounts for 5% to 10% of congenital cardiac defects diagnosed in liveborn infants (Fyler et al., 1980; Ferencz et al., 1987).

SONOGRAPHIC FINDINGS

Because right ventricular hypertrophy does not generally develop in utero and visualization of fetal right ventricular outflow tract obstruction is difficult, the prenatal diagnosis of tetralogy of Fallot relies on the demonstration of the aortic outflow tract overriding a VSD at the interventricular septum (Figures 52-1 and 52-2) (Romero et al., 1988). The demonstration of a VSD with overriding aorta may be performed as early as 14 weeks of gestation with the aid of transvaginal sonography (Bronshtein et al., 1990). Because of the difficulties in visualizing small perimembranous VSDs with prenatal sonography, the diagnosis of tetralogy may be missed on a standard four-chamber view of the heart. This emphasizes the importance of careful visualization of the cardiac outflow tracts during prenatal sonography (Shinebourne et al., 2006). In one series of 22 fetuses with tetralogy, the four-chamber view was abnormal in only 1 case (Paladini et al., 1996). The VSD is best imaged by a demonstration of discontinuity between the interventricular septum and the aortic outflow tract in the left parasternal long-axis view rather than by a standard four-chamber cardiac view (DeVore et al., 1988). Color Doppler sonography may also be helpful in demonstrating flow from the right ventricle, across the VSD, and into a dilated aortic root (Anderson et al., 1994).

Figure 52-1 Four-chamber view demonstrating a ventricular septal defect in a fetus with tetralogy of Fallot.

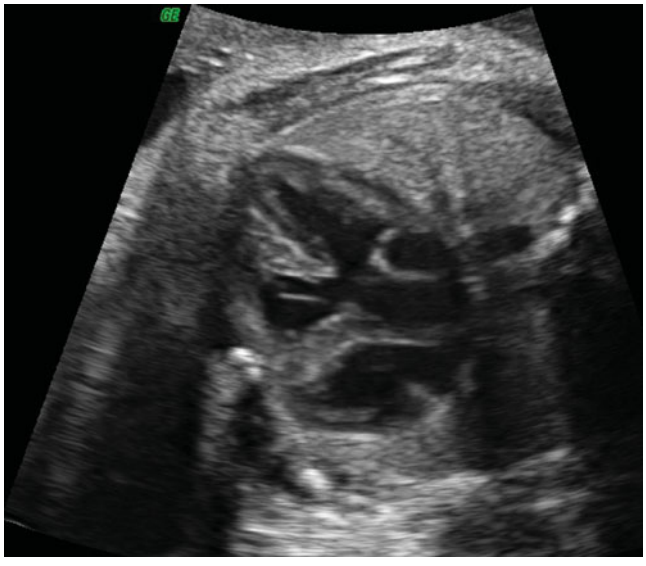

Figure 52-2 Axial image through the chest of a fetus with tetralogy of Fallot. Note the aorta overriding the ventricular septal defect.

Additional features that may assist in the prenatal diagnosis of tetralogy include the right ventricle being slightly larger than the left, a relatively small pulmonary artery (Figure 52-3), a dilated aortic root, and axis deviation (Sanders et al., 1996). In fetuses with tetralogy, the aortic-root diameter is increased as compared with other biometric parameters, such as the biventricular diameter (DeVore et al., 1988). However, the presence of a normal pulmonary artery:aorta ratio does not exclude tetralogy; in many cases the pulmonary artery narrowing may not become apparent until late in gestation (Lee et al., 1995). In some cases of tetralogy with absence of the pulmonary valve, the pulmonary outflow tract may even appear massively dilated (Liang et al., 1997). Polyhydramnios may also be present in cases of tetralogy with absent pulmonary valve, as the massively dilated pulmonary artery may cause tracheobronchial and esophageal compression that lead to impaired fetal swallowing and an increase in amniotic fluid volume (Callan and Kan, 1991).

The usefulness of screening ultrasonography for prenatal detection of tetralogy is unclear. In one study, 13 of the 20 cases (65%) of tetralogy were detected prenatally when careful screening obstetric sonography was performed

Figure 52-3 Narrow right ventricular outflow tract in a fetus with tetralogy of Fallot.

(Kirk et al., 1997). By contrast, in another study only 9 of 66 cases (14%) of tetralogy were detected using fetal echocardiography (Montana et al., 1996). In a population-based screening study from Australia, the prenatal detection rate for tetralogy was 43% (Chew et al., 2007).

DIFFERENTIAL DIAGNOSIS

Cardiac malformations that should be included in the differential diagnosis of tetralogy of Fallot include pulmonary atresia with a VSD (see Chapter 49), truncus arteriosus (see Chapter 54), and double outlet right ventricle (see Chapter 53). Doppler echocardiography may be helpful in confirming the presence of pulmonary atresia as opposed to narrowing of the right ventricular outflow tract, which is more typically seen with tetralogy. The differentiation of truncus arteriosus from tetralogy with coexisting pulmonary atresia is very difficult, with both having almost identical antenatal sonographic appearances. Visualization of more than three leaflets in a truncal valve may help differentiate these two conditions (see Chapter 54). It may be necessary to base differentiation of tetralogy from some cases of double outlet right ventricle solely on the relative area of the aortic outflow tract that arises from the right ventricle (see Chapter 53).

ANTENATAL NATURAL HISTORY

In general, since the pressures in the pulmonary and systemic circulations are similar, tetralogy of Fallot does not cause intrauterine hemodynamic instability. Given that right- and left-sided afterloads are similar, ventricular hypertrophy generally does not occur in the prenatal period (Shinebourne et al., 2006). An exception would be tetralogy with absent pulmonary valve, in which significant regurgitation may lead to hydrops (Romero et al., 1988). In addition, if a major chromosomal abnormality is also present, such as trisomy 13 or 18, there will be a considerably increased risk of intrauterine death. As a general rule, the antenatal natural history of isolated tetralogy of Fallot is relatively uneventful. However, there have been reports of progression of the degree of pulmonary stenosis associated with tetralogy as gestation progresses, which would suggest that fetuses diagnosed with tetralogy should be followed serially as pregnancy continues (Hornberger et al., 1995).

In one series of 22 cases of prenatally diagnosed tetralogy of Fallot, 9 pregnancies (41%) were terminated, no cases resulted in intrauterine death, 6 infants (27%) died during the neonatal period, and 7 infants (32%) survived (Paladini et al., 1996). In another series of 11 cases of prenatally diagnosed tetralogy, 2 pregnancies (18%) were terminated, no cases resulted in intrauterine death, 6 infants (55%) died during the postnatal period, and 3 infants (27%) survived (Smythe et al., 1992).

MANAGEMENT OF PREGNANCY

Following prenatal diagnosis of tetralogy of Fallot, a careful fetal echocardiogram is recommended to exclude additional complex cardiac malformations, such as absence of the pulmonary valve, which is seen in 3% to 6% of cases (Shinebourne et al., 2006). In addition, a detailed fetal anatomic survey is recommended to exclude extracardiac malformations. In particular, malformations associated with the major autosomal trisomies, DiGeorge syndrome (see Chapter 139), and VATER should be excluded (Sanders et al., 1996).

Invasive fetal testing for karyotype analysis is recommended following the prenatal diagnosis of tetralogy, because in reported series the incidence of chromosomal abnormalities ranges from 12% to 50% (Ferencz et al., 1987; Crawford et al., 1988). If a karyotype is performed, additional fluorescence in situ hybridization (FISH) studies for chromosome 22q11 microdeletions that comprise the DiGeorge syndrome (see Chapter 139) should also be performed (Trainer et al., 1996). Referrals for prenatal consultation with a pediatric cardiologist and cardiothoracic surgeon are also recommended.

If the diagnosis is made before fetal viability, termination of pregnancy may be offered because of the neonatal mortality and surgical morbidity associated with this condition. If expectant management is desired, sonographic surveillance to confirm appropriate fetal growth and to evaluate for the development of fetal hydrops is recommended, especially if additional cardiac malformations such as absence of the pulmonary valve are present. If fetal hydrops occurs, the prognosis is poor; the optimal management of such pregnancies is unknown. Delivery should occur at a tertiary care center,

with the immediate availability of a neonatologist, pediatric cardiologist, and cardiothoracic surgeon. There is no indication to alter the timing or method of delivery based on the prenatal diagnosis of tetralogy of Fallot.

FETAL INTERVENTION

No fetal intervention has been described for tetralogy of Fallot.

TREATMENT OF THE NEWBORN

Initial clinical presentation of neonates with tetralogy is quite variable. The presence of cyanosis in a newborn with tetralogy suggests that significant right ventricular outflow tract obstruction is present. In such cases, or if there is any other reason to suspect ductal dependence, prostaglandin E_1 infusion should be started to maintain patency of the ductus arteriosus. The infant should be transported to a neonatal intensive care unit as soon as possible.

Consultation with a pediatric cardiologist should be obtained promptly and echocardiography performed to confirm the prenatal diagnosis and to exclude additional cardiac malformations. The degree of pulmonary arterial obstruction should be assessed, which may require the use of cardiac catheterization. Cardiac catheterization is useful in delineating the anatomy of the coronary arteries, the degree of pulmonary artery narrowing, the anatomy of the pulmonary arterial branches and aorta, and the extent of the VSD (Graham and Gutgesell, 1990). Further medical management in the neonatal intensive care unit will include maintenance of adequate oxygenation and treatment of metabolic acidosis and congestive heart failure. If assisted ventilation, oxygen supplementation, and prostaglandin E_1 infusion cannot maintain adequate oxygenation, consultation with a pediatric cardiothoracic surgeon should be obtained to decide on timing and method of surgical intervention, such as a palliative shunt procedure or definitive repair (Sanders et al., 1996). Optimal age for complete surgical correction of tetralogy has been falling and is now considered to be between 3 and 12 months of age, but is individualized in all cases (Shinebourne et al., 2006).

Some neonates with tetralogy of Fallot do not have significant cyanosis, may have minimal right ventricular outflow tract obstruction, and may not be dependent on a patent ductus arteriosus. Such infants generally do not require prostaglandin E_1 infusion, provided they can maintain adequate oxygenation, even after spontaneous closure of the ductus arteriosus. In such cases, cyanosis may only be visible intermittently, for example after crying (Shinebourne et al., 2006). Eventually however, all children with tetralogy will present with "tet spells" as the degree of pulmonary vascular resistance increases leading to a significant right-to-left shunt. In such mild cases, cardiac catheterization can generally be delayed until 3 to 6 months of age, with surgical repair planned for soon after onset of symptoms or electively at 18 to 24 months of age (Pinsky and Arciniegas, 1990). However, in more than 70% of infants with tetralogy, symptoms sufficient to warrant surgical intervention develop within the first year of life (Castaneda and Jonas, 1990).

SURGICAL TREATMENT

Debate still exists on the timing of surgical repair for tetralogy of Fallot and the role of palliative shunting procedures prior to definitive correction. Infants with isolated tetralogy of Fallot and favorable anatomy generally receive complete primary repair soon after the onset of symptoms or within the first year of life. Infants with more complex tetralogy, such as hypoplasia of the pulmonary arteries or anomalous coronary arterial anatomy, are initially treated with a systemic-to-pulmonary shunt followed by final repair at 18 to 24 months of age (Pinsky and Arciniegas, 1990; Derby and Pizarro, 2005). As surgical techniques advance, the age at which complete primary repair is performed continues to decrease (Castaneda and Jonas, 1990).

Primary repair of tetralogy of Fallot requires cardiopulmonary bypass and a median sternotomy approach (Castaneda and Jonas, 1990). The infundibulum of the right ventricular outflow tract is incised, and the incision is carried up to the bifurcation of the pulmonary artery. Thickened or dysplastic pulmonary valve leaflets are usually excised. A Dacron patch is used to close the VSD and a patch of pericardium is used to augment the right ventricular outflow tract and pulmonary artery. If a patent foramen ovale or patent ductus arteriosus is present, these are also closed at this time. For the few patients who are not candidates for complete primary repair, the most commonly performed palliative procedure is a Blalock–Taussig systemic-to-pulmonary shunt, in which the subclavian artery is anastomosed to the pulmonary artery.

The operative mortality rate for primary repair of tetralogy of Fallot during infancy has improved, with mortality quoted as 14% in 1979 but subsequently improved to as low as 3% more recently (Tucker et al., 1979; Touati et al., 1990; Bashore, 2007). At one center, of 467 infants who underwent surgery for tetralogy of Fallot, there were only 16 (3.4%) early postoperative deaths (Pinsky and Arciniegas, 1990). In another series of 366 infants who had complete correction of tetralogy, one center reported an operative mortality rate of only 0.5% when using a 6- to 8-kg weight cutoff for surgical eligibility (Karl et al., 1992). Recent national outcome data from the United Kingdom suggests a 97% survival rate 1 year postoperatively (Shinebourne et al., 2006). Operative mortality now appears to be most affected by the presence of complex cardiac anatomy or an abnormal metabolic state, rather than infant age or weight (Castaneda and Jonas, 1990).

LONG-TERM OUTCOME

A study of the long-term outcome of 163 patients who survived complete repair of tetralogy of Fallot demonstrated a 90% 30-year actuarial survival rate, with 94% of survivors being in either New York Heart Association functional class I or II (Murphy et al., 1993). However, up to 12% of patients who survive surgical correction may have unsatisfactory results, and reoperation may be required for those with residual right ventricular outflow tract obstruction or residual VSD (Pinsky and Arciniegas, 1990). Other long-term complications include the development of pulmonary valve insufficiency and arrhythmias, possibly leading to sudden death.

GENETICS AND RECURRENCE RISK

Tetralogy of Fallot has been described with velocardiofacial syndrome, DiGeorge syndrome (see Chapter 139), and the VATER associations (Sanders et al., 1996). In addition, tetralogy has been described with trisomies 13, 18, and 21. Chromosome 22q11 microdeletions that are seen as part of the DiGeorge syndrome have been noted in many infants with tetralogy, being present in 21% of infants with tetralogy in one series (Trainer et al., 1996).

The recurrence risk for tetralogy of Fallot is 2.5% if one previous sibling has been affected and increases to 8% if two previous siblings have been affected (Nora and Nora, 1988). If the mother has tetralogy, the recurrence risk for her offspring is 2.5%. If the father is affected, the recurrence risk for his offspring is 1.5% (Nora and Nora, 1988).

53 CHAPTER Double Outlet Right Ventricle

Key Points

- Double outlet right ventricle (DORV) is a complex cardiac malformation in which the majority of both pulmonary and aortic trunks arise from the right ventricle, typically coexisting with a VSD.
- While DORV represents a heterogeneous group of abnormalities with various classification systems, a combined anatomic-surgical classification system is now used as it predicts optimal surgical intervention.
- Prenatal diagnosis depends on accurate delineation of the outflow tract paths, including localizing the VSD.
- The majority of cases have associated cardiac malformations, abnormalities of organ situs, or chromosomal abnormalities.
- Because of the variable clinical presentation at birth, delivery should occur in controlled circumstances at a center with pediatric cardiology backup available, and the ability to begin a prostaglandin infusion.
- Definitive surgical correction should occur during the first year of life, with most cases achieving a biventricular repair using an intraventricular tunnel.

CONDITION

Double outlet right ventricle (DORV) refers to a congenital cardiac malformation in which most of the pulmonary artery and the aorta arise from the right ventricle, one subtype of which is known as the Taussig–Bing heart. Such an abnormality is generally compatible with life only when there is an additional malformation that allows blood flow from one side of the heart to the other, most commonly a ventricular septal defect (VSD).

Attempts have been made to define the malformation based on the relative area of each outflow tract arising from the right ventricle, with an anatomic threshold of 50% being used. The surgical definition of DORV requires that at least 90% of the area of the outflow tracts arise from the right ventricle. The most commonly used definition requires one great artery to arise fully over the right ventricle and at least 50% of the other great artery to also originate from the right ventricle (Aoki et al., 1994). Therefore, cases of tetralogy of Fallot (see Chapter 52) in which the majority of the aortic outflow tract arises from the right ventricle could also be defined as DORV. Such anomalies may arise because of arrest of normal rotation of the outflow tracts (Bostrom and Hutchins, 1988). DORV has also been classified based on the relationship of the outflow tracts. The most common is where the aortic outflow tract is situated posterior to the pulmonary outflow tract, each spiraling around the other as they exit the heart (Romero et al., 1988). The Taussig–Bing heart is a subtype of DORV in which the aortic outflow tract ascends posterior to the pulmonary outflow tract in a parallel fashion. In the third type of DORV, the aortic outflow tract ascends anterior to the pulmonary outflow tract in a parallel fashion. DORV may also be classified based on the location of the VSD, either subaortic or subpulmonary; in the Taussig–Bing heart the VSD is subpulmonary (Bashore, 2007).

Because of this confusion in classification of DORV anatomically, the Society of Thoracic Surgeons (STS) and the European Association of Cardiothoracic Surgery (EACTS) have agreed a new classification system based on clinical presentation and surgical management (Walters et al., 2000). The four types are: (1) VSD-type, (2) tetralogy of Fallot-type, (3) transposition of great arteries-type (Taussig–Bing), and (4) DORV with noncommitted VSD. Patients with a subaortic VSD present clinically very similar to tetralogy of Fallot (Bashore, 2007).

Additional cardiac malformations are almost always present, with the most common being a VSD. Other coexisting cardiac malformations include atrial septal defect, atrioventricular canal defect, pulmonary stenosis, coarctation of the aorta, and anomalous venous return. Noncardiac

malformations may also be present, including chromosomal abnormalities, such as trisomy 18 or 13, tracheoesophageal fistula, cardiosplenic syndrome, and orofacial clefting (Rowe et al., 1981; Wladimiroff et al., 1989; Kim et al., 2006).

INCIDENCE

DORV is rare and accounts for approximately 1% of all congenital cardiac malformations. However, this incidence may be higher if cases of tetralogy of Fallot that can also be defined as DORV are included. In one multicenter series, DORV accounted for 4.1% of all cases of prenatally diagnosed congenital heart disease (Paladini et al., 1996). The presence of pre-existing maternal diabetes mellitus seems to be a significant risk factor for the development of DORV, with an odds ratio of 21.3 (Ferencz et al., 1990). The incidence of DORV is approximately 1 to 2 per 10,000 livebirths (Hoffman and Kaplan, 2002).

SONOGRAPHIC FINDINGS

Definitive prenatal sonographic diagnosis of DORV is difficult, as successful prenatal diagnosis requires careful examination of both the four-chamber view and the outflow tracts. On the four-chamber view, a VSD is almost always present, either in a subpulmonary or a subaortic location. In DORV, both outflow tracts are visible arising from the right ventricle and are often in a side-by-side, or parallel position (Figures 53-1 to 53-3) (Stewart et al., 1985).

Figure 53-1 Prenatal sonographic image from a fetus with DORV, demonstrating parallel outflow tracts emanating from the right ventricle. RV = right ventricle; OT = outflow tract.

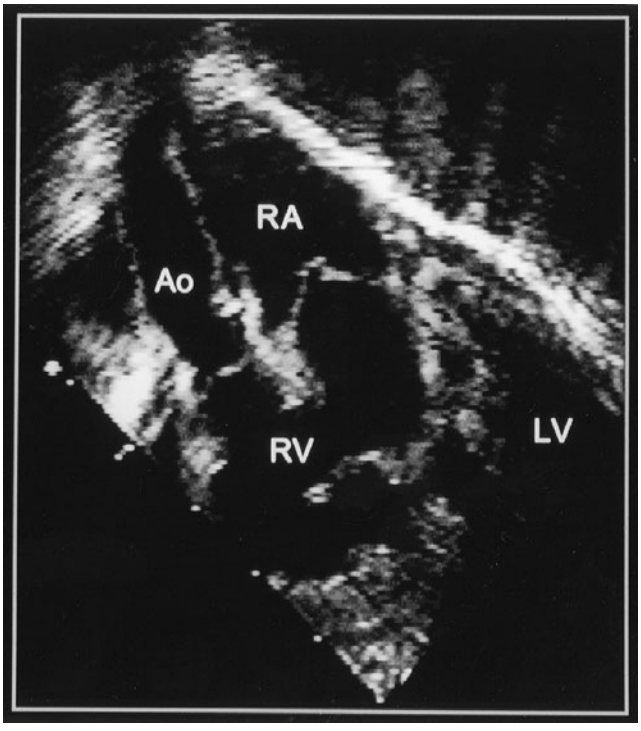

Figure 53-2 Subxiphoid long-axis transthoracic echocardiographic view of an infant with a variant of DORV. Both great vessels arise from the right ventricle in a side-by-side arrangement. RA = right atrium; LV = left ventricle; RV = right ventricle; Ao = aorta. (*Image courtesy of Dr. Jonathan Rhodes.*)

In one series of 24 fetuses with parallel outflow tracts, 7 were found to have transposition of the great arteries, while the remaining 17 had DORV (Allan, 1997). In that series, most of the mothers were referred for fetal echocardiography because of an initial abnormal four-chamber cardiac view. In another series, 13 cases of DORV were correctly diagnosed by fetal echocardiography, 5 of which had an abnormal four-chamber cardiac view (Paladini et al., 1996). A transverse three-vessel view through the upper fetal mediastinum, demonstrating the main pulmonary artery, ascending aorta, and superior vena cava, may also be helpful in diagnosing DORV (Yoo et al., 1997). In a population-based study from Australia, 54 of 73 (74%) cases of DORV were correctly identified prenatally (Chew et al., 2007). When DORV is suspected prenatally, the diagnosis will subsequently be proven correct in approximately 75% of cases (Gelehrter et al., 2007). It appears clear, therefore, that maximal prenatal detection of DORV requires careful visualization of both the four-chamber view and the cardiac outflow tracts.

DIFFERENTIAL DIAGNOSIS

Because DORV is almost always associated with additional cardiac malformations, a final diagnosis is often not possible until postnatal life. The prenatal sonographic appearance of DORV can be similar to that of tetralogy of Fallot (see Chapter 52) and transposition of the great arteries with a

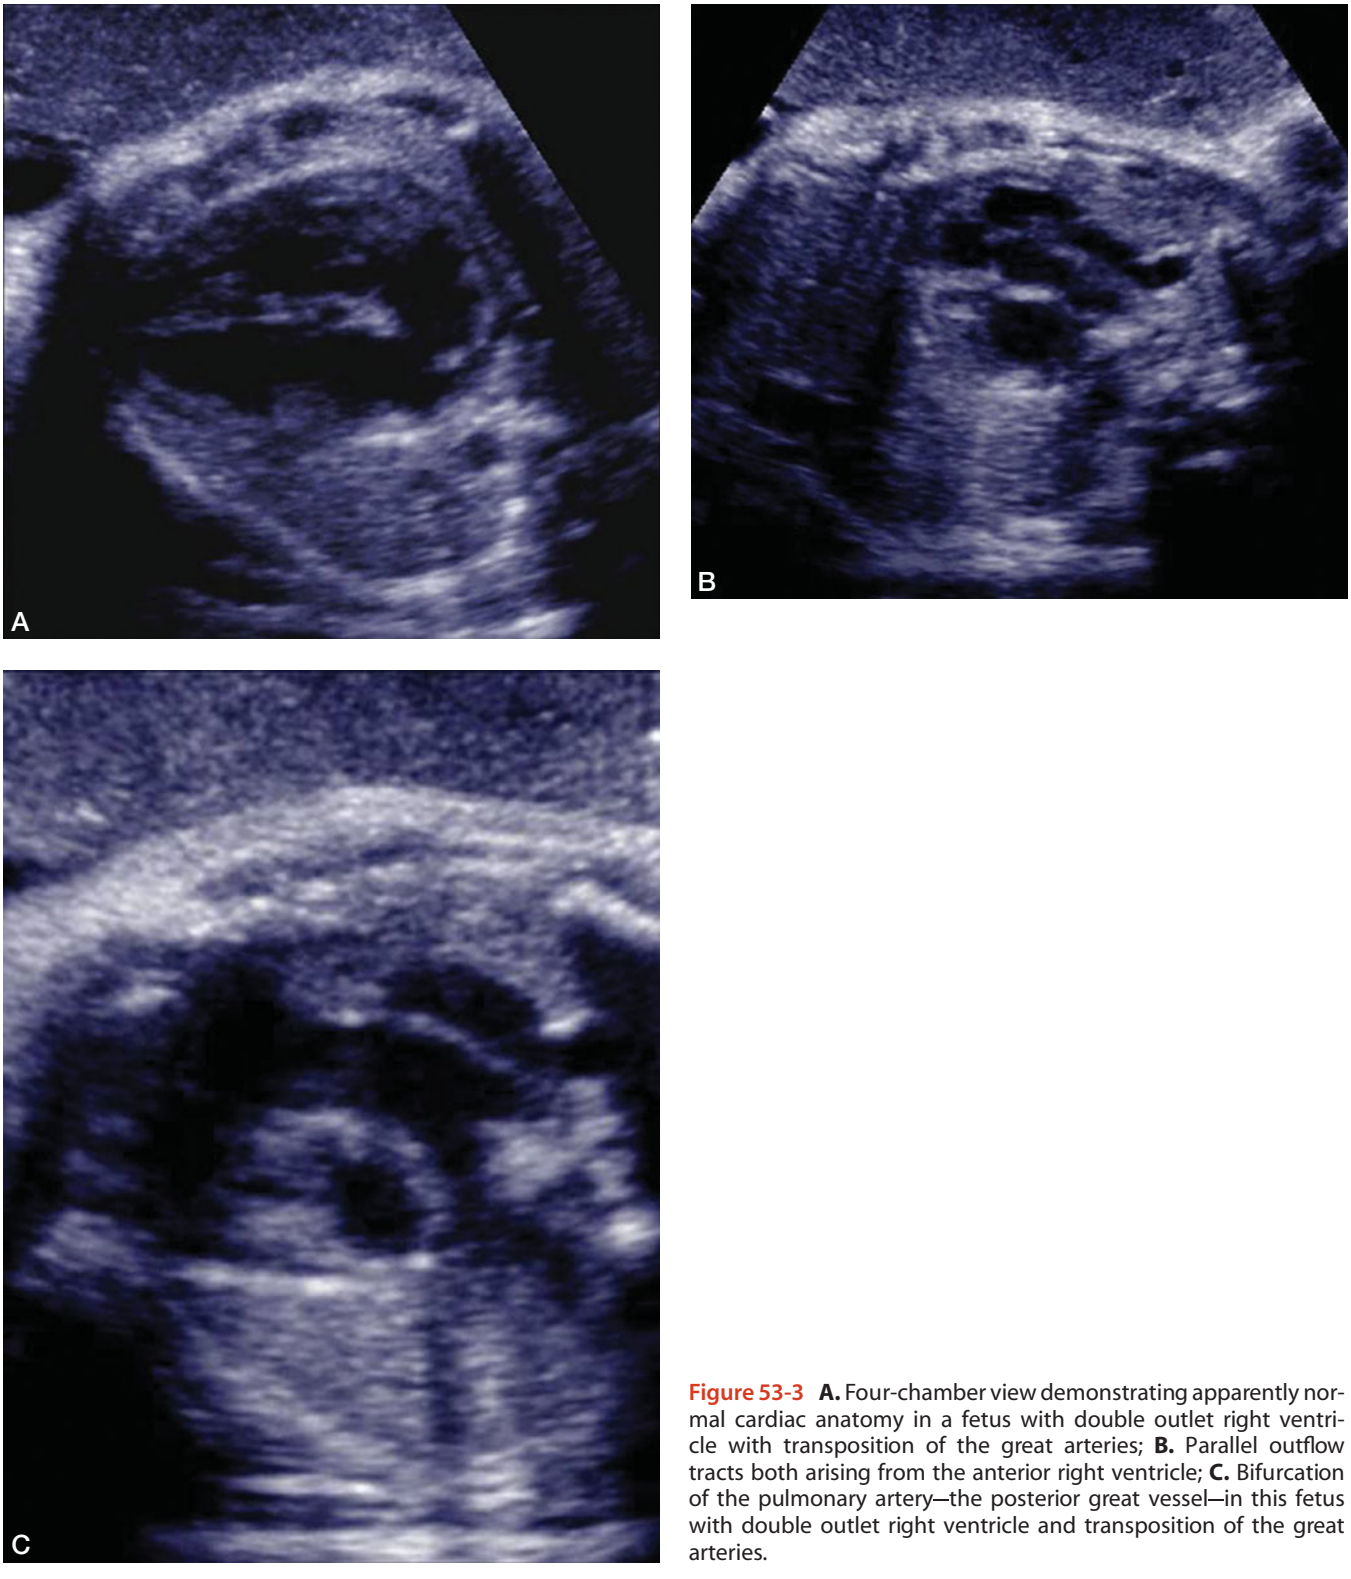

Figure 53-3 **A.** Four-chamber view demonstrating apparently normal cardiac anatomy in a fetus with double outlet right ventricle with transposition of the great arteries; **B.** Parallel outflow tracts both arising from the anterior right ventricle; **C.** Bifurcation of the pulmonary artery—the posterior great vessel—in this fetus with double outlet right ventricle and transposition of the great arteries.

coexisting VSD (see Chapter 55). Indeed, the differentiation of some cases of DORV and tetralogy of Fallot may be based solely on the relative area of the aortic outflow tract that arises from the right ventricle. The appearance of parallel great arteries, which is present in some subtypes of DORV, may aid in differentiation from tetralogy of Fallot, but does not help to differentiate from transposition of the great arteries.

ANTENATAL NATURAL HISTORY

The antenatal natural history of DORV depends on the presence and nature of any additional cardiac or extracardiac malformations. For isolated DORV with a VSD, in utero development should be normal, and should not lead to congestive

heart failure. In postnatal life, however, congestive heart failure may develop because the right ventricle provides both pulmonary and systemic circulation. In cases of DORV with pulmonary stenosis, in utero cardiac failure and hydrops may develop, but this is much more likely to occur during postnatal life as the ductus arteriosus closes.

In a series of 13 cases of DORV diagnosed prenatally, 7 resulted in elective termination of pregnancy, 3 in intrauterine fetal death, and 3 in liveborn neonates (Paladini et al., 1996). There were 5 cases of chromosomal abnormalities in this series, 4 of which were trisomy 18 and 1 trisomy 16. Of the 3 cases of intrauterine death, one fetus had extracardiac malformations in addition to trisomy 18. In a series of 24 fetuses with parallel great vessels, 17 of which had DORV, 22 had additional cardiac malformations, 8 had extracardiac anomalies, and 1 had trisomy 18 (Allan, 1997). This series resulted in 6 terminations of pregnancy, 1 intrauterine fetal death, and 17 liveborn neonates, 15 of whom required early surgical intervention. More recently, in a series of 19 cases of prenatally diagnosed DORV, 3 were terminated and the 16 remaining cases resulted in livebirths (Kim et al., 2006). Among the 14 cases in which postnatal follow-up was available, all but 1 had additional cardiac malformations, and 8 had extracardiac malformations (including 2 cases of aneuploidy).

MANAGEMENT OF PREGNANCY

Following prenatal sonographic detection of DORV, fetal echocardiography should be performed to confirm the diagnosis and assess for additional cardiac malformations. In addition, a careful sonographic evaluation of extracardiac fetal anatomy is required to exclude orofacial clefting, tracheoesophageal fistula, and cardiosplenic syndrome. In a series of 19 cases of prenatally diagnosed DORV there were 4 cases of atrial isomerism, one case of situs inversus, and one case of asplenia (Kim et al., 2006). Because up to 40% of cases of DORV will have a chromosomal abnormality, most commonly trisomies 18 and 13, fetal karyotyping should also be offered. Careful genetic counseling is required to provide parents with a complete set of options for management of the pregnancy. Prenatal consultations with a neonatologist, geneticist, pediatric cardiologist, and pediatric cardiac surgeon are recommended to ensure timely and appropriate treatment during the newborn period.

In the absence of hydrops, there is no indication to alter management of the pregnancy, timing of delivery, or mode of delivery. Serial sonographic assessment to confirm appropriate fetal growth and absence of hydrops is recommended. The optimal management of the fetus with congenital heart disease and secondary hydrops fetalis is unclear. Mortality in such cases is usually very high (Kleinman et al., 1982), and it is uncertain if either early delivery or cesarean delivery will change the outcome. Delivery should occur in a tertiary care center, with the immediate availability of a pediatric cardiologist and pediatric cardiac surgeon.

FETAL INTERVENTION

No data on fetal intervention for DORV are available.

TREATMENT OF NEWBORN

Initial care of the newborn with DORV depends on the presence of additional cardiac or extracardiac malformations. For example, if significant pulmonary stenosis is also present, a duct-dependent situation may exist, and the infant may benefit from prostaglandin infusion to maintain the patency of the ductus arteriosus (Allan, 1997). In addition, initial treatment requires prompt postnatal evaluation by a pediatric cardiologist, with echocardiography to confirm the prenatal diagnosis and to assess for the presence of additional cardiac malformations.

The presence of a VSD should be categorized according to the STS-EACTS classification described earlier as this system suggests the optimal surgical approach (Walters et al., 2000; Artrip et al., 2006). Coronary artery anatomy should be defined, and tricuspid to pulmonary valve annular distance should be measured, as these have implications for surgical repair (Sakata et al., 1988). The treatment of the newborn with DORV requires early surgical intervention, which today usually involves a single primary repair procedure rather than an initial palliative procedure (Tchervenkov et al., 1995).

SURGICAL TREATMENT

Contemporary data on operative mortality and reoperation rates suggest that repair of DORV should be performed early in infancy, thereby avoiding the need for additional palliation procedures (Aoki et al., 1994; Tchervenkov et al., 1995). The main principles behind surgical repair of DORV are to achieve an anatomic biventricular repair by connecting the left ventricle to the systemic circulation and to repair all associated cardiac lesions simultaneously (Tchervenkov et al., 1995; Walters et al., 2000).

Preoperative echocardiographic evaluation is crucial in planning the surgical approach to DORV. When the tricuspid to pulmonary valve annular distance is greater than the diameter of the aortic annulus, intraventricular rerouting is the surgical procedure of choice in the repair of DORV with a coexisting VSD, particularly if the VSD is subaortic in location (Aoki et al., 1994). With this procedure, an intraventricular tunnel is created to take blood flow directly from the VSD to the aortic outflow tract, while maintaining the pre-existing continuity of flow from the right ventricle to pulmonary outflow tract (Kirklin et al., 1964; Walters et al., 2000). A right ventricular outflow patch may be required to direct blood flow appropriately.

When the tricuspid to pulmonary valve annular distance is small, or if the anatomy otherwise prevents an intraventricular rerouting procedure, other surgical techniques are

performed, such as an arterial switch procedure, with blood flow taken directly from the VSD to the pulmonary outflow tract. If significant pulmonary stenosis is also present, or if coronary artery anatomy is abnormal, a conduit procedure may be needed, in which blood flow is directed from the VSD to the aortic outflow tract and a conduit is placed to channel blood flow from the right ventricle to the pulmonary artery (Rastelli-type procedure).

Immediate operative mortality following repair of DORV ranges from 8% to 11% (Aoki et al., 1994; Tchervenkov et al., 1995). Risk factors for early mortality include the presence of multiple VSDs, or aortic-arch obstruction (Kleinert et al., 1997). In a series of 50 cases of DORV with two viable ventricles, the vast majority (44 of 50, 88%) successfully underwent a biventricular repair, with surgery being performed at a median age of 9 months (Artrip et al., 2006). Surgical mortality was between 4% and 6% in this series.

LONG-TERM OUTCOME

Long-term survival following surgical repair of DORV has been estimated to be from 73% to 88% at 5 to 8 years (Serraf et al., 1991; Aoki et al., 1994; Tchervenkov et al., 1995). The incidence of reoperation ranges from 26% to 42% (Serraf et al., 1991; Aoki et al., 1994). Reasons for reoperation include subaortic stenosis, subpulmonary stenosis, and the presence of a significant residual VSD. In another series, the probability of survival, free from reoperation, was calculated as 65% at 10 years (Kleinert et al., 1997). The presence of a noncommitted VSD was a significant risk factor for reoperation, while the presence of a subaortic VSD was protective against reoperation (Aoki et al., 1994). In one series, 95% of long-term survivors had no restriction on physical activities and required no cardiac medications (Tchervenkov et al., 1995).

GENETICS AND RECURRENCE RISK

An association exists between DORV and both trisomies 13 and 18. The recurrence risk for these syndromes is extremely low, unless one parent is a balanced translocation carrier. In one consanguineous family, either tetralogy of Fallot or DORV with subaortic VSD and pulmonary stenosis were found in three of four offspring (Bindewald et al., 1994). This implies the existence of a rare autosomal recessive syndrome involving DORV.

Truncus Arteriosus

54 CHAPTER

Key Points

- Truncus arteriosus is a rare form of congenital cardiac disease in which a single cardiac outflow tract gives rise to the pulmonary, coronary, and systemic circulations.
- Prenatal diagnosis relies upon failure to visualize three separate vessels in a transverse view through the upper mediastinum, and failure to visualize the normal branch pulmonary arteries and their origin from the right ventricle.
- Up to 40% of cases are associated with a 22q11 deletion and the DiGeorge syndrome, thereby making amniocentesis a crucial part of the prenatal diagnostic evaluation.
- While timing and mode of delivery do not need to be altered following the diagnosis, planned delivery in a tertiary care setting with appropriate pediatric cardiology backup is critical, as congestive cardiac failure can occur in the neonatal period.
- Early definitive surgical repair is recommended, typically by means of a homograft from the right ventricle to the pulmonary artery, with closure of a VSD.
- Long-term survival rates of 80% can be expected.

CONDITION

Truncus arteriosus (also known as common aorticopulmonary trunk, truncus arteriosus communis, and single-outlet heart) refers to a single large ventricular outflow tract arising from both right and left ventricles. This single large outflow tract, or truncus, gives rise to the coronary arteries, aorta, and pulmonary arteries.

In the original anatomic classification of Collett and Edwards (1949), four subtypes were described:

Type I demonstrates a single pulmonary trunk arising from the truncus, which then subdivides into right and left pulmonary arteries.
Type II demonstrates two pulmonary arteries arising directly from the posterior surface of the truncus.
Type III demonstrates two pulmonary arteries arising from the lateral aspects of the truncus.
Type IV demonstrates absent pulmonary arteries, but collateral arteries arising from the descending aorta supply the pulmonary vasculature.

Van Praagh and Van Praagh (1965) subsequently described a different classification system in which type A truncus is associated with a ventricular septal defect (VSD) and type B truncus is not associated with a VSD. Type A truncus is divided further into four subtypes, which closely resemble the classification of Collett and Edwards:

Type A1 demonstrates a partially separated pulmonary trunk.
Type A2 demonstrates two pulmonary arteries arising directly from the truncus.
Type A3 demonstrates a single pulmonary artery arising from the truncus together with further collaterals arising from the descending aorta.
Type A4 demonstrates significant arch anomalies in association with the truncus.

Additionally, The Society of Thoracic Surgeons has further modified the classification by combining Types A1 and A2 from the Van Praagh and Van Praagh classification system (Jacobs, 2000).

Almost 60% of cases of truncus are type I, based on the classification of Collett and Edwards, 35% are type II, 5% are type III, and a small minority are type IV (Bharati et al., 1974). In 65% of cases, the single truncus seems to arise predominantly from the right ventricle that may make differentiation from tetralogy of Fallot difficult. The truncus arises entirely from the right ventricle in 15% of cases, straddles the

ventricular septum equally in a further 15% of cases, and arises mostly from the left ventricle in less than 5% of cases (Bharati et al., 1974). The single valve within the truncus is known as the truncal valve, and it is tricuspid in more than 65% of cases, although the number of leaflets may range from one to six (Bashore, 2007). Truncal valve dysplasia is very common, although significant truncal stenosis is rare, occurring in only 5% of cases (Bharati et al., 1974). Truncal valve regurgitation may be common, occurring in up to 40% of cases (Di Donato et al., 1985).

Associated cardiac malformations are common with truncus arteriosus; a VSD is present in the vast majority of cases. Right-sided aortic arch, atrial septal defect, abnormal origin of brachiocephalic vessels, aortic coarctation, atrioventricular canal defect, mitral atresia, and abnormal cardiac situs have all been described in association with truncus (Bharati et al., 1974). Approximately 50% of patients will have a patent ductus arteriosus in childhood, and approximately 20% will have an interrupted aortic arch (Bashore, 2007). Extracardiac abnormalities include situs inversus, heterotaxy syndrome (see Chapter 56), DiGeorge syndrome (see Chapter 139), and genitourinary anomalies (Collett and Edwards, 1949; Bharati et al., 1974).

INCIDENCE

Truncus arteriosus is a rare form of congenital heart disease, accounting for only 1.5% of all severe cardiac malformations seen during infancy (Fyler et al., 1980). Its incidence is estimated to be 1 in 10,000 livebirths and may be slightly more frequent in females (Hoffman and Kaplan, 2002). Truncus arteriosus likely accounts for only 7% to 10% of prenatally diagnosed conotruncal malformations (Sivanandam et al., 2006). The incidence of truncus arteriosus may be increased 12-fold in the presence of pregestational diabetes mellitus in the mother (Ferencz et al., 1990).

SONOGRAPHIC FINDINGS

Prenatal diagnosis of truncus arteriosus is possible with obstetric sonography and targeted fetal echocardiography. Visualization of the outflow tracts should demonstrate a single large ventricular outflow tract, overriding a VSD (Romero et al., 1988) (Figures 54-1 and 54-2). The right ventricular outflow tract should be absent, and pulmonary arterial branches may be visible arising from the truncus or from the descending aorta. A distended coronary sinus may also be visible directly posterior to the left atrium (de Araujo et al., 1987). Diagnosis in utero may also be aided by the identification of additional anomalies, such as those involving the aortic arch, as well as by Doppler identification of truncal-valve regurgitation (Marasini et al., 1987). Truncus arteriosus may also lead to the development of congestive heart failure in utero, leading to the typical sonographic features of hydrops.

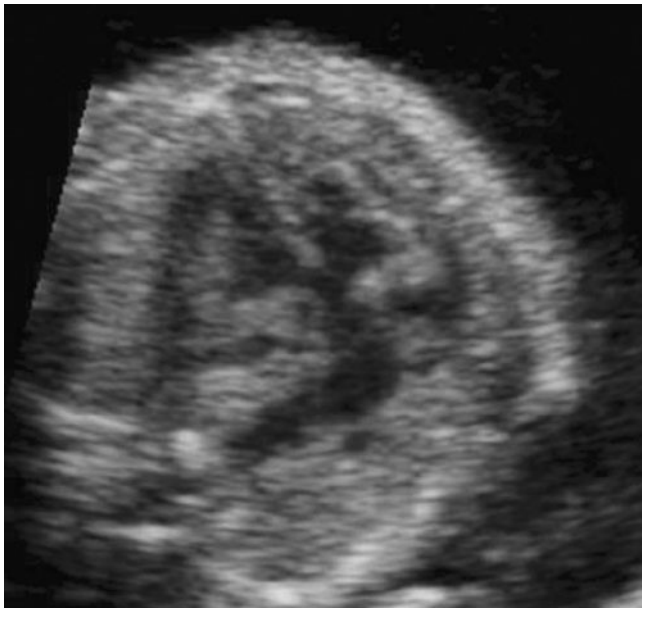

Figure 54-1 Axial image in a fetus with truncus arteriosus demonstrating a large single outflow tract overriding the intraventricular septum.

A transverse view through the upper fetal mediastinum, which normally contains the main pulmonary artery, ascending aorta, and superior vena cava, should demonstrate only two vessels in cases of truncus arteriosus (Yoo et al., 1997). The importance of visualization of the outflow tracts is evident from a series of six cases of prenatally diagnosed truncus arteriosus in which only two of the six cases were detected

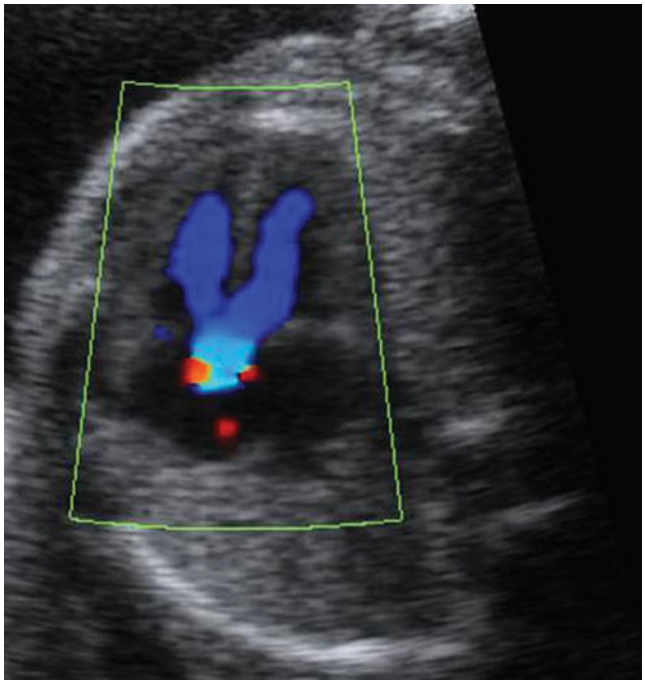

Figure 54-2 Color Doppler demonstrating presence of single large outflow tract consistent with a diagnosis of truncus arteriosus.

with the four-chamber cardiac view (Paladini et al., 1996). The remaining four cases were detected using a combination of four-chamber and outflow tract views.

In the hands of experienced fetal medicine and pediatric cardiology specialists, accurate prenatal diagnosis of the relationship of the arterial outflow tracts is possible. In a series of 113 consecutive fetuses with conotruncal malformations, including 8 cases of truncus arteriosus, the great arterial spatial relationship was correctly identified in 92% (Sivanandam et al., 2006). In an Australian population database study of prenatal detection of congenital heart defects, 18 of 27 cases (67%) of truncus arteriosus were successfully identified prenatally (Chew et al., 2007).

DIFFERENTIAL DIAGNOSIS

Differentiation between truncus arteriosus and tetralogy of Fallot (see Chapter 52) with coexisting pulmonary atresia may be extremely difficult because both have virtually identical sonographic appearances. Visualization of pulmonary arteries arising from the back of the truncus and the presence of more than three leaflets in the truncal valve may aid in the correct diagnosis (Houston et al., 1981). Truncus arteriosus may also be difficult to differentiate from aorticopulmonary window, in which the clinical features of truncus are present, but without a VSD and with a normal pulmonary valve (Riggs and Paul, 1982; Graham and Gutgesell, 1990).

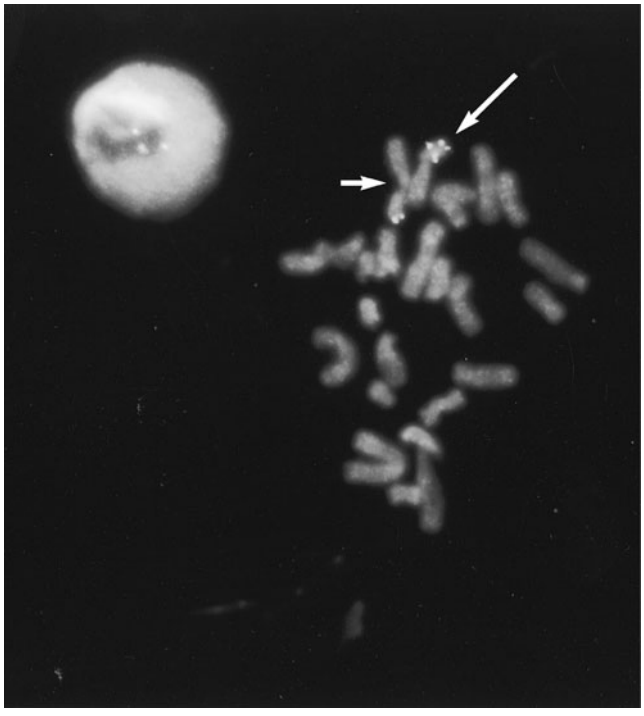

Figure 54-3 Fluorescence in situ hybridization studies using a DNA probe specific to DiGeorge region. The long arrow indicates chromosome 22 with distal flanking marker and presence of DiGeorge probe. The short arrow indicates the other chromosome 22 with distal flanking probe but absent DiGeorge probe. This is diagnostic for a microdeletion of chromosome 22. (*Courtesy of Janet Cowan.*)

ANTENATAL NATURAL HISTORY

Few reports of the antenatal natural history of truncus arteriosus are available. In one series of six cases diagnosed prenatally, three pregnancies were terminated, two cases resulted in neonatal death, and one fetus survived (Paladini et al., 1996). The antenatal development of hydrops is rare with truncus arteriosus, as the relatively high fetal pulmonary vascular resistance prevents the development of significant ventricular dysfunction. Immediately after delivery, however, the drop in pulmonary vascular resistance leads to significantly increased pulmonary flow, truncal valve insufficiency, and ventricular dysfunction. Development of congestive heart failure in utero is likely only if significant truncal-valve dysplasia and obstruction are present.

MANAGEMENT OF PREGNANCY

Once the diagnosis of truncus arteriosus is suspected on a prenatal sonographic image, referral to a tertiary care center is recommended for a thorough targeted sonographic evaluation as well as fetal echocardiography by an appropriately trained specialist. Prospective parents should meet with a pediatric cardiologist. Attention should be paid to the potential presence of additional cardiac malformations, as well as the possibility of heterotaxy syndrome (see Chapter 56). Invasive testing for prenatal karyotype is recommended. Although only a small number of fetuses with truncus arteriosus will be aneuploid (de Araujo et al., 1987; Ferencz et al., 1987; Paladini et al., 1996), there is a strong association between truncus arteriosus DiGeorge syndrome (see Chapter 139). DiGeorge syndrome can be diagnosed prenatally by use of a fluorescence in situ hybridization probe for chromosome 22q11 (Figure 54-3). All patients undergoing prenatal karyotyping should have fluorescence in situ hybridization studies for the 22q11 microdeletion. If a chromosome abnormality or DiGeorge syndrome is diagnosed, the prospective parents should meet with a medical geneticist.

After prenatal diagnosis, serial evaluation with obstetric ultrasonography is recommended to confirm adequate fetal growth and to exclude the development of congestive heart failure. Infants with this condition can deteriorate rapidly as pulmonary vascular resistance falls after birth. Therefore, delivery of the fetus with truncus arteriosus should occur at a tertiary care center, with the immediate availability of a neonatologist, pediatric cardiologist, and pediatric cardiothoracic surgeon. The timing and route of delivery should not be changed by the diagnosis of truncus arteriosus. The onset of spontaneous labor should be awaited, and cesarean delivery should be reserved for standard obstetric indications. It

is unclear if intervention with early or cesarean delivery is of any benefit when the diagnosis is complicated by the presence of hydrops. The prognosis in such cases is almost always poor, irrespective of obstetric interventions (Romero et al., 1988).

FETAL INTERVENTION

No fetal intervention has been described following the prenatal diagnosis of truncus arteriosus.

TREATMENT OF THE NEWBORN

Immediately following delivery, the newborn with truncus arteriosus should have an evaluation by a pediatric cardiologist, including an echocardiographic examination to confirm the diagnosis and to exclude the presence of additional cardiac malformations. If complete visualization of cardiac and major-vessel anatomy is not obtained with echocardiography, cardiac catheterization may be required, with particular attention paid to the branching pattern of the pulmonary arteries, the anatomy of the aorta, and the presence of truncal insufficiency (Graham and Gutgesell, 1990). More recently, cardiac magnetic resonance imaging is playing an important role in delineation of cardiac anatomy, and may enable cardiac catheterization to be minimized (Dorfman and Geva, 2006).

Newborn infants with truncus arteriosus may initially appear cyanotic at birth, but this usually improves as pulmonary blood flow increases (Qu, 2004). Progressive congestive heart failure may then occur soon after delivery because pulmonary vascular resistance falls, often as early as 1 or 2 weeks after birth. Coronary artery perfusion may also be compromised, which, in combination with increased postnatal myocardial oxygen demand, may predispose to subendocardial ischemia (Graham and Gutgesell, 1990). To treat congestive heart failure during the newborn period, aggressive medical therapy is required, including the use of diuretics and digoxin. Medical therapy is often inadequate to prevent further deterioration of cardiac failure in these patients. Early intervention with definitive surgical repair may be the only option to prevent worsening cardiac failure and also to prevent the development of pulmonary hypertension secondary to increased pulmonary flow. Delaying surgical repair may also lead to the development of chronic ventricular dysfunction secondary to volume overload, which may compromise later repair (Graham, 1982).

SURGICAL TREATMENT

Surgical palliation of truncus arteriosus by means of pulmonary artery banding in an effort to reduce pulmonary flow and prevent the development of irreversible pulmonary hypertension has yielded disappointing results. In one series of 15 cases of pulmonary artery banding for truncus arteriosus during infancy, the overall mortality rate was 73% with all but one death occurring soon after surgery (Singh et al., 1976). Early definitive surgical repair of truncus arteriosus now seems to be the treatment of choice (Graham and Gutgesell, 1990; Bashore, 2007). In one series of 153 cases of truncus arteriosus repair from 1986 to 2003, the median age at surgery was 35 days (Henaine et al., 2008).

The standard surgical procedure for repair of truncus arteriosus involves placing a homograft between the right ventricle and the pulmonary artery and closing the VSD. This leaves the left ventricle in continuity with the truncus leading to the aorta. Hospital mortality for this procedure has been quoted as almost 30%, although the reported series often span a long period, include patients with many complicating factors, and use a valveless conduit (Spicer et al., 1984; Di Donato et al., 1985). Today however, the procedure generally also uses a valved conduit, yielding much better results with hospital mortality rates ranging from 11% to 17% of cases (Ebert et al., 1984; Pearl et al., 1992). Increased mortality occurs if significant truncal valve insufficiency is present, and in such cases a truncal valve replacement or truncal valve repair is generally also performed (Elami et al., 1994). Other risk factors for early death include the presence of coronary-artery anomalies, interrupted aortic arch, and age greater than 100 days at repair (Hanley et al., 1993). In a series of infants with simple truncus arteriosus repaired within the first 100 days of life, the operative mortality was 0% (Hanley et al., 1993).

LONG-TERM OUTCOME

The long-term outcomes associated with truncus arteriosus repair appear good. In one recent series of 153 cases, the 6-month survival rate was 82% while the 18-year survival rate was 79% (Henaine et al., 2008). The most common long-term complication following surgical repair of truncus arteriosus is the requirement for replacement of the right ventricle–pulmonary artery conduit because of body growth or development of pseudointimal proliferation within the conduit. Conduit replacement may be required in up to 60% of long-term survivors (Ebert et al., 1984). Reoperation may be associated with a further 4% to 7% risk of mortality (Pearl et al., 1992). Late deaths following contemporary surgical repair are uncommon, with only 3 late deaths in a series of 89 hospital survivors following repair; 2 of these 3 deaths were unrelated to the underlying cardiac condition (Ebert et al., 1984). The quality of life following surgical repair appears to be excellent, with 97% of patients in one series being very functional (Di Donato et al., 1985).

GENETICS AND RECURRENCE RISK

Truncus arteriosus may occur as part of the spectrum of the DiGeorge sequence. In a series of 26 infants with truncus

arteriosus, a high prevalence of facial dysmorphism, aortic-arch abnormalities, and immunodeficiency possibly consistent with DiGeorge sequence was noted (Radford et al., 1988). Familial clustering of truncus arteriosus is rare, with one case report of the abnormality recurring in a subsequent pregnancy and one case report of dizygotic twins concordant for the abnormality (Lang et al., 1991; Ferry et al., 1994). Generalized estimates of recurrence risk suggest a 1% rate of recurrence if one previous sibling has been affected and 3% if two siblings have been affected (Nora and Nora, 1988). If chromosomal analysis was not performed prenatally, it should be performed postnatally with fluorescence in situ hybridization studies for a microdeletion of chromosome 22q11. A 22q11 microdeletion will be found in up to 40% of cases of truncus arteriosus (Momma et al., 1997; Goldmuntz et al., 1998; Goldmuntz, 2005). In some cases, the microdeletion is inherited from one of the parents, who may not have cardiac disease. Diagnosis of DiGeorge syndrome in an infant necessitates study of the parental karyotypes before accurate recurrence risk counseling can be given.

55 CHAPTER

Transposition of Great Arteries

Key Points

- Transposition of the great arteries is a relatively rare congenital cardiac malformation that has potential to cause major morbidity and mortality in the neonatal period.
- Complete TGA results in separation of the systemic and pulmonary circulations, because of ventriculoarterial discordance, and leads to severe hypoxia in the early neonatal period.
- Corrected TGA has both atrioventricular and ventriculoarterial discordance, so that effectively pulmonary and systemic circulations are normal, thereby rarely resulting in pediatric morbidity.
- Prenatal diagnosis of complete TGA is achieved by noting a parallel path of the ventricular outflow tracts, with lack of the normal crossover of these vessels.
- Prenatal recognition of complete TGA is critical, as immediate pediatric cardiology intervention in the early neonatal period will be required.
- The surgical treatment of choice for complete TGA has changed from the atrial switch to the arterial switch procedure, and is associated with excellent long-term survival.

CONDITION

Transposition of the great arteries (TGA) may be either complete or corrected. Complete TGA is also known as d-transposition, simple transposition, or atrioventricular concordance with ventriculoarterial discordance. This anomaly probably occurs because of failure of the aorticopulmonary septum to follow a spiral course during embryogenesis, resulting in the aorta arising from the right ventricle and the pulmonary artery arising from the left ventricle (de la Cruz et al., 1981). Atrial septal defect (ASD) and ventricular septal defect (VSD) are commonly seen with complete TGA and may also be associated with pulmonary artery obstruction. This is a potentially critical abnormality because, without a persistent communication between right and lefts sides of the heart, both the systemic and pulmonary circulations will run in parallel thereby preventing adequate oxygenation. Complete TGA usually causes no significant hemodynamic compromise when the fetus is in utero, but rapid deterioration occurs soon after birth in those cases without sufficient mixing of the right- and left-sided circulations.

In a cohort of 130 neonates delivered with TGA, Jouannic et al. (2004) noted that 13 of 130 neonates (10%) with TGA had profound hypoxemia (defined as a $Pao_2 < 25$ mm Hg) and metabolic acidosis (pH < 7.15) in the first 30 minutes of life (Jouannic et al., 2004). Fortunately, concurrent cardiac structural anomalies such as VSDs may allow for communication between right and left sides of the heart to allow adequate mixing of blood. Even in infants with an intact ventricular septum, a nonrestrictive foramen ovale and patent ductus arteriosus may also allow for adequate mixing of systemic circulation and oxygenated venous return to avoid significant hypoxemia early in the neonatal course. However, neonates with an intact ventricular septum and either a restrictive foramen ovale or constricted ductus arteriosus may experience significant preoperative morbidity due to inadequate intracardiac mixing. In these cases, severe hypoxemia may necessitate immediate balloon atrioseptostomy in order to prevent end organ damage from ongoing hypoxemia.

In order to optimally plan for delivery and neonatal management, efforts have been directed at identifying fetal echocardiographic predictors of fetuses who will require emergent atrial septoplasty at the time of birth. Jouannic et al. (2004) retrospectively assessed the degree of antenatal restriction of the foramen ovale and/or constriction of the ductus arteriosus in 119 fetuses (mean GA ~ 36 weeks' gestation). Twenty-four of 119 (20%) fetuses were noted to

have at least one abnormal shunt on prenatal echocardiography, and 4 (3.4%) had restriction of both the foramen ovale and the ductus arteriosus. Although the specificity of prenatal echocardiography in predicting neonatal emergency was high (84%), the sensitivity was only 54% and the authors concluded that prenatal echocardiography cannot detect all fetuses that will require required immediate balloon atrioseptostomy as neonates (Jouannic et al., 2004).

By contrast, corrected TGA refers to the connection of the right atrium to the morphologic left ventricle, which connects to the pulmonary artery, while the left atrium connects to the morphologic right ventricle and then to the aorta. This anomaly is also known as l-transposition, or atrioventricular discordance with ventriculoarterial discordance. Because both right and left cardiac blood flow follow their intended paths from systemic to pulmonary and back to systemic circulations, this anomaly effectively cancels itself out (Romero et al., 1988). While the right atrium empties into the anatomic right ventricle, this ventricle is in fact the morphologic left ventricle with a transposed pulmonary artery as its outflow tract. Similarly the left atrium empties into the anatomic left ventricle, which is in fact the morphologic right ventricle, connected to a transposed aorta. Physiologically it might be expected that this anomaly would not lead to hemodynamic compromise; however, because of a frequent association with other abnormalities such as VSD, pulmonic stenosis, conduction defects, and atrioventricular valve abnormalities, significant neonatal morbidity and mortality may still occur.

INCIDENCE

Earlier studies suggested that TGA may account for up to 10% of all infants born with congenital cardiac defects, representing approximately 2 to 3 per 10,000 livebirths (Fyler et al., 1980; Hoffman and Kaplan, 2002). In a more recent birth defects registry from Australia covering 631,209 births from 1993 to 2002, there were 4897 cases of congenital heart disease, of which 47 were TGA (Chew et al., 2007). This represents a birth prevalence of 0.7 per 10,000 births, or 1% of all cases of congenital heart disease.

SONOGRAPHIC FINDINGS

Complete TGA is recognized on prenatal sonography by careful visualization of the cardiac outflow tracts. Sonographic diagnosis relies on the demonstration of parallel outflow tracts, with absence of the normal crossover (Morelli et al., 1996). The normal crossover of the pulmonary artery and aorta is not seen, and the outflow tracts appear to run parallel to each other. Each outflow tract should be followed to its branches to positively differentiate the pulmonary artery from the aorta (McGahan et al., 2007) (Figures 55-1 and 55-2). The pulmonary trunk should be visible arising from the posterior ventricle, bifurcating into the left and right pulmonary arteries and ductus arteriosus. The aorta is visible arising anterior to the pulmonary artery and connecting to the aortic arch with brachiocephalic vessels. One of the most reliable prenatal diagnostic signs of complete TGA is the visualization of a straight vessel arising from the left ventricle, and giving off lateral branches, which represents the pulmonary artery bifurcation (Vinals et al., 2006).

Figure 55-1 Sonographic image of a fetus with TGA demonstrating the parallel arrangement of the great arteries as they arise from the ventricles.

Prenatal sonographic diagnosis of corrected TGA is extremely difficult because the ventricular outflow tracts may appear to arise correctly from the anatomic right and left ventricles. In addition, the morphologic appearance of the anatomic left ventricle is more suggestive of a right ventricle, with a moderator band and triangular-shaped ventricular

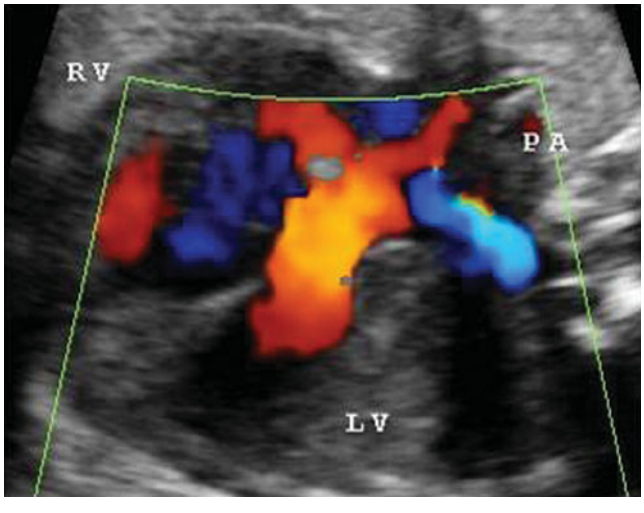

Figure 55-2 Color Doppler image in a fetus with transposition of the great arteries demonstrating the aorta arising from the anterior right ventricle and the pulmonary trunk from the left ventricle.

cavity. A normal left ventricular cavity should not demonstrate a moderator band and should be elliptical, rather than triangular, in shape.

Prenatal sonography is an important means of diagnosing or excluding additional coexisting cardiac malformations. VSD may be present in 50% of cases of TGA and, when found, is commonly accompanied by subvalvular pulmonic stenosis (Schiebler et al., 1961). As a result of interference with the conduction apparatus of the heart, arrhythmias are common, with complete heart block found in 4 of 21 fetuses with corrected TGA (Gembruch et al., 1989). Other cardiac malformations that may be detectable include ventricular hypoplasia and coarctation of the aorta (Santoro et al., 1997). The presence of situs inversus may also be found in the presence of corrected TGA (Abossolo et al., 1996). In a series of nine neonates with TGA, five were diagnosed prenatally and four of these five had complex cardiac malformations (McGahan et al., 2007). These complex cardiac malformations that were amenable to prenatal diagnosis included abnormal cardiac axis, abnormal ventricular size, and VSDs.

The precision of sonography as a tool in the prenatal diagnosis of TGA is unclear. In one series of screening sonograms of 11,894 fetuses, none of the 4 cases of TGA were detected prenatally (Tegnander et al., 1995). In another series of 50 infants operated on for TGA, 17 (34%) were successfully diagnosed prenatally through the use of obstetric sonography (Lupoglazoff et al., 1997). In addition, in another recent series of 111 congenital cardiac abnormalities, 5 of the 8 cases (63%) of TGA were detected on prenatal screening sonography (Kirk et al., 1997). In a review of all congenital cardiac malformations in one geographical area, only 5 of the 80 cases (6%) of TGA were detected prenatally (Montana et al., 1996).

It would appear that in the hands of expert sonologists in a referral population, the accurate prenatal detection of TGA is relatively high, but in general population screening, the vast majority of such cases go undiagnosed. This is supported by a review of all livebirths in Victoria, Australia, from 1993 to 2002, when only 17% of TGA cases were correctly identified prenatally (Chew et al., 2007). In fact, TGA was the least likely major congenital cardiac malformation to be diagnosed prenatally.

DIFFERENTIAL DIAGNOSIS

One of the most difficult congenital cardiac anomalies to differentiate from TGA is double outlet right ventricle, especially when TGA is accompanied by a VSD (Sanders et al., 1996). Careful attention should be paid to any potential straddling or overriding of atrioventricular valves. The Taussig–Bing heart, a variant of double outlet right ventricle in which the aortic and pulmonary outflow tracts ascend in a parallel fashion, may mimic the appearance of TGA (see Chapter 47).

ANTENATAL NATURAL HISTORY

In general, both complete and corrected forms of TGA are well tolerated by the fetus in utero because both ventricles pump into the systemic circulation. However, the presence of additional cardiac malformations, such as VSD or pulmonic stenosis, may alter the antenatal natural history, potentially leading to the development of congestive heart failure, or hydrops, in utero.

In a series of five fetuses with TGA diagnosed prenatally, one pregnancy was terminated, and the remaining five resulted in livebirths; two of these infants died during the neonatal period (Smythe et al., 1992). In another series evaluating the outcome of various prenatally diagnosed cardiac malformations, all three fetuses with TGA survived (Sharland et al., 1990). More recently, in 23 cases of prenatally diagnosed TGA, 6 pregnancies (26%) were terminated, 3 (13%) fetuses died in utero, 8 (35%) died during the neonatal period, and 6 (26%) survived (Paladini et al., 1996).

MANAGEMENT OF PREGNANCY

Following prenatal diagnosis of TGA, a careful sonographic fetal anatomy survey is recommended to exclude additional cardiac malformations, such as VSD, pulmonic stenosis, aortic coarctation, and arrhythmias. A sonographic search for extracardiac malformations should also be performed, although in general such abnormalities are rarely found with TGA. Fetal echocardiography should be performed by an appropriately trained specialist to confirm the diagnosis and to exclude other cardiac malformations. Invasive fetal testing for karyotype analysis is recommended following the prenatal diagnosis of most cardiac malformations, although the incidence of chromosomal abnormalities is likely to be very low. In one series of 23 cases of prenatally diagnosed TGA, chromosomal analysis was normal in the 21 cases in which karyotype was known (Paladini et al., 1996). Referral for prenatal consultation with a pediatric cardiologist and cardiothoracic surgeon is also recommended.

If the diagnosis of complete TGA is made prior to fetal viability, termination of pregnancy may be offered because of the significant neonatal mortality and surgical morbidity. If expectant management is desired, sonographic surveillance to confirm appropriate fetal growth and to evaluate for the development of fetal hydrops is recommended, especially if additional cardiac malformations such as VSD and pulmonic stenosis are present. If fetal hydrops occurs, the prognosis deteriorates further; the optimal management of such pregnancies is uncertain.

Delivery should occur at a tertiary care center, with the immediate availability of a neonatologist, pediatric cardiologist, and cardiothoracic surgeon. In an effort to identify fetuses that may require immediate balloon atrioseptostomy, predelivery echocardiography may be performed to assess for restriction of the foramen ovale and/or the ductus arteriosus.

For those fetuses noted to have restriction of either the foramen ovale and/or the ductus arteriosus, delivery plans should be discussed with neonatalogy and pediatric cardiology in order to facilitate timely intervention if emergent balloon atrial septostomy is needed.

FETAL INTERVENTION

No fetal intervention has been described for the obstetric or prenatal management of TGA.

TREATMENT OF THE NEWBORN

The condition of most infants with isolated complete TGA will deteriorate soon after birth, resulting in death, without surgical intervention. Indeed, complete TGA is one of the most common cyanotic defects seen in newborns, with cyanosis presenting within hours of life if the ventricular septum is intact (Warnes, 2006). Following delivery, care should be taken with the administration of supplemental oxygen so as to avoid significant reduction in pulmonary vascular resistance, which may decrease the amount of blood shunted across the ductus arteriosus. The infant should be transported to a neonatal intensive care unit and, if cyanosis is present, prostaglandin E_1 infusion should be started to maintain patency of the ductus arteriosus (Sommer et al., 2008).

Consultation with a pediatric cardiologist should be obtained promptly, and echocardiography should be performed to confirm the prenatal diagnosis and to determine the absence of additional cardiac malformations. Patency of both ventricular outflow tracts should be assessed, and the coronary-arterial anatomy should be mapped in preparation for surgical repair. When an intact ventricular septum exists and when inadequate atrial communication is present, balloon atrial septostomy may be needed during the initial resuscitation to maximize oxygenation of systemic blood (Graham and Gutgesell, 1990). Such balloon atrial septostomy may be performed either during cardiac catheterization or using echocardiographic guidance. This usually results in sufficient bidirectional shunting of blood to improve the systemic oxygen content. Occasionally, atrial septostomy is insufficient to improve systemic oxygenation, which may be secondary to inadequate atrial defect size, abnormal ventricular compliance, elevated pulmonary vascular resistance, or left ventricular outflow tract obstruction (Graham and Gutgesell, 1990). Consultation with a pediatric cardiothoracic surgeon should then be obtained to decide on the timing and method of surgical intervention, such as surgical atrial septostomy or arterial switch procedure.

Infants with TGA and a coexisting large VSD are usually stable initially, and then after a few weeks of life congestive heart failure occurs. These infants account for less than 25% of all cases of TGA. Such patients can usually be treated medically, with digoxin and diuretics, before surgical repair is considered. However, delay in surgical repair beyond the end of the third month of life may lead to the development of abnormal pulmonary vascular resistance, which occurs earlier in infants with TGA and VSD as compared with infants with left-to-right shunts without TGA (Graham and Gutgesell, 1990).

SURGICAL TREATMENT

Surgical repair is indicated for all infants with complete TGA and is generally best performed soon after birth, often within the first 2 weeks of life. Initial procedures, such as the Senning or the Mustard operation, were designed to physiologically correct cardiac blood flow through the use of the atrial septum or a baffle to redirect vena caval return to the left ventricle and pulmonary venous return to the right ventricle. However, such atrial repairs were associated with high operative mortality as well as significant late complications (Castaneda and Mayer, 1990). Such significant late complications included bradyarrhythmias and tachyarrhythmias (Warnes, 2006). Subsequently, an anatomic repair, known as the arterial switch procedure, has been devised, and involves dividing the pulmonary artery with reanastomosis to the right ventricular outflow tract, and dividing the aorta with reanastomosis to the left ventricular outflow tract. To be successful this procedure must be done early in neonatal life, before the left ventricle adapts to the lower pressure pulmonary circulation that would prevent it being able to subsequently support the systemic circulation.

Arterial switch repair is performed through a median sternotomy incision and with cardiopulmonary bypass (Castaneda and Mayer, 1990). The aorta is transected distal to the origin of the coronary arteries. The coronary arteries are then excised and transposed to the origin of the pulmonary artery from the left ventricle (Warnes, 2006). The pulmonary artery is then transected distal to this coronary artery connection but proximal to the bifurcation, and is reanastomosed to the original right ventricular outflow tract stump. Similarly, the aorta is reanastomosed to the left ventricular outflow tract stump. This results in complete anatomic repair of the great vessels and coronary arteries.

The operative mortality rate for the arterial switch repair is between 5% and 8%, with a 1-month survival of 84% (Kirklin et al., 1992; Qamar et al., 2007). Risk factors for perioperative death include the presence of multiple VSDs, anomalous coronary artery anatomy, additional cardiac malformations, and long aortic cross-clamp time. In another series of 432 arterial switch procedures performed in a single center at an average of 3 days of life, the operative mortality rate was 8%, with anomalous coronary artery anatomy being the only identified risk factor for early death (Serraf et al., 1993). A further series of 168 cases that underwent arterial switch suggested that weight less than 2.5 kg, premature gestational age at delivery, and more than 150 minutes of

cardiopulmonary bypass time as being associated with decreased hospital survival (Qamar et al., 2007). Complications of the arterial switch procedure include coronary stenosis that may lead to sudden death or myocardial infarction (Warnes, 2006; Sommer et al., 2008).

One other surgical approach that may be considered includes the Rastelli procedure, which is used when complete TGA coexists with a large VSD and pulmonary stenosis. The pulmonary valve is oversewn and a new valved conduit is placed between the right ventricle and the pulmonary artery (Warnes, 2006).

LONG-TERM OUTCOME

Overall long-term results for TGA suggest a 60% actuarial survival at 15 years of age (Morris and Menashe, 1991). Long-term results specifically for the atrial switch repair (Senning or Mustard procedures) suggest that up to 10% die while waiting for surgery, but of those operated on, 80% are alive after 20 years (Kirklin et al., 1990). There seems to be a progressive decline in the prevalence of normal sinus rhythm in these patients, which may account for sudden late deaths. Although atrial switch survivors can live normal active lives, exercise testing is generally subnormal (Kirklin et al., 1990).

Survival data on long-term outcome following the arterial switch repair is as readily available because of relatively short duration of use. Five-year survival following the arterial switch repair was 82% in one multicenter series, with almost all survivors in New York Heart Association functional class I (Kirklin et al., 1992). In a series of 168 arterial switch procedures, 3-year actuarial survival was 89% (Qamar et al., 2007). In one of the largest series of long-term follow-up of cases of arterial switch surgery, 224 patients were followed and revealed 83% survival at 15 years after surgery (Wong et al., 2008).

The long-term fate of the coronary arteries is unclear, as there may be significant kinking or compression following the arterial switch procedure. Surveillance with echocardiography and myocardial scintigraphy is therefore recommended for survivors to detect early ventricular ischemia (Kaplan and Allada, 1992). In one series of 58 children with coronary-artery surveillance following the arterial switch procedure, 8% had evidence of late coronary artery complications (Bonnet et al., 1996). Delayed repair of TGA may be associated with progressive impairment of cognitive function (Newburger et al., 1984).

GENETICS AND RECURRENCE RISK

Almost all cases of TGA occur as isolated cardiac malformations with normal karyotype (Paladini et al., 1996). Risk of recurrence has been estimated as 1.5% if 1 prior sibling has been affected, and this may increase to 5% with 2 prior affected siblings (Nora and Nora, 1988).

56 CHAPTER

Heterotaxy Syndrome

Key Points

- Heterotaxy is an abnormality of formation of the left–right axis of the body.
- Heterotaxy refers to any arrangement that deviates from situs solitus or complete situs inversus.
- Left atrial isomerism or polysplenia syndrome usually has absent right-sided organs and bilaterally placed left-sided organs with multiple splenic masses along the greater curvature of the stomach.
- Right atrial isomerism or asplenia syndrome usually has bilaterally trilobed lungs, globular central lines, severe congenital heart defects, and absent spleen.
- Fetal echocardiography is indicated in all suspected cases of heterotaxy.
- Delivery in a tertiary care center is recommended.

CONDITION

Heterotaxy is defined as any arrangement of the body organs that deviates from complete situs solitus with levocardia and dextrocardiac loop (the normal arrangement) or from complete situs inversus with dextrocardia and a levocardiac loop.

During development there is a failure to form asymmetry along the left–right axis in the heterotaxy syndrome. In normal development, this asymmetry is first manifested at 2 to 23 days of gestation, with looping of the cardiac tube to the right (Gutgesell, 1990). During this same period, abdominal situs is determined (Chandra, 1974; Gray et al., 1994). The

270-degree counterclockwise rotation of the intestine about the axis of the superior mesenteric artery is completed by 10 weeks. Because looping of the cardiac tube and intestinal rotation both occur during the 4th week of gestation, defects of the cardiac situs are frequently associated with abnormal intestinal rotation. Because development of the heart is dependent on the formation of a normal left–right relationship, heterotaxy is associated with congenital heart disease in the majority of cases (Chandra, 1974; Gutgesell, 1990; Cohen et al., 2007).

There is a spectrum of defects in heterotaxy syndrome, varying from isolated levocardia with abdominal situs inversus or isolated dextrocardia with abdominal situs solitus to total absence of asymmetry along the left–right axis. The most significant forms of heterotaxy syndrome are seen in left isomerism (also known as the polysplenia syndrome) or right isomerism (also known as asplenia syndrome). The term *asplenia* originated from Ivemark's (1955) initial description of cardiac malformations associated with congenital asplenia. Moller et al. (1967) subsequently reported another syndrome, also with cardiac and visceral abnormalities, but because it was associated with multiple splenic masses, it was called "polysplenia syndrome."

Sapire et al. (1986) further described these syndromes in relation to anatomic features of the atria, such as right atrial isomerism (asplenia syndrome) and left atrial isomerism (polysplenia syndrome). This distinction was suggested because the anatomic features of the atria more reliably reflect the visceral abnormalities than does the spleen. Usually asplenia occurs in right atrial isomerism and polysplenia occurs in left atrial isomerism, but discrepancies have been reported (Caruso and Becher, 1979). In addition, each condition has been described with both the presence of a normal spleen (Laman et al., 1967; Landing et al., 1971) and normal cardiac anatomy (Peoples et al., 1983). Left atrial isomerism accounts for most cases of "polysplenia syndrome" (Moller et al., 1967; Van Mierop et al., 1972; Rose et al., 1975; Peoples et al., 1983). Polysplenia is usually manifested as multiple splenic masses along the greater curvature of the stomach. The combined weight of the splenic tissue is approximately equivalent to a normal spleen. Left atrial isomerism usually has absent right-sided organs and bilaterally placed left-sided organs. Left atrial isomerism is usually associated with less severe cardiac anomalies and better survival than right atrial isomerism (Peoples et al., 1983; Sapire et al., 1986).

Left Atrial Isomerism

The organs most involved in left atrial isomerism are the lungs, liver, heart, and intestines. The lungs are symmetric mirror images of the left lung with only two lobes. Each side has left-sided relationships between the pulmonary artery and the mainstem bronchi (Moller et al., 1967). The pulmonary artery courses over and behind the mainstem bronchus on both sides, as in a normal left lung. The bronchi branch in a pattern similar to the left tracheobronchial tree and there is no horizontal minor fissure on the right because there are only two lobes.

The liver usually is abnormal in shape and position and typically has a central globular appearance, as it is symmetric. The gallbladder may be midline, hypoplastic, or absent. In 10% of the cases, biliary anomalies can also be seen (Peoples et al., 1983). Several cases of biliary atresia have been reported in left atrial isomerism (Mayo et al., 1949; Teichberg et al., 1982).

The intestines demonstrate nonrotation or reverse rotation of the midgut loop. The initial 90-degree counterclockwise rotation occurs, but the final 180-degree rotation about the superior mesenteric artery does not occur. The result is that the small intestine is on the right side of the abdomen and the colon is on the left. In severe reverse rotation, the midgut rotates clockwise instead of counterclockwise. The result is that the duodenum lies inferior to the superior mesenteric artery and the transverse colon behind it. These rotational abnormalities are prone to proximal intestinal obstruction or midgut volvulus.

Cardiac anomalies in the left atrial isomerism can occur at every level of the heart (Moller et al., 1967; Van Mierop et al., 1972; Rose et al., 1975; Tommasi et al., 1981; Peoples et al., 1983). In 50% of the cases, there are bilateral venae cavae connecting to the superior posterior aspect of the ipsilateral atrium. In rare cases, a single superior vena cava (SVC) connects to the coronary sinus, but the coronary sinus is usually absent. In 65% of the cases, the intrahepatic inferior vena cava (IVC) is interrupted. The IVC above the renal veins connects to the azygous system. The hepatic veins connect directly to the floor of the atrium. Anomalous pulmonary venous return occurs in 40% of the patients (Ware et al., 2004). This is usually partial, with the veins from each lung entering the ipsilateral atrium on the opposite sides of the midline. The atria each show features of the left atrium with a long narrow atrial appendage. The atrial septum is usually absent, with an ostium primum defect in 65% of the cases.

Peoples et al. (1983) reviewed the ventricular anatomy of 127 cases of left atrial isomerism and found that in 38 the ventricular septum was intact, in 80 a ventricular septal defect (VSD) was present, and in 9 there was a univentricular heart. The VSD was either a form of endocardial cushion defect or a VSD in one of the typical locations. The atrioventricular connection is ambiguous through either a common or two-leaflet valve (Tommasi et al., 1981). In a univentricular heart, there is usually a double inlet ventricle to a chamber of right or left ventricular morphology.

The great vessels in the left atrial isomerism are concordant in 69% (Peoples et al., 1983). The remainder are equally divided between discordant atrioventricular connection and double outlet ventricle (usually of the right, but sometimes double outlet left ventricle can be seen). In 20% of the cases, the side of the aortic arch is opposite the side of the cardiac apex.

The pulmonary valve of the right ventricular outflow area is normal in 65% of the cases. In the remaining cases, the pulmonic valve is stenotic (20%) or atretic (10%) with isolated subpulmonic stenosis in the remainder. In the left side

of the heart, Peoples et al. (1983) found obstructive lesions in 22% of cases. These included valvular or subvalvular aortic stenosis (11 cases), coarctation of the aorta (7), hypoplastic left heart, hypoplastic left ventricle (6), mitral stenosis (3), and cor triatriatum (1).

Right Atrial Isomerism

The asplenia syndrome is now best described, in terms of the visceral asymmetry, as right atrial isomerism. Although most patients will lack a spleen, some patients will have a normal spleen or multiple spleens. These patients usually come to the attention of a pediatric cardiologist early in life, secondary to severe associated congenital heart disease. Although historically 90% of the patients with the asplenia syndrome died by 1 year of age, survival has significantly improved due to advances in cardiac diagnosis, the use of prostaglandin E_1 in duct-dependent lesions, and improvements in cardiac surgery (Ivemark, 1955; Van Mierop et al., 1972; Chang et al., 1993).

In right atrial isomerism, there are multiple visceral abnormalities that affect the heart, lungs, liver, and gastrointestinal tract. The lungs are both trilobed and the pulmonary arterial relationships with the tracheobronchial tree may be obscured by proximal pulmonary atresia. The lungs often derive significant blood flow from systemic vessels. The liver occupies a central position in the upper abdomen with the globular transverse lie.

Some take exception to the concept of atrial isomerism in heterotaxy (Van Praagh, 1985; Van Praagh and Van Praagh, 1990). Van Praagh has written that the concept of atrial isomerism is conceptually and anatomically flawed, as the atrial appendages are not mirror images of each other. The heart is organized initially as a cephalocaudally oriented blood vessel. In contrast to other viscera, in the heart left–right organization is not initially present in the embryo but is acquired later in development. This group suggested criteria to define the morphologic right atrium as one that receives: (1) all of the systemic veins, while a separate atrium receives all of the pulmonary veins; or (2) all of the systemic veins and some or all of the pulmonary veins, without losing a common atrium because a second atrium is present; or (3) the orifice of a normal coronary sinus. In contrast, the morphologically left atrium can be defined as the atrium that receives: (1) all or half of the pulmonary veins, but none of the systemic veins (except for a persistent SVC associated with an unroofed coronary sinus in cases with bilateral SVC); or (2) none of the pulmonary veins and none of the systemic veins. In addition, the left atrial appendage is usually smaller and more posterior than the right atrial appendage.

INCIDENCE

It is difficult to estimate the incidence of heterotaxy, because birth defect registries track each anomaly separately. A recent study with strict diagnostic criteria estimated the prevalence of heterotaxy to be 1 in 10,000 birth (Lin et al., 2000). The observed male-to-female ratio is 2 to 1. Overall, heterotaxy account for 3% of cases of congenital heart disease (Ware et al., 2004).

SONOGRAPHIC FINDINGS

Accurate prenatal diagnosis in heterotaxy is not only possible but offers the advantage of assisting postnatal management (Allan et al., 1994; Copel et al., 1997; Lin et al., 2002; Taketazu et al., 2006).

The determination of visceral situs may be quite challenging for the ultrasonographer. Often, abnormal cardiac situs and a structural defect are detected simultaneously, raising the suspicion of heterotaxy. Certain cardiac defects are more commonly associated with asplenia syndrome. These include total anomalous pulmonary venous return, VSD, single ventricle, transposition of the great arteries, and dextrocardia. In polysplenia, bilateral SVC, absent or interrupted IVC, anomalous pulmonary venous return, dextrocardia, atrioventricular septal defect, transposition of great arteries, and double outlet right ventricle are typical anomalies (Van Mierop et al., 1972). The sonographic findings that distinguish between polysplenia and asplenia are summarized in Table 56-1.

Detection of visceral situs can be difficult, as the liver may have a central position and the stomach bubble location may be right, left, or central (Figure 56-1). In the asplenia syndrome, the relationship between the IVC and aorta is helpful in diagnosing heterotaxy. Huhta et al. (1982) noted in newborns that in asplenia syndrome the descending aorta and the IVC run on the same side of the spine, either to the right or left. The aorta is usually positioned posterior to the IVC. This relationship is best appreciated in a transverse cross section of the fetal abdomen below the diaphragm (Figure 56-2). The IVC and aorta should then be followed proximally to the right atrium and descending thoracic aorta, respectively. The IVC is often interrupted in the polysplenia syndrome, with blood flow continued via communication though the azygos vein on either the left or right side of the spine. The aorta usually courses anterior to the spine in the midline. There is a good deal of overlap between these conditions, and identification of IVC and aorta on the same side of the spine has been described in both asplenia and polysplenia syndromes.

Echocardiographic assessment should attempt to identify the presence of right, left, or bilateral SVC and its connection to the atria. In bilateral SVCs, the left may connect to the coronary sinus or the left atrium. An attempt should be made to identify the pulmonary veins. In total anomalous pulmonary veins, if a venous connection is seen with situs ambiguous, then right atrial isomerism should be suspected. In contrast, partial anomalous venous connection to the right atrium suggests left atrial isomerism. In addition, the atrioventricular connection and ventriculoatrial connection should be determined.

Table 56-1

Prenatal Sonographic Findings in Heterotaxy Syndromes

Finding	Polysplenia	Asplenia
Sidedness	Left	Right
Spleen	Present (multiple)	Absent
Gallbladder	Absent	Present
Liver	Left or right side	Midline
Heart malformations	ASD, AVC, TGA, DORV	AVC, single ventricle, TGA, PS
Vena cava	Interrupted IVC Bilateral SVC	Same side as aorta Bilateral SVC
Anomalous pulmonary	70% of cases	100% of cases
Venous return		
Sex ratio	Equal in males and females	2 females : 1 male

KEY: ASD = atrial septal defect; AVC = atrioventricular canal defect; DORV = double outlet right ventricle; IVC = inferior vena cava; PS = pulmonic stenosis; SVC = superior vena cava; TGA = transportation of great arteries.

ANTENATAL NATURAL HISTORY

Little is known of the antenatal natural history of heterotaxy because it has been recognized prenatally only relatively recently (Berg et al., 2003; Cohen, 2006). Abnormal situs does not in itself pose adverse consequences for the fetus, with two notable exceptions. The prenatal as well as postnatal courses are thought to be determined primarily by the severity of the cardiac defect. Most structural heart defects associated with heterotaxy are well tolerated in utero. Because most cases of right atrial isomerism have pulmonary stenosis or atresia and total anomalous pulmonary venous return, they will usually need palliative treatment early in postnatal life (Masood et al., 1996; Wu et al., 1998). Patients with left atrial isomerism tend to have less complex cardiac anomalies and in general a better prognosis than patients with right atrial isomerism (Rose et al., 1975; Van Praagh et al., 1992). Exceptions to this are cases of left atrial isomerism associated with heart block, which result in nonimmune hydrops (Phoon et al., 1996).

Figure 56-2 Transverse section through the abdomen of a fetus with total sinus inversus. The fetal right side is superior in this picture. Ao = aorta; IVC = inferior vena cava. (*Courtesy of Dr. Marjorie Treadwell.*)

Prenatal mortality in left atrial isomerism may be as high at 31% due to heart block and extracardiac pathology (Taketazu et al., 2006).

In cases in which heterotaxy results in intestinal malrotation, the risk of midgut volvulus exists. However, no case of prenatal midgut volvulus due to heterotaxy has been reported to date. The presence of biliary atresia or intestinal obstruction is more frequently identified in nonsurvivors (Taketazu et al., 2006). The presence of biliary atresia or other gastrointestinal malformations is associated with 2- and 2.5-fold increased risk of mortality, respectively (Gilljam et al., 2000).

MANAGEMENT OF PREGNANCY

In cases of suspected heterotaxy, obstetric management should include a detailed sonographic evaluation to delineate the situs and extent of visceral abnormalities. Fetal echocardiography should be performed in all cases to determine the nature and severity of associated cardiac defects. Chromosome abnormalities are associated with major congenital heart defects, but they are not typically associated with heterotaxy (Lin et al., 2000). Nonetheless, if a cardiovascular malformation is present with heterotaxy, amniocentesis is warranted. The prospective parents should meet with a medical geneticist to review the family history and discuss DNA mutation testing.

There is no indication for changing the mode or timing of delivery except for standard obstetrical indications. However, because of the potential for severe structural heart disease, referral for delivery in a tertiary care center with neonatologists, pediatric cardiologists, and pediatric cardiac surgeons available is recommended.

FETAL INTERVENTION

There is no fetal intervention for heterotaxy. However, in cases of left atrial isomerism, heart block may result in hydrops and fetal mortality. Complete heart block complicates as many as 15% of left isomerism cases (Taketazu et al., 2006). If caught early in the progression to hydrops, fetal cardiac pacemaker placement may be an option to salvage fetuses with correctable cardiac anomalies.

TREATMENT OF THE NEWBORN

Much of the initial treatment of the infant with heterotaxy will be dictated by the specific associated cardiac defect. The reader is referred to the individual chapters on structural heart disease (see Chapters 43–55). The newborn with heterotaxy should undergo plain abdominal radiography of the chest and abdomen to confirm the diagnosis of heterotaxy. Postnatal echocardiography should be performed to confirm prenatal

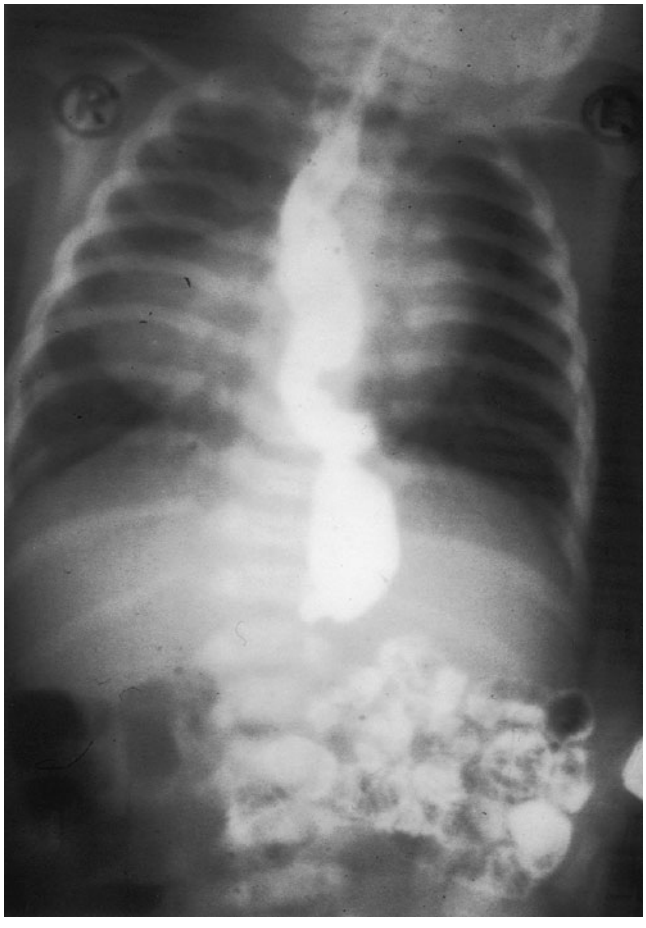

Figure 56-3 Postnatal contrast study in an infant with heterotaxy. Note that there is dextrocardia, vascular congestion, and situs ambiguous with the stomach lying centrally. The stomach is small and the liver fills the upper abdomen. (*Courtesy of Dr. Roy McCauley.*)

echocardiographic assessment and to define the anatomic defect. When the infant is stable for transport to the radiology suite, an upper gastrointestinal series and small-bowel follow-through should be performed to evaluate abnormalities in intestinal fixation that may predispose to midgut volvulus (Figure 56-3). In cases of asplenia, the newborn should be maintained on prophylactic penicillin and receive the pneumococcal vaccine.

LONG-TERM OUTCOME

The long-term outcome of children with heterotaxy is directly related to the severity of the associated cardiac anomaly and/or the presence of biliary atresia (Zhu et al., 2006).

GENETICS AND RECURRENCE RISK

There is evidence to support multiple patterns of inheritance of heterotaxy. Most cases of heterotaxy are single

occurrences in a family. Approximately 10% of infants with heterotaxy, however, have a family history of a close relative with congenital heart defects (Belmont et al., 2004). Analysis of the Baltimore-Washington Infant Study data from 1980 to 1989 suggests the potential importance of a positive family history of cardiac malformations (odds ratio 5.1; 95% CI, 2.0–12.9), maternal diabetes (odds ratio 5.5; 95% CI, 1.6–19.1), and parental cocaine use (odds ratio 3.7; 95% CI, 1.3–10.7) as risk factors for heterotaxy (Kuehl and Loffredo, 2003).

Heterotaxy occasionally occurs in families in a recurring pattern, suggestive of autosomal recessive, X-linked, or autosomal dominant inheritance. Alonso et al. (1995) reported six families with a pattern of recurrence suggestive of an autosomal dominant inheritance. Ferraro et al. (1997) studied a large family in which a gene for heterotaxy (*HTX-1*) was mapped to Xq26.2.

There is a growing body of evidence that supports the role of single-gene mutations in heterotaxy. The occurrence of families with X-linked inheritance has been demonstrated by linkage analysis (*HTX1*, Xq26.2) and confirmed by mutations in the gene *ZIC3*. *ZIC3* is a zinc finger protein that localizes to the nucleus with potential DNA binding activity. The 5 zinc finger motifs in *ZIC3* share sequence similarities with the *GL1* family of transcription factors. Mutations in *ZIC3* may result in absent or abnormal transcriptional activator function (Ware et al., 2004). There have been several reports of deletion nonsense, frameshift, and missense mutations in *ZIC3*. Some of these mutations have occurred in phenotypically normal subjects, and individuals with situs inversus without congenital heart defects, or with congenital heart defects such as hypoplastic left heart syndrome, which would not usually be considered in the spectrum of left–right patterning defects. Mutations in *ZIC3* account for 1% of all cases of heterotaxy (Belmont et al., 2004; Ware et al., 2004). Commercial DNA testing is available for *ZIC3* mutations. If consultation with a medical geneticist was not obtained prenatally, it should be obtained postnatally to take a complete family history, consider DNA testing options, and to discuss recurrence risk. Studies in model organisms suggest that more than 80 genes must function to develop normal asymmetric left–right organs (Zhu et al., 2006).

In the *Zic3*-deficient mouse, there is improper nodal expression (Purandare et al., 2002). The node is a transient midline structure that forms during gastrulation and is critical for decisions regarding laterality. In null mutations in *ActRIIB* and *Cryptic/EFG-CFC* there is a failure of *nodal* signaling and right atrial isomerism. Null mutations in *lefty-1* result in left isomerism due to failure of nodal signaling restricted to the left. Human mutations do not replicate exactly the mouse phenotype. For example, the phenotype of patients with mutations in *LEFTYA*, the human homolog of mouse *lefty-1* is not characterized as left or right patterning failure (Kosaki et al., 1999). There are numerous possible reasons that may account for discrepancies between murine and human phenotypes which include, but are not limited to, haploinsufficiency versus null mutations, deficiencies in *NODAL* functions between mouse and human alternative roles for *CRYPTIC* or *ACVR2B*, or differential role of modifier genes (Belmont et al., 2004). The differences between the mouse and human phenotypes highlight the complexities involved in left–right patterning at the level of signaling pathways and regulatory interaction, even when the mutations are the same.

57 CHAPTER

Cardiomyopathy

Key Points

- Generally classified as dilated or hypertrophic cardiomyopathy.
- Incidence is 1.2 per 100,000. Higher in males due to X-linked conditions.
- Most common causes of hypertrophic cardiomyopathy are maternal diabetes, twin–twin transfusion, Noonan syndrome, inborn error of metabolism, and familial single-gene disorder.
- Most common causes of dilated cardiomyopathy are infection, endocardial fibroelastosis, dysrhythmia, carnitine deficiency, and familial single-gene disorder.
- Associated with high incidence of antenatal cardiac dysfunction and in utero mortality (except if due to maternal diabetes).
- Twenty percent of cases are familial. Obtain a family history and consider evaluating both parents.
- As many as 40% of cases require postnatal heart transplant.
- Increasing numbers of causative mutations in genes for sarcomeric and cytoskeletal proteins have been identified. Most are inherited as autosomal dominant disorders with variable penetrance.

CONDITION

Cardiomyopathy refers to cardiac hypertrophy manifested by an increased interventricular septal size and/or free ventricular wall size in the absence of an increased cardiac load, accompanied by decreased cardiac function and by ventricular dilation (Michels et al., 1992). More broadly, cardiomyopathy is defined as a disease of the myocardium characterized by the presence of systolic or diastolic dysfunction or abnormal myocardial structure (Schwartz et al., 1996). The condition is rarely observed during fetal life. Cardiomyopathy is generally classified as dilated or hypertrophic.

INCIDENCE

The incidence of fetal cardiomyopathy is not precisely known, but it is rare. In one study, dilated cardiomyopathy was present in approximately 2% of fetal cardiac abnormalities (Sivasankaran et al., 2005).

Relatively recently, two large-scale population-based cohort studies of cardiomyopathy in children were published. One was performed in Australia (Nugent et al., 2003) and one involved American children in New England and the Central Southwest (Lipshultz et al., 2003). In the Australian study, the incidence of cardiomyopathy was 1.24 per 100,000. Of these, 58.6% had dilated cardiomyopathy, 25.5% had hypertrophic cardiomyopathy, 9.2% had cardiomyopathy due to noncompaction of the left ventricle, and 2.5% of cases were restrictive. There was a large familial component (19.8% of cases). Indigenous children had a 2.67-fold relative risk of having the disease compared to nonindigenous children. The American study showed a similar incidence (1.13 per 100,000) and identified a peak incidence in the first year of life. In this study, 51% of cases were due to dilated cardiomyopathy, 42% to hypertrophic, 3% to restrictive, and 4% to unspecified. The American study noted a higher incidence in black children. Both studies documented a higher incidence in males, presumably due to the X-linked conditions that are associated with cardiomyopathy, such as Duchenne, Becker, and Barth syndromes.

SONOGRAPHIC FINDINGS

Relatively few reports of the prenatal diagnosis of fetal cardiomyopathy exist. One of the most comprehensive encompasses a 9-year retrospective review of fetuses studied in the Fetal Cardiac Program at the Hospital for Sick Children in Toronto (Pedra et al., 2002). This study reported on 55 affected fetuses. Evaluation included a complete two-dimensional study, spectral Doppler, and color flow mapping. The authors measured cardiothoracic ratio, left and right ventricular end-systolic and end-diastolic diameters, and wall thickness. Measurements in affected pregnancies were compared with values obtained in 55 normal fetuses. Ventricular systolic and diastolic function was assessed. Dilated cardiomyopathy was diagnosed in the presence of systolic dysfunction with or without significant chamber enlargement but without wall thickening. Hypertrophic cardiomyopathy was diagnosed when the ventricular wall thickness was $\geq$2 SD above the normal mean for gestational age, with or without ventricular systolic or diastolic dysfunction (Pedra et al., 2002).

Although the incidence of hypertrophic cardiomyopathy in the Pedra et al. (2002) study was higher than dilated cardiomyopathy, the numbers are affected by two reasonably common conditions, maternal diabetes and twin–twin transfusion syndrome (see Chapter 119). A significant body of literature exists on the fetal heart in the offspring of the diabetic mother. Gutgesell et al. (1980), studied 47 infants of diabetic mothers by echocardiography. In this study, 24 of the infants were clinically symptomatic. Five had marked septal hypertrophy with echocardiographic features that suggested left ventricular outflow obstruction. Five infants had hypertrophy of the right ventricular free wall. One symptomatic infant died from an unrelated bacterial infection. In the clinically asymptomatic infants, three were shown to have septal hypertrophy, two had right ventricular free wall hypertrophy and no patients had left ventricular outflow obstruction. None of the patients in the entire study had evidence of dilated or congestive cardiomyopathy, and all patients had resolution of their echocardiographic abnormalities during the first 6 months of life. This was the first report to suggest the use of echocardiography to follow cardiac changes occurring in infants of diabetic mothers. The alterations in the hearts of infants of diabetic mothers were shown to be due to an increased mass of myocardial nuclei and sarcoplasm, but they were self-limited.

Subsequently, fetuses in mothers who had well-controlled type I insulin-dependent diabetes were studied at 4-week intervals between 20 and 30 weeks of gestation by M-mode and Doppler echocardiographic studies (Rizzo et al., 1992). These investigators measured intraventricular septal thickness, left and right ventricular wall thickness, and the ratio between the peak velocities during the early passive ventricular filling and active atrial filling at the level of the atrioventricular valves. They also studied peak velocities and time to peak velocity at the level of the ascending aorta and pulmonary artery. The findings in the 14 fetuses of diabetic mothers were compared with those in 10 normal control fetuses. This study revealed that all indices investigated increased linearly with advancing gestation. The fetuses of the diabetic mothers showed an accelerated increase in cardiac size occurring during the late second trimester, manifested by progressive thickening of the intraventricular septum and ventricular walls. These investigators demonstrated that strict control of maternal diabetes did not prevent the accelerated fetal cardiac growth and abnormal development of cardiac function, which was mainly manifested by impaired diastolic function (Rizzo et al., 1992). The study was followed by a related report that compared fetal echocardiographic indices in fetuses of mothers with well-controlled insulin-dependent

diabetes to normal fetuses during the second and third trimester (Gandhi et al., 1995). An increase in right ventricular shortening fraction was associated with global cardiac enlargement, which did not adversely affect myocardial contractility. These authors hypothesized that metabolically stable maternal diabetes may be associated with a mild but definite myocardial hypertrophy that affects the growth of the ventricular and septal walls (Gandhi et al., 1995). The echocardiographic changes associated with maternal diabetes are not, strictly speaking, a cardiomyopathy, but rather a self-limited cardiac hypertrophy. Only in extremely rare cases does the maternal diabetes result in systolic or diastolic cardiac dysfunction, progressing to congenital heart failure.

Prenatal sonographic manifestations of familial hypertrophic cardiomyopathy are increasingly being appreciated. In one report, a 25-year-old primigravida was described with hypertrophic apical cardiomyopathy whose fetus had normal echocardiographic examinations at 19 and 21 weeks of gestation. At 27 weeks of gestation, two-dimensional and M-mode echocardiograms revealed a generalized fetal cardiac hypertrophy with a markedly thickened intraventricular septum. This was confirmed at 32 and 36 weeks of gestation but did not worsen throughout the rest of the pregnancy. The patient was studied postnatally and followed to age 15 months, when stable cardiac hypertrophy was observed (Stewart et al., 1986).

Genetic syndromes, such as Noonan syndrome, can present with hypertrophic cardiomyopathy. In one case report, a fetus with cystic hygroma and a normal karyotype, diagnosed postnatally with Noonan syndrome, was referred for fetal echocardiography at 23 weeks of gestation. A small primum atrial septal defect, increased echogenicity of the mitral valve, and modest hypertrophy of both ventricles were observed (Sonesson et al., 1992). In the same fetus, observed serially at 35 weeks of gestation, prominent hypertrophy of both ventricles was demonstrated. Retrospectively, these authors noted that the first sign of myocardial abnormality was observed in the diastolic filling of both ventricles. However, this may be a subtle finding, as all fetuses have different diastolic filling velocities compared with newborn infants.

In a retrospective review of six cases of fetal dilated cardiomyopathy, Schmidt et al. (1989) made a sonographic diagnosis by numerous approaches, including the four-chamber, long-axis, short-axis, and aortic-arch views. Prenatal sonographic imaging was complemented by M-mode echocardiography for better definition of the motion patterns of the atrioventricular and semilunar valves (Schmidt et al., 1989). This group defined the right and left ventricular fractional shortening (FS) index as:

$$FS = (EDD - ESD) \times 100/EDD,$$

where EDD is the end-diastolic diameter of the ventricle and ESD the end-systolic diameter of the ventricle. These investigators demonstrated that in five of the affected fetuses, the right ventricular FS index was less than 2 SD below the normal mean for gestational age, and in four, the left ventricular FS index was less than 2 SD below the normal mean. In addition, they observed significantly larger mean end-diastolic diameters. In affected fetuses, the FS decreased progressively during gestation while the chamber enlargement increased (Schmidt et al., 1989).

DIFFERENTIAL DIAGNOSIS

The most important consideration in the differential diagnosis is to determine whether the cardiomyopathy is dilated or hypertrophic (Table 57-1). In dilated cardiomyopathy, the ventricle is thin-walled and dilated; mitral and or tricuspid regurgitation is also present (Figures 57-1 and 57-2). In the study performed at the Hospital for Sick Children (Pedra et al., 2002) 22/55 fetuses had dilated cardiomyopathy and 33 had hypertrophic. The various causes of the dilated cardiomyopathy were endocardial fibroelastosis (6 cases), familial (5), cytomegalovirus infection (2), and idiopathic (9). The underlying diagnosis in the hypertrophic cases included: twin–twin transfusion (18 cases) (Figure 57-3), maternal diabetes (7), Noonan syndrome (2), alpha thalassemia (2), familial (1), and idiopathic (3).

The important potentially treatable conditions to be ruled out include dysrhythmias, infection, endocardial fibroelastosis due to maternal antibodies, and severe anemia (usually accompanied by hydrops fetalis). Viruses potentially involved in fetal cardiomyopathy include cytomegalovirus, group B Coxsackie, echovirus, rubella, and herpes (Boston et al., 1994). Carnitine deficiency, although not directly diagnosable prenatally, should be considered, because postnatal treatment exists.

Inborn errors of metabolism associated with infantile cardiomyopathy are listed in Table 57-2. These include storage disorders, such as Pompe disease (glycogen storage

Table 57-1

Differential Diagnosis of Fetal Cardiomyopathy

Hypertrophic
Maternal diabetes
Twin to twin transfusion
Noonan syndrome
Inborn error of metabolism

Endocardial fibroelastosis
Dysrhythmia
Familial single-gene disorder
Carnitine deficiency

Figure 57-1 Antenatal four-chamber view of a fetal heart, demonstrating dilation of all four chambers. Arrows indicate the presence of a pericardial effusion.

disease, type II). This autosomal recessive condition results in symmetric massive hypertrophy of individual muscle fibers due to infiltration with glycogen. Pompe disease is diagnosed histochemically by the presence of vacuolar myopathy with positive periodic acid Schiff (PAS) staining and fiber reactivity for acid phosphatase. Frozen sections of liver reveal the absence of lysosomal acid α-glucosidase (Cottrill et al., 1987). For the sake of completeness, inborn errors of enzymes or transport proteins involved in mitochondrial β-oxidation of fatty acids are included in Table 57-2. Disorders of fatty acid oxidation are among the most common metabolic diseases known, with an incidence of 1 in 10,000 to 1 in 15,000 livebirths (Kelly and Strauss, 1994). However, they generally become apparent only during a fasting episode associated with infection and are unlikely to be recognized during fetal life.

Single-gene disorders associated with hypertrophic cardiomyopathy include neurofibromatosis, Friedreich ataxia, LEOPARD syndrome (lentigines, echocardiographic abnormalities, ocular hypertelorism, pulmonary stenosis, abnormal genitalia, restriction of growth, deafness), and Noonan syndrome (Schwartz et al., 1996). Of these, Noonan syndrome is the only one that has been described during fetal life (Battiste et al., 1977; Sonesson et al., 1992).

ANTENATAL NATURAL HISTORY

There is a high incidence of cardiac dysfunction and in utero mortality when fetal cardiomyopathy is observed, except in the setting of maternal diabetes. Pedra et al. (2002)

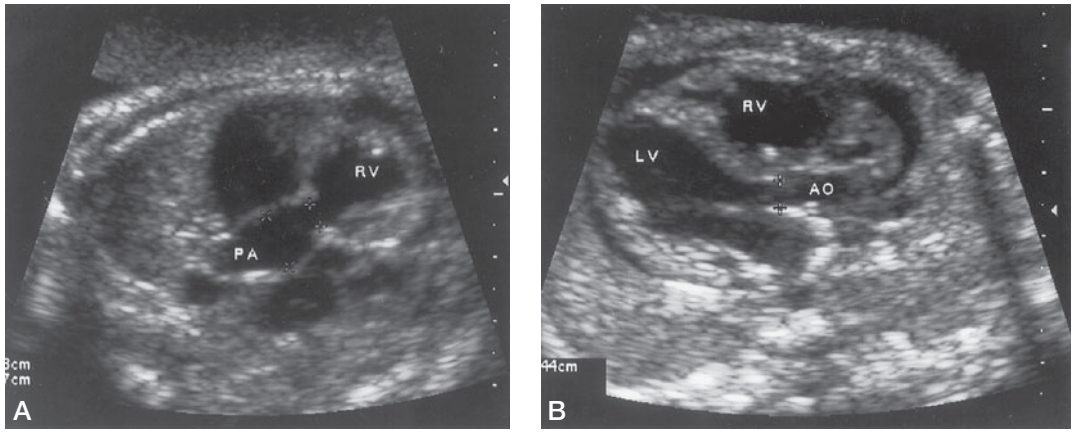

Figure 57-2 **A**. Antenatal sonographic image of same fetus shown in Figure 57-1, demonstrating significant dilation of the pulmonary outflow tract. **B**. Corresponding view of the left ventricular outflow tract, also showing dilation.

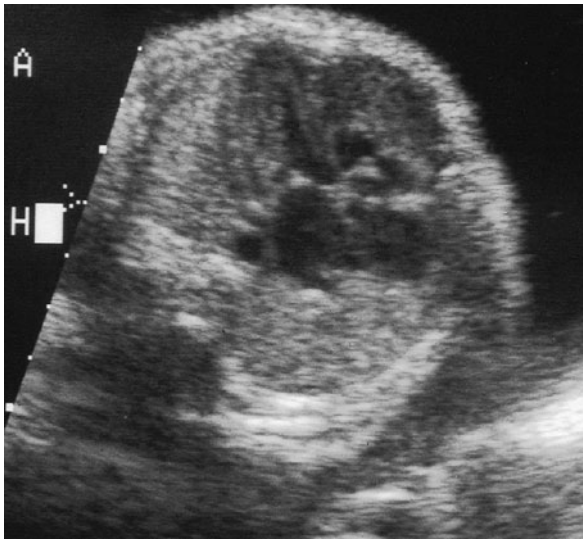

Figure 57-3 Antenatal four-chamber view of a fetal heart, demonstrating marked biventricular hypertrophy in a recipient of twin–twin transfusion.

demonstrated that systolic dysfunction was present in all cases of dilated cardiomyopathy and 15/33 cases of hypertrophic cardiomyopathy. Eight of the fetuses in their study were hydropic, and 23 had signs of early hydrops. The risk factors for mortality in utero included evidence of systolic or diastolic dysfunction, and significant atrioventricular valve dysfunction. Diastolic dysfunction was associated with the highest risk of mortality.

In another study, Sivasankaran et al. (2005) reported on outcome in 50 fetuses diagnosed with dilated cardiomyopathy. Two-thirds became hydropic at some point during gestation. Ten fetuses were terminated. Of the 40 remaining fetuses, only 25 survived to delivery, indicating a 37.5% mortality in utero.

MANAGEMENT OF PREGNANCY

Fetuses in which cardiomyopathy is suspected should be referred to a center capable of performing fetal echocardiography to rule out structural heart disease. Ideally, this center should be able to serially monitor the fetal cardiac function, including repeated measurement of the ventricular FS index and cardiac chambers, and rule out dysrhythmias such as supraventricular tachycardia and atrial flutter. It is important to rule out dysrhythmias, because they are treatable. If a high index of suspicion exists for an arrhythmia, 24-hour monitoring of the pregnant patient and fetus in the hospital is recommended. A targeted fetal sonographic study should be performed to identify any additional anomalies that could help in the diagnosis of a specific genetic syndrome. An attempt should be made to identify whether the mother has evidence of diabetes or infection. If the fetus has dilated cardiomyopathy, some centers screen maternal blood for the presence of anti-Ro (SS-A) and anti-La (SS-B) antibodies. If positive, the pregnant woman can be treated with oral dexamethasone.

It is important to obtain a complete family history, with specific questions directed toward sudden death in family members. Consideration should be given to performing echocardiography on both parents due to the high incidence of familial cases (Burkett and Hershberger, 2005).

Table 57-2

Metabolic Causes of Cardiomyopathy in Infancy

Storage Disorders
Glycogen storage disease, type II (Pompe disease)
Lysosomal glycogenosis without acid maltase deficiency
Glycogen storage disease, type III
Cardiac glycogenosis
GM1-gangliosidosis (β-galactosidase deficiency)
GM2-gangliosidosis (Sandhoff disease)
Ethanolaminosis
Familial steatosis
Inborn Errors of Fatty Acid Oxidation
Carnitine transport defect
Carnitine-acyl carnitine translocase defect
Carnitine palmitoyltransferase II defect
Long- and medium-chain acyl coenzyme A (COA) dehydrogenase deficiencies
Long-chain 3-hydroxyacyl-coA dehydrogenase deficiency
Inborn Errors of Mitochondrial Oxidative Phosphorylation
Lethal infantile cardiomyopathy
Benign infantile mitochondrial myopathy and cardiomyopathy
Maternally inherited myopathy and cardiomyopathy
Inherited cardiomyopathy with multiple deletions of mitochondrial DNA
Myoclonic epilepsy and ragged red fiber (MERRF) disease
Mitochondrial myopathy, encephalopathy, lactic acidosis, and strokelike episodes (MELAS)
Kearns–Sayre syndrome

FETAL INTERVENTION

If a dysrhythmia is diagnosed, medical treatment is indicated (see Chapters 41 and 42).

TREATMENT OF THE NEWBORN

Infants born after a fetal diagnosis of cardiomyopathy need to be delivered in a center capable of newborn resuscitation and aggressive cardiac management. Symptomatic infants may have respiratory distress and require mechanical ventilation with oxygen administration. A chest radiograph should be obtained to demonstrate cardiomegaly. An electrocardiogram should also be obtained. Infants with cardiomyopathy may have left ventricular hypertrophy with or without strain. If the electrocardiogram demonstrates giant QRS complexes in all leads with a shortened P–R interval, glycogen storage disorders may be considered (Kohlschütter and Hausdorf, 1986). A complete physical examination is indicated. Additional anomalies or dysmorphic facies may suggest a particular genetic disorder, such as Noonan syndrome. If inborn errors of metabolism are suspected, the infant should be evaluated for evidence of enlargement of the liver, spleen, or tongue, as well as clinical evidence of seizures, skeletal changes, or corneal opacities. Work-up should also include measurement of carnitine and acylcarnitine levels, as supplementation with carnitine will result in clinical improvement if a deficiency exists.

Further treatment for infants with dilated cardiomyopathy consists of administration of diuretics, together with digoxin and afterload reduction if pulmonary edema develops. Hypertrophic cardiomyopathy is treated with calcium-channel blockers and β-blockers to relax the heart. It is our experience that infants of mothers with diabetes almost never require treatment, even when their hypertrophic cardiomyopathy is severe.

SURGICAL TREATMENT

The only surgical treatment for severe dilated cardiomyopathy is heart transplantation, which may be needed in as many as 40% of cases (Lipshultz et al., 2003).

LONG-TERM OUTCOME

The postnatal natural history for 20 infants identified with cardiomyopathy during the first year of life has been described (Maron et al., 1982). Fourteen of the infants presented with a murmur that suggested evidence of outflow obstruction. For all these infants, the initial diagnosis was a suspected congenital cardiac malformation. Twelve of the 14 infants who presented with a murmur underwent cardiac catheterization, which demonstrated substantial left and right ventricular outflow tract obstruction, asymmetric hypertrophy of the ventricular septum relative to the left ventricular free wall, and a thickened interventricular septum. This study indicated that the onset of pulmonary edema during the first year of life was an unfavorable prognostic sign, as 9 of the 11 infants who developed this finding died. Several patients were treated with propranolol to decrease left ventricular outflow tract obstruction, but the authors expressed caution regarding the negative inotropic effect on ventricular contractility, and recommended administration of diuretics as a more conservative and safe regimen.

In Maron et al.'s report (1982), 6 of the 20 infants were documented to have a family history of dilated cardiomyopathy, as demonstrated by at least one of the parents having echocardiographic evidence of asymmetric septal hypertrophy. Although this report is over two decades old, it does emphasize that the familial and genetic contribution is probably greater than was originally appreciated.

In another report, the clinical course of 63 consecutive infants and children who presented with idiopathic dilated cardiomyopathy was described (Burch et al., 1994). The age at diagnosis was 1 day to 15 years (median, 12 months), with follow-up occurring through 1 day to 13 years of life (median, 19 months). The survival of this group from clinical presentation onward was 79% at 1 year after diagnosis and 61% at 5 years after diagnosis. Predictors of adverse outcome in this group included the presence of a mural thrombus, a left ventricular end-diastolic pressure of greater than 20 mm Hg, and an age at presentation of greater than 2 years. In 36 of the 63 patients, left ventricular echocardiography showed a decline or no improvement. Of these 36, 17 died, and 3 required cardiac transplantation. In 16 of 63 patients, partial improvement was noted; 3 patients in this group died. In the group whose left ventricular function returned to normal (11 of 63), all patients survived. These authors concluded that with no documentation of improvement in left ventricular echocardiographic dimensions or function, a poor prognosis exists, and these infants or children should be considered for cardiac transplantation.

GENETICS AND RECURRENCE RISK

Approximately 20% of cardiomyopathy cases are familial (Michels et al., 1992; Nugent et al., 2003; Burkett and Hershberger, 2005). The genetics of isolated cardiomyopathy are increasingly being explained at the molecular level. Some cases of familial dilated cardiomyopathy are inherited as autosomal recessive or X-linked (Berko and Swift, 1987) condition, but in the majority of families, the disease is inherited as an autosomal dominant disorder with age-related penetrance (Krajinovic et al., 1995). X-linked conditions associated with dilated cardiomyopathy include Duchenne and Becker muscular dystrophies, and Barth syndrome (dilated cardiomyopathy, cyclic neutropenia, and skeletal myopathy).

Much progress has ensued regarding the understanding of the molecular basis of the hypertrophic cardiomyopathies (Table 57-3). Approximately 50% of familial hypertrophic cardiomyopathies are due to mutations occurring in genes on chromosomes 1, 14, and 15, although other disease loci are known at chromosomes 11p13-q13, 7q3, and 9q13-q22 (Krajinovic et al., 1995; Watkins et al., 1995b). Approximately

Table 57-3

Major Genes and Gene Products Involved in Hereditary Cardiomyopathy

Hypertrophic (primarily involve sarcomeric problems)
Beta myosin heavy chain
Myosin-binding proteins
Troponin

Dilated (primarily involve cytoskeletal proteins)
Dystrophin (Duchenne and Becker syndromes; X-linked dilated cardiomyopathy)
Beta myosin heavy chain
Lamin
Taffazin (Barth syndrome)
Desmin
Actin
Titin

Genes Involved in Metabolic Processes
Phospholamban (calcium metabolism)
Adenosine monophosphate-activated protein kinase
Carnitine transporter
Fatty acid oxidation enzymes
Respiratory chain oxidative phosphorylation pathway

30% of cases of familial hypertrophic cardiomyopathy and some sporadic cases are due to missense mutations in the cardiac β-myosin heavy-chain gene on chromosome 14q11. All these mutations are single-nucleotide substitutions that result in a change of a single amino acid in the globular head or the head-rod junction of the myosin heavy-chain molecule. These mutations are not null alleles. They act as dominant-negative alleles, which means that they result in the production of an alternative molecule that impairs cross-bridge cycling and interferes with the assembly of the sarcomere (Watkins et al., 1995a). Approximately 15% of cases are due to mutations occurring in the cardiac troponin T gene on chromosome 1q3. These mutations are associated with a poor prognosis and a high incidence of sudden death before age 35 years (Watkins et al., 1995a). Approximately 3% of cases of familial hypertrophic cardiomyopathy are due to mutations in the α-tropomyosin gene on chromosome 15q2. All these loci are important in specifying genes for a sarcomeric contractile protein.

Because of the substantial progress being made in the molecular mapping of genes that affect families with cardiomyopathy, presymptomatic diagnosis is now possible, although only a few cases of prenatal diagnosis using DNA analysis have been published. In one family, a 24-year-old man was diagnosed with a cardiac β-myosin heavy-chain gene mutation following identification of his affected sister. At the time of his diagnosis, his partner was expecting a child. He asked for DNA testing on his daughter shortly after her birth. She was diagnosed as carrying the same mutation. An ethical debate ensued as to the wisdom of identifying a healthy newborn infant as a carrier of this gene mutation (Ryan et al., 1995). The parents very strongly wanted this information so that they would be able to redirect the child's lifestyle to avoid energetic activities and to ensure regular medical and cardiac surveillance. Physicians argued against this diagnosis because of the future stigmatization of the child with regard to employment, life insurance, and loans. In addition, the question has been raised as to whether the presence of the mutation is equivalent to having clinical evidence of the disease. For this condition, the presence of the responsible gene is necessary but not sufficient for the development of clinical symptoms of cardiomyopathy.

In a French family with a known R403L mutation in the beta myosin heavy-chain gene (*MYH7*), prenatal diagnosis was performed and demonstrated that the fetus was affected. The couple elected to terminate the pregnancy, as the phenotype in their particular family was severe and they already had one affected child (Charron et al., 2004). This family's experience is somewhat atypical. In another report, 22 couples with a family history of cardiomyopathy were seen in one center for prenatal genetic counseling. In 15/22 families the underlying molecular abnormality was known. During the counseling session autosomal dominant inheritance was explained, as well as the variability in the expression of the disease. In other words, *absence* of the gene mutation means that the child will not have cardiac disease, but *presence* of the gene mutation could mean anything from no symptoms to severe symptoms. Given this information, none of the couples counseled requested prenatal diagnosis (Charron et al., 2002).

CHAPTER 58

Intracardiac Tumors

Key Points

- Intracardiac tumors are extremely rare in fetuses, occurring in 0.11% to 0.14% of fetal echocardiographic studies.
- Most fetal intracardiac tumors (60%–80%) are due to rhabdomyoma. Other causes (in order of decreasing frequency) are teratoma, fibroma, vascular tumors, and myxoma. If multiple tumors are present, the diagnosis is almost always rhabdomyoma.
- Sixty to ninety-five percent of cases of rhabdomyoma are due to tuberous sclerosis, an autosomal dominant disorder.
- Antenatal management includes evaluation of fetal cardiac function and determining if dysrhythmias are present.
- Hydrops and dysrhythmias are associated with in utero demise. Overall, there is a 66% survival rate for fetuses with intracardiac tumors.
- Genetic consultation, examination of parents and siblings, fetal brain MRI, and level II sonography are all indicated to rule in or rule out tuberous sclerosis.
- Delivery should occur at a tertiary center.
- Most tumors regress postnatally, but if surgical removal is necessary, the postoperative prognosis is excellent.
- Tuberous sclerosis is associated with relatively high rates of new mutation and gonadal mosaicism, so the affected fetus/neonate should undergo DNA testing to both confirm diagnosis and provide a definitive means of prenatal diagnosis in future pregnancies.

CONDITION

The most common intracardiac tumors found in fetuses, infants, and children are rhabdomyomas (Abushaban et al., 1993; Holley et al., 1995). Rhabdomyomas can involve the myocardium, endocardium, pericardium, papillary muscles, cardiac valves, and the pulmonary and aortic outflow tracts (Gava et al., 1990). Rhabdomyomas occur with equal frequency in the right and left ventricles. In 30% of cases, one or both atria are involved (Deeg et al., 1990).

Tuberous sclerosis is a neurocutaneous disorder resulting from hamartomatous growths that can occur in any organ. Interestingly, there is an age-related presentation of the lesions in different organs in tuberous sclerosis (Kwiatkowski and Short, 1994). Rhabdomyomas are primarily the fetal manifestation of tuberous sclerosis (Bader et al., 2003). The classic presentation of tuberous sclerosis, however, is later in life, when the hallmark findings are facial angiofibromas, seizures, and mental retardation.

INCIDENCE

Overall, intracardiac tumors are extremely rare in infants and children. In one series of children presenting to a pediatric cardiology referral unit, 0.08% had an intracardiac tumor as their referring symptom. Cardiac tumors are found in 0.0017% to 0.25% of pediatric autopsies (Groves et al., 1992). The most likely diagnosis for an intracardiac tumor is rhabdomyoma.

The incidence of intracardiac tumors has been estimated from antenatal sonographic studies. In a series of 794 congenital cardiac malformations derived from more than 10,000 fetal scans, 11 cardiac tumors were identified (0.11%) (Groves et al., 1992). Similar numbers were reported by Holley et al. (1995), who identified 19 fetuses with intracardiac tumors in ~14,000 fetal echocardiographic reports (=0.14%).

SONOGRAPHIC FINDINGS

In 1982, DeVore et al. was the first to describe an intracardiac tumor. A fetus was identified at 26 weeks of gestation with a dense, echogenic mass within the heart. On presentation, however, these authors were not sure whether the mass was extrinsic to the heart or within it. M-mode echocardiography demonstrated that the mass was in the heart. This fetus later became hydropic and died in utero. Subsequently there have been multiple reports of fetuses with large echogenic masses demonstrated clearly by prenatal sonography (Figure 58-1). In many of these cases, the mother was known to be affected with tuberous sclerosis. In other cases, the in utero demonstration of a rhabdomyoma prompted further assessment of both parents, with retrospective diagnosis of one of the parents with tuberous sclerosis.

A consistent theme among many of these case reports is that early sonographic examinations were negative for the presence of intracardiac tumors (Brackley et al., 1999). The tumors were found during the late second trimester but no earlier than 22 weeks of gestation. For example, Green et al. (1991) described a mother who was known to have tuberous sclerosis, who had undergone left nephrectomy for multiple angiomyolipomas of both kidneys, and who was known to have subependymal periventricular lesions by her computed tomographic (CT) scan. Sonographic examinations performed on her fetus at 13 and 16 weeks of gestation were completely normal. At 33 weeks, however, multiple solid cardiac

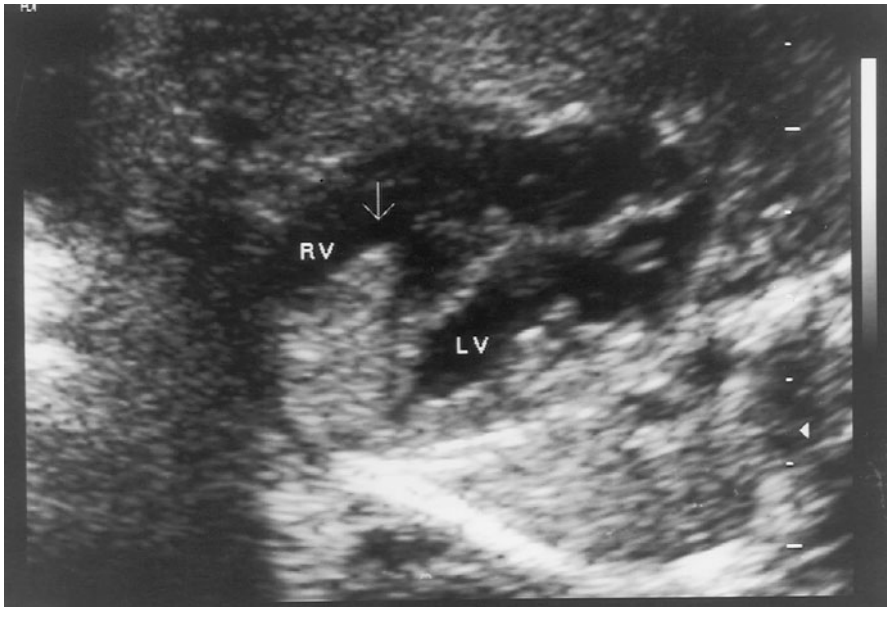

Figure 58-1 Antenatal sonographic image of a large intracardiac echogenic mass, which was postnatally diagnosed as a rhabdomyoma. Arrow indicates tip of mass; RV = right ventricle; LV = left ventricle.

tumors were noted in the left ventricle and intraventricular septum. The fetal central nervous system and renal examinations were within normal limits. In another case reported by Gava et al. (1990), cardiomegaly developed in a fetus with normal sonographic examinations at 10 and 23 weeks of gestation and an echodense mass in the wall of the right ventricle and right atrium at 31 weeks. Over the remaining course of pregnancy, new intracardiac tumors developed in this fetus. The mother, who was previously thought to be healthy, was subsequently diagnosed with a renal angiolipoma, consistent with a diagnosis of tuberous sclerosis.

With increasing prenatal sonographic experience in the diagnosis of intracardiac tumors, it is now clear that they do not become apparent until around 20 weeks of gestation. They undergo their maximal growth between 22 and 32 weeks of gestation and rarely grow after 35 weeks of gestation (Nir et al., 2001).

In fetuses identified with an intracardiac tumor, the following sonographic findings should be noted: the presence or absence of hydrops, whether the tumor is single or multiple, the morphology and characteristics of the intracardiac tumor(s), and the presence of or potential for obstruction of cardiac flow (Groves et al., 1992). The fetal cardiac rhythm should also be observed, as these fetuses are at particular risk for the development of dysrhythmias. Because of the multiple case reports documenting a normal sonographic examination during the first and early second trimesters, all women at high risk for a fetus with tuberous sclerosis (due to a positive family history) should have sequential sonographic examinations, beginning at 20 to 22 weeks of gestation (Journel et al., 1986; Gava et al., 1990; Green et al., 1991; Groves et al., 1992). Another potential intracardiac sonographic finding is diffuse ventricular myocardial thickening (Coates and McGahan, 1994).

Once an intracardiac tumor has been identified, a careful search should be undertaken for associated malformations. The associated findings most likely to occur in the setting of tuberous sclerosis include renal cysts and intracranial abnormalities, such as subependymal nodules (Chen et al., 2005a). Two fetuses have been described with tuberous sclerosis and agenesis of the corpus callosum (Barth et al., 1978; van Oppen et al., 1991). It is unclear whether this finding is related to tuberous sclerosis.

The fetal kidneys should be closely examined. Renal lesions are extremely common in older patients with tuberous sclerosis. For example, angiomyolipoma is found in 47% to 73% of affected patients (Blethyn et al., 1991). Renal cysts are found in 18% to 53% of adult patients with tuberous sclerosis, and both angiomyolipoma and renal cysts are found in 12% to 27% of patients with tuberous sclerosis (Blethyn et al., 1991). Thus, it would seem likely that some patients with tuberous sclerosis will present antenatally with renal cysts. In one case report, a fetus at 28 weeks of gestation was described with a large echogenic unilateral cystic kidney (Blethyn et al., 1991). Initially, this was considered to be consistent with the adult form of polycystic kidney disease or a renal hamartoma. Postnatally, seizures developed in this infant, who had an abnormal electroencephalogram. The definitive diagnosis of tuberous sclerosis was not made until 2 months of age, when calcified cortical tubers were demonstrated on cranial CT examination.

DIFFERENTIAL DIAGNOSIS

If multiple tumors are present, the diagnosis is rhabdomyoma until proven otherwise (Green et al., 1991). If a single intracardiac tumor is demonstrated, the diagnosis is still most likely to be rhabdomyoma, but other causes in decreasing order of frequency of occurrence in the perinatal period are teratoma, fibroma (Figure 58-2), vascular tumors, and myxoma. If the tumor is a rhabdomyoma there is a greater than 50% chance that the fetus has tuberous sclerosis (Table 58-1). Intracardiac myxoma is the most common tumor in adults, but it is extremely rare during the perinatal period (Chitayat et al., 1988). Characteristic findings of myxoma include its location in the left atrium and/or the interatrial septum (Gava et al., 1990). Rhabdomyomas have a characteristic echodense appearance on sonography. If a cyst is present within the mass, it is less likely to be rhabdomyoma. Extracardiac masses that can potentially mimic rhabdomyoma include bronchopulmonary sequestration (see Chapter 34) and congenital cystic adenomatoid malformation of the lung (see Chapter 35) (Calhoun et al., 1991). Fetal echocardiography is recommended to differentiate between intracardiac and extracardiac masses.

ANTENATAL NATURAL HISTORY

Groves et al. (1992) described the natural history of cardiac tumors in 11 cases that were referred because of hydrops ($n = 2$), a positive family history of tuberous sclerosis ($n = 2$), or detection of an intracardiac tumor on routine sonographic examination ($n = 7$). The gestational age at presentation was between 20 and 34 weeks of gestation. There was a high in utero mortality rate for these cases, which included spontaneous antenatal death in 4 of 7 cases (57%) continuing to term. Of the 8 cases that were terminated or died spontaneously, all had postmortem examination; in 7 the cardiac mass was rhabdomyoma, and in 1 the mass was a teratoma. The cases in which death occurred antenatally were caused by obstruction to intracardiac blood flow and secondary fetal hydrops. Autopsy revealed tricuspid-valve incompetence and pulmonary outflow obstruction as direct consequences of tumor growth (Groves et al., 1992). In a subsequent meta-analysis of 89 fetuses with intracardiac tumors, Isaacs (2004) demonstrated a 66% survival rate.

There has never been any evidence that the intracardiac tumors can or will regress during intrauterine life. Maternal hormones have been implicated in the development of these tumors (Chitayat et al., 1988). Postnatally, however, all tumors

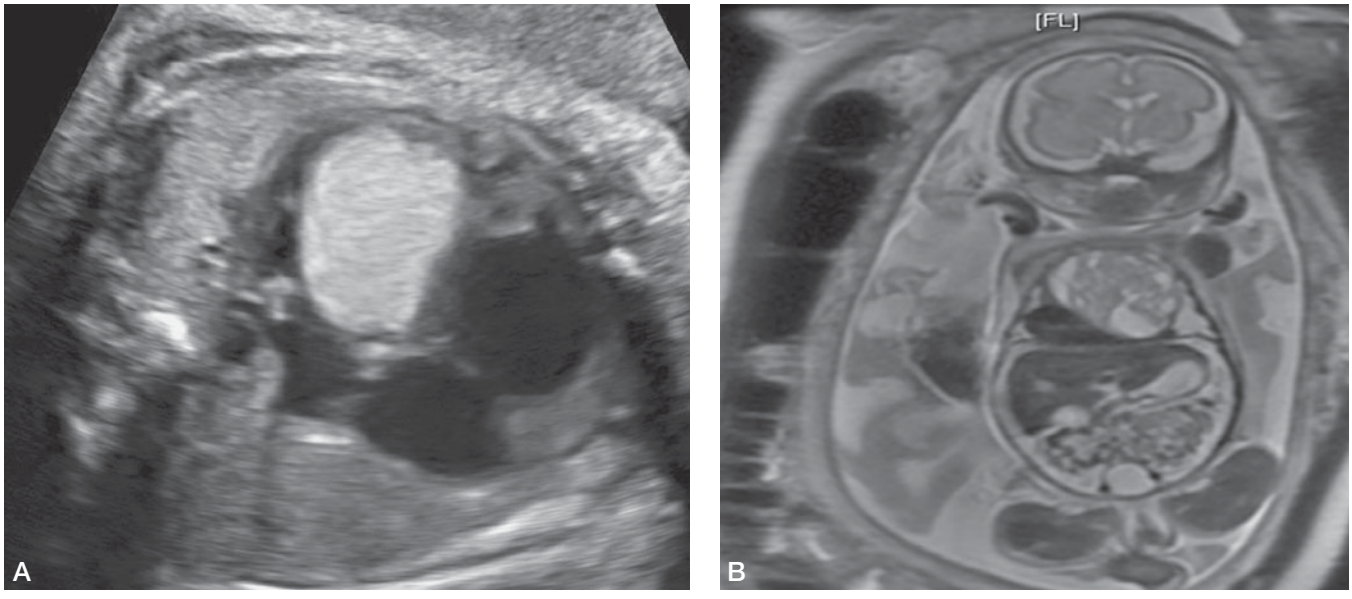

Figure 58-2 **A:** Antenatal sonographic image of a large intracardiac echogenic mass postnatally diagnosed as a fibroma; **B** shows the same mass on fetal MRI.

either stop growing or regress in size. In one report, 4 of 24 cases showed some regression of tumor growth postnatally and in 20 of these 24 cases the tumors completely regressed (Smythe et al., 1990).

Secondary consequences of intracardiac tumors include cardiac failure and dysrhythmias due to interruption of the conduction system (Chitayat et al., 1988). The dysrhythmias most commonly include supraventricular tachycardia, Wolff–Parkinson–White syndrome, atrial flutter and fibrillation, variable atrioventricular block, ectopic atrial tachycardias, premature extrasystoles, and ventricular tachycardia (Mehta, 1993). Two theories have been proposed to account

Table 58-1

Risk of Tuberous Sclerosis in Fetuses with Intracardiac Tumors

Publication	No. of Fetuses Studied	Gestational Age at Diagnosis (wk)	Percent with Single Tumor	Percent Diagnosed with Tuberous Sclerosis*	Notes

for the development of these dysrhythmias. One is that the tumors include an overgrowth of Purkinje cells, which may be capable of impulse conduction (Mehta, 1993). The more prevalent hypothesis is that the arrhythmias develop as a result of disruption of conduction tissue by tumor growth within the intraventricular septum (Groves et al., 1992). Intracardiac rhabdomyomas are composed of large muscle fibers that contain prominent vacuoles that histologically give them a spider web or honeycomb appearance (Thibault and Manuelidis, 1970; Ostör and Fortune, 1978).

In summary, the antenatal natural history of intracardiac tumors is compromised by the development of dysrhythmias, right or left ventricular outflow tract obstruction, valvular insufficiency, myocardial dysfunction due to tumor infiltration, hydrops, and death (Green et al., 1991).

MANAGEMENT OF PREGNANCY

There are two important considerations in the management of a fetus shown to have an intracardiac tumor. The first is to evaluate cardiac function with detailed echocardiography. Early delivery is indicated if there is a suggestion that the cardiac tumor is compromising cardiac function (Chitayat et al., 1988). Administration of digoxin to the mother is indicated if supraventricular tachycardia is the cause of the hydrops as opposed to outflow tract obstruction (Roach and Sparagana, 2004).

The second aspect of management is to evaluate the fetus for other signs and symptoms of tuberous sclerosis. A genetic counselor and/or medical geneticist should meet with the family to obtain a detailed three-generation pedigree and examine the parents and siblings for signs of tuberous sclerosis. Major and minor criteria for the diagnosis of tuberous sclerosis are listed in Table 58-2. Detailed fetal sonographic evaluation should be performed to look for renal cysts and cerebral abnormalities. A fetal MRI (Figure 58-3) may be helpful in evaluating for the presence of subependymal nodules (Chen et al., 2005a). A fetus identified with cardiac rhabdomyoma and renal cysts or subependymal nodules, independent of family history, has a presumptive clinical diagnosis of tuberous sclerosis. When a positive family history exists and a rhabdomyoma is found in the fetus, the fetus can also be presumptively diagnosed as affected. The question of

Table 58-2

Diagnostic Criteria for Tuberous Sclerosis

Major Features	Minor Features
Single or multiple rhabdomyoma in heart*	Multiple renal cysts*
Cortical tuber*	Bone cysts
Subependymal nodule	Multiple pits in dental enamel
Subependymal giant cell astrocytoma	Hamartomatous rectal polyps
Facial angiofibroma or forehead plaque	Cerebral white matter radial migration lines
Ungual or periungual fibroma	Gingival fibromas
Shagreen patch (connective tissue nevus)	Nonrenal hamartoma
Multiple retinal nodular hamartomas	Retinal achromic patch
Lymph angiomyomatosis	"Confetti" skin lesions
Renal angiomyolipoma	
Definite TS = Two major features or one major plus two minor features	
Probably TS = One major feature plus one minor feature

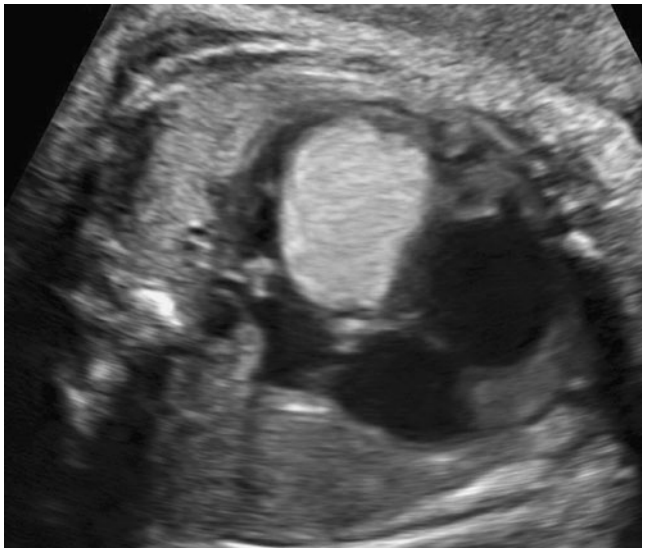

Figure 58-3 Coronal MRI of a fetus with a mass occupying the majority of the chest. Diagnosis was confirmed following fetal surgery as a pericardial teratoma.

termination of the pregnancy can be discussed with the family at this point.

Fetal karyotyping is not indicated for this condition. However, specific effort should be made to obtain DNA from fetal cells, either by amniocentesis or by collection of umbilical cord blood to identify a mutation in *TSC1* or *TSC2*.

FETAL INTERVENTION

There are no fetal interventions for rhabdomyoma indicated at present.

TREATMENT OF THE NEWBORN

The fetus with an intracardiac tumor should be delivered at a tertiary care center, and a neonatologist should be present at the delivery because of the risk of the development of dysrhythmias. Ideally, the infant should be delivered in a center where pediatric cardiologists are also available. In addition to a complete physical examination, the newborn should have a chest X-ray examination, electrocardiography, four-extremity blood pressure measurement, and postnatal echocardiography. Additional diagnostic studies should include postnatal renal sonography to look for the presence of renal cysts (Saguem et al., 1992). Medical genetics consultation should be sought.

Magnetic resonance imaging (MRI) is now considered to be superior to CT examination for the postnatal diagnosis of cortical tubers because MRI provides better soft tissue contrast without exposure to ionizing radiation. White matter tubers are readily identified within the white matter or cortical gyri. These tubers are sclerotic areas that exist throughout the cerebral hemispheres. They are the result of malformations of neuronal and glial elements characterized by decreased neurons and increased glia, and abnormal heterotopic cells (Truhan and Filipek, 1993). MRI has been used to demonstrate the presence of cortical, subcortical, and subependymal tumors in a 3-week-old infant (Christophe et al., 1989). These abnormalities were more completely and clearly seen on the T_1-weighted MR images as opposed to CT images.

Newborns with tuberous sclerosis are at risk for the development of seizures and infantile spasms, which may require anticonvulsant therapy. Children with tuberous sclerosis should be followed with MRI and renal ultrasound examination every 1 to 3 years.

SURGICAL TREATMENT

Surgical intervention should be restricted to cases with significant hemodynamic obstruction or life-threatening arrhythmias (Smythe et al., 1990). Because the natural history of these tumors is that they regress postnatally, a nonoperative approach with careful postnatal follow-up is recommended when possible.

In rare cases, however, surgery must be performed because the tumor affects hemodynamic function. In one review from the University of Padova, eight infants and children underwent operation for removal of an intracardiac tumor and were followed for more than a period of 17 years (Padalino et al., 2005). The diagnoses included myxoma ($n = 2$), fibroma ($n = 2$), rhabdomyoma ($n = 2$), vascular hematoma ($n = 1$), and teratoma ($n = 1$). Complete surgical excision of the cardiac mass was feasible in all but one patient, who underwent orthotopic heart transplantation. All eight children survived the operation, but one died 38 months post heart transplantation due to a cerebral malignancy. Surgical resection was definitive, safe, and effective for this group of patients.

LONG-TERM OUTCOME

Previous reports in the medical literature have emphasized a poor prognosis for fetuses or neonates affected with intracardiac rhabdomyomas. These include a reported 33% mortality rate during the first week of life and an 80% mortality rate during the first year of life (Green et al., 1991). Since approximately 60% of patients with tuberous sclerosis have asymptomatic rhabdomyomas, a better than reported prognosis likely exists. As stated earlier, the natural history of the rhabdomyomas is that they regress and that the cardiac volume increases, so the prognosis should be reasonably good (Webb et al., 1993). Infants in whom symptoms of hydrops or dysrhythmias developed antenatally have an increased risk of mortality.

Concerns regarding long-term outcome are mainly focused on the developmental and health consequences of tuberous sclerosis. The long-term outcome for patients with tuberous sclerosis is extremely variable and can range from completely normal intelligence to severe mental retardation. The prevalence of mental retardation in an unbiased sample of patients with tuberous sclerosis is 38% (Webb et al., 1993). Understandably, most parents are concerned about the risk for the development of seizures and mental retardation. For infants in whom seizures develop within the first year of life, there is a higher likelihood of mental retardation. It has been suggested that there is a correlation between the presence of cortical tubers and the severity of mental retardation (Kwiatkowski and Short, 1994). Other health consequences of tuberous sclerosis include renal angiomyolipomas, pulmonary lymphangiomyomas, seizure disorders, and multiple skin findings that could be considered a cosmetic issue.

GENETICS AND RECURRENCE RISK

The most likely cause for rhabdomyoma is tuberous sclerosis, which is inherited as a single-gene disorder with an autosomal dominant pattern of inheritance. Two-thirds of cases are the result of a new mutation. This means that one-third of the fetuses that present with cardiac rhabdomyoma have an affected parent. The penetrance for known cases of tuberous sclerosis is close to 100%, but one of the characteristics of this condition is that there is extraordinary variability in the expression of the phenotype (Roach and Sparagana, 2004). For example, an affected parent with normal intelligence can have an affected child with severe mental retardation. Although the inheritance pattern is classically described as autosomal dominant, several families have also been described with two affected children being born to normal parents. It is now appreciated that the incidence of somatic or gonadal mosaicism for a mutation in one of the tuberous sclerosis genes is as high as 10% (Verhoef et al., 1999).

If a fetal rhabdomyoma is documented in the setting of a negative family history, both parents should undergo a thorough clinical and radiologic examination for the diagnosis of tuberous sclerosis. The suggested work-up includes a dermatologic examination under ultraviolet light, MRI study of the brain, as well as renal sonography to look for the presence of angiomyolipomas or cysts (Roach et al., 1991).

There are two distinct genes involved in the causation of tuberous sclerosis, *TSC1* and *TSC2* (Jones et al., 1999). Approximately 30% of cases are caused by mutations in *TSC1*, which codes for a protein product called hamartin. *TSC1* is located on 9q34. The other 70% of cases are caused by a mutation in *TSC2*, which maps to chromosome 16 band p13.3 near the adult polycystic kidney disease gene. This gene product has been identified and named tuberin, a 198-kd protein of unknown function (European Chromosome 16 Tuberous Sclerosis Consortium, 1993). In general, *TSC2* mutations are associated with a more severe phenotype. Both hamartin and tuberin have been shown to be present in the tissues of a 19-week fetus affected with tuberous sclerosis (Wei et al., 2002). Hamartin and tuberin are thought to act together to regulate cell proliferation. Loss of heterozygosity due to a tuberin mutation was shown to be associated with a fetal rhabdomyoma, lending credence to the idea that *TSC1* and *TSC2* function as tumor-suppressor genes (Wei et al., 2002).

Prenatal diagnosis for this condition will likely be DNA-based. For families with a positive family history of tuberous sclerosis, DNA mutation studies should ideally be performed prior to contemplation of pregnancy. A comprehensive mutation analysis of the genes *TSC1* and *TSC2* was able to characterize mutations in 120 of 150 (80%) of cases studied (Jones et al., 1999). Mutation analysis of affected individuals' DNA must be performed prior to a subsequent pregnancy in order to facilitate DNA-based diagnosis of chorionic villi in the first trimester.

Chen et al. (2005b) described two different prenatally ascertained cases of rhabdomyoma in which mutation testing was performed using denaturing high-performance liquid chromatography (DHPLC) analysis and direct sequencing. In both cases pathogenic mutations in *TSC2* were identified. Note that the presence of a mutation in *TSC1* or *TSC2* confirms the clinical diagnosis of tuberous sclerosis, but the absence of a mutation does not rule it out.

For families that have not undergone mutation analysis, prenatal diagnosis for tuberous sclerosis consists of serial prenatal sonographic examinations. This has limitations, however, because definitive diagnosis can occur only during the late second trimester.

Ectopia Cordis

59 CHAPTER

Key Points

- Ectopia cordis is a rare malformation in which the fetal heart is present in an extrathoracic location.
- It is easily diagnosable by fetal ultrasound, as early as 10 weeks of gestation.
- Detailed fetal echocardiography is recommended to confirm whether the internal cardiac anatomy is normal, as the prognosis is essentially lethal if associated cardiac malformations are present.
- Detailed general fetal sonographic anatomical evaluation and amniocentesis for fetal karyotype are recommended, because of reported associations with other malformations.
- If a patient chooses to continue the pregnancy and no other malformations are present, planned elective cesarean delivery at term, with immediate availability of neonatologists, pediatric surgeons and cardiac surgeons, is recommended.
- Postnatal survival has been rarely reported in cases in which no associated malformations are present.
- There have been no reported cases of recurrence of ectopia cordis.

CONDITION

Thoracic wall defects arise from failure of part or all of the sternum to develop. These defects may involve only the sternum or may be associated with more severe anomalies. The most striking of these is ectopia cordis. Ectopia cordis is defined as a portion or all of the heart being located in an extrathoracic position. Ravitch (1985) has classified sternal defects into three major groups: cleft sternum without associated anomalies, true ectopia cordis, and pentalogy of Cantrell (see Chapter 61) (Table 59-1).

Sternal defects are commonly associated with ectopia cordis. A spectrum of sternal defects also occurs without displacement of the heart (Skandalakis and Gray, 1994). In rare cases, segments of the sternum are absent. The xiphoid process is the sternal element most commonly absent. Byron (1948) reported a case in which only the manubrium remained. Martin and Helsworth (1962) reported a case of clavicles and upper ribs attached to an abnormally small manubrium separated from lower ribs attached to a sternum element. Complete absence of all sternal elements is rare, but has been reported, and can be successfully reconstructed (Asp and Sulamoa, 1961). In contrast to absent sternal elements, failure of sternal fusion may occur with wide separation of all sternal elements. This is most often seen with associated eventration of the heart. However, several cases have been reported with no herniation of thoracic viscera and intact skin covering the defect (Greenberg et al., 1991).

Superior sternal fusion occurs with a V- or U-shaped cleft in the upper sternum, with variable extension inferiorly even to the level of the xiphoid. Jewett et al. reported nine cases, all with skin-covered defects and structurally normal

Table 59-1

Ravitch's Classification of Sternal Clefts

Cleft sternum without associated anomalies V- or U-shaped clefts of the upper sternum involving manubrium and one or two sternebrae Lower sternum cleft with the xiphoid process united Entire sternum cleft
True ectopia cordis with varying degrees of cleft sternum with the heart outside the chest wall, usually internally malformed and with other malformations
Cantrell's pentalogy composed of the following anomalies: Cleft or absent distal sternum Crescenting ventral diaphragmatic defect Midline ventral abdominal defect or omphalocele Defect at the apical pericardium with communication with the peritoneal cavity Cardiac defects

From Ravitch MM. Congenital deformities of the chest wall and their operative correction. Philadelphia: WB Saunders; 1985:35.

hearts located within the chest cavity. Four of these cases had hemangiomas of the head and neck and a midline raphe indicating a midline fusion defect (Jewitt et al., 1962).

More than 200 cases of ectopia cordis have been reported in the literature (Skandalakis and Gray, 1994). Ravitch (1985) has classified ectopia cordis into four types based on the position of the heart: cervical (3%), thoracic (64%), thoracoabdominal ectopia (18%), and abdominal ectopia (15%). The heart was exposed in 40% of these cases or covered by a serous membrane (31%) or skin (27%) (Schao-Tsu, 1957).

It is important to distinguish true ectopia cordis from failure of sternal fusion in which the heart, though beating prominently beneath the skin-covered gap, is within the chest and is structurally normal. Many cases reported as thoracic ectopia, with intact skin, are more likely examples of isolated failure of sternal fusion.

"Thoracoabdominal ectopia cordis" is better known as the pentalogy of Cantrell and is in part a misnomer, given that the heart is not truly ectopic. In pentalogy of Cantrell the heart is abnormally sited with the apex oriented down, but is positioned within the chest and therefore not true ectopia cordis (see Chapter 61). Both cervical and abdominal ectopia cordis may occur without a sternal cleft. Abdominal ectopia cordis does not belong in this group of anomalies because the defect is diaphragmatic and does not involve the thorax or the anterior abdominal wall.

In true ectopia cordis, internal cardiac anomalies are generally the rule (Medina-Escobedo et al., 1991). Kanagasuntheram and Verzin (1962) suggested that the embryologic basis of ectopia cordis was excessive pericardial coelom formation and subsequent destruction of the transverse septum with rupture of the anterior body wall at 6 weeks of gestation. The frequency of major intrinsic cardiac defects in true ectopia cordis suggests that there may be a primary defect in the splanchnic mesoderm (Ravitch, 1985).

INCIDENCE

Ectopia cordis is extremely rare. The most common form is thoracic ectopia cordis. Only a handful of cases of cervical and abdominal ectopia cordis have been reported. Schao-Tsu (1957) cited figures for ectopia cordis as high as 5.5 in 1000 births at Tubingen and 0.4 in 1000 at Munich. Abbott (1936) found 8 cases in her series of 1000 congenital heart defects. However, most fetuses are lethally deformed and are either stillborn or have no prospect of extrauterine survival. Males tend to be affected more often than females with a ratio of 2.5:1.5 (Blatt and Zeldes, 1942).

SONOGRAPHIC FINDINGS

The first case of ectopic cordis diagnosed in utero by sonographic examination was reported in 1960 by Lumsden (1962) in a fetus near term. Advances in ultrasound examination since that time have allowed recognition of this anomaly as early as the first trimester, using transabdominal and transvaginal ultrasound (Flemming et al., 1991; Achiron et al., 1994; Sepulveda et al., 1994; Tongsong et al., 1999)

True thoracic ectopia cordis (Figure 59-1) is perhaps one of the most startling anomalies to be seen sonographically. The heart is seen entirely outside the thoracic cavity (Bianca et al., 2006). The apex of the heart is usually deviated anteriorly but may also be seen angled up toward the chin (Bennett et al., 1991). Color flow Doppler may be particularly useful in defining the location and anatomy of ectopia cordis (Figure 59-2). Transverse scanning through the fetal chest may allow the sternal defect to be visualized (Figure 59-3). Determining the intracardiac anatomy is of paramount importance in establishing a prognosis. Fetal echocardiography

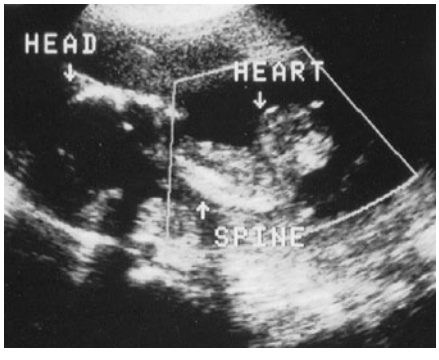

Figure 59-1 Ultrasound image of fetus at 18 weeks of gestation with thoracic ectopia cordis.

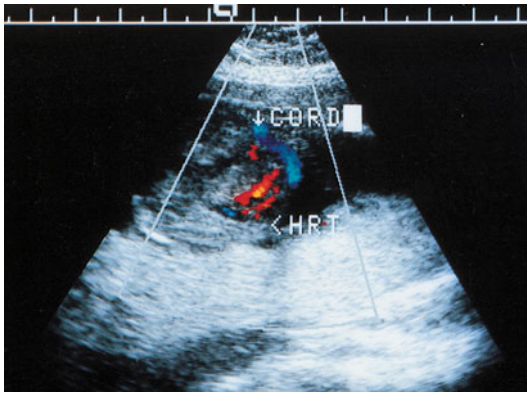

Figure 59-2 Color flow Doppler image of true thoracic ectopia cordis. This fetus was found to have severe associated intracardiac abnormalities and subsequently died in utero.

should be performed in any fetus diagnosed with ectopia cordis.

The cases of cervical and abdominal ectopia cordis are sufficiently rare that none have yet been diagnosed prenatally. The sonographic features of pentalogy of Cantrell (thoracoabdominal ectopia cordis) are covered in Chapter 61. In cases of thoracic ectopia cordis, the size and shape of the fetal chest should be carefully noted. Hypoplasia of the chest wall and lungs has been associated with ectopia cordis.

A careful search should be made for associated anomalies, especially midline defects. A broad range of anomalies have been reported in association with ectopia cordis (Leca et al., 1989; Diaz et al., 1992; Sharma et al., 2001) (see Table 59-2). Particular attention should be paid to possible associated cleft lip or palate. Jewitt et al. (1962) have reported an association between cleft sternum, ectopia cordis, and hemangiomas of the face and neck. Any soft tissue mass in the head and neck region should be scanned with color flow or power Doppler studies.

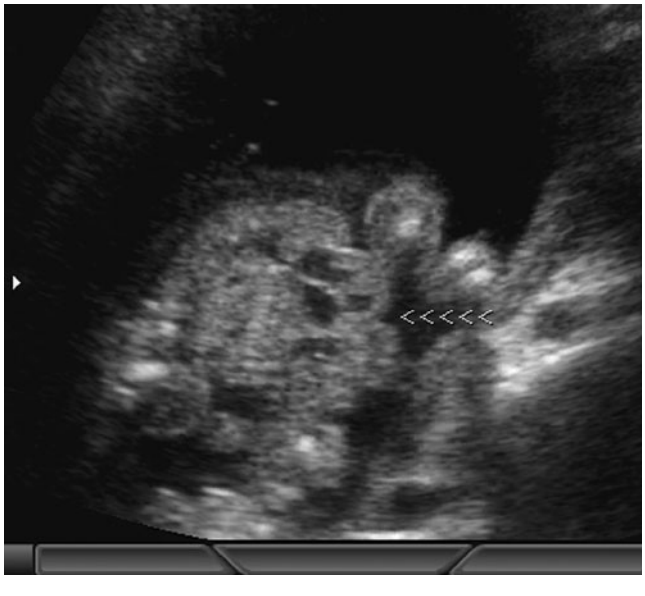

Figure 59-3 Ultrasound image of fetus at 20 weeks of gestation with small arrows pointing to apex of the fetal heart protruding through a sternal defect.

DIFFERENTIAL DIAGNOSIS

The unique appearance of true thoracic ectopia cordis is diagnostic. However, other manifestations of ectopia cordis have a differential diagnosis that may be difficult to sort out prenatally. The pentalogy of Cantrell can usually be diagnosed by the presence of epigastric hernia or marked diastasis of the rectus muscles (see Chapter 61). Complete sternal clefts can be covered with skin or have the heart exposed. In this anomaly, unlike ectopia cordis, the heart is completely within the chest cavity, and there are no associated intracardiac defects. Complete sternal clefts have an excellent prognosis. Similarly, in cases of cervical or abdominal ectopia cordis, the sonographic findings are so striking and pathognomonic that no differential diagnosis is required.

ANTENATAL NATURAL HISTORY

The antenatal natural history of ectopia cordis, similar to the postnatal history, depends on the presence or absence of associated intracardiac defects. Skandalakis and Gray (1994) found that of 138 patients for whom follow-up or survival records were available, 16.6% (23 of 138) were stillborn, and an additional 30% (42 of 138) died on the first day of life. These patients had ectopia cordis with severe intracardiac abnormalities. Abdominal ectopia cordis does not appear to be incompatible with life, but approximately one-third of patients will be stillborn or die on the first day of life because of severe congenital heart malformations. In general, survivors with ectopia cordis are fetuses without associated intracardiac defects. No stillborn infants had isolated ectopia cordis with normal intracardiac anatomy. However, even if a pregnancy goes to term and the infant is born alive, there has never been a long-term survivor who underwent successful reconstruction who had ectopia cordis associated with intracardiac defects. Watterson et al. (1992) reported a case of thoracic ectopia cordis with a double outlet right ventricle that was diagnosed prenatally. This prenatal diagnosis allowed planning of a single-stage reconstruction at birth. Although the procedure was technically successful, the infant died on the 12th postoperative day of sepsis.

MANAGEMENT OF PREGNANCY

Once a diagnosis of ectopia cordis is made, the pregnant patient should have a targeted ultrasound examination to establish the nature and extent of ectopia cordis and, most importantly, to establish the presence or absence of associated intracardiac defects. Similarly, a careful ultrasound

Table 59-2

Anomalies Associated with Ectopia Cordis

Craniofacial	Chest Wall	Intracardiac	Abdominal Wall and Diaphragmatic Defect	Others
Microcephaly	Cleft sternum	Pericardial defects	Omphalocele	Chromosomal anomalies
Hydrocephalus	Bifid sternum	Septal defects	Diastasis recti	Pulmonary hypoplasia
Cleft lip	Absent sternum	Outflow tract obstructions	Gastroschisis	Imperforate anus
Anencephaly	Xiphoid defect	Cardiac diverticuli	Diaphragmatic hernia	Rectovaginal fistula
Neural tube defect	Manubrial defect	Double outlet right ventricle		Amniotic band
	Defect of body or sternum	Anomalies of caval and pulmonary venous return		Dissociation complex
	Partial defect	Transposition of great arteries		Malrotation of bowel
	1/3 lower sternal defect	Aortic coarctation		Liver hemangioendothelioma
	2/3 lower sternal defect	Truncus arteriosus		

examination should be performed to exclude possible associated noncardiac anomalies and evaluate the thorax for signs of pulmonary hypoplasia. Invasive diagnosis of fetal karyotype by means of chorionic villus sampling or amniocentesis is recommended because of a reported association with fetal aneuploidy (Shaw et al., 2006; Yildirim et al., 2008).

Fetal echocardiography is an essential part of the evaluation of any fetus with ectopia cordis. The presence of intracardiac defects is an extremely poor prognostic indicator, and parents should be counseled appropriately.

In cases of ectopia cordis in which the family chooses to continue the pregnancy, serial ultrasound examinations are indicated to monitor fetal growth and well-being. The delivery should occur in a tertiary care setting in which pediatric surgeons, pediatric cardiac surgeons, and neonatologists are available. In most cases of ectopia cordis there is no skin covering the heart, and immediate surgical closure of the defect is necessary to prevent life-threatening infection.

Few reports are available on which to base recommendations for mode of delivery. In cases in which survival is not anticipated because of the presence of severe intracardiac anomalies, vaginal delivery without fetal monitoring is appropriate. In cases in which the cardiac anatomy is normal and full resuscitative efforts are planned, cesarean delivery is justified. The potential adverse effects on venous return to the extrathoracic heart and compromised cardiac output during labor and delivery appear to justify cesarean delivery in cases with normal cardiac anatomy.

FETAL INTERVENTION

There are no fetal interventions for ectopia cordis.

TREATMENT OF THE NEWBORN

The newborn with ectopia cordis should have a planned delivery with neonatologists and pediatric surgeons in attendance. Because the heart is exposed, a detailed examination of the newborn chest to assess sternal defects and prospects for skin coverage should be performed in the delivery room by the surgeon who will close the defect. The heart should be covered loosely with a nonadherent dressing such as gauze covered with petroleum jelly and then wrapped circumferentially with gauze and plastic wrap to minimize evaporative water loss. Immediately after the dressing is applied, the infant's blood pressure and perfusion should be assessed to ensure that the dressing is not restrictive. Plain posteroanterior and

lateral chest X-ray films should be obtained. Venous access should be obtained via the umbilical vein or peripherally and systemic antibiotics should be administered. An arterial line should be placed for continuous arterial pressure monitoring during attempted skin closure (Diaz, 1992). The infant should undergo a detailed physical examination as soon as possible to detect any additional anomalies missed by prenatal ultrasound examination. Postnatal echocardiography should be repeated prior to surgery to verify that the cardiac anatomy is normal.

The evaporative water loss in this defect may be substantial, and initial intravenous fluid administration should be at least 100 mL per kilogram of body weight per day and boluses of crystalloid or colloid administered as necessary. Antibiotics (ampicillin and gentamicin) should be started immediately.

SURGICAL TREATMENT

Reconstruction of ectopia cordis is undertaken in stages. The initial goal of surgery is to achieve skin coverage to protect the heart. This must be achieved without excessive compression or posterior displacement, which may compromise venous return and cardiac output. Successful repair in this defect has been achieved by the use of skin flaps (Dobell et al., 1982; Ravitch, 1985; Amato et al., 1995; Lije et al., 2006) and prosthetic material (Tachibana et al., 1989; Watanabe et al., 1992). In the second stage, a procedure may be performed to reposition the heart within the chest. This may be possible after the infant has been allowed to grow with reduction of the heart and prosthetic coverage over the cleft sternum. Glass and Fernbach (1987) reported the successful use of intrathoracic tissue expanders to create space for subsequent intrathoracic placement of the heart.

LONG-TERM OUTCOME

Although the prognosis is guarded for any fetus with ectopia cordis, long-term survival is possible for cases with normal internal cardiac anatomy. In fact, the first attempted repair of ectopia cordis by Lannelongue in 1988 was successful and he reported follow-up at 20 years of age. However, of 138 patients in whom follow-up or survival records are available, only 32 (23%) survived more than 1 month after birth. Seven of these are known to have reached maturity and 19 others survived infancy and were alive at the time their cases were reported (Skandalakis and Gray, 1994). The oldest reported survivor with ectopia cordis was 75 years old (Byron, 1948).

Among patients with thoracic ectopia cordis, 50% died within 1 day of life, most often from cardiac anomalies (Skandalakis and Gray, 1994). Only seven patients survived to maturity and most of these suffered from only partial ectopia cordis. The prognosis in cervical ectopia cordis is poor, with only two patients surviving to adulthood (Laliberte, 1918; Asp and Sulamoa, 1961). Abdominal ectopia cordis is not incompatible with life, as 10 of 17 patients who were followed have survived (Skandalakis and Gray, 1994). These patients had no intracardiac defects.

GENETICS AND RECURRENCE RISK

True ectopia cordis has not been associated with chromosomal abnormalities. There has not been a reported case of recurrence of ectopia cordis in a sibling.
